Polymer.—One mole of polycaprolactone (PCL), the number-average molecular weight of which was 1.80×10^3, was treated with 2 moles of 4, 4'-diphenylmethane diisocyanate (MDI) in bulk at 65°C for 2 hr. to form a prepolymer. The prepolymer thus obtained was then dissolved in dimethyl acetamide and extended into polyurethane by reaction with equivalent moles of ethylene diamine (ED) at 40°C for 1 hr.

The polyurethane obtained in this manner was designated as the linear polymer E.

The branched polymers were prepared as follows. A mixture of PCL ($\overline{M}_n = 1.80 \times 10^3$) and a small amount of trimethylol ethane (TME) was treated with MDI in bulk at 65°C for 2 hr. to form a prepolymer, where the molar ratio of the isocyanate group to the hydroxyl group was 2. The prepolymer was extended into branched polyurethane with ED under the same conditions as in the case of the linear polymer. Thus, two kinds of branched polymers were obtained.

Table II. Solution properties of fractions for branched polymers F and G

Fraction	$[\eta]_b$	k'_b	$S_{0b}\times10^{13}$	k_{sb}	$k_{sb}/[\eta]_b$	$\bar{M}\times10^{-4}$	$[\eta]$
UF-4	1.505	0.387	2.91	2.92	1.94	20.0	1.647
UF-7	0.947	0.414	2.10	1.76	1.86	9.67	1.029
UG-3	1.120	0.413	2.50	2.43	2.17	13.7	1.292
UG-6	0.748	0.404	1.85	1.59	2.15	7.12	0.847

The molar ratios of PCL to the trifunctional component (TME) in the polymers were as follows:

Branched polymer F (PCL : TME=70 : 1)

Branched polymer G (PCL : TME=42 : 1)

The linear polymer E is symbolized as follows:

$$-(-\text{MDI-PCL-MDI-ED-})_{\bar{n}}$$

whereas the branched polymer contains trifunctional groups:

-(-MDI-TME-MDI-ED-)-
MDI-ED-)-

Fractionation.—In the same manner as in the previous paper,[1] the linear polymer E was divided into 9 fractions, while the branched polymers F and G were divided into 8 fractions.

Viscosity and Sedimentation.—Viscosity and sedimentation measurements were carried out as in the previous paper.[1]

Results and Discussion

The UE-2-8, UF-4, UF-7, UG-3 and UG-6 fractions were selected from the fractions of the linear polymer E and the branched polymers F and G, because the Schlieren patterns for these fractions were narrow enough for an accurate determination of the sedimentation coefficient.

The data of viscosity in dimethyl formamide (DMF) at 25°C, shown in Figs. 1 and 2, were treated in accordance with the complementary relationships for intrinsic viscosity:

$$\eta_{sp}/C = [\eta] + k'[\eta]^2C \quad (1)$$

$$(\ln \eta_r)/C = [\eta] - (0.5 - k')[\eta]^2C \quad (2)$$

where η_r and η_{sp} are the relative and specific viscosities respectively, and where k' is the Huggins constant. The values of $[\eta]$ and k' derived therefrom are listed in Tables I and II.

The reciprocals of the sedimentation coefficients, $1/S$, are plotted against the concentration in Figs. 3—5; the sedimentation coefficients at an infinite dilution, S_0, were estimated from

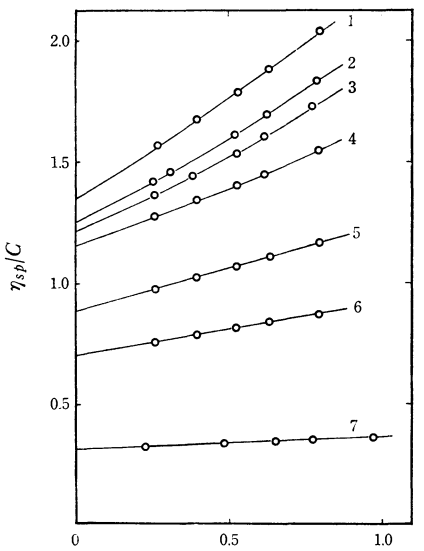

Fig. 1. (η_{sp}/C) vs. C of polymer fractions for linear polymer E in DMF at 25°C.

the intercepts of the straight lines, while the values of k_s were calculated from the relation:

$$1/S = (1/S_0)(1 + k_sC) \quad (3)$$

Results are presented also in Tables I and II.

Figure 6 shows the plot of log S_0 against log $[\eta]$ for the fractions of the linear polymer E in DMF at 25°C, where the solid line through the points corresponds to the equation:

$$S_0 = 2.02\times10^{-13}[\eta]^{0.693} \quad (4)$$

In addition, the molecular weight, M, of each fraction was calculated according to the Mandelkern-Flory equation:[6]

6) L. Mandelkern, W. R. Krigbaum, H. A. Scheraga and P. J. Flory, *J. Chem. Phys.*, **20**, 1392 (1952).

for the linear polymer E were derived from double logarithmic plots, shown in Fig. 7, as follows:

$$[\eta] = 5.90\times 10^{-4}M^{0.65} \quad (6)$$

$$S_0 = 1.18\times 10^{-15}M^{0.45} \quad (7)$$

in DMF at 25°C.

The ratio of the mean-square radius of gyration of a branched molecule, $\bar{r}_b^2$, to that of a linear molecule, $\bar{r}^2$, of the same molecular weght is defined by g:

$$g = \bar{r}_b^2 / \bar{r}^2 \quad (8)$$

where g is related to the number of branches per molecule, m, according to Zimm and Stockmayer's theory.[7]

For a branched molecule, the intrinsic viscosity, $[\eta]_b$, and the sedimentation coefficient, S_{0b}, are expressed by the following equations:

$$[\eta]_b = g'[\eta] = g'\Phi 6^{3/2}(\bar{r}^2)^{3/2}/M \quad (9)$$

$$S_{0b} = M(1-\bar{v}\rho)/N_A\eta_0 hP 6^{1/2}(\bar{r}^2)^{1/2} \quad (10)$$

where $[\eta]$ is the intrinsic viscosity of a linear molecule having the same molecular weight as the branched polymer and where the g' and h factors are a function of g.

Several theories[8-10] have been proposed to relate g' to g. According to the Flory theory, g' and h are related to g as follows:

$$g' = g^{3/2} \quad (11)$$

$$h = g^{1/2} \quad (12)$$

The combination of Eqs. 9—12 leads us to the following equation:

$$S_{0b}[\eta]_b^{1/3}/M^{2/3} = \Phi^{1/3}P^{-1}(1-\bar{v}\rho)/\eta_0 N_A \quad (13)$$

For the calculation of the g factor, intrinsic viscosities measured at Θ-temperature should be used in principle, as the g factor in the Zimm-Stockmayer theory[7] is defined for unperturbed quantities. Many experimental results[2,11,12] show, however, that the value of g' is nearly the same for both good and Θ-solvents. Consequently, the estimation of the value of g' from intrinsic viscosities measured at non-Θ-temperature is permissible.

When the value of M is the same in Eq. 5 for the linear molecule and in Eq. 13 for the branched molecule, the following equation can be derived:

$$S_{0b}[\eta]_b^{1/3} = S_0[\eta]^{1/3} \quad (14)$$

The substitution of Eq. 4 for the linear polymer into Eq. 14 then gives:

$$S_{0b}[\eta]_b^{1/3} = 2.02\times 10^{-13}[\eta]^{1.03} \quad (15)$$

Thus, the value of $[\eta]$ for a linear polymer having the same molecular weight as a branched polymer can be evaluated with $[\eta]_b$ and S_{0b} in accordance with Eq. 15.

The values of $[\eta]$ thus calculated are listed in column 2 of Table III, while calculated values of g' are given in column 3 of that table.

The values of g were calculated in accordance with Eq. 11, they are presented in column 4 of Table III.

Table III. Degree of branching

Fraction	$[\eta]$	g'	g	m
UF-4	1.647	0.914	0.942	0.58
UF-7	1.029	0.921	0.947	0.52
UG-3	1.292	0.868	0.910	0.90
UG-6	0.847	0.883	0.920	0.78

The value of m in Table III is the number of branches per molecule which are estimated to be trifunctional branches of random lengths by Zimm and Stockmayer.[7]

Many investigators have discussed the dependence of the Huggins constant, k', of a branched polymer on the degree of branching. Orofino[11] has shown that k' in a good solvent is not affected by branching, but in a Θ-solvent the k' value for a branched polymer is slightly larger than that for the corresponding linear polymer. Morton[12] has observed, however, that for a branched polymer the values of k' are slightly larger than that for a linear polymer in both good and Θ-solvents. In Pollock's work,[13] there is no evidence for such a difference in k' due to branching. Blachford et al.[5] have observed that the value of k' for a branched polymer increases with the increase in the degree of branching in a good solvent.

13) D. J. Pollock, L. J. Elyash and T. W. DeWitt, ibid., **15**, 335 (1955).

In the present work, the viscosity data on branched polymers in a rather poor solvent give values of k' experimentally indistinguishable from those obtained for the linear polymers. As many factors, such as the molecular weight distribution, may affect k', it is difficult to determine whether the value of k' depends on the degree of branching or not.

Wales[14] has proposed the following relation between k_s and $[\eta]$:

$$k_s/[\eta] = 1.66 \tag{16}$$

This relation has been supported by many investigations for linear polymers. For branched polymers, however, a larger $k_s/[\eta]$ value has been reported.[6]

For the fractions of the linear polymer E, the values of $(k_s/[\eta])$ were about 1.7, but the values for the branched polymer, as may be seen in column 6 of Table II, are higher than that for the linear polymer and it seems that the ratio of k_s to $[\eta]$ increases with the increase in the degree of branching. The larger values of $(k_s/[\eta])$ may suggest that the dependence of k_s on the degree of branching is less than that of $[\eta]$.

The degrees of polymerization of the fractions for the branched polymers are about 85, 41, 62 and 30 for UF-4, UF-7, UG-3 and UG-6 respectively. If the polymer molecules contain trifunctional groups (TME) in proportion to the molar ratio of TME to PCL, then the numbers of branches per molecule may be 1.21, 0.59, 1.47 and 0.71 for UF-4, UF-7, UG-3 and UG-6 respectively. The initial two fractions obtained by precipitation fractionation, however, contained many micro gel particles for both of the branched polymers, F and G. This might mean that the trifunctional groups are localized upon the initial few fractions having high molecular weights. It may be reasonable, therefore, that the degrees of branching for the fractions measured in this study were less than the above-calculated values.

The authors wishes to express his hearty thanks to Professor Masaji Miura of Hiroshima Univeristy, and to Dr. Toshizo Isoshima and Dr. Nobuo Yamada of this laboratory for their encouragement and useful discussions throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2344—2346 (1966)

The Reactions of t-$C_4H_9^+$ in the Radiolysis of Neopentane in the Gas Phase

By Tetsuo MIYAZAKI and Shoji SHIDA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received March 1, 1966)

The yields and reactions of t-$C_4H_9^+$ produced in the radiolysis of neopentane in the gas phase have been studied by the use of ammonia. The yields of *iso*-C_4H_8 increase sharply upon the addition of a small amount of ammonia in the radiolysis of neopentane and show a constant value upon the further addition of ammonia (more than 10 mol.%). Since this increase is due to the following reaction:

$$t\text{-}C_4H_9^+ + NH_3 \rightarrow iso\text{-}C_4H_8 + NH_4^+$$

we get $G(t\text{-}C_4H_9^+)=1.76$ by assuming the increment of *iso*-C_4H_8 to be equal to the yield of t-$C_4H_9^+$. This value is consistent with the value expected from the mass spectrum of neopentane. It has, therefore, been concluded that the ammonia method is a very effective general method for studying the reactions of ions. It is applicable to the study of ions under high pressures, ions which can not be studied by a mass spectrometer. It is especially effective in the study of less reactive ions.

In order to study ionic reactions in general, it is desirable to devise a general method which can easily and definitely discriminate the reactions of ions from those of neutral active species. Ausloos[1] studied ionic reactions using deuterated compounds and radical scavengers in the radiolysis of hydrocarbons. However, the application of his method is limited to highly reactive ions.

The present authors showed in a previous

a) Moles per 1000 mol. of *neo*-C_5H_{12}.
b) C_2 represents the sum of C_2H_6, C_2H_4 and C_2H_2.

paper[2] that ammonia is a very effective reagent for studying the reactions of ions in the radiolysis of *n*-butane and that this method can also be applied to the study of an unreactive ion, such as *sec*-$C_4H_9^+$. Though the *t*-$C_4H_9^+$ ion is the most abundant ion in the mass spectrum of neopentane, the yield and the reaction of this ion in the radiolysis of neopentane have not been decided, since *t*-$C_4H_9^+$ does not produce C_4-products directly because of its low reactivity. Here we have studied the reaction of *t*-$C_4H_9^+$ in the radiolysis of neopentane by the use of the ammonia method.

Experimental

Most of the experimental procedures were identical with those described in the previous study.[2] Neopentane was supplied by the Takachiho Shoji Co.; its gas chromatographic analysis showed the presence of 0.05% *n*-pentane as an impurity. C_5H_{10}-1, used as a radical scavenger, was 99.99% pure. NH_3 was also of a high purity. The samples were irradiated at room temperature with γ-rays from Cs-137 of 5000 c. The total dose was 2.4×10^{21} eV.g^{-1}, and the dose rate was 8.9×10^{18} eV. g^{-1} hr^{-1} The reaction vessel was a glass cylinder (2.0 cm. in external diameter, 15 cm. high, and with a volume of about 50 cc.). The analytical procedures were identical with those described before.[3] C_2–C_4 hydrocarbon products were analysed by gas chromatography (dimethyl sulfolane column, 15 m.).

Results and Discussion

The effect of ammonia on the radiolysis of neopentane in the gas phase is shown in Table I and in Fig. 1. Though H_2, CH_4 and C_2 Products are not significantly affected by ammonia, *iso*-C_4H_8 increases markedly upon the addition of ammonia even only a small percentage, and becomes constant at a high concentration of ammonia. These phenomena are thought to be due to the following reactions, as in the radiolysis of the *n*-C_4H_{10}–NH_3 system[2]:

$$neo\text{-}C_5H_{12} \xrightarrow{I} t\text{-}C_4H_9^+ + CH_3 \qquad (1)$$

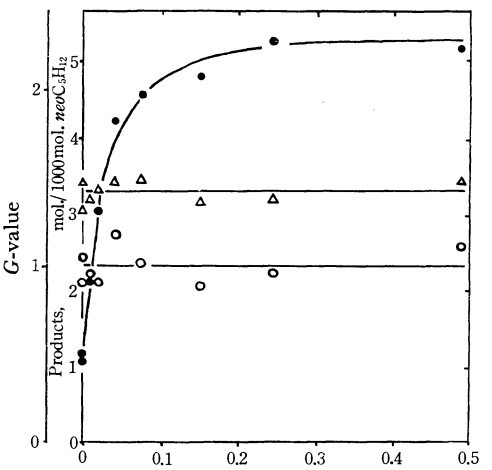

Fig. 1. Effect of ammonia in the radiolysis of *neo*-C_5H_{12}
H_2 ○, CH_4 △, *iso*-C_4H_8 ●

$$t\text{-}C_4H_9^+ \xrightarrow{k_2} P \qquad (2)$$

$$t\text{-}C_4H_9^+ + NH_3 \xrightarrow{k_3} iso\text{-}C_5H_8 + NH_4^+ \qquad (3)$$

(I: Rate of reaction 1; k: Rate constant)

t-$C_4H_9^+$ cannot produce *iso*-C_4H_{10} by the following hydride ion transfer reaction with neopentane, because this reaction is endothermic by about 20 kcal.[4]:

2) T. Miyazaki and S. Shida, This Bulletin, **38**, 2114 (1965).
3) T. Miyazaki, S. Arai, S. Shida and S. Sunohara, ibid., **37**, 1352 (1964).
4) S. G. Lias and P. Ausloos, *J. Chem. Phys.*, **43**, 2748 (1965).

$$t\text{-}C_4H_9^+ + neo\text{-}C_5H_{12} \longrightarrow iso\text{-}C_4H_{10} + C_5H_{11}^+ \quad (4)$$

From a kinetic treatment similar to one described before,[2] we get $k_2/k_3=11.5$ mol./1000 mol. *neo*-C_5H_{12}. If k_3 is taken as 2×10^{-9} cc.molecule^{-1} sec^{-1},[5] we get $k_2=1.38\times10^8$ sec^{-1}. Therefore, the life time of t-$C_4H_9^+$ is about 7×10^{-9} sec., which is the same order of magnitude as the life time of the *sec*-$C_4H_9^+$ produced in the radiolysis of *n*-butane.[2] Since the life time of t-$C_4H_9^+$ is much shorter than the time of neutralization ($10^{-2}-10^{-3}$ sec.),[6] and the time of diffusion to wall of the vessel (about 10^{-1} sec.),[7] t-$C_4H_9^+$ may be consumed by the addition to C_5H_{10}-1;

$$t\text{-}C_4H_9^+ + C_5H_{10}\text{-}1 \longrightarrow C_9H_{19}^+ \quad (5)$$

Then, $k_2=k_5[C_5H_{10}\text{-}1]$. Therefore, we get $k_5=0.45\times10^{-9}$ cc. molecule^{-1} sec^{-1}, which is similar to the ordinary rate constant of ion-molecule reactions. Since the total dose was large in this work and since an unsaturated product, such as *iso*-C_4H_8, may react with radicals, C_5H_{10}-1 was added as a radical scavenger. However, we found that C_5H_{10}-1 may react also as an ion-scavenger. Since *iso*-C_4H_{10} is formed in considerable amounts in the absence of C_5H_{10}-1 in the radiolysis of neopentane (Table I), the neutralization of t-$C_4H_9^+$ may produce the t-C_4H_9 radical as follows:

$$t\text{-}C_4H_9^+ + e \longrightarrow t\text{-}C_4H_9 \quad (6)$$

$$t\text{-}C_4H_9 + neo\text{-}C_5H_{12} \longrightarrow iso\text{-}C_4H_{10} + C_5H_{11} \quad (7)$$

$$t\text{-}C_4H_9 + R \longrightarrow P \quad (8)$$

(R: a radical; P: the products of Reaction 8, a combination- and disproportionation reaction between t-C_4H_9 and a radical of the system.)

In the mass spectrum of neopentane, the fraction of t-$C_4H_9^+$ amounts to 41% of all the ions. Taking $W_{neo\text{-}C_5H_{12}}$ as 24 eV., it may be expected that $G(t\text{-}C_4H_9^+)=1.7$. Since the increment of *iso*-C_4H_8 is equal to the yield of t-$C_4H_9^+$ in the present work, we get $G(t\text{-}C_4H_9^+)=1.76$ in the radiolysis of neopentane; this is in good agreement with the mass spectrometric value. Recently Ausloos reported that the $G(iso\text{-}C_4H_8)$ value in the radiolysis of *neo*-C_5H_{12}–NO in a stainless-steel reaction vessel differs from that in a graphite-coated reaction vessel.[4] Assuming this difference to be equal to t-$C_4H_9^+$, he obtained $G(t\text{-}C_4H_9^+)=1.23$. However, this value seems to be an underestimate.

It can be concluded that ammonia is a very effective reagent for studying the reaction of ions, especially that of the unreactive ions in the radiolysis of hydrocarbon, and that ionic reactions at high pressures, which can not be studied by a mass spectrometer, can be studied easily by the ammonia method.

The authors appreciate the help of Dr. Toshio Sugiura and others of the Japan Atomic Energy Institute in performing the work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2346—2351 (1966)

Nuclear Magnetic Resonance Studies of the Intermolecular Interaction of Amides and Some Other Related Dipolar Molecules

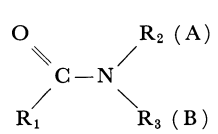
By Teijiro YONEZAWA and Isao MORISHIMA

Department of Fuel Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

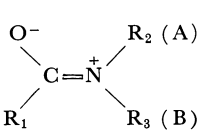
(Received March 5, 1966)

The chemical shifts for *N*, *N*-disubstituted amides and some other isoelectronic compounds as pure liquid and in dilute solutions in CCl_4 are reported. The characteristic shifts generally observed on going from a CCl_4 solution to pure liquid are explained in terms of specific self-association in the pure liquid.

Rotation about the central C–N bond of substituted amides is hindered, and two resonance peaks, those of protons of R_2 at site A and of R_3 at site B, are observed.



I



II

From the temperature dependence of the proton magnetic resonance spectra of substituted amides, the energy barriers restricting the internal rotation about the central C–N bond have been obtained.[1-5]

The barrier height strongly depends on the nature of the solvent and on the concentration when these substances are studied in solution.[4,5] This has been attributed to the changes of a partial double-bond character in the C–N bond arising from the intermolecular interactions. Whittaker and Siegel[5] showed evidence of the dipolar association of *N*, *N*-dimethylformamide (DMF) from their NMR study of solvent effects on the hindered internal rotation about the C–N bond.

However, there has been no dispute over the nature of the self-association which takes place between amide molecules in the pure liquid. Recently, there has been a considerable amount of work on the specific intermolecular interaction by the NMR method; for example, the solvent-solute interaction between benzene and amide.[6] the self-association of azabenzene[7] and of pyrrole[8] have been discussed, along with the configuration or the mode of the interacting molecules. Hence, in the present paper, a detailed investigation of dipolar interactions of highly-polar molecules, amides and some other related dipolar molecules will be made by examining the concentration effect on the proton chemical shifts of amide and some other carbonyl compounds.

It will be made clear that the dilution shift and the change in the proton-proton coupling constant in solution can be interpreted in terms of a "head-to-tail" type of association between amide molecules.

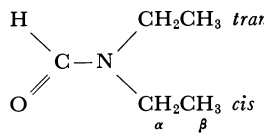
Experimental

Materials.—*N*, *N*-Dimethylformamide (DMF), *N*, *N*-dimethylacetamide (DMAC), *N*, *N*-diethylformamide (DEF), *N*-methyl-2-pyrrolidone, and some other carbonyl compounds listed in Table II were obtained from commercial sources. The remaining compounds were prepared as follows. *N*-Formylpiperidine was prepared from the reaction of piperidine with chloral.[9] *N*, *N*-Dimethylglycolamide (DGA) was prepared by the aminolysis of methyl glycolate. These compounds were so pure that they showed no impurity lines when the spectrometer gain was near its maximum; hence, no further purification of the samples was carried out.

NMR Spectra.—The chemical shifts were measured in c.p.s. from internal tetramethylsilane with a Varian A-60 analytical spectrometer operating at 60 Mc. at a temperature of about 35°C. The precision of the measurement of chemical shifts was within about ±0.3 c. p. s.

Results and Discussion

The Chemical Shift and the Proton-proton Coupling Constant.—The amides studied in this work are listed in Table I, together with the chemical shifts and the association shift, which is defined as the difference between the chemical shifts in the neat liquid and in the carbon tetrachloride solution ($\delta_{\text{in neat}} - \delta_{\text{in CCl}_4}$). The notations used to distinguish the various protons in the groups attached to the nitrogen atom are shown in III; each proton is referred to as *cis* or *trans* with respect to the carbonyl oxygen.



III

The NMR spectra of several amides are given in Fig. 1. The peaks in the NMR spectrum have been assigned by two different methods. The first one utilizes the difference in the long-range coupling constant between the protons of R_1 and R_2 or R_3; the *trans* coupling is believed to be larger than the *cis*.[10-12] The other method makes use of the change in the NMR spectrum of amides when they are diluted with benzene.[6,12] Hatton and Richards[6] proposed a specific interaction between benzene and the amide molecule in which the negatively-charged carbonyl oxygen was located as far away from the center of the benzene ring as possible.[12,13] We will now present our experimental results on the change in the proton-proton coupling constants and proton chemical shifts for each compound.

As to *N*, *N*-dimethylformamides, the magnitude of the long-range coupling constant between the formyl proton and the *N*-methyl protons decreases upon dilution with carbon tetrachloride (as is shown in Fig. 1). With higher concentrations,

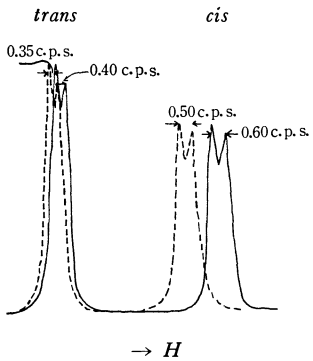

Fig. 1. *N*-Methyl signals of *N*,*N*-dimethylformamide ——: pure liquid, ----: 10% CCl_4 solution.

the polar structure, II, is favored by a dipolar-type interaction and a double-bond character between C and N serves to increase the long-range coupling constant between the formyl proton and the *cis* methyl proton J_{12}, or between the formyl proton and the *trans* methyl proton J_{13}. This may be seen obviously from the value of J_{12} or J_{13} given in Fig. 1. From the chemical shift data of DMF in Table I, it may be seen that the *cis* methyl signal shifts upfield as the concentration increases, while the *trans* methyl signal remains almost constant.

For *N*, *N*-dimethylacetamide, the two *N*-methyl signals are not equally sharp, with the higher field line being broader (as is shown in Fig. 2);

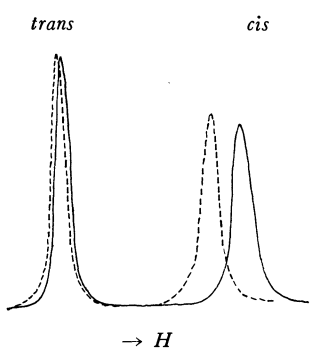

Fig. 2. *N*-Methyl signals of *N*,*N*-dimethylacetamide ——: pure liquid. ----: 10% CCl_4 solution.

the increased breadth of the high field line indicates that this line has a larger unresolved hyperfine interaction between *N*-methyl protons and *C*-methyl protons. When diluted with an inert solvent, carbon tetrachloride, the higher-field *N*-methyl signal line becomes sharp due to the diminution in the long-range coupling with *C*-methyl protons, as is also shown from the change in the H_{cis}/H_{trans} value given in Table I. Here, H_{cis} and H_{trans} indicate the height of the *cis* and *trans* methyl signals, and the H_{cis}/H_{trans} ratio is proportional to the ratio of the two long-range coupling constants, J_{12}/J_{13}. The large double-bond character of the C–N bond in the pure liquid makes J_{13} (*trans* coupling) larger, in turn resulting in a broad *cis* *N*-methyl signal line, that is, a decrease in the H_{cis}/H_{trans} value. This result also demonstrates the dipolar association for DMAC when the concentration increases. The *cis* *N*-methyl proton signal exhibits a larger upfield shift than the *trans* where there is a remarkable dipolar association of amide, as in the case of DMF. On the other hand, *C*-methyl protons show a downfield shift, much as that observed in the case of the formyl proton in DMF. In *N*-methyl-2-pyrolidone, in which rotation about the C–N bond is restricted, an upfield shift of the methyl proton resonance when the concentration is increased is also observed. On the other hand, α-methylene protons resonate downfield at higher concentrations; this is also attributed predominantly to the increment of the polar structure II, as is observed with the formyl proton in DMF and with the *C*-methyl protons in DMAC.

N, *N*-Diethylformamide (DEF) and *N*-formylpiperidine are used to examine the concetration effect on the proton shift. In DEF and *N*-formyl piperidine, compared to DEF, it is very interesting that α-methylene protons exhibit shifts to a lower field in pure liquid than in a carbon tetrachloride solution, while β-methyl protons show an upfield shift in pure liquid, as is the case for *cis* methyl protons in DMF, DMAC, and *N*-methyl-2-pyrrolidone. It is also interesting to note that the β-methyl protons *trans* to the carbonyl bond show a larger downfield shift than the *cis* protons. These interesting results will be discussed below.

In *N*, *N*-dimethylglycolamide (DGA), anomalous[14] chemical shifts of methyl protons have been observed, the methyl signal line at lower field being broader (Fig. 3). When we assumed that the *trans* coupling is larger than the *cis*, as is the case for DMF and DMAC, it follows that the resonance of *cis* methyl protons occurs at a lower field in DGA.

This larger breadth of the lower-field resonance line may be expected to arise from the larger long-range coupling between *cis* *N*-methyl protons and the methylene protons in the methylol group than that for *trans* methyl protons. This is justified from the spin-spin decoupling experiment. The methyl proton signal at a lower field is sharpened by methylene proton decoupling (Fig. 3-a and 3-b). In this compound, as is shown in Table I, the

14) Similar anomalous features are not observed for similar hydroxyl amides, *N*, *N*-dimethylhydracrylamide and *N*, *N*-dimethyllactamide. The details of the NMR spectra of these compounds, together with those of DGA, will be published elsewhere.

proton signal of the *cis* methyl group also shifts upfield as the concentration increases.

The Nature of the Association of Amides.— The dilution of amides with CCl_4 may change the electronic distribution of the amide molecules, the diamagnetic anisotropy effect of the carbonyl bond, and the energy barrier of internal rotation about the C–N bond. All of these effects may cause a change in the proton chemical shift.

The association shift of methyl protons of DMF, DMAC, *N*-methyl-2-pyrrolidone, and DGA, together with β-methyl and methylene protons of DEF and *N*-formylpiperidine, probably does not result from the changes in charge distribution, since, if so, the methyl signal would move to a lower field; this is in contrast with those experiments in which the concentration increases, whereupon the polar structure II is favored due to the dipolar interaction, and the positively-charged nitrogen atom withdraws the σ-electron in the C–H bond.

When the energy barrier restricting the hindered internal rotation about the C–N bond increases with the amide concentration,[4,5] the separation between two methyl proton signals of DMF increases, and the symmetrical shift of two methyl proton signals can be observed. This internal rotation effect, however, will not contribute to the upfield shift of methyl protons of *N*, *N*-dimethylamides at high concentrations, because one of the two methyl proton signals at the higher field shifts upfield more than that of the lower-field methyl signal, resulting in an asymmetrical shift (Fig. 1). In fact, in *N*-methyl-2-pyrrolidone, which has a rigid structure and in which the methyl resonance is not affected by the internal rotation about the C–N bond, the upfield association shift is also observed for *N*-methyl protons. Thus, the upfield association shift is attributable to the long-range shielding effect of the carbonyl group. Two possible explanations of this behavior of chemical shifts come to mind; (1) a dipolar association may modify the magnetic anisotropy of the carbonyl bond, which in turn should change the chemical shift of the *N*-methyl protons. (2) This association may also decrease the average distances between amide molecules, and the proton resonances

of one amide molecule may be affected by the magnetic anisotropy of the carbonyl bond of neighbouring amide molecules. These two effects are referred to as the intramolecular and the intermolecular long-range diamagnetic anisotropic shielding effect (abbreviated as the intra- and intermolecular anisotropic effects respectively). In fact, there may be a superposition of these two effects.

The intramolecular anisotropic effect of the carbonyl group can be ruled out as a main factor from the following considerations. First, a dipolar association like the hydrogen bonding at the carbonyl oxygen[15] enhances the charge polarization of the carbonyl bond. However, when the hydrogen bonding occurs, as is shown in Table I, the *cis* methyl proton resonance shows a larger downfield shift than does the *trans*. Therefore, the upfield shift of *cis* methyl protons as the concentration increases may be due to the intermolecular anisotropic effect. Second, α-methyl proton resonance of DEF and *N*-formylpiperidine show a downfield shift as the concentration of amides increases. If the intramolecular anisotropic effect is the main factor in the association shift, this contrary tendency of the association shift is in contrast to the shift for methyl protons of DMF and DMAC. Thus, not the intra- but the intermolecular anisotropic effect is believed to be mainly responsible for the concentration effect of the chemical shifts of protons neighboring the carbonyl bond.

The anisotropic shielding effect of the carbonyl double bond has been exhibited in amides,[15-17] α, β-unsaturated carbonyl compounds, a series of steroids,[18] and α-methylenecycloketones.[19] In each of these cases, the chemical shift data indicate that the resonance spectra of magnetic nuclei shift to a higher field when the nuclei are constrained to a position in a conical region above and below the carbonyl bond.[20]

In the qualitative sense, it then follows that the association shift to the higher field indicates that the methyl group is in a conical region above or below the carbonyl double bond of another amide molecule. Thus, the structure of the dipolar association of the type demonstrated in Fig. 4 (the "head-to-tail" type of dipolar interaction) is probably favored for DMF, DMAC, *N*-methyl-2-pyrolidone, and DGA.

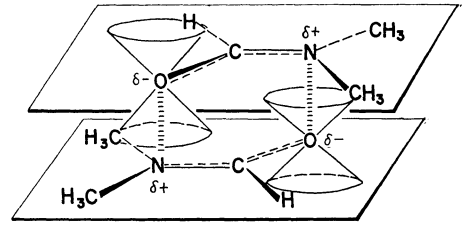

Fig. 4. The proposed model of the specific dipolar association of *N*, *N*-dimethylformamide.

In order to investigate further this type of association for other, similar carbonyl compounds, we measured the association shift of mesityl oxide and phorone. The results are listed in Table II; also shown is the chemical shift change effected by the hydrogen bond. The association shifts of these two carbonyl compounds are also upfield for the *trans* methyl proton; this reveals the same type of dipolar association as when the amides exist.

Table II. Chemical shifts[a] of α, β-unsaturated carbonyl compounds

	Compound	Solvent	Methyl protons

association mentioned above, we propose the dipolar association of the type given in Fig. 4 for amide and other carbonyl compounds. The structure of the dipolar association also indicates that *cis* methyl protons will show a large shielding effect of the carbonyl bond of neighboring amide molecule than those *trans* to the carbonyl bond; this finding is compatible with the experimental.

For *N*, *N*-diethyl amides and *N*-formylpiperidine the upfield shift of the β-proton and the downfield shift of α-protons by the association leads us to the inferences that β-protons may be in the conical region above or below the carbonyl bond and that the α-protons are nearly all in the remaining region of the carbonyl bond. If this model is valid, similar association shifts should be observed for the equimolecular and isoelectronic compounds, and *N*, *N*-diethylnitrosamine, in which the two methylene signals (for *cis* and *trans*) are well separated, unlike DMF. The experimental results are given in Table III for several nitrosamines. An inspection of the data will reveal that the chemical shift of β-protons goes upfield with an increase in the concentration of nitrosamine, while that of α-protons shows a downfield shift. The configuration of the dipolar-associated dimer of *N*, *N*-diethylnitrosamines is considered to be similar to that of *N*, *N*-diethylformamide.

We may summarize our conclusions as follows. In the pure liquid amides and some other isoelectronic compounds, i. e., α, β-unsaturated carbonyl compounds and nitrosamines, it is probable that the high-charge polarization of these molecules favors a structure of dipolar self-association in which the positively-charged nitrogen (or carbon) of one molecule is directly over the negative oxygen atom of the other.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2352—2355 (1966)

Kinetic Studies of Ammonia Oxidation in Shock Waves. II. The Rate of Ammonia Consumption*

By Tetsu TAKEYAMA and Hajime MIYAMA

Basic Recearch Laboratories, Toyo Rayon Company, Ltd., Tebiro, Kamakura, Kanagawa

(Received March 5, 1966)

An investigation was made of ammonia oxidation in shock waves at temperatures from 2100 to 2600°K by monitoring the ultraviolet absorption of ammonia at 2245 Å. The absorption coefficient of ammonia was measured at various temperatures; the rate constant of the decomposition reaction at higher temperatures with a mixture of 1% NH_3 and 99% Ar was found to be in good agreement with the results of other studies. By using several mixtures of ammonia and oxygen highly diluted with argon, the rate of ammonia consumption immediately after an induction period was found to be expressed by:

$$-\left(\frac{d[NH_3]}{dt}\right)_0 = k_0[NH_3]^{1.5}[O_2]^{0.5}[Ar]^{0.5}$$

where: $\log k_0(l^{1.5}mole^{-1.5}sec^{-1}) = 12.77 \pm 0.10 + (-8488 \pm 573)/T$. This corresponds to an apparent activation energy of 38.8±2.6 kcal./mole.

In a preceding paper[1] on the ammonia-oxygen reaction, we reported the results obtained from measurements of the induction periods and time histories of various intermediate species, and a reaction mechanism for the induction period was proposed.

Now, a challenging problem is to study the early stage of the reaction which follows the induction period. We will describe here results obtained from measurements of ammonia absorption at 2245 Å over the range of conditions $2100 \leq T \leq 2600$°K, $2.1 \leq p \leq 5.4$ atm., $0.5 < [NH_3]/[O_2] \leq 2$, and $1.0 \times 10^{-4} \leq [O_2]$, $[NH_3] \leq 4.1 \times 10^{-4}$ mol./l.

Experimental

The experimental details have been described previously.[2] In brief, the velocity of an incident shock wave was measured with two thin-film thermometers, which were placed at a distance of 139.0 mm. from each other, and with an electronic counter. One of the thermometers was placed 5.0 mm. from the endplate where the observation windows of quartz were set.

An ultraviolet absorption of ammonia was measured at 2245 Å.[3] The slit width of a monochrometer was set at 0.6 mm., which allowed a band pass of 7 Å.

The procedures of preparing reaction mixtures as well as the materials used were the same as those described in a previous paper.[1]

Results and Discussion

The Extinction Coefficients of Ammonia at 2245 Å.—The extinction coefficient at room temperature was determined from the decrease in photocurrent when the shock tube (7.6 cm. in internal diameter) was filled with pure ammonia. The absorption of ammonia agreed well with Beer's law up to a pressure of 700 mmHg, which was the upper limit of our glass gas-handling system. The decadic extinction coefficients found were 3.42 and 4.15 l. $mole^{-1}$, at 295 and 300°K respectively.

The extinction coefficients at high temperatures were determined from the initial decreases in photocurrent immediately after the passage of the incident and reflected shock waves, by using mixtures of 1, 2, or 3% ammonia and argon. The absorption increased linearly with the concentration of ammonia up to about a 90% absorption. The extinction coefficients as a function of the temperature are plotted in Fig. 1, which shows a rather definite decrease in their value above 3000°K. This may be due to a rapid decomposition of ammonia at these high temperatures. The solid line in the figure was obtained by a multiple regression analysis, while the dashed line was obtained by Michel and Wagner[4] at 2300 Å. The latter line was calculated from their Arrhenius-type expression up to 3000°K, though its effective temperature range was not explicit in their paper. The difference between these two data is large at lower temperatures;

●, measured by static method at room temperature; ◑, measured in incident shock waves, ○, measured in reflected shock waves. Solid line is the best fit to the points by multiple regression analysis. Dashed line is a result of Michel and Wagner[4] at 2400A.

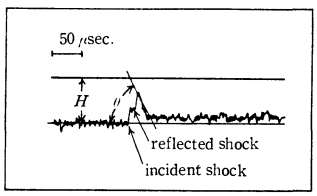

Fig. 2. Typical oscillogram showing NH_3 absorption vs. time.
1%NH_3-99%Ar; p_1, 51.0 mmHg: w_r, 1122 m./sec.; T_5, 2790°K; P_5, 7.3 atm.; [NH_3], 2.05×10^{-4} mole/l.

they differ by a factor of ten at 1000°K. This can be attributed to the strong wavelength dependence of extinction coefficients at lower temperatures.[5]

The Pyrolysis of Ammonia.—Oscillographic records obtained in the measurements of the extinction coefficients of ammonia showed that a detectable amount of decomposition started only after a temperature-dependent induction period at lower temperatures (<2400°K). Therefore, the initial rates of the decomposition of ammonia were determined for higher-temperature runs, in which no induction period was observed, as is shown in Fig. 2. Here, mixture of 1% ammonia and argon were used. The equation used was[6]:

$$-\frac{d[NH_3]}{dt}=\frac{\tan\theta\exp(\varepsilon l[NH_3])}{Hw\varepsilon l} \qquad (1)$$

where ε denotes the extinction coefficient in l. mole^{-1} cm^{-1}; l, the optical length (7.6 cm.), and w, the sweep velocity on the record (sec. cm^{-1}). The height, H, is assumed to be the deflection for 100% absorption, since the room temperature

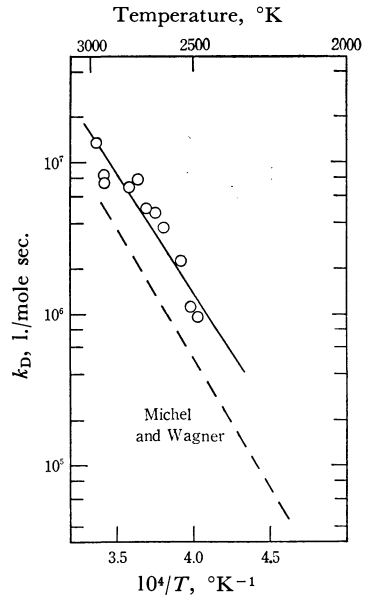

Fig. 3. Second-order rate constants for decomposition of ammonia.

absorption of ammonia is negligibly small, as was described above. The tangent of the angle θ gives the initial rate of change of absorption by ammonia. θ was estimated within a range not exceeding a 10% decomposition of ammonia. Therefore, as an approximation, the authors did not include in Eq. 1 such corrections brought about by the reaction as the temperature decrease, the density increase, and the change in the extinction coefficient.

Thus, the decomposition rate constant, k_D, of the first order with respect to ammonia and argon,* was determined from the initial rate. The results are presented in Fig. 3 as an Arrhenius plot. The solid line obtained by a least-squares calculation is expressed by:

$$\log k_D\ (\text{l. mole}^{-1}\,\text{sec}^{-1})=(12.36\pm0.15)-(71100\pm9200)/2.303RT \qquad (2)$$

For the purposes of comparison, the results of Michel and Wagner[4] obtained from the measurement of the ultraviolet absorption of ammonia at 2300 Å are also shown in the figure. There exists a good agreement among the data of the two groups; this confirms the reliability of the present measurements.

The Rate of Ammonia Consumption in the Oxidation Reaction.—The oxidation of ammonia was studied over the temperature range from 2100

5) H. Gg. Wagner, private communication.
6) H. B. Palmer and D. F. Hornig, *J. Chem. Phys.*, **26**, 98 (1957).

* Michel and Wagner[4] used the second-order expression, $k_D[NH_3][Ar]$, though Jacob[7] obtained $k_D[NH_3]^{1.5}[Ar]^{0.5}$. Although our data are not enough to determine which of these expressions is right, the former expression was used for the sake of simplicity. Even when the latter is applied, however, our data agree well with those of Jacob.

to 2600°K. A typical oscillogram is shown in Fig. 4. An appreciable amount of reaction starts after an induction period, which becomes shorter at higher temperatures, with an initial rate of v_0. Then, the rate increases to a final rate, v, as the reaction proceeds further. As the temperature increases, the v_0 rate becomes greater until finally it coalesces with v. The initial rates were calculated by the procedure used in the preceding section. The order of reaction was determined in the following manner; for example, for the determination of the order with respect to ammonia, the initial rates were measured by using different mixtures, in which only the ammonia content was varied, keeping

those of oxygen and argon unchanged, and by adjusting the pressures of the driving helium and of the reaction mixtures so that a constant temperature was obtained. The results obtained at 2255±10°K are summarized in Table I and shown graphically in Figs. 5, 6, and 7. The reaction orders with respect to ammonia, oxygen, and argon were found

from least-squares calculation to be 1.70±0.06, 0.51±0.01, and 0.42±0.08* respectively. Thus, the initial rate of ammonia consumption may approximately be expressed by the following equation:

$$v_0 = -\left(\frac{d[NH_3]}{dt}\right)_0 = k_0[NH_3]^{1.5}[O_2]^{0.5}[Ar]^{0.5} \quad (3)$$

Next, the rate constant, k_0, was determined over the 2100—2600°K temperature range and the 2.1—5.4 atm. pressure range by using mixtures of 1% ammonia, 1% oxygen, and 98% argon, on the assumption that the rate equation (3) is valid. The results are shown in Fig. 8 as an Arrhenius plot. The solid line calculated by a least-squares method is expressed as follows:

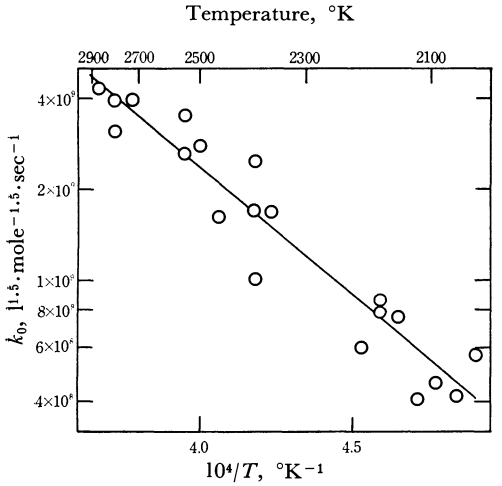

Fig. 8. Arrhenius plot for the rate constants of ammonia consumption in 1%NH_3-1%O_2-98%Ar mixture.

$$\log k_0\ (l.^{1.5}mole^{-1.5}sec^{-1}) = (12.77\pm0.10) + (-8488\pm573)/T \quad (4)$$

The temperature dependence corresponds to an apparent activation energy of 38.8±2.6 kcal./mole. On the other hand, the values of activation energy obtained at lower temperatures[8-10] were in the range of 30—50 kcal./mole. However, a comparison of the present value with those at lower temperatures is useless because the rate expressions in the latter cases are more complicated due to the wall effect.

Also, we were not successful in finding a reasonable chain-branching mechanism to fit the rate expression (3) by using the present and other available data. However, concerning the thermal decomposition of ammonia in shock waves, Jacob[7] obtained the following relation:

$$-d[NH_3]/dt = k[NH_3]^{1.5}[Ar]^{0.5} \quad (5)$$

Here, $k=2.5\times10^{13}\exp(-77\ \text{kcal./}\boldsymbol{R}T)$ l. mole^{-1}· sec^{-1}. In order to explain this relation, Avery and Bradley[11] proposed this reaction scheme:

$$NH_3 + Ar \xrightarrow{k_1} R_1 + \cdots + Ar \quad (I)$$

$$R_1 + NH_3 \xrightarrow{k_2} [R_2 + \cdots] \rightarrow R_1 + \cdots \quad (II)$$

$$R_1 + R_1 \xrightarrow{k_3} \text{stable products}, \quad (III)$$

The assumption of a stationary-state concentration of the R_1 radical leads to a corresponding kinetic expression with $k=k_2k_1^{1/2}/k_3^{1/2}$. If the initiation step I is replaced with the following steps in the case of ammonia oxidation, the rate expression (6) is easily derived by a stationary-state assumption:

$$NH_3 + O_2 \rightleftarrows [NH_3\cdots O_2]$$

equilibrium constant K

$$[NH_3\cdots O_2] + Ar \xrightarrow{k_1'} R_1 + \cdots$$

$$-d[NH_3]/dt = \frac{k_2k_1'^{1/2}K^{1/2}}{\sqrt{2}k_3^{1/2}} \times [NH_3]^{1.5}[O_2]^{0.5}[Ar]^{0.5} \quad (6)$$

This agrees with experimental equation (3). However, the scheme described above is one of many possibilities of explaining the present results; the actual situation in the high-temperature oxidation of ammonia will not be so simple.

In order to explain the present experimental results, it is desirable to compare them with the theoretical rate law and the activation energy, which can be predicted by an analytical solution of several linear differential equation for an appropriate chain-branching scheme. However, no detailed data on elementary reactions are available for this purpose, and so the solution of this problem must be postponed.

The authors wish to express their thanks to Messrs. Kazutoshi Sugiyama and Akio Sawa for their help in the experiment.

*2 Least-squares calculation by using all the data in Table I also gives a reaction order of about 0.5 with respect to argon. However, for the sake of simplicity, typical runs, all conducted under almost the same conditions, except for the argon concentration, in order to keep the effect of the ammonia and oxygen concentrations as small as possible, are shown in Fig. 7.

An NMR Study of Proton Exchange in Alcohols. I. Oxygen Effects in Methanol*1

By Shizuo FUJIWARA, Yuzuru FUJIWARA*2 and Makoto NAGAI*3

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received March 23, 1966)

Molecular interactions between oxygen and organic molecules are investigated in detail. It was confirmed that the broadening of spectral lines due to oxygen is appreciable only with hydroxyl protons. This effect is attributed to the enhancement of the proton exchange of OH groups by oxygen. Detailed investigation was made with methanol-oxygen system. In relation with this, a new method is proposed which makes the measurement of heat of dissolution of oxygen in methanol possible.

It has long been known that the line widths of the electron spin resonance are much broadened by oxygen, but not by nitrogen, argon, and hydrogen.[1] This oxygen effect has tentatively been ascribed to a dipolar broadening of the line from adsorbed paramagnetic oxygen. The reversible interaction of carbon-free radicals with molecular oxygen has also received considerable attention.[2-6]

A similar broadening effect is assumed to exist in high-resolution NMR spectra. Chiarotti and Giulotto made an effort to obtain the T_1 of water which is completely free of oxygen.[7] Gaven, Stockmeyer, an Waugh referred the oxygen effect in the T_1's of methane and other diamagnetic gases.[8] They interpreted the oxygen effect in the same way as in ESR, in terms of local magnetic fields which alter the lifetimes of nuclear-spin states.

However, so far as we know, there is no evidence which shows that the observed line-width broadening with oxygen is mainly due to paramagnetic dipolar interactions. On the contrary, in our preliminary experiment, we encountered several cases where the paramagnetic dipolar broadening due to oxygen is relatively small. The broadening effect is, indeed, so small in several cases that it is only detectable in the wiggles, or in the hyperfine structure. Figure 1 shows the resonance lines of methine protons in degassed and in un-degassed

(By courtesy of Dr. Hayashi of the Japan Electron Optics Company.)

isopropyl chloride. The line width of the degassed sample is slightly narrower than that of the undegassed sample, as may be deduced by the large amplitude of wiggles. A similar fact may be deduced from the resonance lines of the active protons of acetaldehyde (cf. Fig. 2). Figure 3 presents another case where the small difference in line-widths is observed in the change in line shapes of the hyperfine structure. The left-hand-side signal refers to the methyl proton signal at 40 Mc. in un-degassed ethyl ether, and the right-hand side signal, to that in the degassed sample. The line-widths of the degassed sample is smaller than that of the un-degassed one.

It should be noticed that all the compounds referred to above are those which do not contain exchangeable protons. According to the results of these measurements, we may conclude that the dipolar broadening effect of oxygen, present in the liquid in a concentration of a magnitude of contamination, is only about 0.1, or 0.2 cycles per second at room temperature.

This value is about two hundredths of the value calculated by the equation for paramagnetic dipolar broadening derived by Bloembergen[9] with the use of the value of the specific susceptibility of oxygen[10] as $+3449\times10^{-6}$ (293°K), and taking the oxygen content in water or in other liquids, which is in equilibrium with air, as 20 p. p. m. in weight. The latter value was determined by the use of an oxymeter of Magna Corp.[11] On the other hand, those compounds which contain hydroxyl groups give line-widths larger than those which can be ascribed to simple electron paramagnetic dipolar or contact interactions. Typical examples are obtained with methyl alcohol, ethyl alcohol, isopropyl alcohol, aquated acetaldehyde, and hemiacetal.

●; CH_3 of acetal, $CH_3(CH)(OCH_3)_2$
---- instrumental line width

Figure 4(a) shows the spectrum of a proton resonance in an aqueous solution of acetaldehyde. The aquated molecule is coexistent in the same capillary tube with a molecule of pure acetaldehyde. The spectral lines of the two molecular species are distinguished from each other by separate lines which refer to each species. The line-widths of the spectrum of the hydrated molecule are, as shown in the figure, larger than those of the pure acetaldehydre by about 0.5 cycles per second.

Figure 4(b) presents the line-widths of acetaldehyde in a methyl alcohol solution. The width of the methyl signal of hemiacetal, which contains a hydroxyl group, is larger than that of acetal, which does not contain a hydroxyl group. It should be noted that these differences refer to differences between molecular species which are coexistent in the same capillary.

Degassed ethyl alcohol reveals hyperfine structures for all the groups, OH, CH_2, and CH_3, as is shown in Fig. 5. However, in the spectra of the un-degassed sample, the second-order hyperfine structure of CH_2 proton signal, which is observable in the degassed sample, is missed. It must be noted

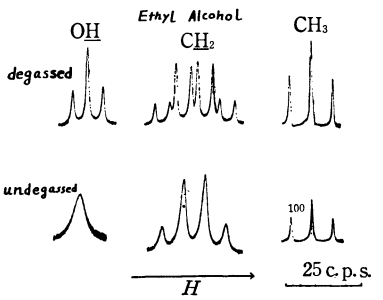

Fig. 5. Hfs. in degassed ethyl alcohol.

that the half-maximum line-widths of one component of the hyperfine lines of the methyl signal is only a few tenths cps. larger in the un-degassed sample than in the degassed sample. This implies that the paramagnetic dipolar or contact broadening effect of oxygen is very small, even in systems which contain hydroxyl protons. It is, therefore, apparent that the large broadening effect which is observed in alcohols and other related compounds is due to the effect of air and to the chemical exchange of hydroxyl protons.

Methyl alcohol is taken as the sample for detailed investigation because it is the simplest alcohol, and a strong oxygen effect is observed in it.

Experimental

Measurements were made at 60 Mc./sec. with a C-60 spectrometer of the Japan Electron Optics Laboratory, and at 100 Mc./sec. with an HA-100 spectrometer of Varian Associates. The sample temperature could be varied from $-100°$ to $+80°C$ with an accuracy of $\pm 1°C$. The line-width was measured in the lower temperature range as the half-maximum line width of one component of the spectra's hyperfine structure. In the higher temperature range, where the hyperfine structure is smeared out, the half-maximum line-widths of the whole envelope of the spectrum was measured. In the intermediate range, measurements were made in line with the nature of the spectrum, according to the method proposed by Alexander.[12]

About twenty samples were prepared and used in the present experiment. They differ according to the procedure used to purify them and according to the impurity concentration. For convenience, however, they may be classified into four groups: (a) the purest one, prepared from anhydrous methanol by a three-stage distillation over magnesium; (b) those prepared by twice distilling them over magnesium: (c) commercial methanol, of the purest guaranteed grade, used as the starting material for the other distillations, and (d) the one prepared by saturating the degassed sample, (a), with one atmosphere of oxygen. Sample (d) will be referred to as "the oxygen sample" in later discussions. As will be shown, these samples show remarkable differences in their chemical shifts and in the exchange rate of their OH protons. It was noticed during the experiment that the spectrum of each sample changed considerably with time. As this happened in sealed-glass tubes, we assumed it to be due to impurities coming from the walls of the glass tubes. Because of this sensitivity in the spectral features, all the results reported here have been obtained from freshly prepared samples.

Degassing was carefully done by repeated freezing and melting, either under a vacuum or under a nitrogen atmosphere. The latter procedure was most effective in removing oxygen.

The chemical shift was measured in two ways: one, by using tetramethyl silane as an internal reference, and the other, by locking the CH_3 signal without any addition of tetramethyl silane. By the former method, the CH_3 signal was found to be independent of the temperature and to be effectively constant, regardless of the presence of oxygen. Figure 6 shows the results of measurements where the methyl signal of tetramethyl silane is locked as the internal standard. It was noticed that tetramethyl silane affects the exchange rate of hydroxyl protons; therefore, precise measurements of the line shape and of the chemical shift of OH protons were made by the latter method. The chemical shift of OH protons in the purest methanol is taken to be -300 ± 1 c. p. s. at 100 Mc., or -3.00 ± 0.01 p. p. m. from CH_3. The fluctuation in this value of ± 1 c. p. s. is due to contamination by trace amounts of oxygen. Contamination by other impurities, such as water and alkali, produces much larger fluctuations. In practice, the chemical shift and the line shape measurements reveal the difficulty of obtaining pure methanol.

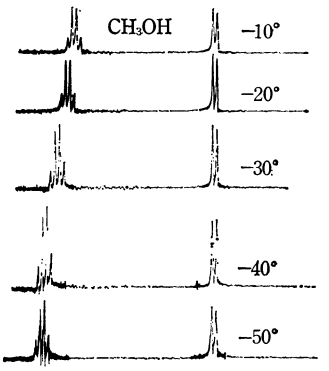

Fig. 6. Chemical shift of OH of MeOH as the function of temperature.

The chemical shift of OH protons is a linear function of the temperature, as has been reported already.[13] The chemical shift of OH protons in the purest methanol can be used as an accurate control of the temperature of an NMR sample.[14]

Results and Discussion

Line-widths.—The line shapes of the proton resonance in methanol are temperature-dependent; they can be divided into three types according to the temperature; one, a single line at a high temperature; two, a well-separated hyperfine structure at a low temperature; and three, a collapsing hyperfine structure at an intermediate temperature. Figures 7 and 8 present typical examples of the temperature dependence of the line shapes of OH protons. The relative position of each spectrum along the horizontal line is with reference to the chemical shift to the temperature at which the spectrum was measured. It may be seen in Fig. 7 that the hyperfine structure begins to appear between 10 and 20°C, and that the components of the quadruplet's structure are well separated at about $-20°C$.

13) J. T. Arnold and M. E. Packard, ibid., **19**, 507 (1951).

14) This technique was also referred to independently by Prof. L. W. Reeves at the NMR Symposium held in Tokyo in 1965.

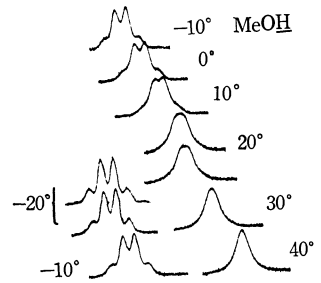

Fig. 7. Temperature dependence of the line shapes of OH protons in MeOH undegassed.

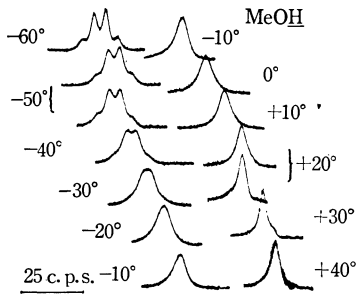

Fig. 8. Temperature dependence of the line shapes of OH protons in MeOH saturated with 1 atmospheric O_2.

However, in Fig. 8, in the oxygen sample the hyperfine structure begins to appear as low as at from −30 to −40°C, and a quadruplet is well separated at −60°C. This is surprising, because both samples have been prepared from the same purified methanol at the same time; they differ only in the concentration of oxygen. If we define T_{hfs} and T_{quad} as the temperature where the hyperfine structure begins to appear and that where the quadruplet structure begins to be well separated respectively, the observed differences in T_{hfs} and T_{quad} between the two samples must be attributed to the effect of oxygen. It may clearly be seen that the critical temperatures for the vacuum-degassed and the nitrogen-degassed samples are lowered by about 5°C in the un-degassed sample. This lowering may also be attributed to the effect of oxygen. It should especially be noted that the observed effect is not due to nitrogen. These results suggest that the lowering of the critical temperature, which is equivalent to the enhancement of the proton exchange between hydroxyl groups, is caused by oxygen.

In order to interpret this effect, we must investigate the interaction of oxygen with methanol. We will do by the method used to investigate the interactions between methanol and transition metal ions,[15] with necessary modifications being made in the course of interpretation. We assume a model which represents the system to be investigated. The system to be considered here consists of two nuclear environments, the coordination sphere of paramagnetic oxygen and the bulk solvent. The two environments are designated by the indices M and A. We will treat a special case where the number of protons in the A environment is much larger than that in the M environment; the ratio of M protons is written as pq, where p is the number of oxygen molecules per solvent molecule, and q, the solvation number of oxygen. Hence, $pq \ll 1$.

The magnetic resonance of A and M protons are characterized by the relaxation times, T_{1A}, T_{2A}, T_{1M}, and T_{2M} respectively. The difference in Larmor frequencies between the two environments is designated by $\Delta\omega$. Protons can be exchanged between the two environments at a rate characterized by the average residence time of a proton in the M environment, τ_M. In fact, we can not assume, in the lower temperature range, a diffusional motion of molecules which produces exchange between bonded and free molecules.

The NMR spectrum actually observed consists essentially of a single peak; i. e., A and M protons do not show separate peaks. We assume that this is not due to the low concentration of oxygen, but to the rapid motion of oxygen, which averages out the resonant sites of all protons in the medium. In such a case, the line-widths of the bonded molecule is related to the electron relaxation time, τ_s, and the hyperfine interaction constant, A. The behavior of the OH and CH_3 peaks is similar, and the same remarks apply to both. At low temperatures, the exchange of molecules between the bulk methanol and the coordination sphere is too slow to affect the spectrum. We assume that the peaks of the bulk methanol are characterized by equal longitudinal and transverse relaxation times, which change little with the temperature.

As the temperature is increased, exchange sets in and the line width increases. It reaches a maximum, and then decreases with an increase in the temperature. This movement is attributed to the exchange between OH protons, resulting in an averaging of the hyperfine lines. It must be noted that the temperature where the maximum width occurs is the same for both the OH and CH_3 signals, and that it depends upon the character of the sample, i. e., the concentration of impurities.

In the lower temperature range, we take the electron spin relaxation time, τ_s, for the correlation time of the interaction between the paramagnetic oxygen and methanol molecules. Kinetic parameters are calculated for molecular interactions in this range by the use of Eqs. 1 to 4. They were originally derived by Solomon and Connick[15] and used by Meiboom.[16]

15) T. J. Swift and R. E. Connick, *J. Chem. Phys.*, **37**, 308 (1962).

16) Z. Luz and S. Meiboom, ibid., **40**, 1058, 1066, 2686 (1964).

$$1/T_{2M}=pq/T_{2M} \quad (1)$$

$$\Delta\omega=pq\Delta\omega_M/[(\tau_M/T_{2M}+1)^2+\tau_M^2(\Delta\omega_M)^2] \quad (2)$$

$$\Delta\omega_M/\omega_I=\frac{s(s+1)}{3kT}\frac{g|\beta|}{\gamma_I}A \quad (3)$$

$$1/T_{2M}=\frac{4}{3}\frac{s(s+1)\gamma_I^2g^2\beta^2}{\gamma^6}\tau_s+\frac{2}{3}\frac{s(s+1)}{\hbar^2}A^2\tau_s^2 \quad (4)$$

In practice, we assume, regarding the relations between τ_s, τ_M, $\Delta\omega_M$, that $\tau_{2M}\gg\tau_M$ and that $\tau_M\Delta\omega_M\simeq 1$. We also assume that r, the distance between oxygen and a methanol molecule, is equal to 3 Å. In Eq. 1, $1/T_2$ is taken to be 0.2 c. p. s. or less, while $\Delta\omega$, in Eq. 2, is taken to be less than 1 c. p. s. The latter is the value for the sample which is saturated with one atmosphere of oxygen; the p value for this solution is found to be 1×10^{-4} from the solubility data. The values obtained are $1/T_{2M}\leqq 500$ c. p. s., $\Delta\omega_M\leqq 1\times10^4$ c. p. s., $A/h=2.3\times10^2$ c. p. s., and $\tau_s=1.5\times10^{-12}$ sec. These values may be compared with those obtained for the methanol-metal ion interactions.[16] It is noted that τ_s is shorter than the correlation time of methanol, which is expected to be about 3×10^{-11} sec., and about the same as that for transition metal ions in methanol. The hyperfine interaction constant is smaller than that of the methanol-metal ion system by a factor of two or three.

The apparent activation energy for the relaxation rate in this range, when calculated from the slope of the temperature dependence of the line widths, is found to be less than several tenths of kcal./mol. This value is about the same order of magnitude as that of the methanol-metal ion system, 0.9 kcal./mol.; it is significantly less than the activation energy for diffusion. This low value of the activation energy may be assumed to be related to the mechanism of relaxation, where the electronic interactions between oxygen and methanol are transmitted rapidly through the methanol medium.

In the higher temperature range, where the hyperfine structure begins to smear out, the activation energy for the change in line width is found, from spectra showing the hyperfine structure, to be about 3 kcal./mol. This coincides with the value generally adopted as the activation energy for the molecular diffusion of methanol; it suggests that the smearing of the hyperfine structure is due to the diffusional or rotational motion of methanol.

Oxygen Effect.—According to the results given previously, it is clear that the oxygen effect in methyl alcohol is far less than expected with regard to paramagnetic dipolar or contact broadening. However, the proton exchange between hydroxyl groups is strongly enhanced by oxygen. This effect may clearly be seen in Figs. 7 and 8; it will be expressed in terms of the exchange rate of hydroxyl protons, $1/\tau$, which is calculated using the data obtained from Figs. 7 and 8. The half-maximum line-width of one component of the spectra showing hyperfine structure is measured and designated as $1/T_2$. The measured line-width parameter, $1/T_2$, is related to the following equation, $1/T_2=1/T_{20}+1/\tau+1/T_1$, where $1/T_{20}$ is the linewidth of the spectrum for the state where there is no proton exchange, and where $1/T_1$ is the contribution of the spin-lattice relaxation of paramagnetic oxygen. The last term can not be neglected in principle; however, its contribution is assumed to be negligible in methyl alcohol which contains oxygen, since the line-width of the un-degassed sample is only by one- or two-tenths cycle per second larger than that of the degassed sample in the lower temperature range where there is no proton exchange. Similarly, the line-widths of methyl proton signals in un-degassed and in degassed ethyl alcohol differ from each other by only one or two cycles per second.

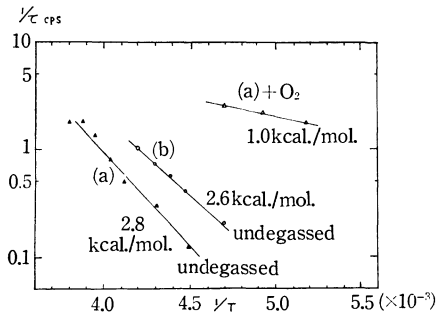

Fig. 9

The Arrhenius plots of the exchange rates obtained are shown in Fig. 9; the activation energy for the exchange, ΔE, is obtained as, for example, ca. 1.0 kcal./mol., and ca. 3 kcal./mol. for the with-oxygen and the un-degassed methyl alcohol respectively. The difference, ΔE, between these two samples may be ascribed to the energy evolved by the dissolution of oxygen in methyl alcohol. This can be done in view of the following considerations. As is clear from the results of Fig. 4 on ethyl alcohol, the molecular interaction between alcohol and oxygen is not homogeneous over a molecule of alcohol, and the oxygen relaxes more strongly at the site of a hydroxyl group than at that of a methyl group. This refers to the specific interaction between hydroxyl protons and oxygen, which results in the evolution of a heat of interaction as well as in an elongation of the OH distance. The latter situation is related to the enhancement of the proton exchange between the hydroxyl group and to the reduction of the apparent activation energy of the proton exchange, ΔE.

We may conclude that the results obtained here suggest a new method of measuring the heat of solution of oxygen in methyl alcohol, Q, which has not yet been made available in the literature. In practice, we could not find any significant difference

in ΔE between degassed and un-degassed methyl alcohol; all differences were within the limits of experimental error. We found $Q=3-1=2$ kcal./mole.

As may be seen in Figs. 7 and 8, the enhancement of the proton exchange between hydroxyl groups is clearly seen in the temperature range where the quadruplet structure begins to be unobservable; that is at -30 or -40°C for the with-oxygen sample, and at 10 or 20°C for the un-degassed sample. A lowering by about 5°C is observed between the degassed and the un-degassed samples. These results refer to the difference in frequency factors, ν_1 assuming a constant activation energy, ΔE. For example, we take:

ν(oxygen sample) $\exp(-3/233\,k)=\nu$(un-degassed) $\exp(-3/293\,k)$.

Hence,

ν(oxygen sample)/ν(un-degassed)$=4.5$

Similarly,

ν(un-degassed)/ν(degassed)$=1.4$

The catalytic effect of trace amounts of oxygen may be related to the short relaxation time of the electronic spin of oxygen; it suggests a very rapid transportation of the spin energies of oxygen. We will not here give a more detailed interpretation of this mechanism of transportation. However, we will note a case of molecular interaction between water and ammonia as an example of how a trace amount of impurity (water) dominates the orientation of the nuclear spins of ammonia.

Summary

1) The dipolar broadening effect of oxygen is small in NMR.

2) The proton exchange rate for hydroxyl groups is enhanced appreciably by the presence of oxygen. This may be attributed to an increase in the frequency factor of the exchange rate.

3) A new method has been proposed for the determination of the heat of the solution of oxygen; this method is based on the oxygen effect referred to in 2).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2361—2364 (1966)

The Superstructure in Fine Aragonite Particles

By Yuzuru HIRAGI,† Sukeji KACHI,† Toshio TAKADA†† and Norihiko NAKANISHI†

†*Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto*
††*Institute for Chemical Research, Kyoto University, Sakyo-ku, Kyoto*

(Received April 9, 1966)

An electron diffraction study was done with fine aragonite particles about 0.5 to 1.0 μ in size. The specimens were obtained by mixing a boiled calcium chloride solution (0.1 N) with 0.1 N of an ammonium carbonate solution. Extra spots were observed with half-integer indices $\{1/2, 1/2, l\}$. This suggests the existence of a structure that differs from that of normal aragonite. From an X-ray diffraction study of the specimen, a $\{1/2, 3/2, 0\}$ diffraction was also observed. The structure for explaining these half-integer diffractions is presented as a superstructure of aragonite; it belongs to the space group of D_{2h}^{15}-*Pbca*, with cell dimensions of $A=8.420$ Å, $B=9.385$ Å, and $C=5.741$ Å, and it containes 8 formula units in a unit cell. A dark-image photograph shows this anomalous area to be comparatively wide and suggests that the anomalous area is dominant in a crystal. The authors conclude that rapidly-precipitated aragonite powders contain a small quantity of the repeatedly-twinned crystals mentioned above.

There are, as is well known, three modifications of calcium carbonate; calcite with a rhombohedral structure, aragonite with an orthorhombic structure, and vaterite with a hexagonal structure. Furthermore, many investigations of polymorphism in calcite have revealed the existence of calcite I, II and III,[1] which differ from each other only in the orientation of their carbonate groups.[2,3]

However, no such anomalous structure has yet been reported for aragonite except for the twin structure proposed by Bragg.[4] This twin structure is made up of two crystals intersecting on the (110) plane, arrangements of the cabonate group being symmetrical with this plane.

In the course of a study of the phase transformation of aragonite to calcite,* the present authors

found a new structure of aragonite. The electron diffraction patterns taken from fine crystals of aragonite exhibited extra spots involving half-integer indices which cannot be explained by the ordinary structures. As a result of the analysis, the new structure was found to correspond to a superstructure with regard to the orientation of the carbonate ion group.

Experimental

To obtain fine particles of aragonite suitable for electron diffraction, the following procedure was carried out: Equal volumes of solutions of calcium chloride (0.1 N) and of ammonium carbonate (1.0 N) were prepared; then both were boiled to 100°C and mixed together to precipitate calcium carbonate. The precipitate was soon filtrated and dried. Although it is difficult to obtain pure and fine aragonite powders, almost 100 percent of the aragonite was precipitated under these conditions. The water suspension of the particles was dispersed by ultrasonic waves to obtain pieces of aragonite crystals, which were a few μ long and a few thousands of Å wide and thick.

They were examined by the direct transmission of a selected area in an electron microscope with an applied voltage of 50 kV. It generally happens that the thickness of the particles is so large that the electron beam can not easily penetrate the particles. However, one can get the diffraction pattern by searching out a thin plate. The X-ray diffraction study was also made by the Debye-Scherrer method, using a diffractometer.

Results and Discussion

Figure 1 (a) and (b) show an electron micrograph and a diffraction pattern taken from aragonite involving half-integer indices. The net diffraction pattern shows that the particle is a single crystal and that it has an orthorhombic lattice. Figure 2 shows the indices of the diffraction pattern, based on the normal aragonite lattice. The results of the analysis are shown in Table I, in which the $d_{calc.}$ values were calculated from the cell dimensions given on the A. S. T. M. card 5—0453. Figure 3 (a) and (b) show an electron micrograph and dark-image photographs of a fine aragonite particle. Figure 4 shows a part of the X-ray diffraction chart of the aragonite powder; the (1/2, 3/2, 0) diffraction was observed as well as the diffraction from normal aragonite.

1, 1, 3	1.78	1.742

In the case of electron diffraction, the planes which satisfy the diffraction conditions are parallel to the incident electron beam. Hence, it necessarily follows from the analysis of the pattern that the plate of aragonite must have been oriented to the (001) and (110) planes parallel to the direction of the electron beam; judging from the dark image photographs, the [001]axis is parallel to the length of the plate.

The half-integer indices on the electron diffraction and X-ray diffraction patterns cannot be accounted for by a normal aragonite structure. The normal aragonite structure belongs to the space group D_{2h}^{16}-*Pmcn*,[4] for which the following conditions limit the possible reflections: for *hkl*: no condition; *hko* : $h+k=2n$, and for *hol* : $l=2n$. Nevertheless, in the present electron diffraction pattern, there appear several forbidden spots which do not satisfy the rule; for example, $(00\bar{3})$, $(00\bar{1})$, (001)...; spots which are denoted by in Fig. 2 cannot satisfy the rule. This observation indicates that the double diffraction occurs in a fairly thick crystal, because generally the electron beam strongly interacts with materials. However, the half-integer indices, whose spots are denoted by ⊠, cannot be accounted for by the normal structure of aragonite, even if the double diffraction effect is taken into account. The half-integer spots can be seen along the [110] axis of the reciprocal lattice shown in Fig. 2. Therefore, the periodicity of the (110) plane must be twice as large as that of normal aragonite; i. e., reflections with $\{1/2, 1/2, l\}$ indices suggest a superstructure which has a repeating unit twice as large as that of normal aragonite. In view of the fact that the l indices still remain integers in both electron and X-ray diffraction

patterns, it must be added that there is no anomaly in the direction of the 'c' axis.

The model for such a structure is presented in the form of the (001) projection in Fig. 5, where only one-half of the structure along the 'c' axis is drawn. The superstructure is constructed so as to repeat the twinning every two layers of carbonate ions on (110) planes; this is called polysynthetic twinning by mineralogists. In Fig. 5, solid lines show the two unit cells of the repeated twinning

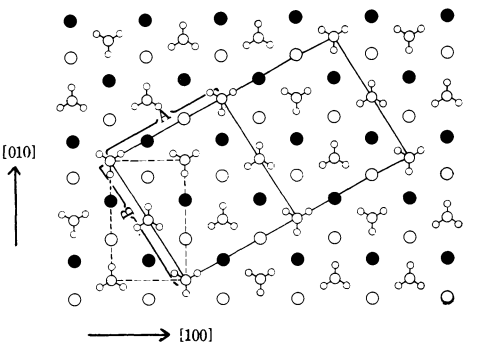

Fig. 5. The (0 0 1) plane projection of the model for superstructure, in which is drawn the position of atoms from 0 to $c/2$. The rigid lines show the unit cells of the superstructure, and broken lines a unit cell of normal aragonite. There is no longer the periodical structure within the broken lines.

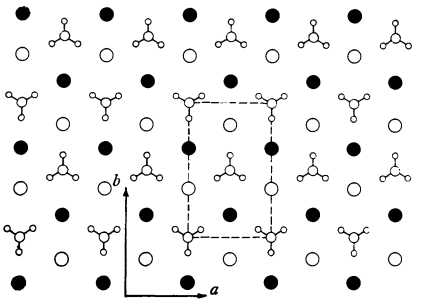

Fig. 6. The structure of normal aragonite projected on (0 0 1) plane.

structure, while the broken lines show a unit cell of normal aragonite. We can see that a periodic structure is lacking within the lines.

For comparison, Fig. 6 shows a (001) projection of the normal aragonite. As can be seen, all CO_3 groups which lie in a row parallel to the 'a' axis are similarly oriented, whereas groups which lie in a row parallel to the (110) plane point alternate ways. Meanwhile, in the superstructure, as Fig. 5 shows, every two CO_3 groups in the row parallel to the 'a' axis of normal aragonite orient in alternate ways, and the groups which lie in a row parallel to the (110) plane of normal aragonite similarly orient in alternate ways, like the case of normal aragonite.

This model is still aragonite, for it has the same layer structure as normal aragonite. It belongs to the space group of D_{2h}^{15}-*Pbca*, with cell dimensions of A=8.420, B=9.385 and C=5.741, and it containes 8 formula units in a unit cell. The relation of normal aragonite to the twinned structure is given by:

$$\boldsymbol{A} = \mathbf{a} - \mathbf{b} \qquad H = h - k$$

$$\boldsymbol{B} = \frac{3}{2}\mathbf{a} + \frac{1}{2}\mathbf{b} \quad K = \frac{3}{2}h + \frac{1}{2}k$$

$$\boldsymbol{C} = \mathbf{c} \qquad L = l$$

where $\boldsymbol{A}$, $\boldsymbol{B}$, $\boldsymbol{C}$, and H, K, L are, respectively, the unit lattice vector and the Miller indices of the superstructure, and where $\mathbf{a}$, $\mathbf{b}$, $\mathbf{c}$ and h, k, l are those of the normal aragonite.

The content of twinned particles is so small compared to the normal aragonite that the diffraction from the twinned structure is very weak in X-ray diffraction studies. Hence, it is necessary to distinguish carefully the diffracted peaks from the backgrounds. In the present experiments both Fe$K\alpha$ and Cu$K\alpha$ radiations were used to take X-ray diffraction patterns. In the pattern of the diffraction with Cu$K\alpha$ radiation shown in Fig. 4, the (1/2, 3/2, 0) diffraction was observed. It must also be added that this peak is also observed in diffractometry using Fe$K\alpha$ radiation. These findings support the theory of the presence of a superstructure and the appropriateness of the model.

The dark-image photographs show that the area of the superstructure is comparatively large; however, it is still not clear whether or not this area covers all the crystal, for it is generally difficult to get a clear dark-image photograph. Nevertheless, as the superstructure region requires a different structure, one may call this another phase, i. e., aragonite II.

The authors are grateful to Dr. Tsuneo Seto of Tokyo Metropolitan University for determining the space group, and to Prof. Hatsujiro Hashimoto of Kyoto Technical University and Dr. Takeo Ueda of our university for their helpful suggestions. They are also grateful to Dr. Yasumasa Goto and Mr. Koji Kosuge of our laboratory for their fruitful discussions. One of them (Y. H.) wishes to express his gratitude to Mr. Shigeki Shimidzu of the Toda Industry Co., Ltd., and Mr. Shigeo Horii of the Reikoo Co., Ltd., for their support during the work.

The Vibrational Assignments of Sulfuryl-Fluoride, -Chloride and -Fluorochloride and Their Transferable Force Constants

By Hiroshi Toyuki and Kazuhiro Shimizu

Osaka Municipal Technical Research Institute, Kita-ku, Osaka

(Received April 13, 1966)

A normal coordinate treatment has been carried out on the basis of the Urey-Bradley force field in order to obtain a set of the most probable assignments and the transferable force constants for the sulfuryl fluoride, the chloride and the fluorochloride series. The assignments selected and the force constants obtained have been satisfactory. The potential energy distributions have been calculated and the vibrational modes have been estimated for each molecule.

Several infrared and Raman spectra of sulfuryl fluoride[1-3] and chloride[3-7] have already been recorded; their normal coordinate treatments have been made on the basis of the valence force field (VFF).[2,8-10]

Siebert[8] assumed the same angular geometry for both molecules and used a seven-parameter VFF. Stammrich et al.[9] simply reported $\nu_5(A_2) < \nu_9(B_2) < \nu_7(B_1)$ as holding for sulfuryl fluoride and $\nu_5(A_2) < \nu_7(B_1) < \nu_9(B_2)$ as holding for sulfuryl chloride, in connection with a normal coordinate analysis of chromyl chloride. Hunt et al.[10] applied the VFF described by Siebert to both the molecules and calculated several corresponding sets of force constants for probable sets of assignment of each molecule by using the correct geometry and the redundant condition. They could find a probable set of the force constants which predicted the fundamental frequencies for an assignment

of sulfuryl chloride, but they could not find a suitable one for the fluoride. However, one of the assignments for the fluoride unsuccssefully treated by Hunt et al. was recently supported, after a useful study of the microwave spectrum, by Lide et al.[11] For this reason, a normal coordinate treatment for both the molecules on the basis of the force field other than the VFF may be useful in the choice of probable assignments. Thus, we will try to carry out the treatment by using the simple Urey-Bradley force field (SUBFF). If necessary, the modified Urey-Bradley force field (MUBFF) will also be employed.

When the force constants obtained for sulfuryl fluoride and chloride predict satisfactorily the observed fundamental frequencies of corresponding molecules, consist with any tentative expectation and moreover they are transferable to sulfuryl fluorochloride, the assignment used is taken as the most probable one for each molecule.

Calculations

Sulfuryl fluoride and chloride both have a tetrahedral configuration and belong to the point group C_{2v}.[12,13] The nine normal vibrations of each molecule are distributed among the four symmetry species: four of the A_1 species, one of the A_2 species, two of the B_1 species, and two of the B_2 species. The A_2 mode is active only in Raman spectra, while the A_1, B_1 and B_2 are both infrared- and Raman- active.

Though we have, unfortunately, no configuration data on sulfuryl fluorochloride, the molecule is supposed to have a configuration similar to that of sulfuryl fluoride and chloride. If the OSO plane is assumed to be at right angles to the FSCl plane, the configuration belongs to the point group C_s. The nine normal vibrations are nondegenerate— six of the A′ species and three of the A″ species. All the vibrations are both infrared- and Raman-active.

The following symmetry coordinates are used for the transformation into the factored $\boldsymbol{F}$ and $\boldsymbol{G}$ matrices defined by Wilson[14]:

For sulfuryl fluoride and the chloride:

$$A_1:\ S_1 = (1/\sqrt{2})(\Delta R_1+\Delta R_2)$$
$$S_2 = (1/\sqrt{2})(\Delta r_3+\Delta r_4)$$
$$S_3 = (1/\sqrt{P})(A\Delta\alpha_{12}-\Delta\theta_{13}-\Delta\theta_{14}-\Delta\theta_{23}-\Delta\theta_{24})$$
$$S_4 = (1/\sqrt{Q})(B\Delta\beta_{34}-C\Delta\alpha_{12}-\Delta\theta_{13}-\Delta\theta_{14}-\Delta\theta_{23}-\Delta\theta_{24})$$
$$S_r = (1/\sqrt{R})(\gamma_1\Delta\alpha_{12}+\gamma_2\Delta\beta_{34}+\Delta\theta_{13}+\Delta\theta_{14}+\Delta\theta_{23}+\Delta\theta_{24})\equiv 0$$

$\gamma_1=2\cos(\beta/2)\sin(\alpha/2)/\sin\theta$, $\gamma_2=2\cos(\alpha/2)\sin(\beta/2)/\sin\theta$, $A=4/\gamma_1$, $B=(4+\gamma_1^2)/r_2$, $C=\gamma_1$, $P=A^2+4$, $Q=B^2+C^2+4$, $R=\gamma_1^2+\gamma_2^2+4$

$$A_2:\ S_5 = (1/2)(\Delta\theta_{13}-\Delta\theta_{14}-\Delta\theta_{23}+\Delta\theta_{24})$$
$$B_1:\ S_6 = (1/\sqrt{2})(\Delta R_1-\Delta R_2)$$
$$S_7 = (1/2)(\Delta\theta_{13}+\Delta\theta_{14}-\Delta\theta_{23}-\Delta\theta_{24})$$
$$B_2:\ S_8 = (1/\sqrt{2})(\Delta r_3-\Delta r_4)$$
$$S_9 = (1/2)(\Delta\theta_{13}-\Delta\theta_{14}+\Delta\theta_{23}-\Delta\theta_{24})$$

and for sulfuryl fluorochloride,

$$A':\ S_1 = (1/\sqrt{2})(\Delta R_1+\Delta R_2)$$
$$S_2 = \Delta r_3$$
$$S_3 = \Delta d_4$$
$$S_4 = (1/\sqrt{S})(D\Delta\alpha_{12}-\Delta\theta_{13}-\Delta\theta_{14}-\Delta\theta_{23}-\Delta\theta_{24})$$
$$S_5 = (1/\sqrt{T})(E\Delta\beta_{34}-F\Delta\alpha_{12}-\Delta\theta_{13}-\Delta\theta_{14}-\Delta\theta_{23}-\Delta\theta_{24})$$
$$S_6 = (1/2)(\Delta\theta_{14}+\Delta\theta_{24}-\Delta\theta_{13}-\Delta\theta_{23})$$
$$S_r = (1/\sqrt{U})(\delta_1\Delta\alpha_{12}+\delta_2\Delta\beta_{34}+\Delta\theta_{13}+\Delta\theta_{14}+\Delta\theta_{23}+\Delta\theta_{24})\equiv 0$$

$\delta_1=2\cos(\beta/2)\sin(\alpha/2)/\sin\theta$, $\delta_2=2\cos(\alpha/2)\sin(\beta/2)/\sin\theta$, $D=4/\delta_1$, $E=(4+\delta_1^2)/\delta_2$, $F=\delta_1$, $S=D^2+4$, $T=E^2+F^2+4$, $U=\delta_1^2+\delta_2^2+4$,

$$A'':\ S_7 = (1/\sqrt{2})(\Delta R_1-\Delta R_2)$$
$$S_8 = (1/2)(\Delta\theta_{13}-\Delta\theta_{23}+\Delta\theta_{14}-\Delta\theta_{24})$$
$$S_9 = (1/2)(\Delta\theta_{14}-\Delta\theta_{24}-\Delta\theta_{13}+\Delta\theta_{23})$$

The internal coordinates used above are shown in Fig. 1.

The molecular constants of sulfuryl fluorochloride must be estimated because there are no experimental constants. The values of the equilibrium distance, S–F and S–Cl, are assumed to be equal to the corresponding one of sulfuryl fluoride and chloride. The S–O distance and the OSO angle proposed by Gillespie et al.[15] are used. This value of the OSO angle and the values of the OSF angle of sulfuryl fluoride and of the OSCl angle of sulfuryl chloride cause the FSCl angle to be 104.1 deg. On the other hand, an arithmetical mean value of the FSF and ClSCl angles shows the FSCl angle to be 103.9 deg. As a result, we regard the value of the FSCl angle as 104 deg. Since the difference between the observed angle, OSF (108.3 deg.), of sulfuryl fluoride and the OSCl angle (106.4 deg.) of the chloride is less than 2 deg., the bond angles, OSF and OSCl, in sulfuryl fluorochloride can be assumed to be equal in a normal coordinate treatment. The

∠FSCl deg.			104
∠OSF deg.	108.3		107.4
∠OSCl deg.		106.4	107.4

For the purpose of obtaining the force constants of sulfuryl fluoride and chloride in order to fit the calculated frequencies to the observed, the method of the minimization of functions described by Shimanouchi et al.[16] is used, because the usual adjustment of least-squares was inadequate for these molecules. At the beginning of the calculation of force constants, the trial set of force constants are transferred from corresponding ones of thionyl halides, sulfur trioxide, sulfate ions, etc. The force constant, F', is assumed to be equal to $-0.1F$, as usual. The observed frequencies of sulfuryl fluoride assigned obviously by Lide et al. and those of sulfuryl chloride which were discussed by Hunt et al. are used in the calculations.

The calculation of the vibrational frequencies of sulfuryl fluorochloride are also carried out by the use of force constants transferred or predicted by applying the usual additive property from the values of sulfuryl fluoride and chloride. The results of calculation are then compared with the observed frequencies.

Results and Discussion

The convergence of force constants for sulfuryl fluoride is obtained readily in the SUBFF. Although Hunt et al. failed to make a normal coordinate analysis of this assignment with the VFF, we have obtained a good agreement between the calculated and the observed frequencies, as is shown in Table II. Moreover, the values of the force constants obtained are reasonable, as Table III shows.

On the other hand, the calculations on the basis of the SUBFF for Hunt et al.'s and our assignments of sulfuryl chloride show no great difference in the average deviation between the observed and the calculated frequencies. These results are listed as the set I and the calc.(1) of set II in Tables II and III. The values of the force constants obtained are reasonable, except for κ in set I having a large negative value. Since the deviation between the observed and the calculated frequencies in set I is found to be not great in the modes related by the κ, this exceptional value of κ in set I can not be corrected through a modification of the potential function. On the other hand, the calc.(1) of set II in Table II shows a great deviation in the rocking mode; this deviation can be corrected by applying the following modified UBFF (MUBFF), in which the l_{ijk} is the interaction force constant:

$$V = (\text{SUBFF}) + \sum l_{ijk}(\Delta\theta_{ij})(\Delta\theta_{ik})$$

The results of the calculation are shown in calc.(2) of set II in Tables II and III. It is not clear why such extra terms are necessary for sulfuryl chloride but unnecessary for sulfuryl fluoride.

The nonbonded O···O distances and the repulsion constants, F(OO)'s, picked up from previous reported data are shown together with our data in Table IV. The value of the constant obtained

* The value is calculated from the assignment-set I of SO_2Cl_2.

from our assignment of sulfuryl chloride seems to be adequate. The corresponding force constants between F and F and between Cl and Cl are approximately equal to the values calculated from the Lennard-Jones 6–12 potential; therefore, they may be considered to be appropriate. (As the force constants for other assignments of sulfuryl chloride treated by Hunt et al.[10] show inadequate values, their results are not reprinted here.)

In Table II, our assignment of sulfuryl chloride, shown as set II, is found to be more suitable than the assignment shown as set I in view of the force constants transferring from sulfuryl fluoride and chloride to sulfuryl fluorochloride, as is shown in Table V. We recorded the infrared spectrum of liquid sulfuryl chloride in the range from 400 cm^{-1} to 200 cm^{-1} with a Japan Spectroscopic spectrophotometer-402G. We can find no band near 280 cm^{-1}, and we find near 350 cm^{-1} the weak band observed at 363 cm^{-1} in the Raman spectrum.* This means that the Raman band at 280 cm^{-1} belongs to the infrared inactive A_2 species. These facts show that our assignment of sulfuryl chloride can be considered satisfactory. Therefore, the force constants of this molecule, listed in column 2 of set II in Table III, seem to be appropriate.

Gillespie et al.[21] reported a Raman band of sulfuryl fluorochloride at 195 cm^{-1} as one of

* The far infrared spectrum in the gaseous state is now being studied; it will be reported on later.

deformations connected with the chlorine atom, but, judging from our calculations, this frequency seems to be unsuitable as a fundamental one. We employ the Raman band at 308 cm^{-1} instead of that at 195 cm^{-1} and identify it as the FSCl deformation, $\nu_6(A')$, superimposed on the twisting, $\nu_9(A'')$, deformation, as is shown in Table V. The band at 195 cm^{-1} might rise from a difference between two vibrations.

The Crystal Structures of L-Tryptophan Hydrochloride and Hydrobromide

By Takaji TAKIGAWA,* Tamaichi ASHIDA, Yoshio SASADA and Masao KAKUDO

Institute for Protein Research, Osaka University, Kita-ku, Osaka

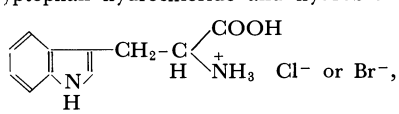
(Received April 26, 1966)

The hydrochloride and hydrobromide of L-tryptophan crystallize in the monoclinic space group $P2_1$. The cell dimensions of the hydrochloride are: $a=7.45$, $b=5.30$, $c=14.67$ Å, $\beta=98.80°$, and those of the hydrobromide are: $a=7.64$, $b=5.41$, $c=14.58$ Å, $\beta=100.47°$. There are two molecules in the unit cell. The two compounds are isomorphous. The crystal structure of the hydrobromide was first determined by the heavy atom method with two-dimensional data, and then that of the hydrochloride was refined by three-dimensional least-squares procedure. The molecular and crystal structure is mainly discussed for the hydrochloride here. The average of six C–C bond lengths in the benzene ring is 1.396 Å, that of C–N bond lengths in the indole ring is 1.384 Å. In the carboxyl group, one C–O bond length, 1.147 Å and two O–C–C angles, 106.8° and 125.7° are significantly different from those reported for amino and carboxyl acids so far investigated. The molecule consists of two planes of the carboxyl group and of the indole ring, the planes making an angle of 70.6° with each other. As to the conformation about the C(α)–C(β) bond, C(γ) lies at the gauche position with both of the carboxyl and the amino groups. The molecules are arranged in double layers parallel to the ab plane; the polar layer is held together by a network of the three N–H··· Cl^- hydrogen bonds, 3.17, 3.19 and 3.24 Å and one O–H···Cl^-, 3.04 Å, and in the non-polar layer, the indole rings are packed mainly by van der Waals forces, the shortest C···C and C···N contacts being 3.74 and 3.42 Å respectively.

The three-dimensional structures of the amino acids have been studied by many authors to furnish the structural basis for protein research.[1] Out of twenty-odd naturally occurring amino acids, some seventeen compounds have been determined by X-ray analysis so far. Although the preliminary examination was reported for DL-tryptophan dihydrochloride by Dawson and Mathieson,[2] detailed X-ray analysis for tryptophan has not yet been published. This paper deals with X-ray analysis of the crystal structures of L-tryptophan hydrochloride and hydrobromide.

Experimental

L-tryptophan hydrochloride and hydrobromide,



were obtained in the form of needle-like crystals by dissolving L-tryptophan in concentrated hydrochloric and hydrobromic acid respectively at room temperature and by standing them at 5°C.

Rotation, Weissenberg and precession photographs showed the crystals to be monoclinic, the unique b being coincident with the needle axis. The unit-cell dimensions were determined from zero layer Weissenberg photographs taken about three crystallographic axes with standard aluminum powder reflections. The densities were measured by flotation in a benzene-carbon tetrachloride mixture.

Crystal data so obtained are:

For hydrochloride,

$a=7.45\pm0.02$, $b=5.30\pm0.01$, $c=14.67\pm0.02$ Å, $\beta=98.80\pm0.07°$, $D_m=1.394$, $D_c=1.396$ g. cm^{-3}, $Z=2$,

$\mu=29.1$ cm^{-1} for Cu$K\alpha$ radiation.

For hydrobromide,

$a=7.64\pm0.02$, $b=5.41\pm0.01$, $c=14.58\pm0.02$ Å, $\beta=100.47\pm0.10°$, $D_m=1.594$, $D_c=1.597$ g. cm^{-3} $Z=2$,

$\mu=49.0$ cm^{-1} for Cu$K\alpha$ and 37.6 cm^{-1} for Mo$K\alpha$ radiation.

The only systematic absence in these two crystals is observed for (0k0) reflections with k odd. The space group was determined to be C_2^2-$P2_1$, an alternative centrosymmetric space group C_{2h}^2-$P2_1/m$ being excluded because of the asymmetry of the molecule.

Somewhat different crystal was obtained by dissolving L-tryptophan in dilute hydrobromic acid (1 N). The cell constants with less accuracy are $a=31.30$, $b=13.86$, $c=5.73$ Å, space group being $P2_12_12_1$. Density was measured to be 1.444 g. cm^{-3}. Elementary analysis and the crystal data indicated that the asymmetric unit consisted of 2tryptophan·HBr·1/2H_2O. No further study was attempted for this crystal.

2) B. Dawson and A. Mathieson, *Acta Cryst.*, **4**, 475 (1951).

For the hydrochloride, three-dimensional intensity data were collected by equi-inclination Weissenberg procedure with nickel-filtered Cu$K\alpha$ radiation. Photographs were taken for layers ($h0l$) to ($h4l$) and ($0kl$) to ($5kl$) by the multiple-film technique. Out of 1387 accessible reflections, 1258 non-zero reflections were observed and they amount to 80% of the reciprocal lattice points within the limiting sphere for Cu-$K\alpha$ radiation.

For the hydrobromide, only intensity data for ($h0l$) and ($0kl$) zones were recorded on Weissenberg and precession photographs respectively, the latter being taken with zirconium-filtered Mo$K\alpha$ radiation.

Intensities were estimated visually against the standard scale and they were corrected for Lorentz and polarization factors. For the equi-inclination Weissenberg data, a correction for spot-shape was made according to Phillips' equation.[3] Sizes of crystals used in the experiment were: $0.10\times0.15\times2.0$ mm. and $0.15\times0.15\times0.40$ mm. for the b and a axis photographs of the hydrochloride respectively, $0.15\times0.15\times2.5$ mm. for the b axis photographs of the hydrobromide.

Three-dimensional structure factors were put on a common scale by comparing data from photographs of the different axis. Estimated errors in the scaling were less than 10%.

Since the a axis data seemed to be less accurate than the b axis data, the former was only used, in the subsequent analysis, for reflections unaccessible by the b axis photographs.

Structure determination

Hydrobromide.—A modified Patterson projection along the b axis was constructed for the hydrobromide. From a heavy Patterson peak, the x- and z-coordinates of the bromide ion were determined to be 0.100 and 0.125 respectively. Based on the signs of the bromide ion, Fourier summation was carried out. Almost all the atoms were resolved on the resulting Fourier projection, and it was not difficult to give approximate coordinates even for a few overlapped atoms. Succesive Fourier refinement was made until the discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, became 0.19, the overall temperature factor $B=4.0$ Å^2 being applied. A least-squares refinement was then proceeded using 240 independent ($h0l$) reflections. Anisotropic temperature factors were applied only for the bromide ion. After three cycles of the refinement, the R factor dropped to 0.086.

In the a axis projection with the plane group pg, the y coordinate of the bromide ion was arbitrarily fixed at 1/4. On the Fourier projection based on the phases of the bromide ion only, much overlapping was observed, since it involved an additional mirror symmetry. With the aid of the molecular model of tryptophan and the b axis projection, the Fourier projection on (100) was interpreted reasonably and approximate y coordinates of all the atoms were obtained. Successive Fourier refinement decreased the R factor to 0.196. Further refinement was carried out by least-squares refinement, and after three cycles the R factor became 0.101.

Hydrochloride.—As seen from Fig. 1, the modified Patterson projections of hydrochloride and hydrobromide were similar to each other in general feature. This observation and approximately the same unit cell dimensions of the two crystals suggested that these two were isomorphous. The x- and z-coordinates of the chloride ion were determined to be 0.100 and 0.122 respectively from the Patterson projection. Fourier projections on (010), (100) and (001) were made with phases which were derived by assuming that the coordinates of the non-hydrogen atoms except the chloride ion were the same as those in the hydrobromide. The approximate coordinates of all the atoms were obtained from these Fourier projections and they were improved by three-dimensional Fourier synthesis.

The refinement of the structure was carried out by three-dimensional least-squares procedure. The least-squares program was constructed with the block-diagonal matrix approximation. In the earlier stage, temperature factor for each atom was taken as isotropic.

Three cycles of the refinement deduced the

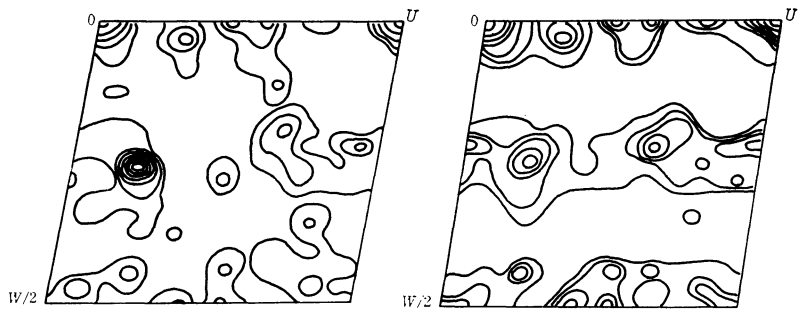

Fig. 1. Patterson projection on (010), modified by the factors of $M(\sin\theta)=\exp\{8(\sin\theta/\lambda)^2\}$
a) of the hydrobromide b) of the hydrochloride

3) D. C. Phillips, Acta Cryst., **7**, 746 (1954).

R factor from 0.193 to 0.131. Disagreement between the observed and calculated structure factors increased with increasing k values. It was suggested that the anisotropic thermal vibration should be taken into account. Three cycles of least-squares refinement, with the anisotropic temperature factors for all the atoms, deduced the R factor to 0.117. Since the systematic disagreement remained, interlayer scales of the b axis data were adjusted by comparing the observed and

the carboxyl group were put on the lines to the chloride ions with which they hydrogen-bonded. After three cycles of the least-squares refinement, average shifts in the coordinates of the non-hydrogen atoms were $\Delta x/a=0.0003$, $\Delta y/b=0.0006$ and $\Delta z/c=0.0001$ and their maximum shifts were 0.0008, 0.002 and 0.004 respectively, and the R factor dropped to 0.087. Additional two cycles of the least-squares were made in order to adjust the interlayer scale factors, leaving coordinates and temperature factors fixed. The R factor was 0.088 and $\sum|F_c|/\sum|F_o|$ for each k value converged fairly to the unity. The weights in the least-squares calculation were given systematically as a function of the absolute values of the structure factors. Damping factors for the shifts were as follows; 0.7 in the overall scale factor, 0.5 in the overall temperature factor, 0.7 in the coordinates of non-hydrogen atoms, 0.5 in the anisotropic temperature factors of non-hydrogen atoms, and 0.1 in the coordinates and isotropic temperature factors of hydrogen atoms. The atomic scattering

factors were taken from the International Tables for X-ray Crystallography.[4]

The final atomic coordinates with their standard deviations are listed in Table I and the anisotropic temperature factors are given in Table II. The estimated standard deviations were caluculated by the Cruickshank's formula.[5] A list of the observed and the final caluculated structure factors is given in Table III, in which reflections with asterisk were omitted in the least-squares refinement. The final superimposed sections of electron density distribution cut through the every atomic centers are shown in Fig. 2.

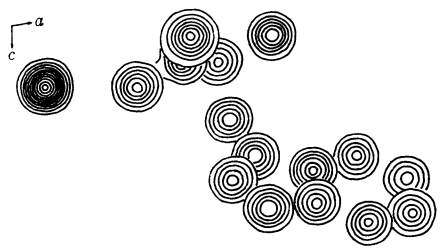

Fig. 2. The final three-dimensional Fourier synthesis. Sections passing approximately through the center of the atoms are superimposed on (010). Contour intervals of 1.5 e.Å^{-3} for light atoms and 3.0 e.Å^{-3} for the chloride ion; the first contour begins at 1.5 e.Å^{-3}.

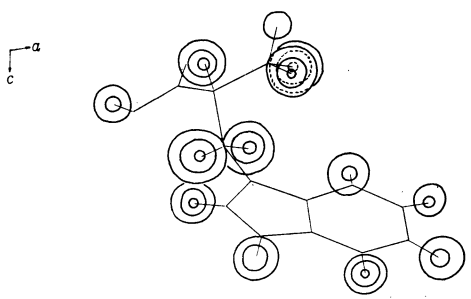

Fig. 3. The three-dimensional (F_o-F_c) synthesis. Sections passing approximately through the center of the hydrogen atoms are superimposed on (010). Contour intervals of 0.2 e.Å^{-3}, the first contour begins at 0.2 e.Å^{-3}. The dotted contours are in the lower section.

A three-dimensional (F_o-F_c) synthesis was then caluculated where F_c did not include the contributions from the hydrogen atoms, and phase was that of F_c. Fourier synthesis in this manner gives somewhat modified electron density distribution for hydrogen atoms.

In the resulting map as shown in Fig. 3, peaks were found in positions which could associate with the thirteen hydrogen atoms, their coordinates and heights being shown in Table IV. Maximum difference between the coordinates from the difference synthesis and those from the least-squares is 0.23 Å.

All the numerical computations were done on a NEAC 2101 of this laboratory, a NEAC 2206 of the computing center of Osaka University, a HITAC 5020 of the computing center of the University of Tokyo and an IBM 7090 of Japan IBM Co. Ltd. Main programs used are 'NLP-W-01-T' for Lorentz polarization and spot shape correction written by Nobuo Tanaka, 'FR-S-01-T' for the two-dimensional Fourier synthesis by Tsunehiro Takano and Yoriko Nishi, 'HBLS' for the least-squares by Tamaichi Ashida and 'SFFR' for three-dimensional Fourier synthesis by Yoshio Sasada.

Discussion of the structure

The present structure determination of L-tryptophan hydrohalides has revealed that the

crystals of the hydrochloride and hydrobromide are isomorphous with each other and conformation of the tryptophan cations is essentially the same in both crystals. As the accuracy of the analysis of the hydrobromide is not so high, the crystal and molecular structure of the hydrochloride will be mainly discussed here.

All the interatomic bond distances and angles caluculated from the final coordinates are shown in Fig. 4, together with their standard deviations. Some of the important intramolecular distances between non-bonded atoms are given in Table V.

Carboxyl and Amino Group.—The planarity of the carboxyl group with α-carbon atom has been established in many investigations. For the present molecule, the equation for this median plane is determined to be

$$1.112X - Y + 2.090Z = 3.522$$

where X, Y and Z in Å refers to the crystallographic a^*, b and c axes respectively and coefficients were obtained by the least-squares method. The deviations of all the atoms from the least-squares plane are less than 0.0001 Å and they are strictly coplanar. The amino nitrogen is 0.154 Å out of the plane, the C–N bond making an angle of 6° with the plane.

The deviations of the amino nitrogen range from 0.00 to 0.82 Å for the amino acids so far investigated. The C–N distance 1.505 Å coincides well with those in, e. g., histidine hydrochloride monohydrate[6] (1.495 Å). Two C–O bond lengths are 1.325 and 1.147 Å and three angles around the C(1) atom are O(1)–C(1)–O(2) = 127.5°, O(1)–C(1)–C(2) = 106.8° and O(2)–C(1)–C(2) = 125.7°. This short C–O bond length 1.147Å and two O–C–C angles, 106.8° and 125.7° differ significantly from those reported for amino acids so far. Hahn's treatment[7] for the relation between bond lengths and angles of the carboxyl groups can not be applied in the present case.

Indole Ring.—The median plane through the atoms in the indole ring with the methylene carbon attached to it can be described by the equation,

$$0.3349X - Y - 1.3642Z = -6.3687$$

The plane forms a dihedral angle of 70.6° with that of the carboxyl group described above. The deviations of the atoms from the least-squares plane are listed in Table VI. The maximum deviation from the plane is 0.019 Å and the average 0.009 Å. It is concluded that the atoms are on nearly the same plane within the limit of error, as in the related compounds, glycyl-L-tryptophan dihydrate[8] and 3-indolylacetic acid[9]. Bond lengths in the indole ring are tabulated in Table VII-a with those of the compounds quoted above. The average of six C–C bond lengths in the benzene ring is 1.396 Å, while that of C–N bond lengths in the indole ring is 1.384 Å respectively. The bond lengths found in the present molecule are all in good agreement with those of 3-indolylacetic acid[9] within the limit of error.

Longuet-Higgins and Coulson[10] have determined the mobile bond orders of the indole molecule by the molecular orbital treatment. Theoretical bond lengths derived from the bond orders by the empirical equation (Coulson,[11] Cox and

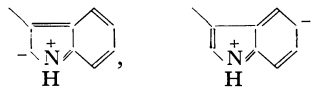
Jeffrey[12]) are given in Table VII-a. The bond lengths in the indole ring of L-tryptophan hydrochloride agree well with the theoretical values within the limit of error.

But in glycyl-L-tryptophan dihydrate,[8]) some bond lengths, especially C(6)–N(2), differ from those in L-tryptophan hydrochloride. Significantly short C(6)–N(2) bond, 1.307 Å of length, in glycyl-L-tryptophan dihydrate[8]) may suggest that in this compound the contribution from the resonance of ortho- or para-benzoquinone type increases.



It will be interesting that the conformation changes as a result of introduction of glycyl residue, as shown in Fig. 5.

Bond angles in the indole ring are also shown in Table VII-b. Bond angles in the indole ring of the present molecule show the fairly good agreement with those of the related compounds and those in the benzene ring do not deviate from 120°.

Conformation about the C(α)-C(β).—Figure 5 shows the conformation about the C(α)–C(β) bond in the present molecule by the stereographic projections together with those in histidine hydrochloride monohydrate,[6]) glycyl-L-tryptophan dihydrate[8]) and L-tyrosine hydrobromide[13]). In the present molecule, C(γ) lies at gauche position with both of carboxyl and amino group. The same conformation has been found in the crystal of histidine hydrochloride monohydrate,[6]) whose

molecule also includes the five-membered ring next to C(β), while Ramachandran and Lakshminarayanan[14] have pointed out that in tyrosine and phenylalanine, both of which contain benzene ring, C(γ) goes only to the position at trans with the nitrogen and gauche with the carboxyl group.

The enviroment of the molecule.—Views of the crystal structure along the b and a axes are shown in Fig. 6 and intermolecular distances less than 4.0 Å and angles including hydrogen bonds are given in Table VIII. An amino nitrogen atom forms three N–H···Cl⁻ hydrogen bonds, in lengths of 3.17, 3.19 and 3.24 Å; three acceptor halogen atoms are approximately at three vertices of regular tetrahedron centered around the nitrogen atom, with the α-carbon atom directed toward the fourth vertex. The fourth hydrogen bond is O–H···Cl⁻ in length of 3.04 Å. Similar hydrogen bond distances are reported for N–H···Cl⁻, 3.08, 3.25 and 3.27 Å, and for O–H···Cl⁻, 2.98 Å in L-cystine hydrochloride.[15]

In L-tryptophan hydrobromide, the corresponding distances between nitrogen and bromide ion are 3.30, 3.31 and 3.35 Å, although the accuracies of these values are not so high. These values are comparable to those found in the other hydrobromide; 3.28, 3.41 and 3.42 Å in L-cystine dihydrobromide.[16] One O···Br⁻ approach of 3.13 Å in the present crystal is similar to a value; 3.17 Å in L-cystine dihydrobromide.[16]

Molecular arrangement in the crystal can be well described as double-layered system parallel to the ab plane, which is characteristic for a structure

containing polar and non-polar groups together. The polar layer is held together by a network of the hydrogen bonds, as described above, between the chloride ions and amino nitrogen and between the chloride ion and carboxyl group. In the non-polar layer, the indole rings are packed mainly by van der Waals forces, in a manner similar to that found for the typical aromatic molecule. No unusually short contacts between non-bonded atoms are found in the crystal structure, and the shortest C···C and C···N distances are 3.74 and 3.42 Å respectively. The weakly basic nitrogen atom of the indole ring does not take part in the hydrogen bond. This structure well interprets the observed cleavage in the ab plane.

Diffusion in Glassy Polymers. III. Temperature Dependence and Solvent Effects

By Hisashi ODANI, Shigeru KIDA and Mikio TAMURA

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto

(Received May 12, 1966)

Absorption and desorption of benzene and ethyl acetate by atactic polystyrene (A-PS) were studied at various temperatures below the glass transition point of the polymer. In the A-PS+benzene system raising temperature did not alter the general feature of the family of successive differential absorption curves, but merely compressed the whole family of curves towards a low concentration region. The critical concentration of penetrant at which the transition from non-Fickian to Fickian behavior occurred became lower in the order benzene, ethyl methyl ketone, and ethyl acetate. The logarithm of the time, t_*, which specifies the inflection point of the second stage on the two-stage absorption curve, were linearly dependent on the initial concentration of penetrant, C_i, and the correlation lines between $\log t_*$ and C_i obtained for various combinations of temperature and solvent were nearly parallel with one another. The features of integral absorptions were essentially the same in all cases, and the absorption curves showed a pronounced dependence on concentration.

Recent studies of absorption and desorption of organic vapors by amorphous polymers have shown that when the polymer is in the glassy state these processes do not conform to the Fickian type; that is, the Fick diffusion equation with a concentration dependent diffusion coefficient and with the usual boundary conditions is not obeyed.[1] It is generally accepted that these non-Fickian processes are controlled not only by the ordinary diffusion mechanism but also by the relaxation mechanism of polymer network chains. When the polymer is in the glassy state the rate at which the network of polymer chains responds to the osmotic swelling pressure is so slow that the rate of absorption or desorption of organic vapors by the polymer may depend markedly upon both temperature and penetrant concentration. However, our present knowledge[2-6] about this problem is insufficient or otherwise incomplete. For example, data on the temperature dependence of the successive differential absorption are as yet not available. The first purpose of the present work is to find out how the behavior of successive absorption processes in systems of amorphous polymer and organic vapor is affected by temperature. To this end we have studied the system atactic polystyrene (A–PS) and benzene.

In a recent publication,[7] we showed that the general features of the family of successive

differential absorption curves for the A-PS+ethyl methyl ketone system was similar to those obtained for the A-PS+benzene system. However, for the ethyl methyl ketone system, the critical concentration at which the polymer-penetrant mixture underwent glass transition at the temperature of the experiment was lower than that for the benzene system, and the characteristic variation of the types of successive differential absorption curves occurred in a relatively lower concentration region. In either of these systems, the second stage portion of the two-stage process shifted rapidly to the short time region as the initial concentration of each step was increased. To express this rate of shift the time t_* for the inflection point of each differential absorption curve was taken as the measure of the location of the second stage portion on the time axis. The plots of the logarithm of t_* against the initial concentration C_i was linear. The slopes of the lines were nearly the same. Ethyl methyl ketone and benzene have nearly the same molar valumes, but the former is less soluble in A-PS than is the latter. To confirm these features and other effects of polymer-penetrant interaction upon absorption and desorption kinetics, we have made similar measurements with the system A-PS and ethyl acetate and have compared the results with our previous results with the benzene system and the ethyl methyl ketone system. These three penetrants have about the same molar volumes, but have different solvent powers for A-PS. The values of the interaction parameter χ_1 of A-PS at 25°C are 0.55, 0.53, and 0.45 for ethyl acetate, ethyl methyl ketone, and benzene, respectively.[8] Thus the solvent power for A-PS becomes larger in the order ethyl acetate, ethyl methyl ketone, and benzene.

Experimental

The atactic polystyrene (A-PS) used was the same as that described previously.[9] Its viscosity-average molecular weight was 2.2×10^5. The films used for sorption measurements were approximately 2.4×10^{-3} cm. thick. Benzene and ethyl acetate used as organic penetrants were of G. R. grade, and no attempt was made to effect further purification. The temperatures at which the sorption measurements were performed were 25, 35, and 50°C for A-PS+benzene and 25°C for A-PS + ethyl acetate. These temperatures are well below the glass transition temperature of the dry polymer.[10]

Results and Discussion

Absorption Isotherms.—Absorption isotherm data for the system A-PS+benzene at 25, 35, and 50°C are given in Fig. 1. Here the ordinate

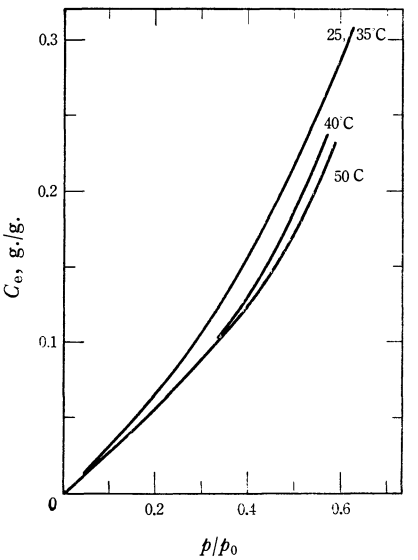

Fig. 1. Absorption isotherms of A-PS+benzene at 25, 35, and 50°C.

represents the mass of absorbed vapor in grams per unit gram of dry polymer and the abscissa the relative pressure of the vapor in the external phase. Although the individual points are not given in the figure, at a given relative pressure the differences in equilibrium gain between integral and differential absorption experiments were negligible at the three temperatures examined (Data at 25°C are shown later in Fig. 2.). It is seen that the data for 25 and 35°C are nearly represented by a single curve, indicating that the isotherms are practically independent of temperature within this narrow range of temperature. The data of Long and Kokes at 40°C[5] are also included in the figure for comparison. Formal application of the Flory-Huggins thermodynamic equation of polymer solutions, with the assumption that no volume change occurs on mixing, shows that at each temperature the interaction parameter χ_1 increases slightly with increase of equilibrium vapor concentration. The average values of χ_1 over the concentration range studied, except at very low penetrant concentrations, were 0.14, 0.14, and 0.32 at 25, 35, and 50°C, respectively. The average value of χ_1 evaluated from the data of Long and Kokes[5] was 0.27 at 40°C.

Figure 2 compares absorption isotherm data for the system A-PS+ethyl acetate, the system A-PS+benzene, and the system A-PS + ethyl methyl ketone,[7] all at 25°C. As expected, it can be seen that the equilibrium mass of absorbed penetrant

becomes less in the order benzene, ethyl methyl ketone, and ethyl acetate when compared at the same relative vapor pressure of penetrant. That is, at a given relative vapor pressure, the poorer the solvent power to a given polymer the lower is the equilibrium vapor absorption. The values of the interaction parameter χ_1 calculated from these isotherm data at 25°C were 0.97 and 0.78 for A-PS+ethyl acetate and A-PS+ethyl methyl ketone, respectively.

Successive Differential Absorptions.— Figure 3 gives the data of successive differential absorptions for the system A-PS+benzene at 35°C in the medium and high concentration regions. The increments of benzene concentration in successive steps were kept about 0.01 g. penetrant per gram of dry polymer, which was almost the same as those used in our previous experiments.[7,9] Although the results in the low penetrant concentration region are not given in the figure, the general character of the absorption steps in this region was quite similar to that for the system polymethyl methacrylate+methyl acetate at 30°C.[9] That is, the absorption behavior was of the sigmoid type. The inflection point characteristic of the sigmoid curve shifted toward the short time region and the initial rate of each absorption increased as the initial concentration was increased. The first step in Fig. 3 exhibits a sigmoid character, and the subsequent absorption curves change their type according to the following scheme: pseudo-Fickian→two-stage→ Fickian. As noted in the previous paper,[9] the data for the A-PS+benzene system did not show a pseudo-Fickian process in the transition from the two-stage to the normal Fickian process.

With increasing temperature the concentration at which the absorption curve change their type from sigmoid to pseudo-Fickian behavior shifted toward low concentration values, and this was also the case with the initial concentration at which the transition from the pseudo-Fickian to the two-stage and from the two-stage to the Fickian occurred. In other words, raising temperature did not alter the general features of the family of successive differential absorption curves but merely compressed the whole family of curves to a lower concentration region. It has been demonstrated

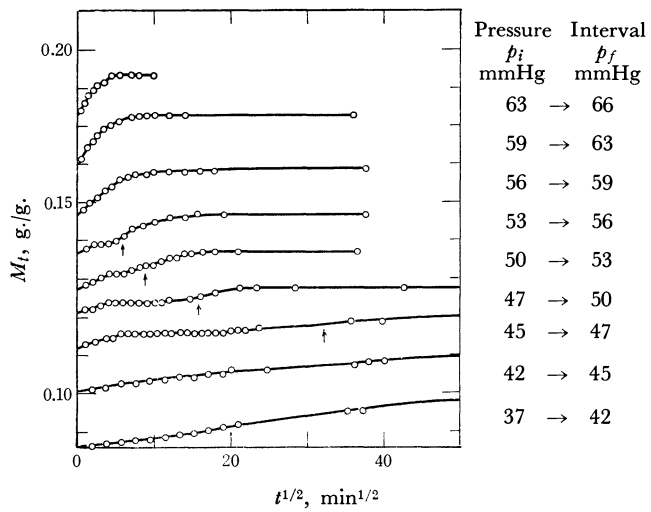

Fig. 3. Successive differential absorptions of A-PS+benzene at 35°C. Initial and final pressures, p_i and p_f, of each step are given in the right columns.

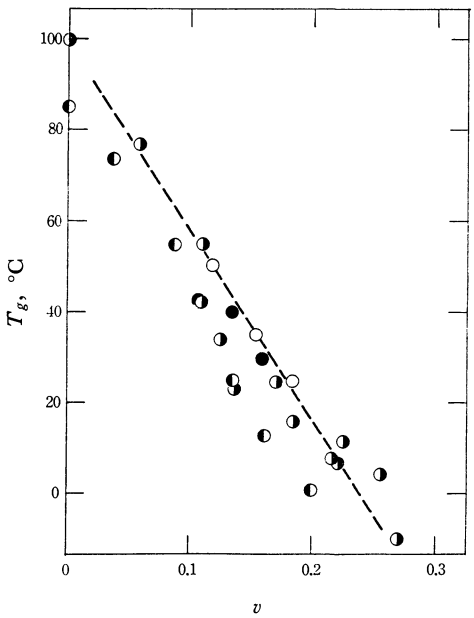

Fig. 4. Comparison of volume fraction for glass transition with critical volume fraction for diffusion.

in the previous papers[7,9] that successive differential absorption curves change their type from non-Fickian to Fickian when the penetrant concentration reaches a value at which the polymer-penetrant mixture undergoes glass transition at the temperature of the experiment. From differential absorption data obtained with concentration intervals of nearly the same magnitude as those shown in Fig. 3, we estimated such a critical concentration for the A-PS+benzene system to be 0.150 at 35°C and 0.113 at 50°C in grams of benzene per gram of dry polymer. At 25°C the critical concentration of benzene was 0.191 g./g.[9] In Fig. 4 the values for the critical volume fraction calculated from these data are compared with the results obtained from dilatometric studies by Fox,[11] from refractive index studies by Jenckel and Heusch,[12] and from sorption experiments by Long and Kokes.[5] It can be seen that the points from different experimental techniques fall satisfactorily on a single line, indicating that the glass transition is closely related to the molecular mechanism which distinguishes Fickian absorption behavior of an amorphous polymer-penetrant system from non-Fickian.

The successive differential absorption data for A-PS+ethyl acetate at 25°C showed features which were quite similar to those of A-PS+ethyl methyl ketone at 25°C investigated previously.[7] That is, the successive curves change their type with increasing penetrant concentration according to the scheme: sigmoid→pseudo-Fickian→two-stage→pseudo-Fickian→Fickian. However, for A-PS+ethyl acetate the critical concentration was 0.112 in grams of ethyl acetate per gram of dry A-PS. This value is well consistent with the data interpolated from refractive index measurements of Jenckel and Heusch,[12] but lower than 0.139 g./g. obtained previously for ethyl methyl ketone at the same temperature. In the previous paper,[7] from comparison of the critical concentrations of ethyl methyl ketone and of benzene, we suggested that for an amorphous polymer at a given temperature a penetrant of poorer solubility gives a lower critical concentration if comparison is made for penetrants of about the same molar volumes. As described in the foregoing lines, the molar volumes of ethyl acetate, ethyl methyl ketone, and benzene are nearly the same. Thus we find that the present result with the system A-PS+ethyl acetate is in line with the deduction from our previous results.[7,9]

Concentration Dependence of the Second Stage Mechanism.—It is generally accepted[7,9] that the rate-determining factor for the second stage portion of the two-stage absorption is the rate at which polymer chains rearragne themselves in the presence of penetrant molecules, while the first stage involves the purely Fickian process. In accordance with the treatment presented in previous studies,[7,9] we here use the time t_* to characterize the position of the second stage portion on the time axis, where t_* is the time corresponding to the inflection point of a differential absorption curve of the two-stage type. The previous study[13] demonstrated for the system A-PS+benzene at 25°C that the value of t_* for a given initial concentration, C_i, increased with decreasing concentration increment and converged to a limiting value taken as characteristic of the given C_i. This was also the case with the A-PS+benzene at 35 and 50°C. The values of t^* characteristic of a given C_i for the system A-PS+benzene at 25, 35, and 50°C are plotted semilogarithmically against C_i in Fig. 5. We see that the plots for different temperatures are linear and nearly parallel with one another, indicating that for a given amorphous polymer the slope of $\log_{10} t_*$ vs. C_i plot is approximately independent of temperature. Thus the plots for $\log_{10} t_*$ vs. C_i at different temperatures may be superimposed with one another by shifting each plot along the

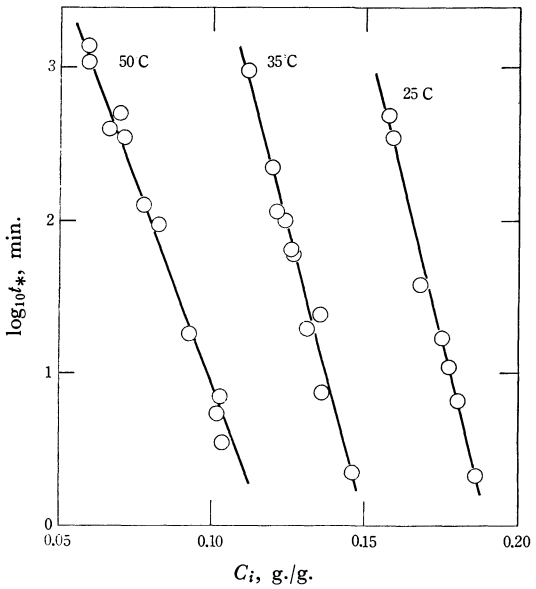

Fig. 5. Logarithmic correlation plots of t_* and initial concentration C_i for A-PS+benzene at 25, 35, and 50°C. t_* is the time corresponding to the inflection point of the second stage of the two-stage process.

ordinate to a particular temperature chosen as reference. This behavior bears resemblance to the time-concentration reduction scheme which was shown to be obeyed by stress-relaxation behavior of polymer-diluent systems in nearly the same concentration regions.[14] In this connection, it is worth-while to note the correlation between t_* and the mean relaxation time or, more properly, retardation time. We have shown for the system A-PS+benzene that the values of the mean retardation time, evaluated from the tensile creep measurements, and their dependence upon C_i are closely correlated with the values of t_* and their dependence upon C_i*. These results lend support to the argument that the second stage of a two-stage absorption process is primarily caused by the slow rearrangements of polymer network chains. Plots for $\log_{10} t_*$ vs. C_i at higher temperatures appear in the region of lower values of C_i. This is the reflection of the fact that the value of C_i at which the transition from pseudo-Fickian to two-stage type absorption occurred shifts toward the lower concentration region with increasing temperature. The values of the apparent activation energy were estimated at $C_i=0.115$ and 0.110 g./g. based on the assumption that the temperature dependence of t_* follows the Arrhenius type equation. They were 64 and 46 kcal./mol., respectively. These values compare favorably with those obtained from the time-temperature shift factor for linear visco-elastic behavior of amorphous polymers in the temperature region near glass transition.

Plots of $\log_{10} t_*$ vs. C_i for the system A-PS+ethyl acetate at 25°C are illustrated in Fig. 6. For the sake of comparison, the corresponding data for A-PS+benzene, A-PS+ethyl methyl ketone, and cellulose nitrate+acetone are included in the figure. The slope of the line for A-PS+ethyl acetate is nearly the same as those for A-PS+benzene and A-PS+ethyl methyl ketone. These slopes for A-PS systems are greater than that for cellulose nitrate. In the previous paper,[7] it was argued that the slopes of $\log_{10} t_*$ vs. C_i plot for a given polymer must be independent of penetrant species, because the second stage absorption primarily reflects the characteristic relaxation-motion of the network chains. Data for A-PS+ethyl acetate establish firmly this view. This, together with the results for the temperature dependence of $\log_{10} t_*$ vs. C_i plots shown in Fig. 5, clearly indicates that the second stage of the

two-stage process is governed by the rate at which the network of polymer chains change its conformation under the osmotic swelling pressure.

Integral Absorptions and Desorptions.— The measurements of integral absorption and desorption with various pressure differences were carried out from and back to zero penetrant concentration. The general features of the integral absorption and desorption processes for A-PS+benzene at 35 and 50° were quite similar to those obtained previously at 25°C.[13] That is, the integral absorption curves were sigmoid for all pressure intervals investigated. On the other hand, the integral absorption curves were concave to the $t^{1/2}$ axis, no linear portion was observed in

the initial stage, and the slope of the curve decreased continuously from the origin. The desorption curve had a much higher initial rate than that of the corresponding absorption and intersected with the latter in the later stage. At 35 and 50°C the absorption curves showed a pronounced dependence on the pressure difference and the general feature of this dependence was similar to that observed at 25°C. As noted in the previous report,[13] the absorption processes from zero to equilibrium concentrations above the critical concentration exhibited non-Fickian features contrary to the data of Long and Kokes,[5] who observed Fickian absorption curve in such cases. This was also the case at 35 and 50°C, and the non-Fickian behavior still persisted at the highest equilibrium concentration studied. At the highest concentration, which was far above the critical concentration, the polymer films hardly supported its own weight from the spring balance.

In the case when absorption and desorption curves do not conform to normal Fickian features, we are not able to evaluate the mutual diffusion coefficient of the system by using the methods which utilize data for the initial slope of the absorption curve. In such a case, as in the previous treatment,[7,13] we may be content with the reciprocal of $(t/l^2)_{1/2}$ being taken as a quantitative measure of the overall rate of an absorption or desorption curve, where l is the thickness of the film and $(t/l^2)_{1/2}$ is the value of t/l^2 for the time t at which the amount of penetrant in the film reaches one half the final equilibrium value. The values of $1/(t/l^2)_{1/2}$ for the system A-PS+benzene, determined from integral absorptions from and to zero penetrant concentration, are plotted semi-logarithmically against the equilibrium concentration, C_f, in Fig. 7. It is seen that at 25 and 35°C the plots from absorption data are convex to the concentration axis in the low concentration region and are linear at medium and high values of C_f. At 50°C. the plots increase linearly with increasing C_f over the entire range investigated. In the linear portion the plots for the three temperatures are nearly parallel and their slopes are larger than those for integral desorption. From this latter behavior it follows that the temperature dependence of sorption rate is greater for absorption than for desorption at fixed values of C_f, and it may be expected that for a glassy polymer the apparent activation energy for absorption is larger than that for desorption.

For a quantitative representation of the temperature dependence of the overall rate of absorption or desorption, we determined the apparent activation energy from the slope of a plot for the logarithm of $1/(t/l^2)_{1/2}$ against reciprocal absolute temperature. Figure 8, which illustrated such plots for A-PS+benzene at $C_f=0.15$ and 0.20 g./g., indicates that for both absorption and desorption the values of $\log_{10}[1/(t/l^2)_{1/2}]$ decrease nonlinearly with increasing $1/T$. This similar feature has been reported for diffusion coefficients of gases

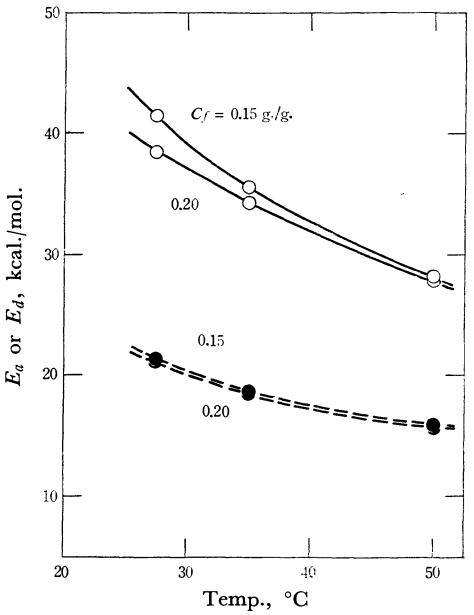

Fig. 9. Temperature dependence of the apparent activation energy for absorption, E_a, or for desorption, E_d, for A-PS+benzene at C_f=0.15 and 0.20 g./g. ○, absorption. ●, desorption.

●, A-PS+ethyl methyl ketone.

or vapors in elastomers.[15-18]

An apparent activation energy for absorption, E_a, may be defined by the equation:

$$E_a = -Rd\{\ln[1/(t/l^2)_{1/2}]_a\}/d(1/T),$$

where $[1/(t/l^2)_{1/2}]_a$ is the value of $1/(t/l^2)_{1/2}$ for absorption. Similarly, an apparent activation energy for desorption, E_d, may be defined. The values of E_a and E_d calculated from Fig. 8 are plotted as a function of temperature in Fig. 9. It is seen that E_a are greater than E_d in the temperature region studied.

For the system A-PS+ethyl acetate integral absorptions and desorptions from and to zero concentration were studied at 25°C in the same range of penetrant concentration as in the case of A-PS+benzene[13] and A-PS + ethyl methyl ketone.[7] The curves obtained had exactly the same features as those for A-PS+benzene mentioned above. Figure 10 gives the plots of $\log_{10}[1/(t/l^2)_{1/2}]$ vs. C_f for A-PS+ethyl acetate at 25°C. For the sake of comparison, the data for the benzene system and the ethyl methyl ketone system at the same temperature are also illustrated in the figure. It is seen that the plots for ethyl acetate and ethyl methyl ketone are almost represented by a single curve. This suggests that the values of diffusion coefficient and its dependence upon penetrant concentration for A-PS+ethyl acetate are nearly the same as those for the system A-PS+ethyl methyl ketone.

Summary

The successive differential absorptions for the A-PS+benzene system at 25, 35, and 50°C change with the initial concentration according to the scheme: sigmoid type→pseudo-Fickian type→two-stage type→Fickian type. The last transition, from two-stage to Fickian types, occurs at a lower concentration as the temperature of the experiment is raised. The values of the critical concentration for this transition are well compared with those for glass transition of the system. The successive differential absorptions for the A-PS+ethyl acetate system change their type with the increase of initial concentration according to the scheme, which is typical of systems of amorphous polymer+ organic vapor; that is, sigmoid→pseudo-Fickian→ two-stage→pseudo-Fickian→Fickian. The critical concentration for the last transition becomes lower in the order benzene, ethyl methyl ketone, and ethyl acetate. For all systems investigated the second stage portion of the two-stage process shifts rapidly to the short time regions as the initial concentration of each step increases. For A-PS+ benzene the dependence of the rate of this shift upon intial concentration is very similar at 25, 35, and 50°C. For A-PS + ethyl acetate the rate of the shift depends upon initial concentration in nearly the same manner as in the A-PS+benzene system and the A-PS+ethyl methyl ketone system.

The general features of integral absorptions for

the A-PS+benzene system at 25, 35, and 50°C are very similar, and the absorption curves show a pronounced dependence on concentration. At 25 and 35°C the logarithmic correlation plots of the overall rate of absorption and final equilibrium concentration are linear at the medium and high values of equilibrium concentration, and at 50°C the plots are linear over a nearly entire range of concentration studied. An apparent activation energy for absorption is greater than that for desorption in the temperature region investigated. The general feature of integral absorptions for the A-PS+ethyl acetate system is very similar to those for benzene and ethyl methyl ketone systems, irrespective of the difference in the penetrant-polymer interaction among these systems. The dependence of absorption rate upon concentration is also similar in general character to that for benzene and ethyl methyl ketone systems.

Non-Debye Reorientation Processes of Molecules. Correlation Functions and Spectral Densities for Spherical Molecules

By Hiroshi SHIMIZU*

Department of Chemistry, Stanford University, Stanford, California, U. S. A.

(Received May 16, 1966)

The non-Debye reorientation processes in which the Debye equation is inapplicable are studied for spherical molecules by using an equation proposed by the author. The physical meaning of the angular correlation in the non-Debye processes is discussed in detail. It is shown that in the non-Debye processes the non-dissipative decay of the mutual-phase correlation of rotating molecules must be taken into account, in addition to the dissipative decay due to molecular collisions, and that the use of the "microscopic viscosity" in the Debye equation is not plausible. It is also shown that, in contrast to the Debye processes, there is no one-to-one correspondence between the correlation time for molecular reorienation and the mean life time of the rotation, since the contribution from the nondissipative decay should be considered also. The vector and the tensor correlation functions,

$$\langle \cos\theta(0)\cos\theta(t)\rangle \quad \text{and} \quad \langle (1/2)\{3\cos^2\theta(0)-1\}\{(1/2)3\cos^2\theta(t)-1\}\rangle,$$

and the corresponding spectral densities, the band shapes of infrared and Raman spectra respectively, are obtained theoretically for various conditions and are shown graphically. As illustravtie examples of the treatment, methane and deutero methane molecules are studied. Vector correlation functions are obtained from the observed band shapes of the infrared spectra of these molecules. Comparing the theoretical correlation functions with experimental ones, it is shown that a reasonable agreement between theory and experiment is obtained and that methane molecules have a typical non-Debye reorientation process even below the freezing point. Some characteristic features of the non-Debye process are also discussed.

The observed correlation times for the reorientation of molecules are, in general, shorter than those derived from Debye's theory of the reorientation of spherical particles in liquids.[1] In particular, for light molecules such as substituted benzenes or some of the lower ethers or alcohols, the observed correlation times, τ_1 and τ_2, for the vector and the tensor correlation function:

$$\Phi_1(t) = N_1\langle \cos\theta(0)\cos\theta(t)\rangle \tag{1}$$

and

$$\Phi_2(t) = N_2\langle \frac{1}{2}\{3\cos^2\theta(0)-1\}\frac{1}{2}\{3\cos^2\theta(t)-1\}\rangle \tag{2}$$

are shorter by a factor of 10—100.[2,3] In these

equations, for instance in (1), $\langle\ \rangle$ refers to the average of the products, $\cos\theta$ at $t=0$ times $\cos\theta$ at $t=t$, over the ensemble, where θ is the angle between a vector fixed on a molecule and the z-axis of a space-fixed laboratory frame. N_1 is a normalization constant which makes $\Phi_1(0)$ unity.

The serious disagreement between the theoretical and the experimental correlation times may be attributed to the use of the macroscopic viscosity, η, in the Debye equation:[1,4]

$$\tau_j = \frac{4\pi\eta a^3}{3kT}(1+\delta_{1j}) \tag{3}$$

In this equation, a refers to the radius of the molecule; $\delta_{1j}=1$ for $j=1$ and is otherwise zero. Since no medium is continuous or homogeneous on the molecular scale, the effective viscosity for molecular reorientation, the microscopic viscosity, must be, in general, different from the macroscopic one. However, the use of the microscopic viscosity in (3) may not be a sufficient improvement on Debye's theory. As is shown below, the disagreement arises from the basic inapplicability of Debye's scheme to the substances mentioned above.

The Debye equation is derived on the assumption that random reorientations of molecules can be described in terms of a diffusion equation.[1,4] Therefore, a molecular reorientation with a finite and large angle is assumed to appear as a result of many rotations which occur successively in time.[4] This situation may be compared with the translational diffusion of molecules in a three-dimensional space, where a molecule moves step by step, at random and in all directions.[5] The assumption of a continuous medium is consistent with the basic concept of the diffusion: the continuous liquid *constantly* exerts against a rotating molecule. This force leads to two important sequences through *constantly* exerts a resistive force against a rotating molecule. This force leads to two important sequences through the reduction of the angular velocity of the rotating molecule: (1) it reduces the magnitude of a step of the tiny rotation, and (2) fluctuating forces must be supplied constantly from the outside in order to keep the average rotational energy constant against the friction.

On the other hand, the discrete and inhomogeneous nature of the medium may not result in a diffusion process, at least not when the medium molecules move at random at a rate that is comparable with that of the rotation of the solute molecule. A fluctuation in the positions of the medium molecules may temporarily give the solute molecule a vacant space and allow it to rotate relatively freely as in the gas phase. Since the duration of such a "vacant" space is fairly close to the mean period of the rotation of the solute molecule, a step of a single rotation must be so large that the reorientation of the solute molecule cannot be related to a diffusion process. Moreover, the appearance of the nature of the "free" rotation in liquids clearly makes the correlation times very short.

The use of the Debye equation, which is equivalent to the assumption of the existence of a well-defined diffusion process in the liquid, is not appropriate in those many cases where we really use a microscopic viscosity instead of η in order to reduce the large disagreement between theory and experiment. We may call such fast reorientation processes "non-Debye processes."

A further step in the study of the random reorientation of molecules has been made in a paper by Gordon.[6] He showed that a tensor correlation function could be obtained from a Raman spectrum as the Fourier transform of the band-shape function whose structures are originally due to the rotation-vibration interaction. In other words, the band shape itself represents the spectral density of the random reorientation of a molecule. This idea was soon extended by Gordon[7] to the infrared case: vector correlation functions were obtained similarly from infrared spectra. He discussed briefly the form of the correlation functions corresponding to a non-Debye process. The correlation functions for CO and CH_4 molecules clearly showed that the reorientation processes for these molecules are non-Debye, even in solution.

A general theory of the random reorientation of molecules, including non-Debye processes, was proposed by Shimizu[8]; he also obtained vector and tensor correlation functions theoretically. Then, by using the theory of linear response,[9] it was shown that band-shape functions corresponding to various kinds of spectra, including infrared, Raman, and dielectric relaxation, could be obtained in terms of the Fourier transform of the theoretical correlation functions, and vice versa. The theory was found to be reasonable from a comparison with the correlation functions obtained experimentally from the infrared spectrum of *trans*-dichloroethylene.

In the present paper, the nature of the non-Debye reorientation of a spherical rotor will be discussed, using as a typical example the methane molecule. Graphical representations of the correlation functions and the corresponding spectral densities will

7) R. G. Gordon, ibid., **43**, 1307 (1965).
8) H. Shimizu, ibid., **43**, 2453 (1965). The terms "the Debye limit" and "the inertial limit" were used there. It was assumed that, in the Debye limit, the correlation function with the correlation time τ_j given by the Debye equation holds. In this paper "the Debye process" means the molecular reorientation process within the Debye limit.
9) R. Kubo, *J. Phys. Soc. Japan*, **12**, 570 (1957).

be given from the theory. The relations between the band shapes of the infrared and Raman spectra and the random reorientation process of molecules will be automatically discussed in the present paper, since the spectral densities corresponding to a vector correlation function and tensor correlation function are equivalent to the band shape of infrared and Raman spectra respectively.[6-8] No effort will be made to discuss the accurate form of the correlation functions. Our principal aim is to show the properties of non-Debye processes in terms of simple physical concepts and straightforward mathematical expressions.

The Correlation Functions for Non-Debye Processes

Though the general form of the correlation functions for non-Debye reorientation processes have already been discussed,[8] the correlation functions for spherical rotors were only briefly given. Therefore, a detailed discussion of the form of the correlation functions and the spectral densities of spherical molecules will be given in this and the next section in order to illustrate the general features of non-Debye processes.

The correlation function for non-Debye processes, more accurately, for the inertial limit, may be approximately given by[8]:

$$\Phi_j(t) = a_j(t)\Phi_j^{(0)}(t) + b_j(t)\Phi_j^{(p)}(t) \qquad (4)$$

with $j = \begin{cases} 1 & \text{for the vector correlation function} \\ 2 & \text{for the tensor correlation function,} \end{cases}$

where $\Phi_j^{(0)}(t)$ is the correlation function for "free" molecules. The perturbed correlation function, $\Phi_j^{(p)}(t)$, is related to the reorientation of the molecule under the perturbation due to the interaction with the neighboring molecules. We may assume that the perturbed correlation function has an exponential form when $t \gg \tau_f$.[8,10] Here the mean period of rotation, τ_f, is a function of the absolute temperature, T, and the moment of inertia, I, of the molecule:

$$\tau_f = (I/\boldsymbol{k}T)^{1/2}$$

For example, we may assume[8,11]:

$$\Phi_j^{(2)}(t) = \exp\left\{-\Delta_j^2 \int_0^t \mathrm{d}t'(t-t') \exp\left(-|t|/\tau_{rj}\right)\right\} \qquad (5)$$

as a first-order approximation, where τ_{rj} is the life time of the rotation. The modulation amplitude is a function of the magnitude of the fluctuation of the angular velocities of the rotating molecules, velocities arising from the perturbation from the neighboring molecules. Equation 5 corresponds an assumption that the fluctuation of the angular velocities is a Gaussian process.[10] A strong collision assumption leads to a simple form[8]:

$$\Delta_1^2 = 3/\tau_f^2 \qquad (6)$$

The Δ_2^2 quantity was not discussed before. Hence, we will give it here. We may assume that a non-Debye process approaches a Debye process as $\tau_{rj}/\tau_f \to 0$, where, due to frequent collisions with the neighboring molecules, the (solute) molecules are allowed such small rotations as occur in rotational diffusion. Debye's theory gives:

$$\tau_1/\tau_2 = 3 \qquad (7)$$

On the other hand, the effective correlation time for $\Phi_j^{(2)}(t)$ is given by[8]:

$$\tau_j' \cong (\Delta_j^2 \tau_{rj})^{-1} \qquad (8)$$

Thus, naively assuming $\tau_{r1} = \tau_{r2}$, we obtain:

$$\Delta_2^2 = 9/\tau_f^2 \qquad (9)$$

from (6)—(8). The modulation amplitude, (6) or (9), was obtained by assuming that the magnitude of the angular momentum was changed at each collision.[8] If only the orientation of the angular momentum is changed by collisions, the correlation function, $\Phi_j^{(2)}(t)$, is improper. A detailed discussion of the correlation function will be presented in the near future. Qualitatively, the nature of the reorientation processes determines the magnitude of the modulation amplitude.

The simplest assumption as to the form of the adjusting functions will be taken as[8]:

$$\left.\begin{aligned} b_j(t) &= 1 - \exp\left(-|t|/\tau_{bj}\right) \\ a_j(t) &= \exp\left(-|t|/\tau_{aj}\right) \end{aligned}\right\} \qquad (10)$$

The time constants, τ_{aj} and τ_{bj}, are roughly the lifetime of rotation.

By using a very simple assumption:

$$\tau_{rj} = \tau_{aj} = \tau_{bj} \equiv \tau_r$$

vector and tensor correlation functions were calculated by varying τ_r/τ_f. The results are shown graphically in Figs. 1 and 2, where the unit of the time scale is τ_f. The correlation functions are not exponential, unless τ_r/τ_f is much smaller than unity. For $\tau_r/\tau_f \gtrsim 1$, the nonexponential contribution of $\Phi_j^{(0)}(t)$ to $\Phi_j(t)$ is appreciable.

An Interpretation of the Form of Correlation Functions

We choose the local frame or the local coordinate system of each molecule in such a way that their

10) R. Kubo, "Fluctuation, Relaxation, and Resonance in Magnetic System," Oliver and Boyd, Ltd., London (1962).

11) The use of (5) is correct only when the random process of ω-fluctuation is a Gaussian process. Therefore, the physical meaning of Eq. 4 with 5 is that all the molecules start to rotate in phase at $t=0$ and then, regarding the molecules which have had more than one collision since $t=0$, the initial memory of the phases of rotation is randomized. Therefore, after a collision the molecular reorientation process may be regarded as a Gaussian process with random phases. This process is given by (5).

origins are common with that of the laboratory frame. A local frame of a molecule coincides with the corresponding molecular frame at $t=0$, except for the origin. One can thus transform between the two frames by a pure translation. The Eulerian angles between a local frame and the laboratory frame may be written as $\Omega\equiv(\alpha, \theta(0), \gamma)$. By introducing Wigner's rotation matrix, $D_{mm'}^{(1)}(\Omega)$, of the first order, the direction cosines between the z-axes of the molecular and the laboratory frames may be written as:

$$\cos\Theta(t) = \sum D_{mo}^{(1)}(\alpha, \theta(0), \gamma) y_m(\Theta(t), \Psi(t)) \tag{11}$$

where $y_m(\Theta, \Psi)$ are the reduced spherical harmonics relating the spherical coordinates of the z-axis of the molecular frame as observed in the local frame;

$$\left.\begin{aligned} &y_1(\theta(t), \Psi(t)) \\ &\quad = -\frac{1}{\sqrt{2}}\sin\Theta(t)\exp\{i\Psi(t)\} \\ &y_0(\Theta(t), \Psi(t)) = \cos\Theta(t) \\ &y_{-1}(\Theta(t), \Psi(t)) \\ &\quad = \frac{1}{\sqrt{2}}\sin\Theta(t)\exp\{-i\Psi(t)\} \end{aligned}\right\} \tag{12}$$

From (11)—(12), with the assumption $\Theta(0)=\Psi(0)=0$;

$$\begin{aligned} \langle\cos\theta(0)\ \cos\theta(t)\rangle &= \langle\cos\theta(0)\cdot\cos\theta(0)\cos\Theta(t)\rangle \\ &+ \langle\cos\theta(0)\cdot\sin\theta(0)\sin\Theta(t)\cos(\Psi(t) \\ &- \alpha(0))\rangle \qquad (13) \\ &= \langle\cos^2\theta(0)\rangle\langle\cos\Theta(t)\rangle \qquad (14) \end{aligned}$$

where the last expression is only when the system is spatically isotropic. In fact, for an isotropic system the statistical average of a physical quantity of an ensemble must be independent of the directions of the coordinate axis of the laboratory frame. From this it follows that the average over the fraction of the molecules, $f(\theta, \varphi)\sin\theta d\theta d\varphi$, is independent of θ and φ, provided that the magnitude of the solid angle, $\sin\theta d\theta d\varphi$, is properly chosen. The $f(\theta, \varphi)$ function is a normalized distribution function of the molecular axis (the z-axis of the molecular frame) in terms of the spherical coordinates defined with respect to the laboratory frame. The ensemble average is, in general, equivalent to the average over the molecules in an arbitrary fraction, $f(\theta, \varphi)\sin\theta d\theta d\varphi$. In Function 13, the averages of $\cos\Theta$ and $\sin\Theta$ are independent of $\theta(0)$. Hence, the functions of $\theta(0)$ and Θ may be averaged independently. Denoting the average over the molecules whose initial orientations are in a small solid angle, $d\Omega$, around $\theta(0)=0$ as $\langle\ \rangle_{\theta(0)=0}$, we may obtain:

$$\Phi_1(t) = \langle\cos\theta(t)\rangle_{\theta(0)=0} \tag{15}$$

since in an isotropic system it is clear that:

$$\begin{aligned} &\langle\cos\theta(0)\cos\theta(t)\rangle_{\theta(0)=0} = \langle\cos\theta(t)\rangle_{\theta(0)=0} \\ &\quad = \langle\cos\Theta(t)\rangle_{\theta(0)=0} = \langle\cos\Theta(t)\rangle = \Phi_1(t) \end{aligned}$$

The definition of the correlation function, 15, was used in a previous paper[8] without explicit proof. The use of the new definition (15) instead of (1) has the great advantage that a correlation function may be discussed in terms of a simple model of molecular motion. For instance, it immediately turns out from (15) that the $\Phi_1(t)$, correlation function, is a periodic function of the time, when all the molecules rotate with a uniform frequency and phase. On the other hand, if the phases of the rotating molecules are random, the correlation function decays in a monotonic manner. The $\Phi_1^{(0)}(t)$ correlation function in Fig. 1 is interesting from this point of view, since it is a hybrid of these two extremes.

As an introductory example, the $\Phi_1^{(0)}(t)$ function for diatomic molecules will be discussed first and then the discussion will be extended to spherical molecules. Molecules whose initial orientations are not in the solid angle, $d\Omega$, around $\theta(0)=0$ will not be explicitly discussed. This does not, however, imply that we assume that all the molecules in the system have the same orientation at $t=0$. In the discussion below the word "molecules" in quotation marks refers to the molecules characterized by $\theta(0)=0$.

The correlation function may be given in terms of two different representations, the orientation representation by Debye and the angular momentum representation by Schwinger.[12] The latter representation was used in the discussion of the nuclear magnetic relaxation of hydrogen molecules in the gas phase. There the Hamiltonian

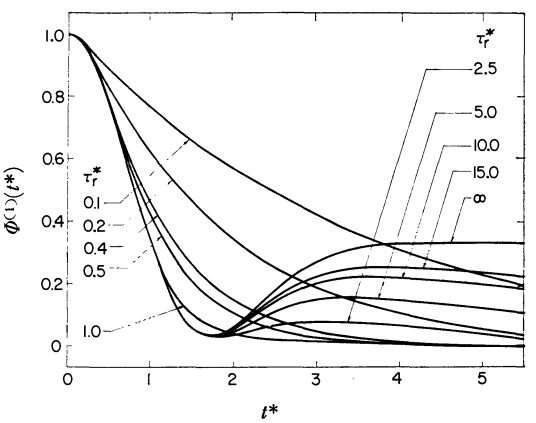

Fig. 1. The vector correlation functions for a spherical rotor obtained by using Eq. 4. The asterisks on t and τ_r indicate that these quantities are measured on the τ_f-scale. Note that $\Phi_1^{(0)}(t^*)=\Phi_1(t^*)$ for $\tau_r^*=\infty$.

for the magnetic dipolar coupling between two protons was given in terms of the angular momentum vector of the molecule by replacing the interatomic vector by the angular momentum vector using the Wigner-Eckart theorem.

The vector correlation function in the orientation representation may be given as:

$$\Phi_1^{(0)}(t) = \cos \omega_0 t \tag{16}$$

for the *free* "molecules" with a uniform frequency, ω_0, and a uniform phase. Since the "molecules" have two rotational degrees of freedom, they rotate around the uniformly-distributed axes in the x-y plane. The 16 function never decays, since the mutual phase correlations among the "molecules" are never randomized. In the angular momentum representation, the abovementioned correlation function should be a constant:

$$\Phi_{1J}^{(0)}(t) = 1 \tag{17}$$

because the angular momenta of the "molecules" are never changed. In order to get a better image of the angular momentum representation, we will introduce a description of the molecular motion in terms of the rotating coordinate system; each "molecule" is observed from the corresponding rotating frame, where the axis of rotation is the same as that of the observed "molecule." Moreover, the angular frequency, ω_0, of the rotation of the frame is the same as that of the "molecule." Therefore, the "molecules" are fixed on the rotating frames, where the z-axes are chosen parallel to the μ vectors on the "molecules." We assume that the fraction of the "molecules" whose axes of rotation are in $d\varphi$ around φ' can be observed from the same rotating frame, $S_R(\omega_0;\ \theta,\ \varphi)= S_R(\omega_0;\ \pi/2,\ \varphi')$. We choose the value of $d\varphi$ so that the statistical behavior of the "molecules" in such a fraction is independent of φ. It is clear that the description of the motion of molecules in terms of the angular momentum representation is basically equivalent to that in the rotating frames, provided that ω_0 is proportional to the magnitude of angular momentum and provided that the direction specified by θ and φ is parallel to the direction of angular momentum. We thus obtain:

$$\Phi_{1R}^{(0)}(t) = 1 \tag{18}$$

in a rotating frame, for instance, in $S_R(\omega_0;\ \pi/2,0)$. For the "molecules" which are fixed in the laboratory frame, we obtain:

$$\left.\begin{aligned} \Phi_1(t) &= 1 \\ \Phi_{1J}(t) &= \Phi_{1R}(t) = \cos \omega_0 t \end{aligned}\right\} \tag{19}$$

The relationship between the two representations is not straightforward, as is shown above, if the "molecules" have nonuniform angular velocities. Even in such a case, however, the 17 correlation function is valid for the free "molecules." However, in a rotating frame, $S_R(\omega_0:\ \pi/2,\ \varphi)$, the correlation function, $\Phi_{1R}^{(0)}(t)$, is, in general, not so simple as in (18), because there are many "molecules" whose angular frequency is different from ω_0. In general, the "molecule" has the angular frequency of $\omega-\omega_0$ in $S_R(\omega_0:\ \pi/2,\ \varphi)$. As a result, the "molecules" with $\omega>\omega_0$ and $\omega<\omega_0$ rotate in positive and negative directions respectively. Hence, the directions of the vectors $\boldsymbol{\mu}$ in S_R will gradually be randomized.

To treat this process more explicitly, we will consider a subensemble of the "molecules" whose rotation is to be described in $S_R(\omega_0:\ \pi/2,\ 0)$, The distribution of ω may be given by the Boltzmann distribution, $\exp(-I\omega^2/2\boldsymbol{k}T)$. If ω_0 is defined by the equation:

$$\int_0^\infty \exp\left(-I\omega^2/2\boldsymbol{k}T\right) \sin\left(\omega-\omega_0\right)d\omega=0 \tag{20}$$

or, more explicitly, by:

$$\omega_0(t) = \frac{1}{t}\tan^{-1}\left\{\frac{2}{\sqrt{\pi}}E_{rf}(t/\sqrt{2}\tau_f)\right\} \tag{21}$$

then the expectation value of the vector sum of each vectors, $\boldsymbol{\mu}$, over the subensemble in the rotating frame, $S_R(\omega_0:\ \pi/2,0)$, is always parallel to the z-axis of $S_R(\omega_0:\ \pi/2,0)$. The $\omega_0(t)$ frequency is roughly independent of the time:

$$\omega_0(0) = \frac{\tau_f}{\sqrt{2\pi}} \tag{22}$$

for small t values and gradually decreases with time. As has been mentioned before, the phase correlations among the vectors $\boldsymbol{\mu}$ in $S_R(\omega_0:\ \pi/2,0)$ eventually vanish and the directions of the vectors are eventually randomized. Hence, the $\Phi_{1R}^{(0)}(t)$ function, which is proportional to the z-component of a vector-sum, $\boldsymbol{p}$, of the vectors, $\boldsymbol{\mu}$, on each member of subensemble "molecules," decreases with time. It can be shown that:

$$\Phi_{1R}^{(0)}(t)=\int_0^\infty \exp(-I\omega^2/2\boldsymbol{k}T)\cos(\omega-\omega_0)t\mathrm{d}\omega$$
$$=\frac{\sqrt{2}}{\tau_f}\mathrm{e}^{-t^2/2\tau_f^2}\{\sqrt{\pi}\cos\omega_0 t + E_{rf}(t/\sqrt{2}\tau_f)\sin\omega_0 t\} \quad (23)$$

from which $\Phi_{1R}^{(0)}(t)\to 0$, as $t\to\infty$ is clear. Thus, roughly speaking, the mean period of rotation, τ_f, is the relaxation time of $\Phi_{1R}^{(0)}(t)$, namely, the relaxation time of $\Phi_1^{(0)}(t)$. To facilitate discussion, we will call the vectors on each "molecules" the μ-vectors, and the sum of the μ-vectors on all the "molecules," the $\boldsymbol{P}$-vectors.

The decay of $\Phi_{1R}^{(0)}(t)$ due to the loss of the phase correlation of the μ-vectors in the rotating frame may be compared to the free-induction decay of a macroscopic magnetization vector, $\boldsymbol{M}$, which was discussed by Hahn,[13] namely, the decay of the magnetization vector after a 90°-pulse. This pulse changes the direction of the magnetization vector by 90°. Then the vector begins to precess in a plane perpendicular to the direction of the magnetic field. In properly-chosen rotating frames, the motion of an ensemble of the μ-vectors with a uniform angular frequency may be compared to that of an ensemble of the noninteracting microscopic magnetization vectors, $\boldsymbol{m}$, in a homogeneous magnetic field. In both cases the $\boldsymbol{P}$ and $\boldsymbol{M}$ vectors are constant in the rotating frames. The motion of the $\boldsymbol{M}$-vector in an inhomogeneous field is similar to that of the $\boldsymbol{P}$-vector when the molecules have nonuniform frequencies; the phase memory among the $\boldsymbol{m}$-vectors is gradually lost as a result of the inhomogeneity of the magnetic field, which gives nonuniform frequencies to the precessing $\boldsymbol{m}$-vectors. It should be noted that no energy exchange process is involved here between the microscopic vectors, or between the microscopic vectors and the external degrees of freedom. In any case, the $\boldsymbol{P}$ vector relaxes or goes to zero, efficiently. Though the existence of this mechanism in the relaxation of the correlation function has not yet been noticed explicitly, it must be one of the important relaxation mechanisms, even when interactions are introduced among the molecules. This decay process may be tentatively called a *non-dissipative process,* though it must be more properly named in the future. The correlation function in the Debye representation is given, in terms of $\Phi_{1R}(t)$, as:

$$\Phi_1(t) = \Phi_{1R}(t)\cos\omega_0 t \quad (24)$$

where ω_0 is a function of the time as shown by (21).

The constant term, 1/3, in the correlation function, $\Phi_1^{(0)}(t)$, for spherical molecules results from three rotational degrees of freedom of spherical molecules. In other words, the "molecules" can rotate around any arbitary axes. For example, for the fraction of "molecules" whose axis of rotation is parallel to the z-axis, the μ-vectors are constants of motion. Thus, the $\Phi_1^{(0)}(t)$ function must have a constant term, which is contributed by the "molecules" to be described in the $S_R(\omega_0;\ \theta\neq\pi/2,\ \varphi)$ rotating frames.

Summarizing the discussions given above, we may describe the characteristic features of the $\Phi_1^{(0)}(t)$ correlation function for free spherical molecules as follows: (a) it is a periodic function of time; (b) however, the frequency of the periodicity, ω_0, is a function of time and is inversely proportional to t in a rough sense of the word; and (c) as a result of the existence of a non-dissipative process, the function relaxes, with a relaxation time of the order of τ_f, to a constant value which, qualitatively, arises from the fraction of "molecules" whose axis of rotation is parallel to the z-axis of the laboratory frames. The correlation function, $\Phi_1^{(0)}(t)$, shown in Fig. 1 has all these features.

We may use a similar argument for interacting molecules, or when there are collisions amoung the molecules in the system. The magnitude and the direction of the angular momentum of a "molecule" will be changed when it collides with other molecules. The transition of a μ-vector from one rotating frame to another is involved when the orientation of the angular momentum is changed. Thus, we may assume that the orientation of the μ-vectors after a collision may be randomized in the y-z plane of the rotating frames. As a result, the magnitude of $\boldsymbol{p}$ is reduced. This process of the relaxation of the angular correlation may be called a *dissipative process,* one which gives a non-periodic decay of the correlation function. In general, to $\Phi_1(t)$, correlation function is decreased by two causes which reduce the phase correlations among the rotating "molecules", the dissipative and the non-dissipative processes. Using the analogy of the free induction decay, we may compare these relaxation processes with the phase memory relaxation of the $\boldsymbol{m}$-vectors due to the spin-relaxation and due to the inhomogeneties of the external field.

When $\tau_r \gg \tau_f$, the correlation function has an extra maximum between $t=2\tau_f$ and $5\tau_f$. The decay before the maximum is mainly due to the non-dissipative process, while the one after the maximum is due to the dissipative process, where, qualitatively speaking, the orientation of the vectors which were parallel or nearly parallel to the z-axis at $t=0$ is changed by collisions. Quite similar discussions may be applied to the tensor correlation functions.

The form of the correlation functions near $t=\tau_f$ sharply depends on the τ_r/τ_f ratio when $\tau_r/\tau_f=0.5$—2.5, in other words, when τ_r is of the order of magnitude of τ_f. It is insensitive when

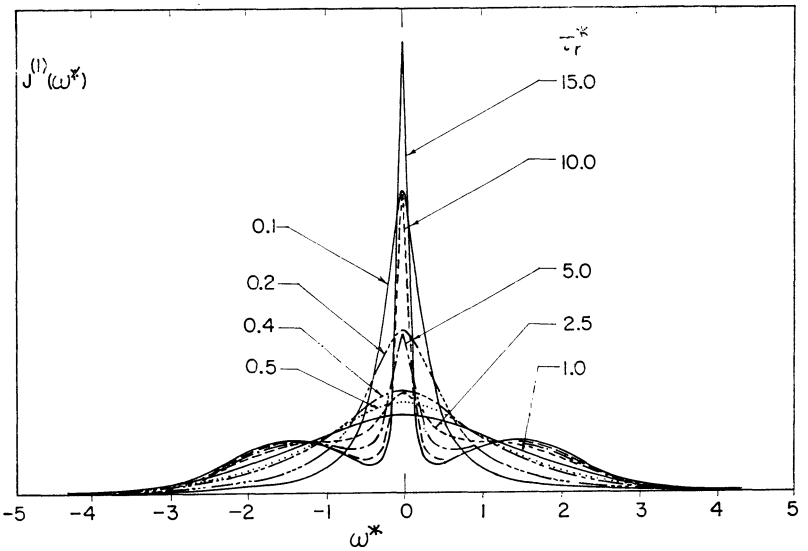

Fig. 3. The spectral densities or the infrared band spectrum for a spherical rotor, $J_1(\omega^*)$, obtained by using Eqs. 4 and 17. The asterisk on ω indicates that it is given in units of $1/\tau_f$. An arbitrary units is used for the ordinate.

$\tau_r/\tau_f \geqslant 10$. There is no bump in the correlation function when $\tau_r/\tau_f \leqslant 1.0$.

The Spectral Density and the Band Shape of Spectra

Spectral Densities.—The spectral densities corresponding to the correlation functions discussed above may be defined by[8]:

$$J_j(\omega) = \frac{1}{2}\int_{-\infty}^{\infty} \Phi_j(t) e^{-i\omega t} dt \qquad (25)$$

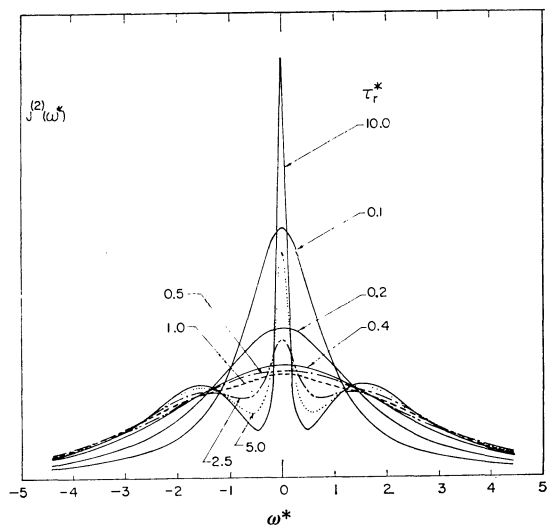

Fig. 4. The spectral densities or the Raman band spectrum of a spherical rotor, $J_2(\omega)$, obtained by using Eqs. 4 and 25.

The forms of the $J_1(\omega)$ and $J_2(\omega)$ functions are given in Figs. 3 and 4 respectively, where $1/\tau_f$ is chosen as the unit of the angular frequency These figures also show the band shapes of respectively, the infrared and Raman spectra of spherical molecules.

For $\tau_r/\tau_f \gg 1$, the spectral density is composed of three distinguishable parts, that is, the so-called P, Q, and R branches.[14] The spectral density, $J_j^{(0)}(\omega)$ for a free rotor has a δ-function-like line at $\omega=0$; this line results from the constant term in the $\Phi_j^{(0)}(t)$ correlation function. Collisions give a finite width to this line. When $\tau_r/\tau_f \gg 1$, the width of the central line is roughly the inverse of the "relaxation time" for the decay of the correlation function after the bump, that is, the relaxation time for the dissipative process. Mathematically, the bump of the correlation function gives bumps in the corresponding spectral density, or vice versa. Hence, when there is no bump in the correlation function, we cannot distinguish the P, Q, and R branches in the spectral density. When $\tau_r/\tau_f \ll 1$, the shape of the spectral density is close to a Lorentz form.

Correlation Times.—The correlation time for a $\Phi_j(t)$ correlation function may be defined as:[6,8,9]

$$\tau_j \equiv \frac{1}{2} J_j(0) = \frac{1}{2}\int_{-\infty}^{\infty} \Phi_j(t) dt \qquad (26)$$

Fig. 6 shows the dependence of the normalized correlation times, $\tau_j^* \equiv \tau_r/\tau_f$, on the normalized

14) C. Herzberg, "Molecular Spectra and Molecular Structure. I. The Spectra of Diatomic Molecules," D. Van Nostrand Company, Princeton (1950).

lifetime of the rotation, $\tau_r^* \equiv \tau_r/\tau_f$. On a semilogarithmic scale, τ_i^* is almost symmetric with respect to $\tau_r^* = 1$. This is also appproximately true for τ_2^*. In the Debye process there is a one-to-one correspondence between τ_r and τ_j, while in the non-Debye process this is not true, because of contributions from the non-dissipative decay of the angular correlation. Therefore, the reorientation rate cannot be determined by measuring only the correlation times. In particular, it is difficult to determine the value of τ_r^* from τ_2^* when τ_r^* is between 0.3—1.2.

Reorientation of Methane Molecules

It has been shown experimentally[15,16] that methane molecules have a non-Debye reorientation process in the liquid state. To show this clearly, vector correlation functions are obtained from the observed infrared spectra of methane molecules by the relation:[6-8]

$$\Phi_1(t) = \int_{-\infty}^{\infty} \omega^{-1}\sigma_1(\omega) \exp(i\omega t)\mathrm{d}\omega \qquad (27)$$

where $\sigma_1(\omega)$ is the band-shape function. The results are shown in Fig. 5, where τ_f is chosen as the time unit. Clearly, the functions are not exponential; this suggests non-Debye processes in the molecules. The characteristic features of the experimental functions are quite well approximated by Eq. 4, as is shown in Fig. 5. One of the remarkable points of Fig. 5 is that the vector correlation functions for CH_4 and CD_4 in the liquid state of 104°K are fairly close. The molecular structures of CH_4 and CD_4 were studied by Kuchitsu and Bartell[18] by means of the electron diffraction. The values of $r_0 = 1.0940$ Å and $r_e = 1.0850$ Å were reported for the C–H bond, and $r_0 = 1.0918$ Å and $r_e = 1.0850$ Å for the C–D bond, where r_0 and r_e refer to the bond lengths corresponding to the minimum potential and the equilibrium distance respectively. In our calculation we roughly assumed that $r_e(\mathrm{C\text{-}H}) = r_e(\mathrm{C\text{-}D}) = 1.085$Å at various temperatures, since there were no serious results of this assumption in the final results.

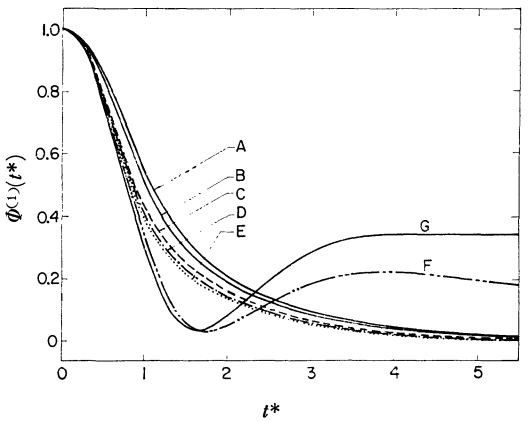

Fig. 5. The vector correlation functions $\Phi_1(t^*)$ for methane or deuteromethane molecules. The functions were obtained from experimental IR spectra by using Eq. 27, where the band shape functions for A—E and for F were, respectively, taken from Ewig's[14] and Armstrong and Welsch's[17] data. A=(CD_4 in CH_4, liquid at 104°K), B=(CD_4 in CD_4, liquid at 104°K), C=(CH_4 in CH_4, liquid at 104°K), D=(CH_4 in CH_4, liquid at 98°K), E=(CH_4 in CH_4, solid at 95°K), F=(CH_4 in He, gas at 294°K, 201 Amag.), and G=$\Phi_1^{(0)}(t)$. In this figure the wiggles which appear after a long time in the correlation functions are properly smoothed out.

It should be noted that the time scale in Fig. 5 has a unit of $\tau_f = (I/kT)^{1/2}$; the length of the time unit in Fig. 5 for the CD_4-function is larger than that for the CH_4-function by about 1.4 times. If we assume that the Debye equation is reasonable for the reorientation processes of methane molecules, there must be no significant difference between the CH_4- and CD_4- correlation functions, and the two functions must be quite different in Fig. 5. In addition, in contrast to Fig. 5, the CD_4-function must be inside the CH_4-function. Hence, it is clear that Debye's picture is entirely inapplicable to methane molecules.

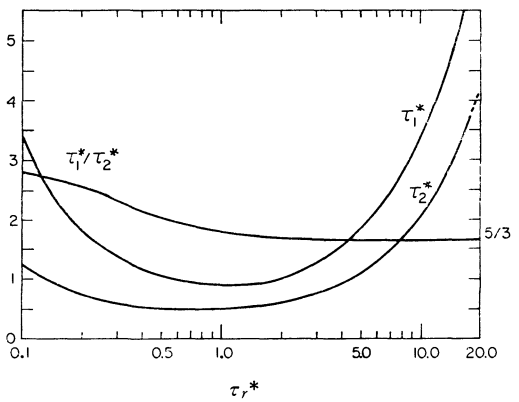

Fig. 6. Dependences of τ_1^*, τ_2^*, and τ_1^*/τ_2^* on τ_r^*. These curves were obtained by using Eq. 4.

The above-mentioned difficulties in Fig. 5 may be interpreted as follows. In Fig. 5, the unperturbed functions, $\Phi_1^{(0)}(t)$, for CH_4 and CD_4 are equivalent. In other words, the contribution from the nondissipative process to the correlation functions, $\Phi_1(t^*)$, of CH_4 and CD_4 are the same in Fig. 5. Hence, the observed small differences

among the $\Phi_1(t^*)$ correlation functions may be attributed to the differences in $\tau_r^*=\tau_r/\tau_f$, the normalized mean lifetime of the rotation. For the sake of convenience, the notation $\Phi_{CH_4/CD_4}(t;\ 100°K)$ will be used for the vector correlation function of CH_4 measured at 100°K in a CD_4 solution. The times, τ_f and τ_r, corresponding to this correlation function may be denoted as $\tau_f(CH_4/CD_4;\ 100°K)$ and $\tau_r(CH_4/CD_4;\ 100°K)$. Comparing Fig. 5 with Fig. 1, we have:

$$\tau_r^*(CH_4/CH_4:\ 104°K)>\tau_r^*(CD_4/CD_4:\ 104°K)>\tau_r(CD_4/CH_4:\ 104°K) \quad (28)$$

Qualitatively, this relation may be proved as follows. We may assume that the translational energy of a molecule is so much larger than the rotational energy that the rate of the change in the rotation of molecules depends only on the collision frequency. Therefore, $1/\tau_r$, the rate of the change in the rotational motion of molecules, is proportional to the frequency of collisions per second.

The total number of N_{12} collisions occuring per unit volume and per unit of time between pairs of the 1 and 2 gas molecules whose masses are, respectively, m_1 and m_2, is given by[19]:

$$N_{12}=2n_1n_2\sigma_{12}^2\left[\frac{2\pi kT(m_1+m_2)}{m_1m_2}\right]^{1/2} \quad (29)$$

where n_1 and n_2 are the number of the 1 and 2 molecules in a unit of volume, and where σ_{12} is the mean diameter of the molecules and is given in terms of the diameters of the 1 and 2 molecules, σ_1 and σ_2, by:

$$\sigma_{12}=\frac{1}{2}(\sigma_1+\sigma_2)$$

We may also consider other models of collisions. For example, we may treat molecules as harmonic oscillators which are restricted to their equilibrium positions. The frequencies of oscillators are inversely proportional to the square root of the m_1 or m_2 masses. We may assume that a collision occurs when one of the oscillating molecules is at the maximum deviation from its equilibrium position. Hence, we obtain:

$$N_{12}\propto\left(\frac{1}{\sqrt{m_1}}+\frac{1}{\sqrt{m_2}}\right) \quad (30)$$

In any case, the reduced lifetime of the rotation, τ_r^*, is portional to:

$$\tau_r^*\propto\sqrt{I}N_{12} \quad (31)$$

By neglecting the contribution from CD_4–CD_4 collision to $\tau_r^*(CD_4/CH_4)$ and by using (29) or (30), the inequality (28) is obtained. From (29) and (30) we obtain $\tau_r^*(CH_4/CH_4)$: $\tau_r^*(CD_4/CD_4)$: $\tau_r^*(CD_4/CH_4)=1:.79:.72$ and $1:.79:.75$ respectively. The difference between $\tau_r^*(CD_4/CD_4)$ and $\tau_r^*(CD_4/CH_4)$ is very small in the latter case.

Another interesting feature is that the Φ_{CH_4/CH_4} $(t:95°K)$ correlation function obtained from the infrared spectrum of solid methane is very close to those Φ_{CH_4/CH_4} $(t:98°K)$ and Φ_{CH_4/CH_4} $(t:104°K)$. Ewing[14] discussed this point in terms of the infrared spectra. It was also pointed out by deWit and Bloom[16] after their measurement of the nuclear magnetic relaxation of methane and deuteromethane. The latter found that there was no discontinuity in the nuclear magnetic relaxation time, T_1, just before and after the melting point of the solid methane. In addition, the temperature dependence of the relaxation time, T_1, was much weaker than that predicted by Debye's theory. From Fig. 5 we may say that the reorientation process of methane near the melting point is a non-Debye process. The $\Phi_{CH_4/He}$ $(t:294°K)$ correlation function shows very clearly that the decay of the angular correlation is caused by two different effects, the dissipative and the nondissipative processes.

By comparing Figs. 1 and 5, we find that $\tau_r^*(CH_4/CH_4:\ 95°K)$, $\tau_r^*(CH_4/CH_4;\ 98°K)$ and $\tau_r^*(CH_4/CH_4:\ 104°K)$ are of the order of 0.4—0.5, that $\tau_r^*(CD_4/CD_4:\ 104°K)$ and $\tau_r^*(CD_4/CH_4:\ 104°K)$ are roughly equal to 0.3—0.4, and that $\tau_r^*(CH_4/He_4:\ 294°K)=5.0$—10.0, as is suggested by a rough estimation that the rotational states of methane molecules are changed at each collision.

Discussion

The characteristic differences between the Debye and the non-Debye processes may be observed in the following phenomena: (a) the temperature dependence of the correlation function or of the correlation time, (b) the dependence of these quantities on the moment of inertia of molecules, and (c) the deviation of the form of correlation functions from an exponential one. Of course, it is also clear that the correlation function depends on the macroscopic viscosity, η, quite differently from what is predicted by the Debye equation. However, we do not wish to become involved in a discussion of ways of improving the Debye model by simply introducing the concept of the microscopic viscosity or that of the effective molecular radius.

The Temperature Dependence.—If we use the reduced time, t^*, whose unit is chosen as τ_f, the correlation functions for the free rotor, $\Phi_f^{(0)}(t^*)$, will be independent of the temperature. This is because τ_f is the correlation time corresponding to the $\Phi_f^{(0)}(t)$ function and, in addition, the temperature dependence of this function comes only through τ_f. In the inertial limit the temperature

19) S. Chapman and T. G. Cowling, "The Mathematical Theory of Non-Uniform Gases," Cambridge University Press, London (1952).

dependence of the $\Phi_j(t^*)$ function is given only through τ_r^*. For example, when τ_r is proportional to τ_f, that is, when it is proportional to $T^{-1/2}$, the $\Phi_j(t^*)$ correlation function is independent of the temperature. Such a case is given when (29) is satisfied. Then, the spectral density,

$$J_j(\omega^*) \equiv \frac{1}{2}\int_{-\infty}^{\infty} \Phi_j(t^*)e^{-i\omega^* t^*}dt^* \qquad (32)$$

must also be independent of the temperature where $\omega^* = |\tau_f|\omega$. The dimensionless quantity, $|\tau_f|$, is used to indicate that ω^* is measured in units of $1/\tau_f$. From (25) and (32) we obtain:

$$J_j(\omega) = |\tau_f| J_j(\omega^*/|\tau_f|) \qquad (33)$$

which gives the temperature dependence of the spectral density. Similarly, we obtain from (33) and (26):

$$\tau_j = \frac{1}{2}|\tau_f| J_j(0^*) \qquad (34)$$

Of course, (32)—(34) are valid only in a limited range of temperature, and a phase transition must not be involved in such a temperature range. Equation 34 gives a weaker temperature dependence of the correlation time than the Debye equation (3). The motional narrowing effect of the anisotropic potential due to the motion of the solvent molecules[8,20] has another effect on τ_j. If this effect is included, the $J_j(0^*)$ quantity becomes a function of the temperature; $J_j(0^*)$ will be increased when the temperature is raised.[8,20] Therefore, the temperature dependence of τ_j through $|\tau_f|$ is partially cancelled by this effect. Hence, we have here a weaker temperature dependence than that obtained from (34).

The Dependence on the Moment of Inertia.—In the Debye process the correlation time depends on the viscosity and on the size of the molecule. Hence, the effect of the isotopic substitution on the correlation time is, in general, so small that we can neglect it for all practical purposes. On the other hand, in the non-Debye process, the isotopic effect must be fairly large, as it is clearly shown in (34). Note that the *reduced* correlation function for the free rotor is independent of the moment of inertia.

The Form of Correlation Functions.—Correlation functions do not have an exponential form when the nondissipative loss of the phase correlation is appreciable. Experimentally, this can be checked by two different methods; from the infrared or Raman spectra, and from the nuclear magnetic relaxation. In the former experiment, the band shape of a spectrum must be quite different from a Lorentz form, provided that the nondissipative loss is appreciable. The measurement of the nuclear magnetic relaxation due to the spin-rotation interaction is also very helpful, because we can estimate the lifetime of the rotation, τ_r directly. If τ_r is comparable with or larger than τ_f, the form of the correlation function must not be exponential.

Effective Viscosities.—It is not accidental that methane shows non-Debye processes. This is because of the highly symmetric structure of this molecule. In general, rotational motions of molecules are perturbed by the anisotorpic part, V_{aniso}, of the intermolecular potential, but not by the isotropic part, V_{iso}, which perturbs the translational motion. Since the macroscopic viscosity for translational diffusions is used in the Debye equation (3), a necessary condition for Debye's theory must be $V_{\text{aniso}} \fallingdotseq V_{\text{iso}}$. Clearly this is not true for methane molecules. The concept of the effective viscosity for a given effective radius of a molecule or that of the effective radius for a given viscosity is nonsense in the strict sense of the words in non-Debye processes: the correlation times, τ_1 and τ_2, for which the τ_1/τ_2 ratio is not equal to 3 result in different viscosities or in effective radii from those produced by the Debye equation. In other words, these phenomenological quantities depend on the methods of measurement. Note Fig. 6

Conclusion

If the correlation time, τ_j, obtained from the experimental data is quite different from the corresponding one obtained from the Debye equation (3), there is a high possibility that the molecular reorientation is of a non-Debye process, where the nondissipative decay of angular correlation is not negligible. Therefore, the use of the Debye equation with an effective viscosity or microscopic viscosity is physically nonsense in such processes. However, it may not always be true that any non-Debye process gives a very much smaller correlation time than the corresponding Debye process. In the non-Debye processes correlation times may have a weaker temperature dependence than in the Debye processes, and they depend on the moment of inertia of the molecule. Often the forms of the correlation functions are different from the exponential ones as a result of the existence of the nondissipative decay of angular correlation, as we showed in the case of methane.

When the correlation functions of spherical particles for non-Debye processes are needed, we may conveniently use Eq. 4 as an approximate expression. It has been proved that (4) is a reasonably simplified expression for the correlation function of non-Debye processes, being related to the two kinds of decays of angular correlation. Or, experimentally, the vector and the tensor

20) M. Bloom, to be published.

correlation functions may be obtained from infrared and Raman spectra respectively in terms of the Fourier transform of the band-shape functions. Fourier transform of the band-shape functions. Conversely, the infrared and Raman spectra can be calculated from Function 4 by means of the Fourier transformation. Therefore, the theory of the band shape of the vibrational spectra is basically equivalent with the theory of the angluar correlation of molecules. Information on the reorientation process is obtained through the measurements of the vibrational spectra or of the nuclear magnetic relaxation due to the spin-rotation interaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2395—2399 (1966)

Studies of the Formation of Condensed Phosphates Containing Alkyl-groups*

By Shiro UEDA and Mitsuyasu TADA**

Department of Industrial Chemistry, Faculty of Engineering, Chiba University, Yayoicho, Chibashi

(Received September 9, 1965)

Alkyl ammonium polyphosphate (AAPP) was prepared readily by a thermal reaction of alkyl (ethyl, *n*-propyl, *n*-butyl) dihydrogen phosphate and urea at temperatures ranging from 120°C to 200°C. At the same time, a small amount of cyanuric acid was obtained as a by-product. 1) AAPP was confirmed, from a study of the data of infrared spectroscopy, paper chromatography and chemical analysis, to have a long-chain structure possessing P–O–P linkage. The three types of AAPP were of almost the same form, according to the X-ray diffraction patterns. 2) AAPP was more or less hygroscopic, although the hygroscopicity of AAPP decreased with an increase in the carbon number of the alkyl group. 3) AAPP is reasonably stable, keeping a P–O–P linkage even upon degradation in an acidic aqueous solution.

In a previous paper,[1] the present authors reported that when a mixture of phosphoric acid and urea was heated at 140—160°C, the decomposition of urea and the condensation and neutralization of phosphoric acid took place simultaneously. The products formed were ammonium polyphosphate and a small amount of cyanuric acid.

By a method similar to those used in preparing ammonium polyphosphate, the reaction of urea with alkyl dihydrogen phosphates was investigated. Alkyl phosphates with two hydroxyl radicals were thus found to bring about a poly condensation reaction with urea, giving alkyl ammonium polyphosphate (hereinafter this compound will simply be abbreviated as AAPP). All of the reaction products were identified by infrared absorption, X-ray diffraction, paper chromatography and quantitative chemical analysis. Several properties of AAPP were also investigated.

Experimental

The Formation of Alkyl Dihydrogen Phosphate.—Ethyl, *n*-propyl and *n*-butyl alcohol was reacted with phosphorus oxychloride at about 25°C. Alkyl phosphorodichloridate was obtained in about a 75—85% yield by means of vacuum distillation in each case. Alkyl phosphorodichloridates were hydrolyzed with water,[2] and de-hydrogenchloride carried out by blowing dry air into a volumetric flask under reduced pressure. The alkyl dihydrogen phosphate thus obtained was a light yellow, transparent liquid.

The Reaction of Alkyl Dihydrogen Phosphate with Urea.—Alkyl dihydrogen phosphates and urea were mixed so that the molar ratio of phosphorus pentoxide to urea in each alkyl dihydrogen phosphate corresponded to 1 : 2. The mixture was then gradually heated until the urea dissolved completely into the

alkyl dihydrogen phosphate. The reaction proceeded rapidly; a stimulative gas which contained carbon dioxide was evolved at about 130—135°C. At the initial stage of the reaction, the reaction product was remarkably expanded, and within several minutes the reaction was completed, the end point of the reaction being indicated by the formation of solid matter. Also, at the end of the reaction, a small amount of ammonia gas was generated. The resultant product was a light yellow, humid substance containing small amounts of unreacted urea and a water-insoluble substance.

The reaction product was then dissolved in water, and the insoluble substance was filtered off. Three times as much acetone as mother liquor was added to the latter, with constant stirring.

A white crystalline phosphate was separated as a precipitate, the urea remaining in the mother liquor. The precipitate was then again filtered off. After having been washed with anhydrous ethanol and acetone, the purified reaction product was dried using silica-gel under reduced presure.

Paper Chromatography.[3]—Paper chromatography was carried out in a constant-humidity cabinet manufactured by the Mitamura Co., Ltd.

The solvent used for the development consisted of:

isopropyl alcohol	735 ml.
trichloroacetic acid	50 g.
distilled water	265 ml.
concentrated ammoniacal water	2.5 ml.

A spray reagent was prepared by mixing 5 ml. of 60% perchloric acid, 1 ml. of hydrochloric acid, and 1 g. of ammonium molybdate, and by then diluting this mixture to 100 ml. with water. Toyo filter paper No. 53 were used, and the development was conducted for 4—5 hr. at room temperature.

Chemical Analysis.—Ammonia was analyzed by a conventional chemical method. The phosphorus was spectrophotometrically determined at the 410 mμ wavelength, using a vanadomolybdate as the color reagent.[4] The alkoxyl groups were analyzed by the Zeisel method.[5]

X-Ray Diffraction.—The X-ray diffraction of samples was carried out with a Rigaku-Denki, D-2F unit using a nickel filter and copper K_α radiation. The unit was operated with a voltage of 30 kV., a current of 15 mamp., a scale factor of 400, a time constant of 2/sec., and a scanning speed of 2°/min.

Infrared Spectroscopy.—All of the spectra were recorded over the range from 4000 to 700 cm^{-1}, using a Hitachi EPIS-11 Double beam Spectrometer. The infrared spectra of the samples were taken both by potassium bromide pellet and by Nujol mull methods.

Results and Discussion

All of the resulting products were obtained as colorless crystalline substances. These products was of a somewhat hygroscopic nature and seemed to have a good solubility in water. The hygroscopicity of the products containing *n*-butyl and *n*-propyl groups were less pronounced than that containing the ethyl group.

The Composition of the Reaction Products.—Analytical results of the reaction products obtained from alkyl dihydrogen phosphates and urea are given in Table I. Small amounts (0.5—1.8%) of cyanuric acid as an insoluble substance in water, the identity of which was established by X-ray diffraction, were also obtained.

These phosphate polymer contained considerable amounts of water. In calculating the number average chain length, we disregarded the water in the phosphate.

M^1 stands for the mono-valency cation. The amonia and alkyl groups were expressed as $(NH_4)_2O$ and A_2O respectively in calculating the composition of the phosphates.

The nitrogen exists in phosphate as an ionized ammonium radical; this is confirmed by the fact that a barium salt prepared by adding barium chloride to an aqueous solution of phosphate does not contain the nitrogen.

As is shown in Table I, the molar ratio of $M^1{}_2O$ to P_2O_5 is approximately unity. The composition of poly-condensed phosphate can be expressed as $xM^1{}_2O{\cdot}yP_2O_5$, corresponding to the molar ratio of $R=x/y$. The general formula for the long-chain polyphosphates is usually given as:

$$\lim_{n\to\infty} M^1{}_{n+2}P_nO_{3n+1} = M_nP_nO_{3n}$$

For linear polymers, molar ratio, R, approaches 1 for sufficiently long chains. Judging from the analytical results, AAPP can, therefore, be thought of as being a long chain phosphate.

The average chain length of the polyphosphate can be determined by calculating the molar ratio, R. It is well known that the average chain length, $\bar{n}$, of polyphosphates is given by the equation:

$$R = M^1{}_2O/P_2O_5 = (n+2)/n$$

As the molar ratio, R, approaches unity, $\bar{n}$ approaches infinity. From the data in Table I,

Table I. Analytical results of the reaction products

Alkyl dihydrogen phosphate	$(NH_4)_2O$ wt. %	A_2O* wt. %	P_2O_5 wt. %	$(NH_4)_2O/A_2O$ mole ratio	$M^1{}_2O/P_2O_5$** mole ratio	pH of 1% solution
Ethyl	15.3	2.1	47.2	9.1	1.0	5.9
n-Propyl	19.3	4.4	52.5	8.6	1.1	5.7
n-Butyl	20.6	7.6	58.0	6.8	1.1	5.9

* Alkyl ** $M^1{}_2O=(NH_4)_2O+A_2O$

4) O. B. Michelsen, *Anal. Chem.*, **29**, 60 (1957).
5) "Hand book of Analytical Chemistry," Maruzen Book Co., Tokyo (1961), p. 538.

we can calculate the average chain length, $\bar{n}$, of AAPP as having a value of more than 20.

Paper Chromatography. — Chromatograms and R_f values are shown in Fig. 1 and Table II respectively. When alkyl dihydrogen phosphate was used, almost all the phosphates produced were high polymers which could not be developed by paper chromatography. Even though a two dimensional development technique was used, no evidence of the formation of a ring-form phosphate was obtained.

In Fig. 2 are illustrated chromatograms of the hydrolysis products of AAPP, which were produced in an aqueous solution at pH 2.5 (adjusted by hydrochloric acid) and at 60°C.

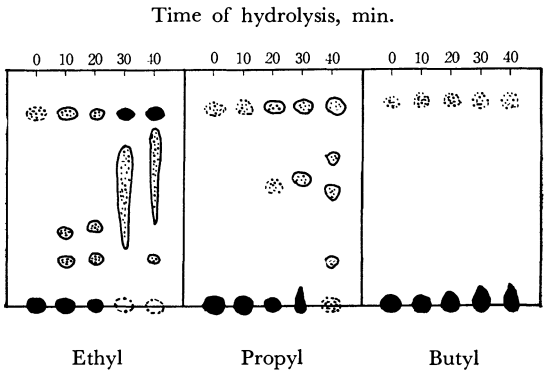

Fig. 2. The formation of hydrolysis products at pH 2.5 and 60°C.

As is shown in Fig. 2, the AAPP possesses a considerable stability upon hydrolytic degradation in an acidic solution.

The X-Ray Diffraction Pattern of AAPP and Its By-product.—The X-ray diffraction pattern of AAPP is illustrated in Fig. 3.

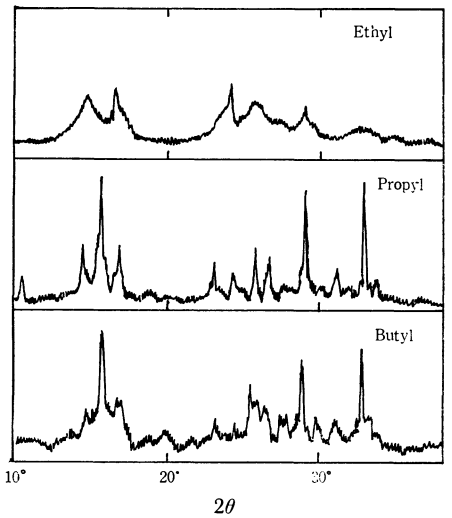

Fig. 3. The X-ray diffraction pattern of the reaction products.

As is apparent from the diffraction patterns, AAPP is always a crystalline substance. As the number of carbon atoms in the alkyl group increases, however, the crystallinity of the AAPP tends to increase. The crystallinity of the AAPP obtained from mono-ethyl dihydrogen phosphate is fairly poor in comparison with that obtained from propyl and butyl compounds. The poor crystallinity of the ethyl compound may be thought of as being caused by the hygroscopicity of the product.

Table III shows the spacing of the main interference with AAPP; it is always almost the same

interferecne, regardless of the alkyl type. Therefore, the products can reasonably be regarded as phosphates with similar crystalline structures.

A water insoluble by-product was recrystallized in hot water (85—90°C) and then dried. The recrystallized substance was identified by the X-ray diffractometry as cyanuric acid, which was formed by the thermal decomposition of urea. The X-ray diffraction pattern and the spacing of the main interference of an insoluble substance and a pure reagent of cyanuric acid are shown in Fig. 4 and Table IV respectively.

As can be seen, the pattern and the main interference of the insoluble substance agree well with those of pure cyanuric acid.

The Infrared Absorption Spectra of AAPP. —In this work the infrared spectra of samples were examined as powder in the 4000—700 cm^{-1} range. These spectra have been investigated with a view to assigning characteristic frequencies to molecular groupings and to generally correlating the absorption with the molecular structure.

AAPP was mixed with potassium bromide and pressed into a disk; then the infrared spectra were measured and further compared with Nujol mulls. Figure 5 shows some typical spectra of these products; a potassium bromide tablet technique was employed for the measurements.

As can be seen from Fig. 5, a considerable variation was observed throughout the spectra. Some salts, e. g., *n*-propyl and *n*-butyl compounds, particularly afford broad and poorly resolved peaks.

The characteristic absorption bands of P–O–P, P–O–C (where C is aliphatic carbon) and the NH_4^+ ion were found in each spectrum in the ranges ~890 (P–O–P stretching), 760—740 (harmonics of P–O–P bending), 1010 (P–O–C stretching), 1390—1410 (NH_4^+, N–H stretching) cm^{-1}.

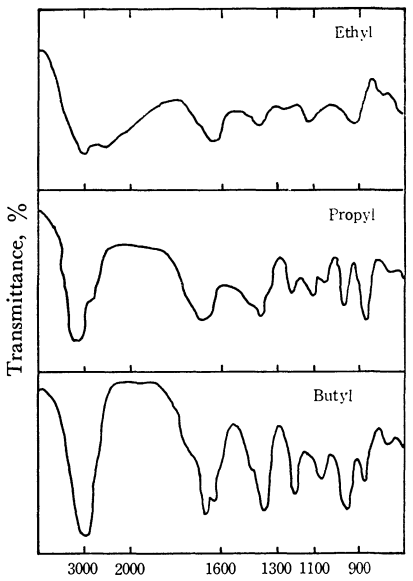

Fig. 5. The infrared absorption spectra of the reaction products.

This evidence strongly supports the view that AAPP is poly-condensed phosphate containing alkyl and ammonium radicals in the molecule.

The Mechanism of the Reaction.—A useful method for the preparation of condensed phosphate containing nitrogen has recently been developed by the present authors,[1] in this method a phosphoric acid or alkali metal dihydrogen phosphate is thermally treated with urea.

Similar condensation reactions have also been observed in the interaction of alkyl dihydrogen phosphate with urea. As has been stated above, the preparation of AAPP through the thermal reaction of alkyl dihydrogen phosphate with urea

is accompanied by the following chemical reactions; alkyl dihydrogen phosphate and urea are subjected to the thermal reaction with greater ease; carbon dioxide gas and a stimulative gas (which is considered to be isocyanic acid) are generated, small amounts of ammonia gas and cyanuric acid as trimer of isocyanic acid are formed in the final stage of the reaction. On the basis of these observations as well as of chromatographic, infrared and X-ray diffractometric measurements, the mechanism given below seems reasonable for the reaction of alkyl dihydrogen phosphate and urea.

Assumption for the Mechanism of the Reaction.—First of all, urea is decomposed into ammonia and carbon dioxide with water.

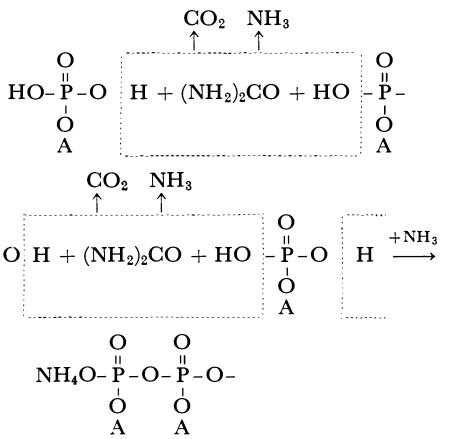
$$(NH_2)_2CO + H_2O \rightarrow 2NH_3 + CO_2 \qquad (1)$$

The water is thought to come from the hydroxyl radical of two moles of dihydrogen orthophosphates.

A small part of the urea can also be decomposed into cyanuric acid and ammonia in the following way when cyanuric acid is formed as a by-product of the reaction:

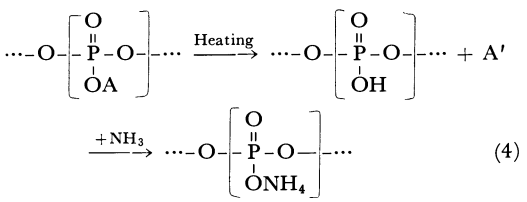
$$3(NH_2)_2CO \rightarrow (HNCO)_3 + 3NH_3 \qquad (2)$$

Thus, the formation of AAPP may be illustrated by the following equation:



(3)

As has been recognized by Hochwalt and his co-workers[6] in the thermal decomposition of alkyl hydrogen phosphate, the alkyl group in phosphate may also be decomposed partially into free acid and olefine by heating. The ammonia produced by the reactions 1, 2, and 3 can subsequently be neutralized with the hydroxyl radical of the poly-condensed phosphate according to the following equation:



(4)

Where $A = C_nH_{2n+1}$, $A' = C_nH_{2n}$, etc.

Therefore, the alkyl group of this compound may partially be replaced by the ammonium group in a random way.

Summary

When alkyl dihydrogen phosphate and urea are mixed and subjected to thermal reaction at 120—200°C, the thermal decomposition of urea, the condensation of alkyl dihydrogen phosphate, and a partial neutralization of the acid with ammonia have been brought about, this yielding alkyl ammonium polyphosphate (AAPP).

Observations with infrared spectroscopy, paper chromatography and chemical analysis have disclosed that the reaction products are long-chain phosphates containing alkyl and ammonium group in a skeleton P–O–P.

The average chain length, *n*, of AAPP is estimated by calculation to be more than 20.

No substantial difference in crystalline form has been found among the various AAPPs' tested.

The products are more or less hygroscopic, although the hygroscopicity of AAPP decreases with an increase in the number of carbon atoms in the alkyl group.

It has also been found that AAPP is reasonably stable upon the hydrolytic degradation of the P–O–P linkage in an acidic, hot aqueous solution.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2400—2405 (1966)

A Spectrophotometric Determination of Iron(III) with ω-Aminoacetophenone-*N*, *N*-diacetic Acid Oxime*

By Takeshi ANDO** and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

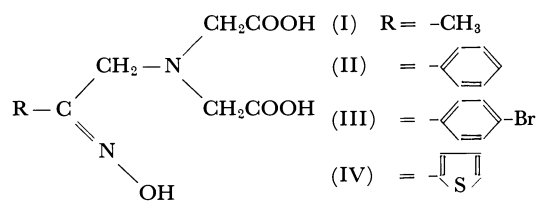
(Received September 10, 1965)

The oximes of aminoacetone-*N*, *N*-diacetic acid, ω-aminoacetophenone-*N*, *N*-diacetic acid, *p*-bromo-ω-aminoacetophenone-*N*, *N*-diacetic acid and 2-glycylthiophene-*N*, *N*-diacetic acid have been synthesized as the colorimetric reagents for iron(III). The most favourable result was obtained with the oxime of ω-aminoacetophenone-*N*, *N*-diacetic acid, which forms a stable orange red chelate with iron(III), showing an absorption maximum at 420 mμ. With the use of this reagent, 0—25 p. p. m. of iron(III) can be determined at pH 5.5. It should be noticed that this reagent is almost specific for iron(III); serious interferences were only observed for copper(II), vanadate, fluoride and phosphate ions.

During the course of our investigation of the synthesis of keto derivatives of methyliminodiacetic acid,[1] the color reactions of these ligands with various metal ions have been studied with a hope of finding new colorimetric reagents of analytical importance. In these studies, it has been found that 1-amino-propan-2-one-*N*, *N*-diacetic acid or aminoacetone-*N*, *N*-diacetic acid (I) (AADA) gave a red coloration with iron(III) in the presence of hydroxylamine hydrochloride and hydrogen peroxide; the photometric determination of iron (III) based on this color reaction has been reported.[2] The results of the detailed investigation of the mechanism of the color reaction with AADA proved that the chromogenic substance was an oxime of AADA(AADA-OX), which reacted with iron(III) to form a red chelate. This finding, together with the fact that the molar absorptivity of iron chelate of AADA-OX is not large enough (1.6×10^3), stimulated us to investigate new colorimetric reagents of the related structure.

The compounds investigated in this study are ω-aminoacetophenone-*N*, *N*-diacetic acid oxime (II) (AAPDA-OX), *p*-bromo-ω-aminoacetophenone-*N*, *N*-diacetic acid oxime (III) (Br-AAPDA-OX), and 2-glycylthiophene-*N*, *N*-diacetic acid oxime (IV) (GTDA-OX).

The comparative study of these compounds showed that AAPDA-OX and Br-AAPDA-OX



gave the most intense coloration with iron(III) with an absorption maximum in the 410—420 mμ region and that these compounds could be used as a specific colorimetric reagent for iron(III). However, AAPDA-OX may be more suitable for practical purposes because this compound can be synthesized more easily than Br-AAPDA-OX.

This paper will report on the results of an investigation of the synthesis and the use of AAPDA-OX as a colorimetric reagent for iron(III). The molar absorptivity of Fe-AAPDA-OX chelate is 2.0×10^3. This is smaller than that of Fe-1, 10-phenanthroline (1.1×10^4); however, AAPDA-OX is almost specific for iron(III). Of the common ions investigated, serious interferences were observed for only copper(II), vanadate, fluoride and phosphate ions. The results suggest that AAPDA-OX can be used as a specific iron reagent in the practical determination of iron at a relatively higher concentration level in the presence of a large amount of foreign ions. The results also indicate that a new type of colorimetric reagent for iron(III) can be developed using AAPDA-OX as a mother compound.

Experimental

The Syntheses of Reagents.—Oximes of the Keto-derivatives of iminodiacetic acid were synthesized by the condensation of the corresponding acid and the free hydroxylamine. As an example, the synthesis of AAPDA-OX(II) be described.

* Contribution No. 87 from the Department of Organic Synthesis, Faculty of Engineering, Kyushu University.

** Present address; Chemical Laboratory, Department of General Education, Kyushu University, Ootsubomachi, Fukuoka.

1) a) T. Ando, This Bulletin **36**, 1593 (1963); b) T. Ando and K. Ueno, *Inorg. Chem.*, **4**, 375 (1965).

2) H. Takama, T. Ando and K. Ueno, *Japan Analyst*, **13**, 345 (1964).

Anhydrous sodium carbonate (1.05 g.) was added slowly to a suspension of 5 g. of ω-aminoacetophenone-*N*, *N*-diacetic acid[1b] in 15 ml. of water; this made a clear solution of the monosodium salt of the acid. To this solution was added 14 ml. of an aqueous ethanol (1 : 3 by volume) solution of free hydroxylamine prepared from 1.50 g. of hydroxylamine hydrochloride; the mixture was then heated on a water bath at 70—80°C, with occasional shaking. After the mixture had stood overnight at room temperature, the pale yellow solution was concentrated under reduced pressure almost to dryness, while the bath temperature was kept below 60°C. To the residue, 250 ml. of ethanol was added, and the solution was kept in a refrigerator overnight. The resulting monosodium salt of the oxime was filtered off, and washed with ethanol and then with ether. Yield: 7 g. The pure monosodium salt of AAPDA-OX was obtained by repeated recrystallizations from 90% ethanol. The pure oxime was obtained as colorless needles which decomposed at 129—130°C (they colored at 122°C). This material has two moles of the water of crystallization; one mole of which was lost when it was heating at 40°C over phosphorus pentoxide in vacuo, while the remaining water was removed only by heating, the material at 70°C. However, reliable analytical data corresponding to the anhydrous material could not be obtained since it was very hygroscopic.

The structure for oxime was also supported by the infrared spectra, in which a carbonyl band at 1690 cm^{-1} characteristic of the starting material disappeared in the oxime derivatives.

The physical properties and the results of analyses of the oximes are summarized in Table I. The monosodium salts of these oximes are very soluble in water and soluble in hot methanol and ethanol, but insoluble in ether, benzene, dioxane and petroleum ether. All attempts to obtain the free acid form of oximes were unsuccessful, since the oximes were easily hydrolyzed in a low pH region.

pH Titration Study.—An automatic recording titrator, Metrohm Potentiograph E 336, was employed for the pH titration study. The titration was conducted in an atmosphere of nitrogen at room temperature. A 100-ml. portion of a 1×10^{-3} M solution of monosodium salt of AAPDA-OX was titrated with a 0.1 N sodium hydroxide solution in the absence and in the presence of equimolar amounts of metal ions.

Absorption Spectral Study.—*Reagents.*—AAPDA-OX solution. A 0.001 M solution was prepared by dissolving a monosodium salt of oxime.

A 0.01 M standard iron(III) solution was prepared from ferric nitrate. This solution was standardized by EDTA titration.

The buffer solutions were acetates of standard compositions.

All the other reagents were of analytical grade unless otherwise specified.

Apparatus.—A Hitachi Model EPS-2 recording spectrophotometer was used for the measurements of the absorption spectra, while a Hitachi Model FPW-4 filter photometer was used for the photometric measurements. A Hitachi-Horiba Model P glass electrode pH meter was used for the pH measurements.

Standard procedure for the measurements of the absorption spectra: To a solution containing 312 μg. of iron(III), 5 ml. of a buffer solution (pH 5.5) and 5 ml. of a 0.001 M oxime solution were added; the mixture was then diluted to 25 ml. After 30 min., an absorption spectrum of the resulting solution was measured against water, using standard 1-cm, cells. The results are shown in Fig. 1. For the absorbance measurements, a similar procedure was followed, using a photometer equipped with a filter with a maximum transmittance at 420 mμ.

Results and Discussion

Absorption Spectra.—The absorption spectra of the iron(III) chelates of oximes and of the reagent blank are shown in Fig. 1. The reagent blank consists of iron and the buffer solution.

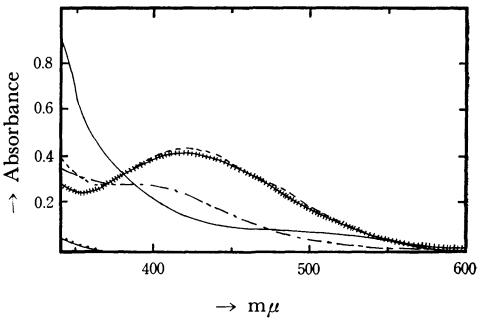


Fig. 1. Absorption spectra of oximes (12.5 p.p.m. of Fe).

- – – AADA-OX Na
- ||||||| AAPDA-OX Na
- – – – *p*-Br-AAPDA-OX Na
- —— GTDA-OX Na
- ▲▲▲ Blank···Fe(III)-Acetate Buffer

None of free oxime reagents showed any absorption in the visible region. The iron(III) chelate of GTDA-OX gave no absorption maximum in this region. On the contrary, the iron(III) chelates of AAPDA-OX and Br-AAPDA-OX gave a maximum at around 420 mμ. The iron(III) chelate of AADA-OX gave a shoulder at around 390 mμ, and the absorption spectra is identical with that of the aminoacetone-*N*, *N*-diacetic acid—hydroxylamine hydrochloride — hydrogen peroxide—iron(III) system, which was reported on previously.[2] Therefore, the colored complex due to iron(III) was proved to be the iron(III) chelate of AADA-OX.

The molar absorptivity of the iron chelates of AAPDA-OX and Br-AAPDA-OX were calculated as 2.0×10^3 and 2.1×10^3 respectively. These values are not so high as 1, 10-phenanthroline, but these oximes are still effective as the colorimetric reagents for iron(III). However, the synthesis of AAPDA-OX is much easier than that of Br-AAPDA-OX. After considering these results, AAPDA-OX was chosen as a colorimetric reagent for iron(III) in this study.

Structures of the Ligand and the Iron Chelate.—As has been described in the Experimental part, the results of elementary analyses

agree fairly well with the proposed formula of the oximes. The infrared spectra of oximes, observed as Nujol mull on the solid sample as well as on the deuterium oxide solution, indicated the disappearance of the carbonyl band of the starting materials. These results all support the oxime structure.

In order to get semi-quantitative information on the interaction of various metal ions with oximes, a pH titration study was carried out on AAPDA-OX in the absence and in the presence of various metal ions. The titration curves are reproduced in Fig. 2. As is clear from the figure, a fairly strong interaction between iron(III) and AAPDA-OX can be seen in the acid region.

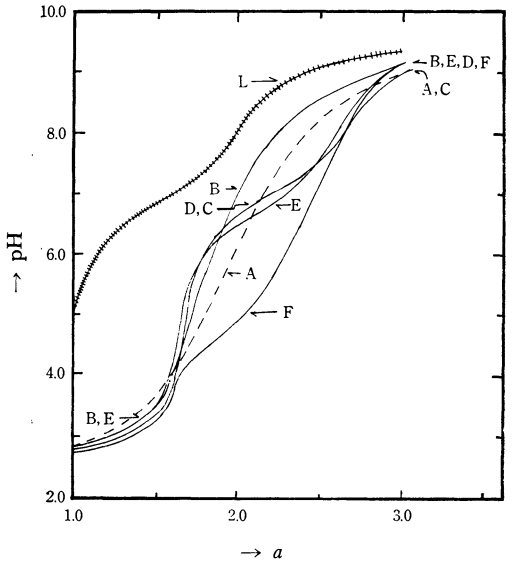

Fig. 2. Titration curves of monosodium AAPDA-OX in the abssence and presence of equivalent amount of various ions.
L, ligand; A, Fe(III); B, Cd(II); C, Zn(II); D, Ni(II); E, Co(II); F, Cu(II). *a* denotes moles of base (0.1 N NaOH) added per mole of ligand. Concentration of ligand and metal ions···about 1×10^{-3} M.

To determine the combining ratio of iron to a ligand, the continuous variation study was carried out on the Fe-AAPDA-OX system at pH 5.5. As is shown in Fig. 3, the results clearly indicate the formation of the chelate in only a 1 : 1 metal ligand ratio. Since iron(III) has a coordination number of 6, the iron(III) chelate of AAPDA-OX may possibly have a structure such as is shown in Fig. 4. Since there still remains a problem of the geometric arragement of the imino hydroxyl group (syn and anti), more experimental data is needed to settle this problem.

Conditions for the Photometric Determination of Iron(III).—In order to find the optimum conditions for the photometric determination of

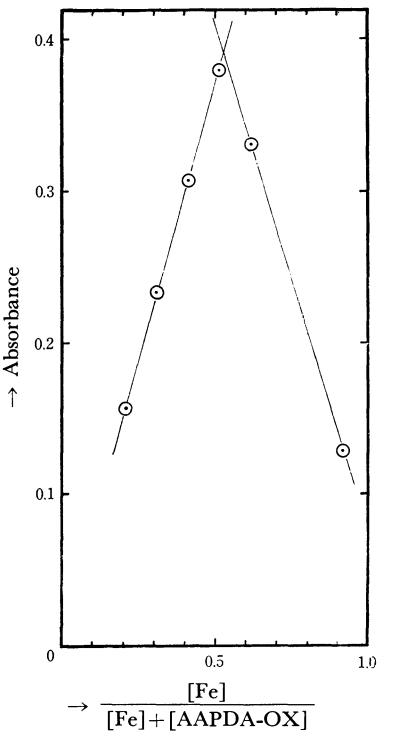

Fig. 3. Continuous variation study on AAPDA-OX-iron(III) system. [Fe(III)]+[AAPDA-OX] =0.01 M. pH=5.5. wavelength=420 mμ.

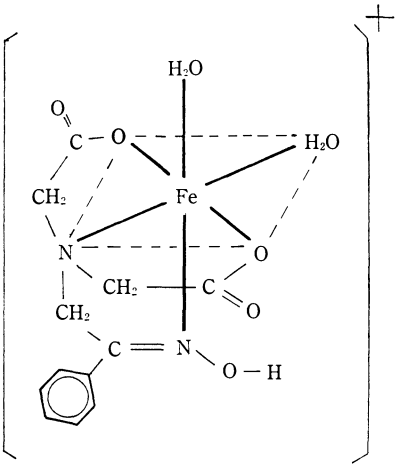

Fig. 4. Possible structure of the colored complex.

iron(III) with AAPDA-OX, various factors influencing the coloration, such as the pH, the amount of reagent, and the standing time, have been investigated.

The Effect of the pH.—The variations in the absorbance of the iron(III) chelate of AAPDA-OX at 420 mμ with a change in pH are shown in Fig. 5. The standard procedure for the measurement of absorption spectra was followed, with acetate

⊙———⊙ standing time 20 hours

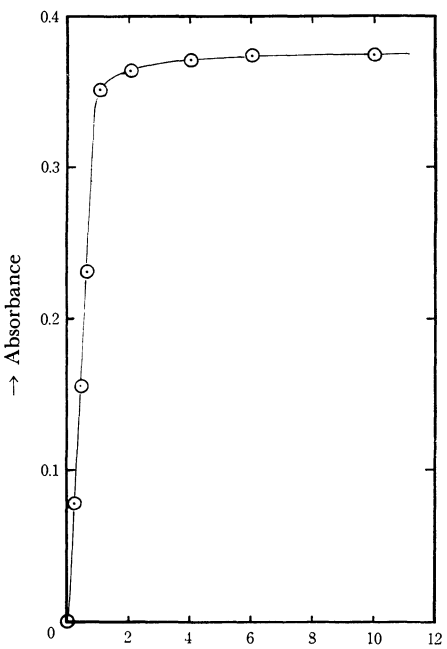

Fig. 6. Effect of the amount of reagent on the color developement (11.0 p.p.m of Fe).

buffers of different pH values, and their absorbances were measured after various standing times. It may be seen from this figure that the absorbance changes very slightly over the pH range from 4.0 to 7.0. Especially, in the pH range from 5.0 to 6.0, the absorbance is almost constant within the limits of experimental error. Therefore, the acetate buffer solution of pH 5.5 was chosen in this experiment. The amount of buffer solution had not much influence on the absorbance, since the acetato-iron(III) complex has no significant absorption at 420 mμ under these conditions.

The Amount of AAPDA-OX.—The effect of the amount of the reagent on the color development was studied. As is shown in Fig. 6, when more than four times as much reagent as iron was employed,

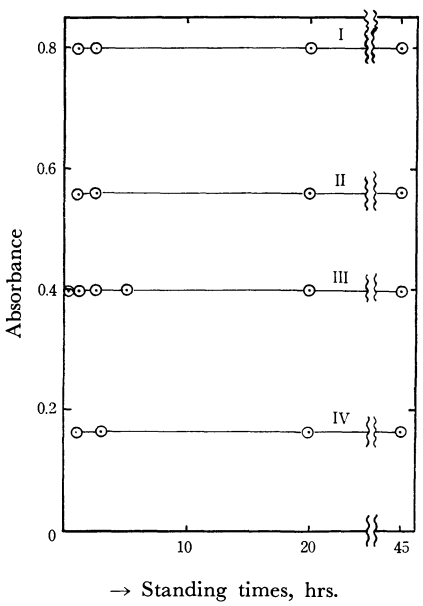

Fig. 7. Effect of the standing time for the color development.
I, Fe=25.0 p.p.m.; II, Fe=17.5 p.p.m.; III, Fe=12.5 p.p.m.; IV, Fe=7.0 p.p.m.

the absorbance became almost constant. Accordingly, 5 ml. of a 1×10^{-1} M solution of AAPDA-OX was added to a sample solution containing 50 to 625 μg. of iron(III).

The Stability of the Color.—The color developed by the standard procedure was found to be very stable over many hours, as is shown in Fig. 7. It was not neccessary to wait for the full color development, as the color reached its maximum immediately after the reagents were mixed. However, the absorbance was measured after 0.5—1.0 hr. in this experiment.

Calibration Curve.—To the series of sample solutions containing 60—600 μg. of iron(III), the standard procedure described in the experimental part was applied, and the absorbances of the resulting color at 420 mμ were plotted against their concentrations. As is shown in Fig. 8, the system follows Beer's law in the concentration range from 0 to 25 p. p. m. of iron(III).

The Effects of Diverse Ions.—The effects of diverse ions were investigated on the solutions containing 312 μg. of iron(III) and various amounts of individual diverse ions. The cations, except for manganese and chromium, were added as the nitrate, but manganese and chromium were added as sulfate and chloride respectively. The data in Table II show the tolerance limits of each ion.

As the table shows, cadmium, manganese(II), lead and ammonium do not interfere, even if they are present at a concentration level hundreds of

times that of iron. Nickel, aluminum, and zinc do not interfere up to concentrations of several tens times of the amount of iron. The negative errors observed in the presence of a large amount of these interfering ions may be due to the consumption of the reagent by the formation of stable but colorless complexes with these cation; the error may be lessened by the use of a fairly large amount of the reagent. Cobalt(II) and chromium(III) show a positive error if they are present in an amount more than twice that of iron(III). Copper(II) seriously interferes, giving a positive error. The cations which give a positive error are apt

to form stable and colored complexes, and so they should be masked or separated by appropriate methods. The anions, such as chloride, sulfate and acetate, do not interfere, even if they are present at concentration levels several thousands of times that of iron. Hundreds times of the level of molybdate and tens times of the level of tungstate do not interfere either; however, as was expected for iron(III), fluoride and phosphate seriously interfere with the determination by the formation of stable fluoro- and phosphato-complexes respectively.

It is clear from these results that AAPDA-OX is almost specific for iron, and that this reagent can be used as a colorimetric reagent for iron(III) in the presence of fairly large amounts of various ins.

It is interesting to note that the degrees of interference by these cations are parallel with the degrees of chelate formation, as estimated from the titration curves in Fig. 2. The extent of the pH drop is largest for copper, intermediate for cobalt and nickel, and smallest for cadmium and zinc. Thus, the interference with the cations is caused not only by the formation of colored complexes with the reagent, but also by the formation of stable chelates even if they are colorless.

A Comparison with Other Methods. — Of the various colorimetric reagents for iron, 2, 2'-bipyridine, 1, 10-phenanthroline and 5, 8-diphenyl-1, 10-phenanthroline have been known as the most favourable reagents because of their sensitivity.[3] They form strongly-colored complexes of the hexacovalent type and chelates (FeA_3^{2+}) with iron(II) in weakly acidic, neutral, or weakly alkaline media. The complexes are fairly stable, and the reagents are highly selective for iron. However, nickel, cobalt and copper are known to form colored complexes with these reagents, giving erroneous results. The limiting amounts of the interfering ions for various reagents are compared in Table III.

As has described above, the molar absorptivity of Fe-(AAPDA-OX) is about one fifth that of Fe-(phenanthroline)$_3$. Therefore, AAPDA-OX can not compete with the phenanthroline reagents in it's sensitivity; however, as is shown in Table III, AAPDA-OX is more specific than the phenanthroline reagents for iron. As has been discussed in the previous section, by the use of this reagent iron(III) can be determined in the presence of a fairly large amount of cations, especially in the presence of nickel. It should also be noticed that AAPDA-OX reacts with iron(III) ion immediately, resulting in a maximum coloration, whereas it is necessary to wait for a while to reach a maximum coloration with phenanthroline reagents, because that color reaction involves the reduction of iron(III) to iron(II).

The result of this investigation also indicates that a new type of colorimetric reagents for iron could be developed by starting from AADA-OX or AAPDA-OX as a mother compound.

The authors wish to thank Mrs. Hiroko Yamaguchi for her laboratory assistance in the analytical work. They are also grateful for the Ministry of Education of the Japanese Government for its financial assistance.

A Study of the Hydration of Calcium Orthoplumbate. VII. The Mechanism of the Formation of Hydrate

By Masumi Koishi

Department of Applied Chemistry, Faculty of Science, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received November 15, 1965)

The hydration processes of calcium orthoplumbate are studied by means of a twin-type conduction calorimeter. The curves of the differential electromotive force vs. the hydration time have two characteristic maxima, corresponding to two exothermic processes: the first one is due to the immersion and dissolution of calcium orthoplumbate, while the second one is caused by the formation of crystalline hydrates. The heat liberated by the first process is about 1.14 cal./g. Ca_2PbO_4, while that liberated by the second process is about 52.22 cal./g. Ca_2PbO_4. The reaction in the second process proceeds by the 2/3 order; this may be explained by assuming that the rate of the reaction is determined by the surface area of the calcium orthoplumbate being hydrated.

Many investigations of the reactions of calcium orthoplumbate with water have been reported[1] but most of the investigations have been those of reactions above 100°C; few experiments[2] have been carried out concerning hydration below 100°C.

In previous papers[2] we reported the compositions of completely hydrated products of calcium orthoplumbate and the process of hydrating them at various temperatures below 100°C; we made our study by the use of X-ray diffraction analysis, thermobalance analysis, chemical analysis, and electron microscopy. In this paper, the hydration of calcium orthoplumbate will be examined by a twin-type conduction microcalorimeter in order to obtain the heats of hydration and, therefrom, some information on the mechanism of the hydration process.

Experimental

Material.—*Calcium Orthoplumbate.* — Ca_2PbO_4 (or $2CaO \cdot PbO_2$) was prepared by heating an equimolar mixture of lead oxide and calcium carbonate in air at 700°C for 8 hr. The product was identified by X-ray diffraction and chemical analysis. The composition found was PbO_2: 66.71%, CaO: 32.00%, and free calcium as $Ca(OH)_2$: 1.47%. The specific gravity was 5.7. The specific surface area determined by the BET method with an nitrogen adsorption of 3.01 m^2/g. Four chemical reagents, lead oxide, lead peroxide, calcium hydroxide, and calcium carbonate, were employed as reference samples for the analysis of X-ray diffraction patterns, using CuK_α radiation.

Apparatus and Procedure

Apparatus for Hydration Reaction.—*Calorimeter.*—The twin-type conduction calorimeter employed in this work was a commercial model, CM-502, of Ôyodenki Kenkyujo.[3] While this calorimeter is based on the principle which Tian & Calvet first developed, a brief description of the apparatus will be appropriate here. The apparatus is shown in Fig. 1. The main part of the apparatus consists of two pairs of similar calorimeters, each having a 70 ml. reaction cell, a stirrer,

two sample-holding tubes, breakers, a calibrated electric heater, and a thermoelement. The two calorimeters are surrounded by an aluminum block. All the tubes are sealed with rubber membrane and are supported by a lid attached to a main rod from the top plate of the aluminum block. The needles for breaking the rubber film in order to drop the sample into water are connected to the stirrer. The needles slip down with the rotation of the stirrer and so break the rubber membrane. The temperature difference between the two calorimeters produced by the immersion of sample into water is detected by a thermoelement. The electromotive force of the thermoelement of this apparatus is 6.5 mV./deg., and the optimum sensitivity is about 5×10^{-4}°C under the present operating conditions.

Procedure.—After the bottom of all the tubes have been sealed with rubber membrane, about 1.0—14.0 g. of calcium orthoplumbate is weighed into one of the sample-holding tubes of the sample calorimeter. This tube and another empty one* of the sample calorimeter are set on a lid. Another pair of empty tubes are placed on a lid in the reference calorimeter to serve as compensators. Equal volumes of distilled water (20 ml.) are then introduced both into the sample cell and into the reference cell. After the two calorimeters have been set in position, they are kept for about 5 hr. at the desired temperature in order to attain an equilibrium. Then, the sample is dropped into water and the heat liberated in the calorimeter is recorded as the differential electromotive force. After the hydration reactions of calcium orthoplumbate have been completed in the calorimeter, a known amount of electrical energy is supplied to one of the calorimeters to calibrate for the heat liberated. One example of the recorded thermograms is shown in Fig. 2. The amount of heat (Q_1 cal.) liberated by the reaction is calculated by the following equation:

$$Q_1 = \frac{S_1}{S_2} \times Q_2$$

where S_1 denotes the area under the curve of the diagram, corresponding to the liberated heat Q_1, and where, similarly, Q_2 and S_2 denote the heat supplied as electrical energy and the corresponding area respectively.

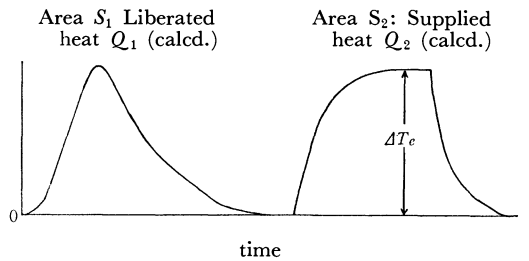

Fig 2. Standard diagram of record.

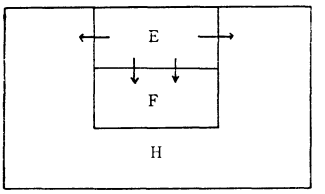
* The empty tube is for use in the case of a bulky sample.

The Determination of the Apparatus Constant of the Calorimeter.—The calorimeter of this experiment is schematically shown by the block diagram in Fig. 3. The heat liberated in the reaction cell, E, is conducted away in two ways; one is the direct escape from E to H (aluminum block), and the other is that through F (the thermoelement). If the heat is assumed to escape exclusively through the thermoelement, F, both the generation and the absorption of the heats by the sample per unit time (dQ/dt) are given by the following equation:



E: Reaction cell
F: Thermoelement
H: Aluminum block

Fig. 3. Block diagram of calorimeter.

$$dQ/dt = \sigma\cdot\Delta T + H\cdot d(\Delta T)/dt \quad (1)$$

where Q denotes the heat liberated in the sample calorimeter, σ is the effective thermal transmissive coefficient of the thermoelement, F (cal./deg. sec.), and ΔT is the temperature difference between the reaction cell and the cell of the reference calorimeter. The constant H stands for the effective heat capacity of E.

The ΔT recording for the electrical energy in Fig. 2 tends to level off, and in this region Eq. 1 reduces to:

$$\sigma = W/\Delta T_e \quad (2)$$

where W denotes the supplied electrical energy (watt), and ΔT_e is the temperature difference from the base line at the stationary state, because $d(\Delta T)/dt=0$ at the stationary state. H is calculated by:

$$d\ln(\Delta T) = -\frac{\sigma}{H}dt \quad (3)$$

from the ΔT recording curve after the supply of electrical energy is stopped.

The values of σ and H obtained here are 4.72×10^{-2} cal./deg. sec. and 25.30 cal./deg. Using these values, Eq. 1 may be rewritten as:

$$dQ/dt = 4.72\times10^{-2}\times\Delta T+25.30\times d(\Delta T)/dt \quad (4)$$

Results and Discussion

The Heat of the Hydration of Anhydrous Calcium Orthoplumbate.—The determination of

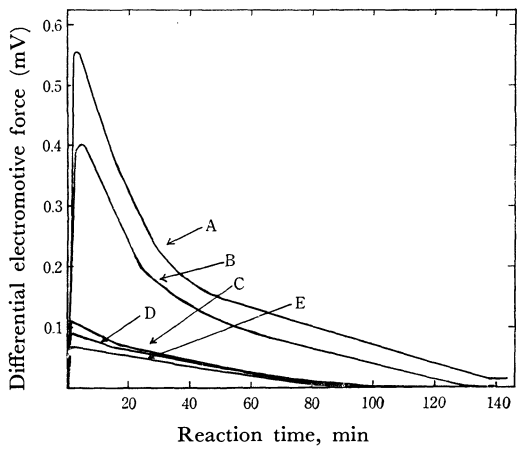

Fig. 5. Recorded curves in the first process at the hydration of calcium orthoplumbate.

the heat liberated in the process of hydrating calcium orthoplumbate is carried out at 20°C. In the hydration of calcium orthoplumbate, the recorded curves which have two maxima corresponding to to the first and the second exothermic processes of hydration are shown in Figs. 4 and 5.

Table I lists the heats of hydration in each process separately. The values of the total heat evolved in the two processes are proportional to the weight of the calcium orthoplumbate specimens; it was about 53.36 cal./g. This proportionality can be explained on the assumption that only a part of the water reacted with calcium orthoplumbate, while the rest of the water did not take part in the hydration reaction.

The X-ray diffraction of the solid, which was filtered off after the first process, did not show the presence of the hydrate of calcium orthoplumbate, as Fig. 6 shows. This suggests that the first process is the immersion and dissolution of calcium orthoplumbate, and that it does not involve the hydration process.

Zettlemoyer[4] observed that the heat of immersion of a solid in various butyl derivatives forms a nearly linear plot against the dipole moment of the functional group in the wetting liquid, and that the slope of the line can be used as a measure of the polarity of the solid. By Zettlemoyer's treatment, the polarity of calcium orthoplumbate can be shown to be as small as that of Teflon and Graphon. In fact, the heats of immersion of calcium orthoplumbate in *n*-butyl alcohol* and *n*-butyric acid* are less than 0.035 cal./g. (1.16×10^{-6} cal./cm^2), as is shown in Fig. 7. Considering the small amount of the heat of immersion, the heat evolved in the first process is mainly due to the heat of dissolution of calcium orthoplumbate into water. The heat of dissolution calculated by neglecting the heat of immersion is about 1.14 cal./g. Ca_2PbO_4.

Separated product B: intermediate one during the second process
Separated product C: after the second process

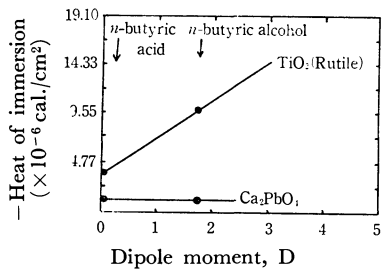

Fig. 7. Heat of immersion versus dipole moment relation for calcium orthoplumbate and titanium dioxide (rutile).

Analysis of the Second Process. — After the immersion and dissolution of calcium orthoplumbate have been completed, the second process (the hydration process) is followed by the X-ray diffraction of the solid, as is shown in Fig. 6. The growth of the peaks of the hydrate with the lapse of the hydration time is evident in this figure. Assuming that water rapidly reaches the surface of calcium orthoplumbate through its hydrated layer, and that the rate of the second process is proportional to the surface area of calcium orthoplumbate as a spherical particle, the following relation holds:

$$dx/dt = k \cdot n \cdot s \tag{5}$$

where x is the amount of hydration at t min. per gram of calcium orthoplumbate; s, the area of the calcium orthoplumbate surface at t min., and n, the number of particles per gram of calcium orthoplumbate.

If the reaction proceeds uniformly on the spherical particles with the diameter a, including the hydrated layer with thickness of $\Delta/2$, as is shown in Fig. 8, s is given by:

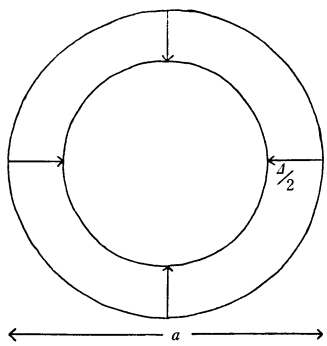

Fig. 8. Simplified model for hydration of calcium orthoplumbate with water.

$$s = 4\pi(a-\Delta)^2/4 = \pi(a-\Delta)^2 \tag{6}$$

When the reaction is completed, $t \to \infty$ and $x \to x_\infty$; then we have:

$$\frac{4/3 \cdot \pi(a/2)^3 \cdot n}{4/3 \cdot \pi\{(a-\Delta)/2\}^3 \cdot n} = \frac{a^3}{(a-\Delta)^3} = \frac{x_\infty}{x_\infty - x} \tag{7}$$

Taking account of Eq. 7, s is given by:

$$s = \pi \cdot a^2 \cdot \{(x_\infty - x)/x\}^{2/3} \tag{8}$$

The n value is expressed in terms of density, ρ, as:

$$n = \frac{1}{4/3 \cdot \pi(a/2)^3 \cdot \rho} = \frac{6}{\pi \cdot a^3 \cdot \rho} \tag{9}$$

From Eqs. 5, 8, and 9, we obtain:

$$dx/dt = (6k/a\rho) \cdot \{(x_\infty - x)/x_\infty\}^{2/3} \tag{10}$$

The integration of Eq. 10 gives:

$$-3\{(x_\infty - x)/x_\infty\}^{1/3} = (6k/a\rho x_\infty) \cdot t \tag{11}$$

Thus, the value of $(x_\infty - x)^{1/3}$ may be expected to be proportional to t.

In the present experiment the value of x was not measured directly, but it can reasonably be assumed that the value of x is porportional to the value of Q, and that the value can be calculated from the following equation:

$$Q = 4.72\times10^{-2}\times\Delta T\cdot t + 25.30\times\Delta T$$

which can be derived by integration of Eq. 1.* Thus, the term $(x_\infty - x)^{1/3}$ may be replaced by

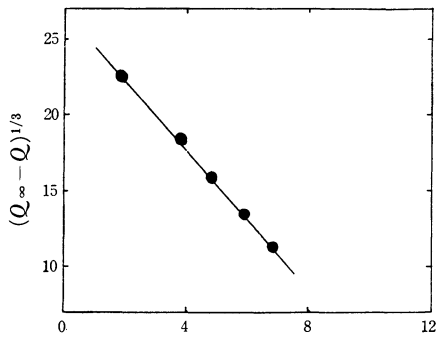

Fig. 9-(a)

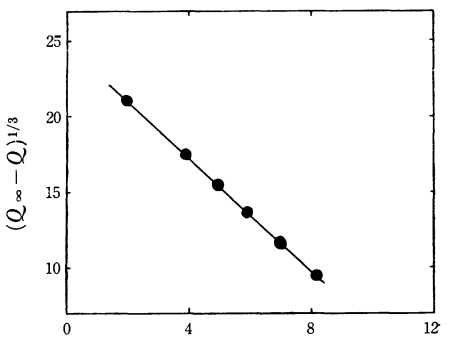

Fig. 9-(b)

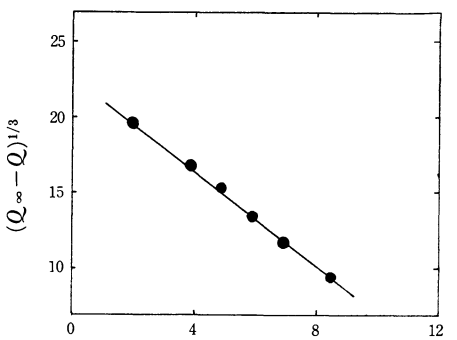

Fig. 9-(c)

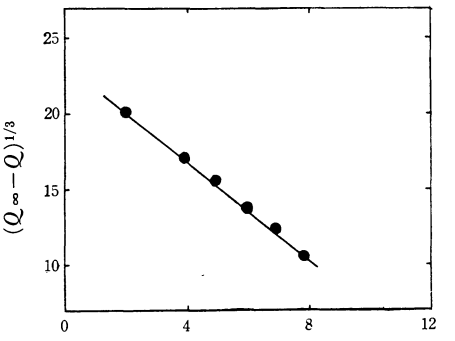

Fig. 9-(d)

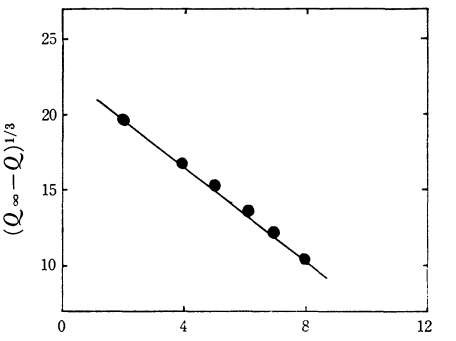

Fig. 9—(e)

Figs. 9-(a)—(e). The relation between the reaction time and $(Q_\infty - Q)^{1/3}$. Molar ratio of Ca_2PbO_4/H_2O are kept (a)=1/30, (b)=1/70, (c)=1/200, (d)=1/300 and (e)=1/400.

$(Q_\infty - Q)^{1/3}$ without any serious error. Figure 9-(a)—(e) show the $(Q_\infty - Q)^{1/3}$-t plot. The linear relation in Figs. 9-(a)—(e) indicates the general correctness of the assumption that the second process proceeds through the hydrated layer as a 2/3 order reaction.

The author wishes to express his gratitude to Professor Tsunetaka Sasaki of Tokyo Metropolitan University for his continuous encouragement and the inspection of this paper. The author also wishes to express his gratitude to Professor Kenjiro Meguro of Tokyo College of Science for his helpful discussions throughout this work, and to thank Kiyoichi Hagiwara and Shogo Enomoto for their help during the course of these experiment.

* The effective heat capacity, H, in Eq. 1 depends, in principle, on the amount of the specimen employed. However, all the ΔT-vs.-time calibration curves coincide for different fillings of the specimen within the precision of the present experimental set-up.

The Chemical Equilibrium of the $2H_2S+SO_2=3S+2H_2O$ Reaction in Solfataras of the Nasudake Volcano

By Yoshihiko MIZUTANI and Tsutomu SUGIURA

Institute of Earth Sciences, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received February 7, 1966)

The stability of native sulfur in solfataras depends upon the temperature, the pressure, and the chemical composition of the solfataric gases with which native sulfur is in equilibrium. The equilibrium constant of the $2H_2S+SO_2=3S_{(s,l)}+2H_2O$ reaction may be expressed as:

$$K = \frac{X^2_{H_2O}}{X^2_{H_2S} X_{SO_2} P},$$

where X is the mole fraction of the gaseous components in the system and where P is the total pressure on the system. By the use of this relationship, the equilibrium temperature of natural solfataric gases with respect to the reaction may be estimated, provided the theoretical value of K, the chemical composition, and the pressure of natural solfataric gases are known. The attainment of chemical equilibrium of the reaction in solfataric gases of the Nasudake Volcano has been examined by comparing the estimated equilibrium temperature with the observed outlet temperature of the solfataras. The results indicate that the native sulfur occurring in the solfataras is approximately in equilibrium with the solfataric gases. On this basis, an attempt has also been made to explain the behavior of hydrogen sulfide and sulfur dioxide in solfataric gases.

Many investigators have discussed the chemistry of volcanic gases in terms of thermodynamics. Ellis[1] made comprehensive thermodynamic calculations on the variation in the chemical composition of volcanic gases with the temperature and with the pressure. Krauskopf[2] also made thermodynamic calculations on the feasibility of the vapor transportation of heavy metals in magmatic vapor. Recently, Matsuo[3] presented similar calculations with relevance to the possibility of a heterogeneous reaction in magma effecting the creating of volcanic gases.

On the other hand, the thermodynamics were applied to interpreting the results from the analyses of natural volcanic gases by Oana[4] and by Matsuo[5]. Their studies showed that, in high-temperature volcanic gases, the chemical equilibrium is seemingly established, at least with respect to the $3H_2+SO_2=H_2S+2H_2O$ and $CO+H_2O=CO_2+H_2$ reactions.

In the present paper, the authors will attempt to extend the application of thermodynamics to the heterogeneous reaction, $2H_2S+SO_2=3S_{(s,l)}+2H_2O$, in natural solfataras. The authors wish to examine the attainment of chemical equilibrium in solfataric gases during its ascent toward the surface. In addition, it is important to consider the effect of the chemical equilibrium of the reaction upon the hydrogen sulfide and sulfur dioxide portions of solfataric gases.

Results and Discussion

The Character of Solfataric Gases of the Nasudake Volcano.—Mizutani, Sugiura and Oana[6] analyzed solfataric gases of the Nasudake Volcano, Tochigi, Japan, and found some correlation between the temperature of the solfataras and the behavior of the major chemical components of the gases. For example, there is a notable increase in the amounts of hydrogen sulfide and sulfur dioxide in the temperature range between 100 and 200°C when the amount of the sulfur compounds in the gases is plotted against the outlet temperature of the solfataras. This finding led the present authors to conclude that the major part of the sulfur compounds in the gases at temperatures between 100 and 200°C was contributed secondarily by subterranean native sulfur accumulated through previous solfataric activities of this volcano. There is also a trend toward an increase in the ratio of hydrogen sulfide to sulfur dioxide in the gases with a lowering of the temperature.

In this solfataric area, native sulfur is mined by introducing solfataric gases into artificial gas channels, where native sulfur is then deposited as the

temperature falls. Small pools of liquid sulfur are usually found at the openings of gas channels.

The Chemical Equilibrium of the $2H_2S+SO_2=3S+2H_2O$ Reaction.—In solfataras, native sulfur usually occurs in three different forms: rhombic, monoclinic, and liquid, depending on the temperature. Therefore, the following three reactions must be considered:

$$2H_2S + SO_2 = 2H_2O + 3S_{(rh.)}, \quad \text{for } T<95.6°C \quad (1)$$

$$2H_2S + SO_2 = 2H_2O + 3S_{(mono.)}, \quad \text{for } T=95.6—119°C \quad (2)$$

$$2H_2S + SO_2 = 2H_2O + 3S_{(s,l)}, \quad \text{for } T>119°C \quad (3)$$

The appearance or disappearance of native sulfur in solfataras may be controlled by the temperature, the total pressure, and the chemical composition of the gases in equilibrium with the native sulfur. The equilibrium constants of these reactions may be expressed as:

$$K = \frac{X^2_{H_2O}}{X^2_{H_2S}X_{SO_2}P} \quad (4)$$

where K is the equilibrium constant, X is the mole fraction of the gaseous components in the system, and P is the total pressure on the system.

The theoretical equilibrium constant for these reactions may be calculated from the free-energy change for these reactions by using the $\ln K=-\Delta F/RT$ relation, where ΔF is the free-energy change, R is the gas law constant, and T is the absolute temperature of the system. The values of the free-energy change for these reactions may be obtained from the thermodynamic data given by Kubaschewski and Evans[7] and Rossini et al.[8] The temperature functions of the equilibrium constant obtained are:

for Reaction 1:

$$\log K_1 = -11.43+0.333\log T+1.53\times10^{-3}T + 7720\,T^{-1}+1.73\times10^4\,T^{-2} \quad (5)$$

for Reaction 2:

$$\log K_2 = -11.35+0.302\log T+1.76\times10^{-3}T + 7690\,T^{-1}+1.73\times10^4\,T^{-2} \quad (6)$$

and for Reaction 3:

$$\log K_3 = -18.90+3.09\log T+1.28\times10^{-3}T + 7900\,T^{-1}+1.73\times10^4\,T^{-2} \quad (7)$$

The relation between the equilibrium constant and the temperature obtained from these equations is shown in Fig. 1.

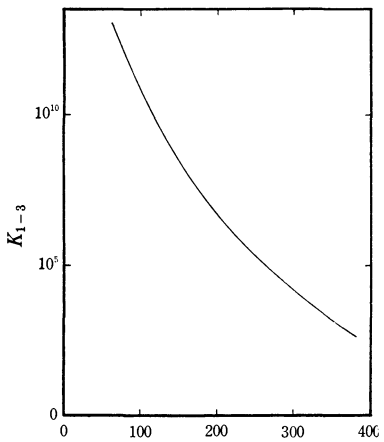

Fig. 1. Relation between equilibrium constant and temperature with respect to reaction $2H_2S+SO_2=3S_{(s,l)}+2H_2O$.

By the use of these relations, the equilibrium temperature of natural solfataric gases with respect to the above reactions may be estimated from the observed value of K. For solfataric gases of the Nasudake Volcano the observed value of $X^2_{H_2O}/X^2_{H_2S}X_{SO_2}$ may be obtained from the analytical data of the gases given by Mizutani et al.[9] Some examples of the data are given in Table I. The observed values of $X^2_{H_2O}/X^2_{H_2S}X_{SO_2}$ thus obtained are given in Table II. The equilibrium temperature of the solfataric gases may be estimated from these values, provided the total pressure on the system is known. The total pressure of the gases is assumed to be 1 atm. for the first approximation, because the gases are emitted from openings of gas channels with a rather low static pressure (close to 1 atm.).[10] The equilibrium temperatures thus estimated are given in Table II.

By comparing the estimated equilibrium temperatures with the observed outlet temperatures, the degree of the attainment of the chemical equilibrium of the reaction at the outlet of the solfataras may be examined. As is shown in Table II, the equilibrium temperatures obtained for the solfataras with native sulfur deposits are almost in agreement with the observed temperatures, although the former are always slightly higher than the latter. This implies that the native sulfur deposits occurring in solfataras are approximately in equilibrium with the solfataric gases from which the native sulfur deposit is formed, and possibly that, in the solfataric gases, the sulfur vapor is also in equilibrium with the water vapor, hydrogen sulfide and sulfur dioxide, through the reaction:

* $X_{H_2O}+X_{H_2S}+X_{SO_2}=1$

$$3/n\,S_{n(gas)} + 2H_2O = 2H_2S + SO_2 \qquad (8)$$

The Behavior of Hydrogen Sulfide and Sulfur Dioxide in Solfataric Gases.—The foregoing finding facilitates the understanding of the behavior of sulfur compounds in solfataric gases. If it is assumed that ascending volcanic water vapor comes into contact with subterranean native sulfur deposits for a sufficient time to react with them, the following reactions may be expected between water vapor and native sulfur:

$$3S_{(s,l)} + 2H_2O = 2H_2S + SO_2 \qquad (9)$$

$$H_2S = H_2 + S_{(s,l)} \qquad (10)$$

Then, on the assumption that the chemical equilibrium is established in this system, the hydrogen sulfide, sulfur dioxide, and hydrogen contents of the gas phase at a given P, T condition may be estimated by solving the following simultaneous equations:

$$K_4 = \frac{X^2_{H_2O}}{X^2_{H_2S}X_{SO_2}P} \qquad (11)$$

$$K_5 = \frac{X_{H_2}}{X_{H_2S}} \qquad (12)$$

$$\frac{2(X_{H_2S}+X_{H_2}+X_{H_2O})}{2X_{SO_2}+X_{H_2O}} = 2 = \text{Ratio of hydrogen to oxygen atoms} \qquad (13)$$

$$X_{H_2O} + X_{H_2S} + X_{SO2} + X_{H_2} = 1 \qquad (14)$$

where K_4 and K_5 are the equilibrium constants of reactions 9 and 10 respectively, P is the total pressure on the system, and X is the mole fraction of the gaseous components in the system. For the value of K_4, Eqs. 5, 6 and 7 are used again, and the value of K_5 is calculated from the standard thermodynamic properties of the chemical components in the way described above. The equation of K_5 obtained is:

$$\log K_5 = -9.475 + 2.470 \log T + 0.343 \times 10^{-3} T - 770\, T^{-1} + 1.313 \times 10^{3}\, T^{-2} \quad (15)$$

The equilibrium amounts of hydrogen sulfide, sulfur dioxide, and hydrogen in the gas phase, as calculated from the simultaneous equations, are illustrated graphically in Fig. 2.

The equilibrium figure obtained shows that the H_2S/SO_2 ratio of the gas phase is always approximately 2.0, while the hydrgoen sulfide, sulfur dioxide, and hydrogen contents in the gas phase vary with the change in the P, T condition, because the hydrogen content is always so small as to be negligible as compared with the hydrogen sulfide and sulfur dioxide contents.

In the Nasudake Volcano, some solfataric gases of the low-temperature type show a H_2S/SO_2 ratio close to 2 and a paucity of hydrogen (in

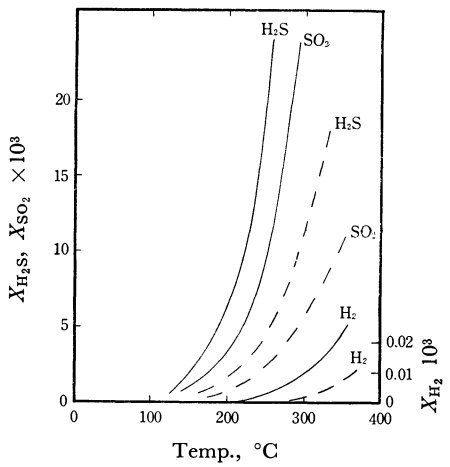

Fig. 2. Equilibrium amounts of H_2S, SO_2 and H_2 for system $S_{(liquid)}$-$H_2O_{(vapor)}$.
Solid line: $P_{H_2O}+P_{H_2S}+P_{SO_2}+P_{H_2}=1$ atm.
Broken line: $P_{H_2O}+P_{H_2S}+P_{SO_2}+P_{H_2}=100$ atm.

Table I, OE-1 and U-1). This probably implies that the major part of the sulfur compounds in the gases is derived from native sulfur deposits through the above reactions. The addition of sulfur compounds of this sort may also occur in low-temperature solfataras other than OE-1 and U-1. The situation must, however, be somewhat different from that considered for OE-1 and U-1, because the H_2S/SO_2, ratio of the gases from those solfataras is far different from 2. The gases coming from such solfataras may be considered to be products of reactions between native sulfur deposits and volcanic gases containing

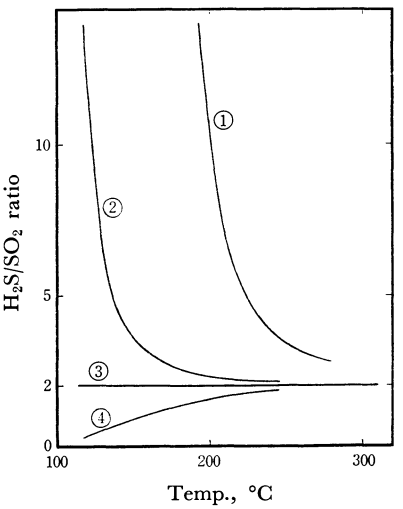

Fig. 3. Equilibrium ratio of H_2S to SO_2 for system S - H_2O - extra H_2S, SO_2 or H_2.
P=1 atm.
①: H/O=2.020 (H_2O : extra H_2S or H_2=990 : 10)
②: H/O=2.002 (H_2O : extra H_2S or H_2=999 : 1)
③: H/O=2.000
④: H/O=1.996 (H_2O : extra SO_2=999 : 1)

appreciable amounts of hydrogen sulfide, sulfur dioxide, and hydrogen. When such reactions proceed and reach an equilibrium in the gases, the equilibrium ratio, H_2S/SO_2, should deviate from 2 because the mass balance, the H/O atomic ratio in the system, is different from 2; Fig. 3 shows the effect of adding extra chemical components to the water vapor in the S-H_2O system. In other words, the equilibrium amounts of hydrogen sulfide and sulfur dioxide in the final products of the reactions at a given P, T condition are varied by the change in the amounts of such extra chemical components as hydrogen sulfide, sulfur dioxide, and hydrogen in the gases.

The natural situation in most low-temperature solfataras may be more complicated than this simple model indicates, but the general features of the variation in hydrogen sulfide and sulfur dioxide contents in the gases ought to be accounted for by this model if the above reactions reach equilibrium in the solfataras.

The authors wish to express their deep appreciation to Professor Shinya Oana of Nagoya University and Dr. Sadao Matsuo of Tokyo Kyoiku University for their helpful suggestions and for their encouragement throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPNA VOL. 39 2415—2417 (1966)

Preparation of *cis*- and *trans*-Dichlorobis(ethylenediamine)-Iridium(III) Chlorides

By Sigeo KIDA

Department of Chemistry, Wakayama University, Masago-cho, Wakayama

(Received March 30, 1966)

Potassium tetrachloro(ethylenediamine)iridate(III) and *cis*-dichlorobis(ethylenediamine) iridium(III) chloride were obtained by the reaction of iridium(III) chloride and ethylenediamine in a weakly acid aqueous solution. The condition for the formation of each compound depends on the mole ratio of iridium to ethylenediamine and pH of the solution. Trans-dichlorobis(ethylenediamine)iridium(III) chloride was prepared from potassium tetrachloro(ethylenediamine)iridate-(III) and ethylenediamine.

The geometrical configurations of the two isomers were determined by infrared spectra, and checked by ultraviolet spectra.

In the study of electronic spectra of d^6 complexes, it was desired to discuss the spectra of a series of complexes, *cis*- and *trans*-$[M\ Cl_2en_2]^{n+}$ (M= Co(III),[1] Rh(III),[2] Ir(III) and Pt(IV),[3] where preparation of all compounds, except iridium(III) complexes, have been reported. Therefore, it has been attempted to prepare *cis*- and *trans*- dichlorobis(ethylenediamine)iridium(III) complexes.

Anderson and Basolo[2] have prepared *cis*- and *trans*-dichlorobis(ethylenediamine)rhodium(III) complexes from an aqueous solution of rhodium(III) chloride, ethylenediaminedihydrochloride and potassium hydroxide (with the mole ratio of 1 : 2 : 4). However, iridium(III) analogues have not been obtained by the similar methods so far attempted, because iridium (III) chloride readily hydrolyzes in an alkaline or even neutral solution to form amorphous precipitate, and therefore, boiling this mixture with ethylenediamine leads to formation of tris(ethylenediamine)iridium(III) complex irrespective of the ratio of ethylenediamine to iridium.

In the present study, iridium(III) chloride was tried to react with ethylenediamine in a weakly acid medium, with various ratios of ethylenediamine to iridium. In this way, potassium tetrachloro-(ethylenediamine)iridate(III), $K[IrCl_4en]$, was obtained, and then *cis*-dichlorobis(ethylenediamine) iridium(III) chloride, *cis*-$[IrCl_2en_2]Cl$. The trans isomer was prepared from $K[IrCl_4en]$ and ethylenediamine.

Experimental

Preparation of a Solution of Iridium(III) Chloride from Iridium Metal.—Five grams of iridium powder was heated at 300—400°C with 15 g. of sodium hydroxide and 10 g. of sodium peroxide in a nickel crucible for one hour, ($Ir+3\ Na_2O_2 \rightarrow IrO_3+3\ Na_2O$). The resulting black mixture was dissolved in 150 ml. of water forming a colloidal solution. This was neutralized with hydrochloric acid, and added another 20 ml. of concentrated hydrochloric acid. When this solution was boiled for 30 min., iridium(VI) oxide was reduced to iridium(IV) chloride evolving chlorine gas to form dark brown solution, ($IrO_3+6\ HCl \rightarrow IrCl_4+Cl_2+3\ H_2O$). Iridium(IV) chloride was further reduced to iridium(III) chloride by adding hydrogen sulfide, ($6\ IrCl_4+H_2S+2\ H_2O \rightarrow 6\ IrCl_3+SO_2+6\ HCl$). The red-brown solution thus prepared contained iridium-(III) chloride and much excess of sodium chloride and hydrochloric acid.

***cis* - Dichlorobis (ethylenediamine) iridium (III) Chloride.**—The iridium(III) chloride solution, prepared by the method described above, was neutralized with potassium hydroxide and adjusted at pH 3 with acetic acid. This solution, containing 533 mg. of iridium, was diluted with water to 300 ml., and boiled in a 500 ml. round-bottom flask. To the boiling solution 25 ml. of 2% aqueous ethylenediamine(Ir/en=1/3) was slowly added. It was boiled for 3 hr., being frequently supplied with water to keep the volume constant. Then, this solution was evaporated to form crystals of sodium chloride and potassium chloride, cooled, and filtered. This procedure was repeated twice until the solution was concentrated to 15 ml. After one night yellow prisms were formed in the solution. These crystals were separated by filtration, washed with ethanol, and recrystallized from 6 N hydrochloric acid solution; yield, 276 mg.. The well-formed bright light-yellow prisms were obtained. This compound is fairly soluble in water, (soluble more than 1.1 g. in 100 ml. of water at 10°C).

Found: C, 11.42; H, 4.26; N, 12.93. Calcd. for $[IrCl_2en_2]Cl$: C, 11.47; H, 3.85; N, 13.38%.

Potassium Tetrachloro(ethylenediamine)Iridate (III).—The iridium(III) chloride solution prepared by the method described before, was neutralized with

2) S. Anderson and F. Basolo, *J. Am. Chem. Soc.*, **82**, 4423 (1960).

3) F. Basolo, J. C. Bailar Jr. and B. R. Tarr, ibid., **72**, 2433 (1950).

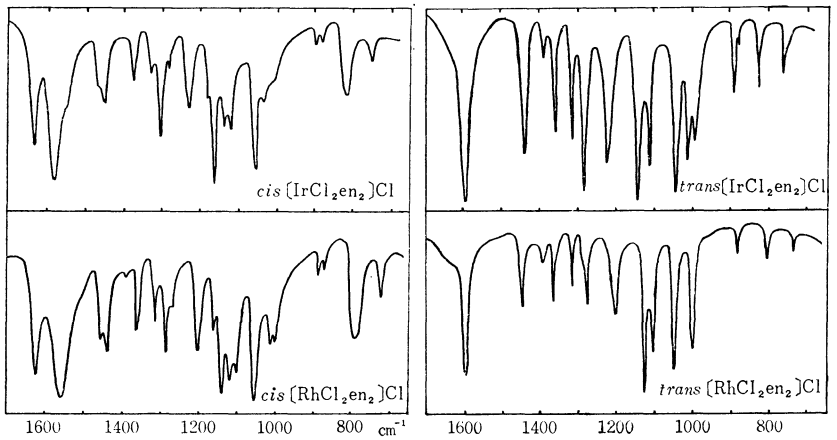

Fig. 1. Infrared spectra of *cis*- and *trans*- $[IrCl_2en_2]Cl$, with comparison of the Rh(III) analogues whose geometrical configurations were already known.

potassium hydroxide, and was again acidified by adding 1.2 g. of acetic acid. The solution containing 1 g. of iridium was diluted to 200 ml. with water, and boiled. To the boiling solution, 0.6 g. of ethylenediamine in 30 ml. of water was slowly added (Ir/en=1/2). The solution was boiled for 3 hr., being kept the volume constant by frequent addition of water, and then evaporated to about 60 ml. When cooled, the solution was quickly filtered to separate off the resulting crystals of sodium chloride and potassium chloride. The filtrate was strongly acidified with conc. hydrochloric acid, and again evaporated to 30 ml., cooled, and quickly filtered. After standing one night at room temperature, the filtrate yielded orange-red crystals, which were separated by filtration, washed with water and ethanol. Upon further evaporation of the filtrate, more crystals may be obtained. All these crystals were recrystallized from 6 N hydrochloric acid; yield, 768 mg.. The orange-red crystals thus obtained contain 2 molecules of water for one atom of iridium, and readily lose crystal water when heated at 100°C. This compound is sparingly soluble in cold water and fairly soluble in hot water.

Found: C, 5.57; H, 2.17; N, 6.25. Calcd. for $K[IrCl_4en]$: C; 5.55; H, 1.86; N, 6.47%.

***trans*-Dichlorobis(ethylenediamine)Iridium(III) Chloride.**—One half gram of $K[IrCl_4en]\cdot 2H_2O$, was dissolved in 30 ml. of hot water. Three milliliters of 1% aqueous ethylenediamine was slowly added to this solution which was stirred and heated on a steam bath. After the addition of ethylenediamine, the solution was kept at 95—100°C for one hour, and its color gradually changed from red to orange. Then another 3 ml. of 1% aqueous ethylenediamine was slowly added to the hot solution, and the solution was heated at 95—100°C for one hour as before. Throughout the above processes, the volume of the solution had been kept at 30 ml. by frequent supply of water. The solution was evaporated on a steambath to a small volume—ca. 3 ml., and left at room temperature for one night. The resulting orange-red crystals, the unreacted starting material, was filtered off. The filtrate was acidified with conc. hydrochloric acid, and concentrated to a very small volume—less than 1 ml. Upon ice cooling, light yellow flakes were formed in the solution. These crystals were filtered, and recrystallized with 6 N hydrochloric acid; yield, 96 mg. This compound is very soluble in water, (much more soluble than the cis isomer), and fairly soluble in 99% ethanol.

Found: C, 11.27; H, 4.33; N, 13.02. Calcd. for $[IrCl_2en_2]Cl$: C, 11.47; H, 3.85; N, 13.38.

Discussion

The *cis*- and *trans*-isomers were identified by infrared spectra. Morris and Busch[4] pointed out that in diacidobis(ethylenediamine)cobalt(III) complexes trans isomer has one strong absorption near 1600 cm^{-1}, while the corresponding band of a *cis* isomer always splits into two bands. Examining the spectra, which are shown in Fig. 1, one could easily determine the geometrical configuration of the two isomers which has been obtained in this study.

The UV spectrum of aqueous solution of each new compound was measured, and the first spin-allowed bands of the cobalt(III), rhodium(III) and iridium(III) complexes were listed in Table I. It is seen in Table I that the first spin-allowed

band of *cis*-isomer is located in the shorter wavelength region and has higher intensity than that of the trans isomer in the case of the iridium(III) complexes, as in the cases of the cobalt(III) and the rhodium(III) complexes whose geometrical configurations were already determined. This fact implies that the investigation of ultraviolet spectra supports the conclusion on the geometrical configuration deduced from IR spectra. The detailed discussion of electronic spectra will be reported separately.

The author wishes to express his thanks to Mr. Tsuyoshi Yamoto for his help in the experiments. This research has been financially supported in part by a grant of the Ministry of Education, to which author's thanks are due.

Metal Complexes of Amino Acids. III.[1] The Circular Dichroism of Cobalt(III) Ammine and Ethylenediamine Complexes with L-Amino Acids

By Takaji YASUI, Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received May 19, 1966)

In order to study the vicinal effect of the L-amino acid coordinated in a complex on the central metal ion, a number of cobalt(III) L-amino acid complexes of three types were prepared, i. e., $[Co(NH_3)_5(L\text{-amH})]X_3$, $[Co(L\text{-am})(NH_3)_4]SO_4$, and *trans*-$[Co\ en_2(L\text{-amH})_2]X_3$, where L-amH denotes an L-amino acid, and where X is Cl, Br, or I. The circular dichroism (CD) and the rotatory dispersion (RD) spectra of their aqueous solutions were measured in the wavelength range from 650 to 300 mμ. In the region of the first absorption band, both the $[Co(NH_3)_5(L\text{-amH})]^{3+}$ and the *trans*-$[Co\ en_2(L\text{-amH})_2]^{3+}$ ions show one or two CD bands to be expected in complexes of the C_{4v} symmetry with a structure of the $[Co\ N_5O]$-type and of the D_{4h} symmetry with a structure of the *trans*-$[Co\ N_4O_2]$-type respectively. The positions of the CD bands observed in the *trans* complexes coincide well with the maxima of the split components, Ia and Ib, of the first absorption band. The CD spectra of different $[Co(L\text{-am})(NH_3)_4]^{2+}$ ions, in which L-am is a bidentate ligand, show a variety of behavior; they are discussed from a stereochemical point of view. An intense CD band of the $[Co(L\text{-prol})(NH_3)_4]^{2+}$ ion at about 510 mμ can be attributed to the vicinal effect of an asymmetric nitrogen atom of the coordinated L-prolinate ion. For the *trans*-$[Co\ en_2(L\text{-amH})_2]X_3$ complexes, the rotatory parameters and rotatory strengths were calculated by means of analyses of the experimental CD and RD curves.

Circular dichroism (CD) spectra have been proved to give useful information on the splittings of d→d absorption bands of metal complexes with a rather low symmetry. On the other hand, such splittings are not always observed in ordinary absorption curves.

It is well known that a metal complex containing an optically-active ligand (for example, optically-active amino acid,[2-7] tartaric acid, [8,9] or propylenediamine),[10] shows some weak CD bands in the region of its d→d absorption band as a result of the vicinal effect of the optically-active center in the ligand on the central metal ion. Of these ligands, the optically-active amino acids* behave in

* The following abbreviations will be used: L-alaH=$CH_3CH(NH_3^+)COO^-$; L-ala=$CH_3CH(NH_2)COO^-$; L-serH=$CH_2(OH)CH(NH_3^+)COO^-$; L-ser=$CH_2(OH)CH(NH_2)COO^-$; L-valH=$(CH_3)_2CHCH(NH_3^+)COO^-$; L-val=$(CH_3)_2CHCH(NH_2)COO^-$; L-thrH=$CH_3CH(OH)CH(NH_3^+)COO^-$; L-thr=$CH_3CH(OH)CH(NH_2)COO^-$; L-leuH=$(CH_3)_2CHCH_2CH(NH_3^+)COO^-$; L-leu=$(CH_3)_2CHCH_2CH(NH_2)COO^-$; L-isoleu=$CH_3CH_2CH(CH_3)CH(NH_2)COO^-$; L-phalaH=$CH_2(C_6H_5)CH(NH_3^+)COO^-$; L-phala=$CH_2(C_6H_5)CH(NH_2)COO^-$; L-prolH=$NH_2^+CH_2CH_2CH_2CHCOO^-$; L-prol=$NHCH_2CH_2CH_2CHCOO^-$.

an especially interesting way in that they can be coordinated both as unidentate and as bidentate ligands.

In a previous paper,[5] pentammine and tetrammine cobalt(III) complexes containing optically-active amino acids were reported, and it was suggested that the magnitude of the anomalous rotatory dispersion (RD) in the region of the first absorption band depends mainly on the conformational mobility of the optically-active ligand coordinated. In the present paper, the CD spectra of cobalt(III) ammine and ethylenediamine complexes which contain various L-amino acids will be described. The relationship among the ordinary absorption spectra and CD and some RD spectra will be considered precisely on the basis of the vicinal effect. Previously, several workers[2,11-14] made analyses of RD curves, but it was quite difficult to establish the individual inversive dispersions by the RD curve analyses alone. It was, therefore, been desirable to study in more detail the relation among the CD, the RD, and the ordinary absorption curves. In relation to this point, the present paper will discuss some typical d→d absorption bands of the cobalt(III) complexes of a new type, *trans*-[Co en_2(L-amH)$_2$]X_3.

Experimental

Preparation.—By evaporating a mixed aqueous solution of $[Co(OH_2)(NH_3)_5](ClO_4)_3$[15] and an excess of L-amino acid below 60°C, the $[Co(NH_3)_5$(L-amH)$]X_3$ complex was obtained in a good yield. In this condition, the L-amino acid coordinates to cobalt(III) as a unidentate ligand[5] by an oxygen atom of the carboxyl group. At temperatures higher than 60°C, it was difficult to obtain the desired complexes because of the decomposition of $[Co(OH_2)(NH_3)_5]^{3+}$. The complexes with L-valine, L-leucine and L-threonine were readily soluble in methanol and were insoluble in ethanol.

The $[Co(am)(NH_3)_4]SO_4$ complexes have already been reported on by one of the present authors,[2,16] who prepared the complexes from [Co Cl$(OH_2)(NH_3)_4$]-SO_4 and glycine, DL-alanine or L-leucine in ammoniacal alkaline solutions. In the present work, however, all of the $[Co$(L-am$)(NH_3)_4]SO_4$ complexes were obtained from the reaction of $[Co(OH_2)(NH_3)_5](ClO_4)_3$ with L-amino acid in the presence of activated charcoal. This method was proved to be superior to that described previously in respect to the yield and the diminution of the by-product. The *trans*-[Co en_2(L-amH)$_2$]X_3 complex was prepared by the evaporation almost to dryness of an aqueous solution containing $[Co(OH_2)_2$-$en_2](ClO_4)_3$[17] and an excess of L-amino acid at a temperature higher than 70°C. The *trans* complexes are very soluble in water. At temperatures lower than 70°C, $[Co(OH_2)en_2$(L-amH)$]X_3$ is produced mainly.

The preparation of *trans*-$[Co(NH_3)_4$(L-amH)$_2]X_3$ was attempted by similar ways, but all such attempts were unsuccessful.

$[Co(NH_3)_5$(L-valH)$]Cl_3$.—An aqueous solution containing 5 g. of $[Co(OH_2)(NH_3)_5](ClO_4)_3$[15] and 3 g. of L-valine in 30 ml. of warm water was gradually evaporated almost to dryness on a water bath at about 55°C. To the resulting material there was added a solution containing 5 g. of potassium chloride in a small amount of water, and then 50 ml. of methanol was added. After the potassium perchlorate which settled had been removed, a large amount of an ethanol-ether mixture (2 : 1) was added, drop by drop, to the filtrate. The pinkish powder obtained was washed with ethanol and then with ether. The crude complex was recrystallized from 95% methanol by adding ethanol. The pinkish-orange complex obtained was then dried in a vacuum desiccator.

Found: C, 16.28; H, 7.19; N, 22.16. Calcd. for $CoC_5H_{26}N_6O_2Cl_3$: C, 16.33; H, 7.14; N, 22.86%.

$[Co(NH_3)_5$(L-leuH$)]Cl_3$ and $[Co(NH_3)_5$(L-thrH$)]$-Cl_3.—These complexes were prepared by the method described above for the L-valine complex.

Found: C, 18.29; H, 7.23; N, 22.21. Calcd. for $CoC_6H_{28}N_6O_2Cl_3$: C, 18.88; H, 7.41; N, 22.02%.

Found: C, 13.45; H, 6.68; N, 22.67. Calcd. for $CoC_4H_{24}N_6O_3Cl_3$: C, 13.00; H, 6.56; N, 22.74%.

$[Co(NH_3)_5$(L-serH$)]Cl_3$.—The crude complex was obtained by the same way as was used for the L-valine complex; it was recrystallized from a small amount of water by adding methanol.

Found: C, 9.98; H, 6.25; N, 23.56. Calcd. for $CoC_3H_{22}N_6O_3Cl_3$: C, 10.13; H, 6.25; N, 23.64%.

$[Co(NH_3)_5$(L-prolH$)]I_3\cdot 3H_2O$.—This was isolated by adding potassium iodide to a reaction mixture prepared by the method mentioned above.

Found: C, 9.00; H, 4.56; N, 11.88; H_2O, 8.04. Calcd. for $CoC_5H_{24}N_6O_2I_3\cdot 3H_2O$: C, 8.65; H, 4.37; N, 12.11; H_2O, 7.79%.

$[Co$(L-val$)(NH_3)_4]SO_4\cdot H_2O$.—To an aqueous solution containing 5 g. of $[Co(OH_2)(NH_3)_5](ClO_4)_3$ and 1.5 g. of L-valine in 50 ml. of warm water, about 0.2 g. of activated charcoal was added. The mixture was evaporated on a water bath at 80°C to a volume of about 12 ml. After the resultant solution had been cooled to room temperature, a solution of 2.5 g. of potassium sulfate in 10 ml. of water was added to it. The solution was filtered, and then about 50 ml. of methanol was added, drop by drop, to the filtrate. The crude compound formed was collected, and washed with methanol and then with ether. The pinkish-orange crystals were separated into flakes by adding a small amount of methanol to an aqueous solution of the product.

Found: C, 16.81; H, 6.63; N, 19.20; H_2O, 4.93. Calcd. for $CoC_5H_{22}N_5O_6S\cdot H_2O$: C, 16.81; H, 6.78; N, 19.60; H_2O, 5.04%.

$[Co$(L-ser$)(NH_3)_4]SO_4$, $[Co$(L-leu$)(NH_3)_4]SO_4$ and $[Co$(L-prol$)(NH_3)_4]SO_4\cdot 3H_2O$.—These complexes were

***trans*-$[Co\ en_2(L\text{-alaH})_2]Cl_3$.**—To an aqueous solution containing 5 g. of $[Co(OH_2)_2en_2](ClO_4)_3$[17] in 50 ml. of water, 2.2 g. of L-alanine was added. The mixture was then evaporated almost to dryness on a water bath at about 80°C. After cooling, the crude product obtained was dissolved in 80 ml. of water. To the solution was added 3.5 g. of potassium chloride, and then 10 ml. of methanol. The potassium perchlorate which was deposited was removed from the violetish-red solution by filtration. A few drops of concentrated hydrochloric acid and a small amount of ethanol were added to the filtrate, and the solution was kept in a refrigerator for several hours. The violetish-red crystals obtained were then washed with a water-ethanol mixture (1 : 1), with ethanol, and then with ether. This complex was recrystallized from water by adding a small amount of ethanol.

Found: C, 25.92; H, 6.66; 18.33. Calcd. for $CoC_{10}H_{30}N_6O_4Cl_3$: C, 25.90; H, 6.53; N, 18.13%.

***trans*-$[Co\ en_2(L\text{-serH})_2]Cl_3$, *trans*-$[Co\ en_2(L\text{-thrH})_2]Cl_3\cdot 2H_2O$, and *trans*-$[Co\ en_2(L\text{-prolH})_2]Br_3$.**—These complexes were prepared by procedures similar to that described above for the L-alanine complex.

Found: C, 24.39; H, 6.22; N, 17.40. Calcd. for $CoC_{10}H_{30}N_6O_6Cl_3$: C, 24.25; H, 6.11; N, 16.96%.

Found: C, 25.98; H, 7.00; N, 15.04; H_2O, 6.19. Calcd. for $CoC_{12}H_{34}N_6O_6Cl_3\cdot 2H_2O$: C, 25.73; H, 6.86; N, 15.01; H_2O, 6.43%.

***trans*-$[Co\ en_2(L\text{-leuH})_2]Br_3\cdot 2.5H_2O$.** — The violet needle crystals were separated by adding a large amount of acetone to a solution which was obtained by a method similar to that used for the L-alanine complex.

Found: C, 26.92; H, 6.54; N, 11.35; H_2O, 5.99. Calcd. for $CoC_{16}H_{44}N_6O_4Br_3\cdot 2.5H_2O$: C, 26.38; H, 6.51; N, 11.54; H_2O, 6.19%.

Measurements.—The visible and ultraviolet absorption spectra were measured by using a Beckman DU spectrophotometer. The CD curves were obtained by a Model ORD/UV-5 spectrophotometer of Japan Spectroscopic Co., and by a Shimadzu QR-50 spectrophotometer with a CD attachment, while the RD curves were recorded with an ORD/UV-5 spectrophotometer. The concentrations of complexes were 1/20 or 1/30 mole/l. for $[Co(NH_3)_5(L\text{-amH})]X_3$, 1/30 mole/l. for $[Co(L\text{-am})(NH_3)_4]X_2$, and 1/20 or 1/30 mole/l. for *trans*-$[Co\ en_2(L\text{-amH})_2]X_3$. All the measurements were made in aqueous solutions and at room temperature.

Results and Discussion

Circular Dichroism.—The CD and absorption data of $[Co(NH_3)_5(L\text{-amH})]^{3+}$ ions are summarized in Table I, while representative curves are shown, with their RD curves, in Fig. 1. The absorption curve is one typical of a $[Co\ N_5O]$-type complex; this indicates that the L-amino acid is coordinated to the cobalt(III) ion as a unidentate ligand.

Recently, Larsen and Olsen[18] have reported on the $[Co(NH_3)_5(OCOR^*)]^{2+}$ and *trans*-$[Co(NH_3)_4(OCOR^*)_2]^+$ of an optically-active carboxylic acid anion, $OCOR^{*-}$. According to their CD measurements, no CD band was found in the region of the first absorption band. All of the present complexes with L-amino acid as a unidentate ligand, however, exhibit CD bands in the corresponding region. These facts suggest that the

* These values were estimated from the curve analysis.

vicinal effect of the asymmetric carbon atom on the cobalt(III) ion may be more effective in the amino acid complexes than in the carboxylic acid complexes. The $[Co(NH_3)_5(L\text{-amH})]^{3+}$ ion belongs approximately to the C_{4v} symmetry, so two absorption components, $^1A_1 \rightarrow {}^1A_2$ and $^1A_1 \rightarrow {}^1E_a$, may be expected in the first absorption band region.[19] As may be seen in Fig. 1 and Table I, the L-alanine complex shows two weak CD bands, with signs opposite to each other. It is reasonable to assign these two CD bands to the transitions of $^1A_1 \rightarrow {}^1A_2$ and $^1A_1 \rightarrow {}^1E_a$.

The other L-amino acid complexes show only a negative CD band at about 505 mμ. It may be assumed that each single CD peak of these complexes is a residual one resulting from an overlap or a cancellation of the two CD components. On the other hand, a positive CD peak was observed for the L-proline complex at 525 mμ. The difference in sign between the L-proline complex and the other L-amino acid complexes may be explained from the occlusion of the asymmetric carbon atom of L-proline in a sieged pyrrolidine ring.

The CD and absorption data of the complex ions containing L-amino acid as a bidentate ligand are also summarized in Table I. Some CD and RD curves of these complex ions are shown in

19) H. Yamatera, This Bulletin, **31**, 95 (1958).

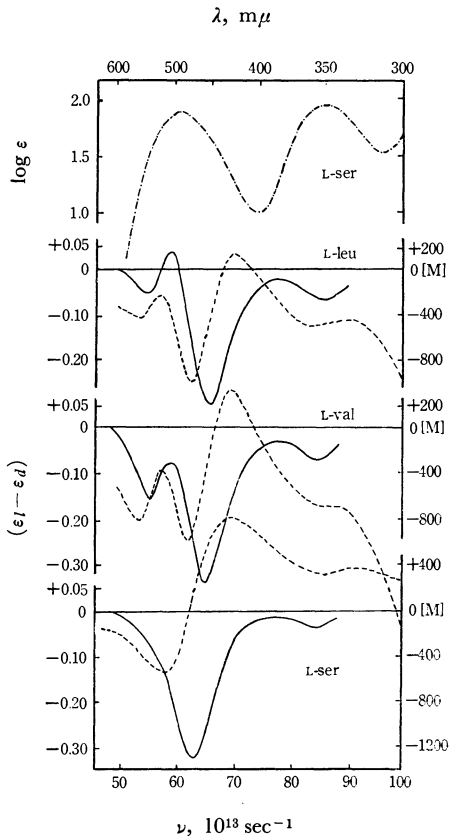

Fig. 2. Absorption (—·—), CD (——) and RD (- - -) curves of $[Co(L\text{-am})(NH_3)_4]^{2+}$ ions.

Fig. 2. The first absorption band does not show any indication of a split on the ordinary absorption curve. Now, the true symmetry of $[Co(L\text{-am})(NH_3)_4]^{2+}$ is C_1, so a T_{1g} level under an O_h symmetry should split into three ^1A levels, and three $^1A \rightarrow {}^1A$ transitions, which are magnetic-dipole allowed, should be observed in the first absorption band region. As may be seen in Fig. 2, the CD curve of the L-leucinato complex shows three components, at 544, 505 and 458 mμ, in this region. This fact suggests that the first absorption band of a complex of this type can actually split into three components.

Experimentally the L-amino-acidato-tetrammine complexes are divided into the following three groups, according to the behavoir of the CD curves in the region of the first absorption band:

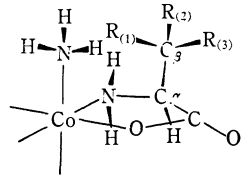
(1) L-am=L-ala, L-leu and L-phala. The complexes of this group exhibit three CD bands in the first absorption band region; their signs are (−), (+) and (−) (from longer to shorter wavelengths).

(2) L-am=L-val and L-isoleu. These complexes exhibit two CD bands, of a negative sign, in the first absorption band region.

(3) L-am=L-ser and L-thr. These complexes exhibit only one CD band, of a negative sign, in the first absorption band region.

The differences among these groups are less explicit in their RD curves than in their CD curves.

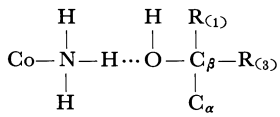
Stereochemically, the differences among these complexes are concentrated in the three substituents, $R_{(1)}$, $R_{(2)}$ and $R_{(3)}$, on the β-carbon atom of the amino acid ligands; in the group 1, $R_{(1)}=R_{(2)}=H$ and $R_{(3)}=H$, $CH(CH_3)_2$ or C_6H_5; in group 2, $R_{(1)}=H$, $R_{(2)}=CH_3$ and $R_{(3)}=CH_3$ or C_2H_5; in group 3, $R_{(1)}=H$, $R_{(2)}=OH$ and $R_{(3)}=H$ or CH_3. By the construction of molecular models, it is shown that some intramolecular interactions exist between a coordinated ammonia molecule and the substituents on the β-carbon atom (Fig. 3).



L-leu: $R_{(1)}=H$, $R_{(2)}=H$, $R_{(3)}=CH(CH_3)_2$
L-val: $R_{(1)}=H$, $R_{(2)}=CH_3$, $R_{(3)}=CH_3$
L-ser: $R_{(1)}=H$, $R_{(2)}=OH$, $R_{(3)}=H$

Fig. 3. The interaction between a coordinated ammonia molecule and substituted groups at the β-carbon atom of the chelated amino acid in $[Co(L\text{-am})(NH_3)_4]^{2+}$ ions.

Of course, internal rotations occur around the C_α—C_β axis, and it will be pointed out that, for example, the internal rotations are more hindered in the L-valinato complex ($R_{(1)}=H$, $R_{(2)}=R_{(3)}=CH_3$) than in the L-alaninato complex ($R_{(1)}=R_{(2)}=R_{(3)}=H$). In the group 3 complexes, the intramolecular interactions of another kind may also be possible, namely, a hydrogen bond between the coordinated ammonia and the $R_{(2)}=OH$ substituent on the β-carbon atom:



It is difficult, however, at present to relate the behavior of CD curves to the stereochemical differences considered above.

On the whole, the CD curve of $[Co(L\text{-prol})(NH_3)_4]^{2+}$ shows a behavior similar to that of the L-leucinato complex, but the positive CD component at about 508 mμ is more intense than that of the other complexes (Fig. 4 and Table I). As was pointed out in previous papers,[6,7] the asymmetric nitrogen atom of the bidentatically-coordinated L-prolinate has a forced configuration antipodal to that of the similarly-coordinated D-prolinate. In the present complex, one of the reasons why the CD band at 508 mμ predominates is the vicinal effect of such a nitrogen atom of the L-prolinate.

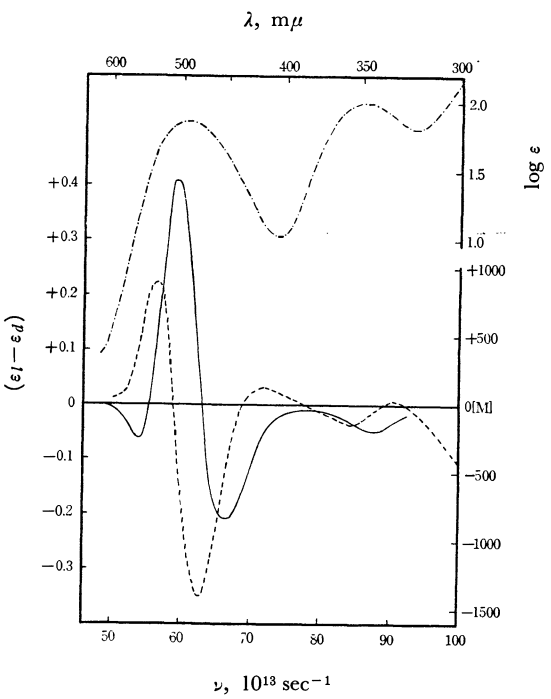

Fig. 4. Absorption (—·—), CD (——) and RD (- - -) curves of $[Co(L\text{-prol})(NH_3)_4]^{2+}$ ion.

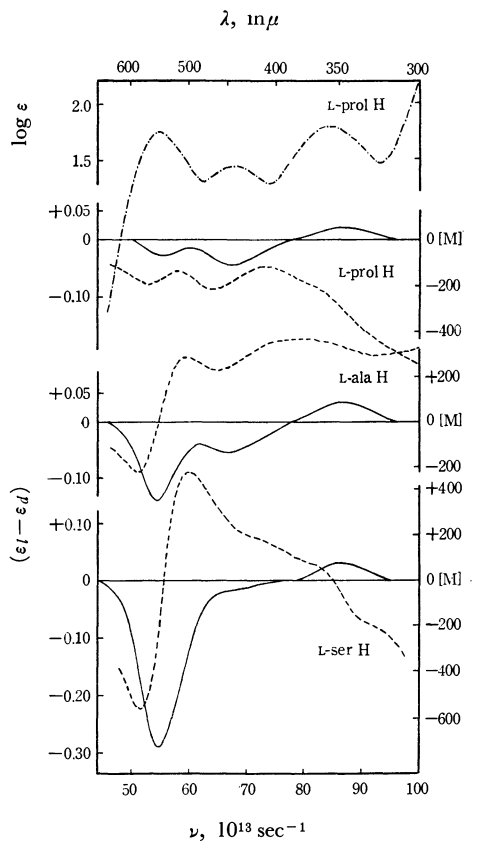

Fig. 5. Absorption (—·—), CD (——) and RD (- - -) curves of *trans*-$[Co\,en_2(L\text{-amH})_2]^{3+}$ ions.

Single negative CD bands are commonly observed in the second absorption band region of the $[Co(L\text{-am})(NH_3)_4]^{2+}$ complexes. They are all almost the same in magnitude and are located in the region from 342 to 355 mμ; these CD bands will be useful in the determination of the configurations of amino acids.

The CD and absorption data of *trans*-$[Co\,en_2(L\text{-amH})_2]^{3+}$ ions are listed in Table I, while their CD and RD curves are shown in Figs. 5 and 6. Their absorption spectra coincide well with those of *trans*-$[Co(OCOR)_2en_2]^+$ and of *trans*-$[Co(OCOR)_2(NH_3)_4]^+$.[20] It is well known that the first absorption band of the *trans*-$[Co\,N_4O_2]$-type complex with the D_{4h} symmetry splits into two components, Ia ($^1A_{1g} \rightarrow {}^1E_g$) and Ib ($^1A_{1g} \rightarrow {}^1A_{2g}$),[20,21] which are magnetic-dipole allowed.

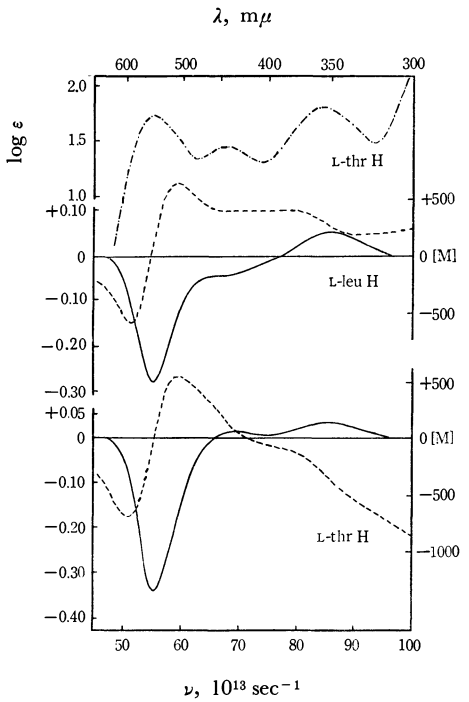

Fig. 6. Absorption (—·—) CD (——) and RD (- - -) curves of *trans*-[Co en$_2$(L-amH)$_2$]$^{3+}$ ions.

The absorption and the CD spectra of *trans*-[Co-en$_2$(L-amH)$_2$]$^{3+}$ exhibit the two first band components; their extremum positions are consistent with each other (Table I).

In the region of the second absorption band, the CD bands of the *trans*-[Co en$_2$(L-amH)$_2$]$^{3+}$-type complexes are situated in a narrow range from 350 to 345 mμ. It is interesting that all of these CD bands have a positive sign, in contrast to those of the [Co(L-am)(NH$_3$)$_4$]$^{2+}$-complex ions.

Rotatory Strength.—In general, it is quite difficult to analyze the observed CD and RD curves into individual component curves, since the first or the second absorption bands are contributed by two or three absorption components which are located very close to each other. When the absorption band splits largely, however, the analysis can be made easily and precisely. In the case of the first absorption band of *trans*-[Co en$_2$(L-amH)$_2$]$^{3+}$, this condition is quite well satisfied, as may be seen in Figs. 5 and 6. The rotatory parameters and rotatory strengths of the individual absorption components were calculated by curve analyses from the observed CD and RD curves of *trans*-[Co en$_2$(L-amH)$_2$]$^{3+}$; the results are summarized in Table II.

The RD curves were analyzed using Moscowitz's Eq. 1:[22]

$$[M_K(\lambda)] = \frac{2[\theta^\circ_K]}{\sqrt{\pi}}\left[\exp\left(-\frac{\lambda-\lambda_K^{CD}}{\Delta_K^{CD}}\right)^2 \times \int_0^{\lambda-\lambda_K^{CD}/\Delta_K^{CD}} e^{x^2}dx - \frac{\Delta_K^{CD}}{2(\lambda+\lambda_K^{CD})}\right] \quad (1)$$

where $[\theta^\circ_K] \simeq 3300(\varepsilon_l-\varepsilon_d)_{ext}$ is the extremum value of the CD band for the Kth transition, λ_K^{CD} is the wavelength of the CD band extremum, and Δ_K^{CD} is the $1/e$-halfwidth of the CD band.

The curve analyses were made by the following steps. In the first, the CD bands which were assumed to be Gaussian on the wavelength scale of the abscissa were separated from the observed CD curve by using the equation:

$$(\varepsilon_l-\varepsilon_d) = (\varepsilon_l-\varepsilon_d)_{ext} \exp\{-(\lambda-\lambda_K^{CD})^2/(\Delta_K^{CD})^2\} \quad (2)$$

Each inversive RD curve was calculated by substituting the parameters estimated from the Gaussian CD band into Eq. 1, and then the resultant individual RD curves were subtracted from the observed RD curve. From the residual curve, the constants in Drude's equation (λ_0 and k) were

22) A. Moscowitz, "Optical Rotatory Dispersion" (C. Djerassi, ed.), McGraw-Hill, New York (1960), p. 150.

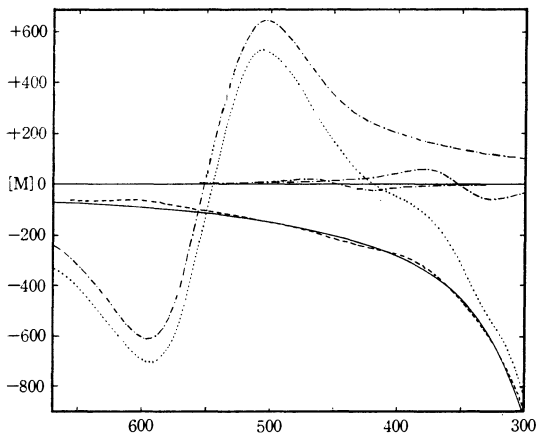

Fig. 7. The analyses of RD curves of *trans*-[Co en$_2$(L-thrH)$_2$]$^{3+}$ ion; (·····) observed RD curve, (—·—) individual RD curves of each absorption components, (- - -) observed curve minus the sum of individual RD curves and (——) Drude's curve.

estimated by the method of Lowry[23] (Table II).

In the second step, independent of the CD data mentioned above, the individual RD curve of each absorption component was again determined by subtracting Drude's curve from the observed RD curve, and by analyzing the residual curve into several individual RD curves. These treatments were made separately both on the longer and on the shorter wavelength sides of the inversive center, λ_K^{RD}. The individual RD components obtained for *trans*-[Co en$_2$(L-thrH)$_2$]$^{3+}$ are shown in Fig. 7 as an example.

It is possible to estimate the rotatory strengths from the data of the CD bands in the first step, and also from the RD data in the second step.

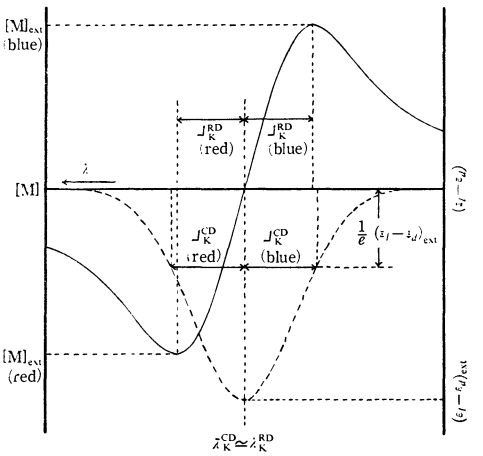

Fig. 8. Parameters for the isolated CD and RD curves.

The rotatory strength from the CD data, R_K^{CD}, is given by:

$$R_K^{CD}\simeq 2.03\times 10^{-39}(\varepsilon_l-\varepsilon_d)_{ext}\{\Delta_K^{CD}(\text{red})+\Delta_K^{CD}(\text{blue})\}/(\lambda_K^{CD}) \quad (3)$$

while the rotatory strength from the RD data, R_K^{RD}, is given by:

$$R_K^{RD}\simeq 5.46\times 10^{-43}\{[M]_{ext}(\text{red})-[M]_{ext}(\text{blue})\}\times\{\Delta_K^{RD}(\text{red})+\Delta_K^{RD}(\text{blue})\}/(\lambda_K^{RD}) \quad (4)$$

The parameters which appear in Eqs. 3 and 4 are defined as in Fig. 8, and a relation, $\Delta_K^{RD}\simeq 0.9233\times\Delta_K^{CD}$, exists[24] for the ideal case in which Moscowitz's Eq. 1 holds perfectly.

As may be seen in Table II, the experimental values of R_K^{CD} are approximately equal to those of R_K^{RD}; furthermore, the positions of λ_K^{RD} coincide well with those of λ_K^{CD} within the range of ± 5 mμ. These facts prove the adequacy of the equations used and of the curve analyses.

The Oligomerization of Isoprene by Cobalt or Iron Complex Catalysts

By Akira MISONO, Yasuzo UCHIDA, Masanobu HIDAI and Yoshiro OHSAWA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received November 26, 1965)

The reaction of isoprene by the catalyst systems composed of cobalt(III) or iron(III) acetylacetonate, an electron donor, and triethylaluminum was studied. It was found that isoprene is selectively dimerized to form a mixture of 1, 5- and 2, 5-dimethyl-1, 5-cyclooctadiene by the catalyst prepared by the reaction of iron(III) acetylacetonate, 2, 2'-dipyridyl, and triethylaluminum. The intermediate complex of the reaction was then examined by studying the effects of the molar ratio of the catalyst components on the reaction or by the measurement of the electronic absorption spectra of the reaction solution. The reaction of butadiene with the catalyst systems described above was also carried out and compared with that of isoprene.

Several complex catalyst systems for the selective dimerization or trimerization of butadiene have been reported, most of them composed of first-row transition metal complexes and organometallic compounds. On the other hand, only a few complex catalyst systems for the dimerization or trimerization of isoprene[1] have been found, although various cyclic dimers of isoprene have been obtained by thermal or photosensitized reaction. It has now been found that isoprene is selectively dimerized to form a mixture of 1, 5- and 2, 5-dimethyl-1, 5-cyclooctadiene by the catalyst combining iron(III) acetylacetonate, triethylaluminum, and a proper bidentate electron donor such as 2, 2'-dipyridyl or *o*-phenanthroline. This paper will be concerned with the reaction of isoprene by the catalyst systems composed of cobalt(III) or iron(III) acetylacetonate, an electron donor, and triethylalumium, in particular, by the above-mentioned catalyst system. Moreover, the intermediate complex of the reaction will be discussed by studying the effects of the molar ratio of the catalyst components on the reaction and by analyzing the electronic absorption spectra of the reaction solution.

Experimental

Reagents. — Isoprene and 2, 3-dimethylbutadiene were dried over anhydrous calcium sulfate and distilled under an atmosphere of nitrogen.

Triethylaluminum (Ethyl Corp., U. S. A.) was used without further purification.

The electron donors were those of commercial reagents or were prepared by the usual methods.

Benzene was purified by conventional procedures.

Procedure.—Experiments were carried out in a 30-ml. glass tube, a 200-ml. glass autoclave, or a 100-ml. stainless autoclave. Benzene, isoprene and triethylaluminum were added in a dry nitrogen atmosphere.

In a typical reaction, 20 ml. of benzene, 10 ml. of isoprene, and 0.33 g. of triethylaluminum were added, in this order, to an autoclave which had been charged with 0.353 g. of iron(III) acetylacetonate and 0.156 g. of 2, 2'-dipyridyl. The autoclave was then heated at 90°C and stirred for 1 hr.

After the reaction, the solution was washed with dilute hydrochloric acid and with water, and dried over anhydrous sodium sulfate. Then the solution was fractionated by distillation. The dimers were isolated by fractional distillation at a reflux ratio of at least 1 : 6 in a rectifying column, or by preparative gas chromatography. For the analysis of the products, gas chromatography was also used.

Analysis.—*Gas Chromatography.*—The dimers of isoprene were analyzed by using a copper tube (3 m. long and 4 mm. in diameter) packed with polydiethylene glycol succinate on Diasolid (Nihon Kuromato, Ltd.). The conditions were as follows; column temperature, 110°C; flash evaporator temperature, 220°C; carrier gas (helium) speed, 30 ml./min. The isomers of dimethyl-1, 5-cyclooctadiene were detected by using a 3 m. β, β'-oxydipropionitrile column (column temperature, 124°C; flash evaporator temperature, 220°C; carrier gas speed, 30 ml./min.).

Infrared Spectra.—The infrared spectra of the products were taken with a Nihon-bunko double-beam spectrometer, Model 401-G.

Electronic Spectra.—The electronic spectra of the reaction solution were recorded by using 0.1 mm.-path-length spacer cells on a Hitachi spectrometer Model EPS.

NMR Spectra.—The spectra were recorded on a Nihon Denshi apparatus JEOL Model 3H-60.

Results and Discussion

Structural Assignments of Products.—The products formed by the reaction of isoprene with a catalyst combining cobalt or iron acetylacetonate, an electron donor, and triethylaluminum are given in Table I. The product with a relative retention time below 3.7 based on benzene was supposed to be a dimer of isoprene.

* Relative retention time of product based on benzene

Reaction conditions:

Al/Fe: 3; Donor/Metal acetylacetonate: 1 (mole ratio); React. temp.: 90°C; React. time: 1 hr.

The analytical gas chromatography of reaction products formed by the catalyst prepared by the reaction of iron(III) acetylacetonate, 2, 2'-dipyridyl, and triethylaluminum showed three peaks, of which the relative retention times were 1.6, 2.3, and 3.7 respectively. Here, at present, these will be designated as A, B, and C respectively, in which C was the main product, the yields of A and B being low. The main product, C, was isolated by fractional distillation. The analytical results of C were as follows, where the values in parentheses are the theoretical values calculated for $C_{10}H_{16}$;

Molecular weight	138 (136)
Elementary analysis	C: 87.70%, H: 11.82% (C: 88.17%, H: 11.84%)
Refractive index	n_D^{20}: 1.4881
Boiling point	80°C/23 mmHg
Iodine value	350

The results of molecular weight determination, elementary analysis, and iodine value indicated that C had the formula of $C_{10}H_{16}$, with two double bonds; hence, it was considered a cyclodimer. Twelve cyclodimers of isoprene of $C_{10}H_{16}$ can be formulated; their structures may be grouped as six cyclobutenes, four cyclohexenes, and two cyclooctadienes. All of cyclobutenes and cyclohexenes contain one terminal vinyl or methylene group at least. The infrared spectrum of C (shown in Fig. 1), however, showed no bands characteristic of the group. Therefore, C was supposed to be 1, 5-dimethyl-1, 5-cyclooctadiene (I), or 2, 5-dimethyl-1, 5-cyclooctadiene (II), or a mixture of them. The infrared spectrum, the boiling point, and the refractive index of C were essentially identical with those of a mixture of I and II given

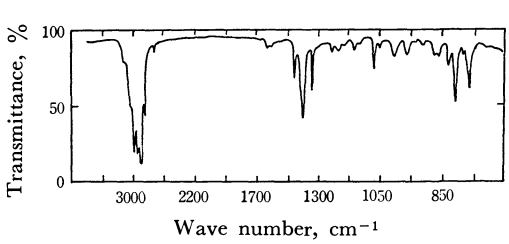

Fig. 1. Infrared spectrum of the fraction of b. p. 80°C/23 mmHg.

by Binder.[2] Furthermore, on the basis of the relative intensities of the bands in the infrared specturm at 1070 and 1093 cm^{-1} which have been considered to be characteristic of I and II respectively,[3] it was concluded that C was a mixture of I and II, and that II was the main constituent. These two isomers, I and II, were also detected by gas chromatography by using a β, β'-oxydipropionitrile column; here the ratio of II to I was determined to be about 4. On the other hand, the NMR spectrum of C (shown in Fig. 2) showed three resonances, at 8.3, 7.8, and 4.8 τ, which were assigned, respectively, to six

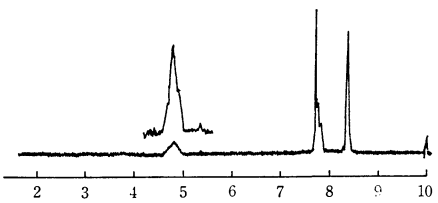

Fig. 2. NMR spectrum of the fraction of b. p. 80°C/23 mmHg.

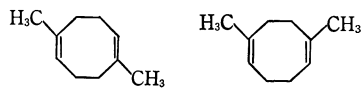
methyl protons next to a double bond, eight methylene protons next to a double bond, and two ethylenic protons.



(I) (II)

The boiling points of A and B were so near that their separation was difficult. As they were also formed in the case of thermal reaction, however, they were considered to be thermal dimers. The fraction with a b. p. of 75—77°C/23 mmHg was about 70% B and 30% C. By the infrared spectrum of the fraction, B was identified as 1-methyl-4-isopropenyl-1-cyclohexene or/and 2-methyl-4-isopropenyl-1-cyclohexene. The fraction with a b. p. of 69—71°C/23 mmHg was about 50% A and 50% B. The infrared spectrum of the fraction indicated that A was 1, 4-dimethyl-4-vinyl-1-cyclohexene or/and 2, 4-dimethyl-4-vinyl-1-cyclohexene.

The Effects of Electron Donors.—Table II shows the effects of electron donors upon the reaction of isoprene with the catalyst prepared by the reaction of iron(III) acetylacetonate and triethylaluminum. Isoprene did not react to the catalyst composed of iron(III) acetylacetonate, triphenylphosphine, and triethylaluminum, although the linear dimers are formed in the case of butadiene.[4] When triphenylphosphite or tri(*o*-tolyl)phosphite was added as a catalyst component, polymers were formed. The addition of a bidentate ligand such as 2, 2'-dipyridyl or *o*-phenanthroline gave the cyclodimers selectively, while the addition of a bidentate ligand such as 2(2'-pyridyl)imidazoline or 2(2'-pyridyl)benzimidazole led to the formation of polymers. These facts indicate that the reaction of isoprene by the catalyst composed of iron(III) acetylacetonate, an electron donor and triethylaluminum was greatly affected by the nature of the electron donor as a catalyst component.

The Reaction of Isoprene by the Catalyst Composed of Iron(III) Acetylacetonate, 2, 2'-Dipyridyl and Triethylaluminum.—*The Effects of the Molar Ratio of the Catalyst Components.*—The effects of the molar ratio of 2, 2'-dipyridyl to iron-(III) acetylacetonate on the reaction are shown in Fig. 3. The most active catalyst system for the cyclic dimerization was formed when one mole of 2, 2'-dipyridyl was added to one mole of iron(III) acetylacetonate. When more than one mole of 2, 2'-dipyridyl was added to one mole of iron(III) acetylacetonate, both the conversion of isoprene and the yield of the cyclic dimers decreased. The same phenomena had been observed in the cyclic dimerization of butadiene with the same catalyst system.[4] On the other hand, 2, 3-dimethyl-1, 3-butadiene did not react with the same catalyst.

Figure 4 shows the electronic absorption spectra of the solution prepared by the reaction of iron(III) acetylacetonate, 2, 2'-dipyridyl, triethylaluminum and a diene monomer in various ratios at room temperature. The solution obtained by the reaction of iron(III) acetylacetonate, 2, 2'-dipyridyl, and triethylaluminum (molar ratio; 1 : 1 : 3) showed a maximum absorption peak at about 600 mμ and a dark blue color. This absorption peak, which was considered to be due to the charge transfer between the iron atom and 2, 2'-dipyridyl, shifted to about 550 mμ and the solution became purple when butadiene or isoprene was present. However, the shift was not observed when an excess of 2, 2'-dipyridyl was added.

These facts indicate that a dark blue complex is formed by the reaction of iron(III) acetylacetonate, 2, 2'-dipyridyl, and triethylaluminum, and that this blue complex is changed into a purple complex by the addition of butadiene or isoprene, in which the diene monomers besides 2, 2'-dipyridyl are coordinated to a low valent iron atom. When an excess of 2, 2'-dipyridyl is present, the ligands occupy all, or at least the greater part, of the coordinating sites of the low valent iron atom and, therefore, prevent the approach of the diene monomer. Thus, when an excess of 2, 2'-dipyridyl was present, the reaction of isoprene was depressed. On the other hand, the fact that the solution obtained by the reaction of iron(III) acetylacetonate, 2, 2'-dipyridyl, and triethylaluminum (molar ratio: 1 : 1 : 3) in the presence of 2, 3-dimethyl-1, 3-butadiene was dark blue indicates that the monomer is not coordinated to the low valent iron atom.

Figure 5 shows the effects of the molar ratio of triethylaluminum to iron(III) acetylacetonate on the reaction. When the molar ratio of triethylaluminum to iron(III) acetylacetonate was below 3, the reaction solution was purple and the cyclic

dimers of isoprene were formed selectively. However, when the molar ratio was above 6, the reaction solution turned reddish brown, as is shown in Fig. 4, and only polymers were formed.

The Effect of the Mixing Order of the Catalyst Components. — In the dimerization of butadiene with a cobalt complex catalyst or in the trimerization of butadiene with an iron complex catalyst, it has been reported that the order of mixing the catalyst components and butadiene had a great effect on the reaction.[6] The effects of the mixing order of the catalyst components on the formation of the cyclic dimers of isoprene or butadiene by the catalyst composed of iron(III) acetylacetonate, 2, 2'-dipyridyl, and triethylaluminum are shown in Table III. Evidently the rate of the formation of the cyclic dimers was greater when iron(III) acetylacetonate, 2, 2'-dipyridyl, isoprene or butadiene, and triethylaluminum were mixed in this order than when triethylaluminum was allowed to react with iron(III) acetylacetonate and 2, 2'-dipyridyl in the absence of isoprene or butadiene. These results indicate that when iron(III) acetylacetonate and 2, 2'-dipyridyl are reacted with triethylaluminum in the presence of the diene monomer, a purple complex, which is supposed to be an intermediate complex for the cyclic dimerization, is easily formed, while when iron(III) acetylacetonate, 2, 2'-dipyridyl, triethylaluminum, and the diene monomer are mixed in this order, the dark blue complex first formed by the reaction of iron(III) acetylacetonate, 2, 2'-dipyridyl and triethylaluminum does not easily react with the diene monomer to form the purple complex.

A Comparison of Isoprene and Butadiene.— It has been reported that butadiene is dimerized to form the linear dimers by the cobalt complex catalyst prepared by the reaction of cobalt(III) acetylacetonate and triethylaluminum or by the iron complex catalyst prepared by the reaction of iron(III) acetylacetonate, triphenylphosphine, and triethylaluminum.[4,6] However, in these catalyst systems, the reactivity of isoprene was not so great as butadiene and linear dimers were not formed. On the other hand, when the catalyst composed of iron(III) acetylacetonate, 2, 2'-dipyridyl, and triethylaluminum was used, with which butadiene is dimerized to form the cyclic dimers, isoprene reacted more easily than butadiene and the cyclic dimers were similarly formed. These facts indicate that the coordination state of a diene monomer to a low valent cobalt or iron tom in the case of the formation of linear dimers is different from that in the case of the formation of cyclic dimers, and that isoprene is not likely to have a coordination state giving linear dimers.

Studies of the Organic Reaction of Metal Carbonyl. X.* The Oxo Reaction of Ethyl Acrylate—The Effects of the Reaction Conditions on the Distribution of the Products

By Yoshinobu TAKEGAMI, Chikao YOKOKAWA and Yoshihisa WATANABE

Department of Fuel Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received November 26, 1965)

The ratio between the α- and β-carbethoxypropionaldehyde formed in the oxo reaction of ethyl acrylate is affected by various reaction conditions; the proportion of β-carbethoxypropionaldehyde increases with an increase in the reaction temperature, but decreases with an increase in the partial pressure of carbon monoxide or hydrogen. These effects can be explained on the basis of the reaction mechanism between cobalt hydrocarbonyl and ethyl acrylate (Y. Takegami et al., This Bulletin, **37**, 1190 (1964)): in the first step of the reaction, ethyl acrylate reacts with cobalt hydrocarbonyl to give, selectively, α-carbethoxypropionylcobalt carbonyl (I), and then I isomerizes to β-carbethoxypropionylcobalt carbonyl (II). Accordingly, the rates of two competitive reactions, the isomerization of I to II and the reduction of I to the corresponding aldehyde, may be the factors determining the distribution of the oxo reaction products. Under the oxo reaction conditions, the isomerization of I to II seems to occur more easily at a relatively high temperature and to be prohibited by a high pressure of carbon monoxide. On the other hand, a relatively high pressure of hydrogen seems to be favorable to the reduction of I to the aldehyde.

Previous work[1] in this laboratory has demonstrated that the reaction of ethyl acrylate with cobalt hydrocarbonyl gives two isomeric acylcobalt carbonyls (α- and β-carbethoxypropionylcobalt carbonyl); that is, in the first step of the reaction, the α-carbon atom of the ethyl acrylate is selectively carbonylated to give α-carbethoxypropionylcobalt carbonyl, and then this isomerizies to the acylcobalt carbonyl with a straight chain structure. This fact strongly indicates that, in the reaction between cobalt hydrocarbonyl and olefin, the rates of the addition of cobalt hydrocarbonyl to an olefinic bond and the isomerization of acylcobalt carbonyls are the factors determining the distribution of the products. It is reasonable to consider that, under the oxo conditions, such an isomerization of acylcobalt carbonyls occurs, having a great effect on the distribution of the products. In the oxo reaction of 1-olefins, the effect of the reaction conditions on the distribution of the products has been studied in detail by several workers.[2] However, no attention has been paid to the effect of the isomerization of acylcobalt carbonyls.

The aim of the present investigation is to study whether the isomerization of alkyl and acylcobalt carbonyls does indeed occur in the oxo reaction of ethyl acrylate, by examining in detail the effects of various reaction conditions.

Experimental

Reaction Procedures.—An autoclave (300 ml.), made of 18-8 nickel-chrom-iron steel and equipped with a magnetic stirrer, was used. Eighty milliliters of toluene, 10 ml. of a dicobalt octacarbonyl solution in toluene (containing 0.22 to 0.24 g. of cobalt as calculated from the carbonyl content), and 20 ml. of ethyl acrylate were placed into the autoclave. After the air in the autoclave had been replaced with hydrogen, hydrogen and carbon monoxide were introduced at certain pressures. The autoclave was then kept at a certain temperature until the guage pressure ceased to decline.

Analysis of the Products.—The products were identified by mixed gas chromatography with authentic samples. A column (3 m. long and 3 mm. in diameter), filled with dilauryl phthalate on cerite, was used. The column temperature was 110 to 125°C, and the rate of flow of the carrier gas (hydrogen) was 50 to 100 ml. per min.

The infrared absorption spectrum of the toluene solution was recorded by the use of a Shimadzu Model IR-27 spectrophotometer.

Materials.—Dicobalt octacarbonyl solution in toluene was prepared according to the method described in a

previous paper.[3] Ethyl acrylate, toluene and other materials were commercial products which had been proved by gas chromatography to be sufficiently pure. As authentic samples, the following commercial chemicals were used: α- and β-carbethoxypropionaldehyde and β-carbethoxypropyl alcohol.

Results and Discussion

The effects of the reaction conditions (the temperature, the partial pressures of hydrogen and carbon monoxide, and the solvents) on the ratio of the products were examined; the results are summarized in Tables I and II. Under the conditions used, 80 to 90% of ethyl acrylate was converted to α- and β-carbethoxypropionaldehyde. In Tables I and II, the values of the reaction times during which a pressure drop was observed, relative of that of Exp. 12, are shown as a measure of the relative reaction rate.

The Effect of the Reaction Temperature.— The relation between the reaction temperature and the percentage of α-carbethoxypropionaldehyde, and that between the reaction temperature and the relative rate, are illustrated in Figs. 1 and 2.

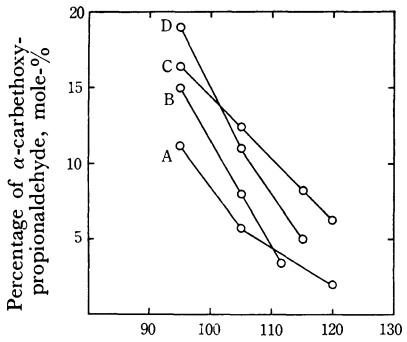

Fig. 1. The percentage of α-carbethoxypropionaldehyde vs. the reaction temperature.
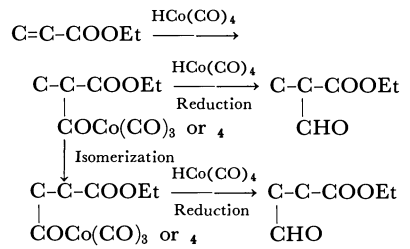
A: H_2 80 atm., CO 40 atm.
B: H_2 80 atm., CO 80 atm.
C: H_2 80 atm., CO 120 atm.
D: H_2 120 atm., CO 80 atm.

As Fig. 1 shows, the percentage of the branched aldehyde decreased almost proportionally with an increase in the reaction temperature, when the initial pressures of hydrogen and carbon monoxide were fixed. With simple 1-olefins, the yield of branched aldehyde increases with an increase in the reaction temperature.[2] In this point, the behavior of ethyl acrylate is different from that of the simple 1-olefins in the oxo reaction. This contrast may be attributed to an ester group of ethyl acrylate. On the other hand, in the reaction of ethyl acrylate with cobalt hydrocarbonyl, a relatively high reaction tmperature is favorable to the formation of a product with a straight chain structure.[1] Therefore, the reaction temperature in the oxo reaction of ethyl acrylate has an effect on the distribution of the products similar to that in the reaction of cobalt hydrocarbonyl. This fact seems to support the consideration[4] that a cobalt catalyst in the oxo reaction acts as cobalt hydrocarbonyl. It may reasonably be considered that the oxo reaction of ethyl acrylate follows this reaction scheme, similar to that of the reaction of cobalt hydrocarbonyl[1]:



In the light of the reaction scheme, the distribution of the two aldehydes seems to be controlled by the isomerization and reduction of α-carbethoxypropionylcobalt carbonyl, which is obtained by the reaction of ethyl acrylate with cobalt hydrocarbonyl. It has been shown[1] that the isomerization of this acylcobalt carbonyl occurs easily at a relatively low temperature (-10 to 25°C). In the oxo reaction, a higher temperature seems to be more favorable to this isomerization, from α-carbethoxypropionylcobalt carbonyl to β-carbethoxypropionylcobalt carbonyl, then causing the percentage of β-carbethoxy propionaldehyde to increase.

*1 Solvent: toluene - ethyl alcohol (60 : 25 in volume). In every case, about 95% of ethyl acrylate.
*2 Cf. Table I. *iso*-Alcohol: α-carbethoxy-*n*-propyl alcohol.

As Fig. 2 shows, the reaction rate increased with an increase in the reaction temperature.

The Effect of the Partial Pressure of Carbon Monoxide.—The relation between the initial pressures of carbon monoxide and the percentage of β-carbethoxypropionaldehyde is illustrated in Fig. 3.

The percentage of α-carbethoxypropionaldehyde increased with an increase in the initial pressure of carbon monoxide when the other reaction conditions were fixed (Fig. 3). Previous work[1,5] in this laboratory has demonstrated that the isomerization of the acylcobalt carbonyls (butyryl- and β-carbethoxypropionylcobalt carbonyl, etc.) generally occurs more rapidly under nitrogen than under carbon monoxide. Under oxo conditions, the isomerization of β-carbethoxypropionylcobalt carbonyl seems to be difficult at relatively high pressures of carbon monoxide; then the percentage of α-carbethoxypropionaldehyde increases with an increase in the carbon monoxide pressure. This fact supports the reaction scheme mentioned above.

5) Y. Takegami, C. Yokokawa, Y. Watanabe, H. Masada and Y. Okuda, This Bulletin, **37**, 181 (1964); ibid., **38**, 787 (1965); ibid., **39**, 1495 (1966).

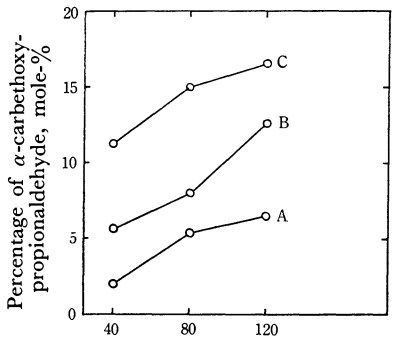

Fig. 3. The percentage of α-carbethoxypropionaldehyde vs. the initial pressure of carbon monoxide.

A: H_2 80 atm., Temp. 120°C
B: H_2 80 atm., Temp. 105°C
C: H_2 80 atm., Temp. 95°C

The relative reaction rate decreases with an increase in the initial pressure of carbon monoxide (cf. Exps. 1, 7 and 8).

The Effect of the Partial Pressure of Hydrogen.—The relation between the initial pressure of hydrogen and the percentage of α-carbethoxypropionaldehyde is shown in Fig. 4.

As Fig. 4 shows, the percentage of α-carbethoxypropionaldehyde increases almost proportionally with an increase in the partial pressure of hydrogen; when the initial pressure of carbon monoxide and the reaction temperature were fixed at 80 atm. and 100—110°C respectively, and when the initial pressures of hydrogen were 40, 80, 120 and 160 atm., the percentages of the aldehyde were 4.0, 8.0, 11.2 and 14.7 mole-% respectively.

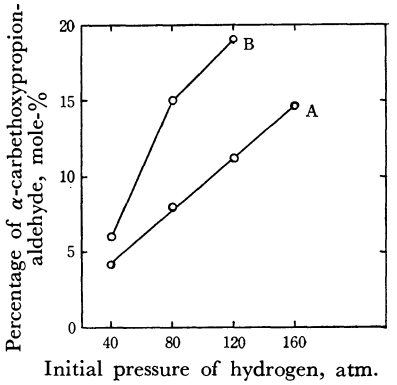

Fig. 4. The percentage of α-carbethoxypropionaldehyde vs. the initial pressure of hydrogen.

A: CO 80 atm., Temp. 105°C
B: CO 80 atm., Temp. 95°C

The relative reaction rate also increases with an increase in the partial pressure of hydrogen (cf. Exps. 1, 3, 4, and 5). The rate of the oxo reaction of simple 1-olefins may be represented as follows:[6]

$$\text{rate} = \frac{k_1 P_{H_2}}{k_2 P_{CO} + k_3 P_{H_2}}$$

k: constant
P: partical pressure

This equation seems to be applicable to the case of ethyl acrylate.

From the standpoint of the reaction scheme, higher pressures of hydrogen are considered to be more favorable to the reduction of α-carbethoxypropionylcobalt carbonyl to the corresponding aldehyde rather than to its isomerization; hence, the formation of α-carbethoxypropionaldehyde seems to be relatively promoted. From this consideration, it may be suggested that the proportion of α-carbethoxypropionaldehyde increases with an increase in the reaction rate when the partial pressure of carbon monoxide and the reaction temperature are fixed. With simple 1-olefins, the oxo reaction rate is remarkably affected by the concentration of the catalyst and solvent.*[1,2] Thus, with ethyl acrylate also the distribution of the products may be affected by solvents.

The Effect of the Solvent.—The effect of a mixed solvent, toluene - ethyl alcohol (60 : 25 in volume), on the reaction rate and the distribution of the products was also examined (Table II).

As the reaction products, the two aldehydes, two alcohols (α- and β-carbethoxy-*n*-propyl alcohol) and diethyl succinate were obtained. The diethyl succinate appeared to be formed by the reaction of β-carbethoxypropionylcobalt carbonyl with ethyl alcohol.

By comparing the results of Exps. 1 and 10 with those of Exps. 23 and 24 respectively, the reaction rate in the mixed solvent was found to be about two times as large as that in pure toluene when the other conditions were fixed; moreover, the percentage of the branched-chain products in the mixed solvent was evidently larger, supporting the assumption that the proportion of the branched-chain products increases with an increase in the reaction rate if the partial pressure of carbon monoxide and the reaction temperature are the same.

* For example, the oxo reaction rate of acrylonitrile in ethyl alcohol is about five times as large as that in benzene.[7]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2434—2437 (1966)

The Isocyanurates. III. The Formation of Tributyl Isocyanurates from Butyl Bromides in the Presence of 1-Butanol

By Atsuo NAGASAWA, Hisao KITANO and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 20, 1965)

The reaction of *n*-butyl or *s*-butyl bromide with potassium cyanate in dimethylformamide was carried out at 100°C for 3 hr. to give tri-*n*-butyl or tri-*s*-butyl isocyanurate. In this process, the presence of unpolymerized *n*-butyl or *s*-butyl isocyanate in the reaction mixture was detected by treating the mixture with benzylamine, thus forming 1-*n*-butyl- or 1-*s*-butyl-3-benzyl urea. The presence of 1-butanol in the reaction system resulted in an increase in the yield of the corresponding isocyanurates. This tendency was remarkable when *s*-butyl bromide was used as a starting material. The addition of *n*-butyl *N*-*n*-butyl- or *n*-butyl *N*-*s*-butylcarbamate to the reaction system strongly accelerated the formation of isocyanurates. The acceleration due to the addition of 1-butanol described above was, therefore, attributed to the effect of carbamates formed in the reaction system. An attempt to trimerize *n*-butyl or *s*-butyl isocyanate in the presence of carbamates and dimethylthylformamide, or in the presence of carbamates and potassium cyanate, resulted in failure. Therefore, carbamates acted as strong accelerators for the trimerization of butyl isocyanates, in cooperation with basic alkali metal salts, such as potassium cyanate, in dimethylformamide.

Previous papers[1] have described how trialkyl or trialkenyl isocyanurates were prepared by the reaction of alkyl or alkenyl halides with alkali cyanates in an aprotic solvent, such as dimethylformamide or dimethylsulfoxide. In this process, the formation of 1, 3-dialkyl urea was often observed when the reaction mixture was poured into water immediately after the desired reaction time. This fact supported indirectly the idea that the reaction between alkyl halides and alkali cyanates generated alkyl isocyanates at the first step,[2] and that those were subsequently polymerized to trialkyl isocyanurates by the catalysis of alkaline compounds (e. g., alkali cyanate)[3] present in the reaction mixture. Therefore, the presence of the unpolymerized alkyl isocyanate in the reaction mixture caused a depression in the yield of trialkyl isocyanurate.

In order to promote the trimerization of isocyanates, an isocyanate-polymerizing catalyst,[4] such as potassium carbonate, sodium benzoate, pyridine or triethylamine, was added to the reaction system. However, all such attempts resulted in failure in the reaction system containing alkyl halides.

On the other hand, some compounds bearing a hydroxyl or an imino group were found to be effective in the trimerization of an initially-formed alkyl isocyanate, even in the presence of alkyl halides.

In the present work, the effects of the addition of 1-butanol, *n*-butyl *N*-*n*-butyl- or *n*-butyl *N*-*s*-butylcarbamate on the reaction of *n*-butyl or *s*-butyl bromide with potassium cyanate in dimethylformamide were studied. The reaction mixture was treated by the following two methods: (I) the reaction mixture was allowed to stand for 24 hr. and then distilled to obtained isocyanurates, and (II) the reaction mixture was quenched at the end of the reaction period and mixed with benzylamine, thus converting the remaining isocyanate into 1-butyl-3-benzyl urea.

A previous paper[1] described how the reaction 1 between *n*-butyl bromide and potassium cyanate, together with water, afforded 1, 3-di-*n*-butyl urea in an 80 to 87% yield (based on the water added) and how the yield of tri-*n*-butyl isocyanurate decreased with the amount of the water added. In this reaction, the decomposition of potassium cyanate proceeded easily in the presence of more than 0.6 mol. of water per mole of the cyanate.

$$n\text{-}C_4H_9Br + KNCO + H_2O \xrightarrow{DMF} (n\text{-}C_4H_9NH)_2CO + (n\text{-}C_4H_9NCO)_3 \quad (1)$$

In the reaction 2 of *n*-butyl bromide with potassium cyanate in the presence of 1-butanol, the use of an equimolar amount of butanol to butyl bromide resulted in the yield of *n*-butyl *N*-*n*-butylcarbamate being limited to 47%, while that of tri-*n*-butyl

	II	40	31	—
s-C_4H_9Br (0.6) KNCO (0.9) *n*-C_4H_9OH (0.6)	I	0	63	12
	II	0	62	11

* Method I: Distillation of the reaction mixture;
Method II: The addition of benzylamine to the reaction mixture.

isocyanurate reached 36%, much higher than in the case of the addition of water (13%). Moreover, when *s*-butyl bromide was used in place of *n*-butyl bromide, this trend became remarkable and a 63% yield of tri-*s*-butyl isocyanurate was obtained (Eq. 3):

$$n\text{-}C_4H_9Br + KNCO + n\text{-}C_4H_9OH \xrightarrow{DMF} n\text{-}C_4H_9NHCO_2C_4H_9\text{-}n + (n\text{-}C_4H_9NCO)_3 \quad (2)$$

$$s\text{-}C_4H_9Br + KNCO + n\text{-}C_4H_9OH \xrightarrow{DMF} s\text{-}C_4H_9NHCO_2C_4H_9\text{-}n + (s\text{-}C_4H_9NCO)_3 + CH_3CH{=}CHCH_3 \quad (3)$$

The two methods, I and II, were adopted for the reaction with and without the use of 1-butanol. Table I indicates the results.

The clear difference between the results from I and II observed in the absence of 1-butanol implies that considerable amounts of isocyanates remained unpolymerized for several hours in the reaction mixture (Eq. 4), while, in the presence of 1-butanol, I and II were not appreciably different, indicating the absence of free isocyanates in the reaction mixture.

$$C_4H_9Br + KNCO \xrightarrow[\text{Method I}]{} (C_4H_9NCO)_3$$
$$C_4H_9Br + KNCO \xrightarrow[\text{Method II}]{C_6H_5CH_2NH_2} C_4H_9NHCONHCH_2C_6H_5 + (C_4H_9NCO)_3 \quad (4)$$

Table I also apparently illustrates that the addition of 1-butanol to the reaction system 4 served to increase the yield of tributyl isocyanurates.

On the basis of our observations that the addition of water to the reaction system 4 did not increase the yield of the isocyanurate,[1] we assumed that the trimerization of butyl isocyanates was accelerated neither by water, nor by urea, nor by 1-butanol, but by *n*-butyl *N*-butylcarbamates derived from the reaction with 1-butanol. In this regard, it may be recollected that Kogon[5] carried out the trimerization of phenyl isocyanate in the presence of ethyl carbanilate and *N*-methyl morpholine.

The effect of the addition of half a more of *n*-butyl *N*-*n*-butyl- or *n*-butyl *N*-*s*-butylcarbamate per mole of *n*-butyl or *s*-butyl bromide on the reaction of butyl bromides with potassium cyanate in dimethylformamide was examined in order to confirm that *N*-monosubstituted carbamates may be expected to promote the trimerization of aliphatic isocyanates. In this reaction 5, the yields of tributyl isocyanurates were about 80% and there was no butyl isocyanate remaining in the reaction mixture which was detectable by the benzylamine method II described above.

$$C_4H_9Br + KNCO \xrightarrow[C_4H_9NHCO_2C_4H_9]{DMF} (C_4H_9NCO)_3 \quad (5)$$

Furthermore, the trimerization 6 of *n*-butyl or *s*-butyl isocyanate with a *n*-butyl *N*-*n*-butylcarbamate-dimethylformamide mixture led to the recovery of the isocyanates in about a 90% yield, while the reaction 7 of the isocyanates in the presence of potassium cyanate and the carbamate in toluene resulted in the recovery of the isocyanates in almost a quantitative yield:

$$C_4H_9NCO \xrightarrow[n\text{-}C_4H_9NHCO_2C_4H_9\text{-}n,\ DMF]{} (C_4H_9NCO)_3 \quad (6)$$

$$C_4H_9NCO \xrightarrow[n\text{-}C_4H_9NHCO_2C_4H_9\text{-}n,\ KNCO]{} (C_4H_9NCO)_3 \quad (7)$$

The trimerization 8 of the isocyanates with the carbamate and potassium cyanate in dimethylformamide gave isocyanurates in twice the yield of the reaction 8 in the absence of the carbamate:

$$C_4H_9NCO \xrightarrow[n\text{-}C_4H_9NHCO_2C_4H_9\text{-}n,\ KNCO,\ DMF]{} (C_4H_9NCO)_3 \quad (8)$$

Consequently, it was concluded that *n*-butyl *N*-butyl-carbamates exhibited a strong accelerating ability in the trimerization of butyl isocyanates

5) I. C. Kogon, *J. Am. Chem. Soc.*, **78**, 4911 (1956).

in cooperation with basic alkali metal salts, such as potassium cyanate, in dimethylformamide, in spite of the presence of butyl bromides, which reduced the isocyanate-trimerizing property of some basic compounds described in the preliminary experiment; this information will be useful for the syntheses of isosyanurates from aliphatic halides and alkali cyanates.

Experimental

Materials.—*n*-Butyl and *s*-butyl bromides were prepared from the corresponding alcohols by the usual methods.[6,7] We described the purity of potassium cyanate[5] and dimethylformamide in a previous paper[1]. *n*-Butyl and *s*-butyl isocyanates were prepared by the phosgenation[9] of anhydrous *n*-butyl or *s*-butylamine hydrochloride in tetralin and were purified by treating them with calcium oxide and molecular sieves, followed by fractional distillation. The specimens used had the following physical properties: *n*-butyl; b. p. 115°C, n_D^{20} 1.4058 (Ref.[10] b. p. 113—116°C, n_D^{20} 1.4060) and *s*-butyl; b. p. 102°C, n_D^{20} 1.3995 (Ref.[10] b. p. 99—101°C, n_D^{20} 1.3989). *n*-Butyl *N*-*n*-butylcarbamate (b. p. 102°C/4 mmHg, n_D^{20} 1.4359) and *n*-butyl *N*-*s*-butylcarbamate (b. p. 91—92°C/4 mmHg, n_D^{15} 1.4429) were prepared by the reaction of an excess of pure *n*-butanol with butyl isocyanates (the specimens described above) and were purified by distillation under reduced pressure. These carbamates were identified with the authentic samples prepared by Curry's method.[11]

The Reaction of *n*-Butyl or *s*-Butyl Bromide with Potassium Cyanate.—*(A) Method I (The Distillation of the Reaction Mixture).*—In a three-necked flask fitted with a reflux condenser, a thermometer, and a mercury-sealed mechanical stirrer, there was placed a mixture of 27.4 g. (0.2 mole) of *n*-butyl or *s*-butyl bromide, 24.3 g. (0.3 mole) of potassium cyanate, and 100 g. (1.4 mole) of dimethylformamide. The mixture was well stirred and then kept at 100±1°C for 3 hr. After the reaction mixture had then been allowed to stand for 24 hr. at room temperature, it was filtered to removed inorganic salts. The filtrate was distilled under reduced pressure to give dimethylformamide and tri-*n*-butyl isocyanurate (b. p. 160—162°C/4 mmHg, n_D^{20} 1.4720[10]) or tri-*s*-butyl isocyanurate (b. p. 138—140°C/4 mmHg, n_D^{15} 1.4600[10]). The yields of the isocyanurates are shown in Table I.

(B) Method II (The Addition of Benzylamine to the Reaction Mixture).—The reaction of *n*-butyl bromide with potassium cyanate was carried out as in the case of Method I. After 3 hr., the reaction mixture was quickly quenched with ice water; the inorganic precipitates were filtered off, and the filtrate was at once mixed with 26.8 g. (0.25 mole) of benzylamine. The resulting mixture was allowed to stand for 24 hr. at room temperature and then poured into cold water to afford a white crystalline mass. The mass was collected by filtration, washed with water and *n*-butyl ether, and recrystallized from a methyl ethyl ketone-ligroin mixture (1 : 1) to give 1-*n*-butyl-3-benzyl urea, m. p. 101°C.

Found: N, 13.5%. Calcd. for $C_{12}H_{18}ON_2$: N, 13.6%.

The filtrate was poured into a saturated sodium chloride solution and extracted with benzene. The extract was dried over anhydrous magnesium sulfate overnight and distilled under reduced pressure to give tri-*n*-butyl isocyanurate.

When *s*-butyl bromide instead of *n*-butyl bromide was used in this experiment, 1-*s*-butyl-3-benzyl urea, m. p. 102.5°C, tri-*s*-butyl isocyanurate and butene-2 were obtained.

Found: N, 13.4% Calcd. for $C_{12}H_{18}ON_2$: N, 13.6%.

These results are summarized in Table I.

The Reaction of *n*-Butyl Bromide with Potassium Cyanate in the Presence of 1-Butanol.—A mixture of 54.8 g. (0.4 mole) of *n*-butyl bromide, 48.6 g. (0.6 mole) of potassium cyanate, 200 g. (2.8 mole) of dimethylformamide and 29.6 g. (0.4 mole) of 1-butanol was kept at 100±1°C for 3 hr. with stirring. The reaction mixture was then treated by the two methods, I and II, to give *n*-butyl *N*-*n*-butylcarbamate (b. p. 97—98°C/3 mmHg, n_D^{20} 1.4726) and tri-*n*-butyl isocyanurate (b. p. 158—160°C/3 mmHg). The results are shown in Table I. The yields of the above products which depend upon the amount of 1-butanol added are listed in Table II.

Table II. The reaction of *n*-butyl bromide with potassium cyanate in the presence of 1-butanol

n-C_4H_9OH / n-C_4H_9Br mole/mole	Yield (A) of n-$C_4H_9NHCO_2$-C_4H_9-n %	Yield (B) of $(n$-$C_4H_9NCO)_3$ %	Total yield (A+B) %
0.5	35	47	82
1.0	47	36	83
1.5	56	28	84
2.0	61	22	83
4.0	83	—	83

The Reaction of *s*-Butyl Bromide with Potassium Cyanate in the Pressence of 1-Butanol.—In both methods, I and II, the top of the reflux condenser was connected with a trap chilled by a dry ice-methanol bath. A mixture of 83.2 g. (0.6 mole) of *s*-butyl bromide, 72.9 g. (0.9 mole) of potassium cyanate, 300 g. (4.2 mole) of dimethylformamide, and 42.6 g. (0.6 mole) of 1-butanol was maintained at 100±1°C for 5 hr. with stirring. The reaction mixture, when then treated by the above methods, yielded *n*-butyl *N*-*s*-butylcarbamate (b. p. 90—91°C/4 mmHg, n_D^{15} 1.4428) and tri-*s*-butyl isocyanurate (b. p. 137—139°C/4 mmHg). The results are shown in Table I, while the effects of the amount of 1-butanol added on the yields of the carbamate and the isocyanurate are summarized in Table III. In this table, the yield of butene-2 was determined from the bromine number of the distillate in the trap.

The Reaction of *n*-Butyl or *s*-Butyl Bromide with Potassium Cyanate in the Presence of *n*-Butyl *N*-Butylcarbamates.—A mixture of 27.4 g. (0.2 mole) of *n*-butyl or *s*-butyl bromide, 24.3 g. (0.3 mole) of potassium cyanate, 100 g. (1.4 mole) of dimethylformamide, and 17.3 g. (0.1 mole) of *n*-butyl *N*-*n*-butyl or *n*-butyl *N*-*s*-butylcarbamate specimens, was heated at 100±1°C for 3 hr. The reaction mixture was then treated by Methods I and II to give tri-*n*-butyl and tri-*s*-butyl isocaynurate respectively. The yields of the isocyanurates by the two methods, are shown in Table IV. The carbamate added was recovered in a quantitative yield.

Table IV. The reaction of *n*-butyl or *s*-butyl bromide with potassium cyanate in the presence of *n*-butyl *N*-butylcarbamates

Reactant	Carbamate	Method*	Yield of isocyanurate, %

		II	72

* Method I: Distillation of the reaction mixture; Method II: The addition of benzylamine to the reaction mixture.

Attempted Trimerizations of *n*-Butyl and *s*-Butyl Isocyanates.—After a mixture listed in Table V was heated at 100±1°C for 3 hr. while being stirred, the resultant mixture was quenched with ice water and 5 ml. of the mixture was pipetted out. The sample was then mixed with 20 ml. of a 0.5 N di-*n*-butylamine-dioxane solution and allowed to stand for 2 hr. at room temperature. The residual isocyanate content in the sample was determined by titrating the excess of di-*n*-butylamine with a 0.1 N hydrochloric acid - ethanol solution, using bromocresol purple as the indicator.[3] The results are shown in Table V.

Table V. The attempted trimerization of *n*-butyl and *s*-butyl isocyanates

* C_4H_9NCO: 0.01 mole, n-$C_4H_9NHCO_2C_4H_9$-n: 0.005 mole, KCNO: 2.5×10^{-5} mole, $CH_3C_6H_5$: 10 ml., $HCON(CH_3)_2$: 10 ml.

With regard to Table V, toluene was used as a diluent of the isocyanates in order to obtain accurate results from the analysis of the reaction mixture in the absence of dimethylformamide, because toluene itself did not influence the polymerization of the isocyanates.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2438—2441 (1966)

The Photochemical Sulfoxidation of Alkylbenzenes[1]

By Yoshiro OGATA, Yasuji IZAWA, Takao TSUDA and Katsuhiko TAKAGI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received February 3, 1966)

The photochemical sulfoxidation of alkylbenzenes with sulfur dioxide and oxygen in acetic anhydride to give the corresponding sulfonic acids has been studied. The sulfoxidation of the higher alkylbenzenes, such as that with a side-chain of trimerized propylene (ABTP) with a total average mol. wt. of 253 and that with a linear side-chain (ABL) with an average mol. wt. of 254, and also that of ethylbenzene give, by homolytic reaction, the corresponding sulfonic acids substituted at their side-chains. In contrast, the sulfonation of *m*-xylene occurs at the benzene ring by ionic reaction, while toluene gives a very poor yield of sulfonic acid. The surface activities of the resulting sodium alkylbenzenesulfonate with their sulfonate group at the side-chain were comparable to the corresponding ring-substituted sulfonates.

The present authors have previously postulated, for the photochemical sulfoxidation of *n*-hexane, a mechanism involving the simultaneous steps of a radical chain reaction and a molecular mechanism; the primary process seems to involve two processes, i. e., energy transfer and hydrogen abstraction with excited sulfur dioxide,[2] the ratio of reactivities of C–H bonds (primary : secondary : tertiary) being 1 : 0.8—1.3 : 3.2—6.2.[3]

It is well-known that the sulfonation of alkylbenzenes with sulfur trioxide occurs via an electrophilic attack on the benzene ring. However, little is known about the photochemical sulfoxidation of alkylbenzenes, though perhaps they are attacked at the side-chain via a radical mechanism. At the same time, the ionic sulfonation with sulfur trioxide is conceivable because of the possible photooxidation of sulfur dioxide to sulfur trioxide.[4]

The present paper will deal with the results obtained in a study of the photochemical sulfoxidation of various alkylbenzenes, such as toluene, ethylbenzene, *m*-xylene, alkylbenzene with a side-chain of trimerized propylene (ABTP) and alkylbenzene with a linear side-chain (ABL).

Experimental

Materials.—ABTP was purified by the fractionation of commercial material, b. p. 80°C/3 mmHg, n_D^{25} 1.4887, average mol. wt., 253, with an alkyl chain of 12—13 carbon atoms. ABL was of a commercial grade, prepared by the Friedel-Crafts reaction of chlorinated paraffin with benzene, b. p. 309—325°C, average mol. wt., 254, with an alkyl chain of 11—16 carbon atoms. The mol. wt. was determined cryoscopically in a benzene solution. Toluene, b. p. 109—110°C, ethylbenzene, b. p. 135—136°C; n_D^{18} 1.4971, and *m*-xylene, b. p. 138—138.5°C, were purified by the fractionation of commercial materials of an extra pure grade. Acetic anhydride, carbon tetrachloride, sulfur dioxide, oxygen, sodium *o*-toluenesulfonate and sodium *p*-toluenesulfonate were commercial materials and were used without further purification.

Sodium toluene-ω-sulfonate was prepared by the same procedure as was used by Johnson and Ambler.[5] Sodium *m*-xylene-ω-sulfonate was prepared by the reaction[5] of ω-bromo-*m*-xylene,[6] b. p. 117—120°C/60 mmHg, with anhydrous sodium sulfite. Sodium *p*-ethylbenzenesulfonate was prepared by the reaction of ethylbenzene with concentrated sulfuric acid at 136°C; the m. p. of its sulfonamide was 106—108°C (lit.[7] m. p. 109°C). Sodium 2, 4-dimethylbenzene-1-sulfonate was prepared by the reaction of *m*-xylene with concentrated sulfuric acid at 100—110°C; the m. p. of its acid was 58—59°C (lit. m. p. 59.8°C[8] and 63—64°C).[9] The sodium sulfonates with a ring-sulfonate group were prepared by the sulfonation of the corresponding ABTP and ABL with concentrated sulfuric acid.

The ultraviolet spectra were measured by a Shimadzu automatic recording spectrophotometer (Type SV-50A), and the infrared spectra, by a Perkin-Elmer grating infrared spectrophotometer (Type 337).

The Photochemical Sulfoxidation of Ethylbenzene.—Ethylbenzene (1.6 g., 0.015 mole), acetic anhydride (0.1 ml.), and carbon tetrachloride (150 ml.) were placed in a quartz reaction vessel. Sulfur dioxide (9 l./hr.) and oxygen (4.5 l./hr.) were introduced simultaneously into the ethylbenzene solution (0.01 mol./l.) at 17—22°C under the irradiation of ultraviolet light (Toshiba HSL-100 UV) for 12 hr. After the irradiation had ended, the resulting sulfonic acid was extracted with hot water (ca. 60 ml.). The extract was then neutralized with sodium carbonate and

evaporated to dryness on a water bath, and the residue was further dried under a vacuum. The residue was then extracted with ethanol to give sodium ethylbenzenesulfonate as a light yellow solid (0.06 g.; 2.2%).

The Photochemical Sulfoxidation of Toluene.—Toluene (21.8 g., 0.24 mol.) and acetic anhydride (1.3 ml.) were placed in a quartz vessel. Sulfur dioxide (2 l./hr.) and oxygen (0.7 l./hr.) were then introduced simultaneously into the solution at 18—20°C under the irradiation of ultraviolet light for 12 hr. After the irradiation had ended, a work-up similar to the sulfoxidation of ethylbenzene gave a trace of a product; its infrared spectrum showed absorptions at 1135, 1015 and 650 cm^{-1} due to characteristic absorption bands of sulfonate.

The Photochemical Sulfoxidation of Alkylbenzenes.—A solution of ABTP (10 g., 0.04 mol.) and acetic anhydride (0.3 ml.) in carbon tetrachloride (100 ml.), after being dried with Drierite, was placed in a quartz vessel. Sulfur dioxide (7 l./hr.) and oxygen (3.5 l./hr.) were introduced simultaneously into the solution at 17—20°C under the irradiation of ultraviolet light (Toshiba H-400PUV) for 12 hr. After the irradiation had ended, water (ca. 1 ml.) was added to the reaction mixture and it was stirred at 40—50°C for 1 hr. in order to complete the decomposition of the acetyl phenylalkanesulfonyl peroxide. The resulting sulfonic acid was extracted with hot water (ca. 60 ml.), and isopropanol (ca. 60 ml.) was added to the extract. The solution was then neutralized with sodium carbonate, and further sodium carbonate added to the solution until the separated aqueous layer was saturated at 40°C. The separated isopropanol layer was dried with anhydrous sodium sulfate and evaporated to dryness on a water bath, and the residue was further dried under a vacuum. The yield of sodium sulfonate was about 0.4 g. (3%). The crude sulfonate was extracted with ethanol to give sodium sulfonate of ABTP (0.16 g.).

The sulfoxidation of ABL was carried out similarly. The yield was 2.9%.

The Photochemical Sulfoxidation of *m*-Xylene.—*m*-Xylene (21.5 g., 0.2 mol.), acetic anhydride (1.3 ml.) and carbon tetrachloride (75 ml.) were placed in a quartz vessel. Sulfur dioxide (7.0 l./hr.) and oxygen (3.5 l./hr.) were introduced simulatneously into the solution at room temperature under the irradiation of ultraviolet light for 9 hr. After the irradiation had ended, a work-up similar to that used for ethylbenzene gave the sodium sulfonate (yield 1.0%).

Results and Discussion

The photochemical sulfoxidation of various alkylbenzenes gave the corresponding sulfonic acids in yields lower than those for *n*-hexane and *n*-decane[2] (see Table I). The lowering of the yields may be due to an inner-filter effect of alkylbenzenes as a substrate, although the λ_{max} value of sulfur dioxide (290 mμ) is longer than those of the substrates. Table II summarizes the ultraviolet and the infrared spectral data on the sodium sulfonates obtained from the sulfoxidized ethylbenzene, ABTP, with an average mol. wt. of 253 (with a side-chain consisting of 12—13 carbon atoms), and ABL, with an average mol. wt. of 254 (with a side-chain of 11—16 carbon atoms). The sulfonate from ethylbenzene showed a λ_{max} value at 256 mμ in water and characteristic infrared absorption bands at 1168 and 1048 cm^{-1} (assigned to the S–O stretching vibrations), at 650 cm^{-1} (assigned to the C–S stretching vibration) and at 734 and 696 cm^{-1} (assigned to the out-of-plane C–H deformation vibrations of five adjacent hydrogen atoms in the benzene ring). Similarly, the sodium sulfonate from ABTP showed a λ_{max} value at 250 mμ in dilute aqueous ethanol and characteristic infrared absorption bands at 1180 and 1045 cm^{-1} (assigned to the S=O stretching vibrations), at 648 cm^{-1} (assigned to the C–S stretching vibration) and at 758 and 695 $cm.^{-1}$ (assigned to the out-of-plane C–H deformation of five adjacent hydrogen atoms in the benzene ring). The sodium sulfonate from ABL showed a λ_{max} value at 258 mμ in ethanol and similar characteristic infrared absorption bands.

As Table III shows, however, the absorption peaks of all authentic alkylbenzenesulfonates with a sulfonate group at the benzene ring are observed above 260 mμ, while those with a sulfonate group at the side-chain shift to below 258 mμ.

On the other hand, the photochemical sulfoxidation of *m*-xylene was found to give a product with a sulfonate group in the benzene ring, i. e., 2, 4-dimethylbenzene-1-sulfonate, which was identified by ultraviolet and infrared spectroscopy (Tables II and III). Although the sulfoxidation of toluene gave a trace of a product which showed the infrared characteristic absorption bands associated with the sulfonate group, attempts to detect the position of the sulfonate group were unsuccessful.

On the basis of these facts, the sulfoxidation of the alkylbenzenes with secondary and/or tertiary hydrogen atoms in the side-chain, such as ethylbenzene, ABTP and ABL, may be described as follows:

$$SO_2 \xrightarrow{h\nu} SO_2^* \longrightarrow SO_2^{**} \quad (1)[10]$$

(Singlet state) (Triplet state)

$$Ph(CH_2)_nCH_3 + SO_2^{**} \longrightarrow PhCH(CH_2)_{n-1}CH_3 + \cdot H + SO_2 \quad (2)$$

$$PhCH(CH_2)_{n-1}CH_3 + SO_2 \longrightarrow PhCHSO_2(CH_2)_{n-1}CH_3 \xrightarrow{O_2} \cdots \quad (3)$$

In contrast, *m*-xylene gave ring-substituted products via an ionic mechanism with sulfur trioxide as an attacking species, since another probable

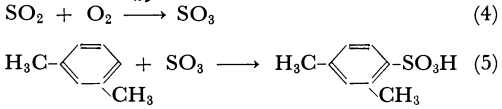
mechanism involving the excitation of a C-T complex between *m*-xylene and sulfur dioxide is unlikely because the complex has not been detected in carbon tetrachloride by ultraviolet spectroscopy. The sulfoxidation of toluene occurred only with difficulty. These facts can be explained by an equilibrium (Eq. 3′) where the benzyl radical is more stabilized than the *ω*-toluenesulfonyl radical.[11]

$$PhCH_2\cdot + SO_2 \rightleftarrows PhCH_2\dot{S}O_2 \qquad (3')$$

Consequently, *m*-xylene is probably sulfonated with the sulfur trioxide obtained from the photooxidation[4] of sulfur dioxide by the reactions of Eqs. 4 and 5:

$$SO_2 + O_2 \xrightarrow{h\nu} SO_3 \qquad (4)$$



(5)

The very poor yield of the toluenesulfonate may be due to the fact that *m*-xylene is attacked by electrophilic sulfur trioxide more rapidly than toluene.

11) M. S. Kharasch and A. T. Reed, *J. Am. Chem. Soc.*, **61**, 3089 (1939).

A similar example of radical and ionic substitutions under irradiation has been reported in photochemical thiocyanation,[12] i. e., the reaction with thiocyanogen chloride in acetic acid occurs completely at the side-chain of ethylbenzene, but only partially at the ring of *m*-xylene, and entirely at the ring of mesitylene.

Table IV. The surface and the water-kerosene interfacial tensions of the aqueous solutions of sodium sulfonates of ABTP and ABL at 20°C

Position of substituted sulfonate group		Surface tension[a] dyne/cm.		Interfacial tension[b] dyne/cm.	
		0.1 g.%	0.05 g.%	0.1 g.%	0.05 g.%
ABTP	Side-chain	45.9	49.3	11.5	15.1
	Benzene	29.8	33.5	2.7	—
ABL	Side-chain	40.6	43.2	2.3	5.2
	Benzene	35.0	37.1	0.7	3.3

a) By Du Nouy tensiometer. The surface tension of distilled water is 68.7 dyne/cm. at 20°C.

b) By Du Nouy tensiometer. The interfacial tension between distilled water and kerosene is 35.8 dyne/cm. at 20°C.

12) R. G. R. Bacon and R. G. Guy, *J. Chem. Soc.*, **1961**, 2428.

m-Xylyl chloride and an aromatic carboxylic acid of an unknown structure were detected by gas chromatography and infrared spectroscopy respectively as minor side-reaction products in the photosulfoxidation of *m*-xylene. The latter showed the characteristic infrared peaks of aromatic carboxylic acid at 1720, 1690 and 1277 cm^{-1}. *m*-Xylyl chloride appears to be obtained by the chlorine-atom abstraction of the *m*-xylyl radical from the solvent, carbon tetrachloride,[13] while the carboxylic acid seems to be formed by the photooxidation of *m*-xylene.

The side-chain sulfonation of ABTP and ABL is a novel reaction. The surface and the water-kerosene interfacial tensions of the aqueous solutions of sodium sulfonates of ABTP and ABL are tabulated in Table IV, together with those of the ring-sulfonated ones. The results show that the side-chain-sulfonated ABTP and ABL are also good surfactants.

The authors wish to thank the Seitetsu Chemical Co., and the Nissan Chemical Co. for their gifts of materials.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2441—2443 (1966)

The Reaction of Optically Active Silver β-Phenylisobutyrate with Halogen

By Shigeru OAE, Teruya KASHIWAGI and Seizi KOZUKA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received February 4, 1966)

The Hunsdiecker reaction of optically active silver β-phenylisobutyrate with bromine was carried out, and racemic β-phenylisopropyl bromide and optically atcive 3-methyl-7-bromohydrocoumarin were obtained as the major products. Meanwhile, the Simonini reaction was also performed with the same optically active acid and iodine; 1-phenyl-2-propyl β-phenylisobutyrate was obtained as the product here. Upon the hydrolysis of the ester, the resulting alcohol, β-phenylisopropyl alcohol, was found to be racemic. From these observations, the mechanisms involving the formation of the incipient free radical during the reactions were suggested for both the reactions.

There are two different pathways for the reaction between silver carboxylate and halogen, depending mainly upon the molarity of halogen used. One is known as the Hunsdiecker reaction[1]; it gives an alkyl halide, carbon dioxide and silver halide, when a silver carboxylate is treated with a one mole equivalent of halogen, usually bromine; the other pathway, known as the Simonini reaction,[1] gives an ester, carbon dioxide and silver halide, using two moles of halogen and generally employing iodine.

As for the Hunsdiecker reaction, a few stereochemical studies have been carried out using various optically active silver carboxylates. Bell and

1) a) R. G. Johnson and R. K. Ingham, *Chem. Revs.*, **56**, 219 (1956). b) C. V. Wilson, *Org. Reactions*, **9**, 332 (1957).

Smyth[2] reported that the Hunsdiecker reaction of optically active silver benzylethylacetates gave an almost completely inactive 2-bromo-1-phenylbutane. A similar racemization was reported by Arnold and Morgan[3] and also by Heintzeler[4]; they favored a radical process for this reaction. Meanwhile, there has been a report by Arcus, Campbell and Kenyon[5] that the Hunsdiecker reaction of silver (+)-α-phenylpropionate gave (+)-α-phenylethyl bromide to the extent of a 43.1% inversion of the configuration. On the other hand, no stereochemical study has been reported of the Simonini reaction.

During our recent studies of the thermal decompositions of diacyl peroxides,[6] we have had occasion to synthesize a few optically active carboxylic acids; thus we have extended the mechanistic investigation into the nature of these two reactions using an optically active silver carboxylate, namely silver β-phenylisobutyrate, in the hope of accumulating additional supporting evidence for the free radical nature of these reactions.

Results and Discussion

The Hunsdiecker Reaction.—A mixture of optically active silver β-phenylisobutyrate and bromine (in a one-to-one molar ratio) was refluxed in carbon tetrachloride for about 11 hr. The products obtained were practically racemized β-phenylisopropyl bromide, carbon dioxide, an optically active lactone (identified as 3-methyl-7-bromohydrocoumarin), silver bromide, and optically active β-phenylisobutyric acid. The yields and optical rotations of these products will be shown in the Experimental section.

The expected product of the Hunsdiecker reaction, β-phenylisopropyl bromide (obtained in about an 18% yield) was almost completely racemized within the range of experimental error. This result agreed well with the previous results reported[2-4] for similar reactions using other optically active carboxylic acids. The present stereochemical outcome can serve to support the free radical mechanism suggested for the formation of the bromide, as has been suggested by previous workers.[2-4,7]

β-Phenylisobutyric acid could be a reaction product, formed via the acyl hypobromite; however, the stereochemical outcome (retention) does not indicate whether β-phenylisobutyric acid is the recovered material or the reaction product.

It is interesting to note here that the formation of a substantial amount of 3-methyl-7-bromohydrocoumarin was obtained in this reaction. Although the formation of lactone in the Hunsdiecker reaction has rarely been reported, it may not be particularly unusual when the Hunsdiecker reaction is applied to a carboxylic acid that bears a phenyl group at the β-position. In fact, Pandit and Dirk[8a] reported that 4-phenylcoumarin and 4-phenylhydrocoumarin were obtained in 43 and 25% yields respectively in the reaction of silver salt of 3, 3-diphenylpropionic acid with bromine, while similar formations of lactones were reported by Berr[1a] and Wilt[8b]. The structure of the lactone, 3-methyl-7-bromohydrocoumarin, was confirmed from the information on infrared spectra, and NMR spectra and from an elemental analysis.

The Simonini Reaction.—The reaction of iodine in ether or a carbon tetrachloride solution with optically active silver β-phenylisobutyrate at a boiling temperature yields optically active 1-phenyl-2-propyl β-phenylisobutyrate, carbon dioxide, silver iodide, and optically active β-phenylisobutyric acid. In this case, however, no detectable amount of the lacton was formed. The ester obtained was then subjected to alkaline hydrolysis in order to examine the stereochemical change in the alcohol moiety. The results will be shown in the Experimental section.

The β-phenylisopropyl alcohol thus obtained from the hydrolysis of the ester was completely racemized, indicating that the ester was formed via a symmetrical intermediate, probably the 1-phenyl-2-propyl radical, at the initial stage of the formation of 1-phenyl-2-propyl iodide; this iodide eventurally would react with the silver salt to form the ester in the following stage of the ionic process.[9]

Experimental

(+)- and (−)-Silver β-Phenylisobutyrate.—Optically active β-phenylisobutyric acid was prepared following DeTar's method.[10] The optically active acid ($[\alpha]_D^{17}$ +21.7, *c* 0.0559 and $[\alpha]_D^{15}$ −9.8, *c* 0.0254) was neutralized with aqueous potassium hydroxide, and the hot solution was treated with a one-equivalent amount of aqueous silver nitrate. The preciptated silver salt was washed with water and acetone, and then dried on phosphorous pentoxide in vacuo.

The Hunsdiecker Reaction.—Silver salt (6 g.) was suspended with stirring in boiling dry carbon tetrachloride (54 ml.), to which bromine (3.6 g.) was then added. The solution was heated under refluxing for about 8 hr., allowed to stand overnight, and then refluxed with stirring for 3 hr. During this period, the evolution of a detectable amount of carbon dioxide was noticed by passing the gas through a saturated barium hydroxide solution. The reaction mixture was filtered. The filtrate was washed with 30 ml. of 10% sodium bicarbonate and then with water, and then the aqueous layer was extracted with carbon tetrachloride. The carbon tetrachloride layers were then combined and dried over sodium sulfate. There were thus obtained 0.8 g. of β-phenylisopropyl bromide (b. p. 90°C/10 mmHg) and 150 mg. of 3-methyl-7-bromohydrocoumarin (b. p. 126—130°C/1 mmHg; m. p. 127—128°C) by fractional distillation, and 0.75 g. of the tarry residue was left. β-Phenylisopropyl bromide, which was identified by comparing its infrared spectrum with that of an authentic sample, was practically all racemized; $[\alpha]_D^{20}$ +1.3, *c* 0.0365 (using (−)-silver salt), +0.88, *c* 0.0756 (using (+)-silver salt). 3-Methyl-7-bromohydrocoumarin was in the form of colorless crystalline plates, m. p. 127—128°C (from ethyl alcohol), Found: C, 50.22; H, 4.11. Calcd. for $C_{10}H_9O_2Br$: C, 49.82; H, 3.76; spectral peaks appeared at: IR: 1760 cm^{-1} and 1715 cm^{-1}; UV: λ_{max}^{EtOH} 275, 283, 321 mμ; λ_{min}^{EtOH} 298 mμ; 60 MC. NMR (Deuterochloroform): a doublet at 1.36 τ, a multiplet at 2.87 τ, and a multiplet at 7.12 τ. The peak areas are in the ratio of 1 : 1 : 1. The position of bromine on the benzene ring was assigned from the NMR spectra, thus, 5-H; multiplet at 6.88 τ, 6-H; doublet at 7.43 τ, 8-H; singlet at 7.29 τ, (intensities 1 : 1 : 1). $[\alpha]_D^{22}$ +12.0, *c* 0.029 (using (+)-silver salt). Meanwhile, 1 g. of optically active β-phenylisobutyric acid ($[\alpha]_D^{20}$ +21.2, *c* 0.0636 (using (+)-silver salt), −9.8 (using (−)-silver salt), b. p. 122°C/2 mmHg) was obtained by acidifying the water layer with concentrated sulfuric acid.

The Simonini Reaction.—Optically active silver β-phenylisobutyrate (8 g.) was suspended in dry ether (50 ml.), into which was then stirred iodine (3.7 g). in dry ether (17 ml.). The solution immediately turned light yellow. It was then refluxed for 3 hr. under a nitrogen stream. The carbon dioxide (about 0.18 g.) evolved was trapped through an aqueous barium hydroxide solution. The silver iodide was separated from the reaction mixture by filtration; the filtrate was washed initially with a 5% aqueous potassium hydroxide solution, then with aqueous sodium thiosulfate, and finally with water, and then dried over sodium sulfate. Only 2.3 g. of optically active 1-phenyl-2-propyl β-phenylisobutyrate ($[\alpha]_D^{15}$ +30.8, *c* 0.0635 (using (+)-silver salt), −12.9, *c* 0.0416 (using (−)-silver salt), b. p. 145°C/1 mmHg) was obtained from the ether layer. One gram of optically active β-phenylisobutyric acid ($[\alpha]_D^{13}$ +21.7, *c* 0.0584 (using (+)-silver salt), −9.8 (using (−)-silver salt)) was obtained from the water layer.

By using carbon tetrachloride instead of ether as a solvent, a similar result was also obtained.

The hydrolysis of the optically active ester (1.3 g.) was performed by allowing it to dissolve in a mixture of potassium hydroxide (0.5 g.), water (0.2 g.), and methyl alcohol (12 ml.) at room temperature for 3 hr. Optically inactive β-phenylisopropyl alcohol (b. p. 74—76°C/3 mmHg, $[\alpha]_D^{15}$ +0.5, *c* 0.054 (using the (+)-ester), +0.7, *c* 0.0353 (using the (−)-ester)) and optically active β-phenylisobutyric acid ($[\alpha]_D^{13}$ +21.7, *c* 0.0431 (using the (+)-ester), −9.8, *c* 0.0254 (using the (−)-ester)) were obtained. In a separate experiment, it was confirmed that there was no change in optical rotation for this and a similar alcohol under the same conditions as in the hydrolysis.

The optical rotations of all the above samples were measured in absolute ethyl alcohol.

The authors wish to thank Dr. Tetsushi Yamashita, Department of Chemistry, Faculty of Science, Osaka City University, for his help in the use of the polarimeter, and Dr. Yutaka Asahi, Laboratory of Takeda Chem. Ind., Ltd., for his collaboration in the NMR study.

Heptafulvenes. V. Some Substitution Reactions of 2, 3-Dimethoxy-8, 8-dicyanoheptafulvenes

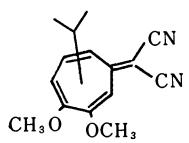
By Yoshio KITAHARA,*1 Kozo DOI*2 and Tadahiro KATO*1

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

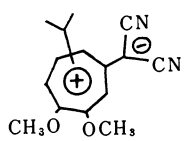
(Received February 19, 1966)

Methoxyl groups of alkyl-2, 3-dimethoxy-8, 8-dicyanoheptafulvenes were easily replaced by various kinds of nucleophilic reagents to give the corresponding substituted-8, 8-dicyanoheptafulvenes. There exists a difference in reactivity between the two methoxyl groups located at the 2 and 3 positions of 8, 8-dicyanoheptafulvenes. The isopropyl group at the 4 position of 2, 3-dimethoxy-8, 8-dicyanoheptafulvene hindered some substitution reactions of the methoxyl group at the 3 position.

The previous paper[1] reported the formation of 2, 3-dimethoxy-8, 8-dicyanoheptafulvene and its alkyl derivatives. Since isopropyl-2, 3-dimethoxy-8, 8-dicyanoheptafulvene (I) possesses the large dipole moment of 8.85 Debye units, there may be considered to be a large contribution of the ionic structure (II).[2a] The π-electron density at each atom in the heptafulvene derivative has also been calculated by Katagiri[2b] (Fig 1).



(I)



(II)

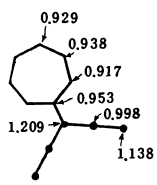


Fig. 1. π-Electron density at each atom in 8,8-divinyl heptafulvene (by Katagiri).

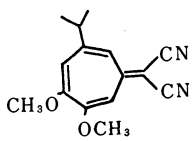
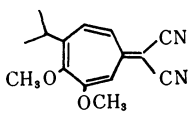
On the basis of these data, the methoxyl groups at the 2 and 3 positions of I may be expected to undergo various kinds of nucleophilic substitution reactions, and it is reasonable to expect that there is a difference between the reactivities of the methoxyl groups at the 2 and 3 positions and that the group at the 3 position might be more reactive if other factors are not considered.

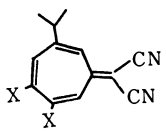
When 5-isopropyl-2, 3-dimethoxy-8, 8-dicyanoheptafulvene (III) is allowed to react with such amines as ammonia, methylamine and dimethylamine, the disubstituted products, V, VI and VII, respectively, are formed.



(III)



(IV)



(V) X=NH_2
(VI) X=$NHCH_3$
(VII) X=$N(CH_3)_2$

V reacts with acids or acid chlorides to give as products VIII, IX, X and XI, all of which have an imidazole nucleus. The possibility of these condensation products being 1, 3-diazaazulene derivatives (structure b) was eliminated by an examination of their infrared and ultraviolet absorption spectra. The infrared spectra of these compounds show conjugated nitriles at 2175 and 2195 cm^{-1}, and their ultraviolet spectra are completely different from that of 1, 3-diazaazulene.[3] III reacts with guanidine to give the corresponding condensation product. From its molecular formula and its spectral data, it was concluded

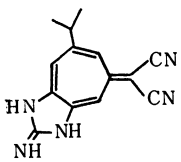
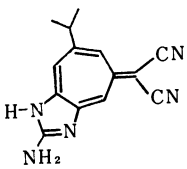
(VIII) R=H
(IX) R=CH_3
(X) R=Ph
(XI) R=*p*-NO_2·Ph

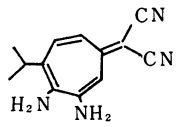


(XIIa)

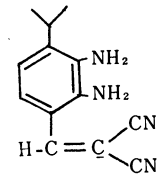


(XIIb)

4-Isopropyl-2, 3-dimethoxy-8, 8-dicyanoheptafulvene (IV) gave a yellow crystalline substance (XIII) and a white crystalline substance (XIV) in almost equal amounts upon reaction with liquid ammonia. The composition of both XIII and XIV satisfies $C_{13}H_{14}N_4$, but their ultraviolet absorption spectra are quite different. The spectrum of XIII is similar to that of 8, 8-dicyanoheptafulvene, but the spectrum of XIV, which shows no absorption in the longer wave region and which is similar to that of dicyanostyrene, suggests that XIV does not possess a heptafulvene structure. XIV seems to be a six-membered ring compound formed by rearrangement reaction* during the formation of XIII.

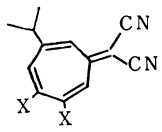


(XIII)

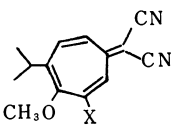


(XIV)

III readily undergoes substitution reactions with sodium ethoxide or sodium ethyl mercaptide, affording a disubstituted product, XV or XVI respectively. In the case of IV, however, the reaction with sodium ethyl mercaptide affords not a disubstituted product but monosubstituted product (XVII); this is due to the steric hindrance of the isopropyl group to the attack of the anionoid reagent.



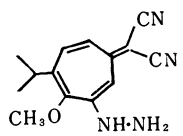
(XV) X=OC_2H
(XVI) X=SC_2H_5



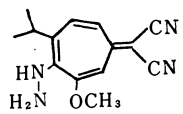
(XVII) X=SC_2H_5

IV reacts with hydrazine to afford a monohydrazino compound (XVIIIa or XVIIIb). The XVIIIa structure is more likely for the compound since the steric hindrance of the isopropyl group would be expected to prevent the 3-methoxyl group from substituting.

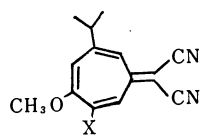
The reaction of III with sodium hydrogen sulfide gives a monosubstituted product whose composition corresponds to XIX. XIX is acidic, and the mercapto group is readily methylated by diazomethane to yield XX. By the reaction with ethylenediamine or with hydrazine, III does not afford a disubstituted product, but gives a monosubstituted product, XXI or XXII. For each of these monosubstituted products, there are two possible structures, a and b.



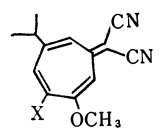
(XVIIIa)



(XVIIIb)

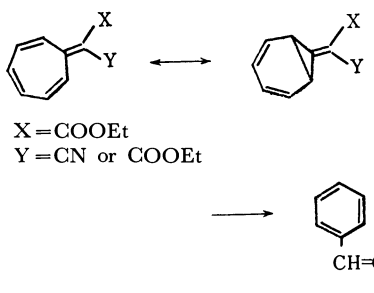


(a)



(b)

(XIX) X=SH
(XX) X=SCH_3
(XXI) X=NH·$(CH_2)_2$·NH_2
(XXII) X=NH·NH_2



X=COOEt
Y=CN or COOEt

* However, the chemical proof of the structure of XIV will be the subject of further investigation. It is known that 8, 8-disubstituted heptafulvenes undergo a base-catalyzed rearrangement to styrene derivatives; for example, Kitahara and Doi[4] found that 8-cyano-8-ethoxycarbonylheptafulvene and 8, 8-diethoxycarbonylheptafulvene are unstable in alkali and that they easily rearrange to styrene derivatives in the presence of sodium methoxide.

4) Heptafulvenes III, ibid., **37**, 1754 (1964).

It is not apparent that the methoxyl group at the 2 position of III is more reactive than that of the 3 position. Because III lacks the steric interference from an adjacent isopropyl group, unlike IV, the two possible structures, a and b, must be considered as equally likely. However, the ultraviolet and infrared absorption spectra support a.[5]

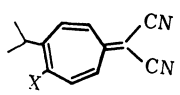
On the basis of these results, it may be concluded that there is a difference between the reactivities of the methoxyl groups at the 2 and 3 positions, and that the one at the 2 position undergoes nucleophilic substitution reactions more easily.

The above conclusion is not in accord with the results calculated by Katagiri. This inconsistency is considered to arise from the interaction between the adjacent two methoxyl groups, and from complication factors, such as the π-p conjugation between the lone paired electrons of the oxygen atom of the methoxyl and the electrons in the ring, which cause discrepancies in the simple calculation.

The hydrazino group of XVIII can be removed by treatment with cupric sulfate - acetic acid to give XXIII, which reacts readily with certain amines to produce the corresponding aminoheptafulvenes, XXIV, XXV or XXVI. However, XXIII does not react with dimethylamine, apparently because of the steric hindrance of the isopropyl group adjacent to the methoxyl group.

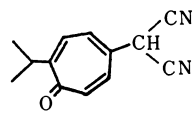
The methoxyl group of XXIII is readily hydrolyzed with alkali to yield the corresponding hydroxy compound, which is considered to have the XXVIIa structure rather than the tautomeric keto form, XXVIIb, on the basis of the following facts: (i) the ultraviolet absorption spectrum of the hydroxy compound is similar to that of heptafulvene, (ii) the infrared absorption spectrum of the compound indicates the presence of a conjugated nitrile, and (iii) the compound gives an acetate (XXVIII).

When treated with cupric sulfate - acetic or hydrochloric acid, XXIV affords 3-isopropyl-8, 8-dicyanoheptafulvene (XXIX) or 3-chloro-4-isopropyl-8, 8-dicyanoheptafulvene (XXX) respectively.



(XXIII) X=OCH_3 (XXVIIa) X=OH
(XXIV) X=$NH \cdot NH_2$ (XXVIII) X=OAc
(XXV) X=NH_2 (XXIX) X=H
(XXVI) X=$NHCH_3$ (XXX) X=Cl

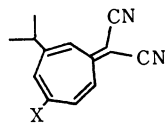
XXII yields XXXI by the analogous dehydrazination reaction. The methoxyl group of XXXI



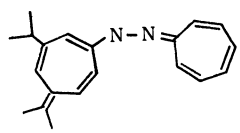
(XXVIIb)

is readily replaced by amino groups to produce the aminoheptafulvenes, XXXII, XXXIII or XXXIV. Because of the absence of the steric interference of the isopropyl group, XXXI gives XXXV by reaction with dimethylamine.

The dehydrazination of XXXII gives 2-isopropyl-8, 8-dicyanoheptafulvene XXXVI. XXXII readily condenses with tropone to yield the corresponding condensation products, XXXVII.



(XXXI) X=OCH_3 (XXXIV) X=$NHCH_3$
(XXXII) X=$NH \cdot NH_2$ (XXXV) X=$N(CH_3)_2$
(XXXIII) X=NH_2 (XXXVI) X=H



(XXXVII)

Experimental

The Reaction of 5-Isopropyl-2, 3-dimethoxy-8, 8-dicyanoheptafulvene (III) with Amines.—*Liquid Ammonia.*—A mixture of 1.5 g. of III and 30 ml. of liquid ammonia was allowed to stand at room temperature for 2 days. The evaporation of the resulting red solution left a yellow crystalline residue which was then dissolved in ethanol and chromatographed over alumina. The recrystallization of the eluted crystals from methanol gave orange needles of V, m. p. >260°C.

Found: C, 68.98; H, 5.92; N, 24.56. Calcd. for $C_{13}H_{14}N_4$: C, 69.00; H, 6.24; N, 24.76%.

UV λ_{max}^{MeOH} mμ (log ε): 245 (4.11), 335 (4.45), 405 (4.45).

Liquid Methylamine.—By a procedure similar to that described above, 500 mg. of III and 30 ml. of liquid methylamine afforded 430 mg. of orange scales (VI) after recrystallization from ethanol, m. p. 260—261°C (decomp.).

Found: C, 71.08; H, 6.54; N, 21.53. Calcd. for $C_{15}H_{18}N_4$: C, 70.83; H, 7.13; N, 22.03%.

UV λ_{max}^{MeOH} mμ (log ε): 258 (4.14), 330 (4.36), 425 (4.42).

Liquid Dimethylamine.—A mixture of 700 mg. of III and 50 ml. of liquid dimethylamine, after recrystallization from ethanol, yielded 500 mg. of VII as red prisms, m. p. 184—185°C.

Found: C, 72.14; H, 7.38; N, 19.44. Calcd. for $C_{17}H_{22}N_4$: C, 72.30; H, 7.85; N, 19.84%.

5) Heptafulvenes VII, to be published.

UV λ_{max}^{MeOH} mμ (log ε): 285 (4.01), 340 (4.17), 455 (4.24).

The Reaction of 2, 3-Diamino-5-isopropyl-8, 8-dicyanoheptafulvene V with Acids or Acid Derivatives.—*With Formic Acid.*—A mixture of 5 ml. of 80% formic acid and 400 mg. of V was refluxed for 30 min. After the excess formic acid had been removed under reduced pressure, the resulting red crystalline material was recrystallized from methanol to yield 180 mg. of red scales (VIII), m. p. >280°C.

Found: C, 71.19; H, 4.74; N, 23.80. Calcd. for $C_{14}H_{12}N_4$: C, 71.16; H, 5.12; N, 23.72%.

UV λ_{max}^{MeOH} mμ (log ε): 245 (4.20), 290 (4.00), 410 (4.52).

With Acetic Anhydride.—A mixture of 300 mg. of V and 20 ml. of acetic anhydride was refluxed for one hr., after which the acetic anhydride was distilled off under reduced pressure. The addition of water to the residue precipitated red crystals (200 mg.) which, after filtration, were taken up in ethanol and passed through an alumina column. The recrystallization of the eluted material from ethanol gave red scales (IX), m. p. >300°C.

Found: C, 71.68; H, 5.11; N, 21.95. Calcd. for $C_{15}H_{14}N_4$: C, 71.97; H, 5.64; N, 22.39%.

UV λ_{max}^{MeOH} mμ (log ε): 250 (4.27), 295 (4.17), 415 (4.54).

With Benzoyl Chloride.—A solution of 400 mg. of V in 10 ml. of anhydrous pyridine was mixed with 1.5 mol. equivalents of benzoyl chloride and allowed to stand at room temperature overnight. After the pyridine had been distilled off, the residue was refluxed in 20 ml. of methanol for one hr. and then allowed to cool. The red crystalline deposit (300 mg.), after recrystallization from an ethyl acetate-methanol (1 : 1) mixture, afforded reddish violet scales (X), m. p. >300°C.

Found: C, 76.93; H, 4.71; N, 17.53. Calcd. for $C_{20}H_{16}N_4$: C, 76.90; H, 5.16; N, 17.94%.

UV λ_{max}^{MeOH} mμ (log ε): 240 (4.30), 265 (4.24), 330 (4.50), 410 (4.57).

With p-Nitrobenzoyl Chloride.—The reaction between V and *p*-nitrobenzoyl chloride was carried out in a manner similar to that described above. The crude crystals obtained from the reaction of 220 mg. of V and 200 mg. of *p*-nitrobenzoyl chloride in 10 ml. of pyridine were recrystallized from acetone to afford blackish-violet scales (XI), m. p.—300°C.

Found: C, 67.42; H, 4.21; N, 19.57. Calcd. for $C_{20}H_{15}N_5O_2$: C, 67.22; H, 4.23; N, 19.60%.

UV λ_{max}^{MeOH} mμ (log ε): 260 (4.31), 337 (4.57), 413 (4.62).

The Reaction of III with Guanidine.—III (500 mg.) was added to a solution of 200 mg. of guanidine hydrochloride in ethanolic sodium ethoxide (prepared from 50 mg. of sodium and 20 ml. of absolute ethanol), and the mixture was refluxed for 5 hr. The removal of the ethanol afforded a red oil which was then chromatographed over alumina. Ethyl acetate was used as the solvent; 100 mg. of the crystals were obtained from early fractions which, after recrystallization from ethyl acetate, afforded XV as orange plates, m. p. 143—144°C.

Found: C, 71.75; H, 6.86; N, 9.27. Calcd. for $C_{17}H_{20}N_2O_2$: C, 71.80; H, 7.09; N, 9.85%.

UV λ_{max}^{MeOH} mμ (log ε): 245 (4.29), 275 (4.16), 295 (4.17), 408 (4.45).

Then (1 : 1 ethyl acetate-methanol) crystals (210 mg.) were obtained; on recrystallization from ethanol, they gave XII as red needles, m. p. >290°C.

UV λ_{max}^{MeOH} mμ (log ε): 255 (4.13), 310 (4.23), 330 (4.28), 410 (4.54).

Picrate: m. p. 262—263°C (decomp.) Found: C, 49.95; H, 3.47; N, 23.02. Calcd. for $C_{14}H_{13}N_5 \cdot C_6H_3N_3O_7$: C, 50.00; H, 3.35; N, 23.32%.

The Reaction of III with Sodium Ethyl Mercaptide.—A mixture of 250 mg. of III and 20 ml. of ethyl mercaptan containing 50 mg. of sodium was refluxed for 8 hr., and then most of the mercaptan was distilled off. The residue was diluted with 50 ml. of water, and extracted with ethyl acetate. The ethyl acetate extract was washed with water, dried over magnesium sulfate, and evaporated to yield 150 mg. of red crystals which, after recrystallization from ethanol, gave red scales of XVI, m. p. 106—107°C.

Found: C, 64.17; H, 6.34; N, 8.50. Calcd. for $C_{17}H_{20}N_2S_2$: C, 64.54; H, 6.37; N, 8.86%.

UV λ_{max}^{MeOH} mμ (log ε): 295 (sh.), 345 (4.27), 438 (4.45).

The Reaction of III and Sodium Hydrogen Sulfide.—A sodium ethoxide solution (prepared from 5 ml. of absolute ethanol and 70 mg. of sodium) was saturated with hydrogen sulfide, and then 200 mg. of III was added. After the mixture had been heated for several minutes, the ethanol was removed and the residue was diluted with dilute sulfuric acid to afford 200 mg. of yellow crystals (XIX), m. p. 219—220°C (decomp.). When XIX was heated in ethanol, it changed into an insoluble blackish-red material which could not be purified.

A suspension of 200 mg. of the crude XIX in ethanol was treated with an excess of diazomethane. After the solvent had been removed, the residue was dissolved in benzene and passed through an alumina column. The evaporation of the solvent afforded red needles (XX), m. p. 174—175°C.

Found: C, 66.13; H, 6.14; N, 9.97. Calcd. for $C_{15}H_{16}N_2OS$: C, 66.16; H, 5.92; N, 10.29%.

UV λ_{max}^{MeOH} mμ (log ε): 260 (4.15), 330 (4.04), 415 (4.47).

The Reaction of III with Ethylenediamine.—To a solution of 50 ml. of absolute ethanol containing 90 mg. of sodium, 260 mg. of ethylenediamine hydrochloride and 510 mg. of III were added, the mixture was then refluxed for one hr. The removal of the ethanol afforded a red oil which, after being chromatographed over alumina using ethanol, yielded 300 mg. of crystals. Recrystallization from ethanol gave orange plates (XXI), m. p. 248—250°C (decomp.).

Found: C, 67.77; H, 6.77; N, 19.37. Calcd. for $C_{16}H_{20}N_4O$: C, 67.58; H, 7.09; N, 19.71%.

UV λ_{max}^{MeOH} mμ (log ε): 250 (4.17), 350 (4.55), 410 (4.37).

The Reaction of III with Hydrazine.—A large excess of 80% hydrazine was added to a suspension of 400 mg. of III in 40 ml. of ethanol at 50°C. The mixture was heated for 5 min., and then diluted with 200 ml. of water to give 260 mg. of crystals. Recrystallization from an ethanol-ethyl acetate mixture afforded orange scales (XXII), m. p. 204—205°C (decomp.).

Found: C, 65.72; H, 5.93; N, 21.84. Calcd. for $C_{14}H_{16}N_4O$: C, 65.60; H, 6.29; N, 21.86%.

UV λ_{max}^{MeOH} mμ (log μ): 240 (4.24), 325 (4.33), 405 (4.44).

The Reaction of 4-Isopropyl-2, 3-dimethoxy- 8, 8-dicyanoheptafulvene (IV) with Liquid Ammonia.—A mixture of 450 mg. of IV and 40 ml. of liquid ammonia was allowed to stand overnight at room temperature, and then the ammonia was distilled off. The residue was treated with methanol. The methanol-insoluble yellow crystalline material (150 mg.) was dissolved in ethanol and chromatographed over alumina to afford yellow crystals (XIII), m. p. >260°C.

Found: C, 68.93; H, 6.23; N, 24.95. Calcd. for $C_{13}H_{14}N_4$: C, 69.00; H, 6.24; N, 24.76%.

UV λ_{max}^{MeOH} mμ (log ε): 225 (4.25), 245 (4.01), 330 (4.38), 410 (4.47).

From the methanol-soluble part, 150 mg. of white needles (XIV), m. p. >270°C, were obtained.

Found: C, 68.43; H, 6.01; N, 24.42. Calcd. for $C_{13}H_{14}N_4$: C, 69.00; H, 6.24; N, 24.76%.

UV λ_{max}^{MeOH} mμ (log ε): 225 (4.26), 300 (4.36).

The Reaction of IV with sodium Ethyl Mercaptide.—To 30 ml. of ethyl mercaptan containing 80 mg. of sodium, 500 mg. of IV were added, and then the mixture was refluxed for 8 hr. After the ethyl mercaptan had been removed, the residue was treated with water and extracted with ethyl acetate. The ethyl acetate extract was washed with dilute sulfuric acid and then with water. Drying over magnesium sulfate and the removal of the solvent afforded 500 mg. of a red oil, which was then taken up in benzene and chromatographed on alumina. Red plates (XVII), m. p. 131—132°C, were obtained after recrystallization from ethanol.

Found: C, 66.82; H, 6.06; N, 9.63. Calcd. for $C_{16}H_{18}N_2OS$: C, 67.11; H, 6.34; N, 9.78%.

UV λ_{max}^{MeOH} mμ (log ε): 225 (3.87), 335 (4.26), 442 (4.42).

The Reaction of IV with Hydrazine.—By the procedure described for the formation of XXII from III, 200 mg. of red needles (XVIII), m. p. 208—209°C, were obtained from 300 mg. of IV.

Found: C, 65.98; H, 6.06; N, 21.99. Calcd. for $C_{14}H_{16}N_4O$: C, 65.60; H, 6.29; N, 21.86%.

UV λ_{max}^{MeOH} mμ (log μ): 243 (4.09), 315 (4.24), 405 (4.42).

The Dehydrazination of 2-Hydrazino-5-isopropyl-3-methoxy-8, 8-dicyanoheptafulvene (XXII).—Into a boiling suspension of 200 mg. of XXII in a mixed solvent of 5 ml. of acetic acid and 5 ml. of water, 10 ml. of a 10% aqueous cupric sulfate solution was stirred, drop by drop. The boiling was continued for 20 min., after which time gas evolution ceased. The reaction mixture was allowed to come to room temperature, and then diluted with water and extracted with ethyl acetate. The ethyl acetate extract was washed with a dilute aqueous sodium hydroxide solution and then with water, dried over magnesium sulfate, and evaporated. The brown crystalline residue was dissolved in ethyl acetate and passed through an alumina column. The crystals (100 mg.) so obtained were recrystallized from ethanol to give orange needles (XXXI), m. p. 175.5—177.5°C.

Found: C, 74.09; H, 5.85; N, 12.51. Calcd. for $C_{14}H_{14}N_2O$: C, 74.31; H, 6.24; N, 12.38%.

UV λ_{max}^{MeOH} mμ (log ε): 238 (4.29), 280 (3.85), 418 (4.48).

The Dehydrazination of XVIII.—The procedure was the same as that described for the dehydrazination of XXII. Red prisms (XXIII), m. p. 141—142°C, after recrystallization from ethanol, were obtained from XVIII.

Fonnd: C, 74.36; H, 6.12; N, 12.54. Calcd. for $C_{14}H_{14}N_2O$: C, 74.31; H, 6.24; N, 12.38%.

UV λ_{max}^{MeOH} mμ (log ε): 238 (4.03), 250 (4.04), 428 (4.50).

Depending on the experimental conditions, orange needles, m. p. 255°C (decomp.), could be obtained in addition to XXIII.

Found: C, 64.36; H, 5.74; N, 18.63. Calcd. for $C_{16}H_{18}N_4O_2$: C, 64.41; H, 6.08; N, 18.78%.

UV λ_{max}^{MeOH} mμ (log ε): 240 (4.09), 307 (4.29), 410 (4.58).

IR: 3250 (NH), 1660, 1626, 1285 cm^{-1}.

From the results of microanalysis and a study of its infrared spectrum, the above compound was deduced to be 2-acetylhydrazino-4-isopropyl-3-methoxy-8, 8-dicyanoheptafulvene.

The Reaction of XXIII with Hydrazine.—To a solution of 100 mg. of XXIII in 2 ml. of ethanol there was added 27 mg. of a 80% hydrazine hydrate aqueous solution. The concentration of this solution afforded 50 mg. of red crystals which were recrystallized from ethanol to give red prisms (XXIV), m. p. 187—188°C (decomp.).

Found: C, 68.92; H, 5.81; N, 25.13. Calcd. for $C_{13}H_{14}N_4$: C, 69.00; H, 6.24; N, 24.76%.

UV λ_{max}^{MeOH} mμ (log ε): 250 (4.12), 330 (3.89), 465 (4.56).

The Reaction of XXIII with Ammonia.—A mixture of 50 mg. of XXIII and 10 ml. of methanolic ammonia was allowed to stand overnight at room temperature; then the solvent was removed. The resulting crystalline material was recrystallized from ethanol to give orange prisms (XXV), m. p. 234—235°C (decomp.).

Found: C, 73.90; H, 5.67; N, 20.27. Calcd. for $C_{13}H_{13}N_3$: C, 73.90; H, 6.20; N, 19.89%.

UV λ_{max}^{MeOH} mμ (log ε): 250 (4.17), 308 (3.88), 465 (4.59).

The Reaction of XXIII with Methylamine.—To a solution of 50 mg. of XXIII in 4 ml. of ethanol, 1 ml. of a 40% aqueous methylamine solution was added; the mixture was then refluxed for 5 min. On cooling to room temperature, 50 mg. of orange needles (XXVI), m. p. 256—257°C (decomp.), were obtained.

Found: C, 75.05; H, 6.26; N, 18.64. Calcd. for $C_{14}H_{15}N_3$: C, 74.64; H, 6.71; N, 18.65%.

UV λ_{max}^{MeOH} mμ (log ε): 220 (4.31), 255 (4.10), 325 (3.85), 465 (4.57).

The Reaction of XXIII with Dimethylamine.—To a solution of 50 mg. of XXIII in 6 ml. of ethanol, 1 ml. of a 33% aqueous dimethylamine solution was added. The concentration of this mixture afforded 20 mg. of orange needles, m. p. 255—256°C (decomp.), which were identified as XXVI by microanalysis and by a study of their infrared spectrum. XXVI seems to be formed by the reaction of XXIII with the methylamine contained in the dimethylamine.

3-Hydroxy-4-isopropyl-8, 8-dicyanoheptafulvene (XXVII).—A mixture of 200 mg. of XXIII, 20 ml. of water, and 2 N sodium hydroxide was heated. The acidification of the resulting red solution with sulfuric acid precipitated crystals which were recrystallized from benzene-methanol to afford orange prisms (XXVII), m. p. 226—227°C (decomp.).

Found: C, 73.36; H, 5.23; N, 13.40. Calcd. for $C_{13}H_{12}N_2O$: C, 73.56; H, 5.70; N, 13.20%.

UV λ_{max}^{MeOH} mμ (log ε): 243 (4.19), 295 (3.64), 440 (4.60).

The Acetylation of XXVII.—After a mixture of 150 mg. of XXVII and 2 ml. of acetic anhydride has been refluxed for 1 hr., the solvent was distilled off. The recrystallization of the residue from methanol afforded 80 mg. of orange scales (XXVIII) m. p. 137—138°C.

Found: C, 71.07; H, 5.24; N, 11.28. Calcd. for $C_{15}H_{14}N_2O_2$: C, 70.85; H, 5.55; N, 11.02%.

UV λ_{max}^{MeOH} mμ (log ε): 235 (4.10), 257 (4.11), 397 (4.43).

3-Chloro-4-isopropyl-8, 8-dicyanoheptafulvene (XXX).—Into a boiling solution of 2 g. of cupric sulfate in 4 ml. of water, a solution of 100 mg. of XXIV in 6 ml. of concentrated hydrochloric acid was stirred, drop by drop. The heating was continued until the evolution of nitrogen gas ceased. After it had then been allowed to cool to room temperature, the mixture was diluted with water and extracted with ethyl acetate. The extract was washed with water and dried over magnesium sulfate, and the solvent was distilled off. The red, oily residue, after being chromatographed over alumina using a mixed solvent of benzene and ethyl acetate (5 : 1), afforded 20 mg. of orange needles (XXX), m. p. 143—144°C.

Found: C, 68.08; H, 4.59; N, 12.20. Calcd. for $C_{13}H_{12}N_2Cl$: C, 67.69; H, 4.81; N, 12.15%.

UV λ_{max}^{MeOH} mμ (log ε): 240 (4.07), 257 (4.09), 397 (4.40).

3-Isopropyl-8, 8-dicyanoheptafulvene (XXIV).—Into a boiling solution of 5 g. of cupric sulfate in 10 ml. of water and 5 ml. of acetic acid, 180 mg. of XXIV were stirred and then the mixture was heated for 10 min. After being allowed to cool to room temperature, the reaction mixture was extracted with ethyl acetate. The extract was washed with dilute sodium hydroxide and then with water, and dried. The removal of the solvent afforded orange crystals which, after being chromatographed over alumina using a benzene-ethyl acetate (10 : 1) mixture, gave 50 mg. of crystals. Recrystallization from ethanol-cyclohexane gave red needles (XXIX), m. p. 120—121°C.

Found: C, 79.49; H, 5.83; N, 14.33. Calcd. for $C_{13}H_{12}N_2$: C, 79.56; H, 6.16; N, 14.28%.

UV λ_{max}^{MeOH} mμ (log ε): 232 (4.06), 255 (4.10), 397 (4.42).

3-Hydrazino-5-isopropyl-8, 8-dicyanoheptafulvene (XXXII).—By the procedure described for the formation of XXIV from XXIII, 200 mg. (after recrystallization from ethanol) of red prisms (XXXII), m. p. 218—219°C (decomp.), were obtained from 300 mg. of XXXI.

Found: C, 69.12; H, 5.73; N, 24.65. Calcd. for $C_{13}H_{14}N_4$: C, 69.00; H, 6.24; N, 24.76%.

UV λ_{max}^{MeOH} mμ (log ε): 244 (4.20), 330 (3.93), 465 (4.50).

The Condensation Reaction of XXXII with Tropone.—To a solution of 50 mg. of XXXII in 10 ml. of methanol, 4 drops of tropone were added; this mixture was then refluxed for 1.5 hr. After the methanol had been removed, 30 mg. of crystals were obtained. Recrystallization from ethanol gave reddish-violet scales (XXXVII), m. p. 227°C (decomp.).

Found: C, 76.38; H, 5.74; N, 17.47. Calcd. for $C_{20}H_{18}N_4$: C, 76.40; H, 5.77; N, 17.82%.

UV λ_{max}^{MeOH} mμ (log μ): 515 (4.64).

The Reaction of XXXI with Ammonia.—According to the procedure described for the formation of XXV from XXIII, 100 mg. of red prisms (XXXIII), m. p. 260—261°C (decomp.), were obtained from 150 mg. of XXXI.

Found: C, 73.80; H, 5.85; N, 19.91. Calcd. for $C_{13}H_{13}N_3$: C, 73.90; H, 6.20; N, 19.89%.

UV λ_{max}^{MeOH} mμ (log. ε): 242 (4.19), 315 (3.81), 455 (4.48).

The Reaction of XXXI with Methylamine.—When treated by the procedure used for the conversion of XXIII into XXVI, 100 mg. of XXXI afforded 90 mg. of orange needles (XXXIV), m. p. 247—248°C (decomp.).

Found: C, 74.96; H, 6.29; N, 19.27. Calcd. for $C_{14}H_{13}N_3$: C, 75.31; H, 5.87; N, 18.82%.

UV λ_{max}^{MeOH} mμ (log ε): 245 (4.32), 300 (sh.) 320 (3.93), 355 (3.93), 463 (4.53).

The Reaction of XXXI with Dimethylamine.—To a solution of 100 mg. of XXXI in 2 ml. of ethanol, 3 ml. of 33% aqueous dimethylamine was added, then the mixture was refluxed for 1 hr. The concentration of the reaction mixture afforded 40 mg. of red prisms (XXXV) after recrystallization from ethanol.

Found: C, 75.48; H, 6.72; N, 18.00. Calcd. for $C_{15}H_{17}N_3$: C, 75.28; H, 7.16; N, 17.56%.

UV λ_{max}^{MeOH} mμ (log μ): 250 (4.19), 333 (3.90), 465 (4.53).

2-Isopropyl-8, 8-dicyanoheptafulvene (XXXVI).—The procedure was the same as that described for the dehydrazination of XXIV. From 100 mg. of XXXII, 40 mg. of red needles (XXXVI), m. p. 111°C, were obtained.

The authors gratefully acknowledge the award of Maintenance Grants from Sankyo Co. Thanks are also due to Miss Yoko Endo and Miss Yukiko Endo for their elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2450—2453 (1966)

Heptafulvenes. VI. The Structure of 2, 3-Diamino-8, 8-dicyanoheptafulvene Hydrochloride

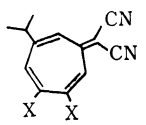
By Tadahiro KATO*

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

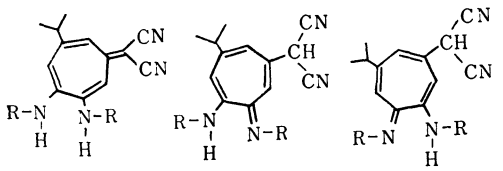
(Received February 11, 1966)

2, 3-Diamino- and 2, 3-bismethylamino-8, 8-dicyanoheptafulvenes gave the corresponding crystalline salts of hydrochloride. From the infrared and ultraviolet spectra, it was concluded that these hydrochlorides are the derivatives of the hydrochloride of 2-aminotropoimine.

In a previous paper,[1] it has been reported that 5 - isopropyl - 2, 3 - dimethoxy - 8, 8 - dicyanoheptafulvene (I) yielded the corresponding diamino compounds II, III and IV respectively, by the reactions with the amines RR'NH (R, R'=H and/or CH_3). It is possible that, besides the heptafulvene structure (A), II and III take a tautomeric 2-aminotropoimine structure, such as B or C.



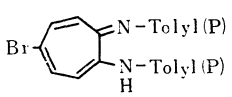
(I) X=OCH_3 (II) X=NH_2
(III) X=$NHCH_3$ (IV) X=$N(CH_3)_2$



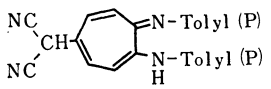
(A) (B) (C)

R=H, CH_3

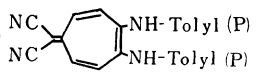
Recently Brasen and his coworkers[2,3] have reported that the product obtained by the reaction of 4-bromo-1-(*p*-tolylamino)-7-(*p*-tolylimino)-1, 3, 5-cycloheptatriene (V) with malononitrile is not 2-aminotropoimine (VIa), but 3, 4-bis-(*p*-tolylamino)-8, 8-dicyanoheptafulvene (VIb).



V



VIa



VIb

The infrared absorption spectra of II, III and IV display absorptions at 2200—2190 cm^{-1} due to the presence of conjugated cyano groups; and four strong absorption bands of two primary amino groups in II, while two strong bands assigned to two secondary amino groups in III are observed in the 3500—3100 cm^{-1} region (Table I).

TABLE I. INFRARED SPECTRA OF 2,3-DIAMINO-8,8-DICYANOHEPTAFULVENES AND THEIR HYDROCHLORIDES

Compound	IR spectra, cm^{-1}		
	NH region	CN region	
II	3490, 3420, 3310, 3254	2170 (S) 2195 (S)	1693, 1643, 1610
III	3380, 3200	2170 (S) 2195 (S)	1625
IV	—	2175 (S) 2195 (S)	1605
VII	3140 3300	2270 (W)	1690, 1645
VIII	3300, 3160	2265 (W)	1695, 1625
X	3430, 3300, 3170	—	1705, 1695, 1645
XI	3440, 3320 3160	—	1735, 1695, 1638

The shapes of the ultraviolet absorption spectra of II and III are similar to that of I in methanol.

It can be concluded from these spectral data that II and III possess a heptafulvene structure, both in solution and in the solid state. This conclusion is in good agreement with the results obtained by Brasen and Benson.

* Present address: Department of Chemistry, Tohoku University, Katahira-cho, Sendai.

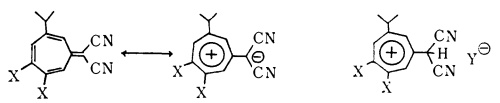
3) W. R. Brasen and R. E. Benson, ibid., **83**, 3135 (1961).

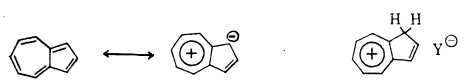
On the other hand, it has become clear that there is a large contribution of an ionic structure, quite similar to that of azulene,[4] to 8, 8-dicyanoheptafulvenes.[5]

Azulene is reported to exist as a tropylium cation in a strongly acidic medium[6,7] and the cation has been isolated as a stable crystalline salt.[8]

It may therefore, be anticipated that heptafulvenes can also exist as cations of the tropylium type in a strongly acidic medium, the cations being stabilized by amino groups at the 2 and 3 positions.



X=OCH_3
=NRR′ (R′=H, CH_3)

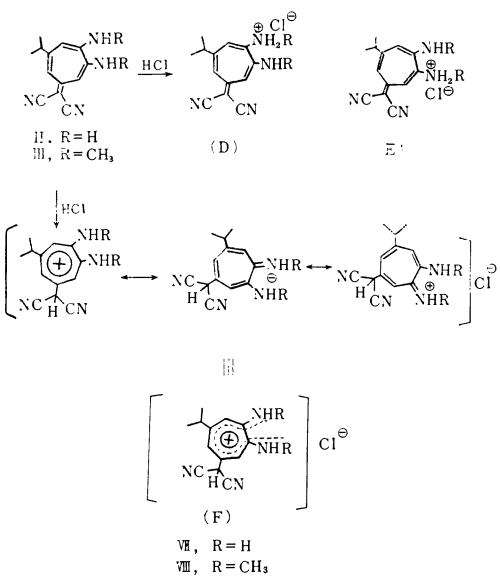


The addition of concentrated hydrochloric acid to compound II at room temperature gives a solution; after several minutes, pale yellow crystals (VII) begin to separate out. The composition of this compound corresponds to $C_{13}H_{14}N_4 \cdot HCl \cdot H_2O$, i. e., an addition product of II with one mole each of hydrochloric acid and water. Compound III also affords a yellow crystalline addition product (VIII), with one mole each of hydrochloric acid and water, i. e., $C_{15}H_{18}N_4 \cdot HCl \cdot H_2O$. Compounds VII and VIII are pale in color compared with the original compounds, II and III, suggesting that they have a different chromophore from those of II and III.

Meanwhile, when compound II or III is treated with hydrochloric acid, two ways of protonation are possible; either the protonation occurs at a nitrogen atom, forming D or E, or the dicyanomethylene groups is protonated, forming a tropylium cation (F), which is similar to the 2-aminotropoimine protonated at the imine nitrogen.

The infrared spectra of VII and VIII show a weak absorption band at 2260—2270 cm^{-1} due to a cyano group which is no longer conjugated. The ultraviolet absorption spectra of these compounds in methanol are similar to that of heptafulvene itself. In 6 N hydrochloric acid, however, they display quite different absorption maxima from those of II or III. Therefore, it can be concluded that VII and VIII have a structure similar to the hydrochloride of 2-aminotropoimine (F).

IV dissolves in 6 N hydrochloric acid, but attempts to isolate a crystalline salt analogous to VII or VIII were unsuccessful. When IV is heated in the same acid, two dimethylamino groups of IV are hydrolyzed, affording 2, 3-dihydroxy - 5 - isopropyl- 8, 8 - dicyanoheptafulvene (IX). Accordingly, the following deduction might be made; owing to the steric interference of the four methyl groups of the two adjacent dimethylamino groups, it becomes impossible for IV to form the structure corresponding to F, in which the lone paired electrons of the nitrogens and the π-electrons of the ring overlap. In a hydrochloric acid solution, IV exists as D or E, i. e., the hydrochloride of a tertiary amine maintaining the heptafulvene structure, which is hydrolyzed to IX. The above deduction is also supported by a similarity between the ultraviolet absorption spectra of IV in 6 N hydrochloric acid and in methanol.



When VII is heated in concentrated hydrochloric acid, a white crystalline compound (X), $C_{12}H_{16}O_2N_2 \cdot HCl$, is obtained, while when it is heated in methanolic hydrochloric acid, VII affords a pale yellow crystalline compound (XI), $C_{13}H_{18}O_2N_2 \cdot HCl$. X and XI are also obtained directly from II by heating it in hydrochloric acid and hydrochloric acid - methanol respectively.

In the infrared spectra of X and XI, no bands to be assigned to cyano groups are present; instead of them, bands at 1705 and 1735 cm^{-1} due to carboxyl and ester groups appear in the spectra of X and

6) Pl. A. Plattner, E. Heilbronner and S. Weker, *Helv. Chim. Acta*, **35**, 1036 (1952).
7) L. H. Chopard-dit-Jean and E. Heilbronner, ibid., **35**, 2170 (1952).
8) K. Hafner, *Ann.*, **625**, 108 (1959); **650**, 35 (1961).

XI respectively. The ultraviolet absorption spectra of these compounds are quite similar to that of VII in 6 N hydrochloric acid; this suggests that VII, X and XI possess the same chromophore (Fig. 1). Accordingly, it can be concluded that X and XI are both hydrochlorides of 2-aminotropoimine derivatives.

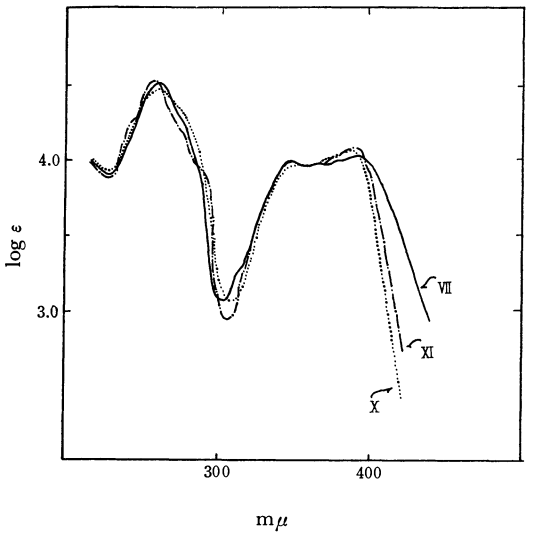

Fig. 1. Ultraviolet spectra of VII in 6 N HCl, X, XI in MeOH.

The infrared absorption spectra of these hydrochlorides, VII, X and XI are similar to each other through the whole spectral region; furthermore, they are very similar to that of the hydrochloride of 2, 5-diaminotropoimine[9] (XII) (Table II). It might, therefore, be assumed that the hydrochlorides of these compounds have similar structures.

TABLE II. IR SPECTRA OF SOME DERIVATIVES OF 2-AMINOTROPOIMINE HYDROCHLORIDES

Similarly, on being heated in hydrochloric acid, 2, 3-diamino-8, 8-dicyanoheptafulvene (XIII) yields XIV, whose ultraviolet and infrared absorption spectra are quite similar to those of X.

When X is heated in 80% formic acid, it gives a 1, 3-diazaazulene derivative (XV).[10,11]

Experimental

2, 3-Diamino-5-isopropyl-8, 8-dicyanoheptafulvene Hydrochloride (VII).—one hundred milligrams of II were dissolved in 1 ml. of 12 N hydrochloric acid; to this solution, active charcoal* was added, and then the charcoal was filtered off. The filtrate, on standing at room temperature, deposited to give pale yellow needles, which were filtered off and washed with water to give 80 mg. of VII, m. p. 216°C (decomp.).

Found: C, 55.60; H, 5.78. Calcd. for $C_{13}H_{14}N_4 \cdot HCl \cdot H_2O$: C, 55.60; H, 6.11%.

UV λ_{max}^{MeOH} mμ (log ε): 260(4.37), 338(4.30), 408 (4.30).

$\lambda_{max}^{6\,N\,HCl}$ mμ (log ε): 263(4.51), 350(3.99), 395(4.0).

5-Isopropyl-2, 3-bis(methylamino)-8, 8-dicyanoheptafulvene Hydrochloride (VIII).—A mixture of 120 mg. of III and 1 ml. of 12 N hydrochloric acid was heated on a water bath for a short time. The mixture then turned orange. The addition of 3 ml. of water to the solution afforded 120 mg. of yellow crystals (VIII); m. p. 211—212°C (decomp.).

Found: C, 58.17; H, 6.43; N, 17.80. Calcd. for $C_{15}H_{18}N_4 \cdot HCl \cdot H_2O$: C, 58.33; H, 6.88; N, 18.11%.

UV λ_{max}^{MeOH} mμ (log ε): 243 (4.26), 338 (4.32), 430 (4.48).

11) T. Nozoe, T. Mukai and I. Murata, *J. Am. Chem. Soc.*, **76**, 3352 (1954).

* Active charcoal was found to be very effective for the purification of the hydrochlorides of 2, 3-diamino-8, 8-dicyanoheptafulvene derivatives.

$\lambda_{max}^{6\,N\ HCl}$ mμ (log ε): 280 (4.63), 358 (4.14), 420 (4.13).

When an ethanol solution of VIII was chromatographed on alumina, using ethanol as the eluting solvent, it yielded yellow crystals, m. p. 255°C (decomp.), which were identified as III by a mixed melting point determination and by a study of the infrared absorption spectrum.

The Reaction of 2, 3-Bis(dimethylamino)-5-isopropyl-8, 8-dicyanoheptafulvene (IV) with Hydrochloric Acid.—The addition of 3 ml. of 6 N hydrochloric acid to a solution of 100 mg. of IV in 3 ml. of ethanol yielded a deep red solution. To this solution a small amount of active charcoal was added, after which the mixture was heated for 30 min. in a water bath. The charcoal was then filtered off, and most of the enthanol of the filtrate was distilled off, affording a crystalline compound (50 mg.), m. p. 234°C (decomp.). An ethanol solution of this compound was treated with diazomethane in ether to yield a yellowish-orange crystalline compound, m. p. 177—178°C, which was proved to be 5-isopropyl-2, 3-dimethoxy-8, 8-dicyanoheptafulvene by a mixed melting point determination with an authentic sample and by a study of its infrared absorption spectrum.

The Reaction of 2, 3-Diamino-5-isopropyl-8, 8-dicyanoheptafulvene (II) with Methanolic Hydrochloric Acid.—a) A mixture of II (100 mg.) and 1 ml. of a 12 N hydrochloric acid-methanol (1 : 1) solution was heated on a water bath for 30 min., and then treated with active charcoal. After the charcoal had then been filtered off, the filtrate was allowed to cool to room temperature; it then gave 80 mg. of yellow prisms (XI), m. p. 221°C (decomp.), after recrystallization from a 12 N hydrochloric acid - methanol (1 : 1) mixture.

Found: C, 57.49; H, 7.09; N, 10.51. Calcd. for $C_{13}H_{18}N_2O_2 \cdot HCl$: C, 57.64; H, 7.07; N, 10.35%.

UV λ_{max}^{MeOH} mμ (log ε): 260 (4.53), 348 (3.99), 390 (4.07).

b) A mixture of II (150 mg.) and 12 N hydrochloric acid (3 ml.) was heated for 20 min., treated with active charcoal, and then filtered. After the filtrate had then been cooled, orange crystals were obtained (100 mg.), those were recrystallized from 12 N hydrochloric acid, affording needles (X), m. p. 275°C (decomp.).

Found: C, 56.31; H, 6.13; N, 10.93; Cl, 14.17. Calcd. for $C_{12}H_{16}N_2O_2 \cdot HCl$: C, 56.30; H, 6.68; N, 10.90; Cl, 13.81%.

UV λ_{max}^{MeOH} mμ (log ε): 260 (4.48), 348 (3.97), 390 (4.00).

2-Amino-4-carboxymethyltropoimine Hydrochloride (XIV).—A mixture of 120 mg. of XIII and 12 N hydrochloric acid (3 ml.) was heated for 5 min. It turned orange. After the heating had been continued at 90°C for 30 min., the solution was treated with active charcoal and the charcoal was filtered off. On cooling, white needles (XIV) (80 mg.), m. p. 270°C (decomp.), were obtained.

Found: C, 50.29; H, 4.86; N, 12.84; Cl, 16.75. Calcd. for $C_9H_{10}N_2O_2 \cdot HCl$: C, 50.35; H, 5.16; N, 13.06; Cl, 16.51%.

UV λ_{max}^{MeOH} mμ (log ε): 257 (4.40), 348 (4.00), 395 (4.04).

7-Isopropyl-5-methyl-1, 3-diazaazulene (XV).—A mixture of 220 mg. of X and 5 ml. of 80% formic acid was refluxed for one hr. The solvent was then distilled under reduced pressure, giving a red oil (XV) (100 mg.), which was then purified by chromatoraphy on alumina, using methanol as the elution solvent.

UV λ_{max}^{MeOH} mμ (log ε): 225 (4.10); 257 (4.18), 370 (3.61), 358 (3.86). Picrate: m. p. 195°C (decomp.).

Found: C, 52.15; H, 4.00; N, 16.95. Calcd. for $C_{18}H_{17}N_5O_7$: C, 52.05; H, 4.13; N, 16.84%.

Intramolecular Hydrogen Bonds. VIII.[1] Isomeric Hydroxycyclohexylcarbinols and Bis-hydroxymethyl-cyclohexanes

By Nobuo Mori and Yojiro Tsuzuki

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received February 21, 1966)

The preferential direction of intramolecular hydrogen bonding in isomeric hydroxycyclohexylcarbinols in dilute carbon tetrachloride solutions has been investigated by infrared spectroscopy. The 1-hydroxy isomer contains a tertiary hydroxyl group predominantly bonded to the oxygen atom of a primary hydroxyl, while the *cis*- and *trans*-2-hydroxy isomers contain a primary hydroxyl group mainly bonded to the oxygen atom of a secondary hydroxyl; the other isomers are internally unbonded. On the other hand, bis-hydroxymethyl-cyclohexanes other than the 1, 1- and 1, 2-isomers are unbonded. These findings can be explained in terms of the acidity of the hydroxyl groups and the steric effect on the orientation of the groups.

The direction and extent of intramolecular hydrogen bonding is particularly sensitive to changes in molecular structure and conformation. In intramolecularly hydrogen-bonded diol systems, the direction of the bonding of one hydroxyl group to another depends on the acidity and/or the basicity of the groups as well as on the steric environment around them; the steric requirement for the orientation of the groups often appears to be more influential than their acidity. For example, when the diols are those which contain a tertiary and a primary hydroxyl group in the 1, 2-position, the steric crowding about the tertiary hydroxyl group causes its hydrogen atom to be directed towards the primary hydroxyl group, resulting in hydrogen-bond formation with the oxygen atom of the latter,[2] although the former group is more basic or proton-accepting than the latter.[3] In *cis*-cyclohexane-1, 2-diols the so-called 1, 3-diaxial steric interaction being exercised on an axial hydroxyl group causes its hydrogen atom to be directed out of the cyclohexane ring; then the hydrogen atom is bonded with the oxygen atom of an equatorial hydroxyl.[2]

In the present investigation, such a preferential direction of hydrogen bonding has been investigated in hydroxycyclohexylcarbinols by means of infrared spectroscopy. Further, this investigation has dealt with the intramolecular hydrogen bonding in bis-hydroxymethyl-cyclohexanes.

Experimental

Samples.—Hydroxycyclohexylcarbinols were prepared in the usual manner by reducing the corresponding hydroxycyclohexane-carboxylates[4] with lithium aluminum hydride in ether. Bis-hydroxymethyl-cyclohexanes were similarly synthesized from the diethyl esters of cyclohexane-dicarboxylic acids.[5,6] They were purified through recrystallizations or redistillations; their physical constants closely agreed with those reported in the literature (see Table I).

Infrared Measurements.—The hydroxyl stretching region was measured by a method previously described,[4] using lithium fluoride optics with carbon tetrachloride solutions in concentrations of 0.004 mol./l. or less at ca. 25°C. Such a concentration was sufficiently low to avoid any intermolecular hydrogen bonding.

Results and Discussion

The data of the observed apparent hydroxyl bands are summarized in Table I, together with the physical constants of the samples.

In cyclohexane systems, characteristic unbonded hydroxyl frequencies[3,13,14] are 3635—3640 cm^{-1} for primary hydroxyl groups, 3627—3632 cm^{-1} and 3623—3630 cm^{-1} for axial and equatorial secondary hydroxyl respectively, and 3613—3619 cm^{-1} for tertiary hydroxyl; each frequency is that of the apparent band peak, which is practically assigned to the hydroxyl group in the sterically-most-preferable one of the three orientations around the C–O axis.[15] In practice for the exact assignment of an apparent free hydroxyl band one should also take account of an additional weaker absorption due to the hydroxyl group in the

XI	*trans*-4-CH_2OH	(66—66.5[6])		3637	1.17	28

other less-preferable orientations; this absorption appears generally as a broadening of the band, centered at a frequency lower by 10—15 cm^{-1} than the apparent peak frequency.[15] In fact, 1, 3- and 1, 4-bis-hydroxymethyl-cyclohexanes (IX—XI), which are internally unbonded, show only one sharp band, at ca. 3637 cm^{-1} somewhat broadened on the lower frequency side. 3-Hydroxycyclohexylcarbinols (IV and V) which are also internally unbonded show two band-peaks at ca. 3637 and 3625 cm^{-1}; the higher intensity of the lower frequency-free secondary hydroxyl band (see the table) may be attributed to such an absorption of the free primary hydroxyl group overlapped with the band. However, when the free secondary hydroxyl band is much stronger than the free primary hydroxyl, as is observed in the spectra (cf. Fig. 2) of 2-hydroxycyclohexylcarbinols (II and III), such an absorption of the primary hydroxyl group, overlapped with the stronger band, is practically negligible, especially for the purpose of confirming the preferential direction of hydrogen bonding.

In this paper, the term "free hydroxyl group" includes both the hydroxyls which contain an unbonded hydrogen atom (i. e., those not participating in any hydrogen bond) and the hydroxyls whose oxygen atom is bonded to the hydrogen atom of another hydroxyl, since the bonding of the oxygen atom of a free hydroxyl group to the hydrogen atom of another hydroxyl has, in general, little effect upon the frequency of the free hydroxyl.[2,3]

1-Hydroxycyclohexylcarbinol (I).—The resolution of the observed spectrum is far from complete, in spite of the relatively wide spacing of 52 cm^{-1} between the band-peaks (3638 and 3586 cm^{-1}), so its graphical separation has been examined by a method previously described.[1,4] This method, shown in Fig. 1, assumes, for convenience, that the individual band-components are symmetric; after subtracting two strong, substantially symmetric bands from the spectrum, a weak broad band remains with a peak frequency

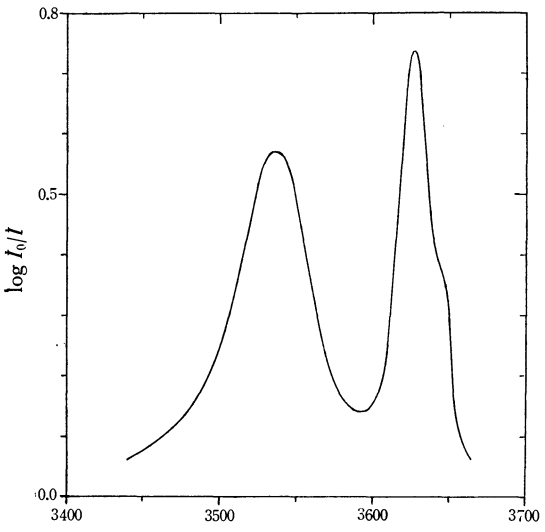

Fig. 2. Infrared spectrum of *cis*-2-hydroxycyclohexylcarbinol (II).

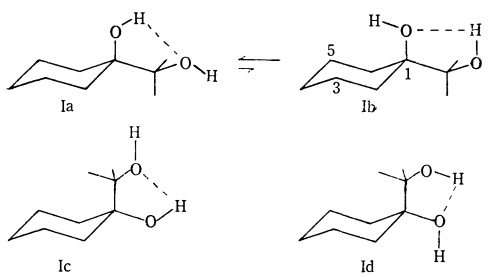
of 3615 cm^{-1}. The resulting band absorbances (and half-band widths in cm^{-1}) are 0.17 (38) for the 3638 band, 0.04 (30) for the 3615 band, and 0.25 (36) for the 3586 band. The separated weak band seems to be due to an additional absorption, (which will be assigned later), rather than to the intrinsic unsymmetry of the strong bands.

This carbinol may take the four interconvertible, internally bonded chair-forms Ia—Id, in which all the valence bonds of any two adjacent atoms are fully staggered:



In assigning the bands to the hydroxyl groups in these forms, one must first take the thermodynamical stability and the population of these forms into account. The difference in free energy between equatorial and axial hydroxyl groups lies in a range of −0.4 to −0.9 kcal./mol.[16]; for the hydroxymethyl group the difference is unknown, but it is expected to be nearly equal to the −1.5 to −1.9 kcal./mole given for the methyl.[16] Since the difference of −1 kcal./mole (the difference between the two averaged values) at 25°C corresponds to an equilibrium constant of ca. 5.3, as calculated using the van't Hoff isotherm, the carbinol may exist predominantly in a chair form containing the hydroxyl group in the axial position. The preference of the axial hydroxyl-containing form holds even when the hydrogen bonding is present, since no large entropy and enthalpy effect may be expected on the equilibrium between the bonded forms. Of the axial hydroxyl-containing forms, Ia and Ib, the preferable one may be Ia, in which the tertiary hydroxyl group is bonded to the oxygen atom of the primary hydroxyl, in spite of the former being more basic or proton-accepting than the latter. The reason is that the axial hydrogens on C_3 and C_5 in Ib may sterically repel the hydrogen of the tertiary hydroxyl group, causing it to be directed out of the cyclohexane ring and then towards the primary hydroxyl, as in Ia. The repulsion can then be removed by going to Ia. This expectation agrees well with the infrared data; the strong bands at 3638 and 3586 cm^{-1} are predominantly due to the free primary hydroxyl group and the bonded axial tertiary hydroxyl group respectively in Ia. The latter frequency agrees well with the 3586 cm^{-1} of the bonded tertiary hydroxyl group in 1, 1-diethylethyleneglycol.[2] On the other hand, the free tertiary hydroxyl group and the bonded primary hydroxyl group in Ib may together principally contribute to the weak band at 3615 cm^{-1}; this is supported by the fact that the frequency agrees with that of ordinary free tertiary hydroxyl groups and with the 3612 cm^{-1} of the bonded primary hydroxyl groups in ethyleneglycols.[2,3]

Further, the separation by 29 cm^{-1} between the free and the bonded tertiary hydroxyl band agrees with the 32 cm^{-1} of ethyleneglycol and 1, 1-diethylethyleneglycol,[2] but it is lower than either the 50 cm^{-1} of 1, 1,-diisopropylethyleneglycol[2] or the ca. 80 cm^{-1} of 1, 1-di-*t*-butylethyleneglycol.[2] Such a lowering in frequency resulting from the 1, 1-disubstitution may chiefly be attributed to the so-called Thorpe-Ingold effect,[17] which results in the decrease in valence angle between the other two bonds of C_1; therefore, the above fact suggests that the cyclohexane ring does not suffer from such an effect, and that, at the same time, the steric repulsion between the hydroxyl group on C_1 and the axial hydrogens on C_3 and C_5 is not so high as to change the valence angle of C_1 to any significant extent.

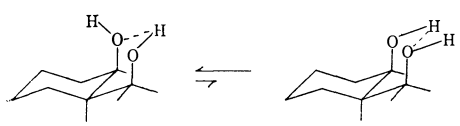
2-Hydroxycyclohexylcarbinols (II and III).— As Fig. 2 shows, the spectra are of a completely-resolved doublet with peak-frequencies of 3625 and 3536 cm^{-1}; the higher frequency band has a weak shoulder, centered at ca. 3640 cm^{-1}. An

16) E. L. Eliel, "Stereochemistry of Carbon Compounds," McGraw-Hill Book Co., New York, N. Y. (1962), p. 236.

17) R. M. Beesley, C. K. Ingold and J. F. Thorpe, *J. Chem. Soc.*, **107**, 1030 (1915); C. K. Ingold, ibid., **119**, 305 (1921); see also Refs. 3 and 12.

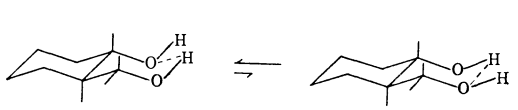
examination of the rough graphical separation shows that the absorbance of the shoulder separated from the spectrum is about 0.19 for II and 0.17 for III.

For *cis*-carbinol II, the axial hydroxyl-containing forms, IIa and IIb, may similarly be preferable to the equatorial hydroxyl-containing forms. The steric environment around the hydroxyl groups included in the hydrogen bond may be essentially the same in both IIa and IIb, so the difference in acidity between the hydroxyl groups may be considered to be a major factor in deciding the direction of hydrogen bonding; therefore, IIa, in which the less basic primary hydroxyl group is bonded to the oxygen atom of the more basic secondary hydroxyl, should be more favorable than IIb. Accordingly, the strong band at 3628 cm^{-1} may primarily be assigned to the free secondary axial hydroxyl group in IIa, while the weak absorption at 3642 cm^{-1} may primarily be assigned to the free primary hydroxyl in IIb. The strong band at 3538 cm^{-1} is mainly due to the bonded primary hydroxyl group in IIa, together with a minor proportion of the bonded secondary hydroxyl in IIb.



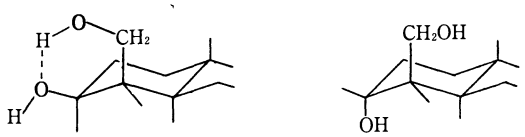
IIa IIb

As for *trans*-carbinol III, only the diequatorial forms, IIIa and IIIb, are possible for hydrogen bonding for the following reasons: (1) any diaxial form should be unfavorable for hydrogen bonding in view of the distance between the hydroxyl groups, and in view of the fact that any such form includes 1, 3-diaxial interactions between the axial hydrogens and the groups, while (2) the diequatorial forms include only the so-called skew interaction between the groups, an interaction which is much lower in energy than the 1, 3-diaxial interaction, and they acquire in addition the stabilization resulting from the hydrogen bond. In IIIa and IIIb, the nature of the hydroxyl groups may similarly be a major factor in controlling the equilibrium between the forms. Accordingly, the strong bands at 3623 and 3535 cm^{-1} may mostly be due to the free secondary hydroxyl group and the bonded primary hydroxyl group in IIIa, while the weak shoulder at 3638 cm^{-1} may be due to the free primary hydroxyl in IIIb.

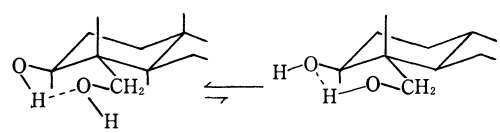


IIIa IIIb

As has been mentioned above, the expected preferential direction of hydrogen bonding of the primary hydroxyl group toward the oxygen atom of the secondary hydroxyl agrees very well with the infrared data. In this connection, there has been an interesting report[18] on the direction of hydrogen bonding in some triterpenoid 3, 24-diols. Urs-12-ene-3β, 24-diol (A) has the primary hydroxyl group bonded to the oxygen atom of the equatorial secondary hydroxyl, the 3α-isomer with the diaxial structure (B) contains no hydrogen bonding, and methyl hederagenin with the diequatorial structure prefers form C to D. It is surprising that the hyderogen bonding in methyl hederagenin is opposite in preferential direction to those in carbinols II and III, the reason for this is not clear at the present time.



A B



C D

3-Hydroxycyclohexylcarbinols (IV and V).— These are internally unbonded. The diaxially fixed structure of *cis*-3-hydroxycyclohexylcarbinol is known[19] to show a bonded hydroxyl band at 3460 cm^{-1}; this fact is not necessarily inconsistent with the absence of bonding in *cis*-carbinol IV for the following reason: the stabilization due to hydrogen bonding in the diaxial conformation can not be sufficient to overcome the instabilization due to the steric repulsion between the diaxial atoms and groups, in view of the fact that the difference in free energy between the diequatorial and the unbonded diaxial conformation is expected to be of the relatively high value of ca. −2.4 kcal./mol.[20] (corresponding to an equilibrium constant of 56), while the ordinary OH–O type intramolecular hydrogen bonding to form a seven-membered ring results in a large decrease in entropy of −10

e. u., with an enthalpy of 2.7 kcal./mol.[23] In other words, the bonded diaxial form, if any, exists in a population so low as to make it impossible to observe its spectral band. In fact, intramolecular hydrogen bonding is present when the difference in free energy is relatively low, e. g., such as the −1.9 kcal./mol.[21] for *cis*-cyclohexane-1, 3-diol, which is known to be hydrogen-bonded.[3]

Bis-hydroxymethyl-cyclohexanes (VI—XI). —The 1, 3- and 1, 4-isomers are internally unbonded, while the 1, 1- and 1, 2-isomers are bonded. The absence of bonding in the *cis*-1, 3-isomer IX can be explained by essentially the same reason as that mentioned in the case of *cis*-3-hydroxycyclohexylcarbinol IV; in this case, however, the difference in free energy between the diequatorial and the diaxial form should be much higher. In the case of the *cis*-1, 4-isomer X, on the other hand the most important factor may be that this compound can not take the boat or twist conformation required for ordinary hydrogen bondings between 1- and 4-*cis* groups.[24]

The authors are thankful to Mr. Teruo Kajiura and Mr. Tadao Tamura of the Government Chemical Industrial Research Institute of Tokyo for the infrared measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2458—2463 (1966)

Copolymerization of Vinyl Chloride and Ethylene Initiated by Trialkylboron-Peroxide Catalyst Systems

By Akira MISONO and Yasuzo UCHIDA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

and Kunikazu YAMADA

Central Research Laboratory, Sekisui Chemical Co., Shimamoto-cho, Mishima-gun, Osaka

(Received February 21, 1966)

Low-pressure copolymerization was carried out in a water-methanol mixture(1 : 1 by weight) at 0°C. It was found that, when hydroperoxides were used as cocatalysts, triethylboron and tri-*n*-butylboron were active as catalysts, while triphenylboron was inactive. As cocatalysts, hydroperoxides were more active than disubstituted peroxides. The highest catalytic activity was observed when the cocatalyst/catalyst molar ratio was 0.4. The initiating radical has been suggested to be the hydroxy radical, and the initiating mechanism has been discussed briefly. The yield and the reduced specific viscosity of the copolymer decrease rapidly with an increase in the ethylene content of the monomer mixture. The monomer reactivity ratios were: r_1(vinyl chloride)=4.16 and r_2(ethylene)=0.05. This indicates that the copolymerization reaction proceeds via a normal radical mechanism. The resulting copolymer shows characteristic absorption peaks at 750 cm^{-1} in the infrared spectrum and at 8.37 τ in the NMR spectrum.

Since Furukawa et al.[1] and Ashikari[2] found that alkyl derivatives of boron acted as powerful radical initiators for vinyl polymerization, many studies have been reported on the polymerization and copolymerization of various vinyl monomers. The copolymerization of vinyl chloride and ethylene at a high pressure has been studied in some detail by Burkhalt et al.[3] and Erussalimsky et al.[4] However, no details have been reported on the radical copolymerization of these monomers at a low pressure.

In the course of their studies of the copolymerization of vinyl chloride and ethylene, the present authors found that trialkylboron and hydroperoxides provided excellent catalyst systems which copolymerize these monomers to high-molecular-weight copolymers with a high ethylene content, even at low temperatures. In order to study this subject further, the authors carried out some experiments; they thus obtained the interesting results to be reported here.

Experimental

Materials.—Vinyl chloride supplied by the Chisso Co. was used without further purification; no impurity was detected in it by gas chromatography. Ethylene supplied by the Nihon Petroleum Co. was used without further purification; no impurity was detected in it by gas chromatography. Triethylboron was prepared from ethylmagnesium bromide and boron trifluoride according to the method of Brown[5] (b. p. 92—112°C). Tri-*n*-butylboron was prepared from *n*-butylmagnesium bromide and boron trifluoride according to the method of Johnsen et al.[6] (b. p. 116°C/21 mmHg). Triphenylboron was prepared from phenylmagnesium bromide and boron trifluoride according to the method of Krause et al.[7] The reaction mixture containing triphenylboron was extracted with benzene several times; then the benzene extract was concentrated and distilled (b.p. 154°C/3 mmHg). The peroxides were used without further purification, while methanol was purified by distillation. Ion-exchanged water was boiled prior to use.

Polymerization.—The reaction vessel was a stainless steel autoclave with a 300 ml. capacity and equipped with an electro-magnetic stirring device. Trialkylboron and peroxide were separately sealed into a glass ampule with a 1 ml. capacity attached to the stirring rod of the autoclave. A measured quantity of the reaction medium, a water-methanol mixture (1 : 1 by weight), was introduced into the autoclave, and the inner air was evacuated by a vaccum pump after the autoclave had been cooled to −30°C. Then a measured quantity of vinyl chloride was introduced into the autoclave from a glass pressure tube. When the temperature of the autoclave reached 0°C, ethylene was introduced from a storage tank and the reaction was started by breaking glass ampules containing catalytic components by means of ethylene pressure. Afterward, the reaction temperature was kept within 0±3°C. After a given time, the reaction was stopped by expelling the residual monomers as soon as possible. The resulting copolymer was filtered, washed repeatedly with water and methanol, and dried in vacuo at 50°C. The crude copolymer thus obtained was then precipitated by adding a tetrahydrofuran solution of the copolymer to methanol, filtered, dried in vacuo at 50°C, and subjected to the following analyses.

Analyses of the Copolymer.—The reduced specific viscosity of the copolymer was measured using 5 g./l. cyclohexanone solution at 30°C. The composition of the copolymer was calculated from the results of the elemental analyses of C, H and Cl. The infrared spectrum of the copolymer was masured with a Hitachi double-beam spectrometer, model EPI-S2 (potassium bromide disk). The NMR spectrum of the copolymer was measured with a Nihon Denshi high-resolution NMR spectrometer, model C-60, in a 10% solution of monochlorobenzene at 60°C, using tetramethylsilane as the internal standard.

Results and Discussion

The Effect of the Catalytic Composition.—Henceforth, alkylboron will be called the catalyst, and the other component, the cocatalyst, according to custom. In many studies using alkylboron as the catalyst, oxygen is used as the cocatalyst. However, considering the difficulty of accurately measuring of the oxygen amount, the authors decided to use organic or inorganic peroxides instead of oxygen.

The results of copolymerization with catalytic systems consisting of various catalysts and cocatalysts are summarized in Table I. It may clearly be seen that if either the catalyst or the cocatalyst is absent, copolymerization does not occur. When trialkylboron is used as the catalyst, the cocatalytic activities decrease in the following order:

t-butyl hydroperoxide ≫ cumene hydroperoxide > benzoyl peroxide > hydrogen peroxide, α, α'-azobisisobutyronitrile, di-*t*-butyl peroxide.

Hydroperoxides are more active than disubstituted peroxides when they are combined with trialkylboron. On the other hand, when *t*-butyl hydroperoxide is used as the cocatalyst, the activities of the catalyst are in the following order:

tri-*n*-butylboron ≈ triethylboron ≫ triphenylboron.

On the basis of the above results, the catalyst system consisting of tri-*n*-butylboron or triethylboron and *t*-butyl hydroperoxide was used in every copolymerization experiment to be reported on in this paper unless otherwise mentioned.

Figure 1 shows the influence of the cocatalyst/catalyst molar ratio on the yield and the reduced specific viscosity of the copolymer. The catalytic activity changes remarkably with the ratio, being highest at the ratio of 0.4. The ethylene content of the copolymer also becomes highest at the same ratio. These results are in agreement with those

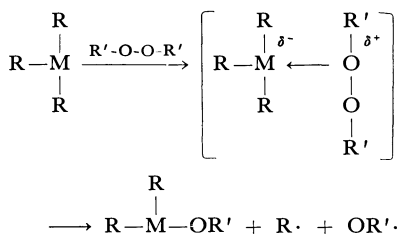
found in vinyl chloride[8] and vinyl acetate[9] polymerizations carried out in the presence of the trialkylboron-oxygen catalyst system, in which the highest catalytic activity has been observed at the point where trialkylboron exists in about a three fold excess over oxygen.

Furukawa et al.[10] have supposed that the initiating mechanism of an organometallic compound-peroxide catalyst system in vinyl chloride polymerization would be as follows:



where the metal may be either aluminum or boron. They have supposed that the resulting radicals might be able to initiate the vinyl polymerization, but no experimental support has been given.

The present authors could isolate a low-molecular-weight copolymer on solution polymerization in *n*-hexane using the triethylboron-cumene hydroperoxide catalyst system. The infrared spectrum of the resulting copolymer is shown in Fig. 2. Before the treatment with benzoyl chloride, the copolymer shows a stretching vibration of the hydroxy group at 3430 cm^{-1}, this vibration disappears when the copolymer is treated with benzoyl chloride, and a new stretching vibration absorption of the carbonyl group appears at 1700 cm^{-1}. The rest of the spectrum is the same as that of the high-molecular-weight copolymer to be shown later.

Hansen et al.,[11] after studying the reaction of triethylboron and oxygen in *n*-hexane, have suggested that an ethyl radical was formed during the reductive decomposition of a peroxide of triethylboron with an excess of triethylboron. In another report,[12] they have shown, from the results of kinetic studies of the polymerization of methylmethacrylate by the triethylboron-oxygen catalyst system, that the highest rate of polymerization was

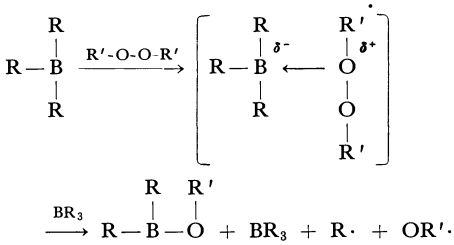
obtained when the triethylboron concentration was twice the oxygen concentration. Also, Bawn et al.[13] and Welch[14] have reported similar findings concerning the initiation mechanism of the trialkylboron-oxygen catalyst system.

From the results of the present authors and those of the other authors cited above, it seems better to consider, also in the case of the trialkylboron-peroxide systems, the initiating radical as arising from such a mechanism in which the 1 : 1 complex of trialkylboron and peroxide is reduced by another molecule of trialkylboron rather than from Furukawa's mechanism. One probable mechanism may be as follows:



Hydroperoxides might be able to coordinate to the boron atom of trialkylboron with less steric hindrance and might, hence, show a greater catalytic activity.

The Effects of the Monomer Composition. —The effects of the monomer composition on the yield and the reduced specific viscosity of the copolymer are shown in Fig 3. As the ethylene content in the monomer mixture increase, both the yield and the viscosity of the copolymer decrease rapidly, ethylene does not polymerize under the present experimetnal conditions.

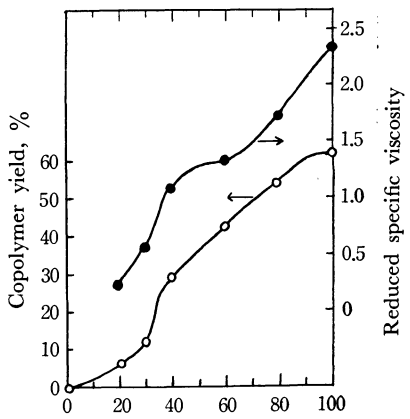


Fig. 3. Effect of monomer composition on yield and reduced specific viscosity of copolymer.
Experimental condition; vinyl chloride+ethylene: 1.0 mol., BBu_3: 2.18 mmol., *t*-BHP/BBu_3: 0.40, water: 93 g., methanol: 93 g., polyvinyl alcohol: 0.25 g., temperature: 0°C, time: 5 hr.

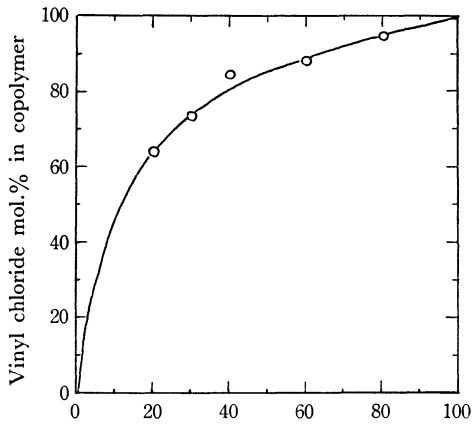

Fig. 4. Effect of monomer composition on copolymer composition.
Experimental condition; vinyl chloride+ethylene; 1 mol., BBu_3: 2.18 mmol., *t*-BHP/BBu: 0.40, water: 93 g., methanol: 93 g., polyvinyl alcohol: 0.25 g., temperature: 0°C, time: 5 hr.

The copolymer composition curve is shown in Fig. 4. The monomer reactivity ratios determined from the Finemann-Ross plot are r_1(vinyl chloride)=4.16 and r_2(ethylene)=0.05. These values almost equal those obtained by the authors using the *t*-butyl hydroperoxide - ascorbic acid catalyst system[15] (r_1=4.70, r_2=0.08). This indicates that the copolymerization reaction proceeds via a normal radical mechanism. The monomer reactivity ratios obtained by the authors are slightly different from those of Burkhalt et al.[1] (r_1=3.60, r_2=0.24) and Erussalimsky et al.[2] (r_1=1.85, r_2=0.20), which have been obtained from high-pressure copolymerization studies.

The Infrared and NMR Spectra of the Copolymer.—The infrared spectra of the copolymers containing 64.08 and 84.55 mol.% of vinyl chloride respectively are shown in Fig. 5. Most of the spectra show features intermediate between those of polyvinyl chloride and those of polyethylene, but a characteristic absorption absent in both homopolymers is observed at 750 cm^{-1}, the intensity of which absorption increases with an increase in the ethylne content of the copolymer.

Sheppard et al.[16] have studied the infrared spectra of polymethylene halides and found that the methylene rocking vibration absorption, which appeared at 720 cm^{-1} in polymethylene, shifted to a higher region, between 770 cm^{-1} and 790 cm^{-1}, in the case of trimethylene or pentamethylene

chloride. From these observations, it seems reasonable to assign the absorption at 750 cm^{-1} observed in the copolymer to the following structure in the copolymer chain:

$$-CHCl-CH_2-CH_2-CH_2-CHCl$$

The NMR spectra of the copolymers containing 64.08 and 84.55 mol.% of vinyl chloride are shown in Fig. 6. The characteristic absorption is observed at 8.32 τ, whereas absorptions at 7.78

τ, 7.96 τ and 5.46 τ are also observed in polyvinyl chloride. Johnsen has made assignments of these absorptions in polyvinyl chloride.[17] An absorption at 8.68 τ is observed also in polyethylene. The characteristic absorption at 8.32 τ may be assigned to the following structure in the copolymer chain:

$$-CHCl-CH_2-CH_2-$$

Summary

The copolymerization of vinyl chloride and ethylene has been carried out by the use of various trialkylbron-peroxide catalyst systems. A catalyst system consisting of triethylboron or tri-*n*-butylboron and *t*-butyl hydroperoxide showed the best activity. As for the molar ratio of the two catalyst components, the highest catalytic activity was observed when the *t*-butyl hydroperoxide/triethylboron molar ratio was 0.4. The initiating radical was supposed to be a hydroxy radical from the results of a study of the infrared spectra of a low-molecular-weight copolymer. The initiating radical might arise from the reductive degradation of a 1 : 1 complex of trialkylboron and peroxide with excess of trialkylboron. The yield and the reduced specific viscosity of the copolymer changed greatly with the composition of the monomer mixture; the richer the vinyl chloride content in the monomer mixture, the higher the yield and viscosity. The monomer reactivity ratios were determined to be r_1(vinyl chloride) : 4.16 and r_2-(ethylene) : 0.05. The infrared spectrum of the copolymer showed a characteristic absorption at 750 cm^{-1}, and also in the NMR spectrum at 8.32 τ. These characteristic absorptions might be assigned to a boundary structure in the copolymer chain as follows:

$$-CHCl-CH_2-CH_2-CH_2-$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2463—2466 (1966)

The Direct Introduction of an Ethoxycarbonyl Group by the Photolysis of Some Substituted Formates in Solution

By Yasuo SHIGEMITSU, Tamotsu TOMINAGA, Takashi SHIMODAIRA,* Yoshinobu ODAIRA and Shigeru TSUTSUMI

Department of Chemical Technology, Faculty of Engineering, Osaka University, Miyakojima-ku, Osaka

(Received February 22, 1966)

The direct introduction of an ethoxycarbonyl group by the photolysis of various substituted formates ($RCO_2C_2H_5$) was carried out. Both ethyl cyanoformate and ethyl chloroformate effectively underwent ethoxycarbonylation by a hydrogen-donating solvent such as cyclohexane, with the yields of 19% and 15%, respectively. On the other hand, the photolysis of ethyl acetate, diethyl carbonate, and ethyl carbamate gives mainly carbinols and carbon monoxide instead of ethyl carboxylate. On the basis of these results, the effects of the substituent in the formate on the ethoxycarbonylation were considered. First, the electronic effect of the substituent R has an influence on the position of the bond fission of the formate. Cyano and chloro groups, which are the electron-withdrawing substituents, weaken the R-carbon bond in the formates. Second, the ability of the hydrogen abstraction of the radical R produced by the photolysis of the formate is very important in the ethoxycarbonylation. Thus, it is clear that there is a relationship between the electron affinity of the radical R and the yield of the ethyl carboxylate.

Since the chloroformylation of cyclohexane by the photolysis of oxalyl chloride was investigated by Kharasch,[1] photochemical studies of the direct introduction of important functional groups, e. g., the nitroso,[2] cyano,[3] carbamoyl[4] and ethyl oxalyl groups,[5] have been extensively carried out. Little attention, however, has been paid to direct alkoxycarbonylation, though this is very valuable

in organic synthesis. In our preliminary report,[6] the possibility of the direct introduction of an ethoxycarbonyl group into cyclohexane by means of the photolysis of ethyl cyanoformate was verified. In this paper, we wish to report on ethoxycarbonylation by the photolysis of various substituted formates, focusing attention on the effect of the substituent in the formate on the ethoxycarbonylation.

Results and Discussion

Although the photochemical reactions of alkyl esters (e. g., RCO_2R') are very complicated, it is generally considered that the following four primary steps proceed through the excitation of the molecule by the $n\rightarrow\pi^*$ transition of the carbonyl group in the esters:

$$R\text{-}\overset{\overset{O}{\|}}{C}\text{-}OR' \xrightarrow[n\rightarrow\pi^*]{h\nu} \left[R\text{-}\overset{\overset{O}{\|}}{C}\text{-}OR'\right]^* \quad [I]$$

$$[I] \longrightarrow R\cdot + \cdot\overset{\overset{O}{\|}}{C}\text{-}OR' \quad (1)$$

$$[I] \longrightarrow R\text{-}\overset{\overset{O}{\|}}{C}\cdot + \cdot OR' \quad (2)$$

$$[I] \longrightarrow RH + CO_2 + \text{Olefin} \quad (3)$$

$$[I] \longrightarrow R\cdot + CO + \cdot OR' \quad (4)$$

Of the above four steps, step 1, leading to the formation of an alkoxycarbonyl radical, will be most important for the alkoxycarbonylation. It is, however, well known that the alkoxycarbonyl radical produced in step 1 is so unstable that it decomposes exothermically to carbon dioxide and a free alkyl radical with an activation energy of only about 1—2 kcal./mol.[7]:

$$\cdot\overset{\overset{O}{\|}}{C}\text{-}OR' \longrightarrow CO_2 + \cdot R' \quad (5)$$

The results of ethoxycarbonylations by the photolysis of various formates in hydrogen-donating solvents are summarized in Table I. In spite of the above disadvantage, the data shown in Table I indicate that both ethyl cyanoformate and ethyl chloroformate, among others, effectively underwent ethoxycarbonylation by hydrogen-donating solvents. However, contrary to expectation, carbinols and carbon monoxide, not ethyl carboxylate, were mainly obtained in the photolysis of ethyl acetate, diethyl carbonate and ethyl carbamate. From these results, it is found that the R substituent in the formate influences the nature of the product of the photolysis of the formate. Therefore, it seems

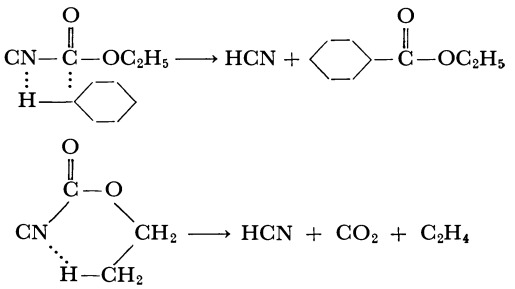
6) T. Tominaga, Y. Odaira and S. Tsutsumi, This Bulletin, **37**, 596 (1964).
7) P. Gray and J. C. J. Thynne, *Nature*, **191**, 1357 (1961).

to be more reasonable to assume that the substituent in the formate plays a very important role in the photolytic behavior of the formate; the following two effects of the substituent may then be considered.

First, the electronic effect of the substituent has a considerable influence on the position of the bond fission of the formate. From the fact that the photolysis of ethyl cyanoformate and ethyl chloroformate affords ethyl carboxylate exclusively, it seems that the electron-withdrawing substituents weaken the R-carbon bond in the formates, thus causing this bond to break easily upon photolysis. Consequently, step 1 proceeds predominantly to produce the ethoxycarbonyl radical. The fact that carbon monoxide and carbinols are the major products in the photolyses of the other formates in Table I means that the electron-releasing substituents, e. g., methyl, ethoxy and amino groups, probably make the R-carbon bond fission conversely difficult. Consequently, the photolysis of the formates must proceed through step 2 to produce an acyl radical and an alkoxy radical. The acyl radical may decompose immediately to carbon monoxide and an alkyl radical. There is also a possibility that carbon monoxide may be produced directly by the photolysis of the formates through step 4.

Second, the ethoxycarbonylation is influenced by the ability of the R radical produced by step 1 to produce hydrogen abstraction. As is well-known, the chloro atom and the cyano radical, which have large electron affinities, effectively abstract the hydrogen of the solvent. On the other hand, the hydrogen-abstraction ability of methyl, alkoxy and amino radicals, which have small electron affinities, is not so powerful as that of the above radicals, even if these radicals are generated through step 1. In the case of the photolysis of diethyl carbonate in cyclohexane, the ethyl cyclohexanecarboxylate obtained was only small amount; carbon dioxide was the major product in the gaseous products. Therefore, the ethoxycarbonyl radical decomposes to carbon dioxide and the ethyl radical, as is shown in step 5.

Interestingly, ethyl cyano- and ethyl chloroformate react in a little different manner, as indicated by the composition of their products. Ethylene was a major gaseous product of the photolysis of ethyl cyanoformate. On the contrary, ethyl chloroformate afforded mainly ethane. In addition, the obtainable dimer of the solvent was very little in the photolysis of the former as compared with that of the latter. These results suggest that the transition state of the hydrogen abstraction is different in the cases of the two formate. Presumably, the ethoxycarbonylation with ethyl cyanoformate proceeds through a somewhat four-centered mechanism, or the intramolecular hydrogen abstraction of the formate leads to hydrogen cyanide, carbon dioxide and ethylene through a six-membered transition state, as is shown hereunder:



On the other hand, ethyl chloroformate may dissociate to a chloro atom and an ethoxycarbonyl radical. Then, the chloro atom generated would abstract the hydrogen of the solvent, thus producing a free solvent radical. This solvent radical may combine with the ethoxycarbonyl radical, or it may dimerize by itself.

Furthermore, in order to examine the effect of the substituent R', the phenoxycarbonylation of cyclohexane by means of the photolysis of phenyl chloroformate was also attempted. In this reaction, phenol was obtained as the major product, together with a small amount of phenyl cyclohexanecarboxylate. This result leads us to assume that a phenoxycarbonyl radical generated through step 1 may be easily decomposed to carbon monoxide and a phenoxy radical because of its large resonance stabilization.

Further studies of ethoxycarbonylation by means of ethyl cyanoformate will be presented elsewhere.

Experimental[8]

Materials.—Ethyl cyanoformate was prepared in a 54% yield from ethyl chloroformate and sodium cyanide according to the procedure of Sheppard,[9] b. p. 116—118°C, n_D^{20} 1.3812: phenyl chloroformate was synthesized in a 54% yield by the method of Raiford and Inman from phenol and phosgene in the presence of dimethylaniline,[10] b. p. 84—87°C/23—24 mmHg, $n_D^{29.5}$ 1.5067, the other formates and solvents were commercial-grade chemicals; they were purified by the usual methods and distilled before use.

The Photolysis of Ethyl Chloroformate.—A mixture of ethyl chloroformate (38 g., 0.35 mol.) and cyclohexane (147 g., 1.75 mol.) was irradiated with a 350 W. high-pressure mercury arc lamp for 25 hr. under nitrogen at room temperature. During the irradiation, the continuous evolution of gas was observed and 450 ml. gas was collected. Hydrogen chloride was identified qualitatively as the precipitate of silver chloride. The other gaseous products were analyzed by gas chromatography using a 2.5-m. active carbon column. The main gaseous products were carbon dioxide, ethane, and carbon monoxide, plus small amounts of methane

8) Melting points are uncorrected.
9) W. A. Sheppard, *J. Org. Chem.*, **27**, 3756 (1962).
10) L. C. Raiford and G. O. Inman, *J. Am. Chem. Soc.*, **56**, 1586 (1934).

and ethylene. The liquid products were fractionally distilled and analyzed by gas chromatography using a 2.5-m. Si DC-550 column and an Apiezone N column. The conversion percentage of ethyl chloroformate was about 6%. The high-boiling products (1.7 g.) were ethyl cyclohexanecarboxylate (15%, based on the ethyl chloroformate consumed), cyclohexyl chloride (4.5%), and bicyclohexyl, plus small amounts of methyl cyclohexylcarbinol, diethyl oxalate, and ethyl cyclohexane.

The Photolysis of Ethyl Cyanoformate.—The irradiation of a solution of ethyl cyanoformate (39.6 g., 0.4 mol.) in cyclohexane (168 g., 2.0 ml.) was carried out under the same conditions as above for 50 hr. The gas evolved amounted to about 300 ml., consisting of carbon dioxide, carbon monoxide, ethylene, and small amounts of methane. Hydrogen cyanide was determined qualitatively as silver cyanide. The conversion percentage of ethyl cyanoformate was about 33%. The main liquid products were ethyl cyclohexanecarboxylate (3.9 g, 19%) and ethyl cyclohexaneglyoxylate (0.7 g., 3%). The above α-ketoester was isolated by preparative gas chromatography using a 3-m. Si DC-550 column. 2,4-Dinitrophenylhydrozone was recrystallized from ethyl alcohol to yield yellow needles, m. p. 158—160°C. A mixed-melting-point determination with an authentic sample of ethyl cyclohexaneglyoxylate 2, 4-dinitrophenylhydrazone showed no depression. Small amounts of ethyl alcohol, cyclohexyl cyanide, propionitrile, and bicyclohexyl were identified by gas chromatography. The photolysis of ethyl cyanoformate in toluene was also carried out using a 1-KW. high-pressure mercury arc lamp for 40 hr. The ultimate yield of ethyl phenylacetate was about 37%. The photolysis of ethyl cyanoformate at the wave length of 3660 Å did not occur to any appreciable extent. The effective wave length in the photolysis of the formates seemed to be shorter than 3660 Å.

The Photolysis of Ethyl Formate.—A mixture of ethyl formate (148 g., 2.0 mol.) and cyclohexane (420 g., 5.0 mol.) was irradiated with a 350-W. high-pressure mercury arc lamp for 68 hr. About 2800 ml. of gas was evolved, consisting largely of carbon monoxide. The other gaseous products were carbon dioxide and ethane, plus small amounts of methane and ethylene. The conversion of ethyl formate was about 32%. The main liquid products were bicyclohexyl (4.8 g.), ethyl cyclohexanecarboxylate (3.8 g., 3.8%), methyl cyclohexylcarbinol (3.2 g.), cyclohexylcarbinol (2.2 g.), ethyl alcohol (2.2 g.), and acetone (2.2 g.). Small amounts of acetaldehyde, diethyl oxalate, and ethoxycyclohexane were also obtained.

The Photolysis of Ethyl Acetate.—A mixture of ethyl acetate (105.6 g., 1.2 mol.) and cyclohexane (252 g., 3.0 mol.) was irradiated for 50 hr. The conversion of ethyl acetate was about 37%. The gaseous products (2500 ml.) were carbon monoxide, ethylene, carbon dioxide, methane, and ethane. The liquid products were methyl cyclohexylcarbinol (5.5 g.), cyclohexylcarbinol (4.6 g.), bicyclohexyl (16 g.), ethoxycyclohexane (1.6 g.), ethyl alcohol (1.6 g.), and acetaldehyde (1.7 g.). Ethyl cyclohexanecarboxylate, however, was present in only a very small amount.

The Photolysis of Diethyl Carbonate.—A mixture of diethyl carbonate (59 g., 0.5 mol.) and cyclohexane (336 g., 4.0 mol.) was irradiated for 30 hr. The conversion rate of diethyl carbonate was about 21%. The gaseous products (300 ml.) were carbon dioxide, carbon monoxide, ethane, ethylene, methane, *n*-butane, and hydrogen. Almost the only liquid product was a polymeric substance (5.8 g.). Small amounts of bicyclohexyl (0.8 g.) and methyl cyclohexylcarbinol (0.1 g.) were also obtained. Ethyl cyclohexanecarboxylate, cyclohexylcarbinol, and ethyl alcohol were present only in trace amounts.

The photolysis of diethyl carbonate in tetrahydrofuran was also carried out. A mixture of diethyl carbonate (47.2 g., 0.4 mol.) and tetrahydrofuran (144 g., 2.0 mol.) was irradiated for 75 hr. under the same conditions. The gaseous products (1100 ml.) were almost the same as those of the above case, except that carbon monoxide instead of carbon dioxide was the main product. The main liquid products obtained were methyl-2-tetrahydrofurylcarbinol (1.7 g.) and 2, 2′-ditetrahydrofuryl (2.8 g.). Small amounts of ethyl 2-tetrahydrofurancarboxylate and 2-tetrahydrofurylcarbinol were also obtained.

The Photolysis of Ethyl Carbamate.—A mixture of ethyl carbamate (44.5 g., 0.5 mol.) and tetrahydrofuran (144 g., 2.0 mol.) was irradiated for 110 hr. The total volume of gas evolved was about 850 ml. The main gaseous product was carbon monoxide. Carbon dioxide, ethane, ethylene, methane, and hydrogen were also identified. After the tetrahydrofuran had been removed, the residue was cooled overnight and then filtered. Hydrochloric acid (1.5 N) was added to the filtrate, and the solution was extracted with ether. The ethereal solution was washed by 5% aqueous sodium bicarbonate and water successively, and dried over sodium sulfate. After the ether had been removed, the residue was fractionally distilled under reduced pressure. 2, 2′-Ditetrahydrofuryl (0.5 g.) and small amounts of methyl-2-tetrahydrofurylcarbinol were obtained. However, ethyl 2-tetrahydrofurancarboxylate was not obtained.

The Photolysis of Phenyl Chloroformate.—A mixture of phenyl chloroformate (109.6 g., 0.7 mol.) and cyclohexane (343 g., 4.2 mol.) was irradiated with a 1-KW. high-pressure mercury arc lamp for 7.2 hr. The gaseous products were hydrogen chloride and carbon monoxide. The conversion of phenyl chloroformate was about 27%. The main liquid product was phenol (12.6 g.). Phenyl cyclohexanecarboxylate was obtained only in trace amounts.

We are indebted to Mr. Koichi Matsumoto and Mr. Takeshi Fujimoto for their excellent assistance.

Hydrogenation and Hydrogenolysis. IX.[1] The Hydrogenation of Benzyl Alcohol with Platinum Metal Catalysts

By Shigeo NISHIMURA and Michiko HAMA

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo

(Received February 28, 1966)

The rate of the hydrogenation of benzyl alcohol with a rhodium catalyst decreases markedly in the course of the reaction, accompanied by the formation of an increasing amount of cyclohexanecarboxaldehyde with the conversion of the alcohol. The decrease in the rate is only slight with a platinum catalyst, however, and the formation of the aldehyde is much less than with the rhodium catalyst. It has been shown that cyclohexanecarboxaldehyde is an effective catalyst poison in the hydrogenation of benzyl alcohol, but that cyclohexylcarbinol is not. 1-Cyclohexenylcarbinol, an intermediate of the hydrogenation, isomerizes to cyclohexanecarboxaldehyde during the hydrogenation on rhodium and 7 : 3 rhodium-platinum catalysts to a greater extent than on the platinum catalyst. Cyclohexanecarboxaldehyde is hydrogenated only very slowly, but the rate with the platinum catalyst is about four times greater than that with the rhodium catalyst. These results may account for the different behaviors of the rhodium or 7 : 3 rhodium-platinum catalyst and the platinum catalyst observed in the hydrogenation of benzyl alcohol.

It has been reported in a previous paper that the hydrogenation of benzyl alcohol to cyclohexylcarbinol is not successful with a rhodium-platinum catalyst because of a marked decrease in the rate in the course of the reaction,[2] although benzyl ethers, benzyl acetate and α-substituted benzyl alcohols are easily hydrogenated to give good yields of the corresponding saturated compounds with the same catalyst.[2-4] Such a phenomenon was also observed in the hydrogenation with a supported rhodium catalyst.[5] Benzyl alcohol may be hydrogenated to cyclohexylcarbinol in a good yield, either with an Adams platinum catalyst in alcohols containing a small amount of acetic acid[6,7] or, better, with a ruthenium catalyst in the presence of water.[1] The present study was undertaken to elucidate the cause of the deactivation of rhodium and rhodium-platinum catalysts observed in the hydrogenation of benzyl alcohol.

Experimental

Materials.—Benzyl alcohol of the G. R. grade was used after a fresh and careful distillation under reduced pressure. Cyclohexylcarbinol was prepared by the hydrogenation of benzyl alcohol with ruthenium hydroxide catalyst[8] in the presence of water, a typical run being shown in the following: 43 g. of benzyl alcohol was hydrogenated with the addition of 10 ml. of water at 90°C under 80—100 kg./cm^2 of hydrogen pressure, using 0.1 g. of the catalyst. The hydrogen uptake was complete in 3.5 hr. The distillation of the product after extraction with ether gave 37 g. of cyclohexylcarbinol, b. p. 91.5°C/22—23 mmHg (81% yield). Cyclohexanecarboxaldehyde was prepared by the oxidation of cyclohexylcarbinol with chromium trioxide in acetic acid and purified via the sodium hydrogen sulfite adduct.[9] 1-Cyclohexenylcarbinol was prepared by the reduction of methyl 1-cyclohexenecarboxylate[10] with lithium aluminum hydride.[11] The purity of the compounds prepared was well confirmed by means of gas chromatography.

Catalysts.—The oxide catalysts of platinum and 7 : 3 rhodium-platinum were prepared by the Adams method.[12,13] The rhodium hydroxide catalyst was prepared by adding a slight excess of a lithium hydroxide solution to a hot aqueous solution of rhodium chloride, followed by a thorough washing with hot, distilled water.

Hydrogenation. — All the hydrogenations were carried out at 25°C under the atmospheric pressure of hydrogen, using isopropyl alcohol as the solvent. Benzyl alcohol (0.5 g.) and additives were added, together with the solvent, after the metal oxide had been reduced to the metal with hydrogen in the solvent containing a small amount of acetic acid (0.02 ml.), the total amount of the solvent used being 10 ml. Rhodium

hydroxide was reduced to metal in isopropyl alcohol without the addition of acetic acid, since the presence of the acid greatly retarded the reduction of the hydroxide and since the hydrogenation of benzyl alcohol with this catalyst occurred without the addition of acetic acid.[14] Hydrogenation products were analyzed directly by gas chromatography using a column containing PEG-6000.

14) The rhodium hydroxide catalyst used in this study probably contains a much smaller amount of alkaline substances than the oxide catalysts of the Adams type (cf. Ref. 8).

Results and Discussion

The hydrogen uptake in the hydrogenation of benzyl alcohol with rhodium, 7 : 3 rhodium-platinum and platinum catalysts is shown in Fig. 1. It may be seen that the rate of the hydrogenation decreases markedly in the course of a reaction with the rhodium and 7 : 3 rhodium-platinum

- ● Benzyl alcohol

catalysts. The decrease in the rate is only slight with the platinum catalyst, however. Figures 2 and 3 show the changes in the amounts of the products formed in the course of the hydrogenation with the rhodium catalyst and with the platinum catalyst respectively. The most pronounced difference in the products seems to be that, with the rhodium catalyst, the formation of cyclohexanecarboxaldehyde is much greater than with the platinum catalyst and that it increases with conversion, whereas with the platinum catalyst the aldehyde is formed in an amount only 0.1% of the reaction mixture, even at the maximum, and then decreases gradually after about a 40% conversion. 1-Cyclohexenylcarbinol was also detected in the course of the rhodium-catalyzed hydrogenation, but it decreased rapidly after about 40% conversion.

Since it may be supposed from the above results that the cyclohexanecarboxaldehyde formed during the hydrogenation may be a catalyst poison, the effect of the addition of the aldehyde was then studied and compared with the effect of added cyclohexylcarbinol (Fig. 4). It may be seen that the hydrogenation of benzyl alcohol is markedly inhibited by the addition of cyclohexanecarboxaldehyde, while the addition of cyclohexylcarbinol has little effect on the rate of the hydrogenation. The effect of the addition of 1-cyclohexenylcarbinol

- - -: Added before the addition of benzyl alcohol

was also studied (Fig. 5), since the unsaturated alcohol is produced as an intermediate of the hydrogenation and is probably the precursor of the aldehyde formed in the hydrogenation.

It may be seen from Fig. 5 that the addition of 1-cyclohexenylcarbinol also inhibits the hydrogenation, although to a somewhat lesser extent than in the case of cyclohexanecarboxaldehyde. It may also be seen that the decrease in the rate is more pronounced in the hydrogenation with the rhodium catalyst than with the platinum catalyst. It should be noted that the hydrogenation is more retarded when the compounds are added before the addition of benzyl alcohol than when they are previously admixed with benzyl alcohol, as is shown in Figs. 4 and 5. Table I shows the products of the hydrogenation of 1-cyclohexenylcarbinol with rhodium, 7 : 3 rhodium-platinum and platinum catalysts. The hydrogenations with rhodium and and 7 : 3 rhodium-platinum catalysts are accompanied by the formation of cyclohexanecarboxaldehyde (about 18%). Such an isomerization occurs to a much lesser extent with the platinum catalyst (about 5%).[15] Thus, the action of cyclohexenylcarbinol as a catalyst poison probably results from the formation of the aldehyde by isomerization during the hydrogenation. The hydrogenation of the aldehyde was found to occur only very slowly, especially with the rhodium catalyst (hydrogen uptake: 3 ml./hr., 50 mg. catalyst). With the platinum catalyst the aldehyde is hydrogenated at a rate about four times greater than with the rhodium catalyst.

Table I. Products of the hydrogenation of 1-cyclohexenylcarbinol

Catalyst	Product, %		
	Cyclohexylcarbinol	Cyclohexanecarboxaldehyde	Hydrocarbons
Platinum[a]	94.8	5.2	Trace
7:3 Rhodium-Platinum	75.0	18.1	6.9
Rhodium	75.9	17.8	6.3

a) Products obtained in 84% hydrogenation.

From the results described above, it is very probable that the deactivation observed in the hydrogenation of benzyl alcohol with rhodium and rhodium-platinum catalysts is caused by the cyclohexanecarboxaldehyde formed by the isomerization of 1-cyclohexenylcarbinol, which is expected to be produced in a considerable amount as an intermediate of the hydrogenation, although the amount of it detected in the course of the hydrogenation was rather small.[16] The hydrogenation with the platinum catalyst is only slightly poisoned, because the isomerization of 1-cyclohexenylcarbinol occurs to a much lesser extent and the aldehyde formed by the isomerization is hydrogenated much faster than with the rhodium catalyst. It is known that ruthenium catalysts hydrogenate aliphatic aldehydes to alcohols with ease;[17,18]

15) The hydrogenation with the palladium hydroxide catalyst was accompanied by an extensive hydrogenolysis, affording 74% of methylcyclohexane along with 20.5% of cyclohexylcarbinol, 1.6% of cyclohexanecarboxaldehyde, and other products.

18) Y. Takagi, *Sci. Papers Inst. Phys. Chem. Research (Tokyo)*, **57**, 105 (1963).

this may account for the rapid hydrogenation of benzyl alcohol with these catalysts. The formation of cyclohexanecarboxaldehyde is not possible, at least in the absence of water, in the hydrogenation of benzyl ethers and esters, which are both hydrogenated easily with rhodium and rhodium-platinum catalysts. α-Substituted benzyl alcohols, which are also hydrogenated rapidly with rhodium and rhodium-platinum catalysts,[2-5] may give saturated ketones in the course of the hydrogenation, but it is probable that the adsorption of ketones on catalyst metals will not be so strong as that of aldehydes[19] and that the hydrogenation of ketones may occur more rapidly than in the case of aldehydes.[2,20]

It is an interesting fact that the ratio of the toluene to the cyclohexylcarbinol formed in the hydrogenation of benzyl alcohol increases with conversion with the rhodium catalyst, while it is nearly unchanged during the hydrogenation with the platinum catalyst (see Figs. 2 and 3). This suggests that the hydrogenation of the benzene nucleus is more inhibited by the presence of cyclohexanecarboxaldehyde than is the hydrogenolysis of the hydroxyl group. This is further supported by the observation that the hydrogenolysis of benzyl alcohol with a palladium catalyst is not inhibited at all by the addition of the aldehyde.

The authors are indebted to the Mitsubishi Chemical Industries Co., Ltd., for its financial support.

19) The hydrogenation of benzyl alcohol with the rhodium catalyst was not retarded at all, even by the addition of 30 mole% of acetone (unpublished).

Altenin. II. The Structure of Altenin

By Noboru SUGIYAMA, Choji KASHIMA, Yoshitaka HOSOI and Tsuneo IKEDA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

and Ryotaro MOHRI

The Liberal Arts Department, Tottori University, Tachikawa-cho, Tottori

(Received March 15, 1966)

Altenin, a metabolite of *Alternaria Kikuchiana* Tanaka, produces the black spot disease on the leaves and fruits of the pear. The optimum conditions for a 200-l. tank culture of this fungus will be described. Altenin has been tentatively deduced as being an ethyl ester of a C_7-carboxylic acid. Of the four expected tautomeric structures, the probability of a furanose ring structure will be demonstrated. There is only one asymmetric center in altenin, at the position α to the ethoxycarbonyl group; this belongs to the L-lactic acid configuration.

It has been demonstrated that one of the metabolites of the fungus *Alternaria Kikuchiana* Tanaka produces the black spot disease on pear leaves and fruit.[1] This substance has been isolated from the culture filtrate and designated "Altenin."[2,3] Altenin is a faint yellow liquid. The spectral and chemical data of altenin allows one to tentatively deduce it as an ethyl α-hydroxy carboxylate with a methyl reductone residue.

Results and Discussion

Altenin gives only one spot on a silica-gel thin-layer chromatogram with a benzene-acetone (1 : 1 v/v) mixture; its R_f value is 0.76, while that of methyl red, a pilot dye, is 0.37.

The molecular peak in the mass spectrum of altenin appears at *m/e* 218; altenin does not contain sulfur and halogen, as can be seen from the fact that the isotope peak, *m/e* 220 (M+2), is very weak compared with the molecular peak. From the molecular weight, 218, and the results of elementary analysis, the molecular formula of altenin may be determined to $C_9H_{14}O_6$. It is apparent that altenin does not contain an aromatic ring.

In an infrared absorption spectrum, an OH absorption at 3400 cm^{-1} and a C=O absorption at

1) I. Hiroe, S. Nishimura and W. Sato, *Transaction of the Tottori Society of Agriculture Science (Tottori Nogeikagaku Kaishi)*, **11**, 291 (1958).

2) N. Sugiyama, C. Kashima, M. Yamamoto and R. Mohri, This Bulletin, **38**, 2028 (1965).

3) N. Sugiyama, C. Kashima, M. Yamamoto, T. Sugaya and R. Mohri, ibid., **39**, 1573 (1966).

1730 cm^{-1} are observed. However there is no absorption band in the region between 1700 and 1600 cm^{-1}. This suggests that altenin has neither carboxyl group nor an olefinic double bond.

The nuclear magnetic resonance spectrum of altenin is given in Table I. The quartet at 4.83 τ is assigned to a methine proton, which is deshielded by an electron withdrawing group and which is coupled to a methyl group at 8.48 τ. The quartet at 5.80 τ is assigned to an ester methylene proton, which is coupled with a methyl group at 8.71 τ. Therefore, the presence of an ethoxycarbonyl group in altenin may be concluded. Similar to the methine proton of ethyl α-hydroxy levulinate[4] at 5.90 τ, the methine proton of altenin at 5.83 τ is deshielded by the oxygen atom. The doublet of 8.54 τ is coupled with the 5.83 τ methine proton. The broad band between 6.9 and 8.0 τ disappears upon deuterium exchange; it shows the presence of two hydroxyl protons. The nuclear magnetic resonance spectrum lacks signals due to a methyl group attached to a quaternary carbon or acetyl group.

The ultraviolet absorption spectrum shows an absorption maximum at 275 mμ (ε 228) in ethanol; it also shows a small shift to a shorter wavelength in acidic ethanol. The optical rotatory dispersion spectrum of altenin is shown in Fig. 3, the specific rotation at 589 mμ being $-5.1°$.

Altenin behaves as a reducing agent in reaction with Tillman's reagent,[5] manganese dioxide[6]

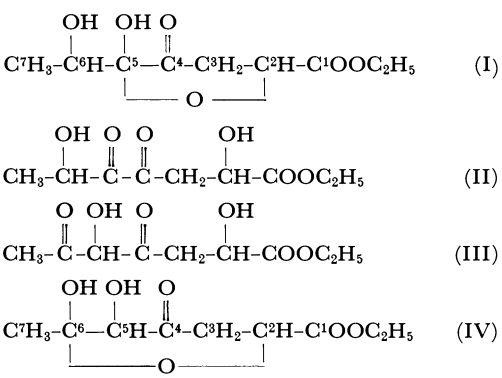

Fig. 1. Structure of altenin.

and Tollens' reagent. The red violet color of Tillman's reagent in acetic acid is decolorized; manganese dioxide is reduced, and silver nitrate is reduced to silver metal in an alkaline solution. These color reactions are characteristic of reductones, acyloins, and ascorbic acid. These properties suggest structures I to IV (Fig. 1) as conceivable for altenin.

4) A. Rossi and A. Lauchenauer, *Helv. Chim. Acta*, **30**, 1501 (1947).
5) F. Cramer and W. Krum, *Chem. Ber.*, **86**, 1586 (1953).
6) F. Feigl and H. T. Cardoso, *Rev. Brasil. Biol.*, **2**, 117 (1942).

The mass specturm of altenin is shown in Fig. 2. The base peak, *m/e* 45, might represents CH_3–CH–OH and C_2H_5–O groups. The peaks at *m/e* 45, 73 and 145 (M-73) suggest the presence of an ethoxycarbonyl group. The peaks at *m/e* 102 and 115 are obtained from the cleavage of the molecule into two parts; that at 102 might also be due to an O–CH–$COOC_2H_5$ fragment. The peak at *m/e* 85 can be accounted for by CH–$COOC_2H_5$ minus one proton, and that at 89 can be accounted for by CH_3–CH(–OH)–C(–O)$_2$ or CH_3–C(–O)$_2$–CH–OH; these high intensive peaks can not be expected from structures II and III. The structures I and IV, in which the lactol ring is present, thus seem to be more reasonable than structures II and III.

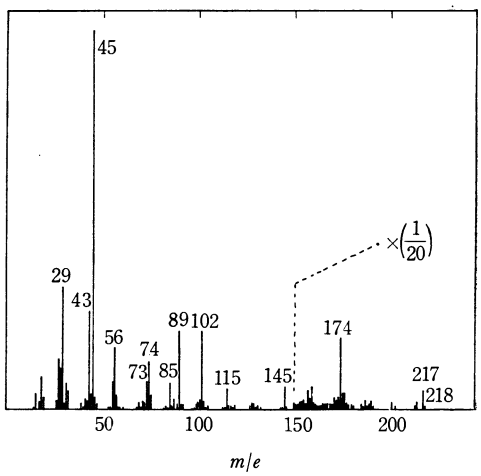

Fig. 2. Mass spectrum of altenin.

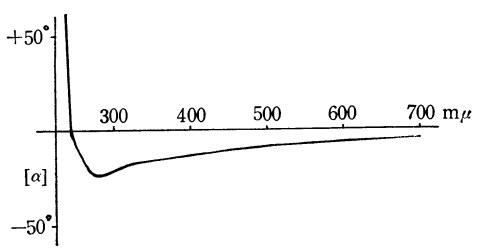

Fig. 3. ORD spectrum of altenin.

The hydroxyl group at C-6 is indicated by the splitting of the methine signal at 4.83 τ to a quartet. However a hydroxyl group of reductones can be rearranged through the endiol tautomer. The presence of an α-hydroxy carbonyl (–CO–CH–OH) group in strucutres II and III, its absence in the structure I, and the absence of the methine proton at C-6 in IV suggest the preference of I to II, III and IV.

Ethyl α-hydroxy levulinate has a structure similar to II and III, and it cannot cyclize to lactol linkage. However, the doublet of methylene

protons of altenin at 8.54 τ is more shielded than the β-methylene protons of ethyl α-hydroxy levulinate at 6.97 τ. In general, the α-methylene protons of aliphatic ketones and cyclohexanones are deshielded but the deshielding effect of the carbonyl group in cyclopentanone is weak[7] and the β-methylene protons of tetrahydrofurane is not influenced by the oxygen atom.[7] Therefore, the methylene protons of C-3 of I may be expected to be at a high field.

The peak intensity of altenin at 7.98 τ is about one half that of a proton; it is probably to be assigned to the methyl group at C-7 of III and IV. The signal of acetyl protons of diacetyl carbinol appears as a singlet at 7.80 τ. Since the peak ratio at 8.48 and 7.98 τ (2.5 : 0.5) is nearly proportional to the ratio of tautomers (I and II): (II and IV), the tautomers I and II may be thought to comprise 85 per cent, while III and IV comprise 15 per cent.

These four tautomeric structures are also found in osones. Petuely[8] reported that D-glucosone preferred the lactol ring form to the open-chain form. Bayne[9] obtained the triisopropylidene glucosone, and demonstrated the presence of a furanose ring. Therefore, it seems most probable for altenin to have the structure I, which has a furanose ring.

Since the carbon at C-6 is enolizable to its endiol tautomer, the only asymmetric center in altenin is the carbon C-2. The specific rotation of altenin is similar to that of α-hydroxy heptanoic acid $[\alpha]_D$ $-4.4°$, which has L-lactic acid configuration.

The substance of structure I or its tautomers was synthesized by the condensation of 3-acetoxy acetylacetone and ethyl glyoxylate with potassium amide; it was thus demonstrated that it showed the same phytopathogenic activity and R_f value as altenin. The details of this will be reported in the near future.

Experimental

The Cultivation of the Fungus Alternaria Kikuchiana Tanaka.—The culture broth (3 l.) of *Alternaria Kikuchiana* Tanaka (No. 5), which was cultured on an ager (0.1%) slant, was transferred into a 200 l. fermenter tank charged with 120 l. of a medium containing sucrose (4.0%), monobasic potassium phosphate (1.1%), dibasic ammonium phosphate (0.2%), potassium chloride (0.05%) and magnesium sulfate (0.05%); it was then cultivated at 30°C for 8 days under aeration (20 l./min.) with stirring. On the second or third day, the fermenter was filled with foam. An antifoam agent (silicon oil) was added on the third day. The activity test with pear leaves showed the highest value on the ninth day; this cultivation was 1.22 times as active as that of the stationary cultivation using the Czapek-Dox medium.

Material.—From the culture filtrate of this fungus, altenin was isolated by a previously-reported method.[3] Altenin is a yellow liquid, which is unstable above 60°C. The R_f value of altenin on silica-gel thin-layer chromatography with a benzene-acetone (1 : 1 v/v) mixture was 0.76, while that of methyl red, a pilot dye, was 0.37. The R_f value on paper (Toyo paper No. 53) chromatography with water saturated with benzene was 0.87.

Found*1: C, 50.95; H, 7.56. Calcd. for $C_9H_{14}O_6$: C, 49.54; H, 6.47.

Mass Spectrum.*2—The mass spectrum of altenin was measured by a Hitachi RMU-6D mass spectrometer; it vaporized at 80°C, and ionized at 70 V., and its ions accelarated at 1800 V. The molecular peak was observed at *m/e* 218, and the base peak, at *m/e* 45.

Infrared and Ultraviolet Absorption Spectra.—In the infrared absorption spectrum (liquid film), absorptions were observed at 3440, 2980, 1740, 1450, 1380, 1270, 1200, 1130, 1100, 1050, 1020, 940, 860 and 760 cm^{-1}. The ultraviolet absorption spectrum showed an absorption maximum at 276 mμ (ε 228) in ethanol and at 273 and 370 mμ in acidic ethanol.

Nuclear Maguetic Resonance Spectrum.*3—An Hitachi H-60 high resolution nuclear magnetic resonance spectrometer was used; the solvent was a mixture of carbon tetrachloride and deuterochloroform for altenin, and only deuterochloroform for ethyl α-hydroxy levulinate. For the deuterium exchange of the hydroxyl proton, deuterium oxide was added to the altenin solution. TMS was used as the inner

*3 The NMR spectra were measured by courtesy of Dr. Kisaburo Yamazaki and Dr. Takamichi Ichimura of Yamanouchi Pharmaceutical Co. Ltd.

standard. The τ value, intensity, coupling type and coupling constant are listed in Tables I and II.

Optical Rotatory Dispersion Spectrum.[*4]—The optical rotatory dispersion spectrum of altenin, which was recorded on a ORD/UV-5 spectrometer made by the Japan Spectroscopic Co., Ltd., in methanol at 28°C, is shown in Fig. 3. Altenin showed a levo specific rotation at 589 mμ and an inversion from levo to dextro specific rotation at 245 mμ.

The Color Reactions.—*With Tillman's Reagent.*—The silica-gel thin layer chromatogram of altenin was obtained by spraying it with Tillman's reagent dissolved in acetic acid. After a few minutes' warming, the color of the thin layer became pink, while the altenin spot remained colorless.

With Manganese Dioxide.—Manganese dioxide was prepared on the filter paper using aqueous potassium permanganate. A drop of an altenin solution was put on a test paper, and after a few minutes the paper was immersed in an aqueous benzidine hydrochloride solution. The paper color became blue, while the altenin spot remained colorless. In this test, ascorbic acid exhibits a strongly positive, while acetoin exhibits only a weak positive, reaction.

With Silver Nitrate.—The paper strip on which altenin had been developed by water saturated with benzene was immersed in a silver nitrate acetone solution, then in an alcoholic sodium hydroxide solution and finally in an aqueous sodium thiosulfate solution. The spot of altenin was blackened by the reduction of silver ions to metal.

The authors wish to express their hearty thanks to Professor Tatsukichi Kobayashi and Dr. Isei Nakamura, Department of Agriculture, Tokyo Kyoiku University, for their kind advice on the cultivation of the fungi and for their generous permission for us to use the 200 l. fermenter at that university. This work was supported by a grant from the Matsunaga Science Foundation.

Studies of Unnatural Amino Acids and Their Peptides. II. The Syntheses of DL-β-(4-Thiazolyl)-α-alanine and Its Peptides*1

By Hiroshi WATANABE, Shigeru KUWATA, Tatsuo SAKATA*2 and Keizo MATSUMURA*3

Laboratory of Chemistry, Faculty of Science, Kōnan University, Okamoto, Higashinada, Kobe

(Received March 15, 1966)

DL-β-(4-Thiazolyl)-α-alanine has been synthesized in a good yield by the condensation of 4-thiazolylmethyl chloride and diethyl acetamidomalonate, and by the subsequent hydrolysis of the product. The *N*-carbobenzoxy derivative of this amino acid could be prepared easily and transformed to its *p*-nitrophenyl ester and *t*-butoxycarbonylhydrazide, but it was found difficult to obtain the methyl ester or the benzyl ester directly from this amino acid. Carbobenzoxy-DL-β-(4-thiazolyl)-α-alanyl-glycine benzyl ester has been synthesized by several coupling methods: its yield decreased in the following order: *p*-nitrophenyl ester > dicyclohexylcarbodiimide (glycine ester was used as a free base) > azide > dicyclohexylcarbodiimide (glycine ester *p*-toluenesulfonate was used without triethylamine) > dicyclohexylcarbodiimide (glycine ester *p*-toluenesulfonate was used with triethylamine) > mixed anhydride. The alkaline hydrolysis of the protected dipeptide ester afforded the *N*-protected peptide in a good yield. Decarbobenzoxylation did not proceed smoothly by catalytic hydrogenation, in which hydrogen was absorbed slowly and incompletely, while it proceeded normally with hydrobromic acid in acetic acid.

As one of a series of studies of unnatural amino acids and their peptides,[1] the syntheses of DL-β-(4-thiazolyl)-α-alanine and its peptides will be reported in this paper. This amino acid has already been synthesized in several ways.[2,3] First, the authors prepared this compound by

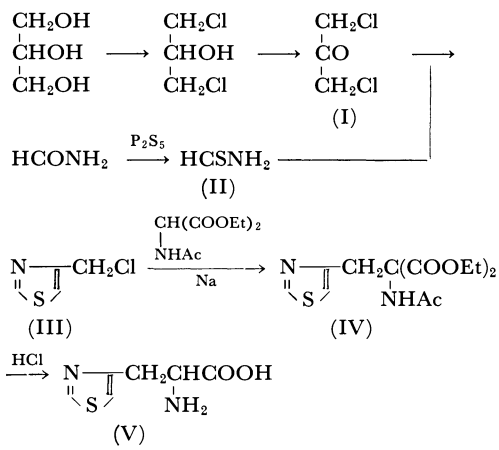
3) W. T. Caldwell and S. M. Fox, ibid., **73**, 2935 (1951).

reproducing the method of Caldwell and Fox[3] (illustrated in Scheme 1), but they found the results unsatisfactory in some step. When 2 mol. of sodium ethyl acetamidomalonate were allowed to react with one mole of thiazolylmethyl chloride hydrochloride, according to the method of the literature,[3] the condensation product was somewhat difficult to separate from the unreacted acetamidomalonate present in a large excess, and the hydrolysate of the product was contaminated with glycine, as was confirmed by paper chromatography. Hence, we modified the method so as to use the thiazolylmethyl chloride as a free base and the equimolar sodium ethyl acetamidomalonate, as in the report of Jones et al.[2] In this way we succeeded not only in avoiding the



Scheme 1. The synthetic route of DL-β-(4-thiazolyl)-α-alanine.

contamination with acetamidomalonate, but also in raising the yield of the condensation product up to 58% of the theoretical amount in a large-scale reaction. The hydrolysis of the condensation product proceeded smoothly when it was boiled with 6 N hydrochloric acid for 8 hr., and the amino acid was obtained as hydrochloride in an almost quantitative yield.

In the case of an unnatural amino acid containing a heterocyclic ring, the methods generally used for the peptide synthesis are not always suitable because they may be accompanied by undesirable side reactions resulting from the heterocyclic ring. For instance, as has already been reported,[1] in order to remove the formyl group from formylfurylalanine the oxidative cleavage method can not be used because of the simultaneous destruction of the furan ring. Thus, the validity of some typical methods of peptide synthesis was examined for this amino acid.

The carbobenzoxy derivative of this amino acid was prepared by a usual method without any difficulty, while the attempts to esterify this amino acid with methyl alcohol and hydrogen chloride, or with benzyl alcohol and *p*-toluenesulfonic acid in the presence of benzene, resulted in failure.

The coupling reaction of carbobenzoxythiazolylalanine with another amino acid was demonstrated using glycine benzyl ester as an amine component. Though the alkyl ester of thiazolylalanine could not be obtained, carbobenzoxythiazolylalanine *p*-nitrophenyl ester could be prepared by condensing the protected amino acid with *p*-nitrophenol by dicyclohexylcarbodiimide. In the same way, the *t*-butoxycarbonylhydrazide of the carbobenzoxylated amino acid could be obtained by condensing both the components by the dicyclohexylcarbodiimide method, and this compound was used as an intermediate for the azide method. The results of some coupling reactions are summarized in Table I. The yield decreased in connection with the coupling methods in the following order: *p*-nitrophenyl ester > dicyclohexylcarbodiimide (glycine ester was used as a free base) > azide > dicyclohexylcarbodiimide (glycine ester *p*-toluenesulfonate was used without triethylamine) > dicyclohexylcarbodiimide (glycine ester *p*-toluenesulfonate was used with triethylamine) > mixed anhydride. It is noteworthy that, in the condensation of carbobenzoxythiazolylalanine with glycine benzyl ester *p*-toluenesulfonate with dicyclohexylcarbodiimide, a somewhat higher yield was obtained in the absence of triethylamine than in its presence.

The alkaline hydrolysis of the protected peptide ester proceeded smoothly, and carbobenzoxythiazolylalanylglycine was obtained in an excellent yield after the neutralization of the reaction mixture with the equivalent hydrochloric acid.

One of the most important problems is that of estimating the validity of the hydrogenolytic decarbobenzoxylation method of these amino acid derivatives, because they contain a sulfur atom as a constituent. Therefore, precise studies were made by using a quantitative hydrogenation apparatus. Carbobenzoxythiazolylalanine was hydrogenated in the apparatus, using palladium as a catalyst in the presence of sodium hydroxide to remove the carbon dioxide which was evolved during the reduction; the absorption-rate of hydrogen was then compared with that of carbobenzoxyphenylalanine. Though the reduction of carbobenzoxyphenylalanine proceeded smoothly and finished in a short time, that of carbobenzoxythiazolylalanine proceeded very slowly and was still incomplete even after 2 hr. On the basis of these results, we have reached the conclusion that the hydrogenolytic removal of the protecting group is unfavorable in these amino acid derivatives. It was shown, on the other hand, that the carbobenzoxy group was easily split off with hydrogen bromide in acetic acid, and a free peptide, which was proved chromatographically pure, was obtained

by the subsequenttreatment of the reaction product with an ion exchange resin.

Experimental

α, γ-Dichloroacetone (I).—α, γ-Dichlorohydrin was prepared from glycerol by passing hydrogen chloride through it at 100—110°C,[4] then it was oxidized to I with sodium dichromate, according to the method of Conant and Quayle.[4] B. p. 170—175°C.

Thioformamide (II).—This was prepared according to the method of Schmitz,[5] by the action of phosphorus pentasulfide on formamide in tetrahydrofuran; the oily, crude product was used for the next reaction without purification.

(4-Thiazolyl)-methyl Chloride Hydrochloride (III).—This was prepared according to the method of Caldwell and Fox[3] by condensing I and II in acetone. When the resulting crude material (65% yield) was sublimed at 130—140°C under reduced pressure, the pure substance was obtained as pale yellow needles melting at 167—168°C (85—90% yield).

Diethyl (4-Thiazolyl)-methyl Acetamidomalonate (IV).—(4-Thiazolyl)-methyl chloride, which was obtained as a viscous oil by treating III with alkali, was condensed with acetamidomalonate in ethanol, using sodium as the condensing agent, at 40°C for 5 days. The yield was 58%; m. p. 104—105°C (lit.[3] m. p. 104—105°C).

DL-β-(4-Thiazolyl)-α-alanine (V).—IV was hydrolyzed by refluxing it with 6 N hydrochloric acid for 8 hr.; V-hydrochloride was thus obtained in a 93% yield. The free amino acid was obtained in a 87% yield by treating the hydrochloride with ion exchange resin (Amberlite CG-120). M. p. 226—229°C (decomp.) (darkened from ca. 200°C) (lit.[2] m. p. 227—230°C). R_f=0.40 (circular paper chromatography; solvent, *n*-butanol : acetic acid : water=5 : 4 : 1).

***N*-Carbobenzoxy-DL-β-(4-thiazolyl)-α-alanine (VI).**—Carbobenzoxy chloride (28.2 g.) was added, drop by drop, to a solution of V (24 g.) in a sodium hydroxide solution (sodium hydroxide 6 g.; water 150 cc.) with stirring under ice-cooling. The solution was kept alkaline by adding a sodium hydroxide solution. After the addition of carbobenzoxy chloride, stirring was continued for 1 hr. The clear reaction mixture was then extracted with ether, and the pH of the aqueous layer was adjusted to 4 with hydrochloric acid. The white crystals which formed were collected and washed thoroughly with water. The yield was 40 g. (94%); m. p. 122—124°C. For analysis it was recrystallized from dichloromethane; m. p. 130—131°C.

Found: C, 55.05; H, 4.71; N, 9.35. Calcd. for $C_{14}H_{14}O_4N_2S$: C, 54.89; H, 4.61; N, 9.15%.

***N*-Carbobenzoxy-DL-β-(4-thiazolyl)-α-alanine *p*-Nitrophenyl Ester (VII).**—Dicyclohexylcarbodiimide (1 g.) was added to the solution of VI (1.5 g.) and *p*-nitrophenol (0.7 g.) in dichloromethane (40 cc.); the mixture was then stirred for 3 hr. and allowed to stand overnight at room temperature. The dicyclohexylurea was filtered off, and the filtrate was washed with a cold potassium carbonate solution and water until the aqueous phase became colorless. The organic layer was dried with sodium sulfate and concentrated under reduced pressure. The residual solid was recrystallized from ethanol. The yield was 0.77 g. (37%); m. p. 101—103°C.

Found: C, 56.27; H, 3.99; N, 9.28. Calcd. for $C_{20}H_{17}O_6N_3S$: C, 56.20; H, 4.01; N, 9.83%.

***N*-Carbobenzoxy-DL-β-(4-thiazolyl)-α-alanine *t*-Butoxycarbonylhydrazide (VIII).** — Dicyclohexylcarbodiimide (2.1 g.) dissolved in dichloromethane (5 cc.) was added to a solution of VI (3.0 g.) and *t*-butoxycarbonylhydrazine (1.4 g.) in dichloromethane (ca. 50 cc.) under ice-cooling. When the reaction mixture was stirred for 1 hr., voluminous crystals were separated (probably due to the crystallization of *t*-butoxycarbonylhydrazine). By adding more dichloromethane (10 cc.) and methanol (26 cc.), almost all the crystals were dissolved; then the mixture was allowed to stand overnight at room temperature. Acetic acid (2 cc.) was added, and the mixture was stirred for 1 hr. The dicyclohexylurea was then filtered off, and the filtrate was concentrated to dryness. The resulting solid mass was recrystallized from methanol. The yield was 2.43 g. (59%). To remove the trace of dicyclohexylurea, the crystals were dissolved in a small volume of hot ethanol, and then water was added into this solution. The dicyclohexylurea which separated was filtered off, and then the filtrate was allowed to stand overnight at room temperature. The crystals obtained in this way melted sharply at 158.5—160°C, and their analytical data agreed well with the theoretical values.

Found: C, 54.25; H, 6.13; N, 13.17. Calcd. for $C_{19}H_{24}O_5N_4S$: C, 54.27; H, 5.75; N, 13.33%.

***N*-Carbobenzoxy-DL-β-(4-thiazolyl)-α-alanylglycine Benzyl Ester (IX).**—*The Azide Method.*—VIII (1.8 g.) was added to methanolic hydrogen chloride (50 cc.); then, after the evolution of carbon dioxide had ceased, the clear solution was evaporated under reduced pressure. The resulting, strongly hygroscopic solid was dissolved in 1 N hydrochloric acid (4.3 cc.), and ethyl acetate (20 cc.) was added. A solution of sodium nitrite (0.3 g.) in water (2 cc.) was added at −10°C and, then, 2 min. later, 50% potassium carbonate (10 cc.) was added at the same temperature. Then the organic layer was separated, and the aqueous layer was extracted with ethyl acetate (20 cc.). The combined organic layer was dried with sodium sulfate. On the other hand, glycine benzyl ester *p*-toluenesulfonate (2 g.) was dissolved in a small volume of water, made alkaline by the addition of 50% potassium carbonate, and extracted with ethyl acetate 3 times (total volume: 40 cc.). After dried with sodium sulfate, the ester solution was combined with the azide solution and kept in a refrigerator for 2 days. After filtered and washed successively with water, a 0.5% sodium bicarbonate solution, and water, the ethyl acetate solution was dried with sodium sulfate. The solid mass (1.3 g.), obtained by evaporating off the solvent, melted at 110—112°C. After recrystallization from ethanol, it melted at 114—115°C (1.13 g., 58%).

Found: C, 61.24; H, 5.24; N, 8.89. Calcd. for $C_{23}H_{23}O_5N_3S$: C, 60.91; H, 5.11; N, 9.27%.

The p-Nitrophenyl Ester Method.—To a solution of VII

Z: $C_6H_5CH_2OCO$–, -Thia-:  , Bz: $-CH_2C_6H_5$, Tos: $CH_3C_6H_4SO_2$–,

DCC: Dicyclohexylcarbodiimide, BOC: $(CH_3)_3COCO$–, ONP: $-OC_6H_4NO_2$

(0.57 g.) in dichloromethane (40 cc.), there was added glycine benzyl ester *p*-toluenesulfonate (0.5 g.) and triethylamine (0.3 cc.); then the mixture was allowed to stand at room temperature overnight. After washed thoroughly with 5% hydrochloric acid, 0.5% sodium bicarbonate, and water, the solution was dried with sodium sulfate and evaporated under reduced pressure, leaving a viscous, pale yellow oil. By cooling the ethyl acetate solution of the oil, white needle crystals were obtained.

The Mixed Anhydride Method.—To a solution of VI (4.2 g.) and triethylamine (2 cc.) in dichloromethane (60 cc.), ethyl chloroformate (1.37 cc.) was added, drop by drop, at −30°C with stirring. The mixture was then kept at −15—−10°C for 5 min. To the somewhat reddish-brown solution thus obtained, a mixture of glycine benzyl ester *p*-toluenesulfonate (5.3 g.) and triethylamine (2.2 cc.) in dichloromethane (20 cc.) was added with stirring, then allowed to stand overnight at room temperature. The dichloromethane solution was washed successively with water, 5% hydrochloric acid, 0.5% sodium bicarbonate, and water, and dired with sodium sulfate. After the solvent had been evaporated off, a yellowish-brown semi-solid (5.1 g.) was obtained. Recrystallization from ethyl acetate afforded needle crystals.

The Dicyclohexylcarbodiimide Method. — To a solution of VI (1.5 g.) in dichloromethane (30 cc.) there was added a dichloromethane solution of glycine benzyl ester (prepared from 1.8 g. of glycine benzyl ester *p*-toluenesulfonate by neutralizing with potassium carbonate and extracting with dichlorometane). After dicyclohexylcarbodiimide (1.2 g.) in dichloromethane (3 cc.) had been added, the reaction mixture was stirred for 3 hr. at room temperature and then allowed to stand overnight at this temperature. After dicyclohexylurea had been filtered off, the solution was washed successively with 5% hydrochloric acid, 0.5% sodium bicarbonate, and water, and dried with sodium sulfate. After the solvent had been evaporated off, the pale yellow, syrupy residue was crystallized from ethyl acetate (the yield was 1.58 g. (71%)). Instead of free glycine benzyl ester, a mixture of glycine benzyl ester *p*-toluenesulfonate and the equimolar triethylamine, in one case, and glycine benzyl ester *p*-toluenesulfonate alone, in the other case, were used.

All of these results are summarized in Table I, together with those of the other coupling methods.

***N*-Carbobenzoxy-DL-thiazolylalanyl-glycine (X).**—To a methanolic solution (400 cc.) of IX (3.3 g.), 1 N sodium hydroxide (10 cc.) was added; the solution was then allowed to stand at 25°C for 1 hr. with occasinal shaking. About a half of the solvent was then distilled off under reduced pressure, and water was added. After filtration, the solution was neutralized with 1 N hydrochloric acid (10 cc.). The resulting white precipitates were collected, washed thoroughly with water, and air-dried. The yield was 2.3 g. (87%); m. p. 179—181°C (from ethanol).

Found: C, 52.63; H, 4.97; N, 11.40. Calcd. for $C_{16}H_{17}O_5N_3S$: C, 52.88; H, 4.72; N, 11.56%.

The Hydrogenation of Carbobenzoxy-DL-phenylalanine and Carbobenzoxy-DL-thiazolylalanine.—A solution of carbobenzoxy-DL-phenylalanine (0.5 g., 1.67 mmol.) in aqueous methanol (methanol, 25 cc.; water, 10 cc.) and 1 N sodium hydroxide (4 cc.) was placed in a hydrogenation flask containing a palladium catalyst (0.1 g.) in water (20 cc.) which had previously been equilibrated with hydrogen. After the air in the apparatus had been completely replaced with hydrogen, stirring was started; the decreasing volume of the hydrogen was measured against the time. The same experiment was then carried out with carbobenzoxy-DL-thiazolylalanine (0.5 g., 1.63 mmol). In the latter case only about one-third of the theoretical amount of hydrogen was absorbed, even after 2 hr., while in the former case the hydrogenation was complete after 15 min.

DL-Thiazolylalanyl-glycine (XI).—To a 25% solution of hydrogen bromide in acetic acid (3 cc.), X (0.5 g.) was added. After the evolution of carbon dioxide had ceased, water was added and the mixture was extracted with ether. The aqueous layer was then decolorized, the pH was adjusted to ca. 6 with aqueous ammonia, and the solution was allowed to pass through an Amberlite CG-120 (H^+ form) column. After the column had been thoroughly washed with water, the absorbed free peptide was eluted with aqueous ammonia. The eluate was then decolorized, concentrated to a small volume under reduced pressure, and finally lyophilized. The yield was 0.31 g. (92% calculated as hemihydrate); m. p. 158—160°C (sintered at 154°C). Paper chromatography gave only one spot: R_f=0.34.

Found: C, 39.93; H, 5.37; N, 16.84. Calcd. for $C_8H_{11}O_3N_3S\cdot{}^1/_2H_2O$: C, 40.33; H, 5.08; N, 17.64.

Studies of Acenaphthene Derivatives. XII.[1] On the Red Substance Obtained from Acenaphthenequinone and Ammonia

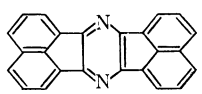
By Otohiko TSUGE and Masashi TASHIRO

The Research Institute of Science and Industry, Kyushu University, Hakozaki, Fukuoka

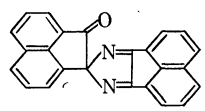
(Received March 17, 1966)

In order to elucidate the chemical structure of red crystals (A) obtained from the reaction of acenaphthenequinone (I) with ammonia, the reaction of I with ammonia, formamide or benzylamine was reinvestigated. It has been made clear again that the compound A is not acenaphthazine (II) but acenaphtho[1, 2-b]isoimidazole-2-spiro-2'-acenaphthenone (III), and that Schönberg's assumption of the structure of the compound A is incorrect. That reaction of I with benzylamine afforded II as yellow needles in a good yield. Also, it has been found that the reaction product (B) of I with formamide is a mixture of almost equal amounts of II and III.

The previous work[2] of this series has shown that the chemical structure of the red compound A, the reaction product of acenaphthenequinone (I) with ammonia, is neither acenaphthenequinonimide anhydride ($C_{24}H_{12}ON_2$)[3] nor acenaphthazine (II),[4] but acenaphtho[1, 2-b]isoimidazole-2-spiro-2'-acenaphthenone (III).



II



III

Recently, Schönberg and Singer[5] obtained a red substance identical with the compound A by the reaction of I with formamide in the presence of acetic acid;[6] they objected to our proposed structure III for the compound A as a misconception resulting from the treatment of an impure substance. On the basis of its analyses, a study of its infrared spectrum,[7] and its being similar to phenanthrazine, they concluded that the compound A is acenaphthazine (II), whose structure was early suggested by Schönberg and Nedzati.[4]

In the preceding paper,[1] however, it has been shown that II is formed as yellow needles in the reaction of I with primary aliphatic amines, such as methyl-, ethyl- and benzylamine, and the reaction course of the formation of II was also suggested.

Consequently, we are compelled to reexamine our assignment of III for the compound A to see whether it is attributable to the results of the treatment of an impure substance, and to see whether II is the main product in the reaction of I with ammonia or formamide.

In the reaction of I with ammonium carbonate in acetic acid, red crystals (A) are formed.[2] The crude product just after the reaction and the product purified by means of recrystallization from pyridine or by means of sublimation over iron powder are in agreement with the formula $C_{24}H_{12}ON_2$ (III), but not with Schönberg's formula $C_{24}H_{12}N_2$ (II), and the infrared spectrum of the crude product, which showed the absorption band at 1704 cm^{-1} assigned to the carbonyl group, was also almost the same as that of the purified

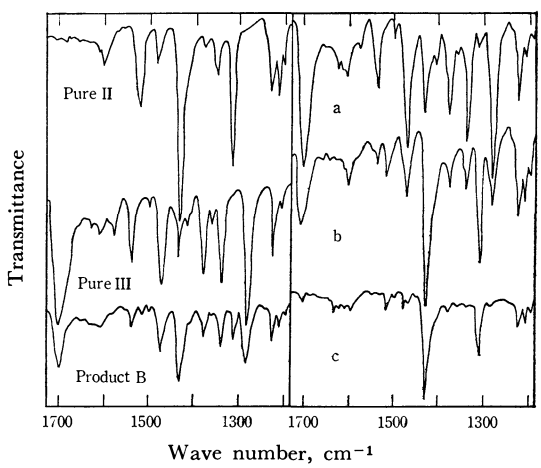


Fig. 1. Infrared spectra of the crude and purified II and III in KBr disk.

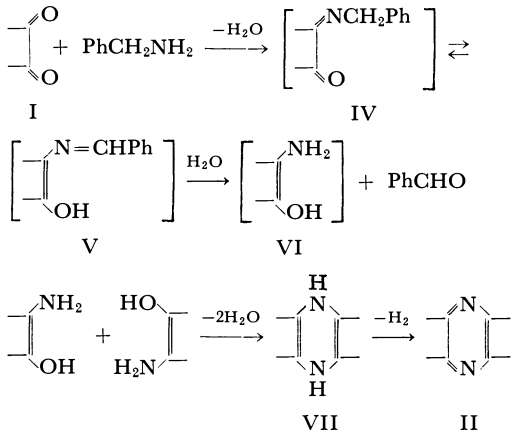
6) It has been reported that the crude product was contaminated by an oxygen-containing substance.[5]
7) Although it was shown that its infrared spectrum did not exhibit any carbonyl bond, its spectrum was not given.

product. These observations indicate that our substance is a pure and single compound.

The reaction of I with an excess amount of benzylamine afforded II, benzal benzylamine and *N*-benzylnaphthalimide. Unlike III, II is yellow needles, and it is more easily purified by sublimation than III. As benzal benzylamine is the condensation product of benzaldehyde[8] and benzylamine, it is resonable to conclude that the reaction proceeds through the previously-proposed course.[1]

As Chart 1 shows, *N*-benzylacenaphthenequinonimine (IV) rearranges to the Schiff base (V), which in turn hydrolyzes to yield benzaldehyde and 1, 2-aminoacenaphthenole (VI). The self-condensation of VI leads to the formation of dihydroacenaphthazine (VII), which easily dehydrogenates to II. On the other hand, benzaldehyde reacts with benzylamine to form benzal benzylamine.



$$PhCHO + PHCH_2NH_2 \longrightarrow PhCH{=}NCH_2Ph$$

Chart 1

The infrared and ultraviolet spectra of II and III are given in Figs. 1 and 2 respectively. The infrared spectrum of III exhibited the sharp band at 1704 cm^{-1} ascribed to the carbonyl group. In view of its elemental analyses and the results of oxidation[2] as well as its infrared spectrum, the compound A may be said to be in accord with the structure of III.

The infrared spectrum of the crude product (B) just after the reaction of I with formamide is also shown in Fig. 1. On the basis of its infrared spectrum, which revealed all the distinctive bands of II and III (as are shown in Fig. 1) and of the ultraviolet spectra (cf. Fig. 2), it may be supposed that the product B is a mixture of II and III.

If the product B was extracted with chloroform and if the chloroform-extract was then recrystallized from pyridine, a red substance whose infrared

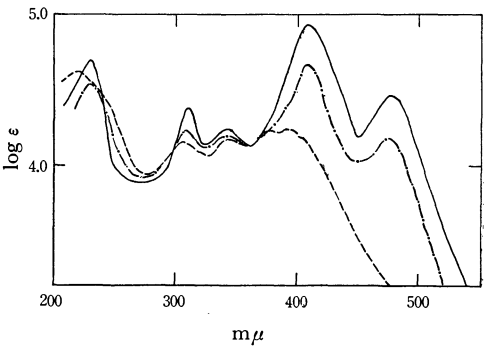


Fig. 2. Ultraviolet spectra of II, III and product B in concentrated sulfuric acid.
—— II
---- III
—·— Product B

spectrum was superimposed on that of III was obtained. On the other hand, the more repeatedly the purification of the product B was done by sublimation, the weaker the strength of the band at 1704 cm^{-1} ascribed to the carbonyl group became; finally yellow needles, m. p. 438°C, the infrared spectrum of which was the same as that of II, were obtained.

The infrared spectra of the product B as purified by recrystallization and by sublimation are also shown in Fig. 1.

The quantitative estimation of II and III in the product B was established by using the ratio method,[9] which was carried out by the measurement of the absorbances, a_1 and a_2, for the bands at 1320 and 1704 cm^{-1}, respectively. Thus, samples of a mixture consisting of specified amounts of II and III were prepared, and the absorbances, a_1 and a_2 were measured according to the baseline

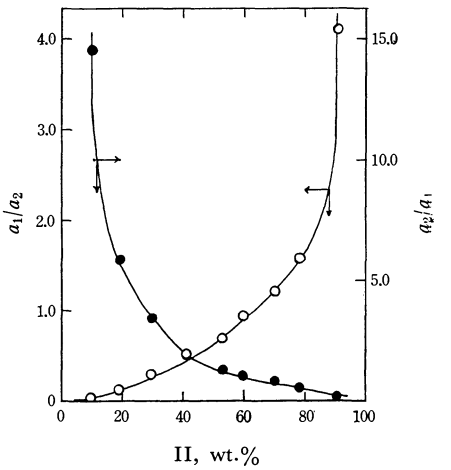

Fig. 3. Calibration curves.

8) Benzaldehyde was isolated and identified as 2, 4-dinitrophenylhydrazone.[1]

9) S. Takagi, "Experiment and Calculation of Quantitative Analyses" (in Japanese), Vol. III, Kyoritsu, Tokyo (1961), p. 91.

method. The calibration curves plotting the relationship between a_1/a_2 or a_2/a_1 and the concentration (wt. %) of II are shown in Fig. 3.

According to the calibration curves thus obtained, it was found that the product B consisted of II (45%) and III (55%). In the reaction of I with formamide known as the Leukart reaction, I reacts with the ammonia which is formed in the reaction process to give III, besides the usual reaction.

Experimental

The Reaction of I with Ammonium Carbonate in Glacial Acetic Acid.—As has been described previously,[2] a mixture of I (1.0 g.) and ammonium carbonate (13.0 g.) in glacial acetic acid (30 ml.) was refluxed for 1 hr. to afford red crystals (0.38 g.). These crude red crystals were washed with hot acetic acid and with acetone, and then dried in vacuo.

Some of the crystals were recrystallized from pyridine, and another part was purified by sublimation over iron powder. The infrared spectrum of the crude product was almost the same as that of the purified product. The elemental analytical data of the red crystals are given in Table I.

Table I. Elemental analytical data of red crystals

Sample	Found, %		
	C	H	N
Crude	83.97	3.33	8.39
	83.81	3.39	8.35
Recrystallized from pyridine	83.97	3.36	8.36
	83.78	3.28	8.40
Sublimated	84.07	3.18	8.47

Calcd. for $C_{24}H_{12}N_2$ (II): C, 87.79; H, 3.68; N, 8.53%.
Calcd. for $C_{24}H_{12}ON_2$ (III): C, 83.71; H, 3.51; N, 8.14%.

The Reaction of I with Benzylamine.—A mixture of I (16 g.) and benzylamine (25 g.) was heated at 80°C for 1 hr. During this time the mixture turned brown. After it had cooled, the mixture was washed with benzene (250 ml.); 6.1 g. of brown crystals were left (m. p. over 400°C). Recrystallization from nitrobenzene or sublimation over iron powder afforded acenaphthazine (II) as yellow needles, m. p. 438°C (decomp.).

Found: C, 87.79; H, 3.65; N, 8.75. Calcd. for $C_{24}H_{12}N_2$: C, 87.79; H, 3.68; N, 8.53%.

After the benzene washings had been dried over sodium sulfate and the benzene had then been removed, distillation in vacuo gave 8.6 g. of a colorless oil (138°C/3 mmHg) and a residue. The distillate was proved, by a study of its infrared spectrum, to be identical with the benzal benzylamine which was prepared from benzaldehyde and benzylamine. On the other hand, the residue was washed with a small amount of hot isopropyl alcohol; this left pale yellow crystals which, on recrystallization from isopropyl alcohol, afforded 3.0 g. of *N*-benzylnaphthalimide as pale yellow needles, m. p. 195—195.5°C.[1]

The Reaction of I with Formamide.—A mixture of I (2.5 g.), formamide (40 ml.), and glacial acetic acid (1 ml.) was heated at 170—180°C for 20 min. The same treatment as has been previously used[2] gave 1.5 g. of red crystals, which were found to be a mixture of II (45%) and III (55%) by the spectroscopic determination. The crude product (300 mg.) was extracted with chloroform (300 ml.), leaving insoluble red crystals which consisted of II (55%) and III (45%). The chloroform extract was concentrated in vacuo to afford red crystals (100 mg.) which were a mixture of II (40%) and III (60%). The fractional recrystallization of the crystals from pyridine gave almost pure III as red needles; their infrared spectrum is also given in Fig. 1.

The chloroform-insoluble crystals were purified by sublimation over iron powder. The more repeatedly sublimation was done, the greater was the relative amount of II in the crystals (Table II).

Table II. Variation in the relative amounts of II and III with sublimation

Number of times	Composition (wt. %)		Number of times	Composition (wt. %)	
	II	III		II	III
1	64	36	4	85	15
2	70	30	5*	~100	
3*	83	17			

* Infrared spectra are given in Fig. 1.

Schönberg et al.[5] may have failed to recognize that II is red crystals, because II as red crystals appears to be contaminated with a trace amount of III.

Also, the reaction in the absence of acetic acid gave red crystals which consisted of II (55%) and III (45%).

The Spectroscopic Determination of II and III in Compound B.—The infrared absorption measurements were made with a Koken IR-S double-beam spectrophotometer equipped with a sodium chloride prism.

Potassium chloride disks containing II and III, in which the weight percentages of III were 10.0, 21.7, 30.0, 39.8, 47.9, 59.7, 70.1, 80.7 and 90.2% respectively, were prepared. The absorbances, a_1 and a_2, for the bands at 1320 and 1704 cm^{-1} respectively were measured by the baseline method.

The calibration curves obtained by the ratio method are shown in Fig. 3.

The authors are indebted to the staff of the Analytical Service Centre of this university and Mr. Eiji Shiozaki of this laboratory for their microanalyses.

Kinetic Studies of the Solution Polymerization of Trioxane Catalyzed by $BF_3 \cdot O(C_2H_5)_2$. VI. The Catalytic Mechanism of Boron Trifluoride Coordination Complexes in Ethylene Dichloride

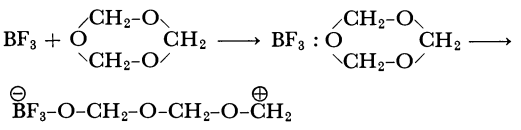
By Tetsuro MIKI, Toshinobu HIGASHIMURA and Seizo OKAMURA

Department of Polymer Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received March 18, 1966)

The initiation mechanism in the cationic polymerization of trioxane by the BF_3 coordination complex catalyst was studied in ethylene dichloride at 30°C. The coordination complexes of BF_3 with diethyl ether (Et_2O), ethyl alcohol (EtOH) and acetic acid (AcOH) were used as catalysts. Under similar conditions, the rates of polymerization decreased in the order: $BF_3 \cdot EtOH > BF_3 \cdot AcOH > BF_3 \cdot Et_2O$, whereas the molecular weights of the polymers decreased in the order: $BF_3 \cdot Et_2O > BF_3 \cdot EtOH \simeq BF_3 \cdot AcOH$. The molecular weight of the polymer formed was unaffected by the addition of the same compound as the donor molecule in the BF_3 coordination complex. However, on the addition of EtOH to the polymerization system catalyzed by $BF_3 \cdot Et_2O$, the rate of polymerization increased and the molecular weight of the polymer decreased. On the other hand, the addition of Et_2O to the system catalyzed by $BF_3 \cdot EtOH$ decreased the rate of polymerization and increased the molecular weight of the polymer formed. The order of catalytic reactivity and the effect of the additive support the idea that the initiation reaction is not an interaction of the BF_3 molecule with trioxane but an addition of the cation produced from the BF_3 coordination complex to the trioxane molecule.

It has been reported that the polymerization of trioxane catalyzed by boron trifluoride (BF_3) is initiated by a direct interaction of BF_3 with trioxane without a cocatalyst such as water, and that it proceeds through a zwitter-ion or by a free-ion mechanism,[1] as is shown in Eq. 1. According to this scheme, the true initiating species of



$$\rightleftarrows BF_3\text{-}O\text{-}CH_2\text{-}O\text{-}CH_2\text{-}O^{\oplus}{=}CH_2 \qquad (1)$$

trioxane polymerization catalyzed by BF_3 coordination complexes may be the BF_3 derived from the BF_3 coordination complex molecule, rather than the actual BF_3 coordination complex molecule itself. On the other hand, as reported in a previous paper,[2] it has been found that water is necessary as a cocatalyst to initiate the polymerization by $BF_3 \cdot O(C_2H_5)_2$ in *n*-hexane. This fact suggests that an initiation mechanism through the formation of a BF_3-trioxane coordination complex does not apply in *n*-hexane.

In this paper, the catalytic mechanism involving BF_3 coordination complexes in the solution polymerization of trioxane will be discussed. In addition, the effect of some additives on the polymerization has been investigated in order to clarify the initiation mechanism. As a result, it is concluded that the BF_3 coordination complex itself participates in the initiation of trioxane polymerization; that is, trioxane is attacked by a cationic species produced directly by the ionization of the BF_3 coordination complex.

Experimental

The procedures of the polymerization, the measurement of the viscosity number, and the method of purifying trioxane, ethylene dichloride and $BF_3 \cdot O(C_2H_5)_2$ were the same as those described in previous papers.[2,3] The coordination complexes of BF_3 with two molecules of ethyl alcohol and acetic acid were purified by distilling, in a vacuum, commercial materials (b. p., $BF_3(C_2H_5OH)_2$: 77.5—78°C/11—12 mmHg, $BF_3(CH_3CO_2H)_2$: 78—79°C/18—22 mmHg). The density of these catalysts was measured approximately by the usual piconometer technique at 20°C; $BF_3(C_2H_5OH)_2$: 1.18_1 (lit.,[4] 1.164, $BF_3 \cdot C_2H_5OH$; 1.272), $BF_3(CH_3CO_2H)_2$: 1.37_6 (lit.,[4] 1.342, $BF_3 \cdot CH_3CO_2H$; 1.496). Although precise measurement was very difficult due to the hygroscopic character of these compounds, these values show that these catalysts can approximately be treated

as the coordination complexes of BF_3 with two donor molecules.

Results

The Effect of the Nature of the Donor Molecule in the BF_3 Coordination Complex Catalyst on the Polymerization Reaction.— Ethyl ether (Et_2O), ethyl alcohol (EtOH) and acetic acid (AcOH) were selected as donor molecules, and the coordination complexes of BF_3 with these compounds were used as catalysts. It was found by preliminary experiments that, in the case of the $BF_3(EtOH)_2$ and $BF_3(AcOH)_2$ catalysts, the order of reaction with respect to the catalyst was smaller than one, and that the molecular weights of the polymers formed decreased with an increase in the catalyst concentration, as was shown in the case of the $BF_3 \cdot Et_2O$ catalyst.[2,3]

Figure 1 shows the effect of the donor molecule

on the polymerization rate, while Fig. 2 shows its effect on the molecular weight of the polymer formed under similar conditions. In all cases, the molecular weights of the polymer formed increased with an increase in the polymer yield. This fact may be explained in terms of a larger initiation rate than the propagation rate and no termination reaction, as has been shown in a previous paper[3] and in another report.[5]

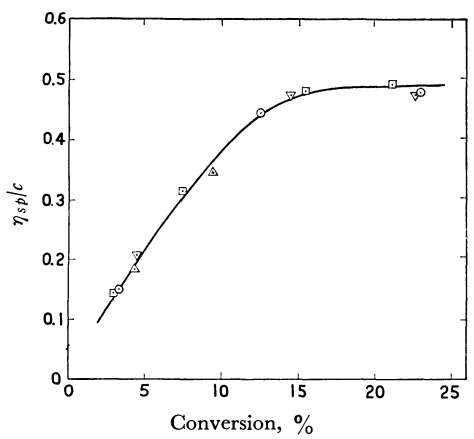

Fig. 5. Effect of the concentration of added Et_2O on the molecular weight of the polymer formed by $BF_3 \cdot Et_2O$ in ethylene dichloride at 30°C. ($[M]_0$; 3.3 mole/l., $[H_2O]$; 7 mmole/l., $[BF_3 \cdot Et_2O]$; 10 mmole/l., $[Et_2O]$; (○): 0, (△): 1.9, (□): 5.0 and (▽): 10 mmole/l.)

5) T. Kagiya, M. Hatta and K. Fukui, *Chem. High Polymers, Japan*, **20**, 730, 737 (1963).

As is clear from Fig. 1, the polymerization rates decrease in the order:

$$BF_3(EtOH)_2 > BF_3(AcOH)_2 > BF_3 \cdot Et_2O.$$

As may be seen in Fig. 2, the molecular weights of the polymers obtained at a fixed polymer yield decrease in the order:

$$BF_3 \cdot Et_2O > BF_3(EtOH)_2 \simeq BF_3(AcOH)_2.$$

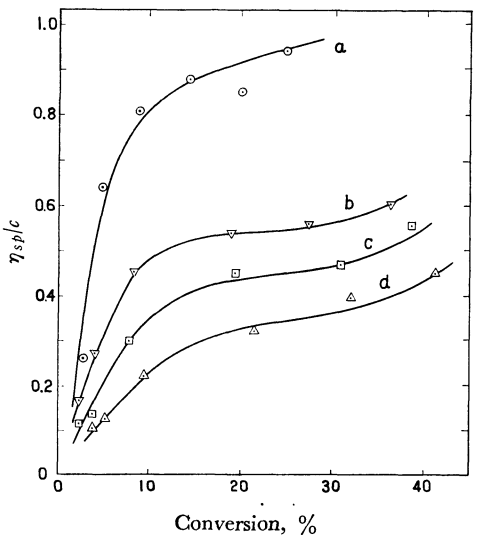

Fig. 7. Effect of the concentration of added EtOH on the molecular weight of the polymer formed by $BF_3 \cdot Et_2O$ in ethylene dichloride at 30°C.
($[M]_0$; 3.3 mole/l., $[H_2O]$; 2 mmole/l., $[BF_3 \cdot Et_2O]$; 10.0 mmole/l., [EtOH]; a(○): 0, b(▽): 2.5, c(□): 4.9 and d(△): 9.9 mole/l.)

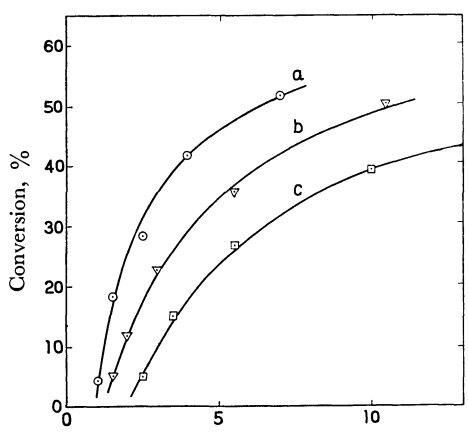

Fig. 8. Effect of the concentration of added Et_2O on the rate of polymerization catalyzed by $BF_3(EtOH)_2$ in ethylene dichloride at 30°C. ($[M]_0$; 3.3 mole/l., $[H_2O]$; 1.8 mmole/l., $BF_3(EtOH)_2$; 7.3 mmole/l., $[Et_2O]$; a(○): 0, b(▽): 2.0, and c(□): 5.0 mmole/l.)

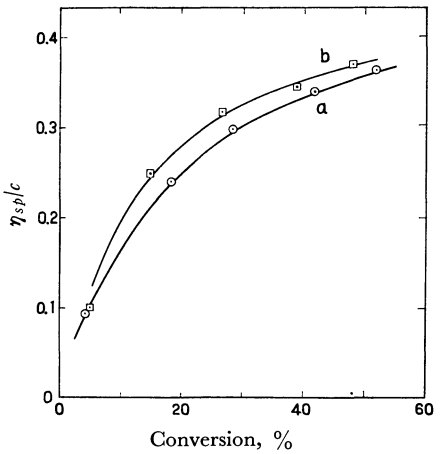

Fig. 9. Effect of the concentration of added Et_2O on the molecular weight of the polymer formed by $BF_3(EtOH)_2$ in ethylene dichloride at 30°C.
([M]$_0$; 3.3 mole/l., [H_2O]; 1.8 mmole/l., [$BF_3(EtOH)_2$]; 7.3 mmole/l., [Et_2O]; a(○): 0 and b(□): 5.0 mmole/l.)

The Effect of Additives on the Polymerization.—Figures 3, 4, and 5 show the effect of the additive (X), when this is the same as the donor molecule in the BF_3·X coordination complex, on the molecular weight of the polymer formed by BF_3·X. The X is EtOH in Fig. 3, AcOH in Fig. 4, and Et_2O in Fig. 5.

Figure 6 shows the effect of added EtOH on the rate of polymerization catalyzed by BF_3·Et_2O, while Fig. 7 shows its effect on the molecular weight of the polymer formed by BF_3·Et_2O.

Figure 8 shows the effect of added Et_2O on the rate of polymerization catalyzed by $BF_3(EtOH)_2$, while Fig. 9 shows its effect on the molecular weight of the polymer formed in the reaction.

Discussion

In vinyl polymerization catalyzed by Lewis acids, there are many cases in which a cocatalyst is necessary.[6] In the trioxane polymerization catalyzed by BF_3, however, no necessity for a cocatalyst has been suggested.[1] In this case, the boron trifluoride - trioxane coordination complex should be formed if the polymerization is to occur according to Eq. 1. Then the ring of this complex opens and the polymerization proceeds either through a free-ion or zwitter-ion mechanism.

According to this suggestion, the following mechanisms may be proposed for the trioxane polymerization catalyzed by BF_3 coordination complexes, where X is a donor molecule:

$$BF_3{\cdot}X \rightleftharpoons BF_3 + X \qquad (2)$$

$$BF_3 + \text{O}\bigcirc \longrightarrow BF_3{\cdot}\text{O}\bigcirc \qquad (2')$$

or

$$BF_3{\cdot}X + \text{O}\bigcirc \rightleftharpoons BF_3{\cdot}\text{O}\bigcirc + X \qquad (3)$$

In either case, the rate of polymerization will be controlled by the concentration of the BF_3-trioxane coordination complex formed. Consequently, the variation in the concentration of this complex with the character of the donor molecule will now be discussed.

According to Eqs. 2 and 3, it may be considered that the BF_3-trioxane coordination complex is more easily produced when the strength of the BF_3-donor bond is weaker. The BF_3-donor bond energy is considered to be larger when the ionization potential of the donor molecule is small.[7] The ionization potential decreases in the order[8]:

$$AcOH > EtOH > Et_2O.$$

Therefore, the BF_3-donor bond energy will decrease in the order:

$$BF_3 \cdot Et_2O > BF_3(EtOH)_2 > BF_3(AcOH)_2.$$

The BF_3-donor bond energy of the 1 : 2 complexes used in this paper is considered to be in the same order as that of the corresponding 1 : 1 complexes, since the 1 : 2 complexes are formed by an additional donor-acceptor interaction of the second molecule, not with BF_3, but with the proton of the donor molecule in the corresponding 1 : 1 complex.[4] Therefore, it might be expected that the rates of polymerization catalyzed by these complexes decrease in the order:

$$BF_3(AcOH)_2 > BF_3(EtOH)_2 > BF_3 \cdot Et_2O.$$

This order, however, does not agree with the experimental results.

According to Eq. 2 or 3 the structure of the growing chain end is considered to be always the same, independent of the kind of donor molecule in the BF_3 coordination complex. As the rate of polymerization catalyzed by $BF_3(EtOH)_2$ is, as Fig. 1 shows, larger than that catalyzed by $BF_3(AcOH)_2$, the concentration of the BF_3-trioxane coordination complex formed by the $BF_3(EtOH)_2$ catalyst is considered to be larger than that formed by the $BF_3(AcOH)_2$ catalyst. Therefore, the molecular weight of the polymer formed by the former ought to be smaller than that formed by

8) J. D. Morrison and A. J. C. Nicholson, *J. Chem. Phys.*, **20**, 1021 (1952).

the latter, at the same polymer yield. This speculation does not agree with the experimental result, either.

However, for the purposes of the above speculation, it is necessary to assume that the free AcOH or EtOH resulting from the exchange reaction does not act as a transfer agent. In fact, as is shown in Figs. 3 and 4, AcOH and EtOH do not act as transfer agents to any significant degree when these additives are employed at lower concentrations than that of the corresponding catalyst.

In view of the above-mentioned facts, the mechanism of the initiation reaction for trioxane polymerization according to Eqs. 2 and 3 must be rejected. Indeed, the exchange reaction according to Eqs. 2 and 3 might occur to produce the BF_3-trioxane coordination complex, but this complex does not seem to play an essential part in the polymerization reaction.

Another mechanism for the initiation reaction of trioxane polymerization must also be taken into account. The vinyl polymerization catalyzed by $BF_3 \cdot X$ coordination complexes is considered to be initiated by the attack of the alkyl cation, resulting from an ionization of the $BF_3 \cdot X$ coordination complex, on the monomer, and to proceed through an ion-pair mechanism, as is shown in Eq. 4:[9]

$$BF_3 \cdot X \rightleftarrows BF_3Y\ominus R\oplus$$

$$BF_3Y\ominus R\oplus + M \longrightarrow R\text{-}M\oplus \cdots BF_3Y\ominus \qquad (4)$$

$R\oplus$: a proton or alkyl cation

We believe that this idea may also be adopted in the trioxane polymerization on the grounds of the following considerations.

The rate of polymerization catalyzed by $BF_3(EtOH)_2$ is, as Fig. 1 shows, larger than that catalyzed by $BF_3(AcOH)_2$. However, the molecular weights of the polymers obtained at the same polymer yield in both systems are nearly equal. The latter fact means that the numbers of the polymer molecules produced in both polymerization systems under similar conditions are equal; that is, the concentrations of the initiating species, or of the growing chains, are equal in both systems. This speculation is supported by the fact that the addition of a small amount of an additive (X) to the $BF_3 \cdot X_2$ catalyst does not affect the molecular weight of the resultant polymer. As the initiating species is a proton solvated by the corresponding donor molecule in both cases, the difference in the polymerization rate between both catalysts can probably be ascribed to that of the rate of propagation reaction. This implies that there is a difference in the structure of the growing chain end or in the gegen ion between the two polymerization systems, as is suggested in the usual vinyl polymerization. Therefore, it may be concluded that, in the trioxane polymerization, the $BF_3 \cdot X$ coordination complex is partially ionized in a polar solvent, and that the resulting cation attacks the monomer.

The rate of polymerization catalyzed by $BF_3(EtOH)_2$ is, as is shown in Fig. 1, much larger than catalyzed by $BF_3 \cdot Et_2O$. The initiating species is considered to be a proton solvated by ethyl alcohol (or an ethoxonium ion) in the $BF_3(EtOH)_2$ catalyst, and an ethyl cation in $BF_3 \cdot Et_2O$, while the gegen ion is considered to be the same in both catalysts according to Eq. 4. This supposition has been confirmed in the polymerization of styrene catalyzed by these similar catalysts.[10] Therefore, the differences between the two catalysts in the rate of polymerization and in the molecular weight of the polymers may be due to the initiation step. As the degree of ionic dissociation of molten $BF_3(EtOH)_2$ is about sixty times larger than that of molten $BF_3 \cdot Et_2O$,[11] it may be anticipated that the former will also be ionized more easily than the latter in ethylene dichloride. Therefore, the larger rate of polymerization and the lower molecular weight of the polymer in $BF_3(EtOH)_2$ than in $BF_3 \cdot Et_2O$ are probably caused by the higher concentration of the initiating species in $BF_3(EtOH)_2$ than in $BF_3 \cdot Et_2O$. Also, the difference in the rate of polymerization between the two catalysts may be partly ascribed to a difference in the reactivity of the initiating species; that is, to the difference in reactivity between a proton (solvated by ethyl alcohol) and an ethyl cation.

Thus, the mechanism for the function of the BF_3 coordination complex according to Eq. 4 can explain the experimental results. As has been shown in a previous paper,[2] $BF_3 \cdot Et_2O$ cannot initiate the polymerization of trioxane without a cocatalyst such as water in a non-polar solvent. It may probably be concluded that, on the basis of such a mechanism, the polymerization of trioxane catalyzed by BF_3 does not occur without a cocatalyst.

In the trioxane polymerization catalyzed by $BF_3 \cdot Et_2O$, the polymer yield in a given period of time increased upon the addition of a small amount of water in ethylene dichloride.[2] In this work the effect of EtOH on the trioxane polymerization catalyzed by $BF_3 \cdot Et_2O$ was also studied. As is clear from Figs. 6 and 7, the addition of EtOH increases the polymer yield in a given period of time and decreases the molecular weight of the polymer formed. This result indicates that, besides the occurrence of the usual transfer reaction of a growing chain to EtOH, it can be supposed that the exchange reaction, as is shown in Eq. 5,

9) e. g., J. P. Kennedy, *J. Polymer Sci.*, **38**, 263 (1959).

10) S. Aoki and M. Imoto, *Makromol. Chem.*, **65**, 243 (1963).

11) N. N. Greenwood and R. L. Martin, *J. Chem. Soc.*, **1953**, 1427 (1953).

takes place upon the addition of $BF_3 \cdot Et_2O$ to a monomer solution containing a small amount of EtOH. Such an exchange reaction with respect to BF_3 has been observed by NMR spectroscopy.[12]

$$BF_3 \cdot Et_2O + EtOH \rightleftarrows BF_3 \cdot EtOH(\text{or } BF_3(EtOH)_2) + Et_2O \quad (5)$$

The increase in the polymerization rate upon the addition of a small amount of EtOH is probably due to the simultaneous occurrence of the polymerization catalyzed by $BF_3(EtOH)_2$, which has a much larger ability to produce the initiating species than does $BF_3 \cdot Et_2O$.

According to this speculation, the addition of Et_2O to the polymerization system catalyzed by $BF_3(EtOH)_2$ ought to lead to the following reaction (Eq. 6); the polymerization may then proceed through two kinds of catalyst.

$$BF_3(EtOH)_2 + Et_2O \rightleftarrows BF_3 \cdot Et_2O + 2EtOH \quad (6)$$

As the concentration of $BF_3(EtOH)_2$ decreases upon the equilibrium of Eq. 6, and as the $BF_3 \cdot Et_2O$ catalyst has only a small tendency to form the initiating species, the total concentration of the initiating species will decrease in comparison with the case without the additive. Consequently, the rate of polymerization will decrease and the molecular weight of the polymer will increase, since the molecular weight of the formed polymer increases with the decrease in the catalyst concentration, as has been reported in a previous paper.[3] The experimental results support this speculation, as is shown in Figs. 8 and 9. That is, the rate of polymerization decreases and the molecular weight of the polymer increases upon the addition of Et_2O to the trioxane-$BF_3(EtOH)_2$ system. The increase in the molecular weight was not caused by an experimental error in the viscosity measurement. In fact, the molecular weight of the polymer was decreased by the addition of AcOH instead of Et_2O under the same conditions.[13]

If the additive acts only as a transfer agent, it should only decrease the molecular weight of the polymer formed. However, in the present paper, the additive caused an increase in the polymerization rate or in the molecular weight of the polymer formed, depending on the particular system examined. These facts mean that the additive participates in the initiation of the polymerization reaction. Therefore, it may concluded that the polymerization reaction of trioxane occurs according to Eq. 4, not according to Eqs. 2 and 3.

The Reaction of *N*-Acylurethans with Phenyl Glycidyl Ether Accompanying Acyl Migration

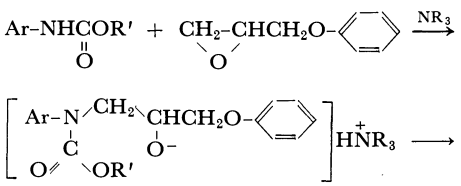
By Yoshio IWAKURA, Shin-ichi IZAWA and Fusakazu HAYANO

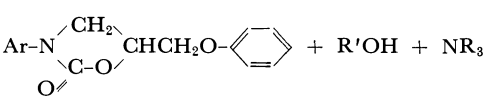
Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received March 19, 1966)

N-Acylethylurethans reacted with phenyl glycidyl ether to produce 3-acyl-5-phenoxymethyl-2-oxazolidones, 5-phenoxymethyl-2-oxazolidone and *N*-(2-acyloxy-3-phenoxypropyl)ethylurethans. The reaction mechanism involving acyl migration was discussed.

In an earlier paper[1] it has been shown that the addition condensation reaction between *N*-arylurethan and phenyl glycidyl ether occurs to form 2-oxazolidone in the presence of tertiary amines as catalysts:

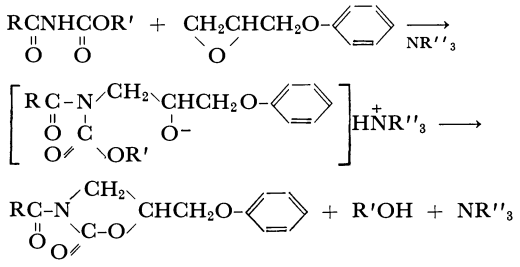




However, *N*-alkylurethans do not react with phenyl glycidyl ether. Further investigation of the reaction between *N*-(*p*-substituted phenyl)-urethans and phenyl glycidyl ether showed that electron-withdrawing substituents facilitated the reaction.

1) Y. Iwakura and S. Izawa, *J. Org. Chem.*, **29**, 379 (1964).

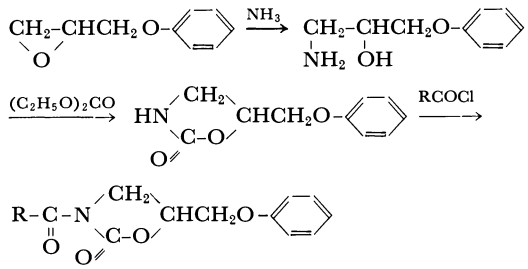
N-Acylurethans have been chosen in this study because of the electron-withdrawing ability of the acyl group. It is expected that 3-acyl-5-phenoxymethyl-2-oxazolidone will be obtained according to the following equation:



Results

The reaction of *N*-acylethylurethan with phenyl glycidyl ether was more complicated than had been expected. When this reaction was carried out at 70°C for 3—8 hr. in an organic solvent such as toluene or dimethylacetamide, using triethylenediamine as the catalyst, the products were 3-acyl-5-phenoxymethyl-2-oxazolidone and also 5-phenoxymethyl-2-oxazolidone. Moreover, *N*-(2-acyloxy-3-phenoxypropyl)ethylurethan, formed as the result of the N→O migration of the acyl group, was obtained. The reaction conditions and product ratios are listed in Table I.

The 3-acyl-5-phenoxymethyl-2-oxazolidones obtained by this reaction were identical with the authentic samples synthesized from acyl chlorides and 5-phenoxymethyl-2-oxazolidone. 5-Phenoxymethyl-2-oxazolidone was synthesized from 2-hydroxy-3-phenoxypropylamine and diethylcarbonate according to Homeyer's method:[2]



The infrared spectra of 3-acyl-5-phenoxymethyl-2-oxazolidones showed two strong absorptions, at 1700 cm^{-1} and 1760 cm^{-1} which were assignable to the carbonyl groups in cyclic urethan and in the acyl substituent respectively. In the infrared spectrum of 5-phenoxymethyl-2-oxazolidone, the carbonyl absorption appeared at 1740 cm^{-1} and the NH-stretching at 3340 cm^{-1}, but no amide band at 1530 cm^{-1} (NH-deformation) was observed. Physical and analytical data on 3-acyl-5-phenoxymethyl-2-oxazolidones are listed in Table II.

N-(2-Acyloxy-3-phenoxypropyl)ethylurethans were characterized by elementary analysis, infrared spectra, and by a study of the saponification equivalent. These data are listed in Table III.

Discussion

The most likely reaction mechanism for the simultaneous formation of 3-acyl-5-phenoxymethyl-2-oxazolidone (IV) and *N*-(2-acyloxy-3-phenoxypropyl)ethylurethan (V) is the one which involves the common intermediate (III) formed by

the addition reaction of *N*-acylurethan (I) to phenyl glycidyl ether (II), as is depicted in Chart 1. The alkoxide anion in III can attack the carbonyl carbon either in the amide or urethan group intramolecularly. If the anion attacks the urethan carbonyl to cleave the acyl-oxygen linkage, IV and the ethoxide ion will be formed, while the attack on the amide carbonyl, followed by acyl-nitrogen cleavage, will result in the formation of V. The 5-phenoxymethyl-2-oxazolidone (VII) is considered to have resulted either from IV or V by the reaction of the ethoxide anion formed from III in the course of the formation of IV. The presence of ethanol and ethyl acetate was detected by the gas chromatographic analysis of the reaction mixture of I and II. As the ethoxide anion may possibly abstract the proton from $\overset{+}{H}N\leftarrow$ to form ethanol, it cannot be expected that all of the ethoxide anions will effect the conversion of IV or V to VII.

When 3-acetyl-5-phenoxymethyl-2-oxazolidone (IVa) was treated with ethanol and sodium ethoxide in toluene, VII was obtained. On the contrary, no reaction occurred when IVa was treated with ethanol in the presence of triethylenediamine instead of sodium ethoxide. VII was also obtained by the hydrolysis of V with alcoholic sodium hydroxide. However, no change in the infrared spectrum of the solution of V in toluene was recognized after it had been heated for 8 hr. in the presence of triethylenediamine. The formation of VII, rather than of *N*-(2-hydroxy-3-phenoxypropyl)ethylurethan, from V by hydrolysis is explained by the reaction scheme as being through the intermediate VI, just as that of IV from I and II proceeds through III.

The phenomenon of acyl migration in 2-aminoethanol derivatives and in similar compounds is well known, and reaction mechanisms have been proposed by many authors.[3-6] According to these authors, acyl migrations are reversible and the N→O migration proceeds in acidic media, whereas the O→N migration proceeds in basic media. In addition, when the amino group is acylated after the N→O migration has taken place, no more reverse migration of acyl group (O→N) proceeds, even when it is treated with alkali.

6) G. E. McCasland, ibid., **73**, 2295 (1951).

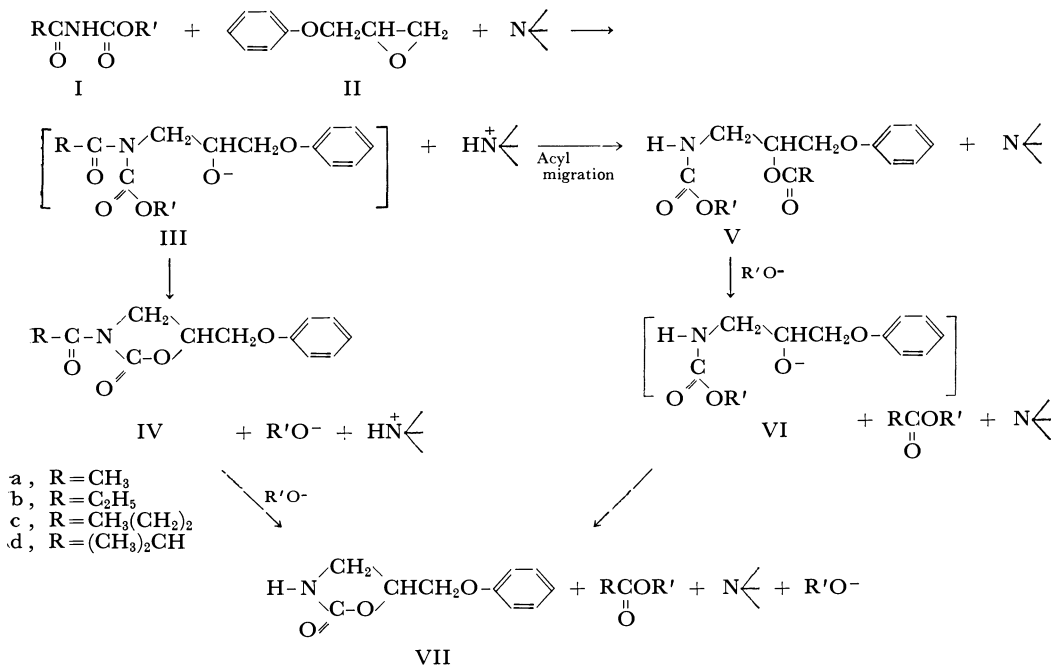

Chart 1

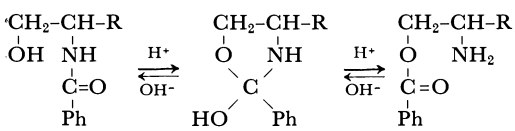

In the reaction of I with II, the N→O migration proceeded in basic media. The reverse migration of the acyl group, from V to III, was excluded, because prolonged reactions did not result in a decrease in V nor in an increase in IV, as is shown in Experiments P-1 and P-2. The change in the yield of V in Experiments A-3 and A-5 is the result of the formation of VII from V. The fact that the infrared spectrum of the solution of V in toluene did not change after it had been heated for 8 hr. also indicates that no migration from V to III proceeds. These experimental results may be explained by the difference in basicity between nitrogen and oxygen atoms.

In the reaction of epoxides with nucleophiles, the latter may attack either of the two epoxide-ring carbon atoms, leading to $-CH_2-O$ or $>CH-O$ fission. These two routes are usually referred to as "normal" and "abnormal" ring-opening respectively. In the reaction of I with II, normal opening was shown by NMR spectral study to occur. As Table IV shows, the methin protons of IV and VII give a signal at a field lower than that of 4-isopropyl-2-oxazolidone prepared from 2-hydroxy-1-isopropylethylamine and phosgene by 1.3 p. p. m. A similar observation about the effect of the neighboring atom on the chemical shift has been shown in the spectra of the $O-CH_3$ proton and the $N-CH_3$ proton, and it has been indicated that the $O-CH_3$ proton gives a signal at a field lower than that of the $N-CH_3$ proton by about 1 p. p. m., presumably because of the inductive effect of the neighboring oxygen atom.[7] The NMR spectra of IVa and VII were completely identical with those of 3-acetyl-5-phenoxymethyl-2-oxazolidone and 5-phenoxymethyl-2-oxazolidone prepared by Homeyer's method. Since the opening of the epoxide ring by ammonia is considered to be normal, the oxazolidones prepared by Homeyer's method are 5-substituted ones.

Found: N, 8.85. Calcd. for $C_7H_{13}NO_3$: N, 8.80%.

N-*i*-Butyryl, m. p. 100—101°C.

Found: N, 8.67. Calcd. for $C_7H_{13}NO_3$: N, 8.80%.

The Reaction of *N*-Acylethylurethan and Phenyl Glycidyl Ether.—A typical procedure (A-2) was as follows. A mixture of 5.24 g. (0.04 mol.) of *N*-acetylethylurethan and 6.00 g. (0.04 mol.) of phenyl glycidyl ether in 10 ml. of toluene was heated to 70°C, and then 0.2 g. of triethylenediamine was added to the mixture. The mixture was refluxed at 70°C for 3 hr. under reduced pressure. After the solvent had been removed in a vacuum, the reaction mixture was distilled at 0.4 mmHg. *N*-Acetylethylurethan was recovered by sublimation at first, and then phenyl glycidyl ether was distilled at 71—74°C. A fraction boiling at 160—190°C at 0.1 mmHg was collected (5.88 g.). This was a pale yellow, viscous liquid consisting of a mixture of 3-acetyl-5-phenoxymethyl-2-oxazolidone, 5-phenoxymethyl-2-oxazolidone and *N*-(2-acetoxy-3-phenoxypropyl)ethylurethan; it crystallized partially after it had stood overnight. It was treated with 30 ml. of cold ether and filtered to remove liquid *N*-(2-acetoxy-3-phenoxypropyl)ethylurethan. The crystalline part weighed 4.24 g. A portion of 2.00 g. of the crystals was treated with 200 ml. of boiling cyclohexane and filtered in hot to extract 3-acetyl-5-phenoxymethyl-2-oxazolidone. The remaining crystals were treated by the same method four times using each 200 ml. of cyclohexane. Finally, 0.15 g. of 5-phenoxymethyl-2-oxazolidone was obtained as an insoluble material which was proved to be free from 3-acetyl-5-phenoxymethyl-2-oxazolidone on the basis of infrared spectral analysis. It was further purified by recrystallization from 1500 ml. of cyclohexane; m. p. 121—122°C.

Found: C, 62.43; H, 5.52; N, 7.40. Calcd. for $C_{10}H_{11}NO_3$: C, 62.16; H, 5.74; N, 7.25%.

Five filtrates obtained from the above treatments were combined and evaporated. The residue (1.75 g.) was recrystallized from a mixture of 500 ml. of ether and 10 ml. of acetone to give 3-acetyl-5-phenoxymethyl-2-oxazolidone, m. p. 114.5—115.5°C.

Found: C, 61.22; H, 5.50; N, 5.89. Calcd. for $C_{12}H_{13}NO_4$: C, 61.27; H, 5.57; N, 5.96%.

A liquid portion of the *N*-(2-acetoxy-3-phenoxypropyl)ethylurethan obtained at the beginning of this fractionation procedure was evaporated to give 1.29 g. of *N*-(2-acetoxy-3-phenoxypropyl)ethylurethan. Distillation gave a pure product, b. p. 147—148°C at 0.03 mmHg.

Found: C, 59.88; H, 6.57; N, 4.97. Calcd. for $C_{14}H_{19}NO_5$: C, 59.77; H, 6.81; N, 4.98%.

The yields of 3-acetyl-5-phenoxymethyl-2-oxazolidone, 5-phenoxymethyl-2-oxazolidone, and *N*-(2-acetoxy-3-phenoxypropyl)ethylurethan were 4.16 g. (44%), 0.35 g. (5%), and 1.37 g. (12%) respectively, on the basis of the above-mentioned fraction collected at 160—190°C at 0.1 mmHg.

The Saponification Equivalent of *N*-(2-Actloxy-3-phenoxypropyl)ethylurethan.—A typical procedure was as follows. Into a 100-ml. Erlenmeyer flask, 0.7465 g. of *N*-(2-acetoxy-3-phenoxypropyl)ethylurethan was taken. Fifteen milliliters of a 0.5 N alcoholic sodium hydroxide solution was then added to the flask. The solution was allowed to stand at room temperature for 1.5 hr., and then it was warmed at 40°C for 5 min. The excess alkali was titrated by means of 0.2 N hydrochloric acid. The saponification equivalent was found from the amount of alkali consumed to be 281 (calcd. 281).

The hydrolyzed mixture was evaporated under reduced pressure, and then the residue was recrystallized from ether to give white crystalline 5-phenoxymethyl-2-oxazolidone.

The Hydrolysis of 3-Acetyl-5-phenoxymethyl-2-oxazolidone.—A solution of 0.820 g. of 3-acetyl-5-phenoxymethyl-2-oxazolidone in 20 ml. of 0.5 N alcoholic sodium hydroxide was allowed to stand for 8 hr. at room temperature. The mixture was then evaporated under reduced pressure, and the residual solid was washed with 1 ml. of water to give 0.376 g. (56%) of 5-phenoxymethyl-2-oxazolidone.

The Acylation of 5-Phenoxymethyl-2-oxazolidone.—A typical procedure was as follows. A mixture of 1.93 g. (0.01 mol.) of 5-phenoxymethyl-2-oxazolidone and 1.1 g. (0.011 mol.) of triethylamine in 50 ml. of benzene was heated to 80°C. Into the mixture, a solution of 1.10 g. (0.01 mol.) of propionyl chloride in 20 ml. of benzene was added, drop by drop, over a 10-min. period. As the reaction proceeded, triethylamine hydrochloride precipitated. The mixture was refluxed for 2 hr. and filtered in hot to remove triethylamine hydrochloride. The filtrate was evaporated under reduced pressure, and the residual white solid was washed with 5 ml. of water to remove the triethylamine hydrochloride completely. The crude product weighed 2.67 g. (100%). It was distilled at 0.04 mmHg, and the fraction boiling at 162—165°C was collected to give 1.95 g. (74%) of 3-propionyl-5-phenoxymethyl-2-oxazolidone. After the recrystallization from diethyl ether had been repeated, pure 3-propionyl-5-phenoxymethyl-2-oxazolidone was obtained; m. p. 122—124°C.

Found: C, 62.95; H, 5.66; N, 5.67. Calcd. for $C_{13}H_{15}NO_4$: C, 62.64; H, 6.07; N, 5.62%.

2-Oxazolidones from Glycidyl Ether Reactions with Acid Amides

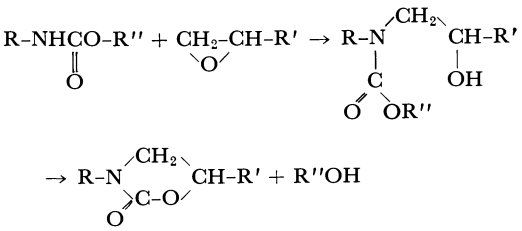
By Yoshio IWAKURA and Shin-ichi IZAWA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received March 19, 1966)

The reaction between acid amides and aryl glycidyl ethers was carried out using tertiary amine as the catalyst. 2-Oxazolidone derivatives were obtained by the reaction of trichloroacetanilide or trifluoroacetanilide with aryl glycidyl ether. Acyl migration occurred in the reaction of acetanilide with phenyl glycidyl ether.

In a previous paper[1] we reported that 2-oxazolidone ring formation occurred in the reaction between epoxides and urethans. The reaction has been shown to proceed through a nucleophilic attack of the imide group of urethans on an epoxy ring, followed by an intramolecular exchange of alcohols with a carbon-oxygen bond scission in urethan linkage. Keeping in mind that the epoxides can react with the imide groups of urethans under the catalysis of tertiary amines, and that acid amides and urethans have the same imide groups, the reactivity of the epoxy ring with acid amide will be studied here.



A mixture of equimolar acetanilide and phenyl glycidyl ether, with a small amount of triethylamine as a catalyst, was heated at 100°C for 5 hr. The infrared spectra of the reaction mixture showed an

a) Identified by preparing acetates (VIa and VIIIa).
b) *N, N'*-diphenyldiketopiperazine was obtained in good yield.
c) It was difficult to estimate the structure of products from the infrared spectra of reaction mixture.
d) 3-Phenyl-5-phenoxymethyl-2-oxazolidone was obtained quantitatively.

1) Y. Iwakura and S. Izawa, *J. Org. Chem.*, **29**, 379 (1964).

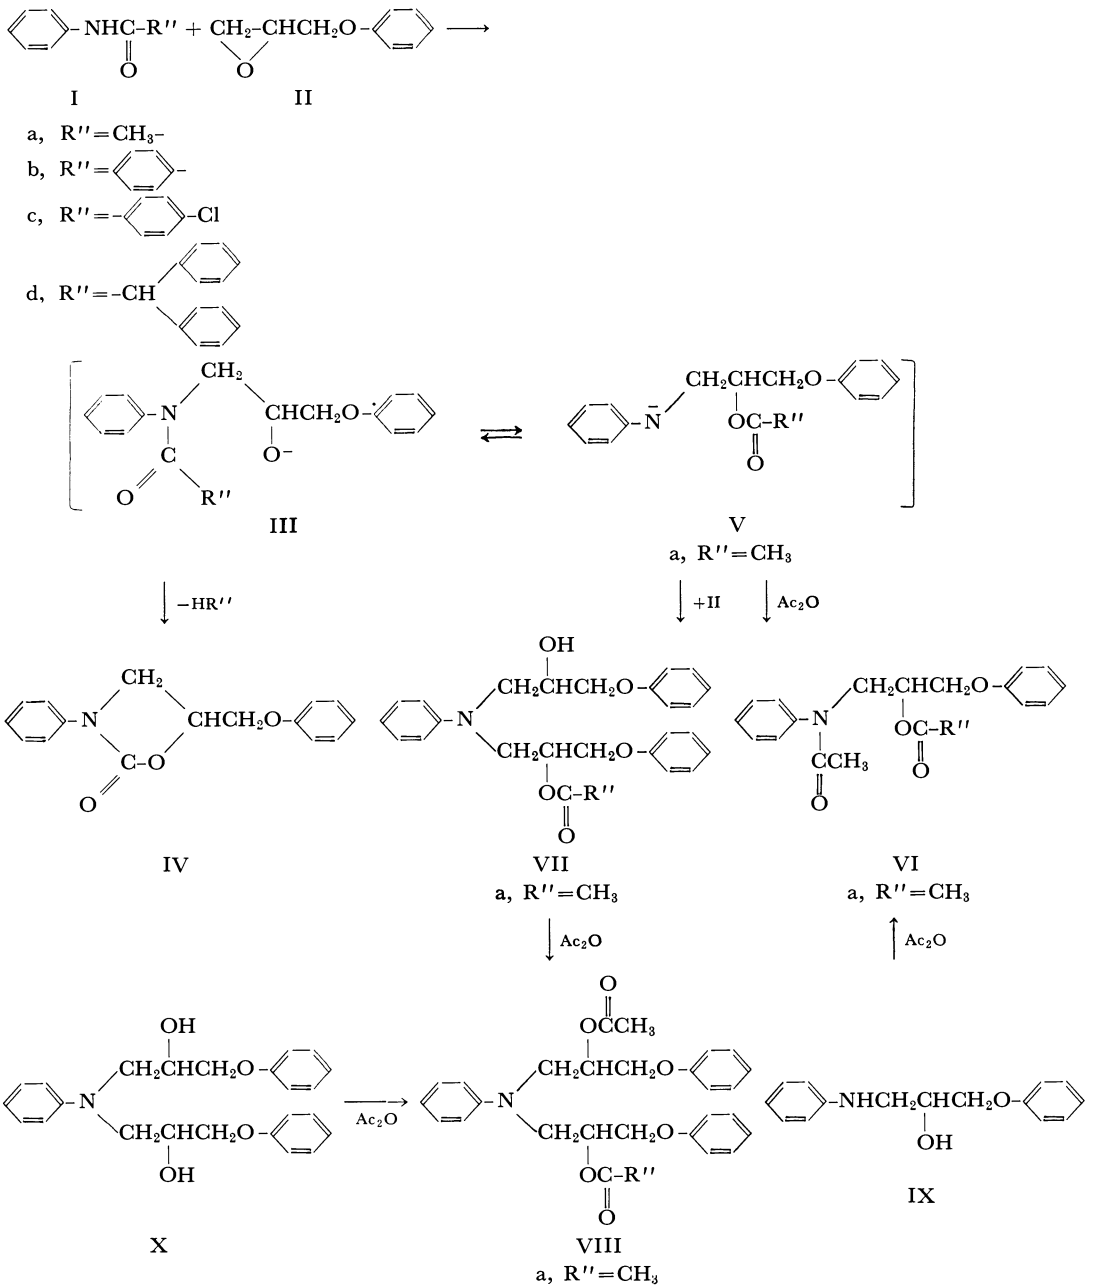

Chart 1

appearance of a new strong absorption at 1735 cm^{-1} and a decrease in the intensity of the amide band of the starting material. The acetylation of the products without separation gave VIa and VIIIa, as Chart 1 shows. The structure of VIa and VIIIa were confirmed to be diacetates of *N*-(3-phenoxy-2-hydroxypropyl)aniline (IX) and *N*, *N*-bis(3-phenoxy-2-hydroxypropyl)aniline (X) respectively, by comparing the melting point and the infrared spectra with the authentic samples prepared via the acetylation of IX and X according to Kier and Penland's method.[2]

These results suggested that the nucleophilic attack of the imide group of acid amide on the epoxy ring occurred easily as had been expected, but that the intramolecular acyl migration reaction proceeded exclusively in the intermediate, III, to give esteramine (Va), since carbon-carbon bond scission was difficult. Further reaction of

Va with phenyl glycidyl ether occurred, yielding VIIa because the reactivity of the imino group of Va was higher than that of Ia.

In order to investigate the possibility of carbon-carbon bond scission in the reaction intermediate, III, an electron-withdrawing group was introduced into the acid component of acid amides. The acid amides prepared and the results of the reaction between these compounds and phenyl glycidyl ether are listed in Table I. The fact that only trifluoro- and trichloroacetanilides gave the 2-oxazolidone derivatives (IV) shows that a moderately strong electron-withdrawing ability is necessary to break the carbon-carbon bond in the intermediate, III.

The infrared spectra of the reaction mixture between phenyl glycidyl ether and *p*-nitrobenzanilide, *p*-nitrophenylacetanilide, dichloroacetanilide, 1, 1, 2, 2-tetrafluoropropionanilide, and cyanoacetanilide showed that some side reactions occurred, but they were not studied further.

N-Aryl-trichloroacetamides and *N*-aryl-trifluoroacetamides were prepared by the condensation of the corresponding amines and trichloro- or trifluoroacetyl chlorides. The reaction between these amides and phenyl glycidyl ether gave 3-aryl-5-phenoxymethyl-2-oxazolidones in good yields, as had been expected. The results are listed in Table II.

Trichloroacetanilide and aryl glycidyl ethers also produced 3-phenyl-5-aryloxymethyl-2-oxazolidones, as Table III shows.

Experimental

Glycidyl Ethers.—These were prepared by the condensation of the corresponding phenols and epichlorohydrin, as has been described in our previous paper.[1] A typical preparation will be described below.

***p*-Chlorophenyl Glycidyl Ether.**—To a mixture of 128.5 g. (1.0 mol.) of *p*-chlorophenol and 370 g. (4 mol.) of epichlorohydrin was added 54 g. (1.0 mol.) of sodium methylate in 400 ml. of methanol drop by drop with stirring during 1-hr. period at room temperature; the mixture was then stirred for an additional 1 hr. After the epichlorohydrin had been removed, the residue was distilled under reduced pressure to give 144 g. (78%) of *p*-chlorophenyl glycidyl ether, b. p. 115—116°C/2 mmHg; n_D^{25} 1.5419.

Acid Amides.—These were prepared by the condensation reaction of the corresponding amines with acid chlorides. Examples will be shown below.

***α*-Chloroacetanilide.**—To a solution of 22.6 g. (0.2 mol.) of monochloroacetyl chloride in 100 ml. of benzene was added 18.6 g. (0.2 mol.) of aniline and 20.2 g. (0.2 mol.) of triethylamine in 200 ml. of benzene with stirring at 10—20°C; the mixture was then allowed to stand for 3 hr. After the triethylamine hydrochloride had been filtered out and the benzene removed, the resulting crystalline solid was recrystallized from water to give 21.7 g. (64%) of α-chloroacetanilide, m. p. 163.5—164°C.

***α, α, α*-Trifluoroacetanilide.**—To a solution of 9.3 g. (0.1 mol.) of aniline and 10.1 g. (0.1 mol.) of triethylamine in 100 ml. of acetone was added 13.3 g. (0.1 mol.) of trifluoroacetyl chloride in 60 ml. of acetone with stirring at −10°C. The mixture was then allowed to stand for 1 hr. at room temperature. After the triethylamine hydrochloride had been filtered out and the acetone had been removed, the resulting crystalline solid was recrystallized from *n*-hexane to give 40.7 g. (72%) of α, α, α-trifluoro-*p*-ethoxyacetanilide, m. p. 139—140°C.

The Reaction between Acid Amides and Glycidyl Ethers.—A mixture of equimolar amounts of acid amide and glycidyl ether, with triethylenediamine as a catalyst, was heated at 100°C for 2 hr. An example will be shown below.

The Reaction of Phenyl Glycidyl Ether with Acetanilide.—A mixture of 13.5 g. (0.1 mol.) of acetanilide and 15.0 g. (0.1 mol.) of phenyl glycidyl ether was heated at 100°C in order to dissolve both ingredients, and then 0.1 g. of triethylenediamine was added. The mixture was heated at 100°C for 2 hr. After cooling, the reaction mixture was poured into a solution of 100 g. of acetic anhydride in 80 g. of pyridine and allowed to stand overnight at room temperature. Pyridine and acetic anhydride were removed by distillation under reduced pressure, and the residue was recrystallized from ethyl acetate to give 9.5 g. of *N*, *N*-bis(3-phenoxy-2-hydroxypropyl)aniline diacetate (VIIIa). After the ethyl acetate had been evaporated from the filtrate, the residue was recrystallized from ethanol to give 9.8 g. *N*-(3-phenoxy-2-hydroxypropyl)aniline diacetate (VIa). Acetanilide (4.1 g.) was recovered from the filtrate. The structures of VIa and VIIIa were confirmed by a mixed-melting-point determination and by comparing the infrared spectra with those of authentic samples.

The Preparation of Authentic Samples (VIa and VIIIa).—*N-(3-Phenoxy-2-hydroxypropyl)aniline Diacetate (VIa).*—To 9.5 g. (0.1 mol.) of redistilled aniline, which was maintained at 120°C, 4.5 g. (0.03 mol.) of phenyl glycidyl ether was added over 1-hr. period. The mixture was then heated for an additional 15 min. and distilled at 10 mmHg to recover the unreacted aniline. The pressure was then reduced further, and 6.5 g. of a viscous oil, b. p. 180—185°C (0.1 mmHg), was distilled. After the oil had been dissolved in a toluene - petroleum ether mixture, upon cooling 5.9 g. (80.9%) of *N*-(3-phenoxy-2-hydroxypropyl)aniline (IX) crystallized, m. p. 60—62°C (lit, 61—63°C). A mixture of IX (5.0 g.), pyridine (30 g.), and acetic anhydride (40 g.) was allowed to stand for 1 day at room temperature. Pyridine and acetic anhydride were removed by distillation under reduced pressure, and the residue was recrystallized several times from ethanol to give 4.8 g. (71.4%) of VIa, m. p. 96—97°C.

Found: C, 69.82; H, 6.43; N, 4.26. Calcd. for $C_{19}H_{21}NO_4$: C, 69.71; H, 6.47; N, 4.28%.

N, N-Bis(3-phenoxy-2-hydroxypropyl)aniline Diacetate (VIIIa).—To a boiling solution of 6.5 g. (0.02 mol.) of IX in 30 ml. of benzene was added drop by drop with stirring 4.5 g. (0.03 mol.) of phenyl glycidyl ether in 50 ml. of benzene. The mixture was then heated under reflux for an additional hour. After the benzene had been removed, the residue, without purification, was dissolved in pyridine - acetic anhydride mixture; the solution was then allowed to stand for 1 day. The

pyridine and acetic anhydride were removed by distillation under reduced pressure, and the residue was recrystallized several times from ethyl acetate to give 5.7 g. (59.7%) of VIIIa, m. p. 171—172°C.

Found: C, 70.29; H, 6.55; N, 3.00. Calcd. for $C_{28}H_{31}NO_6$: C, 70.42; H, 6.54; N, 2.93%.

3-Aryl-5-aryloxymethyl-2-oxazolidones.—The results of the reaction between acid amides and glycidyl ethers are listed in Tables II and III. Experimental examples will be given below.

A. The Reaction of α, α, α-Trichloroacetanilide with Phenyl Glycidyl Ether.—A mixture of 7.2 g. (0.03 mol.) of α, α, α-trichloroacetanilide, 4.5 g. (0.03 mol.) of phenyl glycidyl ether, and 0.1 g. of triethylenediamine was heated at 100°C for 2 hr. After cooling, the adduct was recrystallized from acetone to give 6.5 g. (80%) of 3-phenyl-5-phenoxymethyl-2-oxazolidone, m. p. 138—139°C. A mixed-melting-point determination with an authentic sample showed no depression.

B. The Reaction of α, α, α-Trifluoro-*p*-methylacetanilide with Phenyl Glycidyl Ether.—A mixture of 6.1 g. (0.03 mol.) of α, α, α-trifluoro-*p*-methylacetanilide, 4.5 g. (0.03 mol.) of phenyl glycidyl ether, and 0.1 g. of triethyl benzylammonium bromide was heated at 110°C for 2 hr. After cooling, the adduct was recrystallized from acetone to give 7.4 g. (87%) of 3-*p*-tolyl-5-phenoxymethyl-2-oxazolidone, m. p. 149—151°C. A mixed-melting-point determination with an authentic sample showed no depression.

C. The Reaction of α, α, α-Trichloroacetanilide with *p*-Methoxycarbonylphenyl Glycidyl Ether.—A mixture of 11.9 g. (0.05 mol.) of α, α, α-trichloroacetanilide, 10.4 g. (0.05 mol.) of *p*-methoxycarbonylphenyl glycidyl ether, and 0.2 g. of triethyl benzylammonium bromide was heated at 95°C for 4 hr. After cooling, the adduct was recrystallized from ethanol to give 12.8 g. (78%) of 3-phenyl-5-(*p*-methoxycarbonylphenoxymethyl)-2-oxazolidone, m. p. 144—146°C.

Found: C, 65.83; H, 5.31; N, 4.34. Calcd. for $C_{18}H_{17}NO_5$: C, 66.05; H, 5.24; N, 4.28%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2494—2499 (1966)

Copolymerizations of 1-Phthalimido-1, 3-butadiene and 1-Succinimido-1, 3-butadiene[1]

By Kenichi MURATA and Akira TERADA[2]

Government Industrial Research Institute, Osaka; Ikeda, Osaka

(Received March 24, 1966)

1-Phthalimido-1, 3-butadiene (1-PB) and 1-succinimido-1, 3-butadiene (1-SB) were copolymerized readily with acrylonitrile, methyl methacrylate and styrene, but somewhat less readily with vinyl acetate. The monomer reactivity ratios for the system with styrene were calculated by the Fineman-Ross method and found to be r_1(1-PB)=1.48, r_2(St)=0.32 for the 1-phthalimido-1, 3-butadiene-styrene system, and r_1(1-SB)=1.62, r_2(St)=0.28 for the 1-succinimido-1, 3-butadiene - styrene system. The Q, e-values for these systems were successively evaluated and obtained as Q(1-PB)=1.57, e(1-PB)=+0.06, Q(1-SB)=1.76 and e(1-SB)=+0.09, when Q(St)=1.0 and e(St)=−0.8. Likewise, such values for *N*-vinyl phthalimide (VPI) and *N*-vinyl succinimide (VSI) were investigated in order to compare them with the values obtained above for the imidobutadienes; they were shown to be r_1(VPI)=0.09 and r_2(St)=6.3 for the *N*-vinyl phthalimide - styrene system, and r_1(VSI)=0.07 and r_2(St)=9.6 for the *N*-vinyl succinimide - styrene system. Subsequently, the following Q and e values were determined: Q(VPI)=0.09, e(VPI)=−0.13, Q(VSI)=0.06, and e(VSI)=−0.17.

As part of the investigation of aminobutadienes and related compounds, experiments have presented some results of the syntheses of several imidobutadiene monomers,[3-6] and of attempts to improve the dyeability of polypropylene fiber[7] and to make high-equivalent anion exchange resins.[8] Since it became desirable to determine some of the reactivity parameters of the imidobutadienes toward polymerization and copolymerization, a previous paper has dealt with the polymerization and copolymerization of 2-phthalimido-1, 3-butadiene and the determination of the Q, e-parameters.[9]

Likewise, data presented in one of the previous reports[10] have demonstrated that 1-phthalimido- and 1-succinimido-1, 3-butadienes easily polymerize, using a free radical source, to give high polymers, and that the polymerizations take place smoothly even by a cationic process. The purpose of the present investigation is to extend these data to copolymerization systems with various vinyl monomers, and to supply some of the basic data for the above-mentioned utilizations. The copolymerizations of each of these imidobutadiene monomers with acrylonitrile (AN), methyl methacrylate (MMA), styrene (St) and vinyl acetate (VAc), and, in addition, the copolymerizations of *N*-vinyl phthalimide and *N*-vinyl succinimide with such vinyl monomers will also be described. The monomer reactivity ratios for the copolymerization systems of these imidobutadienes and of vinyl imides with styrene will be determined, and the evaluation of the *Q*, *e*-parameters will also be attempted according to the Alfrey-Price scheme.[11]

Experimental

Materials.—1-Phthalimido-1, 3-butadiene (1-PB) and 1-succinimido-1, 3-butadiene (1-SB) were prepared as previously reported,[5] and obtained as yellow needles with a m. p. of 114.5—116°C, and as white crystals with a m. p. of 75—76°C respectively. *N*-Vinyl phthalimide (VPI) was prepared via the pyrolysis of the *N*-β-acetoxyethylphthalimide obtained after the condensation of monoethanolamine with phthalic acid and following acetylation; it was obtained as pale yellow needles (from methanol), 85—86°C (lit., 86,[12,13] 85.5—86°C[14,15]). *N*-Vinyl succinimide (VSI) was prepared by a similar manner, using succinic acid and monoethanolamine as the starting meterials; it was obtained as white crystals, m. p. 48—48.5°C (lit., m. p. 48,[16] 48.5,[17] 48—49°C)[18]. The other vinyl monomers, acrylonitrile (b. p. 76—77°C), methyl methacrylate (b. p. 44.5—46°C/118 mmHg), styrene (b. p. 46.5—47°C/24 mmHg) and vinyl acetate (b. p. 71—71.5°C), were obtained commercially as reagent grade materials, just prior to use they were purified to the above state according to the usual manner.[19] Benzoyl peroxide (analytical-grade reagent) was purified by repeated precipitations into methanol from a chloroform solution and then dried under a vacuum, m. p. 104°C. Purified dimethylformamide was prepared by repeated fractional distillations through a 30 cm. fractionating-distillation column after dehydration over anhydrous sodium sulfate; the middle fraction was used as a solvent for the polymerization, b. p. 65—66°C/40 mmHg.

Polymerization Procedure.—This was carried out as usual.[9,10]

Results and Discussion

The Copolymerization of 1-Phthalimido-1, 3-butadiene.—Table I shows the results of the radical copolymerization of this monomer with various comonomers in the bulk state or in solution. The infrared spectra of the resulting copolymers are illustrated in Fig. 1.[20] In each of the spectra, there is a strong absorption band, showing a *trans* di-substituted ethylenic bond internal in the polymer chain, as has been shown previously in the case of the homopolymer.[10] This obviously indicates

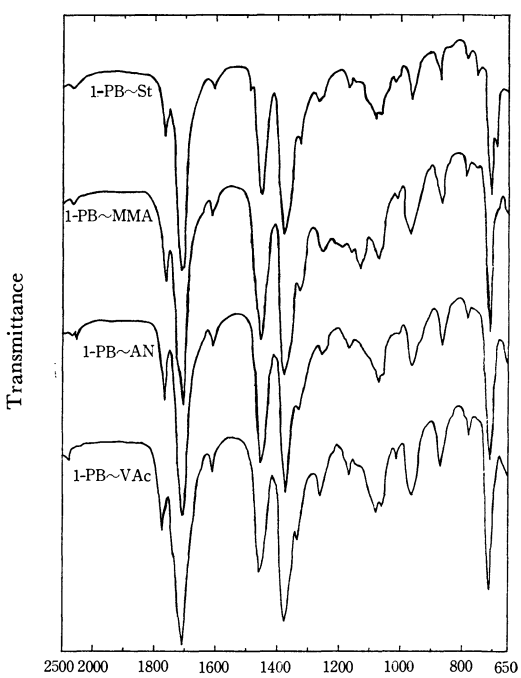

Fig. 1. Infrared spectra of copolymers of 1-phthalimido-1, 3-butadiene with various vinyl monomers.

a) Dimethylformamide.
b) Determined by the Micro-Dumas method.
c) Calculated by means of the nitrogen content.
d) Calculated by means of the average value of the nitrogen content.

that the monomer arrangement in the copolymerization is mainly of the 1, 4-type, also. The absorption peaks at 1710 and 1770 cm^{-1} in these spectra are assigned to the phthalimido-carbonyl; another striking band, at 710 cm^{-1}, is that of the *o*-di-substituted benzene of phthalimido. 1-Phthalimido-1, 3-butadiene easily copolymerizes with these monomers, whereas vinyl acetate enters into the copolymer somewhat less readily.

In an attempt to determine the relative reactivity ratios for the 1-phthalimido-1, 3-butadiene - styrene system, the copolymerization in a dimethylformamide solution was carried out at 60°C; the monomer ratio in the initial charge was varied, while benzoyl peroxide was used as the free radical source at a concentration of 2.0 mol.-% in each case (Table II).

TABLE II. THE COPOLYMERIZATION OF 1-PHTHALIMIDO-1, 3-BUTADIENE (M_1) AND STYRENE (M_2) AT 60°C

a) Calculated by means of the average value of the nitrogen content.

The M_1 and M_2 in Table II represent the molar concentrations of 1-phthalimido-1, 3-butadiene and styrene respectively at the initial feeding, while m_1 and m_2 are the molar fractions of them in the resulting copolymers as determined by the Micro-Dumas method. According to the Fineman-Ross plot,[21] we obtain:

$$r_1(\text{1-PB}) = 1.48$$

$$r_2(\text{St}) = 0.32$$

The copolymer composition curve for this system, calculated from these r_1 and r_2 values, is shown in

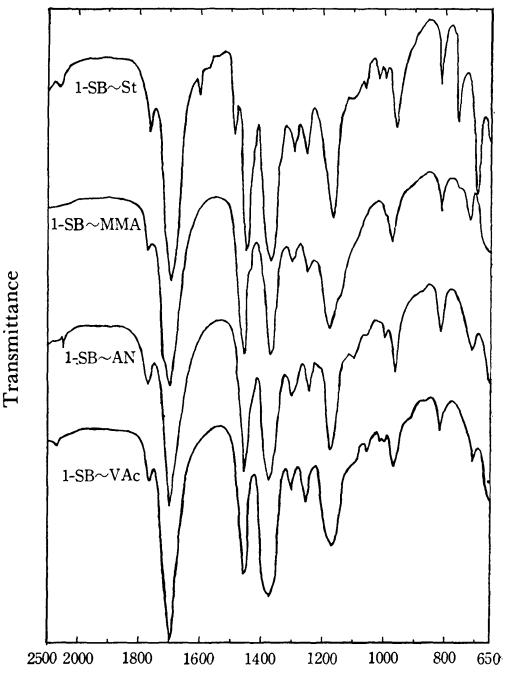

Fig. 2. Infrared spectra of copolymers of 1-succinimido-1, 3-butadiene with various vinyl monomers.

The Copolymerization of 1-Succinimido-1, 3-butadiene.—The results of the radical copolymerizations with various vinyl monomers are presented in Table III, while the infrared spectra of the resulting copolymers are illustrated in Fig. 2.

The strong absorption bands at 1700 and 1770 cm^{-1}, assignable to succinimido-carbonyl, are found in all of the polymer spectra; this fact and the data in Table III clearly show that this monomer could copolymerize preferentially with all of such comonomers as well as in the above case of 1-phthalimido-1, 3-butadiene. However, only vinyl acetate was less reactive to enter into the copolymer.

Table IV. The copolymerization of 1-succinimido-1, 3-butadiene (M_1) and styrene (M_2) in the presence of 1.0 mole-% of benzoyl peroxide at 60°C

M_1	M_2	DMF	Time	Yield	N	m_1	m_2
10^{-4}mole		ml.	hr.	wt.-%	wt.-%	mole-%

28) Nikolaev et al. have obtained the Q and e-values of *N*-vinyl phthalimide as Q=0.41 and e=−1.63 from the copolymerization with vinyl acetate,[29] they also obtained them as Q=0.21 and e=−1.14 from the system with styrene.[28] While there are large differnces between these values and the values we present here, the discrepancy can be explained as follows: In general, when the Q and e values are calculated, two values for the e are usually given. Nikolaev et al. have chosen the more negative e value of the two in each case; however, we have taken the less negative e value (−0.05) between −0.8+0.75 and −0.8−0.75, with regard to the values for *N*-vinyl acetamide (e=−1.39 and −1.44)[30] and for *N*-vinyl pyrrolidone (e=−1.22)[31] and also to those of such other related *N*-vinyl compounds as *N*-vinyl succinimide reported on hitherto.

The *Q*, *e*-Parameters.—The calculated copolymer composition curves of these imido-monomers are figured as in Fig. 3 and in Fig. 4 respectively from the above-obtained monomer reactivity ratios.

From these curves the following considerations are possible. These two imidobutadienes preferentially enter into the copolymers, while the two vinyl imides do so less readily. The curves of the two imidobutadienes are so similar that they are virtually superimposable; those of the vinyl imides are very similar to each other also. Therefore, it may be concluded that the natures and the effects of these two imido groups on the monomer reactivity are very similar and that, therefore, the reactivity differences between the imidobutadienes and vinyl imides on copolymerization are due to the differences between butadienyl and vinyl.

To investigate the structural features of these imido-monomers, the Q and e-parameters were evaluated from the above-indicated monomer reactivity ratios according to the Alfrey-Price scheme,[11] using the values of $Q=1.0$ and $e=-0.8$ for styrene. The calculated Q and e-values, and those of the other monomers of related type which have appeared in the literature, are shown in Table VII, along with their ultraviolet spectral data for the sake of comparison. The respective pairs of the Q and e-parameters of 1-phthalimido- and 1-succinimido-1, 3-butadienes, and of *N*-vinyl phthalimide and *N*-vinyl succinimide are very similar to each other. This fact indicates that the effects of the two substituents on the radical copolymerizations of such monomers closely resemble each other, as has already been established.

The Q values of 1-phthalimido- and 1-succinimido-1, 3-butadienes are much larger than those of *N*-vinyl phthalimide and *N*-vinyl succinimide. This means that, by the substituting butadienyl group for vinyl, the conjugated systems in the former two are more extended and more resonance-stabilized than in the latter two. A clear proof for this is the conclusion to be drawn from their ultraviolet spectroscopic data (Table VII), in which such imidobutadienes exhibit a more bathochromic displacement of their K bands and a much greater increase in intensity than do *N*-vinyl imides.[3,5] Similar relationships also hold in comparison with the Q value of 1, 3-butadiene.[27] Those of 1-imido-1, 3-butadienes indicate somewhat larger values; this means a similar extension of the butadienyl conjugation to the imido-nitrogen.

When the e value of 1, 3-butadiene (-0.8) is compared, those of such 1-imido-1, 3-butadienes exhibit a decrease and become near to zero. This fact may be explained by the M-effect of carbonyls in both the imido rings serving, in the opposite direction, to reduce the electron-donating power of the imido-nitrogen extending over the butadiene chain, because there is a so-called Branch-Calvin cross conjugation in these structures. Similar relationships and explanations should also hold between ethylene and *N*-vinyl imides. The e values for *N*-vinyl pyrrolidone and other *N*-vinyl acylamide are remarkably more negative than that of *N*-vinyl succinimide (Table VII); this fact may give support to our theory here.

The authors wish to thank Professor Shizunobu Hashimoto of Doshisha University for his helpful suggestions in this work and Mrs. Masako Hayashi for her elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2500—2502 (1966)

The Solvent Effect on the Rates of Autoxidation of *o*-Cresol[1]

By Yoshiro OGATA and Takashi MORIMOTO

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received March 25, 1966)

The effects of alcohols, carbonyl compounds and dimethyl sulfoxide on the pyridine-cuprous chloride-catalyzed autoxidation of *o*-cresol in benzene have been studied kinetically by estimating the consumption of oxygen. The rate is first-order in the concentration of *o*-cresol and one-half order in the partial pressure of oxygen at constant concentrations of pyridine and cuprous chloride in a solvent of methanol-benzene (20 : 80 in vol.). The reaction in a benzene solution is retarded by the addition of below 0.1 vol.% methanol or ethanol; having passed through a minimum at ca. 0.1 vol.%, it is accelerated by the addition of alcohol more than 0.1 vol.%. The reaction in a benzene solution is retarded by the addition of carbonyl compounds. A probable mechanism which explains these solvent effects is discussed.

In our previous report[2] it has been suggested that the pathway for the pyridine - cuprous chloride-catalyzed autoxidation of *o*-cresol in a benzene solution involves the reaction of *o*-cresol anion and an autoxidized pyridine - copper complex. The similar autoxidation of 2, 6 - dimethylphenol catalyzed by the pyridine - cuprous salt complex is sometimes carried out in a mixed solvent, e. g., benzene - isopropanol or toluene - isopropanol.[3] However, the autoxidation of aniline by the same catalyst is retarded on addition of methanol.[4]

The present study was undertaken to clarify the kinetic solvent effect on the pyridine-cuprous chloride-catalyzed autoxidation of *o*-cresol.

Results and Discussion

The rates were measured in the presence of anhydrous magnesium sulfate to eliminate the water which is formed as a product and which inhibits the reaction.

The rate of absorption of oxygen at constant concentrations of pyridine and cuprous chloride in methanol-benzene (20 : 80 in vol.) is expressed as:

$$-\frac{dp}{dt} = k[\mathrm{CrlH}]\,p^{1/2} \qquad (1)$$

Here, [CrlH] is the concentration of *o*-cresol and p is the partial pressure of oxygen. This rate law agrees with that in pure benzene as previously reported; therefore, the oxidation in benzene containing 20 vol.% methanol may also involve the same mechanism.

Table I. The 1.5th- and second-order rate constants for the autoxidation of *o*-cresol at constant concentration of catalyst, pyridine (0.2467 M) and cuprous chloride (5.05×10^{-3} M), in methanol-benzene (20 : 80) at 35°C

o-Cresol M	O_2 press. p, mmHg	1.5th-order const $mmHg^{1/2}\,M^{-1}\,min^{-1}$	Second-order const. $M^{-1}\,min^{-1}$
0.1889	100	4.63	5.50
0.1889	200	4.57	3.45
0.1889	400	4.58	2.29
0.0994	200	5.15	3.50

$$o\text{-}CH_3C_6H_4OH + C_5H_5N \overset{\text{fast}}{\rightleftharpoons} o\text{-}CH_3C_6H_4O^- + C_5H_5\overset{+}{N}H \qquad (2)$$

$$m\,C_5H_5N + n\,Cu^+ \overset{\text{fast}}{\rightleftharpoons} (C_5H_5N)_m(Cu^+)_n \qquad (3)$$

$$2(C_5H_5N)_m(Cu^+)_n + O_2 \overset{\text{fast}}{\rightleftharpoons} [(C_5H_5N)_m(Cu^+)_n]_2O_2 \qquad (4)$$

$$[(C_5H_5N)_m(Cu^+)_n]_2O_2 \overset{\text{fast}}{\rightleftharpoons} 2(C_5H_5N)_m(Cu^+)_nO\cdot \qquad (5)$$

$$(C_5H_5N)_m(Cu^+)_nO\cdot + o\text{-}CH_3C_6H_4O^- \overset{\text{slow}}{\longrightarrow} o\text{-}CH_3C_6H_4O\cdot + \text{etc.} \qquad (6)$$

Figure 1 illustrates the effect of the addition of alcohols, carbonyl compounds and dimethyl sulfoxide on the pyridine-cuprous chloride-catalyzed autoxidation of *o*-cresol in benzene. As shown in the figure, the rate constant decreased on addition of below 0.1 vol.% methanol, but with above 0.1 vol.% methanol the constant increased with increasing concentration of methanol, approaching a constant value at more than 20 vol.% methanol. The ratio of the rate constant in 20 vol.% methanol

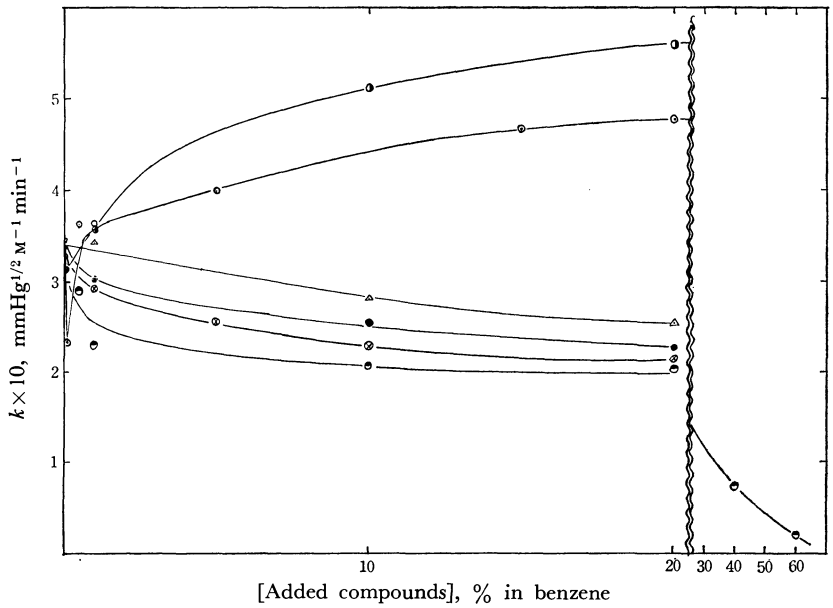

Fig. 1. The solvent effect on the rate constant for the autoxidation of *o*-cresol in benzene at 35°C or at constant oxygen pressure (p=200 mmHg) and at constant concentration of catalyst: [CuCl]=5.05×10^{-5} M and [pyridine]=0.2469 M. Initial concn. of *o*-cresol: 0.1918 M. ⊙, Methanol; ◑, Ethanol; △, Methyl ethyl ketone; ●, Dimethylformamide; ⊗, Ethyl acetate; ◓, Dimethyl sulfoxide.

to that in pure benzene was about 1.3. These phenomena are not due to the formation of formaldehyde from methanol, since no absorption of oxygen was observed in the absence of *o*-cresol and no formaldehyde was detected in the effluent gas.

In contrast, the rate constant gradually decreased with increasing concentration of carbonyl compounds or dimethyl sulfoxide. For example, in 60 vol.% dimethyl sulfoxide in benzene, the rate was too low to measure.

This retardation with carbonyl or sulfoxide compounds may be due to the deactivation of the catalyst, (i) by the substitution of a carbonyl or sulfoxide compound for pyridine molecule:

$$Py_mCu^+{}_n + (\rangle C{=}O) \rightleftarrows Py_{m-1}(\rangle C{=}O)Cu^+{}_n + Py \quad (7)$$

or (ii) by the steric inhibition of the approach of molecular oxygen to the active site of catalyst by a coordinated carbonyl or sulfoxide compound:

$$Py_mCu^+{}_n + (\rangle C{=}O) \rightleftarrows Py_mCu^+{}_n(\rangle C{=}O) \quad (8)$$

Although the rate increased with an increase in the dielectric constant[2,5] by the addition of chlorobenzene (ε=5.62[6]), the reaction was retarded by the addition of dimethylformamide (ε=37.6[7]) or dimethyl sulfoxide (ε=46[8]) to the solvent. These results suggest that the catalyst is deactivated by the coordination of the oxygen atom in these compounds.

On the other hand, methanol may act as an acid, as shown in the following equilibrium:

$$C_5H_5N + CH_3OH \rightleftarrows C_5H_5\overset{+}{N}H + CH_3O^- \quad (9)$$

$$\text{or } C_5H_5N^+\cdots H\cdots\overset{-}{O}CH_3$$

It is expected that methoxide anion, like carbonyl compounds, will coordinate with the catalyst to retard or inhibit the reaction. In fact, the pyridine solution containing *o*-cresol and cuprous chloride absorbs oxygen (1.38×10^{-4} mole after 180 min. at 13.9 mmHg), but no absorption was observed on addition of 10 vol.% methanol to the solvent. At a lower concentration of pyridine (below 1 M) in a benzene solution, the reaction may be retarded by a small amount of methanol, probably because the methoxide ion formed acts much like carbonyl compounds, while the reaction is accelerated by the addition of more than 0.1 vol.% methanol, as is obvious in Fig. 1. It is difficult to explain this acceleration at present, but it is probable that an increase in the dielectric constant and solvation power by the addition of methanol results in an increase in the concentration of the more

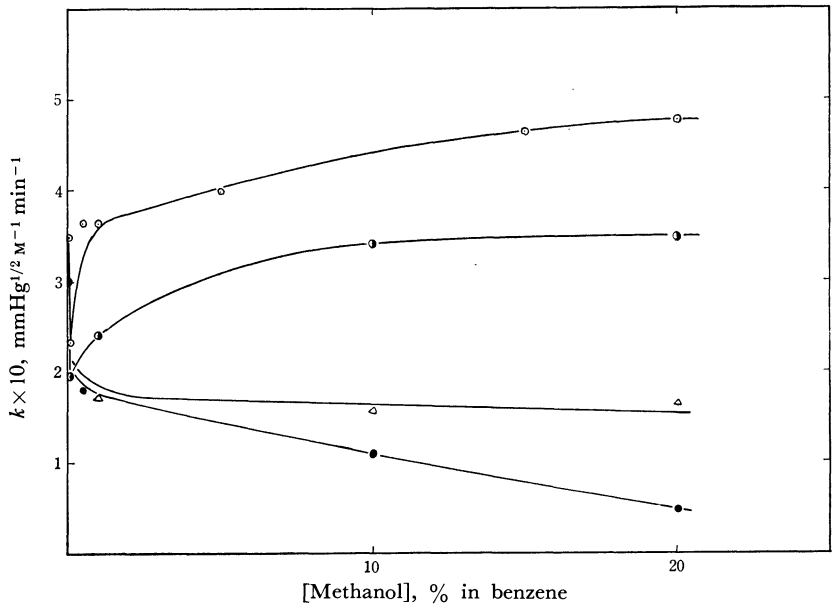

Fig. 2. The effects of concentrations of methanol and pyridene on the rate constant for the autoxidation of *o*-cresol in benzene at 35°C at constant concentration of CuCl (5.05×10^{-5} M) and *o*-cresol (0.1918 M) and constant oxygen pressure (200 mmHg).
⊙, [pyridene]=0.247 M; ◑, 0.99 M; △, 2.48 M; ●, 4.99 M.

reactive *o*-cresol anion and that this effect surpasses the deactivation of the catalyst by methanol.

At higher concentrations of pyridine (over 2 M), the oxidation was always inhibited or retarded by the addition of methanol in any concentration. The effect of the methanol concentration on the rate constant at various pyridine concentrations is illustrated in Fig. 2. Apparently, at higher concentrations of pyridine (e. g., over 2 M), the rate constant decreases with increasing concentration of methanol. On the other hand, at lower concentrations of pyridine (below 1 M), the rate constant sharply decreases and then increases with increasing concentration of methanol. These facts seem to support the above assumption that the deactivation with methanol is not caused by methanol itself, but by methoxide ions, which can only be produced by the presence of pyridine.

A similar effect is expected for the autoxidation of 2, 6-dimethylphenol by the same catalyst. In fact, the acceleration was appreciable by the addition of 20 vol% ethanol or isopropanol to a benzene solution at 0—35°C at initial concentrations of 0.1979 M 2, 6-dimethylphenol, 0.2461 M pyridine, and 5.05×10^{-3} M cuprous chloride. However, the reaction in both pure benzene and the mixed solvent was too rapid for the rate constants to be compared (80% conversion after 20 min. at 35°C in pure benzene).

Experimental

Materials.—*o*-Cresol, cuprous chloride, pyridine, and benzene were purified as reported previously.[2] Methanol (b. p. 64.1—64.5°C), ethanol (b. p. 78.1—78.2°C), methyl ethyl ketone (b. p. 78.8—79.1°C) and ethyl acetate (b. p. 77.0—77.2°C) were purified by rectification. Dimethylformamide (b. p. 56.5—56.7°C/27 mmHg) and dimethyl sulfoxide (b. p. 85—87°C/25 mmHg) were distilled in a vacuum after having been dried over anhydrous potassium carbonate. 2, 6-Dimethylphenol was recrystallized from *n*-hexane (m. p. 44.0—44.5°C).

Rate Measurements.—The same apparatus and procedure[2] were used for the rate measurements.

The Detection of Formaldehyde.—Oxygen gas, after having been passed through the reaction solution, was bubbled into an aqueous solution of sodium sulfate containing thymolphthalein as an indicator. No color was observed. This proved the absence of formaldehyde.

The authors wish to thank Mr. Kazuo Matsuyama for his helpful assistance in performing these experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2503—2508 (1966)

The Synthesis of an Etiojervane Analog of Progesterone[1]

By Tadashi MASAMUNE, Kazuhiko ORITO and Akio MURAI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received March 25, 1966)

N-Acetyl-22, 27-iminojerva-5, 12-diene-3β, 23α-diol-11-one, prepared from jervine by Masamune et al. (*J. Org. Chem.*, **29**, 2282 (1964)), was submitted to a Birch reduction and then to a modified Wolff-Kishner reduction to yield 22, 27-iminojerv-5-ene-3β, 23α-diol. The compound was then degraded, according to the procedure by Johnson et al. (*Tetrahedron Letters*, **1963**, 545), to a methyl ketone, which was then further oxidized by the Oppenauer method to give 17α-ethyletiojerv-4-ene-3, 20-dione.

In the past decade considerable attention has been paid to the modification of the basic steroid skeleton of hormones in search of analogs with enhanced or more specific physiological properties. In view of the natural occurrence[2] of the C-nor-D-homosteroid ring system, the synthesis of hormone analogs seemed to be a particularly attractive subject. Etiojervane[3] analogs of testosterone, epiandrosterone and so on have recently been prepared, using the available hecogenin and/or jervine as the starting materials.[4-6] In the present paper we will describe the synthesis of C-nor-D-homoprogesterone.

Jervine (I), one of the most readily-available veratrum alkaloids, was selected as the starting material for our investigation. Two processes for the degradation of I to nitrogen-free compounds have been reported in the literature. One, which was developed by Fried et al.[7] and improved by Okuda et al.[8] and by us,[9] involves the fragmentation of I, by treatment with Lewis acids, to 17-ethyletiojerva-5, 12, 17(20)-terien-3β-ol-11-one (II).

It was deemed efficient to utilize the ethylidene moiety of II to prepare an acetyl side chain of progesterone, and it was attempted to reduce the 12, 13-double bond selectively. The double bond could not be hydrogenated catalytically, however, without a concomitant reduction of the 17, 20-double bond. The Birch reduction of II gave rise to a mixture containing a considerable amount of the starting material (II), from which only a compound, $C_{21}H_{30}O_2$, m. p. 236—237°C, showing a peak at 1730 cm^{-1}, could be isolated in a very low yield. Next, the selective reduction of the 12, 13-double bond in the glycol[10] (III) prepared from II was reexamined under various conditions, as a glycol system would be converted into an acetyl group by the Serini reaction.[11] However, neither the Birch reduction nor the catalytic hydrogenation of III was shown to be of any value in the proposed synthesis.[10] The treatment of the glycol acetate (IIIa) with alkali yielded a multicomponent mixture, from which only etiojerv-5-ene-3, 11, 17-trione 3-ketal[4] (IV), formed by fission of the 17, 20-bond, was isolated, in a moderate yield, by chromatography.

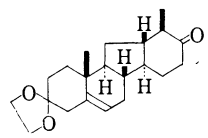
IIIa: R=Ac



IV

The other degradation process was developed by Johnson et al.;[12] it requires the presence of hydroxyl and secondary amino group in the nitrogen ring as in that of veratramine (V). However, V would not be an appropriate starting material, in view of the yield in isolation from natural plants or in chemical preparations.[13,14] On the other hand, in order to obtain intermediates suitable for degradation from the readily-available alkaloids, jervine (I) or 11-deoxojervine[14] (VI), it was necessary to cleave the ether linkage in those compounds. A reexamination of the references revealed that the fission of the ether linkage took place in several ways.[13-17] The following two reactions appeared to be effective, considering the yields and stabilities of the products; the Birch reduction of I to 8, 9-dihydroisojervine[17] (VII), and the catalytic hydrogenation of VI over platinum in acetic acid to 11-deoxo-5, 6, 8, 9-tetrahydroisojervine[18] (VIII).

The degradation of VIII was first undertaken, as VIII possessed no oxygen function on C-11 and appeared to be suitable for the present plan. VIII was converted to a *N*-chloro derivative with *N*-chlorosuccinimide, which gave, when treated with sodium methoxide and then hydrolyzed with acid, an aldehyde (IX) in an over-all yield of 89%. The aldehyde was further degraded, with *n*-butyl nitrite and sodium *n*-butoxide in *n*-butanol, to an oxime, which was extracted with 2 N aqueous sodium hydroxide solution and then purified by acetylation with acetic anhydride and pyridine. The acetate, m. p. 139—140°C, obtained in a 35% yield from IX, exhibited, in agreement with the assigned structure of X, strong peaks at 1788 (*N*-acetoxyl) and 1737 cm^{-1} (3-acetoxyl) in the infrared spectrum and five sharp singlets at τ 7.38, 7.71, 7.99, 8.31 and 9.39 in the NMR spectrum. The singlets were attributed to the 21-methyl, *N*-acetoxyl, 3-acetoxyl, 18-methyl and 19-methyl groups respectively. However, an attempted hydrolysis of the oxime to a ketone was unsuccessful; the treatment of the crude oxime with hydrochloric acid in refluxing ethanol gave a compound with a m. p. of 157°C, in a 40% yield; this compound showed no strong absorption in the carbonyl region of the infrared spectrum. It might probably be an isooxazoline derivative. Next, the oxime acetate (X) was heated in glacial acetic acid on a water bath; it yielded a crystalline material, which showed two superimposable spots on thin layer-chromatograms and which resisted further purification. Furthermore, the elemental analysis showed that it contained almost the same percentage of nitrogen as the original acetate, indicating no fission of the C–N bond.

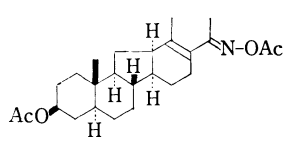
IX



X

The preparation of 8, 9-dihydroisojervine (VII) by the Birch reduction[17] of I was improved by replacing the dioxane used previously as a solvent by tetrahydrofuran. The acetylation of VII, followed by hydrolysis and isomerization with alkali, proceeded smoothly, and afforded an α, β-unsaturated ketone (XI) in a good yield.[17] The next step in the synthesis required the reduction

18) T. Masamune, M. Takasugi and Y. Mori, *Tetrahedron Letters*, **1965**, 489. It was suggested in the reference that a double bond would exist at C-13-C-17. This disposition was confirmed by the transformation of VIII to 11-deoxo-5, 6-dihydrojervine. It will be discussed later (T. Masamune and A. Murai, unpublished results).

of the 12, 13-double bond. Wintersteiner and Moore[15b] observed that the double bond in a 5, 6-dihydro derivative (XII) of XI could be hydrogenated over platinum in acetic acid. However, the product (XIII) was unstable to alkali and readily isomerized.[19] Furthermore, it was supposed that the hydrogenation of the 12, 13-double bond in XI under the aforementioned conditions would accompany the reduction of the 5, 6-double bond. Thus, XI was treated with lithium in liquid ammonia. It produced the corresponding 12, 13-dihydro derivative (XIV), m. p. 148—149°C. The assigned structure was confirmed by a stong absorption at 1737 cm^{-1} in the infrared spectrum and by a broad peak (1H) at τ 4.63 in NMR spectrum. The over-all yield from I to XIV was 40% (4 steps). With the purpose of confirming the stereochemistry, XIV was hydrogenated over platinum in acetic acid. The product, obtained in a good yield, was found to be identical with 22, 27-iminojervane-3β-23α-diol-11-one *N*-acetate (XV), the configuration of which had been established by Wintersteiner and Moore.[19] Thus, both the hydrogens on C-12 and C-13 in XIV were proved to have an α-configuration.

In order to prepare a progesterone analog, the reduction of the 11-carbonyl to methylene group was necessary. A modification of the Huang-Minlon procedure for the Wolff-Kishner reduction of XIV resulted in the removal of the oxygen on C-11, with the concomitant hydrolysis of the *N*-acetyl group; 22, 27-iminojerv-5-ene-3β, 23α-diol (XVI), m. p. 221—223°C, was isolated in a 60% yield after purification. Since XIV was recovered unchanged by reflux with alkali in a mixture of dimethylsulfoxide and diethylene glycol, no epimerization is considered to take place at the carbons adjacent to C-11 during the reduction. A comparison of the NMR spectrum of the triacetate (XVIa), m. p. 155—156°C, with that of XIV supports this conclusion; in the former, the signal due to the 19-methyl protons appeared at τ 9.03, while the corresponding signal of the latter appeared at τ 8.98. The magnitude of the downfield shift caused by the 11-carbonyl function was almost equal to the deshielding effect (0.07 p.p.m.) of a 11-ketonic group found in the study of the NMR spectra of a series of 22, 27-imino-17, 23-oxidojervane derivatives[20]; it was remarkably different from the corresponding effects in compounds possessing a B/C *cis*-fused linkage.[21]

The next step of the synthesis was the degradation of XVI; this was carried out in the way described above to yield an oxime (XVII), m. p. 192—193°C, in a 60% yield from XVI (4 steps). No trouble was encountered in the hydrolysis of XVII; treatment with a mixture of pyruvic acid and acetic acid gave a crude methyl ketone (XVIII) which, in turn, was submitted to the Oppenauer oxidation. Chromatographic purification yielded 17α-ethyletiojerv-4-ene-3, 20-dione (XIX), m. p. 168—169°C, in a 21% yield from XVII (2 steps). In accord with the assigned structure, this C-nor-D-homoprogesterone had prominent peaks at 1715 (20-carbonyl), 1663 (3-carbonyl) and 1616 cm^{-1} (conjugated double bond) in the infrared spectrum, and an absorption maximum at 237 mμ (ε 20200) in the ultraviolet spectrum. It also exhibited two singlets, at τ 8.87 and 7.86 (each 3H, the 19- and 21-methyl groups respectively) and one doublet (3H, J=6 c. p. s., the 18-methyl group) in the NMR spectrum. The acetyl side chain was assigned the α-configuration for the following reasons. The side chain at C-17 of XVI had the β-configuration and was *cis*-oriented relative to the methyl group at C-13. If the acetyl group in XIX had the same (β) configuration, treatment with alkali would cause epimerization at C-17. However, XIX was recovered unchanged after attempts to effect the epimerization by heating XIX under reflux in a 5% methanolic potassium hydroxide solution for 2 hr. This fact indicates that both the methyl at C-13 and the acetyl function at C-17 possess the equatorial conformation and are *trans* to each other. Hence, the acetyl group must have the

20) T. Masamune, N. Sato, K. Kobayashi, I. Yamazaki and Y. Mori, ibid., in press. The deshielding effects of the 3β-acetoxyl and 3β-hydroxyl groups are 0.03 and 0.02 p. p. m. respectively.
21) J. P. Kitney, A. By, T. Inaba and S. Y. Leong, *Tetrahedron Letters*, **1965**, 2911; D. M. Bailey, D. P. G. Hamon and W. S. Johnson, ibid., **1963**, 555.

α-configuration, and the epimerization must have taken place during the hydrolysis or the Oppenauer oxidation.

Experimental

The melting points are uncorrected. The optical rotations and the ultraviolet spectra were measured in 95% methanol and 99% ethanol, and the infrared spectra, in Nujol, unless otherwise stated. The NMR spectra were taken in deuterochloroform at 60 Mc., using tetramethylsilane as an internal standard.

The Alkali Treatment of 17-Ethyletiojerva-5, 12-diene-17, 20-diol-3-one 20-Acetate 3-Ethylene Ketal[10] (IIIa).—To dioxane (5 ml.) containing IIIa (0.2 g.), a 1N aqueous sodium hydroxide solution (5 ml.) was added, and then the whole solution was refluxed for 40 min. After the solvent had been removed, the residue was treated with water and three 10 ml. portions of chloroform. The chloroform solution gave, after it had been washed with water, dried with anhydrous sodium sulfate and evaporated to dryness, an oily substance (0.22 g.) which was then chromatographed on alumina (2.0 g.). Fractions eluted with petroleum ether and a mixture of petroleum ether and benzene (1 : 1) crystallized and amounted to 0.15 g. Repeated recrystallizations from *n*-hexane afforded etiojerv-5-ene-3, 11, 17-trione 3-ethylene ketal (IV, 0.05 g.), m. p. 156—157.5°C, which was identical with a sample prepared according to the literature.[4] IR (chloroform): ν_{max} 1738, 1714, 1104 and 1083 cm^{-1}.

Found: C, 73.32; H, 8.30. Calcd. for $C_{21}H_{28}O_4$: C, 73.22; H, 8.19%.

11-Deoxo-5, 6, 8, 9-tetrahydroisojervine (VIII) and the 3, 23, *N*-Triacetyl Derivative. — When 11-deoxojervine[14] (VI; 7.01 g.) was hydrogenated in the presence of pre-reduced Adams' platinum (2.23 g.) at room temperature in acetic acid (140 ml.), 832 ml. of hydrogen (2.05 mol.) was absorbed after 29 hr. After the catalyst and the solvent had then been removed, the residue was treated with water (40 ml.), 6N aqueous ammonia (30 ml.) and chloroform (50 ml.); the chloroform-addition compounds of VIII remained suspended between the aqueous and the chloroform layers. The chloroform compound (7.23 g.), after being collected by filtration, washed with water, and dried, was recrystallized from acetone to yield VIII (4.96 g.), m. p. 143—146°C. Recrystallization from acetone gave an analytical sample (3.64 g.), m. p. 156—157°C; $[\alpha]_D^{20}$ −59.4°; IR; ν_{max} 3300, 1032 and 878 cm^{-1}.

Found: C, 78.31; H, 10.83; N, 3.33. Calcd. for $C_{27}H_{45}O_2N$: C, 78.02; H, 10.91; N, 3.37%.

Compound VIII (3.37 g.) was acetylated with acetic anhydride (30 ml.) and pyridine (40 ml.) on a steam bath for 2 hr. The residue, obtained after the solvents had been removed by azeotropization with benzene, was crystallized from aqueous methanol; it had a m. p. of 153.5—155°C. Recrystallization from the same solvent afforded a pure sample (3.45 g.) of the triacetyl derivative, m. p. 157—159°C; IR: ν_{max} 1738, 1634 and 1238 cm^{-1}; NMR: a broad multiplet which consisted of three peaks centered at τ 4.93, 5.17 and 5.33 (3H, protons on C-3, C-22 and C-23),[22] a singlet at τ 8.34 3H, 18-methyl protons) and a singlet at τ 9.28 (3H, 19-methyl protons).

Found: C, 73.22; H, 9.40; N, 2.55. Calcd. for $C_{33}H_{51}O_5N$: C, 73.16; H, 9.49; N, 2.59%.

17-Ethyl-20-formyletiojerv-13(17)-en-3β-ol (IX).—A suspended mixture of *N*-chlorosuccinimide (0.50 g.) in ether containing 11-deoxo-5, 6, 8, 9-tetrahydroisojervine (VIII; 1.45 g.) was stirred at room temperature for 1.5 hr. The ether layer was then washed with three 25 ml. portions of water, dried and evaporated to yield a mixture of crystals (1.39 g.). This mixture was used for the next step without further purification, as it colored at room temperature. It was dissolved in methanol (60 ml.); then to the solution there was added a methanol solution containing sodium methoxide (prepared from 0.7 g. of sodium and 30 ml. of methanol) under cooling and in a stream of nitrogen. The solution was allowed to stand at room temperature for 3 hr. and then evaporated below 33°C. The residue was stirred vigorously with 1N hydrochloric acid (120 ml.) at room temperature for 1 or 2 days, until the resinous materials were changed to amorphous powder. The powder (IX) was collected by filtration, washed repeatedly with water, and found to amount to 1.02 g.; UV: only end absorption, ε 1890 at 220 mμ; IR (chloroform); ν_{max} 3575, 3400, 2705 and 1719 cm^{-1}; NMR: a broad peak centered at τ 0.47 (aldehyde proton), a singlet at τ 8.31 (3H, 18-methyl protons), a doublet centered at τ 8.87 (3H, J=7 c. p. s., 21-methyl protons) and a singlet at τ 9.27 (3H, 19-methyl protons).

Found: C, 79.80; H, 10.29. Calcd. for $C_{22}H_{34}O_2$: C, 79.95; H, 10.37%.

17-Ethyl-20-oximinoetiojerv-13(17)-en-3β-ol and the Diacetyl Derivative (X).—To a cooled *n*-butanol solution (2 ml.) containing the aldehyde IX (0.20 g.) and freshly-prepared *n*-butyl nitrite (0.20 g.), was added a 1N sodium *n*-butoxide solution in *n*-butanol (2 ml.), and the whole solution was then kept in a refrigerator for 12 hr. After an excess of dry ice and a small volume of water had been added, the solution was evaporated below 43°C under reduced pressure, and the residue was extracted with chloroform. The chloroform solution was shaken with a 2N aqueous sodium hydroxide solution, which was then neutralized carefully with 2N hydrochloric acid and extracted with chloroform. The chloroform solution gave, after the solvent had been removed, an oxime (0.09 g.) which showed one spot on thin-layer chromatograms but which resisted crystallization; UV: λ_{max} 413 (1760) and 246 mμ (ε 5550); IR (chloroform): ν_{max} 3580, 3290, 1663 and 1602 cm^{-1}.

Found: C, 76.34; H, 10.19; N, 4.02. Calcd. for $C_{21}H_{33}O_2N$; C, 76.09; H, 10.03; N, 4.23%.

The afore-mentioned oxime (0.26 g.) was acetylated with acetic anhydride (1.5 ml.) and pyridine (3 ml.) at room temperature for 14 hr. A crude diacetate, obtained on the removal of the solvents by azeotropization with benzene, crystallized on trituration with isopropyl ether; it was collected by filtration. On recrystallization from acetone-isopropyl ether, the diacetyl derivative (X; 0.22 g.) had a m. p. of 139—140°C; UV: λ_{max} 350 (4660) and 251 mμ (ε 13250); IR: ν_{max} 1788, 1737, 1671 and 1581 cm^{-1}.

Found: C, 72.31; H, 9.05; N, 3.19. Calcd. for $C_{25}H_{37}O_4N$: C, 72.25; H, 8.98; N, 3.37%.

22, 27-Iminojerva-5, 12-diene-3β, 23α-diol-11-one

22) Footnote 33a of Ref. 17.

***N*-Acetate (XI).**—The Birch reduction of jervine (I) to 8, 9-dihydroisojervine (VII) was carried out according to a procedure reported previously,[17] except that tetrahydrofuran was used as the solvent instead of dioxane; because of the high melting point, the latter was frozen in liquid ammonia, including its starting material, and the yield was sometimes decreased. From 4.0 g. of jervine dissolved in tetrahydrofuran (100 ml.), a crude 8, 9-dihydroisojervine (3.21 g.), m. p. 158—160°C, was obtained. Recrystallization from a mixture of acetone and methanol (9 : 1) afforded the pure sample of VII (3.01 g.), m. p. 161—163°C.

The acetylation of VII proceeded much as has been described in the literature;[17] 5.0 g. of 8, 9-dihydroisojervine was converted to 5.81 g. of the triacetyl derivative, m. p. 163—164°; $[\alpha]_D^{29}$ +95.0°; NMR: a broad peak centered at τ 4.62 (1H, proton on C-6), a broad multiplet which consisted of three peaks centered at τ 4.98, 5.18 and 5.37 (3H, protons on C-3, C-22 and C-23), singlet at τ 8.15 (3H, 18-methyl protons), a doublet centered at τ 8.92 (6H, J=6 c. p. s., 21- and 26-methyl protons), a singlet at τ 9.03 (3H, 19-methyl protons).

Found: C, 71.49; H, 8.34; N, 2.26. Calcd. for $C_{33}H_{47}O_6N$: C, 71.58; H, 8.56; N, 2.53.

A solution of the triacetyl derivative (4.14 g.) in methanol (160 ml.) containing 5% potassium hydroxide was refluxed for 40 min. in a stream of nitrogen. The solution was then evaporated, diluted with water (100 ml.), stirred at room temperature overnight, and filtrered. The precipitates thus collected crystallized, after being dried, on trituration with acetone; then those had a m. p. of 214—217°C. Recrystallization from a mixture of ethanol and acetone (2 : 3) afforded XI (3.17 g.), m. p. 218—219°; $[\alpha]_D^{29}$ −93.0°; UV: λ_{max} 254 mμ (ε 19000); IR: ν_{max} 1701, 1614 and 1055 cm^{-1}; NMR: a broad peak centered at τ 4.63 (1H, proton on C-6), a singlet at τ 7.92 (18-methyl protons), two doublets centered at τ 8.73 and 9.15 (each 3H, J=7 and 6 c. p. s., 21- and 26-methyl protons or vice versa) and a singlet at τ 8.98 (3H, 19-methyl protons).

Found: C, 74.26; H, 9.13; N, 2.93. Calcd. for $C_{29}H_{43}O_4N$: C, 74.16; N, 9.23; N, 2.98.

22, 27-Iminojerv-5-ene-3β, 23α-diol-11-one *N*-Acetate (XIV).—To liquid ammonia (350 ml.) cooled with a dry ice - acetone mixture and containing lithium (604 mg.), 22, 27-iminojerv-5, 12-dien-3β, 23α-diol-11-one *N*-acetate (XI, 4.0 g.) was added over a 5-min. period; the whole mixture was then stirred for another 15 min. The blue color of the mixture disappeared on the addition of ammonium chloride (12 g.), and then the ammonia was removed. The residue was extracted with four 40-ml. portions of chloroform, and the chloroform solution was evaporated to dryness after it had been washed with water and dried with anhydrous sodium sulfate. The residue (3.18 g.) crystallized on trituration with acetone; then it was recrystallized from a mixture of acetone and ethanol (3 : 2) to yield XIV (3.04 g.), m. p. 248—249°; $[\alpha]_D^{29}$ −85°; IR: ν_{max} 3425, 1737, 1600 and 1065 cm^{-1}.

Found: C, 73.72; H, 9.59; N, 4.31. Calcd. for $C_{29}H_{45}O_4N$: C, 73.84; H, 9.62; N, 4.23.

The Hydrogenation of 22, 27-Iminojerv-5-ene-3β, 23α-diol-11-one *N*-Acetate (XIV).—Compound XIV (0.10 g.) was hydrogenated in the presence of pre-reduced Adams' platinum (62 mg.) at room temperature in acetic acid (12 ml.); 7 ml. of hydrogen was absorbed in 20 min. After the catalyst and the solvent had been removed, the residue was treated with three 30-ml. portions of chloroform and a 5% aqueous sodium carbonate solution (5 ml.). The chloroform solution was washed with water, dried, and then evaporated to dryness. The residue (97 mg.) was crystallized from acetone, and then recrystallized from 90% aqueous ethanol. The product (92 mg.), m. p. 271—274°C, was identified as a known compound, 22, 27-iminojervane 3β, 23α-diol-11-one *N*-acetate[19] (XV), by a mixed-melting-point determination and by a comparison of the infrared and NMR spectra with those of XV.

The Alkali Treatment of 22, 27-Iminojerv-5-ene-3β, 23α-diol-11-one *N*-Acetate (XIV).—Compound XV (0.1 g.) was suspended in a mixture of diethylene glycol (50 ml.), water (0.5 ml.), and dimethylsulfoxide (10 ml.) containing potassium hydroxide (1.0 g.). The mixture was refluxed at 205°C for 2 hr. in a stream of nitrogen when it was homogenous. To the cooled solution, water (35 ml.) was added, and then the whole mixture was stirred for a while and filtered. The precipitates (62 mg.) thus collected were treated with 1 N hydrochloric acid (7 ml.) and chloroform (45 ml.). The chloroform solution gave a crystalline compound, which had a m. p. of 247—248.5°C and which amounted to 45 mg. after recrystallization from a mixture of acetone and ethanol (3 : 2). It was proved identical with the starting material (XIV) by a comparison of the infrared spectra and by thin-layer chromatography on silica gel (methanol-benzene, 4 : 1). On the other hand, the acidic layer was made alkaline and extracted with chloroform. From the chloroform solution, nothing remained after the solvent had been removed.

22, 27-Iminojerv-5-ene-3β, 23α-diol (XVI) and the 3, 23, *N*-Triacetyl Derivative (XVIa).—To freshly-distilled diethylene glycol (130 ml.), sodium (3.0 g.) was added; the mixture was then heated for a while and cooled. To this solution anhydrous hydrazine[23] (18 ml.) was added, and the mixture was refluxed for 30 min. and cooled. After the addition of 22, 27-iminojerv-5-ene-3β, 23α-diol-11-one *N*-acetate (XIV, 2.0 g.), the entire mixture was heated at 180°C for 48 hr., heated further to 210°C to remove the excess hydrazine, and again refluxed for another 24 hr. To the cooled solution, water (200 ml.) was added, and the mixture was stirred at room temperature overnight. The precipitates thus formed were collected by filtration and dried to yield a crude deoxo derivative (XVI; 1.52 g.). Repeated recrystallizations, each fraction being checked by paper chromatography,[24] afforded a pure sample (1.05 g.) of XVI, m. p. 221—223°C; IR: no absorption near 1700 cm^{-1}.

Found: C, 78.20; H, 10.81; N, 3.08. Calcd. for $C_{27}H_{45}O_2N$: C, 78.02; H, 10.91; N, 3.37.

Compound XVI (0.15 g.) was acetylated with acetic anhydride (1 ml.) and pyridine (2.5 ml.) at room temperature overnight. The solution was poured into ice water (200 ml.), stirred for 4 hr., and then filtered. The crude triacetate (XVIa; 198 mg.), m. p. 153—155°C, obtained after the washing and drying of the

23) L. I. Smith and K. L. Howard, *Org. Synth.*, **24**, 53 (1944).

24) Footnote 40 of Ref. 17.

precipitates, was recrystallized from aqueous methanol to yield pure sample of 22, 27-iminojerv-5-ene-3β, 23α-diol 3, 23, *N*-triacetate, m. p. 155—156°C; $[\alpha]_D^{20}$ −75.0°; IR: ν_{max} 1742, 1732, 1641, 1244, and 1025 cm^{-1}.

Found: C, 73.18; H, 9.66; N, 2.50. Calcd. for $C_{33}H_{51}O_5N$: C, 73.16; H, 9.49; N, 2.59.

17-Ethyl-20-formyletiojerv-5-en-3β-ol.—Into methanol containing 22, 27-iminomerv-5-ene-3β, 23α-diol (XVI; 1.0 g.) *N*-chlorosuccinimide (385 mg.) was stirred below 30°C, and then the entire mixture was stirred for another 2.5 hr. The solution was concentrated to 50 ml. below 30°C under reduced pressure. Into the solution, cooled with an ice bath, there was stirred in a stream of nitrogen sodium (2.3 g.) dissolved in absolute methanol (50 ml.). The whole solution was allowed to stand at 0°C for 2.5 hr. and then evaporated below 35°C under diminished pressure. The residual oil was mixed with water (50 ml.), and then with 2 N hydrochloric acid (50 ml.). The heterogeneous mixture was vigorously stirred at room temperature overnight and then filtered. The precipitates (835 mg.) had a m. p. of 160—165°C after being washed with water and dried. Two recrystallizations from a mixture of acetone and methanol (4 : 1) yielded 17-ethyl-20-formyletiojerv-5-en-3β-ol (720 mg.), m. p. 173—180°C; IR: ν_{max} 3495, 2735 and 1715 cm^{-1}; NMR: a broad peak centered at τ 4.67 (1H, olefinic proton on C-6), a doublet centered at τ 9.02 (3H, J=7 c. p. s., 21-methyl protons) and a singlet at τ 9.01 (3H, 19-methyl protons).

Found: C, 79.85; H, 10.19. Calcd. for $C_{22}H_{34}O_2$: C, 79.95; H, 10.39%.

17-Ethyl-20-oximinoetiojerv-5-en-3β-ol (XVII).—To absolute methanol (2.1 ml.) containing *n*-butyl nitrite (0.3 ml.) and the afore-mentioned aldehyde (0.10 g.), there was added, under cooling with ice and in a stream of nitrogen, sodium (96 mg.) dissolved in absolute methanol (2.1 ml.); the whole mixture was then allowed to stand in a refrigerator for 22 hr. The solution was made acidic to pH 4 with concentrated hydrochloric acid and evaporated to dryness. The residue was treated with water and five 20-ml. portions of warm chloroform; the chloroform solution was then shaken with a saturated aqueous sodium chloride solution, dried and evaporated. The residual oil crystallized on trituration with acetone; it had a m. p. of 180—184°C. The collected crystals (65 mg.) were twice recrystallized from a mixture of acetone and methanol (4 : 1) to yield the oxime (XVII; 52 mg.), m. p. 192—193°; $[\alpha]_D^{20}$ −27°; IR: ν_{max} 3340, 1680 and 1060 cm^{-1}.

Found: C, 76.19; H, 10.04; N, 3.86. Calcd. for $C_{21}H_{33}O_2N$: C, 76.09; H, 10.03; N, 4.23%.

17-Ethyletiojerv-5-en-3β-ol-20-one (XVIII) and 17-Ethyletiojerv-4-ene-3, 20-dione (XIX).—17-Ethyl-20-oximinoetiojerv-5-en-3β-ol (XVII; 0.41 g.) was suspended in a mixture of pyruvic acid (1.8 ml.), water (18 ml.) and acetic acid (18 ml.), and then refluxed for 3 hr. under a stream of nitrogen. The mixture became homogeneous on being heated. The cooled solution was diluted with water (40 ml.) and made strongly alkaline with a concentrated aqueous sodium hydroxide solution. After ethanol (30 ml.) had been added, the solution was treated with five 30-ml. portions of ether. The ether solution gave, after being washed with water and dried, an oil (221 mg.) which was crystallized from isopropyl ether to yield the crude methyl ketone (XVIII; 209 mg.), m. p. 96—103°C. This ketone was used for the next step without further purification.

The afore-mentioned methyl ketone (XVIII; 150 mg.) was dissolved in a mixture of toluene (100 ml.) and cyclohexanone (5 ml.); 3 ml. of the toluene was then distilled off in order to remove the water from the system. Aluminum isopropoxide (500 mg.) was added, and the reaction mixture was refluxed for 5 hr. under stirring and then cooled. It was distilled with steam for 5 hr. to remove the organic solvents. The residual mixture was extracted with four 30-ml. portions of ether; the ether layer, after being washed with water and dried, was evaporated to dryness. The residue (158 mg.) was purified by thin-layer chromatography on silica gel (ether-acetone, 3 : 2). The extraction of the main spot with chloroform and the subsequent evaporation of the solvent afforded the crude 17α-ethyletiojerv-4-ene-3, 20-dione (XIX), which was recrystallized from a mixture of acetone-methanol (7 : 3) to yield a pure sample (60 mg.), m. p. 168—169°C; $[\alpha]_D^{20}$ +129°.

Found: C, 80.20; H, 9.52. Calcd. for $C_{21}H_{30}O_2$: C, 80.21; H, 9.62%.

The authors wish to express their thanks to Professor Toshi Irie for his encouragment, and also to Professor Shigenobu Okuda, the University of Tokyo, and to Dr. Issei Iwai, Sankyo Co., Ltd., for providing them with crude jervine. They are also indebted to Dr. Toshio Sato and to Mr. Shigezo Shimokawa for the measurement of the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2509—2512 (1966)

Sesquiterpenes from *Dictyopteris Divaricata*. II.[1] Dictyopterol and Dictyopterone

By Etsuro KUROSAWA, Motowo IZAWA, Koji YAMAMOTO,* Tadashi MASAMUNE and Toshi IRIE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received March 28, 1966)

The structures of new sesquiterpenes, dictyopterol and dictyopterone, isolated from the essential oil of a brown algae, *Dictyopteris divaricata* Okamura ("Yezoyahazu"), have been shown to be selinen-1β-ol and selinen-1-one, respectively, on the basis of chemical and spectral data. Dictyopterol is an inseparable mixture of α- and β-isomers.

During the course of a search on the sesquiterpenes from the essential oil of *Dictyopteris divaricata* Okamura, a sesquiterpene alcohol has been isolated.[2] The present paper is concerned with the structural elucidation of the alcohol and also of a new ketone isolated during the studies. On the basis of the experimental evidence described below, the alcohol, designated dictyopterol (I), and the ketone, dictyopterone (II), are shown to be selinen-1β-ol and selinen-1-one, respectively.

Dictyopterol (I), $C_{15}H_{24}O$, $[\alpha]_D^{22}$ $-30.8°$, was obtained in ca. 0.12% yield from the neutral fraction of the essential oil of the seaweed. The infrared spectrum indicated the presence of a secondary hydroxyl group at ν 3400 and 1038 cm^{-1} and terminal methylene groups at ν 1642 and 888 cm^{-1}. The NMR spectra measured at 60 and 100 Mc. showed a signal due to an olefinic methyl group at τ 8.25 and two sharp peaks at τ 9.31 and 9.23. The latter peaks altogether involved three protons and the ratio of the intensity of the respective peaks was about 3 : 2. A broad signal due to an olefinic proton, centered at τ 4.7, appeared besides two peaks due to the terminal methylene protons at τ 5.47 and 5.29. However, the intensity of the absorption at lowest field was equivalent to only about 0.4 proton. Similar signals were observed in the NMR spectrum of dictyopterol acetate (III), obtained by acetylation of I with acetic anhydride in pyridine. These NMR spectral data suggested that the alcohol was probably a mixture (about 2 : 3) of structural isomers caused by the different disposition of a double bond, i. e., α- (Ia) and β-dictyopterol (Ib); the peaks in the high field were attributable to a tertiary methyl group. This inference was supported by hydrogenation and the oxidation experiments. The catalytic hydrogenation of dictyopterol acetate (III) over Adams' catalyst in acetic acid followed by hydrolysis gave quantitatively tetrahydrodictyopterol (IV), $C_{15}H_{28}O$, which was shown to be a single compound in all respects. This saturated alcohol should be bicyclic and showed in its NMR spectrum the presence of a secondary methyl group at τ 9.21, a tertiary methyl group at τ 9.17, and an isopropyl group at τ 9.12. Selenium dehydrogenation of III gave eudalene (V), suggesting that IV possessed a selinane skeleton, a view that was confirmed later.

Oxidation of I with chromium trioxide in pyridine afforded a mixture of two isomeric ketones, $C_{15}H_{22}O$, which were separated by chromatography. One of these ketones was identical with dictyopterone (II), isolated from the essential oil, and the other was an α, β-unsaturated ketone (VI), λ 227 mμ

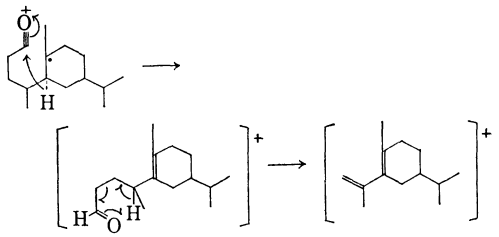
(log ε 4), ν 1680 cm^{-1}. Since only a small amount of the latter was available, no chemical investigation could be carried out. However, neither α- nor β-dictyopterol was characterized as an allylic alcohol. Hence, this α, β-unsaturated ketone was probably formed by migration of a double bond from a β, γ-position, i. e., VII.

Dictyopterone (II), $C_{15}H_{22}O$, $[\alpha]_D^{21}$ −12.5°, was newly isolated from the neutral fraction of the essential oil beside I and was also obtained by the oxidation of I as mentioned above. The infrared spectrum showed the presence of a six-membered ring carbonyl (ν 1710 cm^{-1}) and terminal methylene group (ν 1640, 890 cm^{-1}). The NMR spectrum indicated the presence of two terminal methylene groups at τ 5.34 and 5.07 (total 4H), a methyl group on an olefinic carbon at τ 8.28, and a tertiary methyl group at τ 9.05. This unsaturated ketone II was stable toward alkali, indicating that the double bond is not located at a β, γ-position relative to the carbonyl group. When II was reduced with lithium aluminum hydride in tetrahydrofuran, a corresponding alcohol was obtained, the NMR spectrum of which showed a sharp singlet at τ 9.31 (3H), a doublet (J=2 c. p. s.) at τ 8.25 (3H), and broad peaks at τ 5.47 and 5.29 (total 4H). It was found that this alcohol was identical with one of the components of I, i. e., β-dictyopterol (Ib), by comparisons of the infrared and NMR spectra of this alcohol and I.

Catalytic hydrogenation of II yielded tetrahydrodictyopterone (VIII), $C_{15}H_{26}O$, which was also obtained by the chromium trioxide oxidation of IV; VIII displayed positive Zimmermann test. Treatment of VIII with heavy water in the presence of sodium deuteroxide in dioxane afforded a dideuterio derivative (mass spectrum: *m/e* 224). The ketone therefore has $-CH_2-CO-\dot{C}(\dot{C})-C$ grouping.

The Wolff-Kishner reduction of VIII gave (+)-selinane (IX); this transformation has now established the carbon skeleton as well as the stereochemistry of the tertiary methyl and the isopropyl group in VIII, and tetrahydrodictyopterone should therefore be selinan-1-one (VIII). The alternative structure X (selinan-9-one) is ruled out because the α, β-unsaturated ketone VI was formed by the oxidation of I and because tetrahydrodictyopterone showed the infrared spectrum different from that of dihydrocanarone[3] (X). Optical rotatory dispersion curves of II and VIII showed small positive and samll negative Cotton effects, respectively. Furthermore, the mass spectra of both VIII and its dideuterio derivative showed a remarkable peak at *m/e* 178 which was formulated as follows, supporting the structure of VIII.

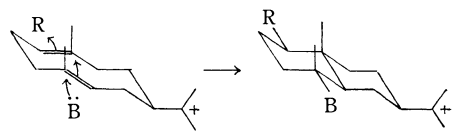


m/e 178

Finally, the conformation of the hydroxyl group in I is equatorially disposed and, therefore, β-oriented because tetrahydrodictyopterol acetate showed in its NMR spectrum a broad multiplet (half-band width ca. 16 c. p. s.) at τ 5.6 attributable to an axial hydrogen on a carbon bearing the acetoxyl group.

All the facts discussed above show that Ia, Ib, and II are the most favorable structures for α- and β-dictyopterols and dictyopterone, respectively.

These 1-oxygenated selinenes may be considered to be formed biogenetically as a result of *trans*-anti-parallel oxidative cyclization of a germacrane-type intermediate XI.[4]



XI

Experimental

The melting points are uncorrected. The ultraviolet and infrared spectra were measured using a Hitachi spectrophotometer and a Nippon Bunko 402-G or IR-S spectrophotometer, respectively. The NMR measurements were performed in carbon tetrachloride with a Nippon Denshi 60-Mc. spectrophotometer using tetramethylsilane as an internal reference unless otherwise stated. The ORD and mass spectra were measured with a Nippon Bunko ORD/UV-5 and a Hitachi RMU-6 mass spectrometer, respectively.

The Isolation of Dictyopterol (I) and Dictyopterone (II).—a) The neutral fraction[2] of the essential oil from *D. divaricata* was submitted to distillation in vacuo; after removal of fractions up to b. p. 106.5°C/4 mmHg, the residual oil (14 g.) was chromatographed on silica gel containing 20% Celite. The benzene eluate was rechromatographed over neutral alumina, and a mixture of dictyopterol and δ-cadinol was obtained. Repeated chromatography afforded dictyopterol free from δ-cadinol, but a better result was obtained by

3) V. K. Hinge, A. D. Wagh, S. K. Paknikar and S. C. Bhattacharyya, *Tetrahedron*, **21**, 3197 (1965); cf. A. D. Wagh, S. K. Paknikar and S. C. Bhattacharyya, *J. Org. Chem.*, **29**, 2479 (1964).

the following treatment. A mixture of dictyopterol and δ-cadinol was treated with acetic anhydride and pyridine, and the crude product was taken up in *n*-hexane and chromatographed over neutral alumina. Elution with *n*-hexane - benzene (3 : 1) yielded dictyopterol acetate (III) (488 mg.) as pure (T.L.C.), colorless oil, $[\alpha]_D^{19}$ −15.5° (*c* 2.0, EtOH); ν_{max}^{film} 3080, 1742, 1642, 1240, 1026, 890 cm^{-1}; NMR: τ 9.25, 9.17 (total 3H, two singlets), 8.29 (more than 3H, doublet, J= 2 c. p. s.), 8.02 (3H, singlet), 5.5 (1H, multiplet), 5.34, 5.28 (total more than 3H, broad multiplets), and 4.8 (ca. 0.4H, broad multiplet).

Found: C, 78.02; H, 10.02. Calcd. for $C_{17}H_{26}O_2$: C, 77.82; H, 9.99%.

The above acetate III (278 mg.) dissolved in a mixture of methanol (50 ml.) and ether (5 ml.) was added to 5% aqueous potassium hydroxide (10 ml.), and the solution was kept aside at room temperature for 2 days. After addition of water and removal of the organic solvent in vacuo, the residue was extracted with ether. The ether extracts were washed, dried and evaporated, giving an oily product which was chromatographed on neutral alumina. Elution with benzene - ethyl acetate (5 : 1) afforded pure (T. L. C.) I as a colorless oil, $[\alpha]_D^{22}$ −30.8° (*c* 2.08, CCl_4); ν_{max}^{film} 3400, 3080, 1642, 1038, 888 cm^{-1}; NMR: τ 9.31, 9.23 (total 3H, two singlets), 8.25 (more than 3H, doublet, J=2 c. p. s.), 6.6 (1H, broad multiplet), 5.47, 5.29 (total more than 3H, broad multiplets), and 4.7 (ca. 0.4H, broad multiplet). Mass spectrum: *m/e* (rel. abund.) 220 (100), 205 (81), 202 (84), 161 (91), 159 (84), 133 (83), 93 (82), 81 (71).

Found: C, 81.47; H, 10.65. Calcd. for $C_{15}H_{24}O$: C, 81.76; H, 10.98%.

The *n*-hexane - benzene (3 : 1) eluate in the chromatography of the residual oil described above, was rechromatographed over neutral alumina, and dictyopterone (II) was obtained (161 mg.), $[\alpha]_D^{21}$ −12.5° (*c* 2.16, CCl_4); ν_{max}^{film} 3080, 1710, 1640, 890 cm^{-1}; NMR: τ 9.05 (3H, singlet), 8.26 (3H, doublet, J=2 c. p. s.), 5.30, 5.07 (total 4H, broad multiplets).

Found: C, 82.73; H, 10.02. Calcd. for $C_{15}H_{22}O$: C, 82.51; H, 10.16%.

b) The neutral fraction (25 g.) of the essential oil was chromatographed on neutral alumina and eluted successively with *n*-hexane, benzene, ether, and ethyl acetate. The product (ca. 7 g.) obtained from the eluates with ether and ethyl acetate was distilled with steam. The distillate was extracted with ether and dried. After removal of the solvent, the residual oil was chromatographed on silica gel. Each eluate was treated as described above, yielding I and II.

The Hydrogenation of Dictyopterol Acetate (III).—Dictyopterol acetate (III) (208 mg.) in glacial acetic acid (15 ml.) was hydrogenated over Adams' catalyst (15 mg.) at room temperature until gas absorption ceased (2 mol. of hydrogen was absorbed after 2 hr.). The catalyst was removed by filtration and the solvent was evaporated under reduced pressure. The residual oil was chromatographed on alumina. The fraction eluted with *n*-hexane - benzene (3 : 1) afforded pure (T. L. C.) tetrahydrodictyopterol acetate (196 mg.). ν_{max}^{film} 1742, 1240, 1024 cm^{-1}; NMR: τ 9.12 (9H, doublet, J=6 c. p. s.), 9.08 (3H, singlet), 8.05 (3H, singlet), 5.6 (1H, broad multiplet).

Found: C, 76.95; H, 11.25. Calcd. for $C_{17}H_{30}O_2$: C, 76.64; H, 11.35%.

Tetrahydrodictyopterol (IV).—To a solution of the afore-mentioned tetrahydro-acetate (190 mg.) in a mixture of methanol (20 ml.) and ether (5 ml.) was added 5% aqueous potassium hydroxide (3 ml.), and the mixture was allowed to stand at room temperature for 2 days. After addition of water to the reaction mixture, the organic solvent was removed in vacuo and the residue was extracted with ether. The ether solution was washed with 0.5 N hydrochloric acid, 2% sodium bicarbonate solution, and then with water, successively. Removal of the solvent afforded an oily material, which was chromatographed on alumina. The fraction eluted with benzene - ethyl acetate (5:1) gave pure (T. L. C.) tetrahydrodictyopterol (IV) (136 mg.). ν_{max}^{film} 3400, 1020 cm^{-1}. NMR: τ 9.21 (3H, doublet, J=6 c. p. s.), 9.17 (3H, singlet), 9.12 (6H, doublet, J=6 c. p. s.), 6.9 (1H, broad multiplet).

Selenium Dehydrogenation of Dictyopterol Acetate (III).—A mixture of III (80 mg.) and selenium (85 mg.) was heated in a sealed tube at 282—294°C for 6 hr. The reaction mixture was extracted with ether and the ether extracts were dried. After removal of the solvent, the residue was chromatographed on alumina thin layer using *n*-hexane. The fraction of R_f=1 33 mg.) was identified as eudalene (V), λ_{max}^{EtOH} mμ (ε): 228 (36.700), 282 (3200), 320 (383). ν_{max}^{film} 1630, 1600, 1510, 1380, 1360, 1300, 1170, 1150, 1080, 1042, 878, 830, 750 cm^{-1}.

Picrate: m. p. 87—89°C, yellow needles (from ethanol).

The Oxidation of Dictyopterol (I).—A solution of I (109 mg.) in dry pyridine (5 ml.) was added to a complex of chromium trioxide (300 mg.) and pyridine (3 ml.) and the mixture was set aside at room temperature overnight. The reaction mixture was distilled with steam and the distillate was extracted with ether. The ether extracts were washed with 0.5 N hydrochloric acid, 0.5 N sodium hydroxide solution, then with water and dried. After removal of the solvent in vacuo, the residual oil was chromatographed on alumina. The fraction eluted with *n*-hexane - benzene (3 : 1) afforded pure (T. L. C.) oily product (61 mg.), which was identified as dictyopterone (II) in all respects.

The fraction eluted with benzene gave an α, β-unsaturated ketone (14 mg.). λ_{inf}^{EtOH} 227 mμ (log ε 4). ν_{max}^{film} 1680 cm^{-1}.

The Alkaline Treatment of Dictyopterone (II).—A mixture of II (12 mg.) and 5% methanolic potassium hydroxide was refluxed for 1 hr. After addition of water and removal of the methanol in vacuo, an oily product was extracted with ether and the ether extracts were washed with water and dried. On removal of the solvent, the starting material II was recovered unchanged.

The Reduction of Dictyopterone (II) with Lithium Aluminum Hydride.—To a suspension of lithium aluminum hydride (25 mg.) in dry tetrahydrofuran (10 ml.), a solution of II (59 mg.) in the same solvent (5 ml.) was added and then the mixture was refluxed for 2 hr. After being cooled, the mixture was decomposed by the addition of water and acidified with dilute sulfuric acid. The solution was extracted with ether and the ethereal layer was washed with 2% sodium

bicarbonate solution and then with water and dried. After removal of the solvent, the residual oily product was chromatographed on alumina. The product eluted with benzene - ethyl acetate (5 : 1) was identified as β-dictyopterol (Ib) by a comparison of the infrared and NMR spectra. ν_{max}^{film} 3400, 3080, 1642, 1038, 888 cm^{-1}. NMR: τ 9.31 (3H, singlet), 8.25 (3H, doublet, J=2 c. p. s.), 6.6 (1H, broad quartet), 5.47 and 5.29 (total 4H, broad multiplets).

Tetrahydrodictyopterone (VIII).—Dictyopterone (29 mg.) in glacial acetic acid (6 ml.) was hydrogenated over Adams' catalyst (3 mg.) at room temperature. After 2 hr. the catalyst was removed and the acetic acid solution was neutralized with 5% aqueous potassium hydroxide. The neutral solution was extracted with ether and the ethereal layer was washed with water and dried. Removal of the solvent afforded an oily product, which was chromatographed on alumina. The fraction eluted with benzene gave oily saturated ketone VIII (22 mg.). $[\alpha]_D^{22}$ −41.6° (c 1.01, MeOH). The ultraviolet spectrum showed only an end absorption. ν_{max}^{film} 1705, 1390, 1372, 1285, 1140, 1077, 1010, 916 cm^{-1}. NMR: τ 9.12 (6H, doublet, J=6 c. p. s.), 8.92 (3H, singlet), 8.92 (3H, doublet, J=7 c. p. s.). Mass spectrum: m/e (rel. abund.) 222 (92), 220 (92), 178 (98), 135 (79), 109 (74), 81 (81), 43 (100).

The Oxidation of Tetrahydrodictyopterol (IV).—The oxidation of IV (110 mg.) with chromium trioxide was carried out as described in the case of I, yielding a crude oily product which was chromatographed over alumina. The fraction eluted with n-hexane - benzene (3 : 1) was identified as tetrahydrodictyopterone (VIII) obtained by the catalytic hydrogenation of II.

The Wolff-Kishner Reduction of Tetrahydrodictyopterone (VIII).—To a solution of sodium (250 mg.) in diethylene glycol (7 ml.), VIII (45 mg.) in the same solvent (3 ml.) and 100% hydrazine hydrate (1.3 ml.) were added, and the mixture was heated at 180—185°C for 20 hr. After addition of water, the mixture was extracted with ether. The ether extracts were washed with water, dried and the ether was removed in vacuo. The oily product thus obtained was chromatographed on alumina. The fraction eluted with n-hexane afforded a colorless oil, $[\alpha]_D^{22}$ +15°, which was identified as (+)-selinane (IX) by a comparison of its infrared spectrum with that appeared in the literature.[5]

Deuterium Exchange Experiment of Tetrahydrodictyopterone (VIII).—Deuterium exchange was effected by heating VIII (32 mg.) in N sodium deuteroxide solution (0.5 ml.) and dry dioxane (1.5 ml.) at 100°C for 10 min. After cooling, the solvent was distilled off under diminished pressure. To the product was added a mixture of heavy water (0.7 ml.) and dry dioxane (1.5 ml.), and the mixture was heated and most of the solvent was then evaporated in vacuo. This procedure was repeated two times, and finally the residue was extracted with dry ether. Removal of the ether yielded tetrahydrodictyopterone-d_2 (24 mg.) as a colorless oil. Mass spectrum: m/e (rel. abund.) 224 (100), 222 (92), 178 (98), 163 (81), 135 (72), 109 (65), 81(64), 43(62).

The authors wish to express their thanks to Professor Koshiro Miyahara for measurements of mass spectra and to Mr. Seiichiro Ohnishi of Toyo Rayon Co. and Mr. Shigezo Shimokawa for measurements of NMR spectra. They are also indebted to Miss Akiko Maeda for her elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2512—2516 (1966)

The Chemistry of Polyazanes. VI. The Oxidation of ω, ω'-Dibenzoylcarbohydrazide

By Hiroshi MINATO, Ryuki HISADA* and Mitsugu TANAKA*

Department of Chemistry, International Christian University, Mitaka, Tokyo

(Received April 7, 1966)

ω, ω'-Dibenzoylcarbohydrazide (DBC) was oxidized with sodium hypochlorite in an aqueous ethanolic solution at $-70°C$. At first the solution had a deep red color, but it gradually faded away. The products of the reaction isolated were benzoic acid, ethyl benzoate, carbon dioxide, 2-phenyl-1, 3, 4-oxadiazol-5-one, and N, N'-dibenzoylhydrazine. Then, DBC was oxidized with hypochlorous acid, the products of this reaction were not very different from those obtained with sodium hypochlorite. A plausible mechanism was presented, which assumed the formation of bis(benzoylimino)urea, which was then decomposed heterolytically by the nucleophilic attack of ethanol and water molecules.

Compounds containing a chain of several nitrogen atoms have been investigated in our laboratories

* The American Chemical Society-Petroleum Research Fund Scholar.

in the last few years.[1-5] In relation to these compounds, our attention has been drawn to a compound in which a chain of four nitrogen atoms is intercepted by a carbonyl group, namely, bis-(benzoylimino)urea (BIU). In BIU, two benzoyl radicals are connected with –N=N–C(=O)–N=N–, which may change spontaneously into gaseous nitrogen molecules and a carbon monoxide molecule. If BIU is prepared and if it then decomposes at very low temperatures into two benzoyl radicals, two nitrogen molecules and one carbon monoxide molecule, BIU might be used as an initiator of polymerization at very low temperatures.

Stollé and Krauch[6] observed that the oxidation of ω, ω'-dibenzoylcarbohydrazide (DBC) with an aqueous sodium hypochlorite solution gave a yellow-red color, and that the color immediately disappeared with evolution of gas. They did not, however, elucidate the structure and the nature of the compound possessing the yellow-red color.

The oxidation of DBC with an aqueous sodium hypochlorite solution and with a hypochlorous acid solution has now been investigated in detail and will be described in this paper.

Experimental

ω, ω'-Dibenzoylcarbohydrazide (DBC).—DBC was prepared according to the method of Stollé and Krauch.[6] Seventy grams of carbohydrazide (0.716 mol.) was dissolved in 750 ml. of a 1.6 N sodium hydroxide solution. To this solution, 202 g. of benzoyl chloride (1.423 mol.) was stirred, drop by drop, with cooling. After the mixture had been allowed to stand for 12 hr., the precipitates were filtered off, and washed with water and ether. The yield of crude DBC was 200 g. (0.672 mol.). It was recrystallized from ethanol. M. p. 204.5°C (lit.: 205°C).

The Oxidation of DBC with a Sodium Hypochlorite Solution.—First, a blank test was run in order to check whether ethanol, used as an antifreeze solvent, is oxidized with sodium hypochlorite. One milliliter of a 6.965% aqueous sodium hypochlorite solution and 3.0 ml. of water were mixed at 0°C. To this solution 25.0 ml. of ethanol was added, and the mixture was immediately cooled to −70°C. Then 1.5 g. of potassium iodide, 3 ml. of glacial acetic acid, and 15 ml. of ethanol were added. After it had been warmed to room temperature, the solution was titrated with a 0.1037 N sodium thiosulfate solution. The titer was 9.70 ml. In the absence of ethanol, the titer was 9.75 ml.

Run 1.—Fifteen milliliters of a 6.965% aqueous sodium hypochlorite solution (13.41 mmol.) and 45 ml. of water were mixed at 0°C. Three-hundred-seventy-five milliliters of cooled ethanol was added to this solution, and this mixture was immediately cooled to −70°C. Then this cooled mixture was added to a solution of 2.091 g. of DBC (6.67 mmol.) in 300 ml. of ethanol which had been cooled to −70°C. The mixed solution had a deep red color at −70°C. After about 3 min., the color turned orange and gradually faded away. The solution was stirred for about 2 more hr. at −70°C, and then warmed to room temperature.

After it had been allowed to stand for a day, the mixture was distilled by the use of a 30-cm. Vigreux column. The ethanol was then distilled off, and a small amount of a brown residue remained. Sixty milliliters of ether was added to this residue, and the ethereal solution was dried with anhydrous sodium sulfate. After the evaporation of ether under reduced pressure, reddish-brown solids, weighing 1.40 g., remained. This solid material was divided into a petroleum ether-soluble fraction and a petroleum ether-insoluble fraction. The infrared spectrum of the petroleum ether-soluble fraction indicated the presence of benzoic acid and ethyl benzoate. It was found, by the use of the absorption of benzoic acid at 1415 cm^{-1} and that of ethyl benzoate at 1110 cm^{-1}, that 0.689 g. of benzoic acid (5.65 mmol.) and 0.164 g. of ethyl benzoate (1.09 mmol.) were present in this fraction.

The petroleum ether-insoluble fraction consisted of crystals weighing 0.261 g. and melting at 135°C. After they had been recrystallized three times from water, the crystals melted at 138—139°C. The crystals were identified as 2-phenyl-1, 3, 4-oxadiazol-5-one from the infrared spectrum and from the melting point of the mixture with an authentic sample (m. p. 139°C).[7]

Run 2.—Run 2 was different from Run 1 with respect to the work-up; after the reaction was over, the solution was acidified and the amount of carbon dioxide was analyzed.

Twenty milliliters of a 0.765 M aqueous sodium hypochlorite solution (15.30 mmol.) and 40 ml. of water were mixed at 0°C. Three-hundred-seventy-five milliliters of cooled ethanol was then added to this solution, and the mixture was immediately cooled to −70°C. Then this cooled mixture was added to a solution of 2.270 g. of DBC (7.61 mmol.) in 300 ml. of ethanol which had been cooled to −70°C in a one-liter, four-necked flask equipped with a mercury-sealed stirrer and with an outlet leading to an apparatus for the measurement of carbon dioxide. The mixed solution had a deep red color at −70°C. After about two minutes, however, the color turned orange. The mixed solution was stirred for two hours at −70°C. Then it was warmed to room temperature, and 13.81 ml. of 1.108 M hydrochloric acid (15.30 mmol.) was added. In order to determine the amount of carbon dioxide present, the solution was swept by a stream of a CO_2-free air, which was then led to a tube containing soda-lime. The increase in the weight of the soda-lime tube

was 0.1575 g. after the carbon dioxide had been completely absorbed. The pH of the mixed solution was 3.0.

After it had then been allowed to stand for a day, the solution was distilled by the use of water bath kept at 85°C. When about 10 ml. of the residual liquid was present in the flask, the distillation was stopped. Then the distillate was carefully redistilled unitl about 100 ml. remained in the flask, and the residual liquid was gas-chromatographed by the use of a Shimadzu GC-2B gas chromatograph; the presence of ethyl benzoate was detected and 2.33 mmol. of ethyl benzoate was found by the use of diphenyl ether as the internal standard.

To the 10-ml. residue of the first distillation, 300 ml. of ether was added. White precipitates were filtered off and found to be sodium chloride. When the ethereal solution was distilled, the residue was a mixture of white precipitates and a brown pasty oil. The white solids were filtered off, washed, and recrystallized from ethanol; m. p. 235—240°C. The infrared spectrum was exactly the same as that of authentic *N*, *N'*-dibenzoylhydrazine (m. p. 234—238°C).[8]

When the filtrate and washings were evaporated, a brown, pasty residue weighing 2.052 g. was obtained. This was found to be a mixture of benzoic acid and ethyl benzoate by a study of its infrared spectrum. 5.39 mmol. of benzoic acid and 2.22 mmol. of ethyl benzoate were found to be present.

Carbon monoxide was found to be absent among the reaction products in a separate experiment using iodine pentoxide and potasssium iodide.

The Oxidation of DBC with Hypochlorous Acid.—First, a blank test was run in order to check whether or not ethanol was oxidized with hypochlorous acid. 2.003 g. of a 0.732 M aqueous hypochlorus acid solution was cooled to 0°C. To this solution 50 ml. of ethanol and 6 ml. of water were added, and the mixed solution was immediately cooled to −70°C. Then 2 g. of potassium iodide, 3 ml. of glacial acetic acid, and 30 ml. of ethanol were added to the solution. After it had been warmed to room temperature, the solution was titrated with a 0.1037 N sodium thiosulfate solution. The titer was 27.65 ml., which corresponded to a 0.728 M hypochlorous acid solution. This test showed that only 0.55% of the hypochlorous acid initially present was consumed by the reaction with ethanol.

21.60 ml. of a 0.640 M aqueous hypochlorous acid solution (13.82 mmol.) and 38.4 ml. of water were mixed at 0°C. After 375 ml. of cooled ethanol had then been added to this solution, the mixture was immediately cooled to −70°C. Then this cooled mixture was added to a solution of 2.052 g. of DBC (6.88 mmol.) in 300 ml. of ethanol which had been cooled to −70°C in a one-liter, four-necked flask equipped with a mercury-sealed stirrer and with an outlet leading to an apparatus for the determination of carbon dioxide. The mixture did not acquire a deep red color, but only a light yellow color. After it had been kept at −70°C for two hours, it was warmed to room temperature. The increase in the weight of the soda-lime tube was 0.1530 g., corresponding to the evolution of 3.47 mmol. of carbon dioxide. After it had then been allowed to stand at room temperature for a day, the mixed solution was distilled. 6.18 mmol. of ethyl benzoate was found to be present in the distillate by the use of a Shimadzu GC-2B gas chromatograph. The residue was washed with petroleum ether, and the white solids (m. p. 127°C) were found, by a study of the infrared spectrum, to be *N*-benzoyl-*N'*-ethoxycarbonylhydrazine (m. p. 127°C). The petroleum ether-washings were evaporated to yield an oil weighing 0.6154 g. Its infrared spectrum showed that it contained 0.671 mmol. of benzoic acid and 2.04 mmol. of ethyl benzoate.

The Oxidation of DBC with Sodium Hypochlorite and the Reduction of the Oxidation Product with Hydrogen Sulfide.—Ten milliliters of a 0.433 M aqueous sodium hypochlorite solution (4.33 mmol.) and 7.5 ml. of water were mixed at 0°C. One hundred milliliters of cooled ethanol was added to this solution, and this mixture was immediately cooled to −70°C. Then this cooled mixture was added to a solution of 0.642 g. of DBC (2.15 mmol.) in 90 ml. of ethanol which had been cooled to −70°C. When the mixed solution possessed a deep red color, 4.5 ml. of a 1.0 M hydrochloric acid solution was added, after which hydrogen sulfide was passed into this mixed solution for five minutes. Then it was warmed to room temperature.

After the mixture had been allowed to stand at room temperature for a day, it was distilled. Most of the liquid was distilled at about 79°C, but a yellowish residue remained. It was shaken with 20 ml. of water, and the precipitates were filtered; this treatment was repeated four times. Then the precipitates were shaken with 20 ml. of ether, and the solids were filtered; this procedure was repeated four times. The white solids obtained weighed 0.115 g. (0.385 mmol.), and melted at 199—203°C. The infrared spectrum was exactly the same as the infrared spectrum of the authentic DBC. After the ethereal washings had been evaporated, a yellowish-brown residue, weighing 0.309 g., remained. The infrared spectrum showed that the residue contained 0.034 mmol. of benzoic acid and 0.306 mmol. of ethyl benzoate.

Results and Discussion

ω, *ω'*-Dibenzoylcarbohydrazide (DBC) was oxidized with sodium hypochlorite at −70°C in a mixture of water and ethanol; the latter was used as the anti-freeze. When DBC and the

oxidant were mixed, the mixed solution had a deep red color, but this gradually faded away. The results of an analysis of the products of the reaction are shown in Table I.

The products of the decomposition of bis-(benzoylimino)urea (BIU), which was supposed to be the oxidation product of DBC, indicate that BIU did not decompose homolytically with the production of free radicals. The products of the reaction are best described by the nucleophilic attack of ethanol or water molecules or ethoxide or hydroxide ions upon benzoyl carbon atoms of BIU, as is shown in Fig. 1. When sodium hypochlorite was used as the oxidizing agent, the medium was alkaline, the ethoxide ions and hydroxide ions present may be supposed to be far more nucleophilic than the ethanol and water molecules.

If DBC was oxidized in a non-alkaline condition, BIU formed might decompose homolytically to yield free radicals. In order to check this possibility, DBC was oxidized with hypochlorous acid. The products of the decomposition of BIU in an acid medium, shown in Table I, indicate that the BIU formed was attacked by ethanol and water molecules and decomposed heterolytically rather than homolytically. The products of decomposition were not very different from those formed in an alkaline condition. 0.24 mol. of 2-phenyl-1, 3, 4-oxadiazol-5-one was produced from one mole of BIU in Run 1 with sodium hypochlorite. In the case of Run 2, hydrochloric acid was added to the reaction mixture after the reaction had been completed; this acidification must have decomposed 2-phenyl-1, 3, 4-oxadiazol-5-one. When hypochlorous acid was used as the oxidant, none of this heterocyclic compound was detected.

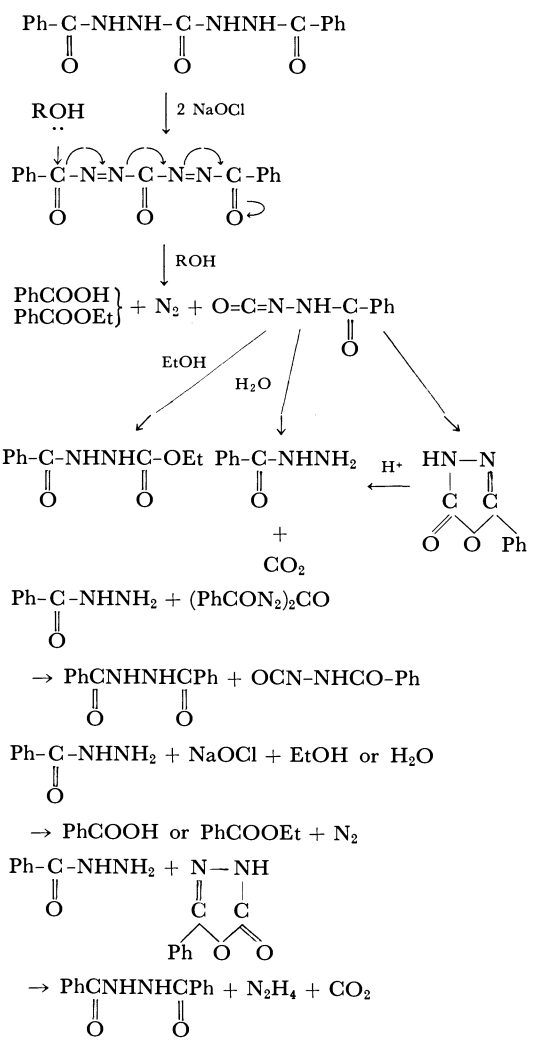

Fig. 1. Plausible scheme of decomposition of BIU.

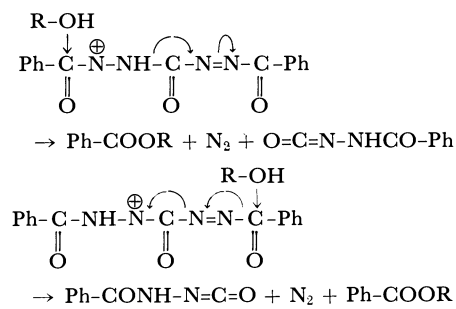
The behavior of the deep red substance can best be explained by assuming that bis(benzoylimino)-urea is produced by the oxidation of DBC. However, in order to confirm this, the deep red substance was reduced by hydrogen sulfide. Stollé oxidized *N, N'*-diacetylhydrazine and obtained diacetyldiimide, which was a deep red and unstable oil. He then reduced it with hydrogen sulfide and thus obtained *N, N'*-diacetylhydrazine again.

Soon after the DBC solution and sodium hypochlorite solution had been mixed and the deep red color produced, hydrogen sulfide gas was introduced in order to reduce the deep red substance. After the work-up, about 18% of the amount of DBC originally present was isolated. All the data, including those of this reduction experiment, can best be explained by assuming that the deep red substance produced by the oxidation of DBC is bis(benzoylimino)urea.

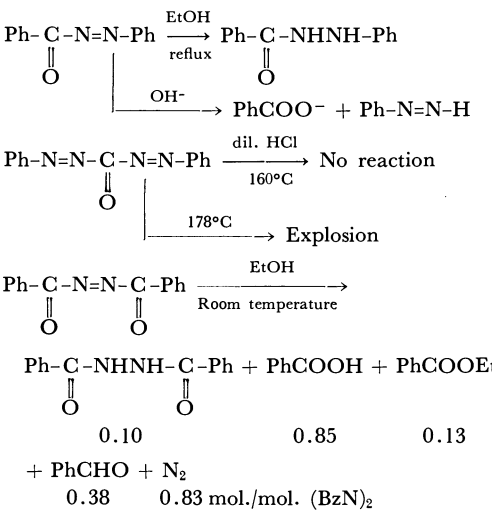
The nucleophilic attack of ethoxide and hydroxide ions upon BIU under alkaline conditions seems reasonable, but the equally fast attack of ethanol and water molecules on BIU under acid conditions seems somewhat surprising. Probably the azo double bonds are protonated, and this protonation induces the nucleophilic attack of ethanol and water molecules.



When DBC was oxidized under acid conditions, no deep red color was observed, even at the instant

of mixing the reactants. This fact is reasonable, since the protonated BIU is not likely to have a deep color.

The structures of benzoylphenyldiimide,[9] bis-(phenylimino)urea,[10] and dibenzoyldiimide[11] are somewhat related to the structure of BIU, and it is interesting to note their behavior in hydroxylic solvents:



The decomposition of dibenzoyldiimide is especially interesting. Leffler and Bond[11] determined the rates of its decomposition and found that $k_1 = 7.33 \times 10^{-6}$ sec^{-1} in benzene at 100°C (initial concentration $(C_0) = 0.03$ M); $k_1 = 137 \times 10^{-6}$ sec^{-1} in benzyl alcohol at 61.9°C ($C_0 = 0.0051$ M); $k_1 = 75.6 \times 10^{-6}$ sec^{-1} ($C_0 = 0.008$ M), and $k_1 = 124 \times 10^{-6}$ sec^{-1} ($C_0 = 0.0135$ M) in ethanol at 19.69°C.

Although both the products and the kinetics of the decomposition seem to suggest that the decomposition of the diimide in ethanol at 20°C is an ionic reaction initiated by the nucleophilic attack of ethanol on the benzoyl carbon, Leffler and Bond favored a free radical mechanism. Since they found acrylonitrile to polymerize in a benzene solution at 75°C, they thought the decomposition of the diimide in benzene at 75°C was likely to involve some homolytic decomposition. They argued that ethyl benzoate could be formed from the radical-ethanol complexes by the loss of hydrogen to another radical or to a molecule of dibenzoyldiimide, and that the second oxygen needed for the conversion of benzoyl radical to benzoic acid probably came from the solvent ethanol. These arguments seem unsatisfactory. They did not explain the formation of *N, N'*-dibenzoylhydrazine, either.

On the basis of the findings of the decomposition of bis(benzoylimino)urea, an ionic mechanism seems to be a better mechanism for the decomposition of dibenzoyldiimide, at least in ethanol near room temperature. The following reaction scheme seems to explain the reaction products:

The Reaction of Halogenated Biacetyl Monoximes with Esters of Amino Acids

By Masatoshi SUGIYAMA, Mitsuo MASAKI and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received April 7, 1966)

1-Chloro-2-oximino-3-butanone (I) was prepared by the nitrosation of chloroethyl methyl ketone with an alkyl nitrite. I was treated with the L-leucine ethyl ester (II) to give 2-(2-oximino-3-oxobutylamino)-4-methylvalerate (III) and 2-[*N*, *N*-bis(2-oximino-3-oxobutyl)amino]-4-methylvalerate (IV). In a similar manner, 1-bromo-3-oximino-2-butanone (V) was treated with II to give 2-(3-oximino-2-oxobutylamino)-4-methylvalerate (VI). The reaction of the carbonyl group of III and VI with hydroxylamine and hydrazine was also studied. The treatment of VI with ammonia gave 6-(2-oximinoethyl)-3-isobutyl-2-hydroxypyrazine. Reactions of I and V with other esters of amino acids were also carried out.

It has been shown in our laboratory[1] that the reaction of α-haloximes with amino acid derivatives gives *N*-(2-oximinoalkyl)amino acid derivatives in good yields and that it is useful for synthesizing 2-hydroxypyrazines. In the present research this reaction was further studied by using monohalogenated biacetyl monoximes, in which a reactive carbonyl group is present besides a halogen atom.

Recently, Ogloblin has prepared 1-chloro-2-oximino-3-butanone (I) by treating methyl vinyl ketone with nitrosyl chloride and showed that the reaction of I with hydroxylamine hydrochloride or phenylhydrazine yielded the corresponding carbonyl derivatives, while I reacted with diethylamine to give 1-diethylamino-2, 3-butanedione-2-oxime.[2] However, it has not yet been clarified in the reaction of I with primary amines whether the carbonyl group is condensed or the chlorine atom is displaced.

1-Chloro-2-oximino-3-butanone (I) was prepared by a more convenient method than Ogloblin's: the chloroethyl methyl ketone obtained from acetyl chloride and ethylene[3] was treated with an alkyl nitrite to give I in a good yield.

When I was treated with two mole equivalents of the L-leucine ethyl ester (IIa) in an ethereal solution, one mole equivalent of hydrochloride of IIa separated immediately, and ethyl 2-(2-oximino-3-oxobutylamino)-4-methylvalerate (IIIa) was obtained in a 44% yield, while there was also a 38% yield of ethyl 2-[*N*, *N*-bis(2-oximino-3-oxobutyl)amino]-4-methylvalerate (IVa). Both products were characterized by hydrolysis with 2 N sodium hydroxide to the corresponding acids (VIIa and VIIIa). The infrared spectrum of IIIa showed strong absorption bands at 1730 ($COOC_2H_5$) and 1685 cm^{-1} (C=O conjugated with C=N). The acid (VIIa) was treated with hydroxylamine in an alkaline solution to give 2-(2, 3-dioximinobutylamino)-4-methylvaleric acid (IXa). When I was treated with the DL-phenylalanine ethyl ester (IIb) in the same manner as in the case of IIa, ethyl 2-(2-oximino-3-oxobutylamino)-3-phenylpropionate (IIIb) was obtained.

From the above facts, it became clear that, in the reaction of I with esters of amino acids, condensation with the carbonyl group did not occur, but the chlorine atom was exclusively displaced. The reaction of 1-bromo-3-oximino-2-butanone (V)[4] with the ester of amino acids was then attempted, though the reactions of α-halo ketones with primary amines have been known to be generally very complex.[5] There has been no report about the reaction of V except with thioformamide or thiobenzamide.[6]

When V was treated with piperidine in an ethereal solution, 1-piperidino-3-oximino-2-butanone was obtained in a good yield. The treatment of V with the L-leucine ethyl ester (IIa) in an ethereal solution gave the expected ethyl 2-(3-oximino-2-oxobutylamino)-4-methylvalerate (VIa) in a 46% yield. In the same manner, V reacted with other esters of amino acids to yield *N*-(3-oximino-2-oxobutyl)amino acid esters (VI) (Fig. 1). VI was characterized by a study of its infrared spectrum, in which strong absorption bands at 1720

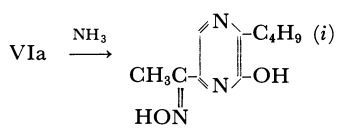
$(COOR_2)$ and 1685 cm^{-1} (C=O) appeared, as well as by the reactions described below. VIa was converted to IXa by treatment with hydroxylamine, followed by the hydrolysis of the oily product in an aqueous alkali; VId gave 2-(2-hydrazono-3-oximinobutylamino)-3-phenylpropionic acid (Xd) when treated with hydrazine hydrate and then subjected to hydrolysis.

When VIa was treated with ammonia in methanol, 6-(2-oximinoethyl)-3-isobutyl-2-hydroxypyrazine was obtained in a poor yield.



Experimental

1-Chloro-2-oximino-3-butanone (I). — 4-Chloro-2-butanone was prepared from acetyl chloride and ethylene according to Sondheimer's method.[3] Into a solution of 4-chloro-2-butanone (64 g.) in absolute ether (300 ml.), hydrogen chloride was introduced at the rate of 3—5 bubbles a second. The gaseous ethyl nitrite (1.5 mole equivalent) [prepared from sodium nitrite (55.2 g.), ethanol (36.8 g.), and sulfuric acid (39.2 g.)] was introduced with vigorous stirring into the solution at 30—35°C during a six-hour period. After all the ethyl nitrite had passed in, the stirring and the addition of hydrogen chloride were continued for an additional thirty minutes. The ethereal solution was then treated with activated charcoal and concentrated under reduced pressure to give a brown crystalline product, which was washed with carbon tetrachloride to yield I (43 g., 53%). The product was sufficiently pure for further experiments. A part of the product was recrystallized twice from benzene into the form of colorless plates, m. p. 92—93°C (lit.[2] 89—90°C).

The Reaction of I with L-Leucine Ethyl Ester (IIa).—To a solution of the L-leucine ethyl ester (IIa, 7 g.) in absolute ether (30 ml.), I (3 g.) was added with ice-cooling. Hydrochloride of the ester (IIa) separated immediately. The mixture was then allowed to stand at room temperature overnight. The hydrochloride (4.3 g.) was filtered off and washed with ether. The combined ethereal solution was extracted with 130 ml. (50+50+30 ml.) of 1 N hydrochloric acid. The aqueous extract was neutralized with sodium carbonate until pH 3, thus separating a small quantity of an oil, which was removed by extracting with ether. The aqueous layer was further neutralized with sodium carbonate to pH 6 to give ethyl 2-(2-oximino-3-oxobutylamino)-4-methylvalerate (IIIa; 2.5 g.; 44%, calculated on I). Two recrystallizations from n-hexane gave colorless needles, m. p. 96.5—97.5°C.

Found: C, 55.98; H, 8.82; N, 11.00. Calcd. for $C_{12}H_{22}N_2O_4$: C, 55.79; H, 8.58; N, 10.85%.

The combined ethereal layer and extract were dried over anhydrous sodium sulfate and concentrated to give an oily product (1.9 g.), which was then dissolved in 2 N sodium hydroxide (20 ml.) and allowed to stand at room temperature overnight. After being diluted with water (40 ml.) and treated with activated charcoal, the solution was neutralized with 4 N acetic acid to give 2-[N, N-bis(2-oximino-3-oxobutyl)amino]-4-methylvaleric acid (VIIIa; 1.4 g.; 38%, calculated on I), which was then recrystallized twice from 50% aqueous

dimethylformamide into the form of colorless prisms, m. p. 171—172°C.

Found: C, 50.66; H, 6.97; N, 12.66. Calcd. for $C_{14}H_{23}N_3O_6$: C, 51.05; H, 7.04; N, 12.76%.

2-(2-Oximino-3-oxobutylamino)-4-methylvaleric Acid (VIIa).—In 2 N sodium hydroxide (10 ml.) IIIa (0.46 g.) was dissolved; the resultant solution was allowed to stand at room temperature overnight. The solution was treated with activated charcoal, and then neutralized with 4 N acetic acid to afford a product (0.35 g., 85%) which was then recrystallized from dimethylformamide into the form of colorless prisms, m. p. 230°C (decomp.).

Found: C, 52.43; H, 7.91. Calcd. for $C_{10}H_{18}N_2O_4$: C, 52.16; H, 7.88%.

Ethyl 2-(2-Oximino-3-oxobutylamino)-3-phenylpropionate (IIIb).—To a solution of the DL-phenylalanine ethyl ester (IIb, 12.6 g.) in absolute ether (150 ml.), I (4.2 g.) was added with ice-cooling; the mixture was then allowed to stand at room temperature overnight. After the precipitate (6.8 g.) had been removed from the mixture, the filtrate was allowed to stand in a refrigerator to separate crystals gradually. After three hours the crystals (3.1 g.) were collected, and the filtrate was washed with water and extracted with 1 N hydrochloric acid. The acidic extract was treated with activated charcoal and neutralized with sodium carbonate until pH 6 to give the product (1.9 g.). The total yield was 5 g. (55%). An analytical sample was obtained, by recrystallization from ethyl acetate, as colorless needles, m. p. 119—120°C.

Found: C, 61.87; H, 7.03; N, 9.69. Calcd. for $C_{15}H_{20}N_2O_4$: C, 61.63; H, 6.90; N, 9.58.%

2-(2, 3-Dioximinobutylamino)-4-methylvaleric Acid (IXa).—To a solution of VIIa (1.9 g.) in 1 N sodium hydroxide (30 ml.) hydroxylamine hydrochloride (0.8 g.) was added. After the resultant solution had been allowed to stand at room temperature for two days, it was treated with activated charcoal and acidified with 20% aqueous acetic acid to give IXa (1.9 g., 94%), which was then recrystallized from dimethyl formamide into the form of colorless prisms, m. p. 257—258°C.

Found: N, 17.04. Calcd. for $C_{10}H_{19}N_3O_4$: N, 17.13%.

1-Bromo-3-oximino-2-butanone (V).—This compound was prepared from bromobiacetyl and hydroxylamine according to Doerner's method.[4] Colorless plates; m. p. 85—86°C (lit.[4] 86—87°C).

1-Piperidino-3-oximino-2-butanone.—To a solution of piperidine (1.7 g.) in absolute ether (70 ml.) V (1.8 g.) was added, after which the mixture was allowed to stand at room temperature for three hours. The precipitate was then collected by filtration and washed with water in order to remove the hydrobromide of piperidine, thus obtaining a product (1.1 g.). The above ethereal filtrate was washed with water, dried over anhydrous sodium sulfate, and concentrated under reduced pressure to give a crystalline product (0.4 g.). The total yield was 1.5 g. (82%). Recrystallization from ethyl acetate gave colorless needles, m. p. 135°C (decomp.).

Found: N, 15.28. Calcd. for $C_9H_{16}N_2O_2$: N, 15.21%.

Ethyl 2-(3-Oximino-2-oxobutylamino)-4-methylvalerate (VIa).—The following experiment was typical of the procedures used for the reaction of V with amino acid esters (II).

To a solution of the L-leucine ethyl ester (IIa, 12.7 g., 0.08 mole) in absolute ether (150 ml.), V (7.2 g., 0.04 mole) was added, the mixture was then allowed to stand at room temperature overnight. The precipitate was collected by filtration and washed with water, and the collected crystals were treated with water, in order to remove the hydrobromide; this yielded the product (1.3 g.). After being washed with water and dried over anhydrous sodium sulfate, the combined ethereal filtrate and washing were concentrated under reduced pressure. The crystalline residue was dissolved in carbon tetrachloride in order to filter it, thus giving VIa (3.4 g.). The total yield was 4.7 g. (46%); an analytical sample was obtained, by recrystallization from carbon tetrachloride, as colorless needles, m. p. 124.5—125.5°C (decomp.).

Found: C, 55.85; H, 8.34; N, 11.07. Calcd. for $C_{12}H_{22}N_2O_4$: C, 55.79; H, 8.58; N, 10.85%.

Ethyl 2-(3-Oximino-2-oxobutylamino)-3-phenylpropionate (VIb).—This ester was obtained from V (3.9 g.) and the DL-phenylalanine ethyl ester (IIb, 8.4 g.) in a 51% yield. Recrystallization from ethanol gave colorless needles, m. p. 121—122°C (decomp.).

Found: C, 61.58; H, 6.96; N, 9.63. Calcd. for $C_{15}H_{20}N_2O_4$: C, 61.63; H, 6.90; N, 9.58%.

Methly 2-(3-Oximino-2-oxobutylamino)-4-methylvalerate (VIc). — This ester was obtained from V (14.4 g.) and the L-leucine methyl ester (IIc, 23 g.) in a 40% yield. Recrystallization from methanol gave colorless needles, m. p. 149°C (decomp.).

Found: C, 54.09; H, 8.40; N, 11.62. Calcd. for $C_{11}H_{20}N_2O_4$: C, 54.08; H, 8.25; N, 11.47%.

Methyl 2-(3-Oximino-2-oxobutylamino)-3-phenylpropionate (VId).—This ester was obtained from V (7.2 g.) and the DL-phenylalanine methyl ester (IId, 14.3 g.) in a 40% yield. Recrystallization from ethanol gave colorless needles, m. p. 138—139°C (decomp.).

Found: C, 60.61; H, 6.82; N, 9.90. Calcd. for $C_{14}H_{18}N_2O_4$: C, 60.42; H, 6.52; N, 10.07%.

The Reaction of VIc with Hydroxylamine.—To a solution of hydroxylamine [from hydroxylamine hydrochloride (0.43 g.) and sodium (0.15 g.) in methanol (20 ml.)], VIc (1.5 g.) was added; the suspension was warmed at 60—64°C for four hours and then allowed to stand at room temperature overnight. The resultant solution was evaporated under reduced pressure, and the residue was dissolved in ethyl acetate (10 ml.) and filtered. After the ethyl acetate had been removed under reduced pressure, the resultant brown oil was dissolved in 2 N sodium hydroxide (10 ml.) and allowed to stand at room temperature overnight. The alkaline solution was treated with activated charcoal and neutralized until pH 6 with 4 N acetic acid, thus obtaining crystals (0.55 g., 36%); these crystals were recrystallized from dimethylformamide into colorless prisms, m. p. 239.5°C (decomp.). The identity of this product with the IXa prepared from VIIa was confirmed by a mixed-melting-point determination and by a comparison of their infrared spectra.

2-(2-Hydrazono-3-oximinobutylamino)-3-phenylpropionic Acid (Xd).—To a suspension of VId (1 g.) in methanol (20 ml.) hydrazine hydrate (0.4 g.) was added, after which the suspension was refluxed for four hours. The resultant solution was concentrated

under reduced pressure, and the residual brown oil was dissolved in 2 N sodium hydroxide (10 ml.). After being allowed to stand at room temperature overnight, the solution was neutralized until pH 6 with 4 N acetic acid, thus giving yellowish crystals (0.4 g., 40%) which were recrystallized from dimethylformamide into the form of yellow prisms, m. p. 168—169°C (decomp.).

Found: N, 19.99. Calcd. for $C_{13}H_{18}N_4O_3$: N, 20.13%.

6-(2-Oximinoethyl)-3-isobutyl-2-hydroxypyrazine.—A suspension of VIa (4.8 g.) in methanol (100 ml.) was saturated with ammonia with ice-cooling and then allowed to stand at room temperature for two days. The resultant red solution was concentrated under reduced pressure to afford a red residue, which was dissolved in water (100 ml.) and extracted with ether. The ethereal extract was dried over anhydrous sodium sulfate, and then concentrated under reduced pressure to give a mixture of a yellow oil and crystals. The mixture was dissolved in ethyl acetate (2 ml.) for filtration, and the crystals (0.2 g., 5%) were recrystallized twice from ethyl acetate to give colorless needles, m. p. 200.5—201.5°C (decomp.).

λ_{max}^{EtOH} 245 mμ (ε=11100), 330 (10200), and 340 (10100, sh.).

Found: C, 57.63; H, 7.26; N, 20.29. Calcd. for $C_{10}H_{15}N_3O_2$: C, 57.40; H, 7.23; N, 20.08%.

Styrene Derivatives. IX. 2-Benzyl-2-phenyl-3-aminomethyl-trimethylene Oxides and Related Compounds[1]

By Akira TERADA

Department of Industrial Chemistry, Kyushu Institute of Technology, Tobata-ku, Kitakyushu

(Received April 14, 1966)

3-Chloromethyl-4-chloro-1, 2-diphenylbutan-2-ol was obtained by a Grignard reaction of 2-benzoyl-1, 3-dichloropropane using benzyl chloride, which was turned into 2-benzyl-2-phenyl-3-chloromethyl-trimethylene oxide by the alkali dehydrochlorination. Heating this oxide with an excess of piperidine at 170°C for 22 hr. gave 2-benzyl-2-phenyl-3-piperidinomethyl-trimethylene oxide and a small amount of 1, 2-diphenyl-3-piperidinomethyl-2, 4-butanediol. The same procedures with morpholine gave 2-benzyl-2-phenyl-3-morpholinomethyl-trimethylene oxide; with ethanolic dimethyl amine, however, afforded only 1, 2-diphenyl-3-dimethylamino-methyl-2, 4-butanediol.

During the synthetic studies of styrene derivatives which have been developed in our former laboratory,[2] 2-benzoyl-1, 3-dichloropropane (I) was previously prepared from acetophenone via the 5-benzoyl-1, 3-dioxane obtained by the acidic-aldol condensation of acetophenone with formaldehyde.[3] The present paper will deal with the syntheses of 2-benzyl-2-phenyl-3-aminomethyl-trimethylene oxides and the hydrated aminodiol compounds, using this 2-benzoyl-1, 3-dichloropropane as a synthetic intermediate. We expect to be able thus to determine the physiological activities of these amino compounds and the availabilities in the field of synthetic drugs, and also some information about the reaction course.

The reaction of I with a Grignard solution prepared from benzyl chloride easily gave 3-chloromethyl-4-chloro-1, 2-diphenylbutan-2-ol (II). The dehydrochlorination of II with an excess of ethanolic potassium hydroxide under reflux preferentially afforded III as the product. The compound III did not decolorize permanganate, and its infrared spectrum shows a strong band at 966 cm^{-1} assignable to trimethylene oxide[4] and has neither the characteristic peak of hydroxyl nor of the vinylidene group. Therefore, the structure of III must be 2-benzyl-2-phenyl-3-chloromethyl-trimethylene oxide.

It was found that the remaining chlorine atom in the compound III was too stable to react with either such an alkali as above or the amines used in this report under such mild conditions as below 100°C, but when it was heated at 160—170°C over 20 hr. it could be substituted with such amines to give the attempted amino compounds, besides 1, 2-diphenyl-3-aminomethyl-2, 4-butanediols. The VI amines were also confirmed to be trimethylene oxide compounds; their infrared spectra clearly indicate the characteristic band of the trimethylene oxide ring in the region near 980 cm^{-1}.

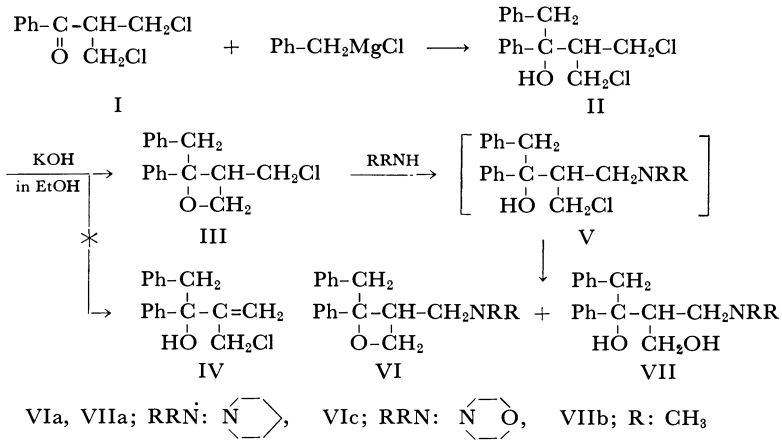

Fig. 1

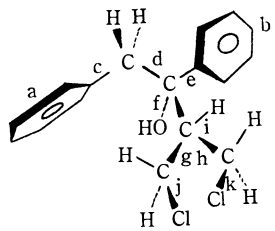

Fig. 2

The conformation of II may be sketched stereochemically as in Fig. 2 using a Stuart-type molecular model in which the ring a is nearly horizontal and the ring b almost vertical. The observation of the model also strongly suggests that the free rotations about the bonds of c, d, e, f, g and h are virtually impossible, and that in view of their preferred conformations, both the chlorine atoms may jut together to this side. The repulsion between two chlorine atoms should, therefore, be so large that it is obvious that one of the chlorines is excessively reactive. However, both the chlorine atoms can not be placed in the *trans* conformation to the *i*-hydrogen, because there are serious restrictions of free rotation about the bonds g and h as has been mentioned above. The chlorine atom will preferentially react with the hydroxyl group of the back side, and the system will proceed to a ring closure to give the trimethylene oxide (III) by an S_N2 reaction rather than to a formation of the vinylidene compound (IV) by a *trans* E2 reaction.

It is believed that the bimolecular substitution of the remaining chlorine atom in the compound III with amine will be hindered greatly by the crowded back and that, therefore, it will be less reactive. We, therefore, assume that the compound III reacts with such amines to form an intermediate V, aminated chlorohydrin, which is a normal addition product of trimethyleneoxide ring opening effected exclusively by steric reasons, and that it immediately turns into the principal product, VI, as is shown in Fig. 1. Support for this conclusion can be obtained by the following fact. Searles and Gregory have reported that, while trimethylene oxide reacts with amines less readily at moderate temperatures, when the temperature rises to 150°C it undergoes ring opening to give the corresponding aminopropanols in good yields.[5]

Experimental

3-Chloromethyl-4-chloro-1, 2-diphenylbutan-2-ol (II).—An ethereal solution of benzyl magnesium chloride was prepared in the usual manner with 50 ml. of anhydrous ether, 6.1 g. of magnesium foils, and 28.2 g. (0.22 mol.) of benzyl chloride in 50 ml. of anhydrous ether. A solution of 43.4 g. (0.2 mol.) of 2-benzoyl-1, 3-dichloropropane[3] in 85 ml. of anhydrous ether was added, drop by drop, into the Grignard reagent under vigorous stirring and ice cooling over a period of 25 min. The reaction mixture became cloudy in the early stages of the reaction, and then it became clear. After it had settled overnight at room temperature, the mixture was treated with ice water, made acidic with hydrochloric acid, and taken up in benzene. The benzene solution was washed with water, a saturated sodium bicarbonate solution, and water again, and then dried over anhydrous sodium sulfate. Upon the removal of the solvent under reduced pressure and cooling, 29.8 g. (48.2%) of crude crystals were yielded. Recrystallization from benzene-petroleum benzine gave an analytical sample of II melting at 76—77.5°C.

Found: C, 65.89; H, 6.03. Calcd. for $C_{17}H_{18}Cl_2O$: C, 66.03; H, 5.87%.

ν_{max}^{Nujol} 3704 (OH); 3035, 1603, 1504 (phenyl); 1344, 1151 (tertiary alcohol); 761, 746, 692 cm^{-1} (monosubstituted benzene).[6]

2-Benzyl-2-phenyl-3-chloromethyltrimethylene Oxide (III).—A sample of 15.2 g. (0.05 mol.) of II

5) S. Searles and V. P. Gregory, *J. Am. Chem. Soc.*, **76**, 2789 (1954).

6) The infrared spectra were taken on a Perkin-Elmer spectrophotometer, Model 21 (NaCl).

was refluxed with 2.8 g. (0.05 mol.) of potassium hydroxide in 10 ml. of ethanol. The reaction was exothermic, and potassium chloride crystals were precipitated immediately. After another hour's refluxing, the reaction mixture was poured into water and taken up in benzene. The benzene layer was washed with water until the washings were neutral, and then dried over anhydrous sodium sulfate. The remaining oil, upon the removal of the solvent, was induced to crystallize by trituration with petroleum benzine under cooling. The isolated crude crystals (5.33 g.; 39%) were recrystallized from petroleum benzine to give an analytical sample of III, white crystals, m. p. 83.5—84.5°C.

The use of a two-molar equivalent of potassium hydroxide against III gave a yield nearly twice as good.

Found: C, 74.71; H, 6.44; Cl, 12.92. Calcd. for $C_{17}H_{17}ClO$: C, 74.85; H, 6.28; Cl, 13.00%.

ν_{max}^{Nujol} 3021, 1600, 1495 (phenyl); 1155, 1145, 1029, 774, 750, 711, 702 (mono-substituted benzene); 966 cm^{-1} (trimethylene oxide).[4]

The Reaction of III with Piperidine.—A mixture of 2.20 g. (8.07 mmol.) of III and 5.50 g. of piperidine (b. p. 106°C) in a sealed tube was heated at 170°C for 22 hr. The contents were then evaporated under reduced pressure, and the remaining oil, after being alkalized with a dilute sodium hydroxide solution, was repeatedly extracted with benzene. The benzene solution was washed with water and dried over anhydrous sodium sulfate. After the removal of the solvent, the oily product was combined with 1.5 ml. of concentrated hydrochloric acid to give a white precipitate of the hydrochloride. Crystallization from water yielded 1.65 g. (55.8%) of crystals, m. p. 197—198°C. An analytical sample was obtained from another recrystallization, m. p. 200—201°C, 2-benzyl-2-phenyl-3-piperidinomethyl-trimethylene oxide hydrochloride · a half hydrate (VIa·HCl·1/2 H_2O).

Found: C, 72.01; H, 8.10; N, 4.13; H_2O, 3.10. Calcd. for $C_{22}H_{27}NO\cdot HCl\cdot 1/2H_2O$: C, 72.01; H, 7.97; N, 3.82; H_2O, 2.45%.

ν_{max}^{Nujol} 3635, 3289, 1621 (H_2O); 2710—2410 (tertiary amine hydrochloride); 979 (trimethylene oxide); 767, 754, 699, 695 cm^{-1} (mono-substituted benzene).

The anhydrous hydrochloride was obtained by drying it at 100°C under a vacuum until a constant weight was obtained, but the melting point remained unchanged. The infrared spectrum of the dried hydrochloride showed no absorption bands characteristic of the water of crystallization in the region of 3635, 3289 and 1621 cm^{-1}.

Free Amine (VIa).—This was obtained as usual, m. p. 49.5—50.5°C. It may be hydrated, because the following infrared spectral data show a weak absorption peak of the hydroxyl group. When the mother liquor, from which VIa·HCl had been effectively removed, was concentrated, a small amount of white crystals remained. Recrystallization from water gave an analytical sample of 1, 2-diphenyl-3-piperidinomethyl-2, 4-butanediol hydrochloride (VIIa·HCl), m. p. 219—220°C.

Found: C, 70.28; H, 8.20; N, 3.92. Calcd. for $C_{22}H_{29}NO_2\cdot HCl$: C, 70.29; H, 8.04; N, 3.73%.

ν_{max}^{Nujol} 3413, 3215 (OH); 2732—2410 (tertiary amine hydrochloride); 3030, 1605, 1502 (phenyl); 1136 (C–O, tertiary alcohol); 1064 (C–O, primary alcohol); 771, 755, 702, 698 cm^{-1} (mono-substituted benzene).

The Reaction of III with Dimethyl Amine in Ethanol.—A sample of 1.37 g. (5 mmol.) of III was dissolved in 7.0 g. of 33% ethanolic dimethyl amine and heated in a sealed tube at 170°C for 33 hr. After working-up as usual, the oily product was repeatedly extracted with dilute hydrochloric acid under heating. The combined extract was concentrated under diminished pressure, and the remaining crystals were washed with acetone to give 0.77 g. (45.9%) of 1, 2-diphenyl-3-dimethylaminomethyl-2, 4-butanediol hydrochloride (VIIb·HCl) as white crystals, m. p. 213—214°C.

Found: C, 66.74, 66.90; H, 7.98, 7.97; N, 4.14, 4.03. Calcd. for $C_{19}H_{25}NO_2\cdot HCl\cdot 1/3H_2O$: C, 66.74; H, 7.27; N, 4.10%.

ν_{max}^{Nujol} 3279 (OH); 3049, 1603, 1493 (phenyl); 2801 (N-CH_3); 1377 (methyl); 1060 (C–O, primary alcohol); 765, 744, 703, 699 cm^{-1} (mono-substituted benzene).

Free Amine (VIIb).—This was obtained as usual, m. p. 135—136°C (from benzene).

Found: C, 75.96; H, 8.38. Calcd. for $C_{19}H_{25}NO_2$: C, 76.22; H, 8.42%.

ν_{max}^{Nujol} 3378 (OH); 3012, 1600, 1493 (phenyl); 2793 (N-CH_3); 1376 (methyl); 1059 (C–O, primary alcohol); 768, 747, 699, 696 cm^{-1} (mono-substituted benzene).

The Reaction of III with Morpholine.—A mixture of 2.725 g. (10 mmol.) of III and 8.70 g. (100 mmol.) of morpholine (b. p. 128°C) was heated in a sealed glass tube at 170°C for 28 hr. After working-up as usual and the subsequent hydrochlorination of the product, crystallization from *n*-butanol gave 1.58 g. (47.2%) of 2-benzyl-2-phenyl-3-morpholinomethyl-trimethylene oxide hydrochloride (VIc·HCl), m. p. 197.5—202°C. Recrystallization from water raised the melting point to 203—204.5°C, white crystals.

Found: C, 69.94; H, 7.57; N, 3.99. Calcd. for $C_{21}H_{25}NO_2\cdot HCl$: C, 70.08; H, 7.03; N, 3.89%.

ν_{max}^{KBr} 3360, 2710, 2690, 2480 (tertiary amine hydrochloride); 1960, 1895, 1815, 1758, 780, 764, 748, 700 (mono-substituted benzene); 1600, 1580, 1490 (phenyl); 980 cm^{-1} (trimethylene oxide).

Free Amine (VIc).—This was obtained by the same procedure in a 48.2% yield, and also from the alkali treatment of the above hydrochloride, white needles (VIc·1/3H_2O), m. p. 67—68°C (from petroleum benzine).

Found: N, 4.37; H_2O, 1.87. Calcd. for $C_{21}H_{25}NO_2\cdot 1/3H_2O$: N, 4.25; H_2O, 1.82%.

ν_{max}^{KBr} 3470, 1631 (water of crystallization); 3080, 3040, 1610, 1500 (phenyl); 1958, 1885, 1818, 1760, 773, 756, 705 (mono-substituted benzene); 980 cm^{-1} (trimethylene oxide).

The anhydrous VIc was obtained as usual; it showed no absorption bands of the infrared spectrum characteristic of the water of crystallization at such regions as 3470 and 1631 in the above hydrated sample.

The author wishes to thank Professor Ichiro Hirao for his excellent support to this work and Mr. Takahisa Masuda for his experimental assistance.

The Analysis of Activators in Several Phosphors

By Yoshihide KOTERA, Tadao SEKINE and Masao TAKAHASHI

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received December 24, 1965)

The activators in the zinc sulfide phosphors were analyzed by colorimetry. The reagents were *p*-dimethylaminobenzylidene-rhodanine for the determination of silver in zinc sulfide and sodium dithiocarbamate, and zinc dibenzyldithiocarbamate for copper. The analytical procedures were discussed, and the range of the activator content to which these procedures are applicable was clarified. The methods were then used to determine the activator contents in the phosphors in the form of powder and single crystals; the results obtained make it clear that the activators are dissipated during the firing process in the preparation of phosphors and that copper is incorporated during the single-crystal preparation.

It is well known that the quantity of activators in the phosphors is one of the most important factors in determining their characteristics. The quantity of activators has been analyzed by several researchers, while, because of a variety of combinations between the host lattice materials and activators, it is necessary to extend the analytical method to all phosphors. We have reported on the application of polarography to the analysis of activators in calcium silicate phosphors,[1] and Rathje[2] has published a paper on the analysis of silver in zinc sulfide phosphors by flame-photometry.

The aim of the present research is to establish the methods of analyzing silver and copper in zinc sulfide phosphors. The method consists of the preparation of a sample solution and the determination of activators by colorimetry; the results obtained make it clear that the activators are dissipated during the firing process in the preparation of phosphor and that copper is incorporated during the single-crystal preparation.

The Analysis of Silver in the Zinc Sulfide Phosphors Activated by Silver by Colorimetry.—*a) Principle.*—It is well known that the colorimetric analysis of silver is carried out by using dithizone or rhodanine derivatives. The absorption curve of silver rhodanine has a peak at ca. 470 mμ, as is shown in Fig. 1; the figure was obtained by using an interference filter and a photocell. This absorption is affected by the presence of oxidizing agent, including chloride ions, therefore, the agents should be completely removed from the sample solution.

b) Experimental.—Reagents and Materials: All reagents were of the reagent grade. Zinc sulfide phosphors were prepared by the usual procedure in our laboratory. The amounts of silver added to zinc sulfide before firing ranged from 10^{-3} to 10^{-5} mole per mole of zinc sulfide. *p*-Dimethylaminobenzylidene-rhodanine was dissolved in methanol.

Apparatus: Tokyo Koden Co.'s Photoelectric Colorimeter 7A.

Sample Preparation: Weigh 0.5—1.0 g. of the sample of phosphor, add ca. 10 ml. of a concentrated hydrogen peroxide solution and heat in a evaporating dish with watch-glass cover until the mixture has completely dried. Repeat the evaporation after adding ca. 5 ml. of concentrated nitric acid, then dissolve the residue with ca. 1 ml. of concentrated nitric acid. After cooling, add water to make the whole volume to 100 ml. Take 10 ml. of this solution out with a pipette, add 0.2 ml. of a 0.05% rhodanine solution, and agitate carefully. After 10 min., measure the absorption at 470 mμ by means of an interference filter.

Standard Preparation: The standards used to obtain the analytical absorption curve were made by dissolving in 0.1 N nitric acid various amounts of silver nitrate crystals dried previously at 110°C. Standards in the range from 0.1 to 4 p. p. m. of silver in 0.1 N nitric acid were prepared and treated in the same manner as the samples.

Absorption Curve: The absorption curve was obtained for the solution which contains 1 p. p. m. of silver and 0.2 ml. of *p*-dimethylaminobenzylidene-rhodanine in 10 ml. by means of interference filter, and is shown in Fig. 1. From the figure it is convenient to use the interference filter at 470mμ.

Color Stability: The stability of the colored solution is shown in Fig. 2, which shows that the analysis is most accurately carried out when the solution is held constant for 5 min., after the addition of rhodanine and for not longer than 15 min. When the colored solution is held for one day, there is a colored precipitate.

The Effect of the Silver Concentration on the Absorbance: The absorbance of the colored solution was obtained

1) Y. Kotera, M. Yonemura and T. Sekine, This Bulletin, **28**, 132 (1955).
2) A. O. Rathje, *Anal. Chem.*, **27**, 1583 (1955).

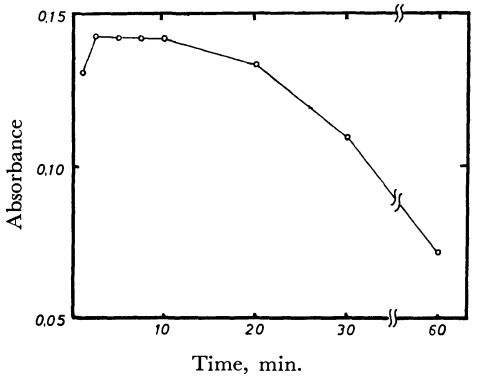

Fig. 2. Effects of standing time on the absorbance.

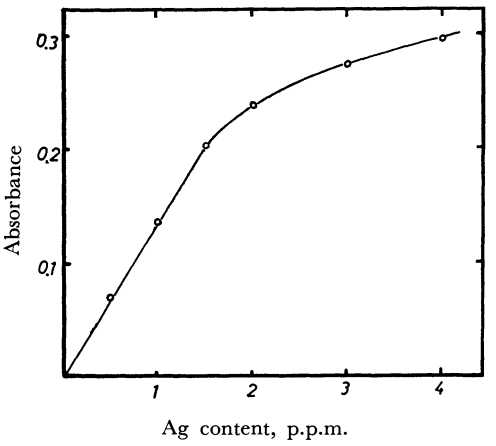

Fig. 3. Effects of silver concentrations on the absorbance.

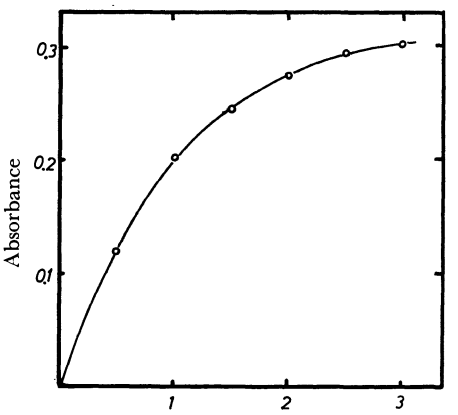

Fig. 4. Calibration curve.
Wavelength 470 mμ

in the 0.1 to 4 p.p.m. range of silver; it is shown in Fig. 3. From the figure it is possible to determine silver in the range from 0.1 to 1 p. p. m.

The Effect of the Presence of Zinc Sulfate on the Absorbance: When a sample of phosphor is treated as described above, the solution contains a certain amount of zinc sulfate prepared by the hydrogen peroxide oxidation of sulfide. It is, therefore, necessary to test the effect of zinc sulfate upon the absorbance. Various amounts of silver were added to the precipitated zinc sulfide; after they had been dried at 110°C, these samples were treated as had been the sample phosphors. The absorbance of the colored solution is shown in Fig. 4 as the function of the amount of silver. A comparison of Fig. 4 with Fig. 3 will show the effect of zinc sulfate; the colored solution was more stable in this case than without sulfate. The determination of the silver amount in sample phosphors was carried out by the use of the curve in Fig. 4.

c) Results and Discussion.—Zinc sulfide phosphors, which had been prepared by adding various amounts of silver before firing and by subsequent firing at 110°C for 2 hr., were analyzed; the results are shown in Table I. The same samples were washed after firing either by distilled water or by a potassium cyanide solution (5%), and the results for both samples were tabulated. As expected, a part of the silver dissipates during firing, while a part of the residual silver does not diffuse in the crystal lattice of zinc sulfide phosphors, but changes to silver sulfide, adhering on their crystal surface; the amount is estimated to be the difference in the results for the two washing agents. As for the analytical procedure, it was difficult to dissolve zinc sulfide phosphors without separating sulfur or its compound. This difficulty was overcome by the use of an oxidizing agent, for example, hydrogen peroxide, in our procedure; the residual oxidizing agent should be removed completely before the addition of rhodanine.

The Analysis of Copper in the Zinc Sulfide Phosphors Activated by Copper by Sodium Dithiocarbamate. — *a) Principle.* — The

TABLE I. ANALYTICAL RESULTS OF SILVER IN SILVER-ACTIVATED ZINC SULFIDE PHOSPHORS

Sample: Amount of silver added to zinc sulfide before firing (g. a./mol.)	Silver content determined, wt.%: treatment after firing: H_2O	KCN soln.
10^{-3}	0.058	0.030
6×10^{-4}	0.033	0.019
3×10^{-4}	0.014	0.016
10^{-4}	0.0051	0.0091
6×10^{-5}	0.0007	0.0017
3×10^{-5}	0.0019	—
10^{-5}	0	0

analysis of a trace of copper has been widely carried out colorimetrically. Dithiocarbamate compounds, dithizone, 1-10 phenanthroline derivatives, cuprizon, etc. are commonly used as the coloring agents. Dithiocarbamate compounds were selected for this research.

b) Experimental.—Reagents and Materials: $CuSO_4\cdot 5H_2O$ was used; it had been prepared in the Osaka Industrial Research Institute for analytical use. The other reagents were of the reagent grade. The zinc sulfide precipitated was given by the Dai Nippon Toryo Co., while the zinc sulfide phosphors and their single crystals were prepared in our laboratory.

Apparatus: This was the same as in the case of silver determination.

Sample Preparation: Weigh ca. 0.1 g. of a sample of phosphor, and then dissolve it in concentrated hydrochloric acid. Add to this solution 10 ml. of a 10% EDTA-2Na aq. solution, 2 drops of a 0.1% Crezol Red solution, and 5 ml. of a 1 N ammonium citrate solution; then add concentrated aqueous ammonia until the color of the indicator changes. Make the total volume to 50 ml. and transfer to a separating funnel. Add 5 ml. of a 0.1% sodium diethyldithiocarbamate solution and 10 ml. of chloroform, and agitate vigorously for ca. 2 min. Take out the colored layer of chloroform in a 25-ml. measuring flask, add 10 ml. of chloroform to the residual aqueous part, and agitate for 1 min. Take out the chloroform layer in the same measuring flask, and make the total volume to 25 ml. by adding ca. 5 ml. of chloroform. Transfer the solution into the colorimeter cell and measure the absorbance by means of a 420 mμ filter.

Standard Preparation: Dissolve the precipitated zinc sulfide in hydrochloric acid, add the standard solution of copper to this solution, treat it in the manner described above, and obtain the relationship between the amount of copper and the absorbance. The results obtained, shown in Fig. 5, indicate that the determination of copper between 0.5 and 1 p. p. m. is possible by this procedure.

c) Results and Discussion.—Single crystals of zinc sulfide prepared by the vapor-transport method were analyzed. The results, shown in Table II, show that copper is easily introduced during the single crystals preparation; work is now in progress in our laboratory attempting to reduce the copper content in the single crystals. Hydrogen chloride, bromine, and iodine are used in the vapor-transport method; they are tabulated in Table II. The difference in copper content among the three samples might be explained by the volatility difference in the materials used in the crystal preparation.

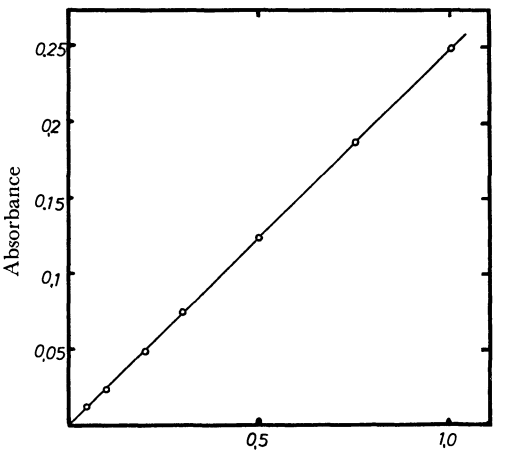

Fig. 5. Calibration curve (relation between the amount of copper and the absorbance).

TABLE II. ANALYTICAL RESULTS OF IMPURITY COPPER IN ZINC SULFIDE SINGLE CRYSTALS PREPARED BY THE VAPOR-TRANSPORT METHOD

Sample	Copper content determined wt.%
ZnS-HCl	0.017
ZnS-Br_2	0.007
ZnS-I_2	0.011

The Analysis of Copper by Zinc Dibenzyldithiocarbamate.—*a) Experimental.—Sample Preparation:* Weigh 0.5 to 1.0 g. of a sample of phosphor, and dissolve it in concentrated hydrochloric acid. After boiling this solution to remove the hydrogen sulfide, add concentrated hydrochloric acid or distilled water to make the whole volume to 100 ml. of a 1 N hydrochloric acid solution, and then transfer it into a separating funnel. Add to this exactly 10 ml. of a 0.01% zinc dibenzyldithiocarbamate solution in carbon tetrachloride, and agitate the mixture vigorously for ca. 1 min. Transfer the yellow-colored layer of carbon tetrachloride into the colorimeter cell, and measure the absorbance at 420 mμ.

The standard preparation and the other procedures are almost the same as in the case of sodium dithiocarbamate. The relation between the

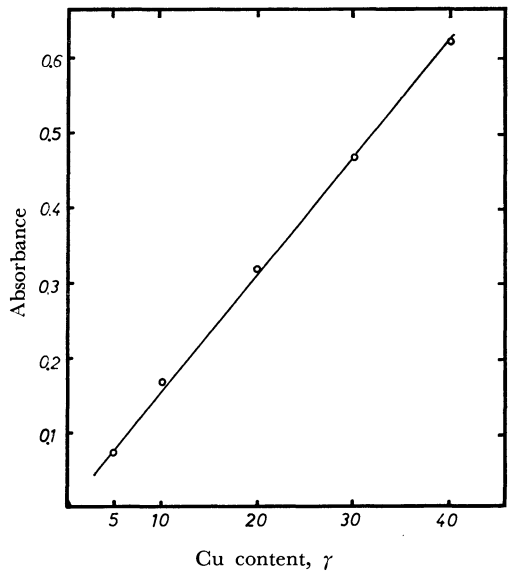

Fig. 6. Calibration curve (relation between the amount of copper and the absorbance).

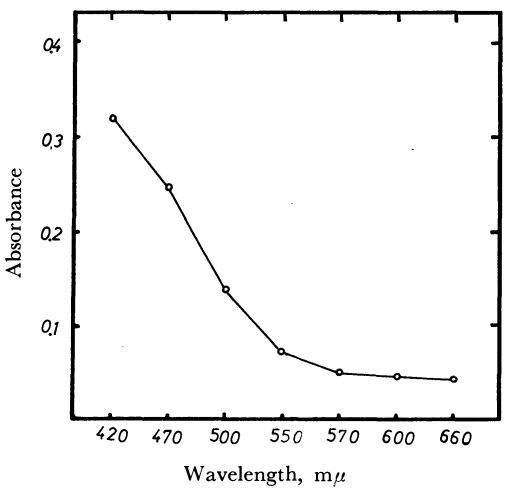

Fig. 7. Absorption curve of Cu-dithiocarbamate.

amount of copper and the absorbance, shown in Fig. 6, indicates the possibility of determining copper in the range from 5 to 40 p. p. m.

The absorption curve of the copper dithiocarbamate solution measured as a function of the wavelength is shown in Fig. 7, while the stability of the colored solution is shown in Fig. 8.

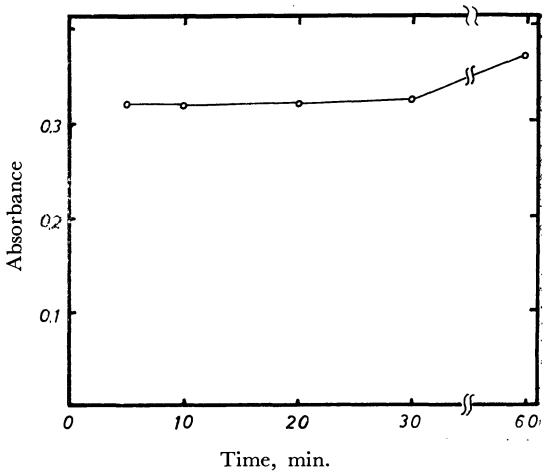

Fig. 8. Effects of standing time on the absorbance.

c) Results and Discussion.—Zinc sulfide phosphors activated by copper were prepared, and the copper content was determined by the procedure described above. The results obtained, shown in Table III, indicate that copper does not dissipate so much in the case of zinc sulfide phosphors, whose copper content is low, as does silver in zinc sulfide.

TABLE III. ANALYTICAL RESULTS OF COPPER IN COPPER ACTIVATED ZINC SULFIDE PHOSPHORS

Sample Amount of copper added to zinc sulfide before firing, g. a/mol.	Copper content determined, wt.%
10^{-4}	0.0067
10^{-5}	0.00077

It may be concluded that the analysis of copper in zinc sulfide phosphors is accurately carried out by the use of sodium diethylthiocarbamate for copper contents ranging from 0.5 to 1 p. p. m. and by the use of zinc dibenzyldithiocarbamate in the range from 5 to 40 p. p. m.

We thank Dai-Nippon-Toryo Co. for offering precipitated zinc sulfide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2527—2531 (1966)

The Catalytic Hydrogenation of Aniline in Fluidized Beds[1)]

By Etsuro ECHIGOYA, Hiroshi HAGIWARA* and Akio SAKURAI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 11, 1966)

The hydrogenation of aniline in fluidized beds was studied. As a result of the experiments, the following conclusions were obtained: 1) The reaction rate of the catalytic hydrogenation of aniline in the temperature range between 150°C and 180°C was approximately first-order with respect to hydrogen. In the case of a large molar ratio of hydrogen to aniline, however, the reaction rate became zeroth-order with respect to aniline. 2) A good agreement was obtained between the conversion by the fluidized-bed experiment and the values calculated on the model of the contact-time distribution for low degrees of conversion. For high degrees of conversion, the deviation of the values calculated using this model from the experimental value was found to be about 10%. It was suggested that this model can well be applied to predicting the conversion for zeroth-order reaction within the limits of uncertainty given above.

Studies of the catalytic hydrogenation of aniline have previously been reported by the present authors. In this paper, the study of the hydrogenation of aniline in fluidized beds will be reported. The fluidization technique has been widely used in the chemical industry. The quantitative design of a fluidized bed reactor is, however, complicated by the gas by-passing the reaction zone via bubbles and channelling, with the result that the conversions obtained in fluidized beds are often lower than those in fixed bed at the same space velocity. Consequently, many modified reactor models have been proposed to represent the behavior of the gas flows in the fluidized bed. The experimental results of fluidized-bed runs will be analyzed in this paper in terms of the contact-time distribution model reported before.[2)]

Experimental

The Preparation of Catalysts.—*20% Cobalt-alumina.*—Powdered alumina was added to a solution of cobalt nitrate. The slurry was stirred for some time, and to it was then slowly added at 20°C a quantity of dissolved ammonium carbonate in a slight excess. The mixture was then heated and kept at 60—70°C for 5 hr. After being filtered and washed, the precipitate was dried at 100°C and calcined at 500°C for 2 hr. At this reaction temperature, the catalyst powder could be fluidized satisfactorily.[3)]

Rate Constant Measurements.—The reaction rate constant was measured by a flow-type fixed bed in a Pyrex reactor (1.8 cm. ID and 80 cm. long). The reactor was immersed in a fluidized thermal bath in order to maintain the desired reaction temperature. The temperature was controlled automatically within a range of 1.0—1.5°C. About 5—10 g. of a cobalt-alumina catalyst was placed on a porous glass disk, and a thin glass thermowell was inserted from the top of the reactor. The heat of the reaction for this process was about 40 kcal./mol. Then, under the experimental conditions, a temperature gradient in the longitudinal direction of the catalyst bed was obtained. The mean temperature was estimated from the temperature distribution curves. The activity of the catalyst became almost constant after 2 hr.; the variation in the catalyst activity with reaction time was almost negligible for 30 hr. No effects of the different particle size of the catalyst on the reaction rate was observed. After the steady state of the catalyst's activity was reached, the reaction rate was estimated by the integral method.

Fluidized-bed Equipment.—The equipment used for the fluidization experiments consisted of a glass tube 90 cm. long and 5 cm. ID. Its lower part had a porous glass plate and was connected to a conical section for preheating. The temperature of the reactor was controlled by an external electric furnace. The equipment was surrounded with heating wires and was insulated with asbestos. The temperatures within the bed were measured by chromel-alumel thermocouples in glass wells located at the axis and on the inside of the reactor wall. The temperature distribution of the bed was occasionally checked by moving the thermocouples vertically throughout the bed. The observed difference in temperature between top and bottom was not more than 1 to 1.5°C.

The Measurement of the Contact-time Distribution Functions.—A method described before[2)] was used in the investigation of the contact-time distribution function in the fluidized bed. Propane was used as the adsorbent, and argon, as an inert gas.

Gas Analysis.—Samples were analyzed by gas chromatography. Separations were made by a 3 m. coulmn of polyethyleneglycol 20000 on polytetrafluoroethylene, with hydrogen as the carrier gas. The temperature of the column was 180°C.

Catalyst.—The cobalt catalyst used in the kinetic studies in both fixed and fluidized beds was the 150—200 Tyler mesh fraction of the catalyst. The bulk density of the catalyst containing 20 wt.% cobalt was 0.998—1.02 g./cc.; it was reduced for 2 hr. at 450°C.

Velocity at the Minimum Fluidization.—The minimum fluidization velocity, (U_{mf}) [cm./sec.] was taken as the value at which the pressure drop across the reactor vs. hydrogen flow curve showed a discontinuity. In cases where no sharp discontinuity occurred, the intersection of the two parts of the curve was selected as the value defining U_{mf}. The average value of U_{mf} over the experimental range used 160 to 200°C was 2 cm./sec.

Experimental Results and Discussion

Kinetic Data.—The rate equation for a catalytic reaction in a flow system may be written as:

$$W/F = y_0 \int_0^x dx/r \qquad (1)$$

where W: the catalyst weight [g.]
F: the total molar feed of the reaction mixture [mol./hr.]
y_0: the mole fraction of aniline in the reaction mixture
x: the conversion
r: the reaction rate [mol./g. cat. hr.]

The hydrogenation of aniline followed approximately a first order reaction kinetics with respect to hydrogen in the 150°C—180°C temperature range, for which the equation is:

$$r = k_c C_{H_2} = k\,(m-3x)/(1+m-3x) \qquad (2)$$

where k_c: the specific reaction rate
C_{H_2}: the concentration of hydrogen
k: $=k_c(\pi/RT)$ [mol./g. cat. hr.], π: the total pressure [atm.]
m: the molar ratio of hydrogen to aniline
R: the gas constant
T: the reaction temperature [°K]
x: the conversion

When Eq. 2 is substituted into Eq. 1 and integrated by assuming an idealized piston flow, the following equation is obtained:

$$1/k(m+1)\int_0^x (1+m-3x)dx/(m-3x) = W/F$$

$$f(m,\ x) = (1/m+1)x + \{1/(3(m+1))\}\ln[1/\{1-(3/m)x\}] = k(W/F) \qquad (3)$$

The value of the rate equation found was as follows (Fig. 2):

Temp., °C		
160	1.35×10^{-3}	(mol./g. hr.)
170	1.9×10^{-3}	
180	2.4×10^{-3}	
190	2.75×10^{-3}	

The temperature dependence of the rate constants was evaluated from the Arrehenius plot over the temperature range from 150 to 180°C. An overall activation energy (E) of 12 kcal./mol. was calculated from the slope of the plot, log k vs. $1/T$. The kinetic data could be written also in the following simple form in the case of a large value of m.[4]

$$k(W/F) = f(m,\ x) = Mx \qquad (M = 1/m) \qquad (4)$$

The above equation shows that the reaction rate is zero order with respect to aniline.

Fluidized-bed Runs.—Fluidized-bed runs were made in a 2-inch-ID reactor over the temperature range between 150°C and 230°C. The results of a fluidized-bed run are shown in Table I, while a typical run is demonstrated in Fig. 3. The conversion data for the fluidized-bed were plotted as a function of the dimensionless number $k/(W/F)$. The dashed line represents the conversion in a fixed bed. All the data fall below the dashed line. An apparent rate constant, k', may be estimated from Eq. 5 for fluidized beds, but it depends on the catalyst activity, the gas-solid contact behavior,

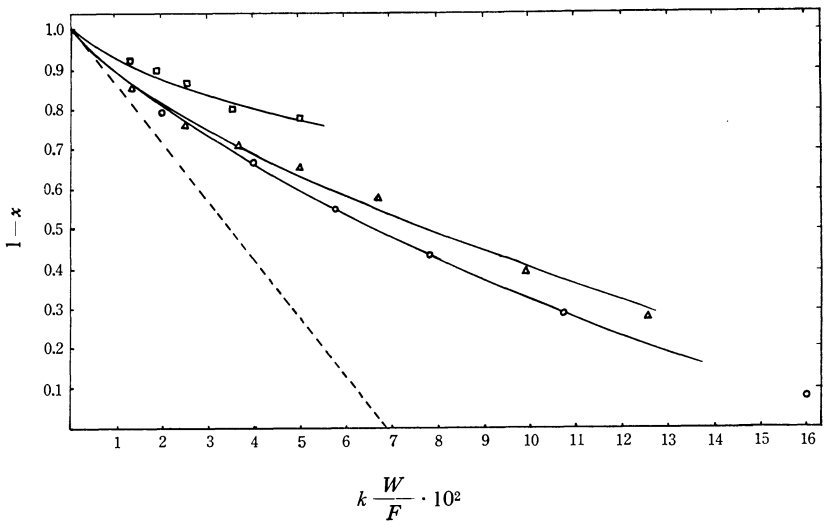

Fig. 3. The experimental data for fluidized bed (Reac. temp. 180°C).
U: ○ 3.34, △ 5.34, □ 10.69 cm./sec.

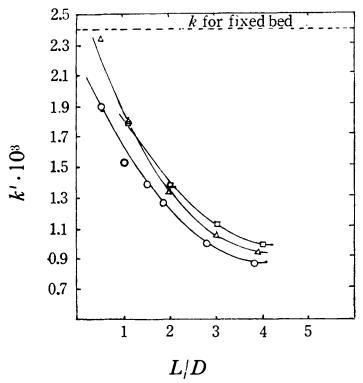

Fig. 4. Apparent rate constant as a function of L/D ratio and gas velocity for a fluidized bed.
k': rate constant (fluidized bed)
k: rate constant (fixed bed)
U: ○ 3.34, △ 5.34, □ 10.69 cm./sec.

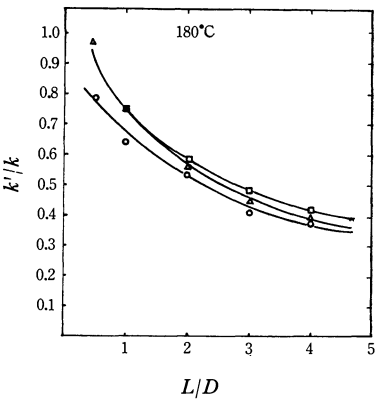

Fig. 4′ k'/k as a function of L/D ratio and gas velocity for the fluidized bed.
k': rate constant (fluidized bed)
k: rate constant (fixed bed)
U: ○ 3.34, △ 5.34, □ 10.69 cm./sec.

and the temperature.

$$k' = (F/W)Mx \tag{5}$$

When the catalyst activity and the temperature are held constant, k'/k is a measure of the efficiency of the fluidized bed as a device for the gas-solid contact. The fixed bed value is also shown in Fig. 4 for the sake of comparison. The value of k' appears to decrease rapidly with an increase in the bed height and to decrease slightly with a decrease in the gas velocity. At a lower temperature (for example, 160°C), the effects of these parameters on k' were not very large.

The Application of the Contact-time Distribution Model.—Fluidized beds have been characterized by the distribution of residence time. The use of a residence-time distribution $E(\varphi)$ is, however, restricted to homogeneous reactions of the first-order. It seems desirable, therefore, to define a contact-time or reaction-time W/F in connection with heterogeneous reactions. For the zeroth-order reaction, the mean fraction of reactant remaining at the exit of the bed is given below in terms of the contact time:[4]

$$1-x = \int_0^{\theta_{11m}} (1-K\theta)C(\theta)\mathrm{d}\theta \tag{6}$$

where $K=(k/M)(W/F)$, $\theta_{11m}=(W/F)_{11m}/(W/F)$; W/F: the mean contact time [hr. g./mol.]; $(W/F)_{11m}$: the contact time when x attains to

Fig. 5. Contact time distribution $C(\theta)$ and sidence time distribution $E(\varphi)$.

1 [hr. g./mol.] $C(\theta)$: contact time distribution function (see lit. 2) [mol./hr. g.]. This equation was normalized with respect to W/F, the average contact time. $C(\theta)$ could be estimated by the input (pulse) response technique. Some examples of the curves of $C(\theta)$ are shown in Fig. 5. The distribution of residence time for an inert gas (obtained by an input-response technique) is superimposed on the contact-time distribution plots in Fig. 5. The conversion curve calculated by Eq. 6 is compared with the experimental values in Fig. 6. From the comparison, a good agreement between the calculated conversion on the model and the experimentally-determined conversion was obtained for low degrees of conversion. However, for high degrees of conversion, the calculated value was a little low compared with that of the experimental conversion. From these data, it may be concluded that the $C(\theta)$ curve can give enough information for predicting the conversion in the zeroth-order reaction.

Summary

1) The catalytic hydrogenation of aniline to cyclohexylamine over a cobalt alumina catalyst was carried out in the fluidized bed under the following conditions; the temperature range: 160—220°C, W/F: [g. hr./mol.] 2.6—67.

2) The reaction rate was found to be of the zeroth-order with respect to aniline in the case of a large molar ratio of hydrogen to aniline, using the fixed bed.

3) It was found that the contact-time distribution model could be usefully applied to predicting the conversion for the zeroth-order reaction in the fluidized bed within limits of 10%.

The authors wish to thank Professor Kiyoshi Morikawa for his useful discussion and constant guidance.

NOTES

A Chemical Examination of *Euphorbia hirta Linn.*

By D. R. GUPTA and S. K. GARG

Department of Chemistry, University of Roorkee, Roorkee, India

(Received September 1, 1965)

Euphorbia hirta Linn. (Fam: Euphorbiaceae; Hindi, Dudhi) is a small herb which grows throughout the hotter parts of India. This plant has been medicinally used in the teratment of bowel complaints, coughs, dysentery, colic pains, bronchial affections, and asthma.[1] Some varieties of *Euphorbia hirta,* viz., procumbens, pedilantus calcaratus and pedilantus tehuacanus, have been chemically examined by earlier workers.[2] We have now undertaken a systematic chemical examination of *Euphorbia hirta Linn.,* which has not yet been worked up. In a previous communication,[3] the free organic acids of the stems and leaves of this plant were reported. The present work will concern the chemical examination of the petroleum ether and ethanol extracts of the stems and the ethanol extract of the flowers of *Euphorbia hitra Linn.*

Experimental

Air-dried, powdered stems (2 kg.) were successively soxhletted with petroleum ether (b. p. 60—80°C) and ethanol for 30 hr.

The Examination of the Petroleum Ether Extract of the Stems.—The petroleum ether extract was concentrated and left in a refrigerator overnight; the white solid (7.2 g.) which thereupon separated, was filtered and dissolved in petroleum ether, and then chromatographed over Brockmann alumina (64×4 cm.) using petroleum ether, benzene, chloroform and their mixtures as eluants, as is shown in Table I. Eluants were collected in fractions of 30—40 ml. each and evaporated to dryness.

Fractions 1—14 gave a waxy material which, on repeated crystallisation from ethanol, afforded silky needles (1.2 g.), m. p. 84°C.

Found: C, 82.14; H, 14.12. Calcd. for $C_{30}H_{62}O$: C, 82.19; H, 14.15%.

The compound was soluble in benzene, chloroform, ethyl ether and petroleum ether, but was insoluble in water. It was identified as myricyl alcohol by a mixed m. p. determination with an authentic sample and by the preparation of its acetyl derivative,[4] m. p. 71.5°C, and a chloro derivative,[4] m. p. 64°C.

Found: Cl, 7.50. Calcd. for $C_{31}H_{63}Cl$: Cl, 7.54%.

TABLE I

Fraction No.	Eluant	Residue left on the evaporation of the solvents
1—14	Petroleum ether (b. p. 60—80°C)	Waxy material
15—24	Petroleum ether+Benzene (5: 1 v/v)	Colourless solid
25—32	Petroleum ether+Benzene (3: 2 v/v)	Colourless solid
33—40	Petroleum ether+Benzene (1: 1 v/v)	Nil
41—49	Benzene	Short needles
50—58	Benzene+Chloroform (3: 2 v/v)	Shining flakes
59—66	Benzene+Chloroform (1: 1 v/v)	Shining flakes
67—72	Chloroform	Nil

Fractions 15—32 gave a colourless solid which, when crystallised from a methanol-chloroform mixture, afforded needle-shaped crystals (1.1 g.), m. p. 281°C.

Found: C, 84.46; H, 11.71. Calcd. for $C_{30}H_{50}O$: C, 84.51; H, 11.74%.

This product gave colour reactions characteristic of triterpenes, including Noller's test. A sequence of colour (yellow→orange→red→purple) was developed when the compound was treated with thionyl chloride in the presence of tin. The compound was identified as taraxerol by a mixed m. p. determination and by the preparation of its acetate,[5] m. p. 304°C, and a benzoate,[5] m. p. 292°C.

Fractions 41—49, on crystallisation from benzene, gave colourless needles (2.4 g.), m. p. 260—261°C.

Found: C, 84.44; H, 11.82. Calcd. for $C_{30}H_{50}O$: C, 84.51; H, 11.74%.

The compound, which gave no colour reaction in Salkowski or Liebermann-Burchard reaction or with tetranitromethane reagent was identified as friedelin

by a mixed m. p. determination and by preparing its derivatives, i. e., friedelinol,[6] m. p. 299°C; oxime acetate,[7] m. p. 239°C, and friedelin-2, 4-dinitrophenyl hydrazone,[7] m. p. 297—298°C.

Fractions 50—66 gave shining flakes which, on repeated crystallisation from a methanol - ethyl acetate mixture, yielded coloruless flakes (1.4 g.), m. p. 136—137°C.

Found: C, 84.15; H, 12.16. Calcd. for $C_{29}H_{50}O$: C, 84.05; H, 12.08%.

The compound was fairly soluble in benzene, methanol ethanol, and was readily soluble in chloroform, ethyl ether and ethyl acetate. The compound gave a positive Salkowskii-Hesse reaction and developed a green colour in the Liebermann-Burchard reaction. It formed an acetate,[8] m. p. 126°C; a benzoate,[8] m. p. 144°C, and a digitonide,[9] m. p. 230°C. The compound was identified as β-sitosterol by a mixed m. p. determination and by the formation of a mixed chromatogram of the compound with an authentic sample of β-sitosterol.

The Examination of the Ethanol Extract of the Stems.—The ethanol extract was concentrated under reduced pressure and then kept overnight in a refrigerator; it thereupon left a greenish, waxy material (4.1 g.), which was then dissolved in petroleum ether and then chromatographed over Brockmann alumina (32×2 cm.) using petroleum ether, benzene, chloroform and their mixtures as eluants, as is shown in Table II. Eluants were collected in fractions of 30—40 ml. each and evaporated to dryness.

Table II

Fraction No.	Eluant	Residue left on the evaporation of the solvents
1—10	Petroleum ether (b. p. 60—80°C)	Way material
11—17	Petroleum ether+Benzene (3: 2 v/v)	White solid
18—25	Petroleum ether+Benzene (1: 1 v/v)	White solid
26—30	Benzene	Nil
31—35	Benzene+Chloroform (3: 2 v/v)	Nil
36—40	Benzene+Chloroform (1: 1 v/v)	Nil
41—44	Chloroform	Nil

Fractions 1—10 gave a waxy material which, on repeated crystallisation from a mixture of methanol-acetone-benzene (1 : 1 : 1 v/v), gave a colourless solid (2.2 g.), m. p. 68°C.

Found: C, 85.44; H, 14.71. Calcd. for $C_{31}H_{64}$: C, 85.32; H, 14.67%.

Its infrared absorption spectrum did not indicate the presence of any functional groups. It did not absorb bromine and, on oxidation with air in the presence of potassium permanganate and boric acid at 200°C, gave an alcohol,[10] m. p. 58°C. The compound was identified as hentriacontane.[11]

Fractions 11—25 gave a white solid which, on crystallisation from a chloroform-methanol mixture, afforded colourless needles (1.3 g.), m. p. 199°C.

Found: C, 84.46; H, 11.78. Calcd. for $C_{30}H_{50}O$: C, 84.51; H, 11.74%.

The substance gave a positive Liebermann-Burchard reaction for a triterpene. It formed an acetate,[12] m. p. 237°C, which produced a yellow colouration with tetranitromethane; a benzoate,[12] m. p. 232°C, and a *p*-nitrobenzoate,[12] m. p. 258°C. The compound was identified as β-amyrin by a mixed m. p. determination with an authentic sample.

The Examination of the Flowers of *Euphorbia hirta Linn.*—Fresh flowers of *Euphorbia hirta Linn.* (2 kg.) were soxhletted with ethanol for 30 hr. Ethanol was distilled off from the extract under reduced pressure, and the sticky mass left was taken up in water (100 ml.). The aqueous solution was extracted with petroleum ether to remove the fatty material and chlorophyll, and then extracted with ethyl ether in a liquid-liquid extractor. The ether was removed, and the residue left was taken up in methanol and filtered. Distilling off the methanol afforded a yellow solid which, on crystallisation from pyridine, gave yellow needles (4.2 g), m. p. 360°C.

Found: C, 55.64; H, 2.02. Calcd. for $C_{14}H_6O_8$: C, 55.62; H, 1.98%.

The compound gave a green colour with ferric chloride, dissolved in aqueous sodium hydroxide with a bright yellow colour, and gave a positive Griessmeyer reaction. The compound was identified as ellagic acid by a mixed m. p. determination with an authentic sample and by the preparation of its tetraacetate,[13] m. p. 342—343°C, and an ellagorubin,[14] m. p. 218—219°C. It was further confirmed by paper chromatography,[15] using Whatman filter paper No. 1, and an aqueous solution of 60% formamide buffered at pH 3.5 with formic acid as the developer. The chromatogram was exposed to ammonia vapours in order to locate ellagic acid as yellow spot. The co-chromatography of the compound with an authentic sample of ellagic acid gave a single yellow spot with a R_f value of 0.58.

Summary

Petroleum ether and ethanol extracts of the stems of *Euphorbia hirta Linn.* were submitted to chromatography over Brockmann alumina using petroleum ether, benzene, chloroform and their mixtures as eluants, myricyl alcohol, taraxerol, friedelin, β-sitosterol, hentriacontane and β-amyrin were isolated, while the ethanol extract of the flowers

of *Euphorbia hirta Linn.* gave only ellagic acid. The above compounds were characterized by their physical and chemical properties and by the preparation of their derivatives.

It is interesting to observe that *Euphorbia hirta Linn.* contains myricyl alcohol, taraxerol and ellagic acid, besides friedelin, β-amyrin, hentriacontane and β-sitosterol already reported[2] in some varieties of *Euphorbia hirta.*

The authors are thankful to Dr. A. R. Kidwai, Aligarh, for supplying authentic samples of ellagic acid and taraxerol; to Dr. W. U. Malik, Professor of Chemistry, University of Roorkee, Roorkee, for providing laboratory facilities, and to C. S. I. R., New Delhi, for a Junior Research Fellowship to one of the authors (S. K. G.).

Ethylene Polymerization by Bisarenechrome π-Complex Compounds

By Yoshio TAZIMA and Sadao YUGUCHI

Central Research Lab. Toyo Rayon Co., Ltd., Otsu, Shiga

(Received November 9, 1965)

Ethylene polymerization by a binary catalyst system composed of bisarenechrome π-complex cations and an organoaluminum compound was investigated. The bisarenechrome π-complex compounds used were bisbiphenylchrome iodide, chromate, dichromate, thiocyanate, tetrathiocyano diammono chromate, etc. Instead of biphenyl, such other benzene derivatives as benzene, toluene, and mesitylene were also used as ligands.

As an organoaluminum compound, $Al(i\text{-}Bu)_3$ was the most suitable; the other organoaluminum compounds, such as $AlEt_3$ and $AlEt_2Cl$, showed less catalytic activity.

Figure 1 shows the relation of the polymerization temperature and the weights of the solid polymer formed during the initial 10 min. with the binary system of the bisbiphenylchrome compound (abbreviated as $(C_6H_5C_6H_5)_2CrX^-$) and 4 mmol. of $Al(i\text{-}Bu)_3$. As a solvent toluene was used, and the ethylene pressure was 40 kg./cm^2.

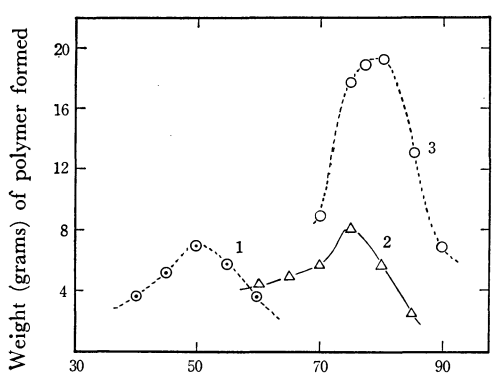

Fig. 1. 1 $(C_6H_5C_6H_5)_2Cr(NH_3)_2Cr(SCN)_4$ $\sim$ $Al(i\text{-}Bu)_3$
2 $[(C_6H_5C_6H_5)_2Cr]_2CrO_4$ $\sim$ $Al(i\text{-}Bu)_3$
3 $[(C_6H_5C_6H_5)_2Cr]_2Cr_2O_7$ $\sim$ $Al(i\text{-}Bu)_3$

Bisbiphenylchrome dichromate showed a maximum activity at 80°C; bisbiphenylchrome chromate, at 75°C, and bisbiphenylchrome tetrathiocyano diammono chromate, at 50°C. The order of the catalytic activity of bisbiphenylchrome compounds as a component of the binary system with $Al(i\text{-}Bu)_3$ is as follows:

$$[(C_6H_5C_6H_5)_2Cr]_2Cr_2O_7 > [(C_6H_5C_6H_5)_2Cr]_2CrO_4 > [(C_6H_5C_6H_5)_2Cr][(NH_3)_2Cr(SCN)_4] > (C_6H_5C_6H_5)_2CrI$$

The same tendencies were observed for other ligands, such as benzene, toluene and mesitylene.

The orders of catalytic activities of bisarenechrome π-complex compounds with the same anion species are as follows:

$$X^- : I^-$$
$$(C_6H_6)_2CrI > (C_6H_5CH_3)_2CrI > [C_6H_3(CH_3)_3]_2CrI > (C_6H_5C_6H_5)_2CrI$$

$$X^- : [(NH_3)_2Cr(SCN)_4]^-$$
$$(C_6H_5C_6H_5)_2Cr[NH_3)_2Cr(SCN)_4] > [C_6H_3(CH_3)_3]_2Cr[(NH_3)_2Cr(SCN)_4] > (C_6H_5CH_3)_2Cr[(NH_3)_2Cr(SCN)_4] > (C_6H_5)_2Cr[(NH_3)_2Cr(SCN)_4]$$

It should especially be noted that bisbiphenylchrome chromate or bisbiphenylchrome dichromate alone has the catalytic activity for ethylene polymerization without the presence of an organoaluminum compound. Table I shows the results obtained at different temperatures by using bisbiphenylchrome chromate or bisbiphenylchrome dichromate. Bisbiphenylchrome chromate showed increased activity above 75°C, and bisbiphenylchrome dichromate, above 80°C. The temperature (75°C or 85°C) accorded with the temperature of the maximum catalytic activity of each binary

system with $Al(i\text{-}Bu)_3$. Bisbiphenylchrome dichromate or bisbiphenylchrome chromate was inferrior to bisbenzene chrome dichromate or bisbenzenechrome chromate in catalytic activity.

Table II. Ethylene polymerization with oxidized product of bisbiphenylchrom

Polymerization temp., °C	Polymer formed, g.
75	0.55
100	0.75
150	0.60

Bisbiphenylchrome $(C_6H_5C_6H_5)_2Cr(O)$ (chrome is zero valency) showed catalytic activity for ethylene polymerization after it had been oxidized and activated by heating it above 75°C.

The results of some experiments obtained by the oxidized product of bisbiphenylchrome are shown in Table II. One procedure was as follows:

After the oxidation of $(C_6H_5C_6H_5)_2Cr$ (0.2 g.) dissolved in toluene (50 ml.) with oxygen (3 kg./cm^2) at 30°C for 1 hr. in an autoclave (100 ml.), oxygen was removed by stirring it at 75°C for 30 min. under a nitrogen atmosphere. Then ethylene was introduced up to a pressure of 40 kg./cm^2. Above 75°C, the oxidized product showed some catalytic activity, but the activity was lower than that of bisbenzene-chrome. Bisarenechromium compounds were prepared[1,2] by reducing chromium(III) chloride with benzene derivatives (benzene, toluene, mesitylene, and biphenyl) in the presence of aluminum and aluminum chloride in a sealed tube at 150°C, and by then decomposing the reduction products with methanol and water, followed by a treatment of the decomposed products with potassium salts. Bisbiphenylchromium was prepared by reducing the preceding product with $Na_2S_2O_3$.

The Preparation and Some Properties of *N*-Monomethylated L-Amino Acids

By Mitsuo EBATA, Yasuo TAKAHASHI and Hideo OTSUKA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received January 10, 1966)

N^{α}-Monomethylated amino acids which can be grouped as the unusual amino acids have been found in natural products. Most of them are present in a series of antibiotics which have been discovered and elucidated during the last several years. They are *N*-methyl-L-isoleucine, *N*-methyl-L-valine (Enniatins);[1,2] sarcosine, *N*-methyl-L-alanine, *N*-methyl-L-valine, *N*-methyl-L-isoleucine (Actinomycins);[3] *N*-methyl-L-phenylglycine (L-α-phenylsarcosine), *N*, β-dimethyl-L-leucine (Etamycin);[4] *N*, *N'*-dimethyl-L-cystine, *N*-methyl-L-valine, *N*-methyl-L-alloisoleucine, *N*, γ-dimethyl-L-alloisoleucine (Quinoxaline antibiotics);[5-7] *N*-methyl-L-phenylalanine (Staphylomycin)[8] and *N*-methyl-L-leucine (Sporidesmolides).[9] Two of the *N*-methylamino acids, *N*-methyl-D-tyrosine (D-surinamine) and *N*-methyl-L-tryptophan (L-abrin),

were found in cabbage tree bark[10] and in *Abrus precatorius*[11-13] respectively. It, therefore, can not be doubted that *N*-methylamino acids play a very important role as constituents of peptide or depsipeptide antibiotics.

For the synthesis of the *N*-methylamino acids, however, there is still no simple and generally applicable method except for the method of Quitt et al.,[14] in which the temporary benzylation and the reductive methylation are involved. They have demonstrated that this method is an excellent one by preparing *N*-methylated L-alanine, L-valine, L-leucine, L-phenylalanine, L-serine, L-lysine and L-arginine. However, it has been considered that the kind of *N*-methylamino acids prepared was not sufficient to claim that this is a generally-applicable method.

In the present work the authors have shown that this method is, certainly, a generally-applicable simple method for the preparation of the most *N*-methylamino acids; they have shown this by preparing *N*-monomethyl derivatives of aspartic acid, glutamic acid, isoleucine, threonine and tyrosine, together with the amino acids described above. However, a few exceptions or limitations have been found; namely, the *N*-methylations of histidine and of tryptophan were not achieved. The final products obtained gave large values of negative optical rotations in both cases, while the values of the elemental analyses agreed very nearly with those of the respective expected methylated products. The structures of the products were still obscure, since these compounds have not yet been investigated in detail. *N*-Benzyl-*N*-methyl-L-methionine was prepared in this work in a 54% yield from L-methionine. However, the debenzylation of the compound was not carried out, even in the presence of large amounts of a palladium-barium sulfate catalyst. The treatment of the compound with sodium in liquid ammonia also failed to remove the benzyl group. *N*-Benzyl-L-glutamic acid was prepared with only a 7.4% yield. This indicates that the γ-carboxyl group of glutamic acid exerts a steric hindrance when the Schiff base of glutamic acid with benzaldehyde is formed. For the synthesis of *N*, *N'*-dimethyl-L-cystine, L-thiazolidine-4-carboxylic acid was more useful as the starting material.[15] *N*-Methyl-L-cysteic acid was obtained by the oxidation of *N*, *N'*-dimethyl-L-cystine with performic acid.

The optical rotations of *N*-methylamino acids have already been described in the literature, although the reported values do not always agree. We measured the rotations in 6 N hydrochloric acid unless we otherwise state. The results obtained are listed in Table I. Among the *N*-methylamino acids prepared, we have found that arginine,

amino acid.
carried out at 100°C for 15 min. at pH 4.9. The ratio, sample solution : ninhydrin solution was 1 : 0.5.
above except ninhydrin concentrations. The ratio, sample solution: ninhydrin solution was 1 : 2.

isoleucine, serine and tyrosine gave somewhat higher values than those of the literature (*N*-methyl-L-arginine, +32.9;[14] *N*-methyl-L-isoleucine, +44.8;[1] *N*-methyl-L-serine, +8.0;[14] and *N*-methyl-L-tyrosine, +19.8[16]). The optical rotations of several *N*-methylamino acids were the same or somewhat lower than those reported by Quitt et al.; nevertheless, they were still higher than those of the derivatives prepared by the classical method (*N*-methyl derivatives of alanine, aspartic acid, lysine, phenylalanine and valine).[16,17] This is one evidence that the method of Quitt et al. is a generally-applicable, simple method for the preparation of *N*-methylamino acids.

The rotational shifts of amino acids induced by *N*-methylation were also observed; they also are listed in the table. In the fact that the values for the latter compounds are invariably more positive than for those for the former, there seems to be a striking rule, as has been pointed out by Izumiya and his associates.[18] However, three exceptions to this rule appeared to occur in the cases of L-alanine, L-serine and L-threonine. We must, therefore, recall the correlation between optically-active amino acid and glycyl-amino acid. In this case, no correlation can be drawn with the introduction of a glycyl residue at the *N*-acyl position.[19-21]

The R_f-values determined upon the one-dimensional paper chromatography of *N*-methylamino acids are listed in Table I as ratios to those of the parent amino acids. The R_f-values of *N*-methylamino acids are usually higher than those of the parent amino acids. Thin-layer chromatography on silica gle G with the same solvent gave almost the same R_f-value as each of the original parent amino acids.

The tastes of *N*-methylamino acids were tested in comparison with those of the L- and D-series of amino acids. The results obtained are shown in Table I. (Of course, the properties are not nowadays important in identifying the individual amino acids.) As far as the tastes of these *N*-methylamino acids were tested, they reproduced the characteristics of the parent L-amino acid series.[22]

The effect of *N*-methylamino acids on the growth of *Escherichia coli* K 12 and *Bacillus subtilis* PCI 219 strains was investigated using the paper-disk method. None of the 14 *N*-methylamino acids tested inhibited the growth of the both microorganisms in a nutrient medium until the concentrations became 0.05 per cent (500 μg./ml.).

It is well known that ninhydrin can react not

only with α-amino acids, but also with *N*-monoalkylated α-amino acids at neutral pH values.[23,24] In the present work, the color yields with ninhydrin of *N*-methylamino acids were compared with those of the original amino acids by an automatic amino-acid analyzer (Hitachi KLA type 2) and by the method of Stein and Moore.[23] The results obtained are listed in Table I. Although the *N*-methylamino acids generally react with ninhydrin quantitatively, at least 20—30 min. are necessary for their complete reaction at 100°C. The color yields were considerably lower than those of the original amino acids under the conditions used, as is shown in the table. This indicates that the heating was not enough to produce the maximum reaction between ninhydrin and *N*-methylamino acids. In the ninhydrin reaction with *N*-methylamino acids, it was considered that demethylation might occur before color developing, since the absorption spectra of the ninhydrin color reaction of amino acid and *N*-methylamino acid gave the same type of curves.

The conversion of an L-amino acid to the corresponding *N*-methylamino acid is accompanied by some shift in the infrared absorption spectrum when these spectra are measured under the same conditions. Comparisons were performed in each case of amino acid esters and *N*-methylamino acid esters in the same solvent. In this work two main shifts of the absorption band were found, from 6.13 μ to 6.36 μ and from 6.58 μ to 6.80 μ, corresponding to the change from the $-NH_2^+ \cdot Cl^-$ to the $-NH^+-CH_3 \cdot Cl^-$ group.

Grateful acknowledgement is hope by made to Dr. Kaoru Kuriyama and his staff for their optical rotation measurements, to Dr. Satoshi Mizukami and his staff for their microanalyses, and to Miss Shizuko Kitamura for her technical assistance.

On 2-Cyanotropone Derivatives

By Toyonobu Asao and Masao Kobayashi*[1]

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received November 24, 1965)

It is known[1] that nucleophilic reagents generally attack at the 7-position of 2-halotropones to give so-called abnormal substitution products. However, it has been reported[2] that the attack of the sulfides on 2-holotropones occurs exclusively at the 2-position (normal substitution).

The present authors have investigated the reaction[3] of 2-bromotropones with cuprous cyanide to see whether the reaction is normal or abnormal. In addition, some reactions of 3-cyanotropolone will be reported in this paper.

The two hydrazinotropones,[4] 2-hydrazino-6-isopropyl- and 2-hydrazino-4-isopropyltropones (I and II), derived from the methyl ethers of hinokitiol were decomposed with cupric sulfate in hydrobromic acid to give isomeric 2-bromotropone derivatives, III and IV respectively. The treatment of III and IV with an excess of cuprous cyanide gave a good yield of two cyanoisopropyltropones (V and VI), which, on being heated with 75% sulfuric acid, were hydrolyzed to the carboxyisopropyltropones, VII and VIII respectively. From the evidence which follows, it is apparent that the formation of the cyanotropones from the bromotropones proceeds by normal substitution; accordingly, V and VII are 2-cyano- and 2-carboxy-6-isopropyltropones respectively, while VI and VIII are 2-cyano- and 2-carboxy-4-isopropyltropones respectively.

In general, yields of the abnormal substitution products of 6-substituted 2-halotropones are very low as a result of the steric interference of the substituents; mainly rearrangement products are obtained, whereas the conversion of III into V results in a good yield. The infrared spectra of V and VII appeared at 810 and 792 cm^{-1} respectively, similar to the out-of-plane deformation band of 2, 6-disubstituted tropones.[5] On the other hand, the out-of-plane deformation bands of

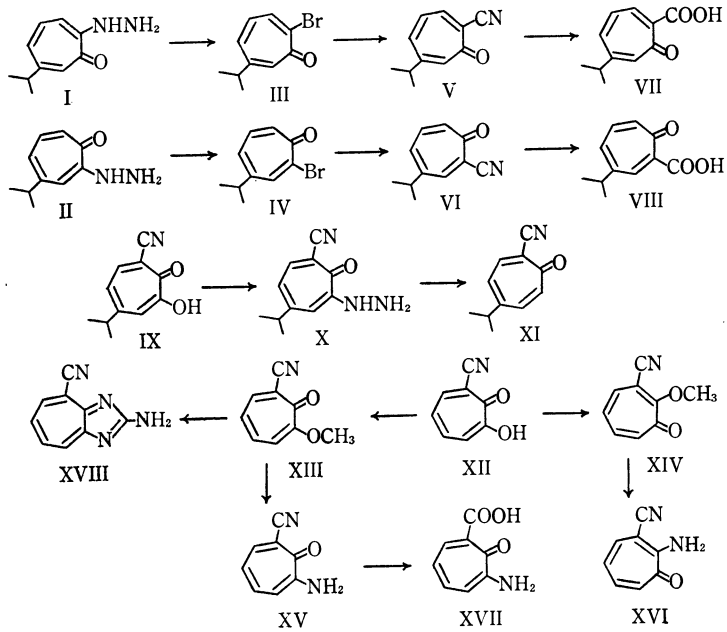
4) S. Seto, *Sci. Repts. Tohoku Univ.*, **I**, **36**, 126 (1952).

5) 2, 4-Disubstituted tropones show characteristic absorptions in the 810—840 cm^{-1} range, while 2, 6-disubstituted tropones show theirs in the 770—800 cm^{-1} range (T. Nozoe, K. Takase and M. Yasunami, to be published).



VI (at 830 cm^{-1}) and of VIII (at 843 cm^{-1}) were similar to those of 2, 4-disubstituted tropones.[5]

The above conclusions were confirmed by the following reactions. 7-Cyano-2-hydrazino-4-isopropyltropone (X), obtained by the reaction[6] of 3-cyano-6-isopropyltropolone (IX) with hydrazine, was decomposed with cupric sulfate in acetic acid to yield 2-cyano-5-isopropyltropone (XI). The compound XI is clearly different from VI; the infrared of XI shows a band at 860 cm^{-1}, which is a reasonable value[7] for the out-of-plane deformation band of 2, 5-disubstituted tropones. The ultraviolet spectra of three isopropyl-2-cyanotropones are shown in Fig. 1.

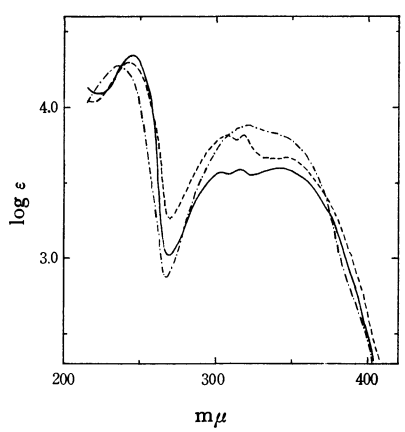


Fig. 1. U. V. absorption spectra of isopropyl derivatives of 2-cyanotropone in methanol.
—— (V) ---- (VI) —·—· (XI)

The two methyl ethers (XIII and XIV)[6] which were obtained from 3-cyanotropolone (XII), when allowed to react with liquid ammonia, afforded 7-cyano- and 3-cyano-2-aminotropone (XV and XVI) respectively, and the hydrolysis of XV afforded 2-amino-7-carboxytropone (XVII).

It is known that the reaction of XIII and ethyl cyanoacetate gives a complex mixture,[8] while the reaction[9] with guanidine affords 2-amino-4-cyano-1, 3-diazaazulene (XVIII) in a good yield.

Experimental*2

2-Bromo-6-isopropyltropone (III).—To a gently boiling solution of cupric sulfate (37 g.) in water (37 ml.), a solution of 2-hydrazino-6-isopropyltropone (I) (3.7 g.) in 48% hydrobromic acid (30 ml.) was added; the mixture was then heated at around 100°C for 3 min. After it had cooled, water (50 ml.) was added, and the solution was extracted with chloroform. The extract was dried over sodium sulfate, chromatographed on an alumina column, and eluted with chloroform. From the first effluent, pale yellow crystals (3 g.) were obtained. Recrystallization from petroleum ether gave III as colorless needles, m. p. 56—57°C.

Found: C, 53.05; H, 4.75. Calcd. for $C_{10}H_{11}$·OBr: C, 52.88; H, 4.83%.

λ_{max}^{MeOH} mμ (log ε): 237^{sh} (4.28), 247 (4.31), 320 (3.83).

*2 All melting points are uncorrected.

2-Bromo-4-isopropyltropone (IV).[*3] — According to the procedure discribed above, 2-bromo-4-isopropyltropone (500 mg.) was obtained as a pale yellow oil from 600 mg. of 2-hydrazino-4-isopropyltropone (II).

Found: C, 52.44; H, 4.93. Calcd. for $C_{10}H_{11}OBr$: C, 52.88; H, 4.83%.

λ_{max}^{MeOH} mμ (log ε): 225[sh] (3.99), 248 (4.17), 323 (3.80).

2-Cyano-6-isopropyltropone (V).—A mixture of III (390 mg.) and cuprous cyanide (800 mg.) was heated at 125°C for 2 hr. while being occasionally stirred. The resulting black solid was extracted with chloroform. The evaporation of the solvent gave dark brown crystals, which were then dissolved in benzene and chromatographed on an alumina column to give 240 mg. of yellow crystals. Recrystallization from methanol gave V as pale yellow plates, m. p. 98—99.5°C.

Found: N, 7.71. Calcd. for $C_{11}H_{11}ON$: N, 8.09%.

λ_{max}^{MeOH} mμ (log ε): 246 (4.35), 303 (3.58), 315 (3.59), 343 (3.60).

IR (Nujol): 2225 cm^{-1} (C≡N).

2-Cyano-4-isopropyltropone (VI).—A mixture of IV (160 mg.) and cuprous cyanide (350 mg.) was heated at 125°C for 2 hr. while being occasionally stirred. The resulting solid was extracted with chloroform; a reddish oil was obtained by the evaporation of the solvent. Distillation gave 100 mg. of VI as a pale yellow oil, b. p. about 125°C/0.5 mmHg.

Found: N, 8.27. Calcd. for $C_{11}H_{11}ON$: N, 8.09%.

λ_{max}^{MeOH} mμ (log ε): 245 (4.31), 305 (3.82), 318 (3.82), 340 (3.67).

IR (Liquid): 2222 cm^{-1} (C≡N).

2-Carboxy-6-isopropyltropone (VII).—A solution of V (150 mg.) in 75% sulfuric acid (1 ml.) was heated at 150—155°C for 30 min., and then poured onto ice thus affording crystals. Recrystallization from benzene-cyclohexane gave 77 mg. of VII as pale yellow needles, m. p. 76—77°C.

Found: C, 69.02; H, 6.20. Calcd. for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29%.

λ_{max}^{MeOH} mμ (log ε): 240 (4.34), 304[sh] (3.74), 316 (3.77).

2-Carboxy-4-isopropyltropone (VIII).—After it had been heated at 155°C for 20 min., a solution of 80 mg. of VI in 75% sulfuric acid (0.5 ml.) was poured onto ice to give crystals. Recrystallization from benzene-cyclohexane gave VIII as pale yellow needles, m. p. 120—121°C.

Found: C, 68.93; H, 6.21. Calcd. for $C_{11}H_{12}O_3$: C, 68.73; H, 6.29%.

λ_{max}^{MeOH} mμ (log ε): 238 (4.27), 319 (3.90).

2-Cyano-7-hydrazino-5-isopropyltropone (X).—A solution of 3-cyano-6-isopropyltropolone (IX) (200 mg.) and 80% hydrazine hydrate (100 mg.) in ethanol (1.5 ml.) was refluxed for 15 min. After the solvent had then been evaporated, the residue was dissolved in ethanol and passed through an alumina column to yield 30 mg. of yellow crystals. Recrystallization from ethanol gave X as orange yellow prisms, m. p. 147—148°C.

Found: C, 64.90; H, 6.12; N, 20.50. Calcd. for $C_{11}H_{13}ON_3$: C, 65.00; H, 6.45; N, 20.68%.

[*3] This experiment was carried out by Dr. Masafumi Yasunami.

2-Cyano-5-isopropyltropone (XI).—To a heated solution of X (130 mg.) in a mixture of acetic acid (3 ml.) and water (3 ml.), a solution of cupric sulfate (0.6 g.) in water (6 ml.) was added. The mixture was then heated for 15 min., water (15 ml.) was added, and the solution was extracted with chloroform. After the solution had been dried over sodium sulfate, the solvent was removed to leave a reddish oil which was distilled under reduced pressure to give XI as a pale yellow oil (30 mg.).

Found: N, 7.95. Calcd. for $C_{11}H_{11}ON$: N, 8.09%.

λ_{max}^{MeOH} mμ (log ε): 237 (4.28), 321 (3.89), 340[sh] (3.83).

IR (Liquid): 2233 cm^{-1} (C≡N).

2-Amino-7-cyanotropone (XV).—A solution of XIII (700 mg.) in liquid ammonia (7 ml.) in sealed tube was allowed to stand at room temperature overnight. The excess ammonia was then removed, and the residue was recrystallized from methanol to give XV as yellow crystals (400 mg.), m. p. 207.5—209°C.

Found: C, 65.19; H, 4.58; N, 18.71. Calcd. for $C_8H_6ON_2$: C, 65.75; H, 4.18; N, 19.17%.

λ_{max}^{MeOH} mμ (log ε): 220 (4.07), 250 (4.34), 273 (4.13), 283[sh] (4.01), 349(3.99), 424 (4.31).

Acetate.—Yellow plates (from ethanol); m. p. 238.5—239°C.

Found: C, 63.66; H, 4.00; N, 14.89. Calcd. for $C_{10}H_8O_2N_2$: C, 63.82; H, 4.29; N, 14.89%.

2-Amino-3-cyanotropone (XVI).—By the procedure described above, XVI was obtained from 3-cyano-2-methoxytropone (XVI) as yellow crystals, m. p. 138—140°C.

Found: C, 65.61; H, 4.05; N, 18.93. Calcd. for $C_8H_6ON_2$: C, 65.75; H, 4.18; N, 19.17%.

λ_{max}^{MeOH} mμ (log ε): 225[sh] (4.12), 248 (4.30), 270 (4.04), 345 (4.01), 406 (4.06).

2-Amino-7-carboxytropone (XVII).—A solution of XV (400 mg.) in 75% sulfuric acid (2.8 ml.) was heated at 160°C for 45 min. and then poured onto ice to yield a brown solid. Recrystallization from methanol afforded XVII as yellow crystals (150 mg.), m. p. 264°C (decomp.).

Found: C, 57.78; H, 4.19; N, 8.27. Calcd. for $C_8H_7O_3N$: C, 58.18; H, 4.28; N, 8.48%.

λ_{max}^{MeOH} mμ (log ε): 249 (4.25), 272 (4.00), 344 (3.88), 418 (4.19).

Acetate.—Yellow needles (from ethanol); m. p. 218—219°C (decomp.).

Found: C, 58.29; H, 4.21; N, 6.71. Calcd. for $C_{10}H_9O_4N$: C, 57.97; H, 4.38; N, 6.76%.

Methyl Ester.—The methylation of XVII with diazomethane gave yellow needles, m. p. 145—146.5°C.

Found: C, 60.60; H, 5.05; N, 7.82. Calcd. for $C_9H_9O_3N$: C, 60.33; H, 5.06; N, 7.82%.

λ_{max}^{MeOH} mμ (log ε): 240[sh] (4.34), 245 (4.36), 265 4.01), 274[sh] (3.93), 344 (3.99), 409 (4.11).

2-Amino-4-cyano-1, 3-diazaazulene (XVIII). — A solution of 2-methoxy-7-cyanotropone (XIII) (100 mg.), guanidine hydrochloride (71 mg.), and sodium methoxide (15.7 mg.) in absolute ethanol (1.5 ml.) was refluxed for 1 hr. The brown precipitate (60 mg.) was washed with water and recrystallized from *n*-butanol, affording XVIII as reddish-orange plates, m. p. 305°C (decomp.).

Found: C, 63.54; H, 3.41; N, 32.65. Calcd. for $C_9H_6N_4$: C, 63.52; H, 3.55; N, 32.93%.

λ_{max}^{MeOH} $m\mu$ (log ε): 263 (4.46), 302 (3.93), 364 (4.11), 428 (3.89).

The authors wish to express their gratitude to Professor Tetsuo Nozoe for his kind and unfailing guidance throughout this work.

A Structural Study of Complex Chromic-Ferrocyanide and -Ferricyanide by Means of Ultrasonic Waves

By Wahid U. MALIK and Jahan SINGH*

Chemical Laboratories, University of Roorkee, Roorkee, India

(Received January 11, 1966)

Sette[1] has discussed and reviewed the use of ultrasonic velocities in the determination of molecular structures and the structure of liquids. Work on complex barium-citrate has been carried out by Prakash and Pandey,[2] and by Subrahmanyam.[3] These methods have, however, not been extensively employed to determine the composition and structure of coordination compounds. This is especially true for metal ferrocyanogen complexes, where, except for some preliminary studies on potassium ferrocyanide, nothing worth mentioning has so far been done. Investigations in this direction were, therefore, considered desirable.

The ultrasonic method cannot be applied to all the known metal ferro-cyanogen complexes, since most of them exist as insoluble compounds. Recently Malik,[4,5] during the course of his investigations into these compounds, came across a number of new ferrocyanogen complexes, like that of chromium, molybdenum, etc., which could exist in a soluble state. It was thought that some of these could be put to ultrasonic analysis and so ascertain their composition. In this communication the preliminary results on sono-metric study of chromic ferro- and ferricyanides have been reported.

Experimental

Standard solutions of chromium(III) chloride and potassium ferrocyanide and potassium ferricyanide were prepared by dissolving A. R. grade reagents in doubly-distilled water. A series of mixtures were then prepared according to Job's method[6] of continuous variation. These mixtures were allowed to stand for some time to attain equilibrium and to complete the reaction (as determined by the change in colour from light yellow to orange-red and by shifts in the absorption maximum). The velocity in each mixture was determined by the optical diffraction[7,8] method. An X-cut quartz crystal was suspended in a rectangular glass vessel containing the experimental mixture in such a manner that the crystal hung parallel to one side of the vessel. This crystal was then connected to a Hartley oscillator to produce ultrasonic waves. The stationary waves were formed in a liquid to give regions of compression and rarefraction, which act like a diffraction grating. The readings of the direct slit and diffraction orders were taken on the scale of the telescope. The velocity was calculated by the formula:

$$V=\frac{n\cdot f\cdot \lambda\cdot D}{x} \qquad (1)$$

where f = the frequency of the Hartley oscillator for the impedance matching of crystal
n = the number of the diffraction order
λ = the wavelength of the source of light
D = the distance between the optical centre of the objective of the telescope and the scale
x = the distance between the nth order and the direct image of the slit.

The apparatus used was made by the Andhra Scientific Co., India. For this apparatus $D=100$ cm., and the least count of the scale is 0.01 cm. In our observations, $f=3$ mc./s., $\lambda=5893$ A. U. and $n=1$ (1st order). By putting these values into Eq. 1, we get:

$$V=\frac{176.79}{x} \text{ m./sec.} \qquad (2)$$

From Eq. 2 the velocity was calculated for different mixtures. These results are shown in Tables I and II.

Results and Discussion

From the graphs for Job's method it was found that the ultrasonic velocity gradually decreases, reaches a minimum, and then increases again. In graph No. 1 the minimum occurs at the point of 0.5 ratio $Cr^{3+}/(Cr^{3+}+Fe(CN)_6^{4-})$ at a composition

of 1 : 1. This indicates the maximum complex formation at that point. In graph 2 the minimum occurs at the point of 0.6 ratio $Cr^{3+}/(Cr^{3+}+Fe(CN)_6^{3-})$ at a composition of 3 : 2.

Had there been no interaction between the two solutions, the curve would be linear. When the complex formation is at a maximum, the ultrasonic velocity is at a minimum.

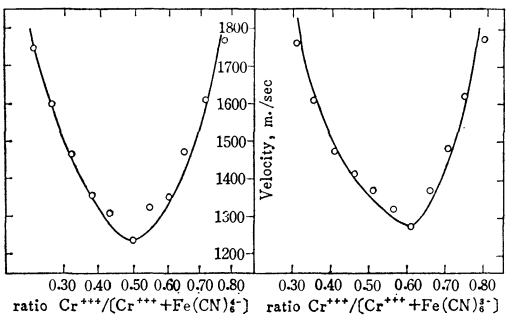

Fig. 1 Fig. 2

Graphs showing the variation of ultrasonic velocities of chromic ferrocyanide (Fig. 1) and chromic ferricyanide (Fig. 2) with different ratio of chromic (Cr^{3+}) to the complex ($Cr^{3+} + Fe(CN)_6^{4-}$ and $Cr^{3+} + Fe(CN)_6^{3-}$).

By a comparison of graphs 1 and 2, it may be seen that the velocity is more in the case of chromic-ferricyanide than in that of chromic-ferrocyanide. This difference may be attributed to the difference in the degree of hydration of chromic ferro- and ferricyanide particles, since both these compounds give colloidal precipitates. A confirmation of these results is found in the work of Malik[9] on the composition (using spectrophotometric and amperometric methods) and colloidal behaviour (sol-gel transformation) of chromic-ferro- and ferricyanides.

Tables I and II show the ultrasonic velocities of chromic-ferrocyanide and chromic-ferricyanide complexes respectively.

Studies of *C*-Substituted Tartaric Acid. III. The Preparation of Isomeric 1, 2-Dihydroxycyclohexane-1, 2-dicarboxylic Acids and the Optical Resolution of the Racemate

By Susumu TATSUMI, Masami IMAIDA and Yoshiharu IZUMI

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received January 28, 1966)

1, 2-Dihydroxycyclohexane-1, 2-dicarboxylic acid is a kind of *C, C'*-dialkyltartaric acid. This hydroxy acid contains two asymmetric centers; hence, it exists in two optically inactive modifications. One is a racemic form which may be resolved into optically active forms, while the other is a meso form. The optically active and inactive forms, therefore, are interesting substances from the stereochemical point of view in relation to tartaric acid. Moreover, in a previous paper[1] from our laboratory, it was reported that a Raney nickel catalyst treated with an aqueous solution of this optically active hydroxy acid exhibits an asymmetric hydrogenation activity in the hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate. However, there have been no reports on the preparation of the two optically inactive or active forms of this hydroxy acid.

In the present work, 1, 2-dihydroxycyclohexane-1, 2-dicarboxylic acid was prepared from 1, 2-cyclohexanedione and was then separated into the meso (I) and racemic (II) forms on the basis of the different solubilities of their calcium salts in water. The purity of each salt was checked by a study of the infrared spectrum.[2] Subsequently, the optical resolution of II was performed in an aqueous solution with brucine. The optical rotation values of the optically active isomers were as follows: (+)-isomer, $[\alpha]_D^{20}$ +31.0° (*c* 2, water); (−)-isomer, $[\alpha]_D^{20}$ −30.5° (*c* 2, water).

Experimental*

The Preparation of 1, 2-Dihydroxycyclohexane-1, 2-dicarboxylic Acid.—One hundred and twenty-nine grams of sodium cyanide was dissolved in 250 ml. of cold water in a 2 l. three-necked flask fitted with a stirrer and a dropping funnel. Into the cold solution, a 220 ml. portion of concentrated hydrochloric acid was added, drop by drop, with the temperature of the solution maintained below 20°C under a hood. After the addition of hydrochloric acid was complete, 3.6 g. of potassium carbonate was added, and then 115 g. of 1,2-cyclohexanedione[3] was added, drop by drop. The reaction mixture was stirred for 3 hr. at room temperature and then allowed to stand overnight. To the mixture, a 600 ml. portion of concentrated hydrochloric acid was added, after which the solution was kept for an hour at room temperature. Inorganic salts were removed by filtration, and the filtrate was refluxed for 5 hr. The hydrolyzed solution was decolorized with charcoal and then evaporated to dryness under reduced pressure. The residue was extracted with four 100 ml. portions of ethanol, and the white residue was discarded. The alcohol extracts were combined and evaporated to a syrup. This was dissolved in 3 l. of ethanol and esterified by blowing dry hydrogen chloride gas into the solution. The alcohol was distilled off in vacuo, and the diethyl ester of the acid was collected at 116—119°C/2 mmHg. Yield, 84 g.

Eighty-four grams of the ester were refluxed with 150 ml. of 12% hydrochloric acid for 5 hr. The hydrolyzate was then concentrated to a syrup under reduced pressure. This was taken up in 100 ml. of water and concentrated again. To remove free hydrochloric acid, water was added and the evaporation was repeated. The resulting viscous syrup was dissolved in 80 ml. of hot ethyl acetate, and then a 20 ml. portion of petroleum ether was added to the solution. After the mixture had stood overnight in a refrigerator, white crystals were collected by suction. Yield, 50 g.

Found: C, 47.31; H, 5.85. Calcd. for $C_8H_{12}O_6$: C, 47.06; H, 5.92%.

Separation into the Meso (I) and Racemic (II) Forms.—*The Preparation of Calcium Salts of I and II.*—Fifty grams of isomeric acids and 36 g. of calcium chloride dihydrate were dissolved in 2.8 l. of water. The resulting solution was adjusted to pH 5 with 10% sodium hydroxide, and then left to stand overnight at room temperature. The calcium salt which precipitated was collected by suction. In order to purify the salt, it was decomposed with hydrochloric acid and then neutralized with a sodium hydroxide solution. The decomposition and neutralization were repeated alternately three times, with the purity of the salt being checked on the basis of its infrared spectrum.[2] In this way, 18 g. of the pure calcium salt of I was obtained.

Found: C, 37.00; H, 4.70. Calcd. for $C_8H_{10}O_6Ca \cdot H_2O$: C, 36.91; H, 4.65%.

The mother liquor of the calcium salt of I was concentrated to dryness under reduced pressure. Four recrystallizations of the residue from boiling water gave 19 g. of the pure salt of II.

Found: C, 39.57; H, 4.20. Calcd. for $C_8H_{10}O_6Ca$: C, 39.66; H, 4.16%.

The Preparation of I and II.—Thirty grams of the

2) S. Tatsumi, ibid., **39**, 2202 (1966).
* All melting points are uncorrected.
3) R. S. Schreiber, "Organic Syntheses," Vol. 32, 35 (1951).

calcium salt of I was dissolved in 120 ml. of 2 N hydrochloric acid, and then the resulting solution was evaporated to dryness under reduced pressure. The residue was extracted with four 50 ml. portions of acetone, and the white residue was discarded. The acetone extracts were combined and evaporated to dryness in vacuo, yielding 23 g. of crude I. Recrystallization from ethyl acetate - petroleum ether (4 : 1) gave 20 g. of pure I. M. p. 154°C.

Found: C, 47.14; H, 5.96. Calcd. for $C_8H_{12}O_6$: C, 47.06; H, 5.92%.

Thirty grams of the calcium salt of II was treated as has been described above. 18.5 g. of pure II was thus obtained. M. p. 180°C.

Found: C, 46.72; H, 5.97. Calcd. for $C_8H_{12}O_6$: C, 47.06; H, 5.92%.

The Optical Resolution of II.—Twenty grams of II and 39 g. of brucine were dissolved in 600 ml. of boiling water, and the resulting solution was allowed to stand overnight in an ice box. The crystals of the brucine salt which precipitated were collected by suction; six recrystallizations of this salt from ten parts of boiling water gave 16 g. of the pure brucine salt of II. This salt was suspended in 150 ml. of water and decomposed with 35 ml. of N sodium hydroxide. The precipitated brucine was removed by filtration, and the alkaline filtrate was washed with 20 ml. of chloroform, neutralized with concentrated hydrochloric acid, and then evaporated to a syrup. To this a small amount of water was added, and the resulting solution was decolorized with charcoal and evaporated to dryness. The residue was extracted several times with 10 ml. volumes of acetone. The acetone extracts were combined and again evaporated to a syrup. The syrupy product was dried over sulfuric acid in a vacuum desiccator. In this way, 4.4 g. of (+) II was obtained. Recrystallization from ethyl acetate - petroleum ether (3 : 1) gave 3.8 g. of optically pure (+)-II. $[\alpha]_D^{20}$ +31.0° (*c* 2, water).

Found: C, 47.11; H, 5.81. Calcd. for $C_8H_{12}O_6$: C, 47.06; H, 5.92%.

The mother liquor of the brucine salt of (+)-II was concentrated to dryness under reduced pressure. The brucine salt of (−)-II was collected and treated as has been described above. 2.0 g. of optically pure (−)-II were thus obtained. $[\alpha]_D^{20}$ −30.5° (*c* 2, water).

Found: C, 47.14; H, 5.94%.

This research was made possible by the support of the Ajinomoto Co., Inc., Tokyo. The authors wish also to express their deep thanks to Miss Kiku Koike of this Institute for carrying out the elemental analyses.

A Redox Titration of Vanadium(IV), Hypochlorite, Hypobromite and a Mixture of Vanadium(IV) and Vanadium(V)

By J. P. TANDON and K. L. CHAWLA

Department of Chemistry, University of Rajasthan, Jaipur, India

(Received February 2, 1966)

Vanadium(IV) in an alkaline solution can be rapidly and quantitatively oxidised to vanadium(V) in an inert atmosphere by the use of a hypochlorite or hypobromite solution. This forms the basis of the methods of the determination of vanadium(IV), hypochlorite and hypobromite to be described in the present paper.

To an alkaline solution of vanadium(IV) sulphate, a known excess of a standardised hypohalite solution is added. After destroying the excess with a known amount of arsenic(III) oxide solution, the excess of arsenic(III) is finally determined by titration with a hypohalite solution, using methyl red as the indicator. For determining the amount of hypohalite, its known volume is added to an excess of a vanadium(IV) solution in the presence of alkali; then the vanadium(V) so formed is titrated with iron(II) sulphate, using *N*-phenylanthranilic acid as the indicator. These methods have the advantage that the reactions are rapid at room temperature, and the excess of the oxidising solution in the determination of vanadium(IV) is easily and completely removed. However, all the titrations must be carried out in an atmosphere of purified nitrogen, since the auto-oxidation of vanadium(IV) is serious in an alkaline medium. A method for the determination of vanadium(IV) and vanadium(V) mixtures is also suggested.

Experimental and Results

Reagents.—All the chemicals used were products of the British Drug House (B. D. H.), Analar (A. R.) or of the E. Merck Company.

The Vanadium(IV) Sulphate Solution.—Prepare an approximately 0.05 M solution containing 0.05 M sulphuric acid and standardise against permanganate at about 80°C.

The Hypochlorite and Hypobromite Solutions.—Prepare approximately 0.05 M solutions as described by Erdey and Vigh[1] and standardise iodometrically.

The Arsenic(III) Oxide Solution.—Prepare a 0.25 M solution.

1) L. Erdey and K. Vigh, *Talanta*, **10**, 439 (1963).

The Procedure for the Determination of Vanadium(IV) with Hypochlorite of Hypobromite.—Place 5 to 10 ml. of a vanadium(IV) sulphate solution in a titration vessel, bubble nitrogen in for about 10 min., and add 5 to 10 ml. of 4 M sodium hydroxide and 5 to 10 ml. of the previously-standardised hypochlorite or hypobromite solution. When the solution becomes almost colourless (after 2—3 min.), add 5 to 10 ml. of a 0.05 M arsenic(III) oxide solution. Add 10 ml. of 6 M hydrochloric acid and 1—2 drops of methyl red indicator, and titrate the excess of arsenic(III) with the hypochlorite or hypobromite solution. A few results are recorded in Table I.

Table I. Determination of vanadium(IV) (V^{IV}—V^{V} change)

Amount of vanadium(IV), mmol.		
Taken	Found	% Error
0.5070	0.5039	−0.61
0.5070	0.5077	+0.14
0.5320	0.5350	+0.56
0.5750	0.5740	−0.17

The Procedure for the Determination of Hypochlorite or Hypobromite.—Place about 10 ml. of a vanadium(IV) sulphate solution in a titration vessel, bubble nitrogen in for about 10 min., and add about 5 ml. of 4 M sodium hydroxide and 2 to 5 ml. of the hypochlorite or hypobromite solution. After 2 to 3 min., add 30 ml. of 6 M sulphuric acid and titrate the vanadium(V) with iron(II) sulphate, using *N*-phenylanthranilic acid as the visual indicator. A few results are given in Table II.

The Procedure for the Determination of Vanadium(IV) and Vanadium(V) in a Mixture.—For the determination of vanadium(IV) in the mixture, follow the procedure described earlier. In another aliquot, acidify the mixture with 6 M sulphuric acid to make the overall acidity about 3 M, and then titrate the vanadium(V) with iron(II) sulphate. A few results are given in Table III.

Table II. Determination of hypochlorite and hypobromite

Oxidising agent		Found by procedure described mmol.	Found iodometrically mmol.	% Error
Hypochlorite	(i)	0.2522	0.2520	+0.08
	(ii)	0.2515	0.2520	−0.12
	(iii)	0.2044	0.2038	+0.24
Hypobromite	(i)	0.0566	0.0567	+0.17
	(ii)	0.1690	0.1688	+0.11
	(iii)	0.1917	0.1910	+0.37

Tables I to III show that, in the concentration ranges from 0.2780 to 0.5750 mmol. of vanadium(IV) and 0.0567 to 0.2522 mmol. of hypohalites, the accuracy of the present method is ±0.6% and ±0.4% respectively. The variation co-efficient is ±0.15%.

The Effects of Foreign Substances.—The determination of vanadium(IV) is subject to interference by even a small amount of ammonia, urea, sulphide, thiosulphate, tetrathionate and hydrogen peroxide, whereas in the determination of hypochlorite and hypobromite, cerium(IV), chromium(VI), vanadium(V), etc., which are reduced by iron(II), interfere.

The authors wish to thank Professor R. C. Mehrotra for his keen interest in the work and for providing the facilities, and to the Council of Scientific and Industrial Research, New Delhi, for the award of a Junior Research Fellowship to K. L. C.

The Oxidation of Terpene Compounds with *t*-Butyl Chromate. IX.[1] The Oxidation of (+)-*p*-Menth-1-ene

By Takayuki SUGA, Masako SUGIMOTO, the late Kôzô FUJITA and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received February 14, 1966)

The oxidation of *p*-menth-1-ene with *t*-butyl chromate in carbon tetrachloride has been reported by Dupont et al.[2] to afford carvotanacetone, piperitone, and possibly 2-methyl-5-isopropyl-1, 4-hydroquinone. On the other hand, Fujita et al.,[3] in a previous paper of this series, have reported that *t*-butyl chromate oxidation of *p*-menth-1-ene in benzene yielded only carvotanacetone. We have now re-examined this oxidation in order to check the point of the oxidative attack.

The oxidation was conducted in accordance with the technique presented in a previous report of ours[3]; it has been confirmed to yield (±)-carvotanacetone (a 25% yield based on the sample taken), (+)-piperitone (26%), and traces of carvacrol, thymol and (+)-phellandric acid, by a combination of fractional distillation, column chromatography, gas chromatography, and a study of the absorption spectra and the functional derivatives. Not even a trace of the hydroquinone, which has been found by Dupont et al.,[2] could be detected.

The present results indicate that *t*-butyl chromate oxidizes equally each of two active methylenes (C-3 and C-6) of *p*-menth-1-ene to a ketone group; this differs from Fujita's results[3] on the oxidation of this hydrocarbon. The presence of phellandric acid suggests that an active methyl group at C-1 was, to a small extent, oxidized to a carboxyl, possibly via an aldehydic group. It was, moreover, noteworthy that optically inactive carvotanacetone resulted from the oxidation of an active methylene adjacent to the C*-atom in the $-C^*(R)=CH-$ system, while piperitone formed by the oxidation of the methylene in the $-C(R)=CH-CH_2-$ grouping partially retained its optical activity. The same phenomenon has also been observed in the *t*-butyl chromate oxidation of (+)-limonene[4] and (+)-*p*-menth-3-ene[5]; the cause of such phenomena is not yet completely clear.

Experimental

Oxidation. — (+)-*p*-Menth-1-ene (b. p. 85°C/40 mmHg, n_D^{25} 1.4531, d_4^{25} 0.8205, $[\alpha]_D^{27}$ 96.6°) was synthesized from (+)-limonene (b. p. 85°C/40 mmHg, $[\alpha]_D^{14}$ 121.9°) by catalytic partial hydrogenation according to the method of Ref. 5 cited in Ref. 3. A benzene solution of *t*-butyl chromate was prepared from 108.6 g. of chromium trioxide, 241.6 g. of *t*-butyl alcohol, and 550 ml. of benzene following the method reported.[1,3] Then, each of this oxidant solution and (+)-*p*-menth-1-ene (50.0 g.) was simultaneously dropped into a flask over a 6 hr. period at 50°C under agitation in an atmosphere of carbon dioxide. After the mixture had been stirred for 24 hr., glacial acetic acid (70 g.) and acetic anhydride (110 g.) was added to the mixture; it was then stirred further at the same temperature for 6 hr. The treatment of the mixture according to the usual method[1,3] gave 51.0 g. of a reaction mixture, which was then fractionated into three fractions and a residue (7.6 g.) by distillation. The residue seemed to be a chromium-containing polymerized substance.

The Identification of the Oxidation Products.— 1) The first fraction (9.0 g.; b. p. 71—84°C/40 mmHg) was the unchanged hydrocarbon, judging from its gas chromatogram and infrared spectrum.

2) The second fraction (25.9 g.; b. p. 88—112°C/10 mmHg) was found to consist of equal amounts of two components by a study of its chromatostrip and by gas chromatographic analyses. This fraction was chromatographed on a silica gel column with a mixture of ethyl acetate and *n*-hexane. The first elute (b. p. 75°C/4 mmHg, n_D^{25} 1.4740, d_4^{25} 0.9382, $[\alpha]_D^{25}$ 0° (*c* 9.5, ethanol); λ_{max}^{hexane} 231 and 312 mμ (ε 12200 and 57); $\nu_{max}^{liq.}$ 1668 (C=O), 1438 ($-CH_2CO-$), 903 (>C=CH–) cm^{-1}; NMR (CCl_4, p.p.m. from internal tetramethylsilane) 0.81_s (3H), 0.96_s (3H), 1.68_s (3H), 6.60_{br} (1H)) gave (±)-carvotanacetone 2, 4-dinitrophenylhydrazone (m.p. and mixed m.p. 192—193°C and semicarbazone (m. p. and mixed m. p. 177—178°C).

The second elute showed the following physical properties: b. p. 78°C/3 mmHg, n_D^{25} 1.4745, d_4^{25} 0.9293; $[\alpha]_D^{11}$ +11.32° (*c* 6.5, ethanol), lit.,[6] $[\alpha]_D^{20}$ +49.8°; λ_{max}^{hexane} 225 and 332 mμ (ε 15000 and 32), lit.,[7] λ_{max}^{hexane} 225 and 333 mμ (ε 17800 and 35); $\nu_{max}^{liq.}$ 1666 (C=O), 1437 ($-CH_2CO-$), 871 (>C=CH–) cm^{-1}; NMR (CCl_4, p. p. m. from internal tetramethylsilane) 0.78_d (J=6 c. p. s., 3H), 0.88_d (J=6 c. p. s., 3H), 1.87_s (3H), 5.68_s(1H); it was confirmed to be (+)-piperitone by

preparing the 2, 4-dinitrophenylhydrazone (m. p. 117—118°C; lit.,[8] 117-—118°C) and the semicarbazone (m. p. 229—230°C; lit.,[9] 226—227°C).

3) The third fraction (3.5 g.; b. p. 112—152°C/10 mmHg) was diluted with petroleum ether and shaken with a 5% sodium hydroxide solution. The extraction of the alkaline solution with ether gave a phenolic substance (λ_{max}^{hexane} 276 and 282 mμ (ε 2000 and 2000); $\nu_{max}^{liq.}$ 3361, 1425, 1229 (OH), 3019, 1621, 1590 (aromatic), 1386, 1370 (isopropyl) cm^{-1}). It was shown, by gas chromatography using a 3 m.-column of 5.6% SE-30 on siliconized Gaschrom P at 150°C, to consist of carvacrol (t_R 6.6 min.) and thymol (t_R 6.9 min.).

4) A crystalline mass (0.25 g.) deposited from the viscid oil which was obtained as a holdup in the distilling apparatus. The recrystallization of the mass from dilute ethanol gave white needles showing a m. p. of 148—149°C ($[\alpha]_D^{25}$ +90.4° (*c* 1.4, methanol), λ_{max}^{hexane} 220 mμ (ε 11000), and *m/e* 168 (M^+), 125 (M-43), 123 (M-45) and 70 (base peak) in the mass spectrum). The needles were confirmed to be (+)-phellandric acid by a comparison of their infrared spectrum in a carbon disulfide solution with that of (−)-phellandric acid (m. p. 146—147°C, $[\alpha]_D^{25}$ 109.0° (*c* 2.5, ethanol); λ_{max}^{hexane} 220 mμ (ε 10800)), which was prepared from (−)-perillaldehyde in our laboratory.

Zero-order Catalysis at Low Catalyst Concentrations

By R. L. Failes and V. R. Stimson

University of New England, Armidale, N. S. W., Australia

(Received February 16, 1966)

Several cases of gas-phase catalysis by hydrogen halides (HX) have been noted where the rate is zero-order in the catalyst; in particular, the hydrogen bromide-catalysed decomposition of tertiary butyl ethyl ether to produce isobutane,[1] and the hydrogen chloride-catalysed decomposition of acetaldehyde[2] have been noted. The kinetic forms assigned to these decompositions are $^{1}c\mu X_{1,0}$ or $^{1}cXXM_{1,0}$, and $^{2}cXXM_{3/2,0}$ at high pressures of hydrogen bromide and hydrogen chloride respectively. (The superscripts 1 and 2 refer to the order of initiation; c indicates a catalysed chain; μ, X and M indicate the entities involved in the termination, and the subscripts give the order of the reaction in the substrate and in the catalyst respectively[3]). The experimental results in the first case are somewhat obscured by another reaction, but in the second case the variation of the rate with the catalyst concentration at low pressures is clear: with an increasing pressure of hydrogen chloride, the reaction velocity increases above that of the uncatalysed reaction in a non-linear manner, attaining a constant value for catalyst pressures above 20—150 mmHg, depending on the temperature. Consideration of this case affords an answer to the interesting question of what happens in a catalysed reaction of the zero order in a catalyst when the catalyst concentration is decreased.

For the mechanism:

$$M + M \rightarrow R_1 + M_1 + M \quad (1)$$

$$R_1 + HX \rightarrow P_1 + X \quad (2)$$

$$X + M \rightarrow HX + R_2 \quad (3)$$

$$R_2 \rightarrow P_2 + R_1 \quad (4)$$

$$X + X + M \rightarrow X_2 + M \quad (5a)$$

$$X + R_1 + M \rightarrow R_1X + M \quad (5b)$$

$$R_1 + R_1 + M \rightarrow R_1R_1 + M \quad (5c)$$

where M=acetaldehyde, $R_1=\dot{C}H_3$, and $X=\dot{C}l$,

$$[R_1]/[X]=k_3[M]/k_2[HX]$$

in the steady state.

From the individual rate parameters listed in Table I

$$[\dot{C}H_3]/[\dot{C}l] \fallingdotseq 5\times[CH_3CHO]/[HCl] \text{ at } 700°K.$$

Even allowing for a considerable error in the rate

Table I.

constants, it is clear that the termination 5a is not likely to persist at low pressures of hydrogen chloride, and that the alternatives, 5b and/or 5c will predominate. These are also likely to be in their termolecular range and to lead to the $^{2}c\beta XM_{1,1/2}$ and $^{2}c\beta\beta M_{1/2,1}$ rate forms respectively. As $[R_1]/[R_2] \doteqdot 60$, for $[HX] = 10^{-6}$ mol. cc^{-1}, termination involving R_2 need not be considered.

The experimental results[2] at low hydrogen chloride pressures indicate that the rate is less than first-order in the catalyst, but it is not apparent whether or not a change of order in the substrate has taken place. If two termination steps occur simultaneously, the order will not be clearly integral or half-integral.

In principle, as the concentration of the catalyst is decreased the uncatalysed reaction must at some point become predominant. Where this takes place depends on the competition between Steps 2 and 6:

$$R_1 + M \rightarrow P_1 + R_2 \qquad (6)$$

Lower pressures of HX favour Step 6. However, in the case of acetaldehyde and hydrogen chloride, the uncatalysed mechanism is evidently slower than the catalysed mechanism down to very small pressures of hydrogen chloride.

The Photolysis of Propylene at 1849Å

By Shigeyoshi ARAI, Shoji SHIDA and Takeo NISHIKAWA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 7, 1966)

A number of studies have been made on the mercury-photosensitized reaction of olefins, but only a few on the direct photolysis.[1-4] In a previous paper[3] we reported a study on the photolysis of butene-1 by the light of 1849 Å, and compared the results with those which had been obtained in the mercury-photosensitized reaction.

The present note concerns a similar study on the photolysis of propylene at 1849 Å. As for the mercury-photosensitized reaction of propylene, it has been known that the primary step is the formation of an excited molecule, which either decomposes or collisionally deactivates,[5] and that the splitting of the C–H bond is the predominant process.[5-8]

The purest propylene commercially available (99.9%) was used after distillation; gas chromatographic analysis did not show any impurity. The absence of mercury vapor in the reacting system was confirmed experimentally.[3] The light source and the method of product analysis are similar to those in the previous work.[3] Dimethylsulfolane and squalane columns were used in gas chromatography. Some experiments were also made on the mercury-photosensitized reaction.

On irradiation the amounts of most products linearly increase initially, but gradually curve off after a few minutes. The latter fact may be ascribed to the decrease in the transparency of the quartz window due to the possible deposit of polymers. The light intensity has no appreciable effect on the relative yields of products. The rates of formation of all the products measured are practically independent of the propylene pressure over the 10—70 mmHg range, although slight, linear increases with the pressure were detected. This pressure dependence is quite different from that observed in the mercury-photosensitized reaction.

TABLE I. RELATIVE YIELDS OF THE PRODUCTS IN THE PHOTOLYSIS OF PROPYLENE AT 1849Å NORMALIZED TO $C_2H_6=1.00$

Time of irradiation, 1 min.
Pressure of propylene, 20 mmHg
Room temperature

Product	Relative yield
Hydrogen	0.76

where all the products showed marked maxima in the pressure region of 10—30 mmHg. This indicates that the life-time before the decomposition of the excited state is very short, less than 10^{-9} sec. This behavior is similar to that found in the photolysis of butene-1. Table I shows the relative yields of products, normalized to $C_2H_6=1.00$.

For simplicity the following three primary processes are assumed, although others could occur.

$$C_3H_6+h\nu \rightarrow H+C_3H_5(\text{allyl}) \quad (1)$$

$$C_3H_6+h\nu \rightarrow CH_3+C_2H_3(\text{vinyl}) \quad (2)$$

$$C_3H_6+h\nu \rightarrow CH_2+C_2H_4 \quad (3)$$

The first two have generally been used for the mercury-photosensitized reaction,[5-8] and the last one has recently been found by Okabe et al. by the field ion mass spectrometer in the photolysis at 1849 Å. All the products found can be qualitatively explained with these primary processes and the subsequent radical reactions. It is to be noted, however, that butene-1 may be formed by the following two reactions.

$$CH_3 + C_3H_5 \rightarrow C_4H_8 \quad (4)$$

$$CH_2 + C_3H_6 \rightarrow C_4H_8 \quad (5)$$

The yield of C–C bond split, 2 and 3, producing methyl and methylene may be given by $CH_4+2C_2H_6+i\text{-}C_4H_{10}+C_4H_8=3.15$. On the other hand, the yield of C–H bond split, 1, producing allyl radicals may be give by the summed yield, 4-methylpentene-1 + allene + methylacetylene + xC_4H_8 = 2.40 + xC_4H_8, where x means the unknown fraction of butene-1 formed by 4.

Apart from the details of the formation of each products, it may be seen from Table I that the C–C bond split occurs to a comparable extent as the C–H bond split. This conclusion is in contrast with the results in the mercury-photosensitized reaction. Further, the result that the C–C bond split is more favored in the direct photolysis at 1849 Å than in the sensitized reaction is in accord with that obtained in the photolysis of butene-1 in the previous work.[3]

The Potassium Fluoride-catalyzed Reaction. IV. The Michael Addition of Nitroalkanes to α, β-Unsaturated Compounds

By Satoshi KAMBE

and Heinosuke YASUDA*

The Institute of Physical and Chemical Research, Bunkyo-ku, Tokyo

(Received March 28, 1966)

Wakamatsu and Shimo[1] recently reported liquid ammonia-catalyzed Michael additions of nitroalkanes to acrylonitrile and other acceptors, but such a catalyst has not generally been utilized in synthesis. In connection with previously-reported additions[2-4] of reactive methylene compounds to α, β-unsaturated compounds, using potassium fluoride as the catalyst, the present study deals with the additions of nitroalkanes to such Michael acceptors as acrylonitrile, methyl acrylate, methyl methacrylate, methyl crotonate, dimethyl fumarate and methyl cinnamate.

The addition of nitromethane to acrylonitrile in 95% ethanol containing potssium fluoride at the refluxing temperature of the solution gave crystalline tris(β-cyanoethyl)nitromethane (I) after one hour, even when a 1 : 1 molar proportion of the reactants was used. When dioxane-water (9 : 1) was employed as the solvent, the addition product I was obtained in a very low yield (0.2%); on the other hand, the starting materials were recovered unreacted in the case of a dioxane (anhydrous) solution under the same conditions. Adamcik et al.[5] have already observed that no cyanoethylation occurs in such nonhydroxylic solvents as dioxane and tetrahydrofuran.

In the cyanoethylation of nitromethane, it is noted that the yield of I is dependent upon the concentration of potassium fluoride used. The use of 0.01 mole of the fluoride per mole of nitromethane yielded 11% of I, but 0.1 mole of the catalyst gave a 63% yield. Furthermore, the nature of the solvent has a remarkable effect on the rate of the reaction and on the product yield. The yield increased with the solvating ability of the solvent in the following order;

$(CH_3)_3COH < (CH_3)_2CHOH <$
50% aqueous $C_2H_5OH \approx$ 95% C_2H_5OH

In general, all primary and secondary alcohols react easily with acrylonitrile in the presence of alkaline catalysts to form the corresponding alkoxypropionitriles, but a negligible amount of ethoxypropionitrile is obtained, even in the presence of ethanol, when potassium fluoride is used.

Acrylonitrile also reacted with other nitroalkanes within two hours (see Table I). Prolonged heating (for more than two hours) did not increase the yield. No bis- or tris-cyanoethylated products were obtained in these reactions even in the presence of an excess of acrylonitrile.

Methyl acrylate readily condensed with nitroalkanes within five hours at about 80°C under the catalytic influence of potassium fluoride. The variation in adducts obtained may be attributed to the difference in the number of replaceable hydrogen atoms of the acidic nitro compounds. 2-Nitropropane, thus, gave only a 1 : 1-addition product, whereas the other nitroalkanes examined yielded 1 : 1- and 1 : 2-adducts in each case (see Table I).

In the addition of nitroalkanes to methyl methacrylate, methyl crotonate and methyl cinnamate in the presence of potassium fluoride, the yield decreased in the following order;

$CH_2=C(CH_3)COOCH_3 > CH_3CH=CHCOOCH_3 > C_6H_5CH=CHOOCH_3$

Methyl 2-methyl-4-nitrobutanoate (XII), for example, was obtained when methyl methacrylate was allowed to react with nitromethane at about 80°C for less than ten hours. Methyl crotonate gave the corresponding adduct XVI with nitromethane, but the relative yield was much lower than those obtained from the methacrylate, even after treatment had been continued for twenty hours. Methyl cinnamate, however, gave no evidence of reaction with the nitroalkanes examined, even after they had been refluxed for thirty hours, and it was recovered quantitatively.

This phenomenon[6] has also been observed in other Michael additions. This suggests that the substitution of the methyl or phenyl group at the β-position of the acceptor would offer a larger steric hindrance to nitroalkane addition than the substitution of the methyl group at the α-position.

The extension of these studies to dimethyl fumarate had disclosed an advantage of employing potassium fluoride as a catalyst; i. e., the fumarate yielded dimethyl 3-methyl-3-nitro-1, 2-butanedicarboxylate (XX) from 2-nitropropane, but the addition products from the other nitroalkanes examined could not be purified by means of distillation.

The results obtained are shown in Table I, along with the infrared data.

Experimental*

The Addition of Nitroalkanes to Acrylonitrile. —A mixture of an appropriate nitroalkane (0.1 mole) and acrylonitrile (0.1 mole, 5.3 g.) in ethanol (50 ml.) containing potassium fluoride (0.01 mole, 0.58 g.) was heated to reflux on a water bath for a suitable number of hours (cf, Table I). After the catalyst had been removed by filtration, the reaction mixture was poured into water (20 ml.). The resulting oily matter was extracted with ether, and the ethereal extract was dried over anhydrous calcium chloride. After the solvent had then been removed, the residual oil was distilled fractionally under diminished pressure. The results obtained are summarized in Table I. In the case of nitromethane, the only product obtained was that of the tris-cyanoethylation; no mono- or bis-cyanoethylated product was detected.

The Addition of Nitroalkanes to α,β-Unsaturated Esters. — The procedure used was essentially the same as that described above. The yields are also listed in Table I.

The authors wish to express their gratitude to Dr. Hiroshi Midorikawa of the Institute of Physical and Chemical Research for his continued encouragement. We also wish to thank Miss Toshiko Takizawa for her able assistance.

The 1 : 1 Complex Formation of Triaryl Isocyanurates with Organic Solvents

By Yoshio IWAKURA, Keikichi UNO and Norio KOBAYASHI

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo

(Received March 18, 1966)

During the course of an investigation of isocyanate polymerization, it has been found that triaryl isocyanurates tend to form 1 : 1 complexes with various organic solvents.

Triaryl isocyanurates have previously been reported by Tsuzuki and his co-workers[1] to form 1 : 1 complexes with alkylene carbonates, such as ethylene carbonate, propylene carbonate, and chloroethylene carbonate. This paper will discuss the formation of 1 : 1 complexes of triphenyl, tri-*p*-tolyl, tri-*p*-methoxyphenyl, and tri-*p*-chlorophenyl isocyanurates with *N, N*-dimethylformamide (DMF), benzene, and acetone.

When triaryl isocyanurates were boiled in such a solvent for about 2 hr., complexes were formed and isolated as colorless crystals on cooling or by the removal of the solvent. They were characterized by elemental analyses (Table I) and by infrared spectra analyses. The infrared absorption spectra of complexes contain almost all the principal bands of both components, but the relative intensity and the frequency of the C=O stretching absorption bands varied remarkably. The C=O bands of triaryl isocyanurates and complexes are summarized in Table II.

Methanol and ether did not form complexes with triaryl isocyanurates, and attempts to prepare such complexes as triphenyl isocyanurate-benzophenone and tri-*p*-tolyl isocyanurate-pyridine were unsuccessful.

The complex was stable for a long period at room temperature under reduced pressure, but it decomposed to the original two components on being heated above 100°C in vacuo. When the complexes of triphenyl isocyanurate-DMF and tri-*p*-methoxyphenyl isocyanurate-benzene were submitted to thermogravinometric analysis, there was observed a weight loss corresponding to the amount of the solvent in the complex in the temperature range from 70 to 150°C. The complexes show the melting points of the original triaryl isocyanurates because of the liberation of the solvents by the heating.

Experimental

Triaryl Isocyanurates.—Triphenyl isocyanurate (m. p. 280°C), tri-*p*-tolyl isocyanurate (m. p. 264°C), tri-*p*-methoxyphenyl isocyanurate (m. p. 260°C), and tri-*p*-chlorophenyl isocyanurate (m. p. 318°C) were prepared by the method given in the literature.[2]

1 : 1 Complexes of Triaryl Isocyanurates with Solvents.—The data of the elemental analysis and the characteristic infrared absorption bands are listed in Table I and Table II respectively. They were prepared by the same procedure. A typical synthesis is described below.

The Synthesis of the Triphenyl Isocyanurate-DMF Complex.—Triphenyl isocyanurate (0.5 g.) was treated with boiling DMF (15 ml.) for 2 hr. After the reaction mixture had cooled, the DMF was removed by distillation under reduced pressure. The colorless crystals which were then precipitated were washed with ether. Yield, 83%.

Studies on Amino-hexoses. X. A Synthesis of *p*-Acetaminophenyl *N*-Acetyl-β-muramide

By Satoko ISEMURA and Yoshio MATSUSHIMA

Department of Chemistry, Osaka University, College of Science, Toyonaka

(Received April 2, 1966)

Lysozyme, the enzyme which exerts a bacteriolytic influence, has been found to split the bacterial cell-wall mucopeptides at the site of the glycosidic bond of the *N*-acetyl muramic acid component.[1] However, the substrate specificity of the enzyme is not very clear because of the complexity of the chemical structure of the mucopeptides. Lysozyme is also known to split the glycosidic bonds of chitin[2] and glycol chitin[3], both of which have no *N*-acetyl muramic acid as a component. The present work has been undertaken as a part of the project for the elucidation of the substrate specificity of lysozyme. The course of the synthesis of the model substrate (Fig. 1) followed basically the method reported by one of the present authors.[4] *p*-Nitrophenyl *N*-acetyl-β-D-glucosaminide (I)[5] was reduced to the *p*-aminophenyl compound (II), which was converted to the *p*-acetaminophenyl compound (IV) by acetylation and *O*-deacetylation. The benzylidene derivative of IV was condensed with L-α-chloropropionic acid, and the product, after mild acid hydrolysis, was the desired *p*-acetaminophenyl *N*-acetyl-β-muramide. The methyl ester was obtained by methylation with diazomethane. Egg-white lysozyme revealed no activity on either of these model substrates.

Experimental

p-Aminophenyl 2-Acetamido-2-deoxy-β-D-glucopyranoside (II).—I (4.4 g.) and 32 g. of ferrous sulfate hydrate ($FeSO_4 \cdot 7H_2O$) were suspended in 600 ml. of water, and then 2 ml. of 2 N hydrochloric acid was added. The suspension was stirred and heated to 60°C. Eight milliliters of concentrated ammonium hydroxide (ca. 28%) was added in one portion, and then three 3 ml. portions of ammonium hydroxide were added at two-minute intervals. After the mixture had been stirred for fifteen minutes, the precipitates were removed by filtration and the filtrates were concentrated in vacuo. The concentrate was extracted with methanol, evaporated, and desalted by passing it through a column of Dowex-1 (OH^- form). The eluate was concentrated in vacuo, and the residue was recrystallized from ethanol, giving 2.7 g. (67%) of colorless crystals which melted at 225—228°C (uncorr.). $[\alpha]_D^{16}$ +7.6° (*c* 0.92, water).

Found: C, 53.87; H, 6.80; N, 8.80. Calcd. for $C_{14}H_{20}O_6N_2$: C, 53.84; H, 6.45; N, 8.97%.

p-Acetaminophenyl 2-Acetamido-3,4,6-tri-*O*-acetyl-2-deoxy-β-D-glucopyranoside (III).—II (5.8 g.) was dissolved in a mixture of 60 ml. of acetic anhydride and 60 ml. of pyridine. The temperature of the reaction mixture was raised to 50°C in ten minutes, and then the mixture was poured into ice water. The crystalline product was collected by filtration and was recrystallized from ethanol. The colorless crystals thus obtained weighed 5.6 g. (63%) and melted at 245°C (uncorr.). $[\alpha]_D^{16}$ −40.3° (*c* 0.92, pyridine).

Found: C, 55.04; H, 5.83; N, 5.79. Calcd. for $C_{22}H_{28}O_{10}N_2$: C, 54.99; H, 5.87; N, 5.83%.

p-Acetaminophenyl 2-Acetamido-2-deoxy-β-D-glucopyranoside (IV).—III (3 g.) was dissolved in 75 ml. of absolute methanol. After the addition of 3 ml. of 1 N sodium methoxide, the solution was shaken for several minutes. A de-*O*-acetylated product separated and was collected and recrystallized from methanol, giving 1.5 g. (68%) of colorless crystals which melted at 236—237°C (uncorr.). $[\alpha]_D^{16}$ +6.1° (*c* 1.02, water).

Found: C, 54.01; H, 6.13; N, 7.79. Calcd. for $C_{16}H_{22}O_7N_2$: C, 54.23; H, 6.26; N, 7.91%.

p-Acetaminophenyl 2-Acetamido-4,6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside (V).—IV (3.2 g.), 40 ml. of freshly-distilled benzaldehyde and 3.2 g. of anhydrous zinc chloride were shaken together in a closed bottle for 24 hr. The reaction mixture was then poured into ice water, and the insoluble material was separated from the water layer by decantation. The product gave, after it had been washed with petroleum ether and recrystallized from ethanol, 2.8 g. (70%) of colorless crystals which melted at 258—262°C (uncorr.). $[\alpha]_D^{16}$ −10° (*c* 1.83, dimethylformamide).

Found: C, 62.01; H, 6.08; N, 6.26. Calcd. for $C_{23}H_{26}O_7N_2$: C, 62.43; H, 5.92; N, 6.33%.

p-Acetaminophenyl 2-Acetamido-4,6-*O*-benzylidene-3-*O*-(D-1'-carboxyethyl)-2-deoxy-β-D-glucopyranoside (VI).—V (2.7 g.) was dissolved in 105 ml. of freshly-distilled dimethylformamide, and the mixture was heated to 30°C. Sodium hydride (0.7 g., suspended in mineral oil at ca. a 50% concentration) was added, and the mixture was stirred for one hour. After the reaction temperature had been raised to 40°C, 3.8 g. of L-α-chloropropionic acid was added, and then 2.8 g. more of sodium hydride was added after 30 min. Stirring was continued overnight without applying any exteranl heating. Water was added in order to decompose the excess sodium hydride, and the mixture was concentrated in vacuo. The concentrate was dissolved in water, and the solution, after it had been washed with chloroform, was made acidic (pH

2.8) by adding hydrochloric acid while the mixture was kept at the temperature of ice water. The precipitates were collected and recrystallized from ethanol, giving 1.4 g. (43%) of colorless crystals which melted at 248—250°C (uncorr.). $[\alpha]_D^{16}$ +15.4° (*c* 0.72, dimethylformamide).

Found: C, 58.73; H, 6.30; N, 5.05. Calcd. for $C_{26}H_{30}O_9N_2 \cdot H_2O$: C, 58.64; H, 6.06; N, 5.26%.

The hydrochloric acid hydrolysis of VI gave a product which showed a spot identical to that of muramic acid on a paper chromatogram with the solvent system of phenol-water (75 : 25). VI showed an absorption band at 1740 cm^{-1} in the infrared spectrum, a band due to carboxyl carbonyl.

***p*-Acetaminophenyl 2-Acetamido-3-*O*-(D-1'-carboxyethyl)-2-deoxy-β-D-glucopyranoside (VII).**—In the 67% acetic acid, VI was boiled for ten minutes. After the solution had then been evaporated in vacuo, there remained a syrup which failed to crystallized.

***p*-Acetaminophenyl 2-Acetamido-3-*O*-(methyl-D-1'-ethylcarboxylate)-2-deoxy-β-D-glucopyranoside (VIII).**—An ethereal solution of diazomethane was dropped into the methanol solution of VII until a persistent yellow color remained. After evaporation in vacuo, the residual syrup was dissolved in a small amount of methanol; the mixture was then allowed to stand at −20°C. The crystals thus obtained were recrystallized from methanol, giving a specimen which melted at 210—213°C (uncorr.). $[\alpha]_D^{16}$ +17° (*c* 0.94, methanol).

Found: C, 54.03; H, 6.54; N, 5.93. Calcd. for $C_{20}H_{28}O_9N_2$: C, 54.54; H, 6.41; N, 6.36%.

On the Relative Rate of Energy Transfer from the Excited Argon Atom

By Masaru NISHIKAWA and Niro MATSUURA

Department of Pure and Apllied Sciences, College of General Education, University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received April 15, 1966)

A reduction in the spark-breakdown potential[1] and the starting potential for the glow discharge in neon by small traces of argon[2] has long been recognized; it is often called the Penning effect. A similar effect of a contaminant gas in reducing W-values upon the ionization of rare gases under irradiation has been interpreted as resulting from energy transfer from the excited species of the latter, leading to the subsequent ionization of the former.[3] The effect has been employed in a sensitive detector for gas chromatography. Recently, Collinson et al. studied the effect in the argon butane system from the viewpoint of radiation chemistry in an electric field,[4] in which it was necessary for them to evaluate the relative rate constant for energy transfer, $k_8/(k_{2a}+k_{2b})$, as in their terminology;

$$Ar^*+B \rightarrow Ar+B^++e^- \quad (2a)$$

$$Ar^*+B \rightarrow Ar+(\text{uncharged species}) \quad (2b)$$

$$Ar^*+Ar \text{ (or wall)} \rightarrow Ar+Ar \text{ (or wall)} \quad (8)$$

They estimated the value from the known relative rate,[3] 4000, for the ionization of argon in trace amounts by metastable neon atoms to the de-excitation of the latter by ground-state neon atoms, together with the correction for the difference in cross-sectional areas for the various species. Thus, $k_8/(k_{2a}+k_{2b}) = (1/4000) \times (\sigma_{Ar}^2/\sigma_{Ne}\cdot\sigma_B)$, which, when suitable figures are supplied, yields 6000 as the value.

The objective of the present note is to show that the rate can be obtained also from their own data on ion current measurements.

In their system primary electrons produced by the action of radiation are accelerated to an energy capable of exciting argon to metastable states;

$$e^- \rightarrow e_{en}^- \quad (5)$$

$$e_{en}^- + Ar \rightarrow Ar^* + e^- \quad (6)$$

Let a "primary" electron - accelerated in the field between each collision - produce α metastable atoms per cm. of its path in field direction. Of the α metastable atoms,[5] a fraction proportional to $k_{2a}[B]/\{(k_{2a}+k_{2b})[B]+k_8[A]\}$ enters into Reaction 2a. Thus the increase in the number of electrons along the length, dx, is $N_x\cdot\alpha\cdot dx\cdot k_{2a}[B]/\{(k_{2a}+k_{2b})[B]+k_8[A]\}$ per N_x electrons. By intergrating from $x=0$ to $x=d$;

$$N/N_0 = i/i_0 = \exp(\alpha\cdot d\cdot k_{2a}[B]/\{(k_{2a}+k_{2b})[B] + k_8[A]\})$$

where N_0 is the number of electrons per sec., and i_0, the current produced initially by irradiation. This is essentially the equation for Townsend discharge,[6] as Collinson et al. noted, although they used a different (but equivalent) expression. If the equation applies to the present case, the plot of $1/\ln(i/i_0)$ vs. [A]/[B] should give straight lines, whose slope-to-intercept ratio should then yield the desired relative rate. The data of i/i_0 read from their Fig. 3, at least the initial portion of the curves where [B] is sufficiently small,[7] are shown to lie on straight lines in Fig. 1. The relative rate

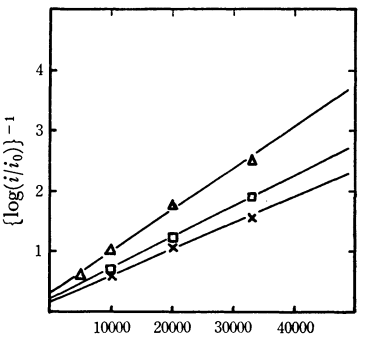

Fig. 1. Plot of $\{\log(i/i_0)\}^{-1}$ vs. [A]/[B]
Field strength; △, 3900 V./cm., □, 4800 V./cm., ×, 5700 V./cm.
(Read from Fig. 3 of Ref. 4.)

thus obtained is approximately 4500, this is in agreement with Collinson's estimation for any one of straight lines, and so seems to indicate the validity of the treatment. The value is of the same order as that of 2270 obtained recently by Lipsky when

4) E. Collinson, J. F. Todd and F. Wilkinson, *Discussions Faraday Soc.*, **36**, 83 (1963).
5) This statement only applies to the case where [B] is sufficiently low compared with [A]. At higher [B], e^- collides with B suppressing electron-multiplication sequence.
6) A. von Engel, "Ionized Gases," 2nd Ed., Chapter 7, Oxford University Press, London (1965).
7) See Ref. 5.

no electron multiplication occurs.[8] The agreement can be said to be fair if a large difference in the experimental conditions and the lack of exact data are taken into consideration. The larger value estimated in this paper may be due to the drastic change in conditions where electron multiplication predominates, and/or to the larger ion current measured by Collinson et al., which, as is pointed out by Lipsky, might be caused by the higher drift velocity of electrons in the presence of polyatomic contaminant than in that of pure argon. Corrections for the latter effect are expected to alter the value to bring it closer to Lipsky's value.

A similar study is now in progress with the Ar-NH_3 system, partly in connection with the sensitized production of hydrazine; the results will be published elsewhere.

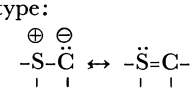
The Stereochemistry of Sulfoxide in the Base-Catalyzed Hydrogen-Isotopic Exchange of Aryl-Methyl Sulfoxide[1]

By Yong-He KHIM, Waichiro TAGAKI, Masahiro KISE, Naomichi FURUKAWA and Shigeru OAE

Department of Applied Chemistry, Faculty of Engineering, Osaka City University

(Received April 23, 1966)

Because of the possible 3d orbital resonance of the following type:



the base-catalyzed hydrogen-isotopic exchange of the methyl or methylene group attached to a trivalent or tetravalent sulfur group has been known to take place very readily,[2] and the stereochemistry of both the sulfone and the sulfoxide stabilized carbanions have been pretty well worked out.[3,4]

When the incipient carbanion is presumed to be stabilized by a trivalent sulfur group, such as sulfinyl or sulfonio, an interesting problem is raised regarding the stereochemistry at the sulfur atom attached to the carbanion if one uses an optically-active sulfur group. A study of this kind would be quite significant, since it would answer the hitherto often-argued question of whether or not the π-bond between the sulfur atom and the carbon atom is of the 2p-3p overlapping type, with the promotion of the unshared outer valence electrons on the sulfur atom to a d-orbital, or if the π-bond is of the 2p-3d overlapping type.[5] That is, if the π-bond is of the 2p-3p overlapping type, the carbanion formation will result in the racemization of the trivalent sulfur group, while the retention of the configuration of the sulfur group will be observed if the carbanion is stabilized by a 2p-3d overlapping-type conjugation. Recently Cram et al. have observed a complete retention of the configuration of the sulfoxide group in the base-catalyzed racemization of optically-active 2-octyl phenyl sulfoxide, that has two asymmetric centers.[3c] We have chosen a simpler system, but with only one asymmetric center, namely, (+)-*p*-toly methyl sulfoxide, we have found that the base-catalyzed hydrogen isotopic exchange does not accompany the racemization of the sulfoxide group.

An optically-active *p*-tolyl methyl sulfoxide was prepared from the reaction of optically-active (−)-menthyl (−)-*p*-toluenesulfinate with methylmagnesium iodide[6] and was then subjected to base-catalyzed hydrogen isotopic exchange in various solvents in order to examine the possible racemization, along with the H–D exchange on the methyl group attached to the sulfoxide.

The solvents used were ethanol-d_1, *t*-butanol-d_1, and dimethyl sulfoxide. Ethanol-d_1 and *t*-butanol-d_1 were prepared from the reaction of deuterium oxide with sodium ethoxide and potassium *t*-butoxide respectively.[7]

TABLE I. THE BASE-CATALYZED HYDROGEN-DEUTERIUM EXCHANGE AND RACEMIZATION REACTION OF *p*-TOLYL METHYL SULFOXIDE

Sulfoxide	Solvent	Base	Molar ratio[a]	Temp. °C	Time hr.	H-D[b] Exchange %	$[\alpha]_D$
	C_2H_5OD[d]	C_2H_5ONa	(1 : 5 : 0.5)	30—35	15	60	+152°
	C_2H_5OD[d]	C_2H_5ONa	(1 : 10 : 0.5)	105—110	15	66	+148.7°
	$(CH_3)_3COD$[e]	$(CH_3)_3COK$	(1 : 10 : 0.5)	105—110	15	20	+149°
	$(CH_3)_2SO$	$(CH_3)_3COK$	(1 : 15 : 2)	105—110	15	—	+148.2°
	$(CH_3)_2SO$	$(CH_3)_3COK$	(1 : 20 : 5)	130—135	20	not recovered[f]	

a) The molar ratio is starting sulfoxide : solvent : base.
b) The deuterium contents were analyzed by means of infrared and nuclear magnetic resonance spectroscopy.
c) $[\alpha]_D^{25}$ +152.3° (*c* 2.68, ethanol).
d) Deuterium content: 70%.
e) Deuterium content: 60%.
f) The starting sulfoxide seems to be decomposed.

The sulfoxide was recovered quantitatively, and from its melting point, ultraviolet absorption, infrared and nuclear magnetic resonance spectroscopic analyses it was found to be identical with the starting sulfoxide, except that the sulfoxide recovered was found to have incorporated a considerable amount of deuterium at the methyl group. However, the sulfoxide was found to have retained its configuration completely. The experimental conditions and the results are shown in Table I.

Although a substantial hydrogen isotopic exchange was observed to occur at the *p*-methyl group at a high temperature and with a prolonged heating, only a very small amount of hydrogen isotopic exchange at the para methyl group was observed when the reaction was performed under the relatively mild conditions in which a substantial amount of hydrogen isotopic exchange was found to take place at the other methyl group.

Moreover, the configuration around the sulfur atom of the trivalent sulfur group is retained regardless of any change in the solvent used.

These observations appear to suggest strongly that the carbanion attached to a trivalent sulfur group such as sulfoxide is stabilized by the resonance involving the 2p-orbital of carbon and the 3d-orbital of sulfur.

Experimental

(−)-Menthyl (−)-*p*-Toluenesulfinate.—The sulfinate was prepared, according to the method reported by Mislow et al.,[6] from 18.8 g. of (−)-menthol and 21 g. of *p*-toluenesulfinyl chloride[8] to give 8 g. of (−)-menthyl (−)-*p*-toluenesulfinate. (60%) M. p. 105—106°C; $[\alpha]_D^{20}$ −201° (*c* 2.0, acetone).

(+)-*p*-Tolyl Methyl Sulfoxide.[6]—To a solution of (−)-menthyl (−)-*p*-toluenesulfinate (6.2 g.) in anhydrous ether (50 ml.), an ether solution of methyl magnesium iodide (prepared from 5.36 g. of methyl iodide and 1.02 g. of magnesium was added drop by drop at room temp. After it had been stirred for an hour, the reaction mixture was quenched with aqueous ammonium chloride. The ether layer was separated, washed with water, and then dried over mangesium sulfate. After the ether had been removed, the residue was cooled in an ice bath, then the precipitate was filtered to give crude (+)-*p*-tolyl methyl sulfoxide, which was recrystallized from *n*-hexane. (3.0 g., 92%) M. p. 75—76°C; $[\alpha]_D^{25}$ +152.3° (*c* 2.0, ethanol). Lit.[6] m. p. 73—74°C; $[\alpha]_D^{25}$ +145.5° (*c* 2.0, acetone).

The Base-catalyzed Hydrogen-deuterium Exchange and Racemization Reaction of (+)-*p*-Tolyl Methyl Sulfoxide.—The H–D exchange and racemization reaction of the sulfoxide was performed using both C_2H_5OD and *t*-BuOD as solvents. The bases used were sodium ethoxide and potassium *t*-butoxide. Ethanol-*O*-*d* and *t*-butanol-*O*-*d* were prepared from the corresponding alkoxides with deuterium oxide.[7] The deuterium contents were determined by means of infrared and NMR studies. The D content was about 70%. A typical run was as follows: optically active (+)-*p*-tolyl methyl sulfoxide (0.3 g.) and sodium ethoxide (0.052 g.) were dissolved in ethanol-*O*-*d* (0.46 g.) and sealed in a glass ampoule. The ampoule was then heated in an oil bath at 105—110°C. After it had been heated for 15 hr., the reaction mixture was evaporated and the sulfoxide was recovered by extracting it with ether. (0.2 g., m. p. 75—76°C from *n*-hexane.) The optical activity of the recovered sulfoxide was checked by using a polarimeter and found to be $[\alpha]_D^{25}$ +148.7° (*c* 2.68, ethanol). The deuterium content of the methyl group attached to the sulfoxide was determined by NMR spectra.

Found: 60—66% (τ=7.27 singlet.).

When DMSO was used as a solvent, the racemization reaction of the sulfoxide was carried out with only one base, namely, potassium-*t*-butoxide.

The authors are grateful to Professor Toshiro Miwa for his collaboration in the NMR study.

SHORT COMMUNICATIONS

Ethylenediamine Conjugates of Bis-*O*-carboxymethylsalicylaldehyde-alkylenediimine-copper*

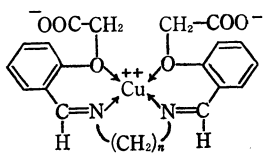
By Tsuguo TANAKA, Shigeharu KONO,** Keiko MIYAHARA and Kazuko KATSUKI

Department of Science and Technology, Saga University, Honjo, Saga

(Received June 23, 1966)

The isolation and the structures of the penta-coordinate addition compounds of bis-salicylaldehyde - ethylenediimine - copper with acids and phenols have previously been reported.[1] Therefore, it now seems of interest to synthesize some side-chain acid bis-salicylaldehyde-ethylenediimine-copper substances and examine their chemical behavior.

Yellow - green bis - *O* - carboxymethylsalicylaldehyde - ethylenediimine-copper (I, $n = 2$) - $2H_2O$, (Found: C, 49.80; H, 4.83; N, 5.71; Cu 13.36. Calcd. for $C_{20}H_{18}N_2O_6Cu$-$2H_2O$: C, 49.84; H, 4.60; N, 5.68; Cu, 13.19%.) was synthesized through copper salt of *O*-carboxymethylsalicylaldehyde. Found: C, 47.13; H, 4.13, Cu, 13.86. Calcd. for $C_{18}H_{14}O_8Cu$-$2H_2O$: C, 47.20; H, 3.69; Cu, 13.88%.



(I, *n*)

The 1660 cm^{-1} peak in its infrared spectra as well as the 830 mμ absorption maximum in its visible spectra support a partially-polarized[2] ionic structure.[3]

Ethylenediamine conjugate (II, $n=2$) was obtained by the reaction of (I, $n=2$) with two moles of ethylenediamine in an alcoholic solution.

The analytical results (Found: C, 46.72; H, 6.49; N, 13.95; Cu, 10.34. Calcd. for $C_{24}H_{36}N_6O_7Cu$-$3H_2O$: C, 45.16; H, 6.63; N, 13.17; Cu, 9.96%.) and the titration curve (Fig. 1) substantiate the formula, [(I, $n=2$)-$2C_2H_4(NH_2)_2$-$H]^+(OH)^-$-$3H_2O$, of the ethylenediamine conjugate (II, $n=2$). The 1578 cm^{-1} peak of the prefectly-ionized carboxylate ion[4] in the infrared spectra and the 570 mμ absorption maximum in the visible region, unlike those of the chelate (I, $n=2$), reveal the structural difference between (I, $n=2$) and (II, $n=2$). By dehydration (II, $n=2$) changes, by way of a blue modification (weight decrease; Found: 8.35%. Calcd. for $3H_2O$: 8.47%), into a green compound (weight decrease: Found; 11.1%; Calcd. for $4H_2O$: 11.3%), which, in dry air or in an oxygen atmosphere, changes into a gray modification (III, $n=2$) (weight increase: 2.56—2.96% and, slowly, 3.6—4.0%).

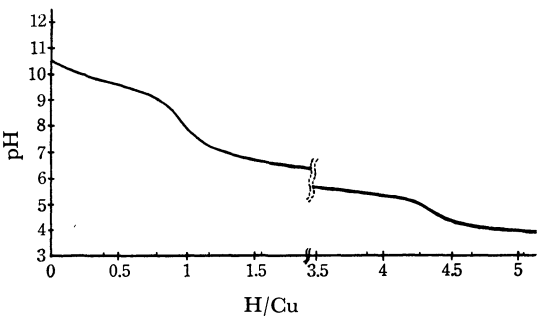


Fig. 1. Titration of (II, $n=2$), 186.67 mg. in 50 ml. H_2O, titrated with 1.0 N HCl ($f=1.135$).

Several bis-*O*-carboxymethylsalicylaldehyde-alkylenediimine-copper (II, $n=2$—6)-$2H_2O$ substances and their ethylenediamine conjugates (II, $n=2$—6) are given in Table I.

Table I. Bis-*O*-carboxymethylsalicylaldehyde-ethylenediimine-copper (I, *n*)-$2H_2O$ and their ethylenediamine conjugate (II, *n*)

The Micro Determination of Palladium with *p*-Ethoxy-chrysoidine

By J. P. TANDON and S. S. GOYAL

Department of Chemistry, University of Rajasthan, Jaipur, India

(Received August 2, 1966)

The use of a number of chromogenic reagents in the determination of platinum metals has been reported. For instance, Grigore Popa and his co-workers[1] described the spectrophotometric determination of palladium with chrysoidine within the range from 1 to 15 μg. palladium/ml. In the present investigations, the use of *p*-ethoxy-chrysoidine, which contains the chromogenic group ($-OC_2H_5$), in the spectrophotometric determination of palladium will be described; it will be shown to be more sensitive than chrysoidine.

The absorption spectra of the dye and palladium complex are shown in Fig. 1. The maximum difference in absorbance (Δ-absorbance) between the dye and the palladium complex is found at 465 mμ at pH 2.2. The complex is formed by adding 0.5 ml. of a 0.002 M palladium solution to a mixture of 10 ml. of a sodium acetate - hydrochloric acid buffer solution (pH 2.2) and 1.0 ml. of a 0.002 M dye solution in a 50-ml. volumetric flask. The solution is then diluted to the mark with double-distilled water and mixed thoroughly. A dye blank is also prepared under similar conditions. The Δ-absorbance between the dye blank and the palladium complex is at its maximum in the 2.0—2.4 pH range. The colour under these conditions develops instantaneously and is stable for at least one hour. There is no variation in the Δ-absorbance over the temperature range of 15—45°C. The presence of excess palladium, however, helps in the coagulation of the complex.

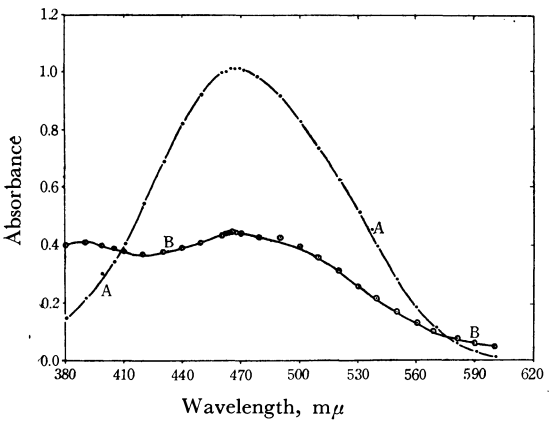

Fig. 1. Absorption spectra. pH 2.2
A: Reagent (4×10^{-5} M), against water
B: Reagent (4×10^{-5} M) + Pd (2×10^{-5} M), against water

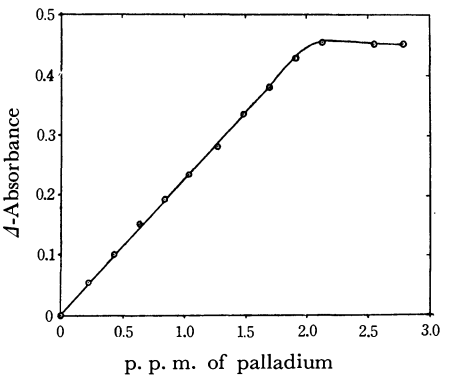

Fig. 2. Beer's law curve. pH 2.2

Beer's law holds over the 0—1.9 p. p. m. palladium/ml. range at 465 mμ (Fig. 2); the molar absorptivity is 2.5×10^4, and the sensitivity is 0.004 μg. palladium/cm^2, corresponding to $\log I_0/I = 0.001$.

Composition studies by Vosburgh and Cooper's method[2] and by the slope-ratio method[3] indicate the formation of only one compound, with a ratio of palladium to dye of 1 : 2.

Further, more detailed studies are now in progress.

The Hydrogen Isotope Effects Arising from the Reaction of Hydrated Electrons

By Shin-ichi OHNO

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki

(Received August 23, 1966)

The measurement of hydrogen isotope effects has been applied to the elucidation of the reactions occurring during the radiolysis of water.[1-3] The question still remains unclear, however, because of the complicated set of reaction processes involved. This communication will present the isotope effect in the formation of H atoms arising from the reaction between e^-_{aq} and proton donors.

In a H_2O-D_2O mixture containing 1 M methanol, the photochemically-produced electron from 10^{-3} M $K_4[Fe(CN)_6]$[4] reacts with the added solute, SH:

$$e^-_{aq} + SH \rightarrow \begin{matrix} H + S^- \\ \searrow \\ D + S^- \end{matrix} \qquad (1)$$

The hydrogen atoms thus produced, H and D, react with CH_3OH to yield H_2 and HD respectively, the observed value of (H_2/HD) giving directly the hydrogen atom ratio, $(H/D)_a$, arising from Reaction 1. The separation factors defined by $S=(H/D)_a/(H/D)_{solvent}$ are given in Table I. The value for the hydrogen ion (H_2SO_4) confirms the values previously arrived at using radiation chemical data.[2,3] The hydrogen ion exists as H_3O^+, HD_2O^+, H_2DO^+ and D_3O^+; the estimated fraction of each species can be obtained from the literature.[5]

Table I. Isotope separation factors for the hydrogen atom formation from some solutes

[SH]	pH	S
0.01—1.2 N H_2SO_4	—	3.5±0.2
0.01—0.2 M KH_2PO_4	—	7.7
0.5—1 M NH_4Cl	—	11.0
0.1—0.8 M HCN, KCN	7.4—9.0	1.8
0.1—0.36 M H_3BO_3, $Na_2B_4O_7$	7.2—7.5	10.4

On the assumption that each species has an equal probability of reaction with e^-_{aq}, one can compute the relative rate of bond breaking, (k_H/k_D), where:

$$e^-_{aq} + HD_2O^+ \begin{matrix} \xrightarrow{k_H} H + D_2O \\ \xrightarrow[k_D]{} D + HDO \end{matrix}$$

An Arrhenius plot of $\log(k_H/k_D)$ vs. $1/T$ (the data of Table II) gave a value of 1340±20 cal. mol^{-1} for the difference in the activation energy of O–H and O–D bond fission in the hydronium ion. This value is close to the value (~1200 cal. mol^{-1}) which the infrared evidence gives[6] for the difference in zero-point energy between O–H and O–D bonds in the hydronium ion. One may further predict that the activation energy for the reaction of e^-_{aq} with D_3O^+ is about 4.5 kcal. mol^{-1}, since the pulse radiolysis study[7] has shown that the activation energy for the reaction, $e^-_{aq}+H_3O^+$, equals 3.2 kcal. mol^{-1}.

Table II. The effect of temperature on the isotope effect in the case of hydrogen ion

Temp., °C	2.0	10.4	21.6	30.2	40.8

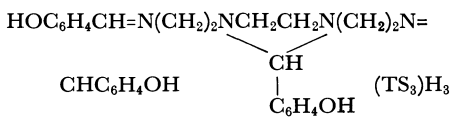
A Schiff base,



from triethylenetetramine and salicylaldehyde was reported as a multidentate ligand by Mukkerjee.[1] Sarma et al.[2,3] have found that when the base, $(TS_3)H_3$, reacts with such metal ions as cobalt(III), iron(III), manganese(III), gallium(III), aluminum(III), cobalt(II), nickel(II) and copper(II), one molecule of salicylaldehyde is hydrolyzed and a metal complex of a sexadentate ligand, HOC_6H_4-$CH{=}N(CH_2)_2NH(CH_2)_2NH(CH_2)_2N{=}CHC_6H_4$-OH $(TS_2)H_2$, is formed. No metal complexes of TS_3 have ever been obtained as pure crystals, in spite of the elaborated investigations.

In this paper we report the preparation of a metal complex of $(TS_3)^{3-}$ using lanthanum(III) ion as a central metal.

White crystals, which were prepared from lanthanum(III) perchlorate and $(TS_3)H_3$ in methanol, were found by the elementary analysis to have the formula of $La(TS_3)$ (Found: C, 54.23; H, 4.63; N, 9.50; La, 23.2. Calcd. for $LaC_{27}H_{27}N_4O_3$: C, 54.55; H, 4.58; N, 9.42; La, 23.3%). The infrared spectrum supported our present conclusion, since no N–H, O–H and ClO_4^- bands were observed in 3500—3000 and 1100 cm^{-1} region. Although this ligand has seven coordination atoms, it is sterically impossible for this ligand to form a heptadentate chelate with one metal ion. The molecular weight determination by the use of the "Vapor Pressure Osmometer" has shown that this compound is dimeric, and the structure as shown in Fig. 1 is assumed as the most probable one.

It appears that the formation of TS_3 complex is due to the fact that the coordination number and coordination place are not so rigid in lanthanide(III) ions as in other metal ions, since metal-ligand linkage of the lanthanum(III) complex is mainly ionic and the ionic radius of lanthanum(III) ion is relatively large.

The preparation of similar complexes of a series of lanthanide ions is in progress. The results will be reported shortly with the more detailed discussion on the structures of this type of compounds.

Solvent Effects on Charge-transfer Spectra with Implications for the Electron-transfer Reaction in the Excited State

By Noboru MATAGA, Tadashi OKADA and Noriyuki YAMAMOTO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received September 2, 1966)

The solvent effects on charge-transfer (CT) spectra are very interesting and important in relation to the electronic structures of and electronic processes in the CT complexes. However, there are only a few clear-cut experimental results concerning this problem. The findings of Czekalla and Meyer[1] on the tetrachlorophthalic anhydride-hexamethylbenzene complex seem to be very important in establishing the mechanism of CT interaction. However, their experimental findings appear to be somewhat complicated by the fluorescence spectra arising from some unknown impurities in the polar solvents.

We have found another very clear-cut example of a very large solvent dependence of the CT fluorescence spectrum at room temperature. It is the pyrene - *N*, *N*-dimethylaniline 1 : 1 complex, which is formed only in the excited electronic state.[2] We have made detailed studies of the electronic structure of the complex, of the complex formation, and of the decomposition processes, by measuring the fluorescence quantum yields and the fluorescence rise and decay curves.

The wave numbers of the band maxima of the CT fluorescence are shown in the table, where ε is the static dielectric constant and n_D is the refractive index of the solvent for the sodium D line. In contrast to the case of the CT absorption spectra,[3] where the values of $\tilde{\nu}_m$ depend on the optical dielectric constant, the $\tilde{\nu}_m$ values in the present case are primarily connected with the static dielectric constant of the solvent. This result is a direct consequence of the very polar structure of this complex in the excited state. The lifetime of the fluorescent state of this complex is very long (ca. 150 ns in *n*-hexane and toluene solutions), according to our measurements. Therefore, the equilibrium state with respect to the solute-solvent interactions may be reached completely during the lifetime of the excited state.

Accordingly, we may be able to apply the ordinary theories of the solvent effect to the present system. The dipole moment of this complex in the excited state has been estimated to be ca. 10 *D* in such slightly or moderately polar solvents as benzene, toluene, and monochlorobenzene. However, in more polar solvents, such as dichloroethane and pyridine, we have observed considerable deviations from the simplified theories; this indicates a large increase in the dipole moment of the complex due to the interactions between the solute and surrounding polar solvent molecules. Moreover, in the even more polar solvent, benzonitrile, the fluorescence yield is very small and the $\tilde{\nu}_m$ value is a little larger than those in the case of pyridine and dichloroethane solutions.

It seems that these findings for the benzonitrile solution can be interpreted as follows. Because the distance between the pairs in the complex may be considerably large as a result of the strong solvation by the polar solvent molecules, the delocalization interaction between them may be rather small, leading to the smaller red shift of the fluorescence. Furthermore, the rather strong fluorescence quenching in benzonitrile may cause a considerable shortening of the excited-state lifetime. Accordingly, the equilibrium state of the solute-solvent interactions might not be established during the lifetime of the fluorescent state.

These results indicate the importance of the higher-order effects of solute-solvent interactions in the case of CT complexes, effects which finally induce electron transfer and complete ionic dissociation, leading to complete fluorescence quenching in such strongly polar solvents as acetonitrile and alcohols.[2]

TABLE I. WAVE NUMBERS OF THE FLUORESCENCE BAND MAXIMA

Solvent	n_D	ε	$\tilde{\nu}$ (10^4 cm^{-1})
n-Hexane	1.37486	1.89	2.30
p-Xylene	1.49581	2.270	2.17
Benzene	1.5011	2.284	2.15
Toluene	1.49413	2.379	2.14
Monochlorobenzene	1.52481	5.621	2.09

The Luminescence of the Heteropolar Excimer in the Cyclohexane Matrix

By Noboru MATAGA, Tadashi OKADA and Hiroo OOHARI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka Osaka

(Received September 2, 1966)

It has been established now that many aromatic hydrocarbons, such as pyrene, perylene, anthracene, chrysene, phenanthrene, and triphenylene, form stable complexes with such aromatic amines as *N*, *N*-dimethylaniline (DMA), *N*, *N*-dimethyltoluidines (DMT's), and *N*, *N*-dimethylnaphthylamines (DMNA's) only in the excited state.[1] The most important contribution to the intermolecular forces in these complexes seems to be charge transfer from the amine to the excited aromatic hydrocarbon.

Because the complexes are formed only in the excited state, it may be convenient to call the complex the "heteropolar excimer" in contrast to a "homopolar excimer" such as the pyrene excimer, in order to distinguish it from the ordinary CT complex which exists in the ground state as well as in the excited state.

In order to study the electronic processes in the heteropolar excimer at low temperatures, we have measured the fluorescence emission and excitation spectra, and also the fluorescence rise and decay curves. From the results of these measurements, we have confirmed that the heteropolar excimer can be produced easily in the rigid cyclohexane matrix at low temperatures. For example, in the pyrene (10^{-5} mol./l.)-DMA(10^{-2} mol./l.) system, only the long-wavelength and structureless fluorescence band, which seems to be ascribed to the heteropolar excimer, can be observed from 300°K to 77°K. However, when the temperature is lowered, the fluorescence band maximum shifts to red at first, and then makes a blue shift to approximately the same position as it has at 300°K, as one can see in the following:

T (°K)	300	273	240	230—210	190—100
λ_{max}(mμ)	440	450	465	480	440

The relative fluorescence yield and the fluorescence decay time change in a similar way; i. e., they both have minima at ca. 220°K. These facts seem to indicate that some state of the heteropolar excimer which differs from that in the solution at room temperature may be forced to arise in the cyclohexane matrix. However, when the DMA concentration is small (10^{-4} mol./l.), the fluorescence of the complex can be observed only at the wavelength region of 440—450 mμ. Therefore, one of the possible mechanisms for the appearance of the longer-wavelength fluorescence might be the formation of a more highly aggregated state than the 1 : 1 complex. In the above-described systems, no time delay of the heteropolar excimer fluorescence from the exciting light pulse (with a half-value-width of ca. 10 ns) was detected, in contrast to the fact that we have observed a time delay of ca. 100 ns in a liquid paraffin solution at room temperature. This fact may suggest that the stable complex is already formed in the ground state. However, the shape of the fluorescence excitation spectra at various temperatures is practically the same as that of the solution at room temperature, where the complex is not formed in the ground state. Accordingly, although the charge transfer interaction in the ground state is very weak, there may be donor-acceptor pairs with such a small distance between them that they can form the heteropolar excimer immediately after excitation.

When aniline, naphthylamines, *N*-methylaniline, and *N*, *N*-dimethylbenzylamine are used as electron donors in a solution at room temperature, contrary to the case where DMA, DMT's, and DMNA's are used as electron donors, we cannot observe any heteropolar excimer fluorescence, but only a quenching of the aromatic hydrocarbon fluorescence. Although the mechanism of this quenching is not very clear at the present stage of the investigation, it seems quite plausible that a charge transfer interaction in the encounter complex, followed by some very efficient, radiationless transition, plays an important role in these cases. Accordingly, if we can stabilize the complex in a rigid matrix at low temperature in order to decrease the probability of the radiationless transition, it might be possible to observe the heteropolar excimer fluorescence even in these cases.

Actually, we have observed the fluorescence spectra of heteropolar excimers of pyrene complexed with *N*, *N*-dimethylbenzylamine, aniline, and *N*-methylaniline at ca. 450—470 mμ in the cyclohexane matrix at low temperatures. However, in the case of these complexes, the fluorescence yield is much smaller than in the case of complexes of pyrene with DMA and DMT's. That is, even at low temperatures in the rigid matrix, the radiationless process is quite predominant in the former complexes compared with that in the latter ones.

More detailed studies, including studies of other heteropolar excimers, will be published in the near future.

The Crystal Structure of Carbazole

By Masayasu KURAHASHI, Makoto FUKUYO and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

and Akio FURUSAKI and Isamu NITTA

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received September 24, 1966)

The analysis has been performed to make clear whether hydrogen bonds N–H···N are formed in carbazole crystal and whether the molecule is planar. Single crystals in colorless plates were obtained by keeping the melted substance slightly below its melting point, 237°C. The crystals are orthorhombic with four molecules in a unit cell of dimensions $a=7.76$, $b=19.15$ and $c=5.74$ Å. The density measured by floatation in sulfuric acid was 1.29 g./cm^3 and the calculated value is 1.31 g./cm^3. The space group was found to be $Pn2_1a$ or $Pnma$. Since Wilson statistics showed the existence of a center of symmetry, it was decided that the corresponding space group was the latter.

Using the multiple-film technique, intensity data were obtained from zeroth-layer Weissenberg photographs around the main axes a, b and c, taken with filtered Cu$K\alpha$ radiation. The intensities of reflexions were estimated visually with a calibrated scale.

The approximate co-ordinates of nitrogen and carbon atoms were obtained by the trial method considering packing. The structure thus obtained was refined initially by electron density projections on (001) and (100) and finally by the least-squares method.

The discrepancy index R calculated with the final least-squares co-ordinates is respectively 0.14 for $hk0$, 0.15 for $0kl$ and 0.14 for $h0l$ if non-observed reflexions were omitted. The final electron density projection along the c-axis and the crystal structure projected on (010) are shown in Fig. 1 and Fig. 2 respectively.

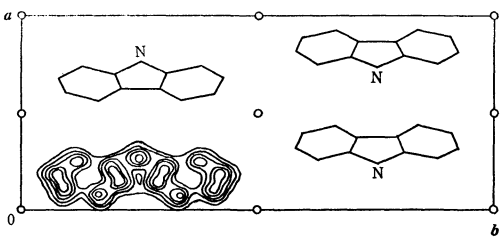

Fig. 1. Crystal structure projected on (001).

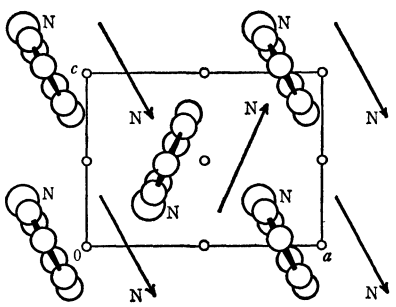

Fig. 2. Crystal structure projected on (010).

Carbazole molecule is planar, and a crystallographic mirror plane normal to the b-axis passes through the N atom and is perpendicular to the molecular plane. The N···N distance is 3.89 Å, and this shows that the hydrogen bond is not formed in the crystal as expected by Aihara[1] (1953) from the measurement of the vapor pressure.

Fluorene[2] crystal takes the same space group as carbazole and resembles closely to that of carbazole in both cell dimensions and atomic parameters. A full paper will be published in the near future.

Vibrational Spectra and Structure of Substituted Unsaturated Carbonyl Compounds. VI. β-Halogeno- and β-Halogenodeuteriovinyl Ketones

By Janusz DABROWSKI and Krystyna KAMIEŃSKA-TRELA

Institute of Organic Chemistry, Polish Academy of Sciences, Warsaw, Poland

(Received March 17, 1966)

The infrared spectra of several chloro-, bromo- and iodovinyl ketones and their partly deuterated derivatives were investigated in the liquid state and in solutions. A Raman spectrum of one of these substances was also obtained. It has been shown that, unlike enamino- and hydroxyvinyl ketones, the title compounds exhibit fairly characteristic absorption bands due to carbonyl and skeletal vibrations. The splittings observed in the double bond stretching region are accounted for by rotational isomerism. Several assignments of the group frequencies are proposed.

It has been shown that β-amino[1-3] and β-hydroxy substituted α, β-unsaturated ketones[4] are characterized by partial equalization of the double and single bonds causing strong coupling of the C=O and C=C stretching vibrations and very large frequency shifts. On the other hand the carbonyl and vinyl bands of the unsubstituted vinyl ketones are less shifted,[5,6] the corresponding vibrations being practically localized. It is therefore, interesting to investigate unsaturated ketones with substitutents of various types in the β position and compare their spectral characteristics with those obtained in the two extreme cases mentioned.

In the present work halogens were the substituents in the β position. In order to obtain as far as possible detailed assignments, all substituents were systematically varied (R–CO–CR′=CR′–X; R= CH_3, C_2H_5, *n*-C_3H_7, *i*-C_3H_7 or *t*-C_4H_9; R′=H or D; X=Cl, Br or I) The $\nu_{C=O}$ and $\nu_{C=C}$ vibrations were found to be practically localized and characteristic. Moreover, a number of vibrations in the fingerprint region are also fairly characteristic as could be established by comparison of the spectra of related compounds; this is particularly distinct in the case of β-chloro, bromo and iodo derivatives of ethyl vinyl ketone (compounds IV, VI and VII, Fig. 1) where large parts of the spectra are almost true copies of each other.

Of particular interest are the band splittings observed within the 1500—1700 cm^{-1} region which have been shown in this study to be caused by rotational isomerism.

Recently a number of β-chlorovinyl ketones were spectroscopically investigated by Benson and Pohland[7]; as already pointed out[8] the resolving power of the apparatus used by these authors must have been insufficient and the significant fact of splitting of the absorption bands was overlooked.

A number of infrared and Raman bands of the parent homologue, i. e. methyl-β-chlorovinyl ketone and three of its deuterated derivatives have been assigned in the previous paper of this series.[8]

Experimental

All substances studied in the present work were prepared according to conventional methods. These are listed in Table I. The syntheses of new compounds are described below.

Alkyl-β-chloro-α, β - dideuteriovinyl ketones were synthesized from deuterioacetylene and acyl chlorides similarly as the nondeuteriated chlorovinyl ketones described previously[9] and purified by threefold distillation:

Ethyl-β-chloro-α, β-dideuteriovinyl ketone (V), b. p. 50—51°C/18mmHg, n_D^{25} 1.4586, yield 68.1%;

n-Propyl-β-chloro-α, β-dideuteriovinyl ketone (IX), b. p. 100°C/60 mmHg, n_D^{25} 1.4609, yield 32.0%

Isopropyl-β-chloro-α, β-dideuteriovinyl ketone (XI), b. p. 75—76°C/43 mmHg, n_D^{25} 1.4582, yield 65.0%.

Spectral purity of the deuteriated species was established by the fact that the bands at 3050—3100 cm^{-1} due to C–H vinyl stretch were absent from all spectra of deuteriovinyl compounds while new bands

due to corresponding C–D vibrations arose at 2260—2300 cm^{-1}.

Ethyl-β-bromovinyl ketone (VI) was prepared according to the method described by Niemirowski and co-workers[10] from 4.3 g. (0.0525 mole) of pentyn-1-one-3 and 14 g. of 41% HBr (0.071 mole, water solution). Yield 5.3 g. (62% theor.). Colourless liquid with b. p. 68°C/16 mmHg, n_D^{25} 1.4961.

Found: C, 37.05; H, 4.44; Br, 48.19. Calcd.: C, 36.84; H, 4.33; Br, 49.03%.

Ethyl-β-iodovinyl ketone (VII) was obtained from 5 g. (0.04 mole), ethyl-β-chlorovinyl ketone and 10 g. (0.067 mole) of sodium iodide in acetone solution in the same manner as described by Kochetkov[11] for other homologues. Yield 8.4 g. (60% theor.); white leaflets with m. p. 32—33°C (from pentane).

Found: I, 60.15%. Calcd.: I, 60.42%.

The solvents were purified by the methods used previously.[2] Measurements were carried out using a Hilger H-800 double-beam spectrometer with sodium chloride and potassium bromide optics. Melted substances were investigated in an electrically heated cell and low-melting, crystalline samples in the low-temperature cell described previously.[2] The spectra

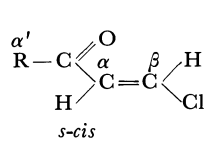
were calibrated with polystyrene and indene.[12] The frequencies are accurate to within ±1—2 cm^{-1}.

Results and Discussion

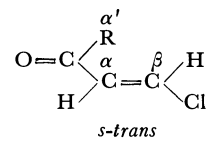
Tables I and II contain spectral data of all compounds examined; in addition representative spectra are depicted in the figures.

The spectra of the great majority of the compounds examined exihibit more peaks in the 1500—1750 cm^{-1} region than expected for molecules containing one C=O and one C=C bond; where only two peaks occur, at least additional shoulders can be observed. The occurrence of these additional absorption bands and/or shoulders cannot be explained by association effects since their intensities are practically independent of concentration. For instance, the relative intensity of the four absorption bands between 1500 and 1700 cm^{-1} in the spectrum of ethyl chlorovinyl ketone remains practically unchanged when the initial 2.4×10^{-1} M solution is diluted to 3.4×10^{-2} M concentration. Besides, the intensity of the band occurring at the lowest of these frequencies increases in hexane solution as compared with pure liquid, while exactly an opposite effect would be expected if association played any role here. *Cis-trans* isomerism can also be excluded in this discussion since β-chlorovinyl ketones were shown by NMR spectra to consist in at least 95% of the trans form[7] and the additional infrared bands are too strong to be caused by small admixtures of other molecules. Moreover substances I, IV and XII were proved by gas-liquid chromatography to be homogeneous in about 99%.

In the previous paper of this series it has been shown that methyl-β-chlorovinyl ketone[8] exists in two rotational forms. No doubt, this is also true for the β-halogenovinyl ketones studied in this work. The present results concerning spectra of several differently substituted homologues of the parent methyl-β-chlorovinyl ketones provide strong support for this concept although neither simplification of the spectra upon crystallization (compounds I, IVand V) nor any marked temperature dependence of the intensity of the absorption bands could be observed in the majority of cases (see, however, discussion on iodo ketones, III and IV, p. 2570). The two rotational forms are



s-cis



s-trans

12) R. N. Jones and A. Nadeu, *Spectrochim. Acta*, **20**, 1175 (1964).

most likely the *s-cis* and *s-trans* ones, the latter being more stabilized by resonance.

According to the data of Jones and Noack[5] and to the Stuart-Briegleb atomic models the *s-cis* form is free of strain while the *s-trans* one is sterically hindered. Therefore, the C=O group in the latter conformation is probably forced out of the plane of the C=C bond, especially in the higher homologues. However, the true gauche form is not likely to exist as its formation would mean a considerable loss of resonance energy; hence, with increasing size of the α'-substituent, the equilibrium between the *quasi-s-trans* form* and the plane, strain-free *s-cis* one will tend to shift towards the latter. This tendency is clearly illustrated by the spectra of five ketones (I, IV, VIII, X and XII) bearing different alkyls in α' position (Fig. 2). In all but one (XII) of these spectra the carbonyl band is distinctly split; the peak occurring at lower frequency (B) weakens with increasing volume of the α' substituent (in XII only an inflection is observable) thus permitting its assignment to the sterically hindered *s-trans* form; consequently band A can be attributed to the *s-cis* form. The remaining chloro ketones investigated here (II, III, V—VII, IX, XI) fit well in this scheme (see discussion below). With the olefinic C=C stretching vibrations the situation is somewhat more complex. In the majority of cases splitting of the $\nu_{C=C}$ band could not be observed; it is likely that the bands of the two conformers coincide in the spectra. The same was noted for unsubstituted α,β-unsaturated ketones.[6] *t*-Butyl-β-chlorovinyl ketone exhibits two intense bands at frequencies consistent with the $\nu_{C=C}$ vibration, but these do not seem to correspond to different conformational forms, since the lack of a distinct second $\nu_{C=O}$ band suggests rather a mono-component system. Besides, the whole spectrum is much simpler than those of the other compounds investigated. Therefore, the splitting in this particular case is probably due to other factors, possibly to Fermi resonance. Only one of the compounds investigated here: 1-chloropenten-1-one-3 (IV, Fig. 3) shows in the double-bond spectral region four intense bands (A, B, C, D), two of which (C, D) can be attributed to the $\nu_{C=C}$ vibrations in the two rotational isomers. The assignments follow from the intensity changes of these bands in solvents of various polarity: in neat liquid and in solution in acetonitrile, bands B and C increase markedly in intensity as compared with the solution in hexane; this simultaneous change means that band C is due to the $\nu_{C=C}$ vibration of the *s-trans* form, since band B was assigned in the above discussion of Fig. 2 to this form. Band D corresponds therefore to $\nu_{C=C}$ of the *s-cis* form.

The authors are aware of the dangers of interpretation based solely on intensity changes in solvents. Nevertheless, the range of these changes exceeds here so much the values expected for the pure solvent effect on band intensity that the interpretation postulating the equilibrium shift *s-cis*$\rightleftarrows$*s-trans* seems to be justified, provided Fermi

resonance is not involved.

The assignments derived here are in agreement with those obtained for unsubstituted α,β-unsaturated ketones.[5,6] In particular, the regularity, consisting in wider frequency separation between the C=O and C=C stretching bands in the case of the *s-cis* isomer, can now be extended on corresponding β-chloro substituted ketones. For *s-cis* 1-chloropenten-1-one-3 $\nu_{C=O}-\nu_{C=C}=120$ cm^{-1} and for *s-trans* $\Delta\nu=86$ cm^{-1}, both values being considerably greater in comparison with those for ketones lacking polar substituents as well as with those containing the dialkylamino group in the β position, where the corresponding differences can be evaluated at about 90 cm^{-1} for the *s-cis* and 70 cm^{-1} or less for *s-trans* form. The fact, that in chloro ketones the differences $\nu_{C=O}-\nu_{C=C}$ are greater than in unsubstituted ketones, while in enamino ketones[3] they are equal or smaller, can be readily understood since a halogen is known to lower the $\nu_{C=C}$ frequency and to enhance the $\nu_{C=O}$ one, whereas an amino substituent lowers both of them, $\nu_{C=O}$ being usually somewhat more shifted.

Furthermore, the assignments presented above can be reconciled with the Raman intensities of 1-chloropenten-1-one-3 (IV, Fig. 4) on the basis of the idea of the in-phase and out-of-phase stretching vibrations of the two double bonds in the system O=C–C=C. In the Raman spectrum bands B and D are very intense while A and C occur in hexane solution as inflections only being undetectable in neat liquid. According to Sobolev and Alexanyan,[15] (see also discussion in[8]) (1) the intense Raman bands of α,β-unsaturated ketones are due to the in-phase vibration both in the *s-trans* and in the *s-cis* form, the bands due to corresponding out-of-phase vibrations being much weaker and (2) the in-phase and out-of-phase vibrations have a reverse order of frequencies in these two rotational isomers, i. e. $\nu_{sym}>\nu_{as}$ in the *s-trans* form, and $\nu_{sym}<\nu_{as}$ in the *s-cis* one. Our results fit in very well in this scheme: the intense Raman band B assigned to the $\nu_{C=O}$ vibration of the *s-trans* form has its counterpart in the weak inflection C due to the $\nu_{C=C}$ mode of the same form (i. e. $\nu_{sym}\approx\nu_{C=O}$ and $\nu_{as}\approx\nu_{C=C}$); correspondingly, inflection A and band D can be ascribed to the C=O and C=C stretch respectively in the *s-cis* form (i. e. $\nu_{as}\approx\nu_{C=O}$ and $\nu_{sym}\approx\nu_{C=C}$).

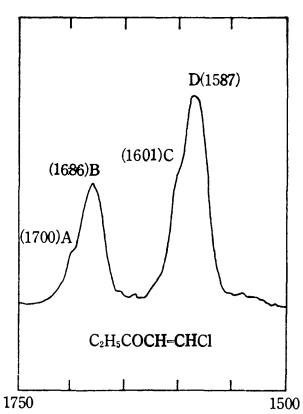

Fig. 4. Raman spectrum of 1-chloropenten-1-one-3; 50% by weight solution in hexane.

In addition to the five β-chlorovinyl ketones discussed above seven other β-halogenovinyl ketones (II, III, V—VII, IX and XI) were examined in order to investigate the influence of bromine, iodine and deuterium substituents on the position of the $\nu_{C=O}$ and $\nu_{C=C}$ bands. It is obvious that all these compounds exist likewise in two rotational forms, since (1) their liquid-state and solution spectra contain additional bands and/or shoulders in the 1700—1500 cm^{-1} region and (2) the spectra of solid methyl- and ethyl-β-iodovinyl ketones (III and VII) are markedly simplified between 650 and 1500 cm^{-1} as compared with the liquids: the bands 1286, 1237, 1150 and 864 cm^{-1} disappear from the spectrum of solid III and band 1273 cm^{-1} from that of solid VII. The fact that crystallization causes simultaneous complication in the 1700—1500 cm^{-1} region (Fig. 5), instead of the expected simplification, can be explained by assuming splittings by crystal field. In other respects the assignments of the $\nu_{C=O}$ and $\nu_{C=C}$ bands coincide with those for chloro ketones (Table I).

The solvent sensitivity of the $\nu_{C=O}$ and $\nu_{C=C}$ bands of halogenovinyl ketones differs strongly from that of aminovinyl ketones.[3] While the $\nu_{C=O}$ bands of both rotational isomers are clearly solvent-sensitive (Table I), the $\nu_{C=C}$ bands are in most cases constant within the limits of experimental error, showing that—contrary to what was observed for aminovinyl ketones—mechanical coupling between the two modes is much weaker than in amino ketones. This conclusion agrees with the calculations made by Sadlej and Sadlej[16] who showed the bond orders of the single and double bonds of the system O=C–C=C to be largely equalized in enamino ketones and but slightly changed (as compared with normal values) in halogenovinyl ketones. It should be noted that the $\nu_{C=O}$ frequencies of β-halogenovinyl ketones coincide almost exactly with those of unsubstituted vinyl ketones.[6] This indicates that the mesomeric effect of halogens counterbalances the inductive effect.

A general tendency, already noticed for enamino ketones, is the lowering of the $\nu_{C=C}$ frequency by 24—31 cm^{-1} upon vinyl deuteration (Table I).

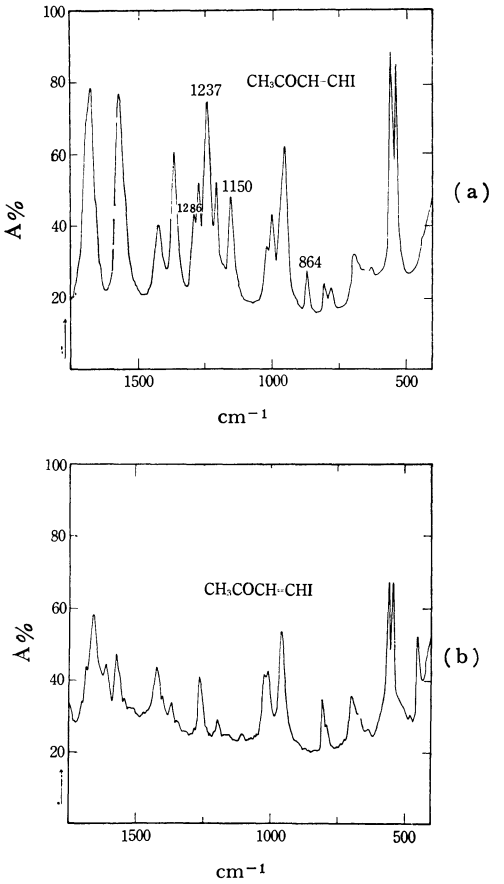

Fig. 5. Infrared spectrum of 1-iodobuten-1-one-3. (a) liquid film, (b) crystalline film

However, the $\nu_{C=O}$ frequency is insensitive to deuteration in chloro ketones, whereas in enamino ketones the reverse is true. This demonstrates once more that mechanical coupling between $\nu_{C=C}$ and $\nu_{C=O}$ in halogenovinyl ketones is not very strong.

The spectral region below 1500 cm^{-1} cannot be fully interpreted because of the occurrence of many noncharacteristic vibrations. Yet, there are some regularities which permit to draw definite conclusions in regard to several important absorptions or, at least, to suggest tentative assignments.

First of all, the CH_2 scissoring and both the doubly degenerate and symmetrical bending modes of the CH_3 group can rather easily be recognized; the data given in Table II show that there is no marked difference with respect to aliphatic saturated ketones.[17] There are, however, in several spectra absorption bands of medium intensity between 1300 and 1358 cm^{-1}, the origin of which cannot be estimated with certainty at the time being.

The C–H vinyl bending modes were assigned on the basis of deuteration studies. The in-plane bending vibration gives rise to a band within the range 1283—1298 cm^{-1}, the only strong deviation taking place in the case of compound XII (1308 cm^{-1}). These bands shift upon deuteration to 952—960 cm^{-1}. The C–H out-of-plane vibration occurs at 940—944 cm^{-1} for chloro ketones (IV, VIII, X and XII), at 946 for bromo ketones and at 948 for iodo ketones; the band of the C–D out-of-plane vibrations of chloro ketones V, IX and XI occurs at 698—701 cm^{-1}. All isotopic shifts are of the expected magnitude ($\nu_H/\nu_D \approx 1.35$).

The assignments of the ν_{C-Cl} frequencies follow from the intensity changes in various solvents. In the previous paper[8] it was noticed, that in hexane solution the lower of the two ν_{C-Cl} bands occurring at about 800—830 cm^{-1} grows up; the same effect was now confirmed in the case of compound IV. On the basis of the interpretation of the intensity changes in the 1700—1500 cm^{-1} region (p. 2569) this frequency can be ascribed to the *s-cis* form. The ν_{C-Cl} frequency of the *s*-trans form of the non-deuteriated ketones falls in most cases to the narrow range 846—853 cm^{-1} (Raman band in IV at 840 cm^{-1}) while those of the *s-cis* form are more variable. In IV the *s-cis* ν_{C-Cl} band occurs at 800 cm^{-1} both in Raman and infrared spectra, in VIII at 829 cm^{-1}. In X first band occurs at 846 cm^{-1} and there is no other strong band in this region except that at 779 cm^{-1}. Since the band splittings in the double-bond stretching region point to rotational isomerism, the latter band can be assumed to correspond to the second conformer. For XII the situation seems to be different: the first band lies at 837 cm^{-1} and the next one at a much lower value 753 cm^{-1}; according to what was already said in the discussion on the 1700—1500 cm^{-1} region (p. 2569) it may be concluded that substance XII containing the voluminous *t*-butyl radical exists practically in one conformational form, viz. *s-cis* with a ν_{C-Cl} frequency of 837 cm^{-1}.

In vinyl deuterated compounds V, IX and XI the ν_{C-Cl} bands are displaced to lower frequencies by 20—79 cm^{-1}. Although, on the basis of the intensity data, we believe our assignments of the ν_{C-Cl} bands to be correct, we admit freely that they are not as unambiguous as was case with methyl-β-chlorovinyl ketone[8] for which no other strong bands occurred in the whole spectral region theoretically possible for the C–Cl stretching vibrations.

The ν_{C-Br} and ν_{C-I} frequencies cannot unambiguously be assigned on the basis of data now available. Assignments for other frequencies within the region 400—1500 cm^{-1} will be given in the coming paper of this series.

The spectra discussed in the present paper will be submitted to the DMS catalogue.

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received March 23, 1966)

In order to determine the angular orientation of the rigid atomic group, such as benzene ring, in a molecular crystal, a new method for interpreting a distribution of peaks near the origin of two-dimensional Patterson function has been described in this paper. Similar methods for solving the Patterson function by the aid of the rigid groups have been proposed by several authors, but the present method, vector-set seeking method, differs from them in the procedure to find a satisfactory fit of a vector-set of the rigid group on the Patterson function and in a criterion for a correct choice of the angular orientation. Satisfactory results for the known structures of salicylamide and α-pyridone and the unknown structure of *m*-hydroxybenzamide were quickly obtained by the application of this method.

In the early stage of crystal structure analysis, the orientation of a rigid atomic group in the unit cell provides useful information of the interpretation of the Patterson function. The optical transform method has been used for this purpose.[1] It has been realized that the interpretation of the Patterson peaks near the origin is also effective in some cases.[2] Recently, several systematic procedures for solving the Patterson function with the aid of the rigid group of known spatial atomic arrangement have been proposed and applied successfully to the practical crystal structure determinations.[3,4] However, a large scale computer would be required and even on such computer it might take rather long computational time.

We have developed on the same line somewhat different procedure, the vector-set seeking method, which is convenient to deal with two-dimensional Patterson function and could be done on the smaller computer. It was proved that this method worked well for some practical structure determinations. The present paper includes the procedure of the vector-set seeking method and its application.

Description of the Method

The angular orientation of the rigid group in a molecule is defined by θ, φ and ψ, which are the angles of the rotations with respect to the three mutually orthogonal reference axes, X, Y and Z respectively. In the application of the vector-set seeking method for the projection of the Patterson function, this expression of the rotation is more convenient than that by Eulerian angles.

The procedure of this method is as follows. A plausible model of the rigid group defined by the orthogonal coordinate system is first rotated about two axes, X and Y, and then finally about the third axis, Z. The model after such three independent rotations is projected along the axis of the final rotation, Z. The vector-set consisting of interatomic vectors in the projected model is superposed on the projected Patterson function, so that two systems coincide in the origin and the axis of projection. The relation of the crystallographic axes with the reference axes is indicated in the figure for each example. The summation of the values of the Patterson function at the ends of the vectors is carried out over all the vector-set. If necessary, the Patterson function may be modified by some function of the distance from the origin.

The sum obtained by this procedure would give a degree of the fitness between the vector-set having a given angular orientation and the Patterson function; we shall call it 'fit-factor'. In the practical applications, the fit-factor is computed at every point (θ, φ, ψ), with suitable intervals of the three angular coordinates. It is natural to assume that the angular coordinates which give the largest value, the best fitting, within a reasonable range of the rotation correspond to the correct orientation of the rigid group in the crystal.

Application

This method was tested with the known structures of salicylamide[5] and α-pyridone[6], and with the unknown structure of *m*-hydroxybenzamide.[7] In these examples, the whole molecules were taken as the rigid group. The Patterson function computed for the grid points at suitable intervals was stored in the computer. The value of the function at the end of the vector was obtained by means of the interpolation by a second order equation.[8] In the case of the non-interpolation, the value on the nearest grid point from the end of the vector was taken. The angles, θ, φ and ψ, were stepwisely changed with intervals of 15° in the first stage, and of 5° to 10° in the search in the neighborhood of the maxima.

Salicylamide.—(a=12.92, b=4.98, c=21.04 Å, β=91.8°, $I2_1/a$). The Patterson function projected on (010) was computed for the grid points at intervals of $a/64$ and $c/128$. A planar molecular model of salicylamide was set up with generally accepted bond lengths and angles. Only the Patterson function within 5.3 Å from the origin was stored in the computer, because all the intramolecular vectors of the model will be within this region. The value of the origin of the Patterson function was taken as zero. Both the seekings with the interpolation and with the non-interpolation were carried out. The difference between the results of these two seekings was very small, and the angular orientation of the molecule in the projection was uniquely determined. Figure 1 shows a part of the result. The highest peak appeared at θ=40°, φ=20° and ψ=−20°. In

α-Pyridone.—($a=13.63$, $b=5.89$, $c=5.67$ Å, $P2_12_12_1$) The Patterson function projected on (001) was computed for the grid points at intervals of $a/60$ and $b/30$. In the seeking with the interpolation, there appeared some broad peaks with the shoulders, and it was unable to determine uniquely the angular orientation. However, it was not so difficult to find out the most probable angular orientation to be $\theta=-15°$, $\varphi=65°$ and $\psi=-45°$,

through the inspection of the Patterson function superposed on the possible vector-sets given by the seeking within a limit of rotations due to the unit cell dimensions. This was in good agreement with the orientation of the true structure in the projection. The result of seeking in every five degree of the rotation is shown in Fig. 3, and the vector-set of the model with the orientation corresponding to these angles and that of the true structure superposed on the Patterson projection is also shown in Fig. 4.

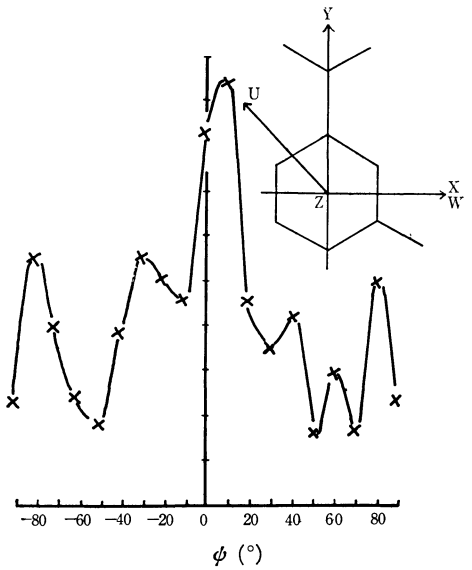

Fig. 5. Variation of 'fit-factor,' in *m*-hydroxybenzamide, by the rotation of ϕ at $\theta=0°$ and $\varphi=45°$.

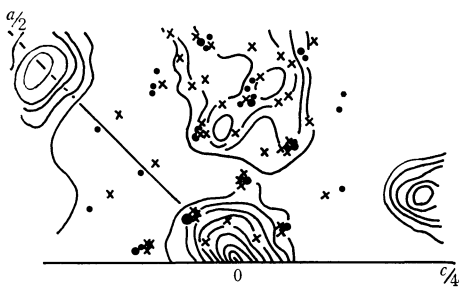

Fig. 6. Patterson projection of *m*-hydroxybenzamide and vector-set at the best fitting.

***m*-Hydroxybenzamide.** — ($a=11.59$, $b=5.03$, $c=15.53$ Å, $\beta=136.1°$, $P2_1/c$). The Patterson function projected on (010) was computed for the grid points at intervals of $a/64$ and $c/64$. In the seeking with the non-interpolation, the angular orientation of the benzene ring in the projection was determined with the planar molecular model consisting of the atoms of equal weight. A complete analysis of the crystal structure has been carried out with the knowledge on the angular orientation of the benzene ring obtained by this method. The result of the seeking is shown in Fig. 5, and the vector-set of the model with the orientation at the best fitting and that of the true structure is also shown in Fig. 6.

Discussion

In the crystals mentioned above, it was possible to find the orientation of the molecule in the projection by the application of this method. Since the maxima corresponding to the best fittings in the crystals of salicylamide and of *m*-hydroxybenzamide were sharp, the angular orientations of these molecules were quickly determined.

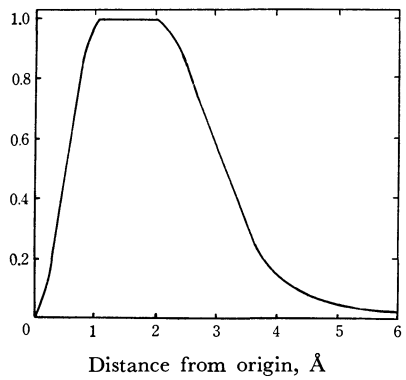

Fig. 7. Modification function against Patterson function to avoid the disturbance from the neighboring molecules.

When a part of the molecule, say the benzene ring, was taken as a rigid group, the peak in the fit-factor distribution became broader and lower. Although it was difficult, in general, to assign the orientation of the group, this method still worked well in some cases.

The fit-factor, especially in the seeking with the non-interpolation, was greatly affected by the rotation about the axis of the projection. Therefore, it may lead to a false orientation unless the rotation about this axis is carried out at relatively close intervals; the interval of the rotation angle should be decided by a correlation between the longest vector in the set and the size of the mesh of the Patterson function calculated. When there is the ambiguity in the estimation of the best fitting, as seen in the case of α-pyridone, the angular orientation may be estimated by the search of the largest fit-factor within the allowable angular region of the rotation; the dimension of the axis of the projection limits correlatively the ranges of θ and φ. However, in such a case, it may be difficult to find out the correct orientation by only the application of this method.

In the crystal of the molecule composed of the atoms of approximately equal weight, as seen from the present examples, it may be not necessary to use the weighted vector-set.

It is not always the case, even in that of the rigid molecule, that the angular coordinates for the best fitting give the correct angular orientation, because of the difference in geometries between the model used and the true molecule. In the crystal of *m*-hydroxybenzamide, in spite of the twist between a carboxyamide group and benzene ring, the angular coordinates obtained from the best fitting was very close to those of the benzene

ring in the true structure. The difference between their geometries was suggested by the disagreement between the vector-set of the model structure and that of the true structure, as shown in Fig. 6. It seems that the small difference between their geometries does not give rise to a serious problem for the determination of the approximate angular orientation of the molecule.

Different orientations due to the symmetry of the projected Patterson function may also influence the correct choice of the angular orientation. In the case of α-pyridone, two vector-sets related by the symmetry may overlap to some extent, and the Patterson peaks may not appear exactly in the positions corresponding to the points of the vector-sets; in fact, the peaks near the origin were mostly unresolved. It seems that the difficulty in the determination of the angular orientation of the α-pyridone molecule arose from this fact.

The intermolecular vectors may disturb the determination of the angular orientation. In order to minimize such obstruction, the values of the Patterson function were modified by a function of the distance from the origin, because the probability that the Patterson function at a point is due to only the intramolecular interactions decreases with increasing distance from the origin. In the present work, the modification as shown in Fig. 7 was used; the modification of this type also corresponded to the removal of the origin peak in the Patterson function. But the removal of the effects from the intermolecular vector and the origin peak was not greatly going to help the search of the best fitting; the latter resulted in the low background in the fit-factor distribution.

The vector-set seeking method was also applied to the crystal of salicylamide with the Patterson function sharpened by the factors of $\{3.5\exp 2\sin^2\theta/\lambda^2)\}$. This brought almost a similar result to the seeking with the unsharpened Patterson function. However, this helped the identification of the angular coordinates for the best fitting, because the maximum peak became sharper than that with the unsharpened Patterson function.

In the present work, a program was written in the machine language of NEAC 2230 computer. The computing time for the seeking with the interpolation is about 3.5 sec. per evaluation of a fit-factor' for a given angular orientation of the model containing ten atoms, while that for the non-interpolation is about 2.5 sec.

The Crystal Structure of *m*-Hydroxybenzamide

By Yukiteru KATSUBE

Himeji Institute of Technology, Himeji

and Yoshio SASADA and Masao KAKUDO

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received March 23, 1966)

Crystals of *m*-hydroxybenzamide are monoclinic with four molecules in a unit cell of dimensions $a=11.59$, $b=5.03$, $c=15.53$ Å, $\beta=136.1°$, space group $P2_1/c$. An approximate angular orientation of the molecule in the cell was quickly obtained by an application of the vector-set seeking method. The location of the molecule was then determined with the help of the orientation. The positional and anisotropic thermal parameters of the carbon, nitrogen and oxygen atoms were refined by means of the least-squares method with three-dimensional intensity data. The final R factor was 0.138. The carboxyamide group and benzene ring twist to each other about the C–C bond by an angle of 24.4°. The interatomic distances and bond angles are close to those expected. The molecules are linked by three types of hydrogen bonds to form the infinite double-layered sheets perpendicular to the c axis, and the crystal structure shows somewhat different features from those of the related compounds.

In the serial studies of the crystal structures of some aromatic carboxyamides, it has been found that there are several types of molecular arrangement connected by hydrogen bonds.[1-4] Although

the complete interpretation of these crystal structures in terms of interatomic interaction is impossible at the present stage, it will be of some significance to determine the crystal structures of carboxyamides with various substitutes.

In the previous paper, the authors have reported the structure of salicylamide (*o*-hydroxybenzamide).[4] In this compound, the hydroxy group in the ortho position to the carboxyamide group plays some role in the molecular association by hydrogen bonding, and in consequence the crystal structure shows somewhat different features from those already reported.

It might be interesting to compare the molecular linkage and molecular dimensions of *m*-hydroxybenzamide with those of salicylamide. The present paper will describ the threedimensional X-ray analysis of *m*-hydroxybenzamide.

Experimental and Crystal Data

Crystals were obtained from an alcohol-water solution as colorless hexagonal plates.

The unit cell dimensions were determined from oscillation and Weissenberg photographs about the b and c axes. The crystal and physical data found are as follows:

m-Hydroxybenzamide: $C_7H_7NO_2$, Molecular weight: 137.14.

Monoclinic: $a=11.59\pm0.03$, $b=5.03\pm0.03$, $c=15.53\pm0.03$ Å, $\beta=136.1\pm0.5°$.

Absent spectra: $(h0l)$ when l is odd, $(0k0)$ when k is odd.

Space group: $P2_1/c$.

Density (by flotation): 1.449 g.cm^{-3}.

Density (calculated): 1.451 g.cm^{-3}.

Four molecules per unit cell.

Volume of the unit cell: 627.78 Å^3.

Linear absorption coefficient for Cu$K\alpha$ radiation: $\mu=10.44$ cm^{-1}.

Total number of electron per unit cell: $F(000)=288$.

Equi-inclination Weissenberg photographs for 0—3 layers around the b axis were taken with filtered Cu$K\alpha$ radiation. In order to determine the approximate interlayer scales, Weissenberg photograph of $(hk0)$ zone was also taken. Intensities of the reflections were estimated visually against a calibrated intensity scale prepared using the same crystal. The multiple-film technique was used to correlate strong and weak reflections, ranging in relative intensities from 12000 to 1. The number of independent reflections observed was 706, representing about 70% of the total accessible reflections in the recorded layers. Corrections for Lorentz and polarization factors were applied in the usual way. The crystal used were square in cross section with rectangular dimensions 0.10×0.05 cm. Therefore, absorption and secondary extinction effect might be negligible, and corrections for them were omitted. The observed structure factors were first set onto an absolute scale by Wilson's method,[5] and the scale factors were further improved during the later stage of the refinement.

Structure Determination

Orientation of the Molecule.—In order to determine the orientation of the molecule, the vector-set seeking method described in the previous paper[6] was applied; the vector set of the planar molecular model was superposed on the Patterson projection on (010) and the best fitting between them was searched by varying stepwisely the angular orientation of the molecule. The maximum of the degree of fitting was found at $\theta=0°$, $\varphi=45°$ and $\psi=10°$, while there were some other high peaks in the fitting at the different rotations. It is naturally expected that the orientation of the molecule is given by the angles corresponding to the best fitting if the carboxyamide group is coplanar with the benzene ring. However, the coplanarity of the molecule may not necessarily be fulfilled in the present compound. Therefore, the orientation corresponding to the second highest peak was also saved for the subsequent refinement.

Location of the Molecule in the Unit Cell.—It was expected from the normal van der Waals radii that the atoms would be located only outside the circles centered at the symmetry elements of the unit cell, as shown in Fig. 1. The initial x and z coordinates of the atoms in the molecule for the possible orientations were assigned easily in a rather limited allowable region. They were adjusted by trial with the aid of the structure factor maps for some strong reflections. The discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, was about 0.6 for both orientations at this stage.

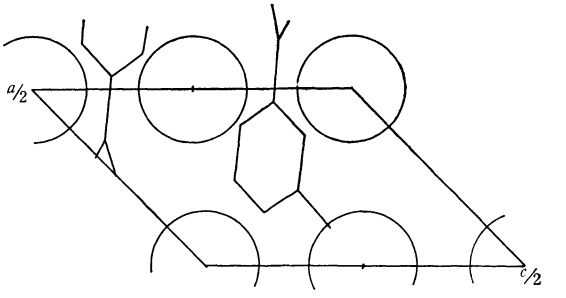

Fig. 1. Forbidden regions for the location of the molecule. The final position of the molecule is indicated.

In the Fourier projection for the model corresponding to the maximum peak in the vector-set seeking, all the atoms except those in the carboxy-amide group were resolved. On the other hand, the Fourier projection for another orientation did not look encouraging to continue the refinement, because there appeared the regions of low electron density around the positions of the assumed atoms and areas of high density where no atom was placed.

The x and z coordinates in the former model were further refined by successive five Fourier syntheses. The R factor reduced to 0.27. Because of the overlapping of the atoms in the carboxy-amide group, their coordinates were improved by the trial method, until the R factor dropped to 0.22.

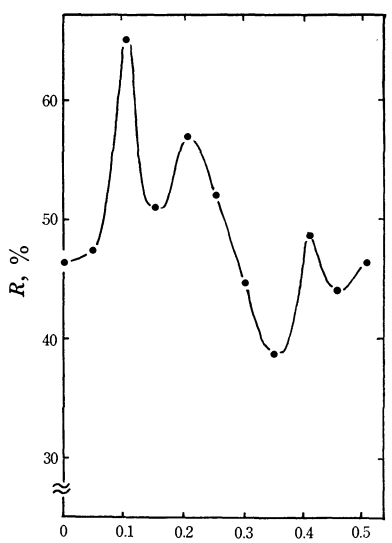

Fig. 2. Minimum residual calculation.

Determination of y Coordinates.—The y coordinates of the atoms were obtained by the one-dimensional minimum residual method.[7] The molecular model constructed from the fixed x and z coordinates was translated successively along the b axis; fifteen ($hk0$) reflections were included in the computation. It gave uniquely the y coordinates, as seen from Fig. 2, where the abscissa shows the coordinates of the reference atom C(7). Successive two Fourier refinements for ($hk0$) reduced the R factor to 0.30.

Three-dimensional Refinement.—Three positional parameters and one isotropic temperature factor for each atom were refined by least-squares method where off-diagonal matrix elements were neglected. The scale factors for the various layer lines were adjusted after every cycle. In the computation, 827 reflections in the four layers about the b axis, some of which were unobserved, were included. Five cycles of the refinement reduced the R factor to 0.23. At this stage, a three-dimensional (F_o-F_c) synthesis was made, but it did not show the positions of hydrogen atoms. Therefore, four hydrogen atoms were placed on the benzene ring plane and at a distance of 1.0 Å outward from the carbon atoms, and the hydrogen atoms of the hydroxy and the amino

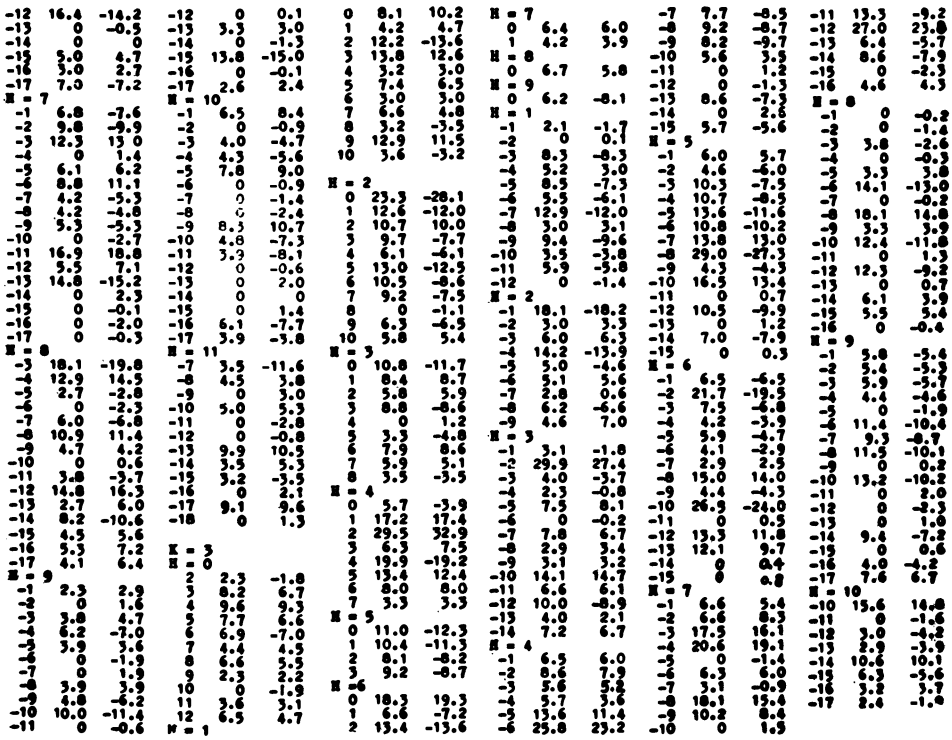
TABLE II. (continued)



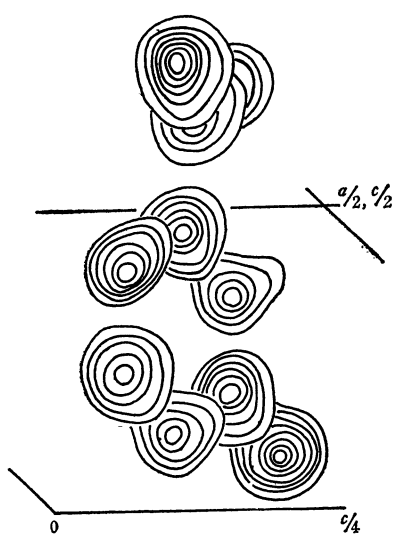


Fig. 3. The final electron density distribution. Composite diagram of sections parallel to the (010). Contours are at intervals of 1.0 eÅ^{-3}, the lowest one being 2.0 eÅ^{-3}.

groups were located at the positions expected from the hydrogen bonding. Further refinement of the structure was made by least-squares with a block-diagonal matrix approximation; anisotropic temperature factors in the form of

$$\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$$

were assigned for the non-hydrogen atoms. Three cycles of the block-diagonal least-squares refinement yielded the R factor of 0.138 for all the independent reflections. If the unobserved reflections were omitted, the R factor became 0.118. Atomic scattering factors for the carbon, nitrogen and oxygen were taken from Berghuis, Haanapple, Potters, Loopstra, MacGillavry and Veenendaal,[8] and those for the hydrogen from McWeeny.[9] The final atomic coordinates and anisotropic temperature factors are given in Table I. Observed and calculated structure factors are listed in Table II. The final three-dimensional electron density distribution viewed down the b axis is shown in Fig. 3.

All numerical computations except for the final refinement were done on NEAC 2230 and NEAC 2206 computers with programs written by the authors. The least-squares method with block-diagonal approximation was made on an IBM 7090 with program written by T. Ashida.

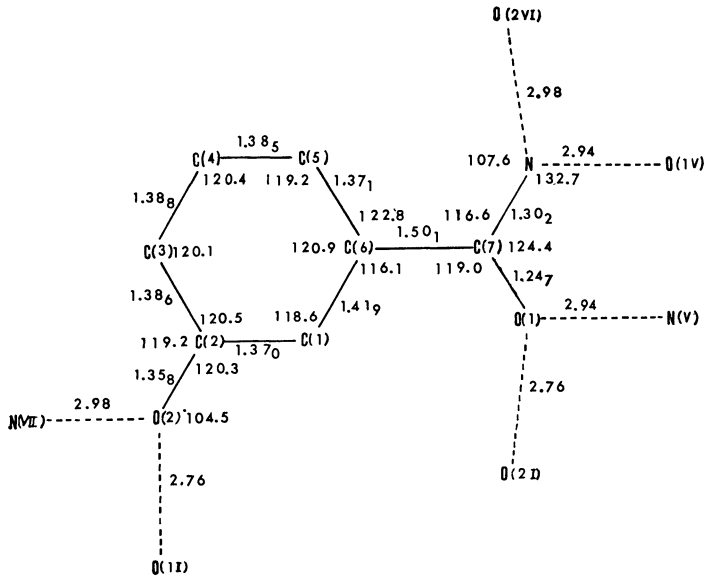

Fig. 4. Bond lengths (Å) and bond angles (°).

Description of the Structure and Discussion

Molecular Structure.—Bond lengths and bond angles found in the *m*-hydroxybenzamide molecule are shown in Fig. 4. The average standard deviations of the atomic coordinates are 0.014, 0.011 and 0.008 Å for carbon, nitrogen and oxygen atoms respectively. Therefore, the estimated standard deviations of the bond lengths are 0.020 Å in C–C, 0.018 Å in C–N and 0.016 Å in C–O. Although small fluctuations among the C–C bond lengths in the benzene ring are probably significant, detailed discussion about this will not be given because of low degree of accuracy. The average C–C bond length, 1.39 Å, and average C–C–C bond angle, 120.0°, in the benzene ring are in good agreement with the standard values. The dimensions of the carboxyamide group in the *m*-hydroxybenzamide, C–N=1.30_2 Å and C–O=1.24_7 Å, are close to those found in the related crystals: C–N=1.31_2 Å and C–O=1.24_4 Å in α-pyrazinamide,[1] C–N=1.29 Å and C–O=1.25 Å in *m*-methylbenzamide,[3] C–N=1.30_9 Å and C–O=1.22_2 Å in salicylamide,[4] C–N=1.34 Å and C–O=1.22 Å in nicotinamide,[10] C–N=1.31 Å, and C–O=1.24 Å in benzamide.[11] The bond length between the ring carbon and hydroxy oxygen atoms is 1.35_8 Å, which does not differ significantly from the values found in the salicylamide, 1.36_1 Å, salicylic acid, 1.358 Å,[12] and α-resorcinol, 1.36 Å.[13]

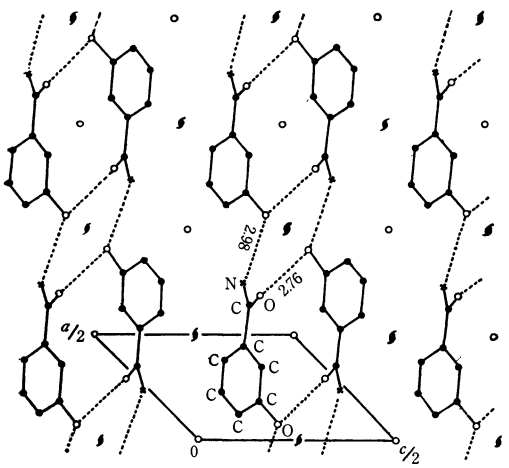

Fig. 5. Arrangement of the molecules viewed down the b axis.

The plane of the benzene ring (including C(7) and O(2)) can be represented by the equation:

$$y' = -0.0368x' - 1.2750z' + 4.3267$$

where $x' = x\sin\beta$, $y' = y$ and $z' = z + x\cos\beta$. The coefficients of the equation were determined by the least-squares method. The perpendicular displacements of the atoms from the mean plane are shown in Table III. The six carbon atoms in the benzene ring are coplanar within an experimental error. On the other hand, the carboxyamide group and the benzene ring twist to each

TABLE III. PERPENDICULAR DISPLACEMENTS OF ATOMS FROM THE MEAN PLANE OF THE BENZENE RING

Atom	Displacement Å
C(1)	0.025
C(2)	0.005
C(3)	0.006
C(4)	−0.001
C(5)	−0.007
C(6)	0.000
C(7)	−0.009
O(2)	−0.019

other around the C(6)–C(7) bond, and the angle between the planes of the benzene ring and the carboxyamide group is 24.4°. In many related crystals, the plane of the carboxyamide group makes an angle of about 25° with that of the benzene ring. This twist has been interpreted as the effect of steric hindrance between the hydrogen atom in the amino group and that in the ortho position of the ring.

Crystal Structure.—The crystal structure projected down the b axis is illustrated in Fig. 5, and the intermolecular distances less than 4.0 Å are listed in Table IV. There are three types of hydrogen bonds. The reference molecule at (x, y, z) is connected by the first set of OH···O (amide) of length 2.76 Å with the molecule at $(1-x, -y, 1-z)$, to form a molecular pair across the center of symmetry. The pairs are piled up infinitely along the b axis by the second set of NH···O (amide) of length 2.94 Å. The third hydrogen bonds, NH···O (hydroxy), of length 2.98 Å join the neighboring piles which are related to each other by the screw axis. Thus all the hydrogen atoms capable of participating the hydrogen bonding have been utilized and the endless double-layered sheets perpendicular to the c axis are formed as seen from Fig. 5. Figure 6 shows a schematical drawing of this double-layered sheet. This type of the molecular linkage by the hydrogen bonds has been first found in the present crystal.

TABLE IV. INTERMOLECULAR DISTANCES

From atom at x, y, z	To atom	In molecule	Distance(Å)
C(1)	C(1)	I	3.87
C(1)	C(6)	II	3.84
C(1)	C(7)	II	3.62

The Radiolysis of Crystalline Oxalato Metal Complexes. The Effects of Coordinating Metal Ions on the Radiolysis of Oxalate

By Akira SUGIMORI*

Japan Atomic Energy Research Institute, Tokai-mura, Naka-gun, Ibaraki

(Received April 14, 1966)

Coordinated oxalates in metal complexes are more reactive under γ-irradiation than are ionic oxalates. This suggests that the covalency between the metal ion and the ligand in oxalato metal complexes promotes the reactivity of the ligand. The reaction of the ligand is also affected by the central metal ions. In $K_3[Co(C_2O_4)_3]\cdot 3H_2O$ and $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$, the coupled reduction of central metal ions with the oxidative decomposition of the ligand to carbon dioxide occurs at relatively high G values. In $K_3[Cr(C_2O_4)_3]\cdot 3H_2O$, the redox reaction of the central metal ion is small and the ligand decomposes into carbon dioxide and carbon monoxide. In $K_3[Al(C_2O_4)_3]\cdot 3H_2O$, the formation of glyoxal and formic acid instead of carbon monoxide is significant.

It is well-known that the reactions of the ligand molecule in coordination compounds are affected by the central metal ions. As for the photochemistry of metal complexes, the photochemical reactions of oxalato metal complexes have been studied extensively.[1,2] It has been concluded that the photo-induced electron transfer from the ligand to such central metal ions as iron(III), cobalt(III) and manganese(III) results in the high quantum yield of the decomposition of the ligand molecule.

Our study aims at the elucidation of the effects of central metal ions on the radiolytic decomposition of the ligand molecule (in this case, oxalate) by comparing the results of radiolysis with those of photolysis.

Several papers have dealt with the radiation-induced reactions of metal complexes in aqueous solutions.[3-6] The radiation-induced reaction of an aqueous system is, however, not suitable for comparison with the photo-induced reaction, because the radiation-induced reaction is initiated by the reactive intermediates produced by the radiolysis of water, while the photochemical reaction is initiated by the direct excitation of the solute. On the other hand, the direct excitation of the complexes by an ionizing radiation can be expected in the radiolysis of crystalline complexes. Therefore, the radiolysis of crystalline oxalato metal complexes was studied in order to elucidate the effects of metal ions in the excitation of the complexes by ionizing radiations. A preliminary report has already been published.[7] Moreover, recently, a study of the radiolysis of several oxalatocobalt(III)-complex salts was reported by Sano, Matsubara and Saito.[8]

Results and Discussion

The Reactivities of Ionic Oxalate in Salts and Coordinated Oxalate in Metal Complexes. —The radiation-chemical reactivities of ionic

oxalate and of coordinated oxalate were compared. In order to avoid the additional effects caused by the reduction or oxidation reactions of central metal ions in metal complexes, the radiolysis of potassium trioxalatoaluminate(III), the central ion of which is resistant to reduction and oxidation, was compared with that of oxalate salts.

Table I lists the G values for the decomposition

TABLE I. THE DECREASE IN THE REDUCING POWER OF THE OXALATE SALTS AND THE OXALATO METAL COMPLEX BY γ-IRRADIATION

Compound	Dose rate eV./g.hr.	Dose eV./g.	G(−Reducing power)
$H_2C_2O_4\cdot 2H_2O$			10.1*
$H_2C_2O_4$	2.6×10^{19}	8.2×10^{21}	8.0
$K_3[Al(C_2O_4)_3]\cdot 3H_2O$			9.9*
$Na_2C_2O_4\cdot H_2O$	1.4×10^{19}	2.8×10^{21}	0.4
	2.5×10^{19}	7.9×10^{21}	0.03
$K_2C_2O_4\cdot H_2O$	4.5×10^{19}	9.6×10^{21}	0.8
	4.5×10^{19}	1.2×10^{22}	0.8
$NaHC_2O_4\cdot H_2O$	2.4×10^{19}	8.5×10^{21}	1.5
$FeC_2O_4\cdot 2H_2O$	8.8×10^{19}	8.1×10^{21}	0.1

* Is obtained from the yield-dose curve.

(the number of molecules decomposed per 100 eV. of the absorbed energy of radiation) of ionic and coordinated oxalates, values which were determined by titration with potassium permanganate.

Ionic oxalates in sodium oxalate, potassium oxalate, and iron(II) oxalate showed lower G values for decomposition than the coordinated oxalate in potassium trioxalatoaluminate(III). The G value of the aluminum complex was similar to that of oxalic acid (hydrous and anhydrous). Sodium hydrogen oxalate showed an intermediate G value. These results suggest that the covalency between oxygen and metal/or hydrogen is important for the reactivity of oxalates against ionizing radiation.

Crystal water has a slight effect on the radiolysis of oxalate. Hydrated oxalic acid and hydrated iron(II) oxalate have reactivities similar to those of anhydrous oxalic acid and anhydrous sodium oxalate respectively.

The Radiolysis of Trioxalato Metal Complexes.—*General Features.*—In addition to the effect of the covalency described above, the oxidation and reduction of the central metal ions affect the reaction mechanism of the ligand. Before discussing this problem, however, the general features of the radiolysis of trioxalato metal complexes should be described. Gamma-irradiation brings about the decomposition of the ligand and a change in the oxidation state of metal ions, and gives gaseous, liquid and solid products. Among the reaction products, gaseous products show an interesting feature. Gamma-irradiation gave two kinds of gaseous products: the gas evolved by irradiation, and the gas evolved by dissolving the irradiated complex in water. In some cases, the content of the gas evolved from the γ-ray irradiated complex was different from that of the gas evolved by dissolving the irradiated complex in water. The most remarkable example is the case of potassium trioxalatochromate(III). When it was irradiated at a total dose of 2.3×10^{22} eV./g., it gave a gaseous product at a G value of 1.8; this product consisted of 58% carbon dioxide, 37% carbon monoxide, and 5% hydrogen. The G value of the gas evolved by treating the irradiated complex with water was 0.5; this gas consisted solely of carbon dioxide. This fact suggests that the gas evolved by dissolving the irradiated complex is not the gas occluded in the irradiated complex crystals. The existence of a precursor for carbon dioxide may be expected. An infrared spectroscopic study of irradiated potassium trioxalatochromate(III) suggested that carbon dioxide was trapped in the form of hydrogen carbonate ions.[9]

The quantities of the evolved gas and the decomposed oxalato metal complexes are plotted against the absorbed radiation dose in Figs. 1, 2 and 3.

As is shown in the figures, the quantities of the evolved gas and the decomposed complexes are proportional to the absorbed dose.

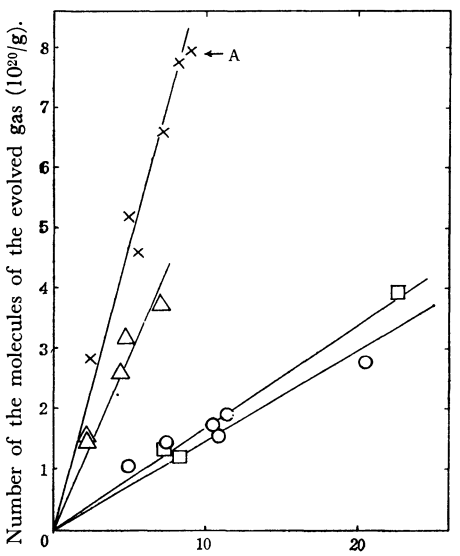

Fig. 1. Relations between the number of the molecules of the evolved gas and the absorbed radiation dose.

—×— $K_3[Co(C_2O_4)_3]\cdot 3H_2O$
A Irradiated at −50°C

9) A. Sugimori, To be published.

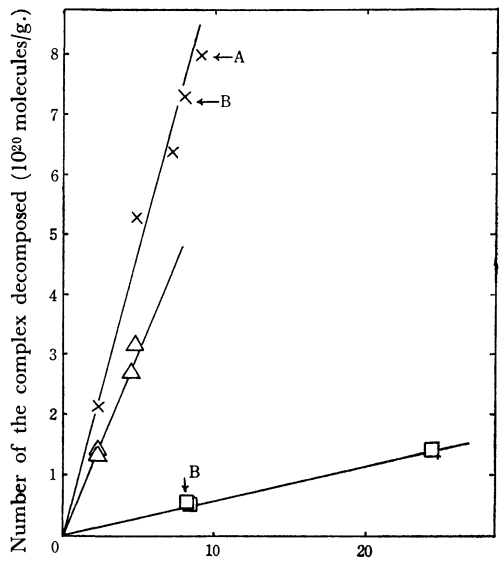

Fig. 2. Relations between the number of the complex decomposed and the absorbed radiation dose.
—□— $K_3[Cr(C_2O_4)_3]\cdot 3H_2O$
—△— $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$
—×— $K_3[Co(C_2O_4)_3]\cdot 3H_2O$
A Irradiated at −50°C
B Irradiated in the air

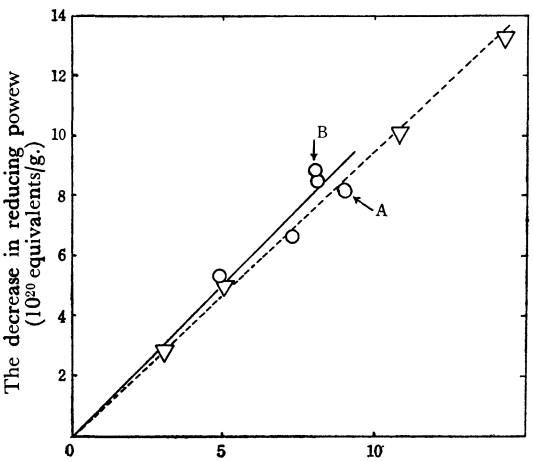

Fig. 3. Relations between the decrease in reducing power and the absorbed radiation dose.
—○— $K_3[Al(C_2O_4)_3]\cdot 3H_2O$
—▽— $H_2C_2O_4\cdot 2H_2O$
A Irradiated at −50°C
B Irradiated in the air

The existence of air and the change in the irradiation temperature from room temperature to −50°C slightly affect the decomposition of the complex (Figs. 1, 2 and 3).

Effects of Central Metal Ions on the Decomposition of the Ligand.—The decomposition of the ligand depends on the nature of the central metal ions.

i) $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$ and
$K_3[Co(C_2O_4)_3]\cdot 3H_2O$.

The results of the radiolysis of potassium trioxalatoferrate(III) and potassium trioxalatocobaltate-(III) are summarized in Table II.

Table II. The radiolysis of potassium trioxalatoferrate(III) and potassium trioxalatocobaltate(III)

	$K_3[Fe(C_2O_4)_3]\cdot 3H_2O$		
	Dose (eV./g.)	*G* value	Composition of the gas (%)
Evolved gas		6.8*	
	7.1×10^{21}	6.3	H_2 0, CO 0, CO_2 100
The gas evolved by dissolving the irradiated complex	7.1×10^{21}	1.5	H_2 0, CO 0, CO_2 100
Fe(II)		7.2*	
The decrease of the complex		6.1*	
	$K_3[Co(C_2O_4)_3]\cdot 3H_2O$		
	Dose (eV./g.)	*G* value	Composition of the gas (%)
Evolved gas		11.1*	
	5.4×10^{21}	8.6	H_2 0, CO 0, CO_2 100
The gas evolved by dissolving the irradiated complex	5.4×10^{21}	1.3	H_2 0, CO 0, CO_2 100
The decrease of the complex		10.3*	

* Is obtained from the yield-dose curve.

The features of the radiolysis of these complexes are:

1) The *G* values of the gaseous products and the decomposed complexes were greater than those of the other complexes.

2) The gaseous product consisted entirely of carbon dioxide.

3) In the case of potassium trioxalatoferrate-(III), iron(II) was produced at a *G* value similar to those of the total gaseous product and the decomposed complex.

The radiation-induced reaction of potassium trioxalatoferrate(III) is very simple. The main reaction of the ligand is the decomposition to carbon dioxide; side reactions to give carbon monoxide and hydrogen are negligible. The coupled reduction of the central metal ion with the oxidative decomposition of coordinated oxalate takes place

solely. This reaction is the same as that of the photolysis of the complex. Excited states which are the same as that in photolysis may be produced selectively and effectively by γ-irradiation. The reaction mechanism proposed for the photolysis[1] may be applied to the radiation-induced reaction:

$$[Fe^{III}(C_2O_4)_3]^{3-} \xrightarrow{\gamma\text{-rays}} [Fe^{III}(C_2O_4)_3]^{3-*} \quad (1)$$
(excited state)

$$[Fe^{III}(C_2O_4)_3]^{3-*} \rightarrow \left[\begin{array}{l} O \\ \| \\ O \end{array}\!\!>\!C\!-\!C\!<\!\!\begin{array}{l} O \\ \| \\ O \end{array}\!\!>\!Fe^{II}(C_2O_4)_2\right]^{3-} \quad (2)$$

$$\left[\begin{array}{l} O \\ \| \\ O \end{array}\!\!>\!C\!-\!C\!<\!\!\begin{array}{l} O \\ \| \\ O \end{array}\!\!>\!Fe^{II}(C_2O_4)_2\right]^{3-} \rightarrow$$

$$C_2O_4^- + [Fe^{II}(C_2O_4)_2]^{2-} \quad (3)$$

$$C_2O^-_4 + [Fe^{III}(C_2O_4)_3]^{3-} \rightarrow$$

$$2CO_2 + [Fe^{II}(C_2O_4)_3]^{4-} \quad (4)$$

Similar reactions would take place in the radiolysis of potassium trioxalatocobaltate(III). In this case, the structure of the cobalt(II) complex has been studied by the infrared spectroscopic method.[9] The cobalt(II) produced by γ-irradiation preferentially forms four coordinate dioxalato complexes. This means that the reduction of the central metal ion is followed by the elimination of one oxalate ion and a reorganization in the coordination sphere.

ii) $K_3[Cr(C_2O_4)_3]\cdot 3H_2O$.

1) The formation of carbon monoxide and hydrogen was remarkable.

2) The G value for the decomposition of the complex was small.

3) The content of the evolved gas was different from that of the gas obtained by dissolving the irradiated complex in water.

The radiolysis of potassium trioxalatochromate(III) is very different from those of potassium trioxalatoferrate(III) and potassium trioxalatocobaltate(III). The reduction of chromium(III) to chromium(II) was not observed. On the other hand, the oxidation of the central metal ion was observed, although the yield was very small. The G value of chromium(VI) was found to be 0.003—0.004. The lack of a conjugation of reactions between the ligand and the central metal ion in potassium trioxalatochromate(III) would result in a lower reactivity toward γ-irradiation.

TABLE III. THE RADIOLYSIS OF POTASSIUM TRIOXALATOCHROMATE(III)

	Dose (eV./g.)	G value	Composition of the gas (%)	
Evolved gas		1.8*		
	2.3×10^{22}	1.8	H_2	5
			CO	37
			CO_2	58
	8.0×10^{21}	—	H_2	2
			CO	36
			CO_2	62
The gas evolved by dissolving the irradiated complex	2.3×10^{22}	0.5	H_2	0
			CO	0
			CO_2	100
The decrease of the complex		0.6*		

* Is obtained from the yield-dose curve.

The lower reactivity of the complex has also been observed in the photolysis of the complex.[2] Trioxalatocobaltate(III) and trioxalatoferrate(III) are easily decomposed by ultraviolet irradiation, but trioxalatochromate(III) is very resistant to ultraviolet light. This fact also suggests that, in the radiation-induced reaction, the same excited molecules as in the photochemical reaction are preferentially produced.

iii) $K_3[Al(C_2O_4)_3]\cdot 3H_2O$

TABLE IV. THE RADIOLYSIS OF POTASSIUM TRIOXALATOALUMINATE(III)

	Dose (eV./g.)	G value	Composition of the gas (%)	
Evolved gas		1.5*		
	1.0×10^{22}	1.7	H_2	2
			CO	5
			CO_2	93
The gas evolved by dissolving the irradiated complex	1.0×10^{22}	2.9	H_2	0
			CO	0
			CO_2	100
Decrease in the reducing power		9.9*		

* Is obtained from the yield-dose curve.

The reaction of the complex is similar to that of potassium trioxalatochromate(III). However, some quantitative differences were observed:

1) The carbon dioxide content in the evolved gas was larger than that of the chromium complex.

2) The contribution of the gas obtained by dissolving the irradiated complex to the total gaseous product is larger than that in the case of the chromium complex.

In this case, the yield of carbon dioxide, the oxidized product, was much superior to the yield of carbon monoxide, the reduced product, if the large contribution of the gas evolved by dissolving the irradiated complex in water was taken into account. Since the oxidation and the reduction of aluminum(III) are difficult, the reduction products of oxalate ions may be expected. The formation of aldehyde and formic acid was observed. The infrared spectra of the aldehyde 2, 4-dinitrophenylhydrazone suggest that the aldehyde consists mainly of glyoxal: G=0.2 was given for the aldehydic product. A volatile acidic substance, presumably formic acid, and with a G value of 0.4, was formed.

A similar reaction occurs in the radiolysis of oxalic acid. The formation of glyoxal and formic acid was also observed.

Since the decomposition of oxalate occurred in a small yield in the case of ionic oxalate, it is evident that the coordination bond between aluminum-(III) and oxalate plays an important role in the radiation-induced reaction of the coordinated oxalate ion.

Experimental

Materials.—Commercially-available oxalic acid, sodium oxalate, potassium oxalate (guaranteed-grade reagent of the Kanto chemical Co.) and iron(II) oxalate (extra pure-grade reagent of the Kanto Chemical Co.) were used without any further purification. Sodium hydrogen oxalate was prepared by mixing the solutions of oxalic acid and sodium oxalate in an equal molar ratio. Potassium trioxalatoaluminate(III), potassium trioxalatochromate(III), potassium trioxalatoferrate(III) and potassium trioxalatocobaltate(III) were prepared according to the method described in "Inorganic Synthesis."[10]

Gamma-Ray Irradiation.—The irradiation cell was a cylindrical tube with a break-off seal. About one gram of the crystalline oxalato metal complexes or oxalate salts was put in the cell, and the cell was sealed off in a vacuum. The cell was covered with black paper to protect the contents from the light when the sample was sensitive to light.

Cobalt-60 γ-ray sources of 10000 and 16000 curies were used. The dose rate was measured by Fricke dosimetry, which was modified for the measurements of larger doses by using acidic solutions of ferrous sulfate saturated with nitrogen gas. The dose was calculated assuming that $G(Fe^{3+})=8.2$.

The correction of the absorbed radiation energy arising from the difference in the electron densities of the dosimeter and samples was also applied.

Irradiation at low temperatures was carried out by using a thermostat placed in the irradiation facility.

Analysis of the Products.—*i) Gaseous products.*—The vessel containing the irradiated complex was connected to the vacuum system, the volume of which had been measured. Then the break-off seal was cut off. The total volume of the gaseous products was calculated from the pressure increase in the vacuum system. The composition of the gas was determined by means of mass spectrometric analysis.

ii) The Gas Evolved by Dissolving the γ-Ray Irradiated Complex.—The vessels containing the irradiated complex and water were arranged in a vacuum line, as is shown in Fig. 4. The water in B was degassed by boiling the contents several times in a vacuum. Then the whole system except for B was evacuated thoroughly. After evacuation, the vacuum system was isolated from the pump. Then the water in B was introduced into A, and the irradiated complex in A was dissolved. After the whole sample had been dissolved in water, the vessel, A, was cooled with dry ice. Then the

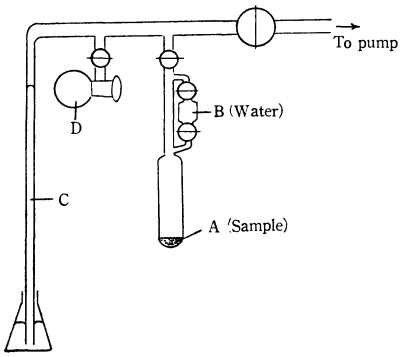

Fig. 4. Vacuum system for the analysis of the gas evolved by dissolving the irradiated complex in water.
A Irradiated sample, B Water,
C Mercury manometer, D Gas sampler for mass spectrometric analysis.

volume and the composition of the gas were determined in the same way as in *i*).

iii) Reducing Power.—After irradiation, the whole contents of the irradiation vessel were transfered into a measuring flask and dissolved in water. The solution was then titrated with potassium permanganate in acidic media. The comparison of the reducing power before and after γ-irradiation gave the decomposition of oxalate ions. This analysis was, however, applied only to oxalic acid, oxalte salts and potassium trioxalatoaluminate(III).

iv) Carbonyl Compound.—The determination of the carbonyl compounds produced in the irradiated oxalic acid and potassium trioxalatoaluminate(III) was

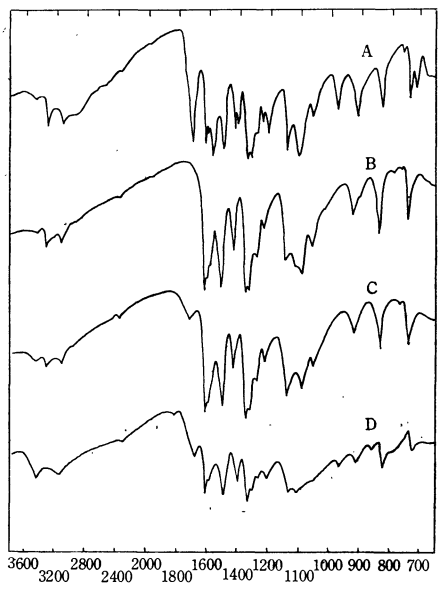

Fig. 5. Infrared spectra of the 2,4-dinitrophenylhydrazones of glyoxylic acid (A), glyoxal (B), and radiolytically-produced aldehydes from $H_2C_2O_4\cdot 2H_2O$ (C) and $K_3[Al(C_2O_4)_3]\cdot 3H_2O$ (D).

10) J. C. Bailar, Jr., and E. M. Jones, "Inorganic Synthesis," Vol. 1, Mcgraw-Hill, New York (1939), p. 35.

carried out by precipitating them with 2, 4-dinitrophenylhydrazine. The melting point of the 2, 4-dinitrophenylhydrazone was 280°C in the radiolytic product of oxalic acid, and 240°C in the radiolytic product of potassium trioxalatoaluminate(III). Since the melting point of glyoxal 2, 4-dinitrophenylhydrazone is 328°C, the carbonyl compound obtained in radiolysis is not considered to be pure glyoxal. However, the 2, 4-dinitrophenylhydrazone was turned purple by the action of alkali, which is specific for bis-2, 4-dinitrophenylhydrazone of $-\overset{O}{\overset{\|}{C}}-\overset{O}{\overset{\|}{C}}-$. The infrared spectra of the 2, 4-dinitrophenylhydrazone of the radiolytically-produced aldehyde, together with those of glyoxal and glyoxylic acid, are shown in Fig. 5. Since the infrared spectra of the 2, 4-dinitrophenylhydazone of the radiolytically-produced aldehyde, especially in oxalic acid, were very similar to those of glyoxal, the main component of the radiolytically produced aldehyde may be assumed to be glyoxal. However, a small peak at $\sim 1700\ cm^{-1}$ which can not be explained by glyoxal is to be ascribed to an impurity, presumably glyoxylic acid.

v) Volatile Acidic Substance.—The solution of the γ-ray irradiated sample was acidified with sulfuric acid. The solution was steam-distilled, and the distillate was titrated with a sodium hydroxide solution.

vi) Iron(II).—Iron(II), which was produced in the radiolysis of potassium trioxalatoferrate(III), was determined to be a bipyridyl complex.

vii) Residual Metal Complex.—The irradiated oxalato metal complex was dissolved in water, and the residual oxalato metal complex was determined by the spectrophotometric method. For the determination of potassium trioxalatochromate(III), the absorption bands at 420 and 570 mμ were used. For potassium trioxalatocobaltate(III), the bands at 420 and 605 mμ were used. For the determination of potassium trioxalatoferrate-(III), the shoulder at 263 mμ was used.

The author is very grateful to Professor Kenjiro Kimura for his kind guidance and encouragement throughout this work. The author is also very grateful to Drs. Akibumi Danno, Gen-ichi Tsuchihashi, and Shin-ichi Ohno for their helpful discussions.

The Quenching Action of Benzoic Acid and Methylbenzoate on the Fluorescence of Naphthalene Derivatives. III. The Solvent Effect on the Quenching of the Fluorescence of Dimethylnaphthylamine by Methylbenzoate

By Takuji MIWA and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received April 15, 1966)

The fluorescence and absorption spectra and the quenching of the fluorescence of *N*, *N*-dimethyl-2-naphthylamine by methylbenzoate have been measured in cyclohexane, benzene, *p*-dioxane, isopropyl ether, ethyl ether, ethyl acetate, tetrahydrofuran, acetone and *N*, *N*-dimethylformamide (in the order of DK values). The fluorescence and the absorption spectra show a red-shift with the polarity of the solvent. By the method of Lippert and Mataga, the dipole moment of the excited fluorescer molecule has been estimated to be 4.1D. In nonpolar and weakly polar solvents, the methyl benzoate-added systems give fluorescence spectra with a swell or a shoulder on the long wavelength side, but this does not occur in *N*, *N*-dimethylformamide. When methyl benzoate is used as the solvent, two peaks of fluorescence are observed. The new emission has been interpreted as a charge-transfer emission, and the temperature-dependence of the fluorescence spectra has led to the conclusion that an encounter of fluorescent and quencher molecules is prerequisite for the appearance of CT emission. The quenching efficiencies in different solvents have been dealt with in reference to that in *N*, *N*-dimethylformamide, since the quenching in this solvent has been found to be almost encounter-controlled. A general correlation has been found between the quenching efficiency and the polarity of the solvent. The quenching mechanism and also the appearance of the CT emission have been discussed.

In previous papers,[1] the quenching action of benzoic acid and its ester on the fluorescence of some naphthalene derivatives was discussed from the viewpoint of a charge transfer (CT) mechanism. Most of the results were favorable to this

1) T. Miwa and M. Koizumi, This Bulletin, **38**, 529 (1965).

viewpoint, but there was no conclusive evidence. The purpose of the present paper is to give further evidence for the CT mechanism of the quenching action of methyl benzoate (MB) on *N*, *N*-dimethyl-2-naphthylamine (DMNA) by studying the solvent effect on the fluorescence spectra and on the quenching action.

Weller was the first to offer confirmative evidence for the CT mechanism of quenching. Leonhard and Weller,[2] for instance, studied the quenching action of aniline, *N*, *N*-dimethylaniline, etc., on the fluorescence of perylene and found that the efficiency of quenching depends largely on the polarity of the solvent; for example, it is large in acetonitrile, but quite small in benzene. They also found that a new emission due to a CT complex between fluorescer and quencher is observable only in nonpolar solvents. Further, by means of a flash technique, they succeeded in detecting the radical anion of perylene in polar solvents, whereas only the enhancement of the T–T absorption was observed in nonpolar solvents. Mataga et al.[3] extended such studies using similar systems. These works led us to expect analogous phenomena in the system of DMNA and MB; we have found that this is really true. Besides, we have ascertained the dipole moment of the excited DMNA by employing the method of Mataga and Lippert.[4]

Experimental

Material.—Acetone of Wako Junyaku, G. R. grade, was stored over potassium permangnate for 3 days, boiled for 2 hr., and then, after distillation, dried over potassium carbonate and finally fractionated. The middle half (b. p. 56.5°C) was used. Ethyl acetate was kept over anhydrous potassium carbonate and then fractionated carefully. Ethyl ether and isopropyl ether of Kanto Kagaku, G. R. grade, were treated with a 10% solution of sodium carbonate for 24 hr. and then dehydrated with anhydrous calcium chloride and finally with sodium. The ethers were repeatedly decanted, and fresh sodium was added until no hydrogen evolved. They were then distilled slowly over sodium. Tetrahydrofuran of Kanto Kagaku, G. R. grade, was repeatedly treated with fresh sodium and decanted until the evolution of hydrogen stopped. It was then distilled over sodium. Methyl benzoate, E. P. grade, was washed with a concentrated aqueous solution of potassium carbonate and dried over anhydrous pottassium carbonate and then over anhydrous mangesium sulfate. After being distilled under reduced pressure, it was passed through 1-meter silica gel column and then distilled in vacuo. The sample thus purified showed no impurity luminescence when the excitation wavelength is longer than 320 mμ. *p*-dioxane, benzene and cyclohexane were purified in the same way as in a previous paper.[1]

Procedure.—The absorption spectra were measured with a Hitachi ESP III recording spectrophotometer. The fluorescence and action spectra were measured with an Aminco-Bowman spectrofluorimeter. The samples were usually not degassed. The temperature was maintained at 25°C. Some measurements were made at low temperatures down to the liquid nitrogen temperature. The concentration of *N*, *N*-dimethyl-2-naphthylamine was always 10^{-4} M. The excitation wavelength was usually 350 mμ. In dealing with the intensity data, the peak intensities were used without any correction for the spectral sensitivity of the instrument. The solvent effect on the optical density at the exciting wavelength, which was usually very small, was taken into account.

Results

The Solvent Effects on the Absorption and Fluorescence Spectra of DMNA in the Absence and in the Presence of MB.—The absorption spectra show a red shift and become broader as the polarity of the solvent increases. The addition of MB has a similar effect, the magnitude of which decreases with the increase in the polarity of the solvent.

In Table I some of the data on the absorption spectra are tabulated. Most of them will be used in the discussion below.

The solvent effects and the effect of the addition of MB on the fluorescence spectra of DMNA are

similar to those on the absorption spectra, but more pronounced. As for the latter effect, it is remarkable in cyclohexane, but very small in dimethylformamide. A notable finding is that the tail in the long-wavelength side grows gradually with the addition of MB, and in most solvents a shoulder and, in favorable cases, a new peak comes to be

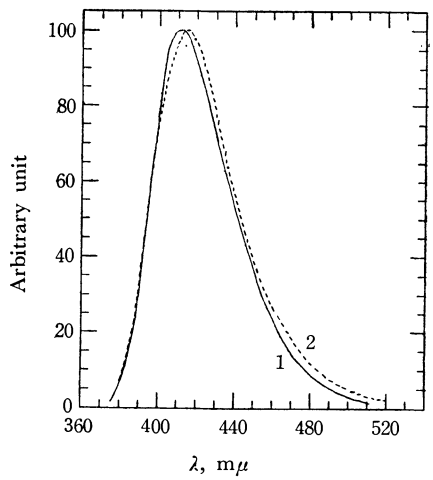

Fig. 4. Fluorescence spectra of DMNA-MB in dimethylformamide.

1) DMNA (1×10^{-4} M) in dimethylformamide
2) DMNA (1×10^{-4} M) + MB (2.40 M) in dimethylformamide

observed. This phenomenon is observed easily in less polar solvents. In *N*, *N*-dimethylformamide, which is the most polar solvent in the present experiment, the above change is very weak. When 10^{-4} M DMNA is dissolved in pure MB, there exist two emission bands, with peaks at 406 mμ and 490 mμ. These two peaks are about the same height, but the integrated intensity for the latter is much larger because of its broad shape. The real difference is probably still larger in view of the spectral sensitivity of the photometer. Some typical examples of the fluorescence spectra are shown in Fig. 1—4, where the peak height of the short-wavelength emission is normalized to unity. The real intensity decreases with the increase in the MB concentration. It may be seen that the solvent effect on the new emission is much larger.

To make sure that this new emission is not due to any impurity which might be present in MB, the excitation spectra were taken on various systems and at various wavelengths of emission spectra. The results confirmed that the new band originates from the light absorption of DMNA, since the excitation spectra agreed quite well with the absorption spectra of DMNA. In Table II some characteristic data on the emission spectra are tabulated. The relative intensities of fluorescence with reference to *N*, *N*-dimethylformamide as the solvent, (F_{0i}/F_{09}), and the relative quantum efficiencies, $(F_{0i}/F_{09})\times(d_9/d_i)_{350}$, where d_i is the optical density in solvent i at 350 mμ (the suffix, 0, indicates the non-existence of MB), are listed since they will be useful for the later discussion. The peak position of the longer-wavelength emission was evaluated by subtracting the shorter-wavelength emission from the total. Since this procedure involves some

arbitrariness, however, the data given are not very reliable.

The Dipole Moment of the Excited DMNA.—Since the absorption and emission spectra in various solvents have been measured, the dipole moment of the excited DMNA molecule can be evaluated by means of the following formula:[4]

$$hc(\tilde{\nu}_a-\tilde{\nu}_f) = \frac{(\mu_e-\mu_g)^2}{a^3}\left[\frac{2(\varepsilon-1)}{2\varepsilon+1}-\frac{2(n_D^2-1)}{2n_D^2+1}\right] + \text{const.} + \text{small terms} \quad (1)$$

The data necessary for the calculation are given in Table III.

The dipole moments and the viscosities of the solvents are listed so that they can be used in the later discussion. ε and n are the values at 25°C. The plot $\tilde{\nu}_a-\tilde{\nu}_f$ vs. $\{2(\varepsilon-1)/2(\varepsilon+1)-2(n_D^2-1)/(2n_D^2+1)\}$ is given in Fig. 5. Assuming a (the cavity radius in Onsager's theory) in Eq. 1 as ~3 Å, the value of $\mu_e-\mu_g$ was found to be 4.1D (Debye). This is reasonable in view of the values of 4.5D, 4.4D, and 3.5D reported for *N*, *N*-dimethyl-1-naphthylamine, 1-naphthylamine, and 2-naphthylamine by Mataga et al.[4] Thus it was confirmed that the excited state of DMNA is highly polar.

Intensity Relations on the Fluorescence of DMNA.—In all the solvents, the fluorescence intensities of DMNA decrease upon the addition of MB. In Figs. 6, 7, and 8, the values of $(F_{0i}d_i/F_id_{0i})-1$ are plotted against the MB concentrations. Since all the plots deviate more or less from the Stern-Volmer relation with the increase in the concentration of the quencher, the quenching constants, K_A, in terms of this equation were evaluated from the slopes of the curves at the point of origin. They are given in Table IV, along with the values obtained from the $(F_{0i}d_i/F_id_{0i})-1$ values at 0.160 and 0.801 M concentrations of MB (K_B and K_C). The moderate agreement of the K_A, K_B and K_C values assures the reliability of the data.

measure of the intensities of this emission, $\{(F_{0i}d_i/d_{0i})-F_i\}/F_{i500}$ (F_{i500} is the fluorescence intensity at 500 mμ) and F_i/F_{i500} are listed in Table IV; for the sake of comparison, $(F_{0i}d_i/F_id_{0i})-1$ for the intrinsic emission of DMNA is also listed. The intensity at 500 mμ was used because the intensity at the peak is difficult to evaluate on account of the superposition of the two emission bands. It should be noted that the values of F_{i500} used as the measures of the new emission become more and more overestimated as the solvent polarity increases, because the solvent effect on this new emission is quite large. Thus, the data are only approximate in nature. However, a general tendency is observed for $\{(F_{0i}d_i/d_{0i})-F_i\}/F_{i500}$ to increase as the quenching constant K increases, whereas F_i/F_{i500} decreases at first, shows a minimum, and then increases again. Such tendencies may clearly be seen from Figs. 9 and 10 where $(F_0d_i/d_{0i}-F_i)/F_{i500}$ and F_{i500}/F_i are plotted, respectively against the concentration of MB. Moreover, Fig. 9 shows that the former quantity increases with the concentration of MB, while a comparison of Fig. 9 with Figs. 6, 7 and 8 indicates that the concentration effect on it is far less than on F_i. Figure 10 shows, on the other hand, that F_{i500}/F_i increases remarkably with the concentration of MB in most cases.

The Effect of Temperature on the Fluorescence Spectra.—To make clear the nature of quenching as well as the origin of a new emission, the spectra were measured at different temperatures down to −182°C. The fluorescence spectra of DMNA 10^{-4} M in cyclohexane at this temperature is extremely sharp in comparison with those at room temperature. When 6.41 M of MB was added to the above solution, the intensity of the fluorescence at room temperature decreases remarkably and the spectra consist of the two emission bands with peaks at 406 and 486 mμ. At −182°C the

emission consists of a single sharp band of a high intensity with a peak at 404 mμ. The shapes of the fluorescence spectra at different temperatures from −182°C up to −31°C are shown in Fig. 11. From the figure it may be seen that, at −31°C and at −38°C, there are two emission bands similar to those at room temperature. Although only one band occurs below −43°C, the tail in the longer wavelength gradually rises with the rise of temperature; the intensity decreases to some extent at −50°C. The intensities at −38°C and at −31°C are quite small.

It should be noted that the above change proceeds as the sample melts. Thus the crystal begins to soften in appearance near −50°C, and around −43°C it partly begins to melt. At −38°C more than two-thirds of the crystals melts, until the melting ends at −31°C. The above observation leads

to the conclusion that the quenching of the fluorescence is dynamic and, further, that a new emission arises from the encounter of an excited fluorescer molecule with a quencher molecule.

All the facts observed strongly support the view that the new emission is due to an excited CT complex. Hereafter, it will be designated as a CT emission.

Discussion

Since the quenching in the present investigation is dynamic in nature, the discussion can be made on the basis of a Stern-Volmer eq. of the following type:

$$\Phi_0/\Phi = F_0/F = 1 + \gamma Z\tau_0[\mathrm{Q}] = 1 + \frac{\gamma Z}{k_f}\Phi_0[\mathrm{Q}] \tag{2}$$

where Φ and Φ_0 are the quantum yields of fluorescence in the presence and in the absence of the quencher. The experimentally-determined quenching constant, K_A, is:

$$K_A = \frac{\gamma Z}{k_f}\Phi_0 \tag{3}$$

where Z is the bimolecular rate constant for an encounter process and γ, the quenching efficiency for each encounter. Further, τ_0 and Φ_0 are written as follows:

$$\tau_0 = \frac{1}{k_f + k_d + k_{q02}[\mathrm{O_2}]} \tag{4}$$

$$\Phi_0 = \frac{k_f}{k_f + k_d + k_{q02}[\mathrm{O_2}]} \tag{5}$$

where k_f, k_d and k_{q0_2} are, respectively, the rate constants for emission, monomolecular deactivation, and bimolecular deactivation due to oxygen.

Now the Z value for each solvent can be estimated from the Stokes-Einstein formula, $8\boldsymbol{R}T/3000\eta$; the values are listed in Table V. $\tau_0 Z$ gives the quenching constant provided γ is unity. The values of $\tau_0 Z$ obtained by putting $\tau_0 = 10^{-8}$ sec. (estimated from the oscillator strength) are also given in the table (K_{cal}). A comparison of K_{cal} with K_A in Table IV will show that, in the case of *N*, *N*-dimethylformamide, they agree quite well. Of course, this is rather fortuitous, but there is no doubt that the quenching in this case is almost entirely diffusion-controlled. In all the other solvents, K_A is much less than K_{cal}. Therefore, it is appropriate to discuss the relative quenching efficiency with reference to $(Z\Phi_0/k_f)_9$ (9 is the numbering index for *N*, *N*-dimethylformamide). The relative quenching constant for solvent i is, then,

$$K_{Ai}/K_{A9} = (\gamma Z\Phi_0)_i/(Z\Phi_0)_9 = \frac{\gamma_i Z_i}{Z_9}\alpha_i = \gamma_i\beta_i \qquad \beta_i = \frac{Z_i}{Z_9}\alpha_i \tag{6}$$

by assuming that $k_{f9} = k_{fi}$. This is approximately correct since the values of $(f/n_D)_i/(f/n_D)_9$ given in Table I are unity within +10% (except cyclohexane). The values for $\alpha_i = \Phi_{0i}/\Phi_{09}$ are given in Table II. The quenching efficiency for solvent i can, thus, be calculated from:

$$\gamma_i = \frac{K_{Ai}}{K_{A9}\beta_i}$$

The values of β_i, K_{Ai}/K_{A9} and γ_{Ai} are tabulated in Table V. The analogous quantities on the basis of K_C are also given to make sure that the values of γ_{Ci} thus obtained are quite reliable for comparing the quenching efficiency. Figure 12

shows the plot of γ_i and $\{(F_{0i}d_i/d_{0i}\alpha_i)-F_i\}/F_{i500}$ against the dipole moments (μ) of the solvent molecules. Broadly speaking, there is a correlation between them except for some irregularity in the solvents with a low polarity. In Figs. 13 and 14, $(F_{0i}d_i/d_{0i}-F_i)/F_{i500}$ and F_i/F_{i500} are plotted against K_C. These two figures suggest that solvents can be classified into two groups, one with a low polarity from cyclohexane to ether type compounds (1 to 5), and the other with a higher polarity from ethyl acetate to *N*, *N*-dimethylformamide (from 6 to 9). Hereafter these two groups will be denoted as group 1 and group 2.

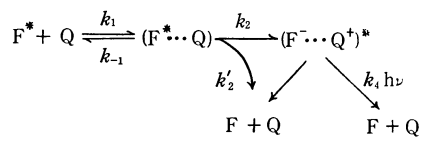
These two types of behaviour, as well as the results in Fig. 12, can well be comprehended on the basis of Weller's scheme for quenching. According to it, the quenching in nonpolar solvents is related to the formation of the CT complex, whereas the quenching in polar solvents occurs through the formation of radical ions. Plausible schemes for the two types of solvents are as follows:[5]

5) Cf. Ref. 3.

A) In nonpolar solvents



and

B) in highly polar solvents

$$F^* + Q \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} (F^*\cdots Q) \underset{k_3}{\rightarrow} F^- + Q^+$$

Thus, in nonpolar solvents an encounter complex $(F^*\cdots Q)$ which has, more or less, a CT character, has two alternative paths, denoted by k_{-1} and k_2 or k_2'; their magnitudes depend upon the solvent, but usually $k_{-1}>k_2, k_2'$. $(F^-\cdots Q^+)^*$, which is reached by the k_2 path, is a stable CT complex capable of emission; its emissivity depends on the environment. k_2', which was included for the sake of generality, denotes another process of deactivation which occurs during the course of CT complex formation. On the other hand, an encounter complex in the highly-polar solvents, being quite a different type from that in nonpolar solvents, proceeds mainly along k_3 instead of k_2 and forms free ionic species. In the solvents with medium polarity, the k_2 and k_3 processes may compete with each other.

If one assumes, as is plausible, that the quenching efficiency in scheme A is far less than in scheme B, then the general tendency seen in Fig. 12 may be easily interpreted. Further, it is natural to consider that the A scheme prevails for group 1, whereas scheme B becomes gradually predominant for group 2. The analysis on the basis of the above scheme, however, requires much more data than those obtained above.

Below we will give only the plausible interpretation of the results shown in Figs. 9, 10, 13 and 14 by introducing a CT emission probability, ϕ_{CT}, which gives a ratio between the CT emission and the effective collisional quenching. Assuming Stern-Volmer's equation, the following relations can easily be derived:

$$F_{500} = \frac{Z\gamma[Q]\phi_{CT}}{k_f + k_d + k_{q0}[O_2] + Z\gamma[Q]} \tag{6}$$

$$\frac{F_{500}}{F} = \frac{Z\gamma[Q]\phi_{CT}}{k_f} \tag{7}$$

$$\frac{F_0 - F}{F_{500}} = \frac{k_f\tau_0}{\phi_{CT}} \tag{8}$$

From Eq. 8, F_0-F/F_{500} or, more rigorously, $(F_0d_i/d_{0i}-F_i)/F_{i500}$ should depend merely on ϕ_{CT}. The slight dependence of ϕ_{CT} on [MB], as seen in Fig. 9, may perhaps be due to the quenching of the CT complex by MB. Alternatively, it may be due to the inadequeacy of the Stern-Volmer relation. Putting approximately $k_f\tau_0 \approx$

1, the solvents belonging to group 1 have ϕ_{CT} values ranging from 0.5×10^{-2} to 2×10^{-2}, whereas the solvents in group 2 have ϕ_{CT} values of $<0.5\times10^{-2}$. As may be seen from Fig. 13, ϕ_{CT} generally decreases with K_C; in group 1 it decreases very little, while in group 2 it decreases to a large extent.

The results in Fig. 14 and 10 can now be interpreted by means of Eq. 7. Thus in group 1, $Z\gamma$ increases while ϕ_{CT} decreases with the polarity, but since the former effect outweighs the latter, F_i/F_{500} decreases, as may be seen in Fig. 14. In group 2, on the other hand, the effect of the decrease in ϕ_{CT} predominates, since the increase of $Z\gamma$ is not so great (the maximum value of γ is 1); as a result, F_i/F_{500} again increases. The rather good linearity holding for the plots in Fig. 10 (as compared with Figs. 6, 7 and 8) may perhaps be due to the ϕ_{CT} factor, which decreases with the concentration of MB.

Thus, all the results can be interpreted if one assumes that, in group 1, $Z\gamma$ increases whereas ϕ_{CT} decreases a little with the polarity, and that in group 2 $Z\gamma$ increases and ϕ_{CT} decreases remarkably. These assumptions are quite natural in view of schemes A and B. It is not possible, however, to decide quantitatively how the contributions of schemes A and B depend upon the solvent polarity, and nor to decide how each elementary reaction in scheme A is influenced by the solvent polarity.

In summary, it may be said that in group 2 the formation of radical ions becomes easier with the solvent polarity, and that this is the main cause of the high quenching efficiency and the low CT emission. Although in group 1, the CT emission seems to become more easily observable with the polarity of the solvent, this is most probably due to the increase in γZ; the probability of the CT emission itself seems to decrease a little with the solvent polarity. The latter remark, however, must be further scrutinized in view of the irregular behavior to be seen in Fig. 12. The influence of the solvent polarity upon the emissivity of CT complex awaits further study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2597—2602 (1966)

Studies of the Quenching of the Fluorescence of Acridine Orange from the Standpoint of Charge-Transfer

By Tomoko KOMIYAMA, Takuji MIWA and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received April 15, 1966)

The quenching action of *N*, *N*-dimethylaniline, nitrobenzene, *s*-trinitrobenzene and tetracyanoethylene on the fluorescence of acridine orange (AO) has been studied using ethanol and dioxane as solvents. In these solvents AO exists as cations or neutral molecules. In the former solvent, the quenching actions of the above substances on these two species have been investigated separately. The quenching constants, *K*'s (in reference to the Stern-Volmer equation) of the above substances (in the above sequence) in ethanol are (34—35), (19.6), (53.6) and (~90) for cations and (8.4), (72.8), (—), and (—) for neutral molecules (in 1./mol.). Thus, when quenchers are electron acceptors, *K* increases with the accepting power: nitrobenzene<*s*-trinitrobenzene<tetracyanoethylene. Further, acceptors are more efficient quenchers on neutral molecules than on cations (nitrobenzene), whereas the reverse is true for donors (*N*, *N*-dimethylaniline). In dioxane the quenching constants are generally somewhat smaller than in ethanol, but a basic similarity has been confirmed. All the results support the view that the present quenching phenomena are closely related to a charge-transfer process.

An electron transfer mechanism for the quenching of fluorescence has been postulated for a long time, but it was only in 1961 that the first evidence for it was presented by Weller.[1]

According to this mechanism, it is expected that a fluorescer with an electron-donating (accepting) power is quenched by an electron-accepting (donating) substance, and that the quenching constant runs parallel with the electron-accepting (donating) power of a quencher. This paper will deal, from such a viewpoint, with the quenching action of a few substances on the fluorescence of acridine orange, which may act as an electron donor or acceptor as the case may be. Besides, acridine orange exists as cations (acid) or neutral

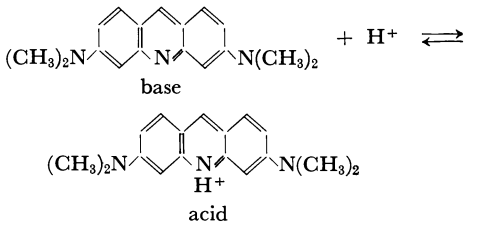
molecules (base) according to the experimental conditions (see below); it is, therefore, interesting to compare the quenching efficiency of each substance on these two species.



Experimental

Materials.—Acridine Orange: a double salt of Tokyo Kasei, G. R. grade, was purified by precipitating the free base from a dilute sodium hydroxide solution, dissolving the precipitate in chloroform (G. R.), and chromatographing it on activated silica-alumina treated with hydrochloric acid. The main band was collected, dissolved in chloroform-methanol, concentrated, and then cooled to −20°C. The precipitate thus obtained was filtered and dried in air and finally in vacuo for several hours at 70°C.[2] M. p. 181°C.

N, N-Dimethylaniline of a G. R. grade of Tokyo Kasei was dried over potassium carbonate, distilled under reduced pressure in a nitrogen atmosphere, and finally submitted to vacuum distillation. The sample was stored in a sealed ampoule.

Triethylamine of a G. R. grade of Tokyo Kasei was dreid over sodium, distilled under reduced pressure in a nitrogen atmosphere, and then stored in a sealed ampoule.

Nitrobenzene, G. R. grade of Tokyo Kasei, was dried with phophorus pentoxide and distilled under reduced pressure. [5.7°C]. *s*-Trinitrobenzene, G. R. grade of Tokyo Kasei, was recrystallized from water two times. After being dried, it was further recrystallized from carbon tetrachloride two times.

Tetracyanoethylene, G. R. grade of Tokyo Kasei, was purified by sublimation three times. The solution soon got a tint of reddish violet, perhaps from an impurity.

Trichloroacetic acid of Kanto Kagaku, G. R. grade, was purified by recrystallization from benzene three times.

Ethanol of Wako Junyaku, G. R. grade, was fractionally distilled. B. p. 78°C.

Dioxane, G. R. grade of Wako Junyaku, was boiled under reflux for a few days over sodium and then distilled twice. B. p. 101°C.

Benzene of Wako Junyaku, G. R. grade, was dried over sodium and then distilled. B. p. 80.1°C.

Methanol of Wako Junyaku, G. R. grade, was fractionally distilled. B. p. 64.5°C.

Procedures.—The fluorescence intensities, fluorescence spectra and action spectra were measured by an Aminco-Bowman spectrofluorimeter. Correction for sensitivity dependence on the wavelength was not made on the fluorescence spectra. The absorption spectra were measured with a Hitachi EPS III autorecording spectrometer.

Results and Discussion

The Absorption and Fluorescence Spectra of Acridine Orange.—According to Zanker,[2] association becomes apparent above 10^{-5} M of acridine orange in an aqueous solution; Mataga reported similar association phenomena in pyridine, acrylonitrile and ethanol.[3] The recent results of Olszowski and Ruziewicz,[4] however, are quite different from Mataga's results. They assigned the two bands with peaks at ~20000 cm^{-1} and ~23400 cm^{-1} which appear separately or simultaneously in various solvents to cations (acid) and neutral molecules (base) respectively. This assignment was confirmed by the present investigation. As is shown in Fig. 1, acridine orange 7.35×10^{-5} M in ethanol gives a single peak at 495 mμ,

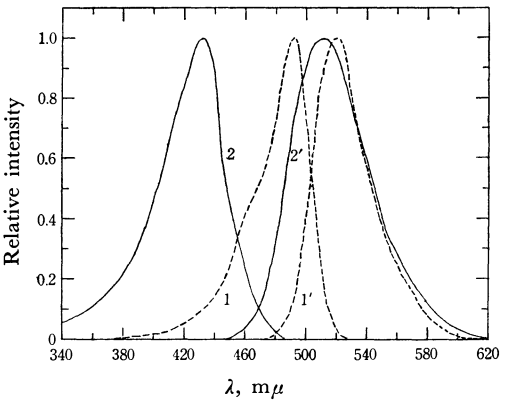


Fig. 1. Fluorescence and absorption spectra of acridine orange (7.35×10^{-6} M) in ethanol.

1′ Fluorescence spectra
} (in ethanol)

2 Absorption spectra
2′ Fluorescence spectra
} (in alkaline ethanol)

with a shoulder[5] near 460 mμ while the fluorescence spectrum obtained by 490 mμ excitation has a single peak at 522 mμ. When ethanol which has been made alkaline by adding a few pieces of sodium hydroxide is used as a solvent, the absorption peak is at 433 mμ with $\varepsilon_{max}=$ 24900 and the fluorescence spectrum obtained by 430 mμ excitation has a peak at 510 mμ. Figure 2 shows the change in the absorption spectra when trichloroacetic acid or triethylamine is added to a 1.96×10^{-5} M solution of acridine orange in

dioxane. When more than 7.1×10^{-3} M of triethylamine is added, only the peak at 426 mμ due to neutral species becomes notable, whereas upon the addition of trichloroacetic acid of 4.14×10^{-5} M, only the peak of the cation at 492 mμ survives. There is an isosbestic point at 442 mμ. Thus, it is in complete accord with the general behavior of the acid-base system. The molar absorbances for cationic and neutral species were estimated to be 4.29×10^{4} and 1.55×10^{4}, respectively. Figure 3 shows a similar change in the fluorescence spectra obtained by the excitation at the isosbestic point. The neutral and cationic species have fluorescence peaks at, respectively, 500 and 530 mμ. From the intensity ratio when excited by the light of the isosbestic point, the ratio of the apparent fluorescence quantum yields of the two species was decided to be neutral: cation=1 : 2.5. Using the data taken from these two figures, the fraction of the cation, x_C can be calculated from the following equations:

$$x_C = \frac{[\text{cation}]}{[\text{total AO}]} = \frac{D_i - D_{iB}}{D_{iC} - D_{iB}} \quad (1)$$

$$x_C = \frac{F_i - 0.4F_{iB}}{F_{iC} - 0.4F_{iB}} \quad (2)$$

where D_i, is the optical density of the solution in question, where D_{iC} and D_{iB} are, respectively, the optical densities of the cation and the base when they exist in a pure form and at the same concentration (all at a certain wavelength, i), where F_i is the fluorescence intensity of the solution in question, and where F_{iB} and F_{iC} are the relative intensities when the intensity for each species at the peak of the fluorescence spectra is taken as unity. It should be added that Eq. 2 is derived on the assumption that there is no shift of equilibrium during the lifetime. Figure 4, which shows the relation between the two sets of x_C-values obtained from Eqs. 1 and 2, verifies that no essential shift occurs during the lifetime of the excited state.

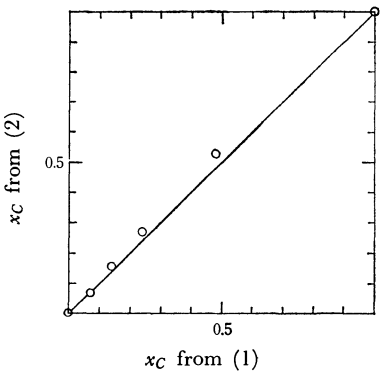

Fig. 4.

The Quenching Action of the Added Substances in Ethanol. — This was examined separately on cations and on neutral molecules. The quenching constants on cations were obtained

by measuring the relative height of the fluorescence spectra at 522 mμ upon excitation at 490 mμ. The quenching constants for neutral molecules were similarly determined by measuring the fluorescence intensity in an alkaline ethanol solution at 510 mμ, with the exciting wavelength at 430 mμ. In all cases it was confirmed that the addition of a quencher does not appreciably affect the absorption spectra of acridine orange. *N*, *N*-Dimethylaniline gives a weak absorption, extending from 380 to 450 mμ, when the concentration is large. This is due to its interaction with the dissolved oxygen,[6] but the excitation in this wavelength region does not give any sign of emission. The absorption spectra of nitrobenzene extend to around 450 mμ; this was taken into account in the measurement in the alkaline solution. *s*-Trinitrobenzene and tetracyanoethylene, both of which are strong electron acceptors, also do not affect the absorption nor the fluorescence spectra of acridine orange. This rules out any specific interaction between fluorescer and quencher. A small band of trinitrobenzene in the 450—600 mμ region is also not affected by the addition of acridine orange. The same holds for the other bands. The absorption spectra of tetracyanoethylene in ethanol is also not essentially affected by the addition of acridine orange. However, trinitrobenzene in the alkaline solution reacts chemically, and the solution becomes red in color. The addition of tetracyanoethylene to the alkaline solution of acridine orange, on the other hand, causes the fluorescence spectra to change into cationic-type spectra. Since tetracyanoethylene is a strong π-acid, some kind of ion-pair may be formed. At any rate, the above situations prevent the determination of the quenching constants of trinitrobenzene and tetracyanoethylene in an alkaline solution.

The results are given in Table I, while some examples of the Stern-Volmer plot are given in Fig. 5.

The results given in Table I can be well comprehended on the basis of a charge-transfer mechanism of quenching. Thus, the order of quenching efficiency on cations, — nitrobenzene < trinitrobenzene < tetracyanoethylene—agrees with that of the electron-accepting power of these substances. Further, *N*, *N*-dimethylaniline, which is considered to act as an electron donor, is a more efficient quencher on cations than on neutral molecules, whereas the reverse is true for nitrobenzene.

The Quenching Action of the Added Substances in Dioxane.—The quenching phenomena were studied with a solution containing both cation and neutral species of acridine orange; suitable

Table I. Quenching constants of some substances on the fluorescence of AO in ethanol

Quencher	Concn. of AO M	Concn. range of quencher, M	Quenching for cation	Const. K^*(l. mol^{-1}) for neutral species
N,*N*-Dimethylaniline	4.90×10^{-5}	2.4×10^{-3}—4.8×10^{-2}	34.5	
	4.90×10^{-6}	8.0×10^{-3}—8.0×10^{-1}		8.4
Nitrobenzene	7.35×10^{-6}	4.9×10^{-3}—9.8×10^{-2}	19.6	
	7.35×10^{-6}	4.9×10^{-3}—9.8×10^{-2}		73
s-Trinitrobenzene	7.35×10^{-6}	3.1×10^{-3}—5.0×10^{-2}	53.6	
Tetracyanoethylene	7.35×10^{-6}	5.6×10^{-3}	(90)	

* $K=(F_0/F-1)/[Q]$
F_0 and F are respectively the fluorescence intensities in the absence and in the presence of a quencher.

exciting wavelengths were chosen and the fluorescence intensities at different wavelengths were compared. The data were analyzed on the basic assumption that no essential shift of equilibrium occurs during the lifetime of the excited state. When the wavelength of the exciting light, i, is not the one at the isosbestic point, F_j, the fluorescence intensity at the j wavelength is approximately given by:

$$F_j = x_C F_{Cj}\frac{\varepsilon_C}{\varepsilon_0} + \frac{1}{2.5}(1-x_C)F_{Bj}\frac{\varepsilon_B}{\varepsilon_0} \qquad (3)$$

where ε_C, ε_B and ε_0 are, respectively, the molar absorbance of cation and base at the i wavelength and that at the isosbestic point. From this equation it was confirmed that, except in very extreme cases, the fluorescence behavior of cation and base can be studied separately by choosing the exciting lights at 490 and 430 mμ respectively and by measuring the intensity at 530 and 490 mμ respectively. In some cases the change in the fluorescence spectra and in the action spectra caused by the addition of a quencher were made use of in getting semi-quantitative information on quenching.

***N*, *N*-Dimethylaniline.**—Figure 6 gives the Stern-Volmer plot for cation and neutral species. The quenching constant for neutral species was determined by the use of a solution containing 2.80×10^{-4} M of triethylamine. The results are, for cation, $K=20$ l./mol. and for base, $K=0$ l./mol.

Nitrobenzene.—With the increase in the concentration of nitrobenzene, the superposition of the absorption of nitrobenzene becomes notable in the shorter wavelength region. The fluorecscence spectra observed when the excitation wavelength is 490 mμ, as well as the action spectra obtained at 530 mμ of the fluorescence spectra, are not essentially affected by the addition of nitrobenzene.

Concentration of nitrobenzene: (1) 0 M, (2) 9.8×10^{-2} M, (3) 9.8×10^{-1} M
Fluorescence wavelength, 500 mμ
Some structures near 500 mμ of curve 3 are due to the characteristics of the Xe - arc lamp emission.

This implies that the fluorescence of the cation is not quenched very much by nitrobenzene. On the other hand, the action spectra taken at 500 mμ of the fluorescence spectra, as Fig. 7 shows, depend on the concentration of nitrobenzene to a great extent. Thus, there is scarcely any doubt that nitrobenzene quenches neutral molecules more efficiently than cations. The quenching constants evaluated from the intensities at 530 and 490 mμ with the exciting lights at 495 and 430 mμ respectively, are ~10 and ~30 l./mol.

Trinitrobenzene.—As in ethanol, a weak absorption from 550 to 600 mμ is not due to the interaction of trinitrobenzene and acridine orange, but to trinitrobenzene itself. The measurement of the fluorescence intensities at 530 and 490 mμ, with the exciting lights at 490 and 430 mμ respectively, gives, as the quenching constants for cations and neutral species respectively, ~55 and ~70 l./mol. The fluorescence spectra taken with exciting lights of shorter wavelengths and the action spectra taken at 490 and 510 mμ of fluorescence spectra also indicated that the neutral species is more quenched than the cation.

Tetracyanoethylene.—With the addition of tetracyanoethylene, the absorption spectra change into cationic-type spectra, just as in ethanol. The fluorescence spectra also become cationic-type spectra; however, their peaks shift slightly toward blue. The quenching constant of tetracyanoethylene on the ion-pair is ~70 l./mol. from the Stern-Volmer plot. The appoximate quenching constants in the dioxane solution are summarized in Table II.

TABLE II. APPROXIMATE QUENCHING CONSTANTS OF SOME SUBSTANCES ON THE FLUORESCENCE OF AO IN DIOXANE

Quencher	K for cation l. mol^{-1}	K for base l. mol^{-1}
N,*N*-Dimethylaniline	~20	~ 0
Nitrobenzene	~10	~30
s-Trinitrobenzene	~55	~70
Tetracyanoethylene	70	

Relations similar to those in ethanol are apparent in this case. All the quenching constants in dioxane are somewhat smaller than in ethanol. This is consistent with the results reported by Miwa and Koizumi.[7]

Conclusion

All the results obtained in the present experiment strongly support a charge-transfer mechanism of quenching. Besides, it has been confirmed that the acid-base equilibrium does not shift essentially during the lifetime of the excited state.

The Photo-ionization of Molecules in Solutions. III. Photo-ionization and Recombination Processes of *N*, *N*, *N'*, *N'*-Tetramethyl-*p*-phenylenediamine in Various Organic Solvent

By Naoto YAMAMOTO, Yoshihiro NAKATO and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received April 21, 1966)

Flash photolysis studies of *N*,*N*,*N'*,*N'*-tetramethyl-*p*-phenylenediamine (TMPD) were made in various solvents at room temperature. The transient absorption spectrum of the cation, $TMPD^+$, was observed in polar solvents. The transient was also observed in a viscous, non-polar solvent. It has a spectrum different from that of $TMPD^+$. Its absorbance is proportional to the flash-light intensity, and it decays exponentially, with $\tau_e=82$ μ sec. This absorption is attributed to the triplet-triplet transition of TMPD. With aerated solutions, no transient spectrum was observed. The fluorescence and the phosphorescence of TMPD caused by direct excitation were investigated, together with those induced by the recombination of electrons and $TMPD^+$ in non-polar matrices stimulated either thermally or by infrared light. The absorption spectra of TMPD in a non-polar matrix at a low temperature were investigated by means of the cross-illumination method, and the time dependence of the absorption was followed. The ionization and the recombination processes were then discussed by the use of these results.

It was found by Lewis and Lipkin[1] that *N*, *N*, *N'*, *N'*-tetramethyl-*p*-phenylenediamine (TMPD) in a rigid matrix at the temperature of liquid air forms the $TMPD^+$ cation by ultraviolet irradiation. The electronic and vibronic properties of the excited states of TMPD and $TMPD^+$ were investigated using the technique of photoselection in a rigid medium at a low temperature.[2] Recently, the existence of an electron ejected into a medium by photo-ionization has been argued by an ESR study.[3] Albrecht and his collaborators have studied the photoionization process of TMPD[4-6] and the recombination process of the ionized species[5-8] in a nonpolar matrix at a low temperature. From these results, they concluded that a two-step mechanism involving the triplet state is responsible for the photo-ionization of benzene derivatives in rigid glasses.[4] Porter et al. sugested the same mechanism for the photo-ionization of aromatic hydrocarbons.[9] Claridge and Willard have found that photoejected electrons from TMPD in matrices containing alkyl halides cause the decomposition of alkyl halides, leading to the appearance of ESR signals of alkyl radicals.[10] Van Voorst and Hoijtink have recently found that solvated electrons are formed by the photo-ejection of electrons from aromatic negative ions in 2-methyl-tetrahydrofuran matrices.[11] Hamill and his co-workers have also been studying similar electron-ejection and capture processes by using radiolysis techniques.[12]

We ourselves have previously studied the photo-excitation and photo-ionization of TMPD and the recombination of the ionized species in a variety of media at various temperatures.[13,14] The work on the room-temperature photolysis has been mainly done by the flash-photolysis technique.

Experimental

Commercially-available TMPD dihydrochloride was neutralized in an aqueous solution with ammonia.

The TMPD thus formed was extracted with ether, dried, and sublimed twice in a vacuum.

The solvent used in this experiment were MP (1 part methylcyclohexane, 1 part isopentane), EPA (5 parts ether, 5 parts isopentane, 2 parts ethanol), pyridine, *n*-heptane, ethanol, acetonitrile, liquid paraffin, and cyclohexanol. The ether was purified by distillation. The methylcyclohexane and isopentane were purified by passing them through activated silica gel. The ethanol was purified by drying it over magnesium ribbon and by distilling it in a 120 cm. column. The acetonitrile was refluxed over phosphorus pentoxide, distilled over anhydrous potassium carbonate to remove the phosphorus pentoxide, and finally fractionally distilled in the same column. The *n*-heptane was fractionally distilled. The EP-grade cyclohexanol, liquid paraffin and pyridine were used without further purification.

In the case of polar solvents, TMPD was dissolved in the solvent after it had been degassed by the freezed-pump-thaw technique. In the case of non-polar solvents, the solution was prepared by the conventional method, and then degassed by the same technique.

Flash-photolysis measurements at room temperature were made by the use of a glass cell with quartz windows (200 mm. long, 16 mm. in diameter). Two photolysis flash lamps, one placed at each side of the cell, were connected in series to a condenser a 5-μF capacity working up to 15 kV. Each lamp was made of a quartz glass tube, 20 cm. long and 1.0 cm. in diameter, with tungsten-electrodes at both ends. Those tubes were filled with argon up to a pressure of about 100 mmHg. A small quartz spectro-flash lamp, with a capillary middle portion, was connected to a 2.5 μF condenser working up to 7.5 kV. The lamps were fired by powerful trigger pulses. The time interval between the photolysis-flash and the spectro-flash can be controlled in the range from 1 μsec. to 1 sec. through a delay circuit. The electric power supply and the trigger pulse generator of this instrument were provided by the Nakano Electric Co. The duration times of both the photolysis-flash and the spectro-flash were found to be less than 3 μsec. The transient absorption spectra were obtained photographically with Fuji Neopan SSS film (ASA 200) by the use of a plane-grating spectrograph 1 m. in focal length (Shimadzu GE-100). The decay-curve measurements of the transient absorption were performed by recording the cathode currents of a photomultiplier (EMI 9552B) with a synchroscope or a recorder.

For the measurements of emission spectra at a low temperature, a degassed TMPD matrix contained in a cylindrical cell 10 mm. in diameter was put into a quartz Dewar. For the measurement of the usual fluorescence and phosphorescence spectra of TMPD, the sample was illuminated by focusing light from a 250-W. high-pressure mercury lamp (Ushio HMB-250D) through a filter (Toshiba UV-D2; transparent from 320 to 390 mμ). The emission of the sample was focused on the slit of a 50-cm. grating spectrograph (Nalumi RM 23), the emission spectra were then photographed. The emission spectrum induced by the infrared illumination of the ultraviolet-irradiated TMPD in the MP matrix was obtained by repeating the following procedures about eighty times: (1) ultraviolet irradiation for 30 sec., followed by (2) a 60-sec. dark period, then (3) infrared illumination and the photographing of the induced emission for 30 sec. The infrared light used was obtained from the mercury lamp through a filter (Toshiba VR-69) transparent from 690 mμ to 3 μ. For the measurement of the thermoluminescence spectrum, the sample was drawn out from the Dewar after irradiation by ultraviolet light at the temperature of liquid nitrogen; it was then held in front of the spectrograph until it melted. The decay of the emission spectra was measured in a MP matrix at 77°K by recording the cathode currents of a photomultiplier (RCA 1P28), placed near the sample, by means of a synchroscope through a cathode-follower circuit.

Results

The Flash Photolysis of TMPD.—The flash photolysis of about 5×10^{-4} mol./l. solutions of TMPD in some deoxygenated solvents at room temperature resulted in the appearance of transient absorption spectra, while in some other no new spectrum was obtained at all. These results are tabulated in Table I. The spectra obtained in ethanol, acetonitrile, and cyclohexanol agree with that of $TMPD^+$ formed by chemical oxidation. The spectrum obtained in liquid paraffin does not exactly agree with that of $TMPD^+$, though they have features similar to some extent, as Fig. 1 shows. Decay curves of the transient absorption spectra in a liquid paraffin solution and an ethanol solution are shown in Figs. 2 and 3 respectively. In the liquid paraffin solution, the decay is of the first order and the life-time is 82 μsec. In ethanol and in acetonitrile, the decay is, rather, of the second order and the life-time is very long. The characteristic violet color of $TMPD^+$ remains visible for more than a day. When these solutions were aerated, no transient absorption spectrum was observed by a flash illumination,

TABLE I. APPEARANCE OF TRANSIENT ABSORPTION BY FLASH ILLUMINATION AT ROOM TEMPERATURE

Solvent	Dielectric constant	Temp., °C	Viscosity (centipoise)	Temp., °C	Appearance
Ethanol	24.30	25	1.20	20	Yes (long life)

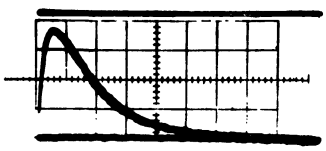

Fig. 2. A decay curve of a transient absorption at 560 mμ formed by flash photolysis of liquid paraffin of TMPD at room temperature. The upper and lower lines indicate 100% and 0% absorption, respectively. The time scale is 50 μsec. per main division.

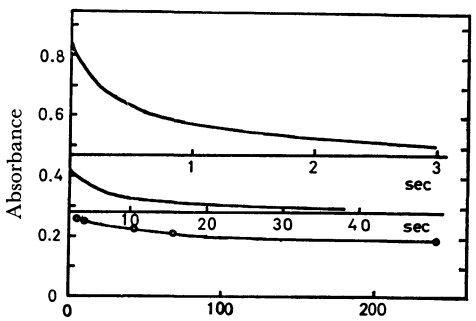

Fig. 3. Decay of the transient absorption (λ= 610 mμ) in ethanol at room temperature produced by the flash photolysis of TMPD.

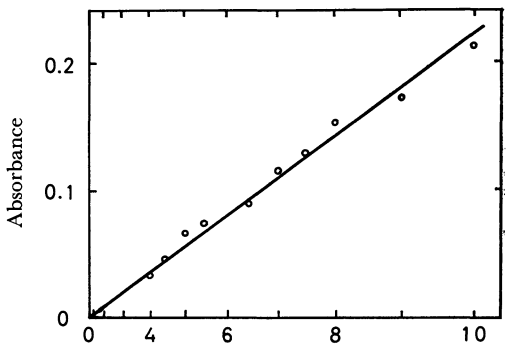

Fig. 4. Dependence of the transient absorption (λ=560 mμ) in liquid paraffin solution of TMPD on the flash light intensity. It is assumed that the flash light intensity is proportional to the square of charging-up-voltage of a 5 μF condenser.

except in the acetonitrile solution.

The correlation between the transient absorption and the intensity of flash light was studied for 10^{-5} mol./l. liquid paraffin solutions of TMPD. Since the intensity curves of the flash light with respect to time do not change with the charging-up-voltages of the condenser, it may be assumed that the light intensity at any moment is proportional to the square of the voltage. The intensity of the transient absorption was found to be proportional to V^2, as Fig. 4 shows.

Luminescence at a Low Temperature.— The UV-irradiated TMPD in non-polar (MP or liquid paraffin) matrices at 77°K shows an afterglow stimulated by infrared light or by warming up the matrix, as has been reported by Albrecht and his co-workers.[7,8] The spectra obtained photographically by the method described earlier in this paper are shown in Fig. 5 by curves b and c. The normal fluorescence (F, λ=375 mμ) and phosphorescence (P, λ=470 mμ) spectra of TMPD are

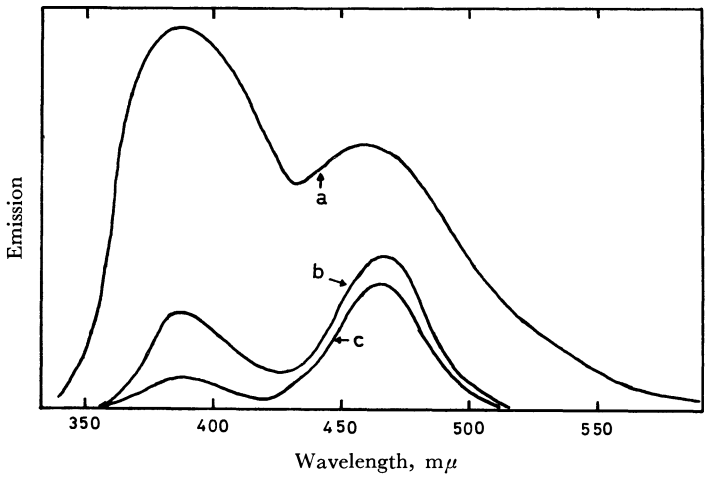

Fig. 5. Emission spectra in MP matrix at 77°K.
a) Emission spectrum of TMPD excited by ultraviolet (mainly 313 mμ). Two peakes at 376 mμ and 470 mμ are the fluorescence and the phosphorescence of TMPD, respectively.
b) Induced emission spectrum obtained by infrared illumination after ultraviolet irradiation.
c) Thermoluminescence spectrum obtained by elevating temperature.

also shown in Fig. 5a. The results of these emission spectra indicate that the induced emission consists of the fluorescence and the phosphorescence of TMPD respectively. The P/F ratios of the induced emission are larger than that of the normal emission of TMPD. In the case of the liquid paraffin matrix, the emission induced by infrared illumination was observed visually at temperatures ranging from 77°K to 120°K. Emission was found to continue until the temperature of the solution became about −30°C. However, no induced emission was observed in the case of polar matrices (ethanol or EPA) by any method. The time dependence of the IR-induced emission in the MP matrix at 77°K was also measured and found to agree with that reported by Albrecht et al.[8]

Absorption Spectra at Low Temperature. —In order to get more information on the nature of the transient absorption obtained by the flash photolysis of TMPD in a viscous solvent at room temperature, the abosprption spectra of about 10^{-5} mol./l. TMPD in a MP matrix at 77°K were measured photographically by means of the cross-illumination method. The 250-W. high-pressure mercury lamp, equipped with a Toshiba UV-D2 filter, was used as the exciting light source. As the spectral light source, a 500-W. Xenon lamp was used. The spectra were photographed by the use of a Nalumi RM 23 spectrograph. In Fig. 6, curve a shows the absorption spectrum taken by an exposure which began 5 sec. after the ultraviolet light came on and continued for 5 sec. Curve b shows the spectrum taken just before the ultraviolet light went off. Curve c shows the spectrum taken by the recording spectrophotometer many minutes after the ultraviolet light went off.

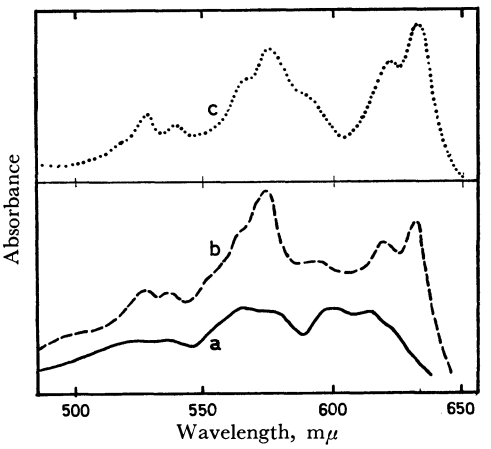

Fig. 6. Absorption spectra of MP matrix of TMPD obtained photographically by means of the cross illumination method at 77°K.

b) The sample was irradiated by UV light for 5 min. The absorption spectrum taken just before the UV light was off.
c) The absorption spectrum taken at many minutes after the UV light was off.

Discussion

We may conclude from the following reasons that the transient absorption spectrum obtained by the flash photolysis of TMPD in liquid paraffin (Fig. 1, curve a) is the T-T′ absorption of TMPD:

1) The spectral feature is different from that of $TMPD^+$ (Fig. 1).

2) Its absorption intensity is proportional to

the intensity of the photolysis flash light, while it would be proportional to its square if the two-step photo-ionization mechanism proposed by Albrecht et al. was correct.

3) Its absorbance is larger than that of $TMPD^+$ formed by a single-flash photolysis with the same flash apparatus of a degassed ethanol solution, while the quantum yield of $TMPD^+$ formation in a non-polar matrix at 77°K is much less than that in a polar matrix at 77°K.[15] On the other hand, if it is the T-T' absorption, the larger intensity in liquid paraffin can reasonably be attributed to its larger viscosity which stabilizes the triplet state.

4) The decay of the transient absorption in a liquid paraffin solution is exponential. This means a first-order decay process; therefore, it does not correspond to a recombination process between a cation and a free electron. The life-time (82 μsec.) is in the range of those of the triplet states of aromatic hydrocarbons.[16]

The transient absorption spectra obtained in polar solvents at room temperature are identical to that of $TMPD^+$, and the decay curve is nearly a hyperbola. For polar solvents, therefore, photo-ionization is easily produced by flash illumination at room temperature and the ionized species has a remarkably long life-time (one or two days).

For solvents with low dielectric constants and low viscosities, no transient absorption is observed at room temperature. In this case, the first excited triplet state of TMPD is supposed to have a life-time so short that it is impossible to detect it. Also, TMPD is not photo-ionized in such solvents.

When these solutions are aerated, no transient absorption is observed, except for the acetonitrile solution. In a liquid paraffin solution at room temperature, the fluorescence of TMPD is not quenched by the existence of O_2.[15] When ethanol or acetonitrile solution is aerated after the transient absorption is formed by the flash, no oxygen effect on the absorption is observed. It is also well known that an excited triplet state of aromatic hydrocarbon is quenched by O_2.[16] Our results concerning the O_2 effect are consistent with the two-step mechanism of the photo-ionization which occurs via the triplet state of TMPD.

It was pointed out by Albrecht and McClain,[8] on the basis of their photo-electric measurements, that the P/F ratio of the phosphorescence and fluorescence intensity in the induced emission is different from that in the normal TMPD emission. They, therefore, suggested that a direct transfer from the recombining electron to the triplet state occurs to some extent, for if the transfer occurs only to the singlet state, the P/F ratio should be the same as that for the normal emission of TMPD. Our results, shown in Fig. 5, curve b, is in agreement with their results, showing that the P/F ratio is much larger in the infrared-stimulated emission. The P/F ratio in the thermoluminescence, as shown by Fig. 5, curve c, is still larger, indicating that the probability of the transfer to the triplet state is larger in this case.

In polar media, no emission is observed either by infrared ($\lambda > 690$ mμ) or by elevating the temperature. This suggests that the potential trough for the electrons is so deep that the energy of infrared light is not sufficient to release it. At an elevated temperature, the electron recombination will lead to the ground state of TMPD. Ultraviolet-irradiated TMPD in an EPA matrix shows an ESR spectrum composed of ill-resolved quintets, which might correspond to a radical $CH_3\dot{C}HOH$,[17] whereas in the MP matrix a strong sharp peak is obtained at the free-spin g value. The results in EPA seem to indicate that most of the ejected electrons react with the solvent, possibly causing $CH_3\dot{C}HOH$ or $C_2H_5O^-$. However, to solve the question of whether the model of electrons-deeply-trapped-in-the-solvent does or does not apply in this case, we need more experimental knowledge on these matters.

The change in the absorption spectrum with time as measured by the cross-illumination method at a low temperature (Fig. 6) clearly indicates that two species are present. One corresponds to Curve a, which coincides well with the T-T' absorption spectrum obtained by the flash illumination of the liquid paraffin solution at room temperature (Fig. 1a), although the vibrational structure is more evident in this case, probably because of the low temperature. Curves b and c are almost identical; they evidently represent the spectrum for $TMPD^+$. The change in these spectra with time is more clearly seen by Fig. 7. When the ultraviolet lamp is on, the T-T' absorption rapidly increases within a few seconds, that is to say, it

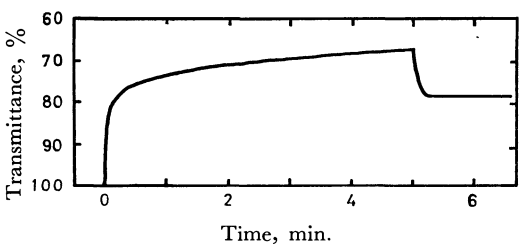

Fig. 7. Time dependence of the absorption (λ= 575 mμ), which consists of the transient and the stable components, in MP matrix of TMPD at 77°K by cross illumination method. At time, t=0, ultraviolet light is on. At t=5 min., light off.

15) Unpublished results in our laboratry.

17) Unpublished results from our laboratry. The details will be reported in the near future.

is of the same order as the life-time, τ_e, of the triplet state. (The life-time, τ_e, of the triplet state of TMPD has been determined by us, from the decay of its phosphorescence, to be 2.12 sec.) Then the absorption increases almost linearly with time. During this period, it may be supposed that the T-T' absorbance keeps a constant value and that the absorbance due to $TMPD^+$ steadily increases. When the ultraviolet lamp is off, the component of the absorbance arising from the T-T' transition decays again within a few seconds, and the total absorbance drops to a constant value due to $TMPD^+$. These results, together with the flash-photolysis results with a liquid paraffin solution, clearly demonstrate that there are two bands due to different species in the same wavelength region. Their spectra have also been unambiguously determined.

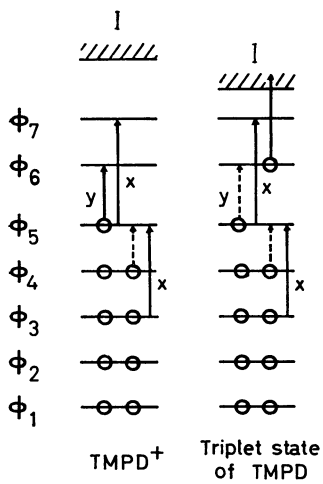

Fig. 8. Scheme of the molecular orbitals and the electron configurations of $TMPD^+$ and the triplet state of TMPD.

It is of theoretical interest to compare the two spectra and to interpret them on the basis of the molecular orbital theory. Figure 8 shows schematically the molecular orbitals (MO's) and the electron configurations of $TMPD^+$ and the triplet state of TMPD. It was determined by Albrecht that the visible spectrum of $TMPD^+$ is X-polarized, that the near ultraviolet hump (λ=370 mμ) is Y-polarized, and that the ultraviolet peak (λ=320 mμ) is X-polarized. According to calculations made by Kimura and Mataga,[18] these bands correspond mainly to the one-electron excitations, $\phi_3 \rightarrow \phi_5$, $\phi_5 \rightarrow \phi_6$, and $\phi_5 \rightarrow \phi_7$. The $\phi_4 \rightarrow \phi_5$ excitation should be in the infrared region, it may not appear because it is a forbidden transition.

If one assume that the MO's and the orbital energies of the triplet states are analogous to those for $TMPD^+$, the visible T-T' band is clearly due to the $\phi_3 \rightarrow \phi_5$ excitation. The $\phi_5 \rightarrow \phi_6$ excitation in this case must inevitably lead to a singlet state, therefore, it is a forbidden transition. The absorption band corresponding to this transition must, therefore, be very weak. This explains very well the lack of a near ultraviolet hump for the spectra of the triplet state of TMPD. The ultraviolet absorption might then correspond to the $\phi_5 \rightarrow \phi_7$ excitation. In this case, however, the ionization threshold will be considerably lower than that for TMPD. It is, therefore, doubtful whether the ultraviolet absorption is due to $\phi_5 \rightarrow \phi_7$ excitation or to the transition leading to ionization ($\phi_6 \rightarrow$ I).

If we tentatively assume that the latter is the case, the wavelength at which the ultraviolet absorption starts (ca. 340 mμ) would correspond to the vertical ionization potential for the triplet-state TMPD in an MP matrix, leading to 3.6 eV., a bit larger than the value proposed by Cadogan and Albrecht (3.2 eV.). By the addition of the excitation energy from the ground to the triplet state of TMPD (3.0 eV.), the ionization potential is found to be 6.6 eV.

The authors are grateful to Professors A. C. Albrecht and J. E. Willard for showing us parts of their papers prior to publication.

Kinetic Studies of Ammonia Oxidation in Shock Waves. III. The Radiation of Excited OH Radicals

By Tetsu TAKEYAMA and Hajime MIYAMA

Basic Research Laboratories, Toyo Rayon Company, Ltd., Tebiro, Kamakura, Kanagawa

(Received April 22, 1966)

Mixtures of ammonia and oxygen in argon were heated by reflected shock waves to temperatures between 1600 and 2100°K, and the ultraviolet radiation from $OH(^2\sum^+)$ was observed by means of monochromator and a photomultiplier. The radiation profiles showed two types of radiation: a strong spike which appeared after an induction period, and a weak and constant-level emission, which followed the spike and persisted for up to 500 μsec. The former emission was observed also in the oxidation of hydrogen, methane, and acetylene, but the latter emission was observed only in the oxidation of methane and acetylene. The temperature coefficients of the intensities of the latter emission divided by the sum of spectral emissivities were found, for the oxidation of ammonia, not large enough to be explained by the thermal excitation of the ground-state $OH(^2\pi)$ to the $^2\sum^+$ state. Possible reaction processes for this chemiluminescence were proposed to explain the experimental results.

OH radicals in the ground state, $^2\pi$, have been found, by absorption spectrophotometry, to persist more than one millisecond in oxidation reactions of hydrogen,[1] methane,[2] acetylene,[3] and ammonia[4] in shock waves. On the contrary, excited OH radicals, $^2\sum^+$, were observed in the detonation of hydrocarbons to last for a very short period, showing spike in their time history of radiation.[5] Also, the chemiluminescence of excited OH in hydrogen-oxygen reactions was studied in detail recently.[6]

In the course of the study of the ammonia oxidation, we have measured the change with time in concentrations of excited OH radicals and other intermediate species simultaneously.[4] We have thereby found the interesting fact that the spike of OH radiation is followed by a weak radiation which persists at an essentially constant level from 100 to 500 μsec. This prompted us to clarify whether the radiation is chemiluminescent or thermal in nature, and to see whether or not the same type of radiation is observed in the oxidation of other fuels.

Experimental

The experimental apparatus and procedure have been described in detail previously.[3,4,7] In brief, the ultraviolet radiation of OH has been observed through a quartz window, mounted 5.5 mm. from the end wall of the shock tube, by a Shimadzu QR-500 monochromator and a Hamamatsu-TV R106 photomultiplier. The monochromator has been set at 3067 Å, and its slit width, at 0.15 mm., allowing a band pass of 6 Å. The incident shock speed has been measured by two platinum-thin-film thermometers, stationed 139.0 mm. apart, and an electronic counter. After each run, the debris of the Lumirror (polyester film) diaphragm was taken out of the shock tube, and the quartz window was cleaned. Gas mixtures were prepared manometrically in an all-glass apparatus, and stirred magnetically for at least an hour before being used in the experiment.

Calculation

That the radiation of OH observed in the oxidation of ammonia is chemiluminescent in nature has been determined in the following manner.

The basic phenomenological law for the emission of radiation at wave-number ω from uniformly-distributed radiators is[8]:

$$R_\omega = R_\omega^0[1-\exp(-P_\omega X)], \quad (1)$$

where R_ω is the total spectral radiancy; R_ω^0, the black body radiancy; P_ω, the spectral absorption coefficient, and X, the optical density. The term in brackets is referred to as the spectral emissivity, α_ω. Thus, the spectral intensity, I_ω, measured in the experiment by a monochromator and a photo-

multiplier may be represented by:

$$I_\omega = AR^0_\omega \alpha_\omega, \tag{2}$$

where A is a constant determined by the selected conditions of the optical system and the measuring instruments. By applying Wien's radiation law, $R^0_\omega = B\exp(-\boldsymbol{h}c\omega/\boldsymbol{k}T)$, to Eq. 2, the following relation can be obtained:

$$I_\omega/\alpha_\omega = C(\omega)\exp\left(-\frac{\boldsymbol{h}c\omega}{\boldsymbol{k}T}\right), \tag{3}$$

where C is a coefficient which is variable with the wave number but which is independent of the temperature, and where $\boldsymbol{h}$, c, and $\boldsymbol{k}$ are Planck's constant, the light velocity, and Boltzmann's constant respectively. Therefore, for the thermal radiation, a plot of $\log(I_\omega/\alpha_\omega)$ vs. $1/T$ would give a straight line, the slope of which corresponds to $-\boldsymbol{h}c\omega/\boldsymbol{k}$.

In the actual measurement, the monochromator allows a band pass of several angstrom, and, hence, a certain number of spectral lines reach the photomultiplier. Accordingly, the observed intensity, I, is a sum of the intensity of each line; namely:

$$I = \sum_i I_i \tag{4}$$

On the assumption that, for a narrow range of wave numbers, the right hand side of Eq. 3 may be represented approximately by the value for the average wave number, ω_{av}, the following relation can be obtained from Eqs. 3 and 4:

$$\frac{I}{\sum_i \alpha_i} = C(\omega_{av})\exp\left(-\frac{\boldsymbol{h}c\omega_{av}}{\boldsymbol{k}T}\right) \tag{5}$$

Thus, the plot of $\log(I/\sum_i \alpha_i)$ vs. $1/T$ gives a check on whether the radiation is thermal or chemiluminesent.

As we measure the spectral-line emission, the radiancy for the isolated spectral line, R_L, must be used rather than R_ω, which refers to the radiancy at wave number ω, in the calculation of emissivities by means of Eq. 5. Taking into account the natural-line-, the collision-, and the Doppler-broadening effects, the following relation is valid[8]:

$$\frac{R_L(\ln 2)^{1/2}}{2R^0{}_\omega b_D} = \frac{1}{2}\int_{-\infty}^{\infty}[1-\exp(-P_{|\xi|}X)]\,d\xi,$$

where;

$$P_{|\xi|} = P'\left(\frac{a}{\pi}\right)\int_{-\infty}^{\infty}\frac{\exp(-y^2)}{a^2+(\xi-y)^2}\,dy, \tag{7}$$

$$P' = \frac{S}{\omega_0}\left(\frac{mc^2}{2\pi\boldsymbol{k}T}\right)^{1/2} = \frac{S}{b_D}\left(\frac{\ln 2}{\pi}\right)^{1/2}, \tag{8}$$

$$a = \frac{(b_N+b_C)}{b_D}(\ln 2)^{1/2}, \tag{9}$$

$$\xi = \frac{\omega-\omega_0}{\omega_0}\left(\frac{mc^2}{2\boldsymbol{k}T}\right)^{1/2} = \frac{\omega-\omega_0}{b_D}(\ln 2)^{1/2} \tag{10}$$

and where b_N, b_C, and b_D refer to the natural line-, the collision-, and the Doppler-broadening respectively; where S refers to the integrated absorption, a, to the line-shape parameter, and ω_0, to the wave number at the line center and where m is the mass of electrons. All these quantities can be estimated from the experimental conditions; accordingly, P can be numerically calculated by using one of several approximate expressions of Eq. 7.[7,8]

However, the results of the computations of these approximate formulae have been conveniently summarized[9] in the "curves of growth," where the dimensionless parameter, $R_L(\ln 2)^{1/2}/2b_D R^0_{\omega_0}$, is plotted against $\log(10.6P'X)$ for various values of the line-shape parameter, a. Therefore, the emissivity for each spectral line, R_L/R^0_ω, can be estimated from the curves of growth.

Results and Discussion

Figure 1 shows profiles of the ultraviolet radiation of OH radicals due to the $^2\Sigma^+ \rightarrow {}^2\Pi$ transition, and of the ultraviolet absorption of ammonia at 2245 Å,[7]

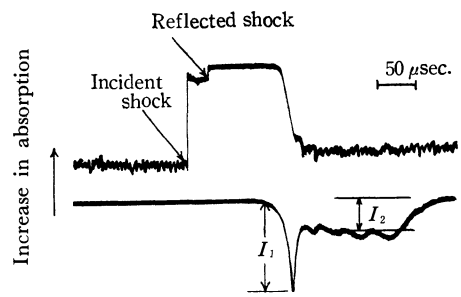

Fig. 1. Typical, oscillogram; upper trace shows NH_3 absorption measured at 2245 Å and lower trace OH emission at 3067 Å. Composition of gas mixture, Ar 90% - NH_3 6% - O_2 4%; initial pressure, 60.1 mmHg; incident shock velocity, 985.8 m/sec.; reflected shock temperature, 1930°K; equilibrium pressure, 4.74 atm.

which have been obtained by shock-heating mixtures of ammonia and oxygen diluted in argon to 1930°K. These profiles are essentially the same for all the experiments: the intensity of OH emission rises steeply, after an induction period, to a sharp maximum; there follows an approximately exponential decay to 1/4—1/8 the level of the maximum, and then the intensity remains at this level for a period varying from 100 μsec. for the strong shock (T_5=1980°K) to 500 μsec. for the weak (T_5=1650°K), until finally it falls to zero emission.

We were more interested in the weak emission, I_2, than in the strong emission, I_1, because, so far as we know, no paper has yet been published on

this emission. Thus, we tried to identify the nature of I_2 by the method described above; measurements were mainly made of two mixture (Ar 90% - NH_3 6% - O_2 4% and Ar 90% - NH_3 4% - O_2 6%) which had been investigated previously.[4]

Since the slit width of the monochromator allowed a band pass from 3064 to 3070 Å, nineteen spectral lines of R_1 and R_2 branches of (0, 0) band in the $^2\Sigma^+\rightarrow{}^2\Pi$ transition were regarded as contributing to the intensity of emission; the satellite branches, R_{21} and S_{21}, were neglected because of their weakness compared with R_1 and R_2. The values of emissivities calculated for one set of experimental condition are presented in Table I. The equilibrium temperature and pressure[13] have been used in the calculation, since the majority of the ammonia (more than 95%) has reacted before I_2 appears, as is shown in Fig. 1; accordingly, the reaction system can be considered to be close to the equilibrium condition.

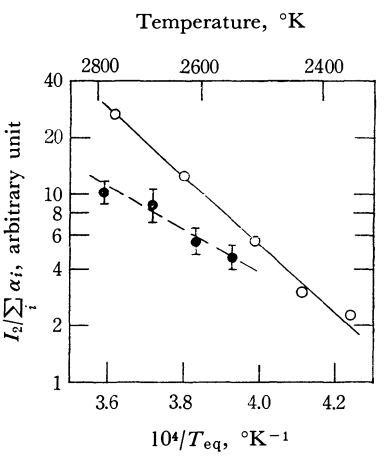

Fig. 2. Plot of log (I_2/α_i) against reciprocal temperature. Open circles represent data obtained for mixture of 90%Ar, 4%NH_3, and 6%O_2, and solid circles for mixture of 90%Ar, 6%NH_3, and 4%O_2.

13) We are greatly indebted to Prof. W. C. Gardiner, Jr. of University of Texas for the equilibrium-state calculation.

The temperature dependence of the intensity of emission is shown in Fig. 2 as a plot of $\log(I_2/\sum_i \alpha_i)$ vs. $1/T$; the temperature coefficients are 56 and 82 kcal./mol., less than the quantity needed for the thermal excitation of OH ($^2\Pi$).

The dependence of the intensity of I_2 upon the equilibrium concentration of OH, H, O_2 and H_2 was studied by using several mixtures presented in Table I of the previous paper[7] (Part II of this series).

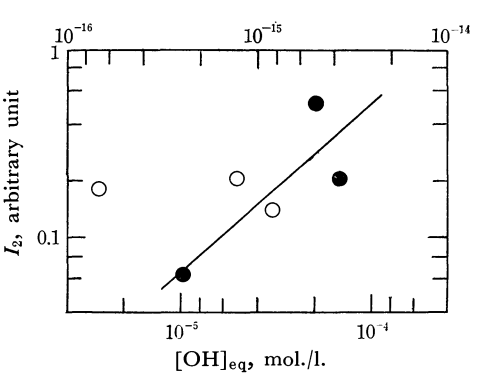

Fig. 3. Intensity of OH emission against equilibrium concentration of OH (open circles) and against the products of equilibrium concentration of H, O_2 and H_2 (solid circles). Slope of the solid line is about 0.9 by inspection.

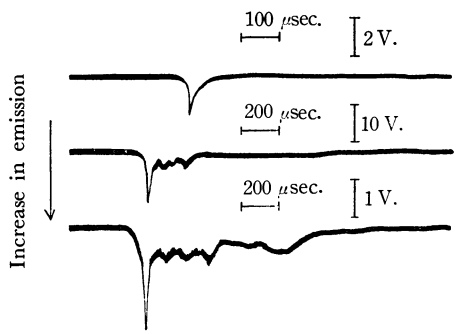

Fig. 4. Profiles of OH emission observed in oxidations of other fuels.
Top trace: Ar 90% - H_2 6.67% - O_2 3.33%; initial pressure, p_1, 100.3 mmHg; incident shock velocity, w_1, 722.3 m./sec.; reflected shock temperature, T_5, 1150°K; reflected shock pressure, p_5, 2.60 atm.
Middle trace: Ar 90% - C_2H_2 4% - O_2 6%; p_1, 100.3 mmHg; w_1, 716.0 m./sec.; T_5, 1135°K; p_5, 2.82 atm.
Bottom trace: Ar 90% - CH_4 3% - O_2 7%; p_1, 79.9 mmHg; w_1, 903.6 m./sec.; T_5, 1690°K; p_5, 4.30 atm.

It was found that the intensity of I_2 is independent of the equilibrium OH concentration $[OH]_{eq}$ over the concentration range from 3.2×10^{-5} to 3.2×10^{-6} mol./l., but that it is approximately proportional to $[H]_{eq}[H_2]_{eq}[O_2]_{eq}$ when $[OH]_{eq}$ is kept almost constant, as is shown in Fig. 3.

For purposes of comparison, measurements were made of the OH emission in reactions of hydrogen, methane, and acetylene with oxygen. The profiles obtained are shown in Fig. 4. Although the profiles for the oxidation of methane and acetylene are similar to those for ammonia oxidation, that for the oxidation of hydrogen is very different from the others; no weak emission following a spike can be observed.

The temperature coefficients of the intensity of OH emission, I_2, obtained in Fig. 2 for both mixtures are definitely less than that required for the termal excitation:

$$OH(^2\Pi) + M \rightarrow OH(^2\Sigma^+) + M \quad -93.5\,\text{kcal./mol.} \qquad (I)$$

indicating that the excited OH radicals are produced by chemical reaction processes. This is supported also by the fact that the intensity of I_2 is independent of the ground-state OH concentration.

The proportionality of I_2 to $[H]_{eq}[H_2]_{eq}[O_2]_{eq}$ seems to suggest that the following excitation mechanism is valied:

$$H + O_2 + H_2 \rightarrow OH^* + H_2O \qquad (II)$$

This mechanism has been proposed by Belles and Lauver[6] for the OH* chemiluminescence observed during the induction period of the hydrogen-oxygen reaction. The absence of I_2 in the hydrogen-oxygen reaction, as is shown in Fig. 4, suggests that most of the hydrogen has been used up before the appearance of I_2 emission. On the contrary, considerable amounts of hydrogen are produced near the end of the ammonia oxygen reaction (order of 10^{-4} mol./l., according to equilibrium calculation); therefore, Reaction II can be considered to be operating during the period when I_2 is observed. A similar explanation may serve for the acetylene-oxygen and methane-oxygen reactions. However, Reaction II is not the only possibility. Further studies will be required to elucidate a detailed mechanism for this chemiluminescence.

The authors wish to express their thanks to Dr. W. C. Gardiner, Jr., and Dr. Soji Tsuchiya for their helpful discussions and criticisms, and to Messrs. Kazutoshi Sugiyama and Akio Sawa for their assistance in the experiment.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2613—2615 (1966)

A Comparison of the Radiation-Induced Reaction with Photochemical and Thermal Reactions. I. The Radiation-Induced Isomerization of *o*-Nitrobenzaldehyde in the Solid State

By Akira SUGIMORI, Kōichi NAKATA and Hachiro HIRAI

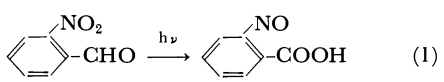
Department of Chemistry, Faculty of Science and Technology, Sophia University, Chiyoda-ku, Tokyo

(Received May 2, 1966)

The radiation-induced reaction of *o*-nitrobenzaldehyde in the solid state was investigated. Isomerization to *o*-nitrosobenzoic acid preferentially took place. This suggests that the γ-ray irradiation produces effectively the excited *o*-nitrobenzaldehyde which is identical with that produced by ultraviolet irradiation.

The radiation-induced reaction has often been compared with the photochemical reaction using rather simple compounds.[1-5] However, only a few studies have been carried out with complex compounds.

The photochemical reaction of *o*-nitrobenzaldehyde was studied by Ciamician and Silber,[6] and by Leighton and Lucy.[7] These studies showed that the following isomerization proceeds intramolecularly both in solid state and in a solution, with no side reaction.



(1)

This system is considered to be suitable for the comparison of radiation-induced reaction with the photochemical reaction from the following reasons. First, little kinetical consideration is needed for the interpretation of the reaction because of the intramolecular rearrangement. Secondly, the photochemical reaction of *o*-nitrobenzaldehyde has already been elucidated, not only with a solution but also with the solid state. Direct excitation by ionizing radiation can not be expected with a solution.

Results and Discussion

The results of the analysis of the gaseous products from the γ-ray-irradiated solid *o*-nitrobenzaldehyde are listed in Table I.

Table I. Gaseous products from the γ-ray irradiated *o*-nitrobenzaldehyde

i) Condition of irradiation
Dose Rate : 3.3×10^{19} eV./g.hr.
Total Dose : 2.0×10^{22} eV./g.

ii) G(total gaseous products)$=0.2$

Component	
CO_2	82%
CO	16%
H_2	2%
NO_2, NO, N_2O	—

No oxides of nitrogen (N_2O, NO and NO_2) were observed to be formed. The evolved gas consisted of carbon dioxide, carbon monoxide, and a small amount of hydrogen. However, the yields of the gaseous products were small and the G value for the total gaseous products was found to be 0.2.

In contrast with the small G value of the radiolytic decomposition, the radiation-induced isomerization of *o*-nitrobenzaldehyde to *o*-nitrosobenzoic acid proceeds in a highly efficient manner. The results of the analyses of the γ-ray-irradiated *o*-nitrobenzaldehyde are shown in Table II.

Table II. The analysis of the γ-ray irradiated *o*-nitrobenzaldehyde

Absorbed radiation dose ($\times 10^{22}$ eV./g.)

Fig. 1. Relation between the yield of *o*-nitrosobenzoic acid and the absorbed radiation dose.

The formation of *o*-nitosobenzoic acid is plotted against the absorbed radiation dose in Fig. 1.

As is shown in Table II, the formation of *o*-nitrosobenzoic acid can explain more than 90% of the reaction of *o*-nitrobenzaldehyde. At a rather high dose of irradiation, where 35.4% of the original *o*-nitrobenzaldehyde was consumed (Run 2 in Table II), the side reaction was only 3.8% of the isomerization.

A linear relationship was observed between the yield of *o*-nitrosobenzoic acid and the absorbed radiation dose in the range where the conversion was below 40%. The *G* value for the *o*-nitrosobenzoic acid formed is found from Fig. 1 to be 5.8.

Since the *G* value of the main reaction is 5.8, the *G* value of the side reaction can be estimated as 0.2—0.5. Most of the side reaction may be explained by the reaction that gives rise to the formation of gaseous products, because the *G* value for the gaseous products is nearly equal to the *G* value for the side reaction. Judging from the composition of the gaseous products, the side reactions may be:

(2)

(3)

The reactions to give oxides of nitrogen and hydrogen are negligible.

Since carbon dioxide is considered to come from the secondary decomposition of the initially-produced *o*-nitrosobenzoic acid, the only side reaction at the initial stage is the decarbonylation reaction (reaction 3). Reaction 3 plays a minor part in the side reactions (it comprises 1/6 of the total side reactions), so the side reactions at the initial stage may be smaller than as evaluated above.

These facts indicate that the γ-ray irradiation gives rise preferentially to the isomerization of *o*-nitrobenzaldehyde to *o*-nitrosobenzoic acid.

It can be said that the identity of the reaction in such a special case as the isomerization of *o*-nitrobenzaldehyde to *o*-nitrosobenzoic acid indicates the identity of the reaction mechanism and the identity of the excited molecules included in the reaction. In the radiation-induced reaction of *o*-nitrobenzaldehyde, the same excitation as that in photochemical reaction is preferentially produced. Analogous results have been obtained in the radiolysis of oxalato metal complexes.[8] These compounds have an efficient reaction path for the absorption of light (the supply of relatively low energy), and the radiation-induced reaction occurs selectively and with a high effciency through this reaction path.

As to the yields of the isomerization by light and by ionizing radiation, the following explanation may hold.

Leighton and Lucy showed that the quantum yield of the isomerization is 0.5 for ultraviolet light of 3660 Å (3.4 eV.), 3130 Å (4.0 eV.), and 2537 Å (4.4 eV.).[7] Therefore, the supply of at least about 7 eV. of light energy is necessary for each *o*-nitrosobenzoic acid molecule. On the other hand, the *G* value of the isomerization in γ-ray irradiation was 5.8. This means that 17 eV. of radiation energy is required for the production of each *o*-nitrosobenzoic acid molecule. This suggests that most of the radiation energy absorbed was lost in the form of heat without bringing the molecules of *o*-nitrobenzaldehyde to excitation.

Experimental

Materials.—Commercially-available *o*-nitrobenzaldehyde (guaranteed reagent-grade; Tokyo Kasei Co.) was used without further purification. The purity of the sample, which was determined by the gravimetric analysis to be 2, 4-dinitrophenylhydrazone, was 97.7%. *o*-Nitrosobenzoic acid was produced by the ultraviolet irradiation of *o*-nitrobenzaldehyde in a benzene solution.[6]

Gamma-Irradiation.—One to two grams of *o*-nitrobenzaldehyde were sealed in a tube with a break-off seal in a vacuum. The samples were irradiated by Co-60 γ-rays in the irradiation facility, equipped with a Co-60 source of 16000 curies, at the Japan Atomic Energy Research Institute.

Gaseous Products.—The break-off seal of the tube containing the γ-ray-irradiated *o*-nitrobenzaldehyde was cut in the vacuum system, the volume of which had been measured in advance. The pressure increase in the vacuum system permitted us to determine the quantity of gas evolved. Some of the gaseous products were analyzed by the mass spectrometric method. A CEC Model 103C mass spectrometer was used. The quantity of CO_2 was estimated from the peak at $m/e=44$. The ratio of CO to CO_2 was evaluated from the peaks.

8) A. Sugimori, This Bulletin, **38**, 2583 (1966).

at $m/e=12$ and 44. The hydrogen content was estimated from the peak at $m/e=2$. The lack of the peak at $m/e=30$ indicates the absence of N_2O, NO and NO_2.[9]

The Determination of *O*-Nitrosobenzoic Acid.—Gamma ray-irradiated *o*-nitrobenzaldehyde was treated three times with each 5-ml. portion of benzene, and the benzene-insoluble substance was collected on a sintered glass filter. It was dried at 80°C and weighed. The substance was identified as *o*-nitrosobenzoic acid from its infrared spectra (Fig. 2).

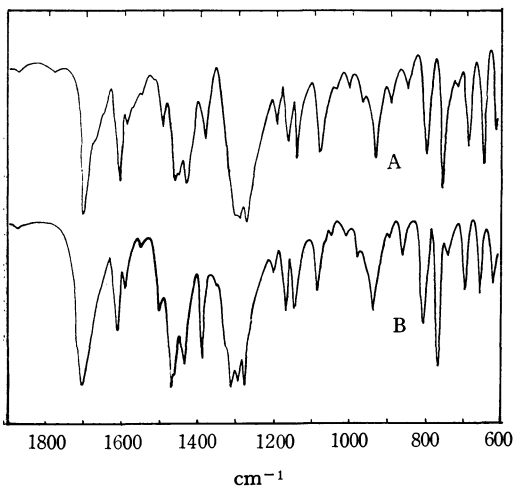

Fig. 2. Infrared spectra of *o*-nitrosobenzoic acid (A) and the benzene-insoluble substance from γ-irradiated *o*-nitrobenzaldehyde (8.0×10^{21} eV./g.) (B). Nujol mull method.

The Determination of the Residual *O*-Nitrobenzaldehyde.—Benzene-soluble portions of the γ-ray-irradiated *o*-nitrobenzaldehyde were collected. The solvent was evaporated by leaving the solution to stand at room temperature for several days in the dark in order to protect it from photo-isomerization. Figure 3 shows the infrared spectra of the benzene-soluble substance from the *o*-nitrobenzaldehyde irradiated at 8.1×10^{21} eV./g. of the absorbed radiation dose (10.7% of conversion).

All of the bands except that at 1785 cm^{-1} can be accounted for by *o*-nitrobenzaldehyde.

All the infrared spectra of γ-ray-irradiated *o*-nitrobenzaldehyde (Fig. 4) can be explained by the superposition of those of *o*-nitrobenzaldehyde and *o*-nitrosobenzoic acid, except for the weak band at 1785 cm^{-1}, which probably came from side reaction.

The quantitative analysis of *o*-nitrobenzaldehyde was carried out by gravimetric analysis in the form of 2, 4-dinitrophenylhydrazone. The residue, after the evaporation of benzene, was dissolved in ethanol and treated with an acidic solution of 2, 4-dinitrophenylhydrazine.

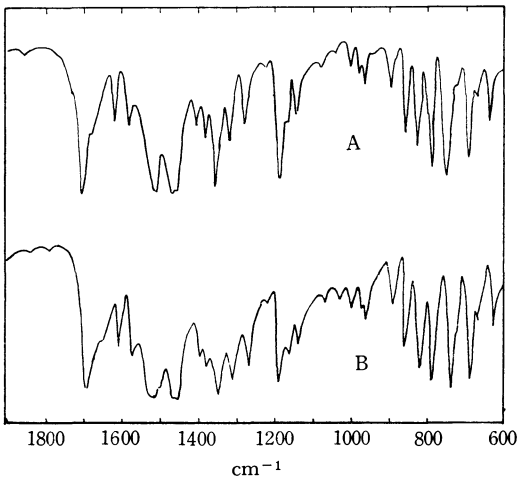

Fig. 3. Infrared spectra of *o*-nitrobenzaldehyde (A) and the benzene-soluble substance from γ-irradiated *o*-nitrobenzaldehyde (8.1×10^{21} eV./g.) (B). Nujol mull method.

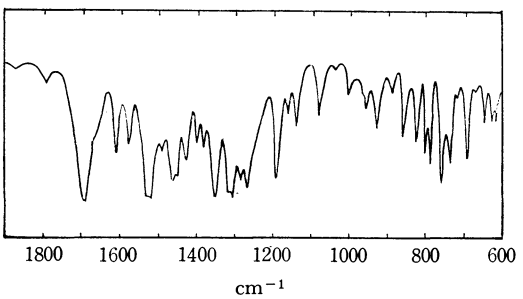

Fig. 4. Infrared spectra of γ-irradiated *o*-nitrobenzaldehyde (2.1×10^{22} eV./g.). Nujol mull method.

The 2, 4-dinitrophenylhydrazone thus formed was then collected on a sintered glass filter and weighed.

Annealing.—It was shown that the prolonged standing of the irradiated sample caused a secondary reaction of the initial product. A sample which had been stored for 8 months after a 1.5×10^{22} eV./g. irradiation showed a higher yield of the side reaction (31% against the isomerization), while the samples which were analyzed soon after irradiation gave side reactions of below 10% as is shown in Table II. The infrared absorption at 1785 cm^{-1} cited above is due to this side reaction.

The authors wish to thank Professor Yoshiyuki Urushibara, Dr. Shin-ichi Ohno and Dr. Akio Hosaka for their helpful discussions. Thanks are also due to Dr. Akibumi Danno and the members of the Cobalt-60 Irradiation Facility of Japan Atomic Energy Research Institute for γ-irradiation and Mr. Hitoshi Hashimoto for mass spectrometric analysis.

Unit Cell Metastable-form Constants of Various Phthalocyanines

By Michio Ashida,* Natsu Uyeda and Eiji Suito

Institute for Chemical Research, Kyoto University, Takatsuki, Osaka

(Received May 2, 1966)

Thin films of phthalocyanine compounds formed on cleaved surfaces of muscovite by the vacuum-condensation method showed well-defined single-directional orientation when their substrates were preheated at 300°C for one hour and then kept at 150°C. Their electron diffraction patterns were fiber diagrams, the fiber period of which coincided with the unit-cell length of the b-axis of the individual compounds. When the substrates were preheated at 400°C for one hour and then kept at 150°C, the films formed on the muscovite surface were composed of discrete crystals with a different orientation. Electron-diffraction patterns from the films revealed that the b-axis of the crystal was inclined to the substrate surface. The cross-grating patterns of the (*h*0*l*) plane were obtained when the inclination of the films was properly adjusted to the incident beam. The unit-cell constants of platinum-phthalocyanine vacuum-condensed on muscovite were revealed to be as follows with the monoclinic space group $C2/c$: $a=23.18$ Å, $b=3.818$ Å, $c=23.84$ Å, and $\beta=91.9°$. Films of Cu-, Co-, Fe-, Ni- and metal-free phthalocyanines exhibited an orientation similar to that of the platinum derivative. High-resolution electron-diffraction patterns revealed that all the compounds assumed a conspicuous isomorphism with one another and occurred in the metastable forms of their dimorphs.

The polymorphism of some phthalocyanine derivatives was very briefly described by German investigators[1] for the first time. Later, Hamm and van Norman[2] examined the microcrystals of copper-phthalocyanine by electron microscopy and identified the dimorphs with two different characteristic electron-diffraction patterns. Susich[3] found the polymorphs of metal-free phthalocyanine by X-ray diffraction. Wiswall[4] also referred to polymorphic pairs of copper-, nickel- and zinc-phthalocyanines. Ebert and Gottlieb[5] reported the differences in infrared absorption spectra and X-ray diffraction diagrams due to the dimorphs with respect to copper-, metal-free, cobalt-, nickel- and zinc-phthalocyanines. Furthermore, Karasek and Decius[6] observed polymorphic crystalline states of metal-free phthalocyanine by depositing a film of the material directly onto a highly-polished and relatively cool rock salt at a pressure of 10^{-5} mmHg.

Robertson[7,8] and Robertson and Woodward[9,10] extensively investigated the crystal structures of the stable forms of phthalocyanine and its metal derivatives by X-ray diffraction using single crystals which had been prepared by sublimation under a low pressure of carbon dioxide. On the other hand, the metastable forms of several phthalocyanine derivatives have been reported by many investigators, as has been mentioned above, but there is very little information available on the crystal data. The only report on the crystal data of the metastable forms was that on copper-phthalocyanine, determined by means of X-ray powder diffraction by Robinson and Klein.[11] Since the metastable form was obtained only as a fine powder, with a small tendency to form single crystals which were large enough, the accurate determination of the crystal data for the metastable form involves many difficulties when the ordinary method is used.

In a previous paper,[12] the present authors reported that films of phthalocyanine compounds vacuum-condensed on a cleaved face of muscovite epitaxialy grew when the substrate was maintained at a temperature of 150°C to 170°C. Since the films thus prepared was composed of crystals which assumed a well-defined orientation, an electron diffraction pattern obtained from the film showed a fiber or a single crystal diagram, from which the crystal axes and the cell dimensions might be

determined with ease even though each crystal was very small. The present authors[13] also studied the orientation overgorwth of platinum-, copper- and zinc-phthalocyanines vacuum-condensed on muscovite by electron diffraction; they thus found that all three compounds showed a conspicuous isomorphism with one another and that copper- and zinc-phthalocyanines occurred in the metastable forms of their dimorphs. As for the metastable form of copper-phthalocyanine, the analysis of the electron diffraction pattern of the film revealed that the crystal data reported by Robinson and Klein[11] failed reasonably to explain the results on the film and that another, more appropriate crystal structure should be proposed instead. Honigmann et al.[14] studied the metastable form of copper-phthalocyanine and its chloroderivatives by X-ray diffraction and supported the present authors' proposition that the metastable form of copper-phthalocyanine was isomorphous with platinum-phthalocyanine.

When the depositing conditions were modified, another, different orientation occurred with the same metastable phase. These condensation methods were also extended to derivatives other than platinum-, copper- and zinc-phthalocyanines, which had previously been reported on. Using films which assumed two different kinds of orientation, the crystal data of the individual materials were estimated directly from the electron-diffraction pattern. In the present paper, the crystal data will be determined for the metastable forms of platinum-, copper-, cobalt-, iron-, nickel- and metal-free phthalocyanines with regard to the vacuum-condensed films by means of high-resolution electron diffraction.

Experimental

Materials.—Platinum-, copper- and metal-free phthalocyanines were supplied by the Sumitomo Kagaku Co. Cobalt-phthalocyanine was synthesized from phthalonitrile and anhydrous cobalt chloride, while iron-phthalocyanine was synthesized from phthalonitrile and anhydrous ferric chloride, by the method established by Barrett et al.[15] All of these materials were purified by repeated sublimation in a low-pressure stream of carbon dioxide at a temperature above 500°C. The products were obtained as small needle-like crystals, which were established as assuming the stable forms reported by Robertson.

The Preparation of Vacuum-condensed Films.—A 2×2 cm^2 cleaved sheet of muscovite was placed in a Pyrex glass tube, and then this tube was inserted in an electric furnace, as Fig. 1 shows. The purified material was sublimated from a conical-type heater of tungsten wire. The heater was placed in the part

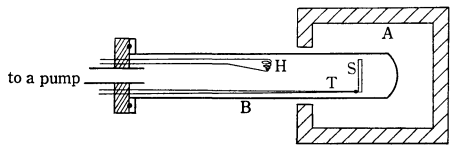

Fig. 1. Schematic diagram of appratus.
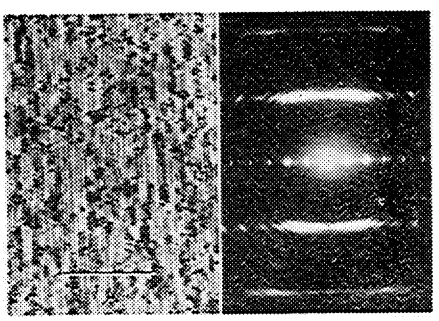
A: electric furnace, B: Pyrex glass tube
S: substrate mica sheet, T: thermocouple
H: tungsten heater (evaporation source)

of the tube protruding from the furnace because of the necessity of keeping the material from sublimation during the preliminary thermal treatment of muscovite. About 2 mg. of the material was condensed vertically onto a cleaved face of muscovite in a vacuum of 5×10^{-5} mmHg. The thickness of the films was estimated to be in a range from 500 Å to 900 Å. The rate of deposition was 20—30 Å/min. The specimen for an electron microscopy was prepared by the wet-stripping method after it had been reinforced by evaporated carbon film. Thalium chloride evaporated on phthalocyanine films was used as the standard specimen for the high-resolution diffraction work.

The Determination of Densities.—As the quantity of the material deposited on muscovite was too small for the density to be measured, powderly crystals of the metastable form prepared by the acid-paste method[16] were used in place of the sublimated films. The densities of the materials were determined by a 5% methyl alcohol displacement in a 25 ml. pycnometer.

Results

a) Platinum-phthalocyanine.—When muscovite was preheated at 300°C for one hour and held at 150°C, the film condensed on it was composed of laminar crystal strips which parallelly grew in a definite direction, as is shown in Fig. 2(a). An electron-diffraction pattern from the film shows the fiber structure shown in Fig. 2(b). The fiber axis coincides with the longitudinal direction of the crystals, and the fiber period is 3.81 Å.



(a) (b)

Fig. 3. Electron micrograph (a) and electron diffraction pattern (b) of single crystal film of Pt-phthalocyanine and its schematic diagram (c).

On the equator, two sets of reflection spots simultaneously appeared, corresponding to an interplanar spacing of 13.1 Å and 11.9Å. As has been reported previously[13] the appearance of the two sets of equatorial reflection spots indicates that the film consists of at least two kinds of crystal strips with different lattice orientations. The crystal structure of platinum-phthalocyanine determined by Robertson has the following unit-cell dimensions with the monoclinic space group $P2_1/a$: $a=23.9$ Å, $b=3.81$ Å, $b=16.9$ Å, and $\beta=129.6°$. Since the fiber period obtained from the diffraction pattern showed a good coincidence with the unit lentgth of the b-axis, the b-axis of the crystal strips turned out to be parallel to the longitudinal direction. As for the two characteristic reflections on the equator, the spacings of 13.1 Å and 11.9 Å corresponded to the (001) and ($20\bar{1}$) planes respectively, planes which are almost perpendicular to each other and which share the b-axis as the zone axis. However, a closer observation of the electron diffraction pattern revealed that it was necessary to reconsider the designation of the crystal axes. A perfect single crystal was obtained in the part of the film prepared as above. Figs. 3(a) and (b) show respectively, an electron micrograph and electron diffraction pattern from the film. In Fig. 3(b), the maximum lattice period along the meridian is 3.81 Å, which is the same value as that of the fiber diagram. On the other hand, the period of 13.1 Å in the equatorial direction corresponded to 001 and its higher-order reflections, according to Robertson's assignment. This means that the diagram shows the reciprocal lattice plane with the index of $0kl$. However, when the reflection spots appearing on the lines of $k=1$ and 3 are taken into account, it is obvious that the period along the equator should take twice as long as that given by Robertson by adding the periods displayed to the broken lines in Fig. 3(c). If the equator is identified as the a* axis of the reciprocal lattice, then all the reflection spots in Fig. 3(b) may be indexed as in Fig. 3(c). The possible reflection is as follows: h is even in ($h00$), k is even in ($0k0$), and $k+k$ is even in ($hk0$).

When a muscovite substrate was preheated at 400°C for one hour and kept at 170°C, the film condensed on it was composed of discrete crystallites, as Fig. 4(a) shows. The electron-diffraction pattern in Fig. 4(b) is apparently a superposition of two identical diagrams, both composed of layered zones of reflection spots. The appearance of these layered zones in the individual diagrams is to be ascirbed to the position of the main-zone axes of the sublimated crystal, which tilts against the substrate face and consequently against the electron beam. The orientation will be described in detail in another report. However, it must be noted here that the crystallites are divided into

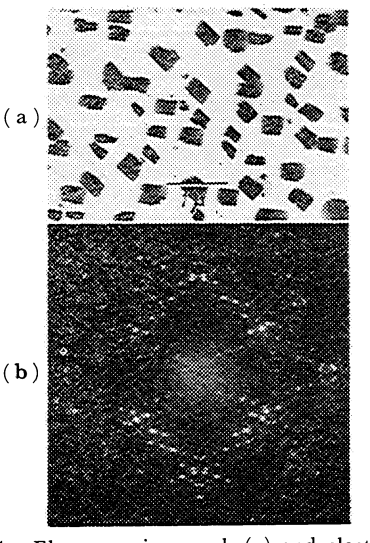

Fig. 4. Electron micrograph (a) and electron diffraction pattern (b) of Pt-phthalocyanine film vacuum-condensed on muscovite which is preheated at 400°C and kept at 170°C.

two groups, which can be defined by a plane of symmetry, normal with regard to the total film plane, as far as the lattice orientation is concerned. The b-axis stands somewhat obliquely to the film plane. Therefore, when the film is tilted against the incident electron beam so that the b-axis of the crystal becomes parallel to the beam, the intensity distribution of the reflection spots is symmetrized with respect to the point of origin, as is shown in Fig. 5. As the incident beam is

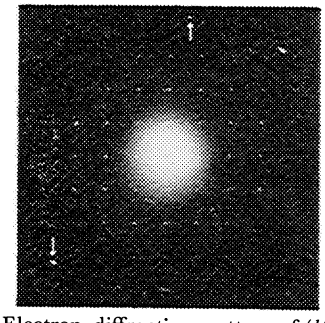

Fig. 5. Electron diffraction pattern of ($h0l$) plane of Pt-phthalocyanine obtained by tilting the film shown in Fig. 4.

parallel to the b-axis of the crystal, the diagram shows the reciprocal lattice points with the $h0l$ indices. Since the b-axis of the crystals taking another orientation does not become parallel to the incident beam, and since the unit length of the b* reciprocal axis is considerably longer than those of the a* and c* axes, the reflection from these crystals of another group gave rise to only a few extra spots, indicated with arrows in the figure. The cross-grating pattern consisted of two arrays of reflection spots, with periods of 13.1 Å and 11.9 Å, which cross each other at an angle of 88.1°. Since the interplanar spacings agreed with those obtained from the fiber diagram, both crystals were assigned the same structure. When the a* axis of the reciprocal lattice was associated with the period of 13.1 Å described above, the c* axis was to be ascribed to the other period, 11.9 Å. The unit lengths of a- and c-axes and the axial angle, β, were directly obtained from the pattern. The possible reflection was as follows: both h and l are even in ($h0l$). Although these possible reflections in ($h00$), ($0k0$), ($hk0$) and ($h0l$) appear in both space groups, C_s^4–C_c and C_{2h}^6–$C2/c$, it is well known that platinum-phthalocyanine is a planar molecule which has a center of symmetry. On the basis of these results, the unit cell constants were determined to be as given in Table I (1). As has been mentioned above, the new designation of the crystal axes was given by the substitution of (200) and (002) respectively for the (001) and ($20\bar{1}$) planes assigned by Robertson.

On the basis of such a transformation of the

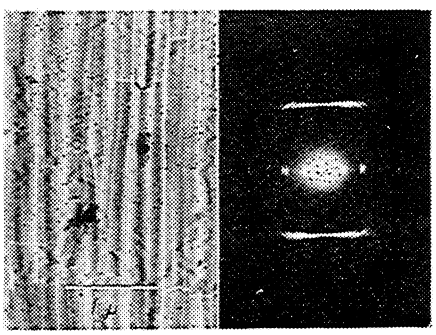
crystal axes, the original crystal data reported by Robertson should be corrected as in Table I (2). When the values in the column (1) are compared with those in the column (2), the coincidence is fairly good except for the value of the axial angle, β. The interplanar spacings evaluated from the fiber diagram are given in Table II (1). Tables II (2) and (3) show the interplanar spacings calculated from the cell constants given in Tables I (1) and (2) respectively. In Table II, the values in the column (2) agreed with those in the column (1) except for sevsral spacings, which had the index of $(h0l)$. These discrepancies were apparently caused by the difference in the axial angle, β, which will be discussed in a latter section.

b) Copper-phthalocyanine.—In the case of copper-phthalocyanine, films showed a fiber structure similar to that of platinum-phthalocyanine when the substrate muscovite was preheated at 300°C for one hour and held at 150°C during the vacuum-deposition. Figures 6(a) and (b) show the electron micrograph and electron-diffraction pattern of the film respectively. The fiber period was 3.79 Å, and the two sets of equatorial reflections had periods of 13.0 Å and 11.9 Å in Fig. 6(b). Since these values were quite similar to those of the platinum derivative, the crystal of vacuum-condensed copper-phthalocyanine film was ac-accounted for in terms of the isomorph with the platinum derivative. Consequently, it seems reasonable to assign the fiber period and the two long periods on the equator for the principal axial lengths of copper-phthalocyanine in the same way as for the platinum derivative.



(a) (b)

Fig. 6. Electron micrograph (a) and electron diffraction pattern (b) of Cu-phthalocyanine film vacuum-condensed on muscovite which is preheated at 300°C and kept at 150°C.

Films sublimated onto muscovite which had been preheated at 400°C for one hour and held at 150°C were composed of many small crystals, as Fig. 7(a) shows. The electron-diffraction pattern from the film revealed that the b-axis of the crystals stood obliquely on the substrate face in a way similar to that of the platinum derivative. When

(b)

Fig. 7. Electron micrograph (a) of Cu-phthalocyanine film vacuum-condensed on muscovite which is preheated at 400°C and kept at 150°C and electron diffraction pattern (b) of $(h0l)$ plane of Cu-phthalocyanine obtained by tilting the film (a).

the film was tilted against the incident beam so that the b-axis of the crystals became parallel to it, the electron diffraction pattern gave the cross-grating pattern of the $(h0l)$ plane shown in Fig. 7(b). In the cross-grating pattern, the interplanar spacings with the periods of 12.9 Å and 11.9 Å, which cross each other at the angle of 89.6°, agreed with those of the two sets of reflections on the equator in the fiber diagram. Since the crystal was found to be the isomorph of the platinum derivative, the reflection spots should be indexed in the same way. Conseuqenctly, the cell constants of the copper-phthalocyanine vacuum-condensed on muscovite were determined to be as given in Table III (1). The interplanar spacings in Table IV (I) were obtained from the fiber diagram, while those in Table IV (2) were calculated from the cell constants given in Table III (1). The values in two series showed good

(1): Film vacuum-condensed on muscovite.
(2): Powder prepared by acid paste method.

agreement. It was found that the crystal vacuum-condensed onto muscovite was the same metastable form as that prepared by the acid-paste method.[16] The interplanar spacings in Table IV (3) were obtained from the latter crystal by X-ray diffractometry. As each value in this column agrees well with those in the columns (1) and (2), each spacing may reasonably be indexed as in the column (3). Reversely, on the basis of the index, the cell constants were calculated from the values in Table IV(3) to be as given in Table III(2). They showed good agreement with those obtained from the vacuum-condensed film.

c) Other Phthalocyanines. — Vacuum-condensed films of iron-, cobalt-, metal-free and nickel-phthalocyanines also assumed the single directional orientation similar to that of the platinum derivative, as Figs. 8(a), (b), (c) and (d) respectively show. Figures 9(a), (b), (c) and (d) are, respectively, the electron diffraction patterns from these films. The fiber periods of these diagrams were in the range from 3.5 to 3.8 Å, and two sets of reflection spots appeared on the equator at definite intervals for each set. The findings suggest

not only that all four compounds occur in the metastable forms of their dimorphs, but also that they are conspicuously isomorphic with the platinum derivative. Table V shows the interplanar spacings evaluated from these fiber diagrams.

When the substrate muscovite was preheated at 400°C for one hour and then maintained at a temperature of 150°C to 200°C for the deposition, the films of iron-, cobalt- and metal-free phthalocyanines were composed of small crystals, the b-axis of which stood obliquely on the substrate face, as Figs. 10(a), (b) and (c), respectively, show. The cross-grating patterns of their ($h0l$) planes were obtained from the films exhibited in Figs. 11(a), (b) and (c) when these films were tilted against the incident beam in a way similar to that used with the platinum derivative. The unit lengths of the b-axes of these phthalocyanines were obtained from the fiber diagrams, while the unit lengths of the a- and c-axes and the axial angle, β, were determined from the cross-grating patterns. The unit cell constants were determined to be as given in Table VI for the metastable forms of these phthalocyanines; in the table the unit cell constants of platinum- and copper-phthalocyanines are again reproduced for the sake of reference. When the

fiber diagram was compared with the cross-grating pattern, the interplanar spacings which are associated with two sets of reflections on the equator were found to be 13.1 Å and 12.5 Å for the iron derivative, and 12.9 Å and 12.5 Å for the cobalt derivative, while the periods corresponding with these reflections in the cross-grating patterns were 12.9 Å and 12.05 Å for the former and 12.94 Å and 12.04 Å for the latter. In the cases of iron- and cobalt-phthalocyanines, therefore, the interplanar spacings calculated from the unit cell constants given in Table VI showed a discrepancy of about 4% from those obtained with the fiber diagrams. No serious difference was observed in metal-free phthalocyanine.

In the case of nickel-phthalocyanine, extra spots always appeared between the equator and the first-layer line in the fiber diagram, as is shown with arrows in Fig 9(d). The film was composed of laminar crystal strips, giving rise to a raft structure as a whole, and beard-like crystals appearing among the raft structure, as Fig. 8(d) shows. The reflections from the former crystals produced the fiber pattern, while those from the latter crystals appeared as extra spots. As for the nickel derivative, no films which showed another orientation

were obtained. In the fiber diagram, the maximum lattice period along the meridian was 3.79 Å and the interplanar spacings were 13.07 Å and 12.13 Å, these spacings are associated with two sets of reflections on the equator. Since these values were very similar to those of other phthalocyanines, the interplanar spacings obtained from the fiber diagram were indexed as in Table V. The unit-cell constants of nickel-phthalocyanine given in Table VI were then calculated from the interplanar spacings thus indexed.

Discussion

Robertson[7] and Linstead and Robertson[17] reported that metal-free, beryllium-, manganese-, iron-, cobalt-, nickel- and copper-phthalocyanines were isomorphic and that the unit lengths of their b-axis fell in the range from 4.71 Å to 4.84 Å, and that only the platinum-phthalocyanine had the unit length of the b-axis of 3.81 Å and was not isomorphic with the others. As is well known, however, their investigations were restricted to the stable forms of these compounds; no account was taken of the metastable form. Honigmann et al.[14] suggested that the individual unit cells of phthalocyanine compounds should contain four molecules and that, considering its isomorphic behavior with other phthalocyanine derivatives, the space group of platinum-phthalocyanine was transformed into $B2_1/a$. However, the space group assigned by them was based on the molecular orientation reported by Robertson and Woodward.[10] Recently, Brown[18] proposed that the space group of platinum-phthalocyanine should be corrected by means of a new interpretation that $C2/c$ of the monoclinic system is more plausible, since it is twice as large as that reported by Robertson. His proposition coincides well with the crystal data reported in the present paper. Consequently, it may be concluded that the unit cell constants of platinum-phthalocyanine should be transformed to those give in Table I(2). In Table II, the values in the column (1) agreed well with those in (2). On the other hand, there were small discrepancies between the values in (3) and those in (1) and (2) as a result of the difference in the axial angle, β. The result shows that the laminar crystals which assume the single directional orientation have the same structure as that investigated by Robertson, while the crystals which have the b-axis standing obliquely on the substrate face are distorted from the original structure, possibly because of the bond forces between the deposited crystal and the substrate muscovite.

As for the metastable form of copper-phthalocyanine prepared by the acid-paste method, Robinson and Klein reported the crystal to be $P4/m$ of the tetragonal system with the following unit cell constants: $a=17.376$ Å and $b=12.790$ Å.[11] This crystal, however, unfortunately cannot explain the present results which are directly obtained by electron diffraction. It should be reasonable to take the lattice spacing of 3.79 Å into consideration in determining the basic configuration of the unit cell, not only because the fiber diagram of the diffraction requires them, but also because this spacing is nearest the case of platinum-phthalocyanine and some other condensed polycyclic aromatic compounds.[19] The cell constants represented in this paper were confirmed with the results obtained by X-ray diffraction.

In the cases of iron- and cobalt-phthalocyanines, the unit length of the c-axis showed a discrepancy of less than 4% between the value obtained from the fiber diagram and that obtained from the cross-grating pattern. This discrepancy may be caused by the lattice distortion of the deposited crystal, which is accompanied by a slight change in the molecular arrangement in the crystal due to the lattice orientation relative to the substrate muscovite. Consequently, except for copper- and platinum-phthalocyanines, which were confirmed with a crystal prepared by another method, the crystal data obtained from the vacuum-condensed films may be expected to show some deviation. In spite of such possible deviations, however, it is believed that these crystal data are very useful for the study of the metastable form of phthalocyanine compounds because the metastable form of phthalocyanine compounds have not yet been obtained in the large, single-crystalline state from which the crystal data were determined by X-ray diffraction.

The authors would like to express their sincere thanks to Dr. C. J. Brown, University College, London, for his kind information about the crystal data of platinum- and copper-phthalocyanines.

The Orientation Overgrowth of Metal-phthalocyanines on the Surface of Single Crystals. I. Vacuum-condensed Films on Muscovite

By Michio ASHIDA*

Institute for Chemical Research, Kyoto University, Takatsuki, Osaka

(Received May 2, 1966)

When substrate muscovite is preliminarily heated at 300°C for one hour and then kept at 150°C to 200°C during deposition in vacuo, Cu-phthalocyanine films condensed on it show parallel b-axis orientations, including single- and triple-directional orientations. The b-axis of the crystal runs parallel to the substrate face. On the other hand, when the substrate is preliminarily heated at 400°C and then kept at 150°C, films vacuum-condensed on it occur in a standing b-axis orientation. The high-resolution electron-diffraction pattern of the film reveals that the a-, b- and c-axes of the crystal are inclined to the normal of the substrate face at angles of about 75°, 32° and 118° respectively. An electron micrograph of the film shows that as discrete crystals grow they orient themselves in either of two different directions. The crystal which assumes the standing b-axis orientation has its $(31\bar{3})$ plane almost parallel to the substrate face. Pt-phthalocyanine film also assumes the standing b-axis orientation, in which the a-, b- and c-axes of the crystal are inclined to the normal of the substrate face at angles of about 74°, 35° and 120° respectively. It turns out that the molecular plane comes in contact with the muscovite surface in the case of the standing b-axis orientation. A plausible explanation of the origin of these orientations is presented in terms of the dehyroxylation of the surface mica layer caused by the thermal treatment.

The epitaxial growth of thin crystalline film has been investigated by many workers; they have mostly been interested in metals or inorganic compounds. As for the organic compounds, Willems[1] and Kleber and Meyer[2] observed the orientation overgrowth of some compounds by light microscopy. However, the method based on light microscopy was limited to cases where the overgrown crystals have a well-defined morphology. Moreover, the lack of exact information on the crystal structures of most of those compounds made it impossible to discuss in detail the orientation of the crystals relative to the substrate in terms of a difinite lattice structure. In a previous paper,[3] it was reported that the condensed polycyclic aromatic compounds, which are frequently referred to as the organic semiconductors, show an epitaxial growth when those materials are condensed onto a cleaved face of muscovite crystal. Furthermore, it was observed by electron microscopy and electron diffraction that platinum-, copper- and zinc-phthalocyanines vacuum-condensed on muscovite assumed the single- and triple-directional orientations.[4] It turned out in previous investgations that the b-axes of crystals always ran parallel to the substrate surface.

When substrate muscovite was treated at a higher temperature in advance of the deposition of these materials, films of many phthalocyanine compounds showed quite a different orientation. Using these oriented films, the crystal data were determined for the metastable forms of several phthalocyanine derivatives by the high-resolution electron-diffraction method.[5]

In this work, the effect of the thermal treatment of muscovite will be studied concerning the orientation overgrowth of copper-phthalocyanine. The orientation of the evaporated film of phthalocyanine will also be examined in relation to the substrate by electron microscopy as well as by electron diffraction.

Experimental

The metal-phthalocyanines used in this work was purified by repeated sublimation in a stream of carbon dioxide at low pressure and at a temperature above 500°C. A freshly-cleaved thin film of muscovite about 20 mm. square was placed in a Pyrex glass tube situated in an electric furnace. The substrate was heated at an appropriate temperature in a vacuum of about 5×10^{-5} mmHg. The purified material was then vacuum-sublimated onto muscovite following the

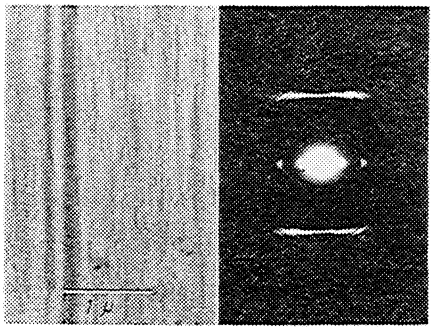
same procedure as that described in the previous work.[5] The crystallographic principal axes of muscovite were determined in its basal plane by polarizing microscopy. The specimen used for electron microscopy was prepared by the wet-stripping method.

Results

Three Types of Orientation.—Films vacuum-condensed onto muscovite showed various orientations according to the evaporating conditions. Generally speaking, the typical orientations may be classified into the following three groups.

A. Parallel b-Axis Orientations. — A-1. The Single-directional Orientation.—When substrate muscovite was preheated at 300°C for one hour and then kept at a temperature between 150°C and 170°C, the film condensed showed a well-defined single-directional orientation, whose electron micrograph and electron diffraction pattern are shown in Figs. 1(a) and (b) respectively. As has been

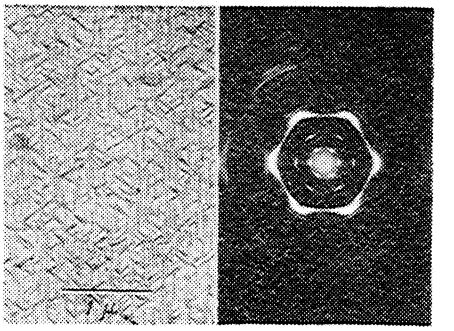


(a) (b)

Fig. 1. Electron micrograph (a) and electron diffraction pattern (b) of copper-phthalocyanine film which assumed the single-directional orientation.

described in a previous paper,[4] films were composed of laminar crystal strips; it was revealed by the analysis of the fiber diagram obtained from the film that at least two kinds of lattice orientations may be assumed to show a longitudinal direction in individual strips which always run parallel to their b-axes. As for the relative orientation of the evaporated film to the substrate, the b-axis of the former was parallel to either of the two directions, which made $\pm 60°$ with the b-axis of the muscovite crystal.[6]

A-2. The Triple-directional Orientation. — The triple-directional orientation was observed when films were prepared at the substrate temperature of 200°C without any preliminary thermal treatment. The electron micrograph shown in Fig. 2(a) exhibits that the film was built up of triangular labyrinthine networks of slender crystal strips.

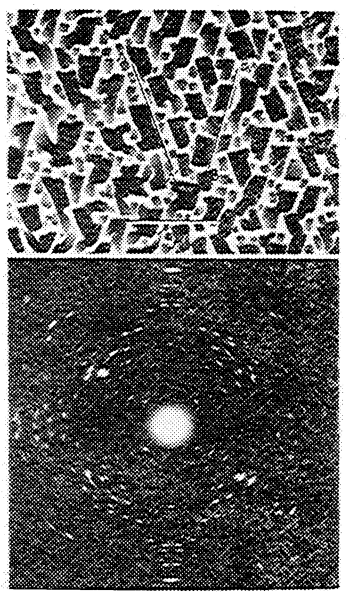


(a) (b)

Fig. 2. Electron micrograph (a) and electron diffraction pattern (b) of copper-phthalocyanine film which assumed the triple-directional orientation.

Corresponding to such a configuration of the film, the diffraction pattern also had a hexagonal appearance, as Fig. 2(b) shows. The pattern is a superposition of three identical fiber diagrams, each of which is essentially the same as that of the single-directional orientation.

B. The Standing b-Axis Orientation.—When the substrate muscovite was heated in advance at 400°C for one hour and then kept at 150°C, the film was composed of small, flaky crystals which grew by orienting themselves along either of the two different directions designated as AA′ and BB′ in Fig. 3(a). These wedge-like crystals were separated from one another, making the total film discrete, unlike the above two cases. The electron diffraction pattern in Fig. 3(b) is apparently



(a)

(b)

a superposition of two identical diagrams, both composed of layered zones of reflection spots. Naturally, the angle defined by those two sets of parallel layered lines is identical with that defined by the two directions AA′ and BB′. The appearance of these layered zones in the individual diagrams should be ascribed to the position of the main zone axes of the evaporated crystal, which are tilted against the substrate face and, consequently, against the electron beam. This orientation will be described in a later section.

The Relation between the Evaporating Conditions and the Orientation Overgrowth of Copper-phthalocyanine.—As has been described above, three groups of orientations of copper-phthalocyanine vacuum-condensed on muscovite take parallel b-axis orientations, which includes single- and triple-directional orientations, and the standing b-axis orientation. The appearance of these different orientations depends on the evaporating conditions, one of which is expected to be the thermal treatment of muscovite. In an effort to determine the effect of thermal treatment, the change in the orientation was also studied with various combinations of the time and the temperature of preheating; the effect of the temperature at which the material was finally deposited was also studied.

Generally, the film formed on substrate muscovite at room temperature was composed of granular crystals with a random orientation. An epitaxial growth of phthalocyanine occurred when the temperature of substrate was not lower than about 100°C. As the substrate temperature was increased, the deposited crystal grew larger and assumed a better orientation until around 200°C, above which point the orientation became worse again. When the substrate was kept at temperatures above 200°C, a film was built up of long, flaky crystals, which occurred in the stable form and which grew in a random direction, without any relative orientation to the substrate structure.

The effect of the preliminary thermal treatment of muscovite on orientation overgrowth is summarized in Fig. 4. In this case, the substrate temperature was kept at 150°C during sublimation for all the experiments. Since the single- and triple-directional orientations both take the b-axis of crystals parallel to the muscovite surface and occasionally mix with one another, the temperature range for the appearance of these orientations can not be defined by sharp critical points. When the temperature of the thermal treatment was under 350°C, the deposited crystals always assumed the parallel b-axis orientation, in which the single-directional orientation occurred only in a considerably limited range of temperature, as follows: the substrate muscovite was treated in advance at 300°C for one hour, and the substrate temperature during sublimation was kept in the range from

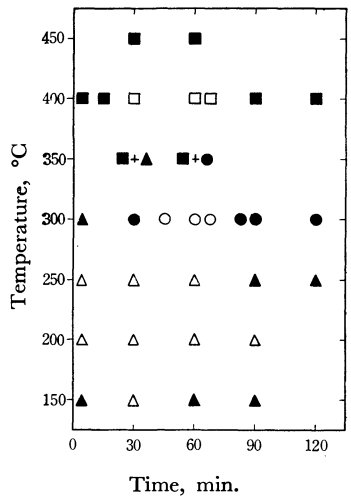

Fig. 4. The effect of preliminarily thermal treatment of muscovite on orientation overgrowth of Cu-phthalocyanine. The substrate temperature is kept at 150°C during sublimation.
□: Standing b-axis orientation
■: Nearly standing b-axis orientation
○: Single-directional orientation
●: Nearly single-directional orientation
△: Triple-directional orientation
▲: Nearly triple-directional orientation

150°C to 170°C. The triple-directional orientation appeared under all conditions, except for the range of temperature mentioned above. On the other hand, when the thermal treatment was carried out above 350°C, the deposited crystals assumed the standing b-axis orientation. Therefore, the orientation overgrowth on muscovite was found to change its state from one to the other when the temperature of the preliminary thermal treatment was around 350°C. Moreover, when the substrate muscovite was exposed to water vapor after a thermal treatment at 400°C and then treated under 300°C in vacuo, the film condensed on it again showed a triple-directional orientation. Consequently, the alternation of orientation seems to depend on the variation in the surface structure of muscovite, which is not necessarily accompanied by the decomposition of the crystal lattice of the substrate but which occurs reversibly in regard to the temperature range mentioned above.

The Determination of the Standing b-Axis Orientation.—Each elementary cross-grating pattern in Fig. 3(b) consists of three parallel zones. On the basis of the unit-cell constants of the metastable form,[5] the reflection spots were indexed as in Fig. 5. The zone which includes the point of origin appears as the intersection of the reciprocal lattice points as well as their elongated intensity regions, which have the index of $k=0$ with the Ewald sphere. The other zones, which do not

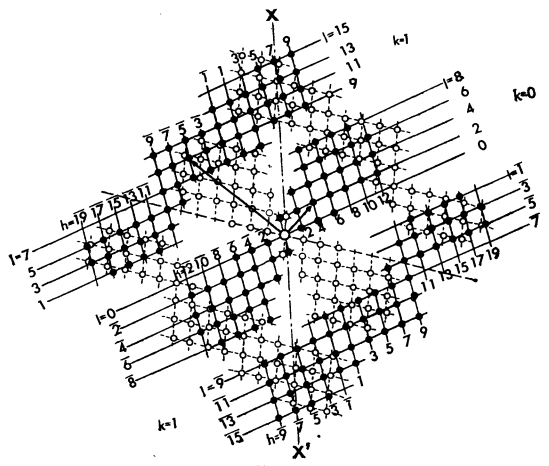

Fig. 5. The interpretation of the diffraction pattern shown in Fig. 3(b). A cross-section of the reciprocal lattice points of the crystal with the Ewald sphere. The reciprocal lattice points 402 and $\bar{5}19$ lie directly on the Ewald sphere.

include the point of origin, correspond to the reciprocal lattice planes of $k=\pm 1$. When the interplanar spacings obtained from the diffraction spots were compared with those calculated from the cell constants, the reciprocal lattice points, 402 and $\bar{5}19$, were found to lie directly on the Ewald sphere. Consequently, the a-, b- and c-axes of the crystal are inclined to the normal of the substrate surface at angles of about 75°, 32° and 118° respectively. On the other hand, the normal of the $(31\bar{3})$ plane is inclined to the a-, b- and c-axes at angles of about 69°, 33° and 113° respectively. When two sets of angles were compared, the crystal which assumed the standing b-axis orientation has its $(31\bar{3})$ plane almost parallel to the substrate face. The reflection diagram in Fig. 5 implies the plane of C_{2v} symmetry, XX', which was found to make an angle of 60° with the

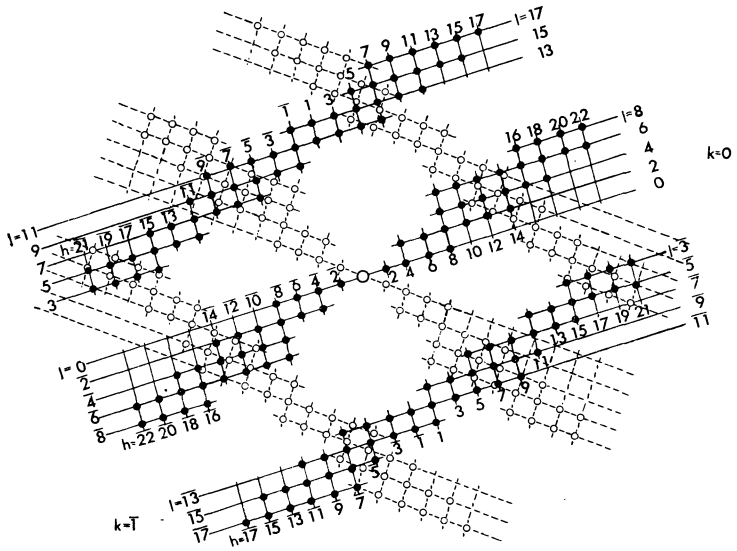

Fig. 9. The interpretation of the diffraction pattern shown in Fig. 8(b).

a-axis of muscovite. The projection of the crystals onto the muscovite face is shown schematically in Fig. 6, where the individual unit cells are designated with hatched zones. The orientation of these four crystals can be defined by two kinds of symmetries, one of which is a plane of mirror symmetry which makes an angle of 60° with the a-axis of muscovite and stands perpendicular to its surface, while the other is an axis of the two-fold symmetry. The projection of the b-axis of the evaporated crystals to the surface makes an angle of about 44° with the plane of symmetry. The top face of the crystal corresponds to the (010) plane, and the side faces, to the (100) and (001) planes.

In the diffraction pattern, the reflections which have the same value of h or l but which differ in the index k, did not appear on the same line. This was probably caused by the elongation in the intensity region in a somewhat unusual direction. Since the external form of the crystal is wedge-shaped, the thickness of the crystal measured normal to the $(31\bar{3})$ plane, which is almost parallel to the substrate face, may be very thin in the vicinity of the edge. Consequently, it may be supposed that the intensity regions of the reciprocal lattice points are elongated along the normal to the $(31\bar{3})$ plane and are crossed by the Ewald sphere, which is parallel to the basal plane of the crystal, as Fig. 7 shows. According to the figure, it is clear that the points with the indices of $51l$ fall on the same line as those with the indices of $\bar{1}\bar{1}l$; it is clear also that the line includes the points with the indices of $20l$. Similarly, the points with the $h$ll indices fall on the same line as those with the h04 indices.

The standing b-axis orientation was also observed in other phthalocyanine compounds. Platinum-phthalocyanine, for example, assumed a similar orientation, as Figs. 8(a) and (b) show. The cross-grating pattern is interpreted as is shown in Fig. 9 by the method described above. In the case of platinum-phthalocyanine, it turned out that two reciprocal lattice points, 402 and $\bar{3}19$, lie directly on the Ewald sphere, and that the a-, b- and c-axes of the crystal which assumed the standing b-axis orientation made angles of about 74°, 35° and 120° respectively with the normal of the substrate face. The projection of the b-axis of the crystal onto the substrate face made an angle of about 44° with the plane of symmetry.

Discussion

Vacuum-condensed films of copper-phthalocyanine occur in the metastable form of its dimorphs and were found to be isomorphic with platinum-phthalocyanine.[4] Such isomorphic behavior of the phthalocyanine derivatives has also been found in the case of stable crystals of beryllium-, iron- cobalt-, nickel-, copper- and metal-free phthalocyanines.[7,8]

According to Robertson,[7] the molecular plane has the same inclination of 45.8° to the b-axis in the cases of nickel- and metal-free phthalocyanines of the stable form. Therefore, the molecule in the metastable form of copper-phthalocyanine is expected to be inclined to the b-axis at an angle similar to that of the platinum derivative, which has a conspicuous isomorphic structure, although

7) J. M. Robertson, *J. Chem. Soc.*, **1935**, 615.
8) R. P. Linstead and J. M. Robertson, ibid., **1935**, 1736.

no exact information has been obtained as far as copper-phthalocyanine is concerned. However, the relative orientation of platinum-phthalocyanine to the substrate may reasonably be interpreted on the basis of this isomorphism.

The crystal structure of the platinum derivative has the following unit cell dimensions with the monoclinic space group $C2/c$: $a=26.18$ Å, $b=3.818$ Å, $c=23.84$ Å, and $\beta=91.9°$.[5] The molecules of platinum-phthalocyanine appear to be strictly planar and stack themselves so that they are closely packed in a column, facing each other, parallel, and inclined alternatively along the c-axis. The central platinum atom lies at the center of a square-bonded configuration with four nitrogen atoms, and four other nitrogen atoms make a bridge between the isoindole rings. The molecular axes, L and M, are defined through the center of the molecule and the latter nitrogen atoms (see Fig. 11). When a projection is taken normal to the molecular plane, the corresponding atoms in parallel molecules along the b-axis shift along the molecular axis, M, one from another. The angles between the molecular axes and the crystal axes are given in Table I. The normal direction of the $(21\bar{4})$ plane, which is approximately parallel to

** The c-axis is transformed from the a-axis assigned by Robertson.

the substrate face, makes such angles with the crystal axes as are given in the last column of Table I. Because the discrepancy between the angles in the third column (N) and those in the last one was quite small, it is evident that the molecular plane is parallel to the surface of muscovite in this case. On the other hand, each molecule in the crystal with the parallel b-axis orientation stands on a carbon atom in one of the outer benzene rings.[4] Consequently, when the crystal assumes the parallel or the standing b-axis orientation, the planar molecules in the individual crystals are located on the substrate face, as is shown schematically in Fig. 10. On the basis of this experimental finding, there may considered to be an atomic matching between the deposited and the substrate crystals at the interface.

When it is tentatively assumed that the hexagonal network of potassium ions on the cleavage face is perfect and that a nitrogen atom on the molecular axis M (e. g., m), defined as the point of origin,

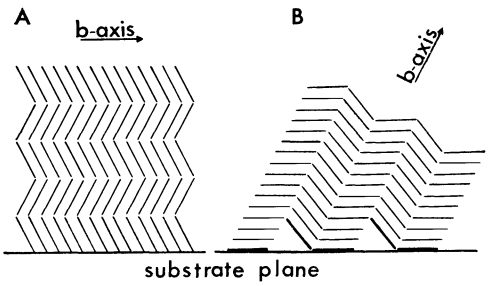

Fig. 10. Schematic diagrams of orientation of platinum-phthalocyanine molecules in the crystal. A: the crystal with the parallel b-axis orientation, B: the crystal with the standing b-axis orientation.

is located on a potassium ion (e. g., K_1), one nitrogen atom on the molecular axis (e. g., p) is in contact with a potassium ion (e. g., K_2), and a nitrogen atom bonded to the central platinum atom (e. g., a) also comes into contact with a potassium ion (e. g., K_3) as is shown schematically in Fig. 11. The projections of the a-, b- and c-axes of the crystal onto the molecular plane are exhibited with a_p, b_p and c_p directively. In this case, the neighboring molecules are distributed on the substrate face as is shown in the figure. The closest molecule along the a-axis is located at the nearest site of potassium ions (e. g., K_4, K_5, K_6 and K_7) with four nitrogen atoms on the molecular axes (e. g., m′, n′, p′ and q′). Similarly, the next parallel molecule in the direction of the c-axis is located at the nearest site of potassium ions (e. g., K_8, K_9 and K_{10}) with three nitrogen atoms (e. g., n″, q″ and c″). If molecules are located on the surface of muscovite in such a manner, the direction of b_p, which is the projection of the b-axis of the crystal onto the substrate face, makes an angle of about 44° with the direction, K, which makes an angle of 60° with the a-axis of muscovite (a_M). The angle of 44° coincides with that between the plane of symmetry of the two different crystal orientations and the projection of the b-axis on the substrate face, which was formerly determined from the electron diffraction pattern. By a comparison of these two results, it may be confirmed that the orientation of the M axis and, consequently, all the molecules have an orientation such as is shown in Fig. 11. Because the phthalocyanine crystal has a symmetry of two-fold screw rotation and the molecule along the b-axis shifts in with the direction of +M or −M, the orientation of the deposited crystals has a symmtery of C_{2v}.

Although the top layer of muscovite apparently has a hexagonal symmetry, the orientation overgrowth of phthalocyanine compounds appeared only in a mirror symmetry. The plane of symmetry made ±60° with the a-axis of muscovite. As has been described in a previous paper,[4] the

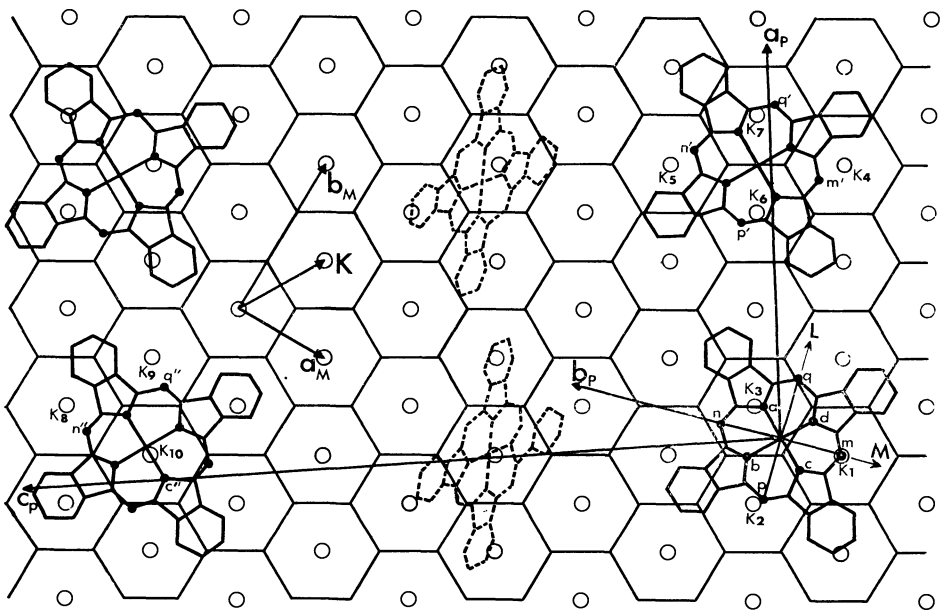

Fig. 11. Schematic diagram of the relative orientation of platinum-phthalocyanine to muscovite face when the crystal assumes the standing b-axis orientation. The directions a_M and b_M are the (100) and (010) directions of muscovite, respectively. Phthalocyanine molecules shown with dotted line are not contacted to the muscovite surface.

intersection of the plane of symmetry with the muscovite face coincides with the direction of the staggering in the top mica layer at the surface. It should be noted that the muscovite structure with a monoclinic symmetry, instead of a hexagonal one, gives rise to a latent influence upon nucleation and to a further growth of deposited films of phthalocyanine compounds, not only in the case of the parallel b-axis orientation, but also in the case of the standing b-axis orientation.

The orientation of the deposited crystal films varied from the parallel b-axis to the standing b-axis as a function of the thermal treatment of muscovite; there was quite a sharp critical transition point. The dehydroxylation of muscovite gradually begins at a temperature about 400°C in vacuo without a general destruction of the crystal lattice.[9] It is known that the phthalocyanine molecule, which has many aromatic rings, shows a strong repulsive force against water. Therefore, it is reasonable to postulate that the deposited molecules of phthalocyanine stand on the substrate muscovite so that the molecular planes separate from its surface as much as possible as a result of the repulsive force between the molecule and water included in muscovite. The resulting film shows a parallel b-axis orientation, whereas when the substrate muscovite was treated at 400°C, the planar molecule lies parallel to the substrate face because of the diminution of the repulsive force by the dehydroxylation of muscovite. The crystals thus nucleated by deposited molecules grow in the direction of the b-axis, which inclines obliquely to the substrate face, and the resulting film becomes discrete in the case of the standing b-axis orientation.

In the case of the metastable crystal of the copper-phthalocyanine film, which assumed the standing b-axis orientation, each crystal axis was observed to incline to the substrate face at an angle similar to that of platinum-phthalocyanine. Therefore, it seems that the molecular plane of copper-phthalocyanine inclines to the crystal axes at approximately the same angles as those of platinum-phthalocyanine. Consequently, it can reasonably be explained that the planar molecule of copper-phthalocyanine comes into parallel contact with the substrate face in a manner similar to that of the platinum derivative.

The author is very grateful to Professor Eiji Suito of the Institute for Chemical Research, Kyoto University, for his interst and support; he wishes also to thank Dr. Natsu Uyeda of the same Institute for his many helpful discussions and suggestions during this work. The Orientation Overgrowth of Metal-phthalocyanines on the Surface of Single Crystals. II. Vacuum-condensed Films of Copper-phthalocyanine on Alkali Halides

By Michio ASHIDA*

Institute for Chemical Research, Kyoto University, Takatsuki, Osaka

(Received May 2, 1966)

Cleaved faces of KCl, KBr and NaCl crystals were used as substrates. When copper-phthalocyanine is vacuum-condensed onto either KCl or KBr, the films on it take a standing b-axis orientation, which shows a C_{4v} symmetry. The major planes of symmetry coincide with those of KCl and KBr. The crystals on KBr show an azimuthal angular shift of about $+12°$ or $-12°$ in respect to the major symmetry axes, [010] and [100], of the substrate crystal. When the films have the standing b-axis orientation, the planar molecule in the crystal comes into parallel contact with the cleavage face of the substrate. It may be presumed that the bridge nitrogen atoms in a phthalocyanine molecule are placed on the potassium ions in the (001) planes of KCl and KBr. The films on KCl and KBr are composed of finely-divided rectangular crystals and dendrites; the former are concentrated at steps on the cleavage face to produce a decorative pattern, while the latter appear on the smooth surface. The formation in various types of crystals are interpreted in terms of the rate of nucleation and growth. The films vacuum-condensed onto NaCl are composed of laminar crystals which have a random orientation.

In previous papers,[1,2] the orientation overgrowth of phthalocyanine compounds was investigated on a cleavage face of muscovite. Films vacuum-condensed onto muscovite occurred in two different types of orientations, which were called the parallel b-axis orientation and the standing b-axis orientation. This difference appeared mostly to depend upon the condition of the thermal treatment of muscovite. With regards to the orientation of the phthalocyanine crystal relative to substrate muscovite, it was suggested that planar molecules in the crystal came into contact with the cleavage face of muscovite, and that bridge nitrogen atoms in a phthalocyanine molecule were connected with the surface potassium ions in the (001) plane of muscovite when the film took the standing b-axis orientation.

In an effort to elucidate the effect of potassium ions in a substrate on the orientation overgrowth of phthalocyanine, the vacuum-condensed film was studied on the cleavage faces of alkali halides. Karasek and Decius[3] reported that vacuum-sublimated films of metal-free phthalocyanine on rock salt appeared in either of its dimorphs, depending upon the substrate temperature. By X-ray diffractometry, they also found that the crystals were of the metastable form if the substrate temperature was lower than 200°C. However, they did not refer to the orientation of the deposited films relative to the substrate.

For the present paper, vacuum-condensed films of copper-phthalocyanine on cleavage faces of alkali halides were observed by electron microscopy. The appearance of various crystals in their growth process was then interpreted on the basis of the topography of the substrate surface. The orientation of the film was determined by electron diffraction. The orientation of the deposited crystal relative to the substrate alkali halides will be discussed on the basis of the molecular arrangement in the crystal.

Experimental

Powdery commercial copper-phthalocyanine was purified by repeated sublimation in a low-pressure stream of carbon dioxide at a temperature above 500°C. The purified material was sublimated from a tungsten basket onto the cleavage faces of alkali halides in a vacuum evaporator. The single crystals of alkali halides used in this work were potassium chloride, potassium bromide and sodium chloride. The crystals were cleaved in air and immediately placed in a Pyrex glass tube, as has been mentioned in a previous paper.[2] The specimens used for electron microscopy were prepared by the wet-stripping method.

was vacuum-condensed onto a cleavage face of potassium chloride at 150°C, various crystal shapes were observed in the growth process of the deposit. At the early stage of condensation, the film was composed of three types of crystals, with different shapes, as is shown in Fig. 1. Very fine

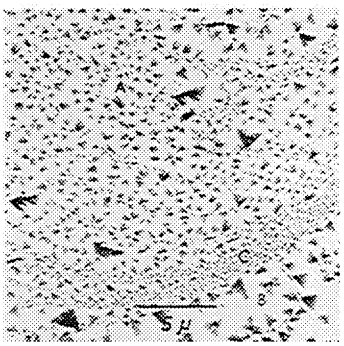

Fig. 1. Electron micrograph of Cu-phthalocyanine vacuum-condensed onto a cleavage face of KCl at the early stage of sublimation.

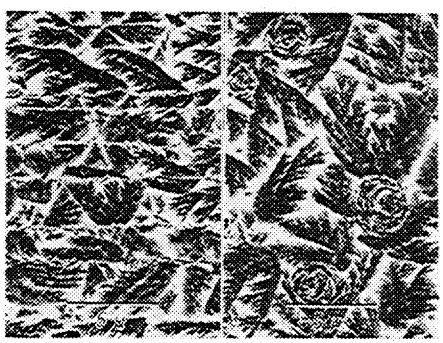
crystals like A, the size of which was about 100 Å, were observed all over the substrate face. In the part B, large dendrites appeared, while relatively small rectangular crystals came together in the part C. The curved pattern was formed by the latter crystals in the part B. As the film thickness was increased, the dendrites grew larger until the ends of their branches reached the curved zone, as is shown in Fig. 2(a), while small crystals condensed on the curved zone came into contact



(a) (b)

with each other without showing any tremendous growth. These curved lines formed by the crystallites may be attributed to the decorative effect similar to that pointed out by Basset and Pashley[4] for the metallic deposit on alkali halides and other inorganic crystals. It is well known that the

decoration pattern shows the topography of the cleavage face. Sometimes, small crystals were observed to lie on concentric circles in the early stages. These crystals were aggregated in the circles to form a cabbage-like shape, shown in Fig. 2(b), when the amounts of the condensed crystals were increased. When the rate of deposition was increased, the film was composed of small crystals which were connected to form a wave-like pattern, as is shown in Fig. 3. When the substrate temperature was higher than 200°C, the film was composed of only discrete crystals with a dendrite structure, as Fig. 4(a) shows. Figure 4(b) shows a selected area-diffraction pattern from the triangular dendtrite shown in Fig. 4(a); this pattern revealed that the dendrite was a well-defined single crystal. Although the deposited crystal occurred in various types depending on either the condensation conditions or the topography of the cleavage face, all the crystals were found to have the same crystal habit on a close observation of electron micrographs as well as of electron-diffraction patterns. It is obvious that the dendrites shown in Figs. 1 and 4 are formed from rectangular crystals which were aggregated to one another with a definite orientation. The cabbage-like

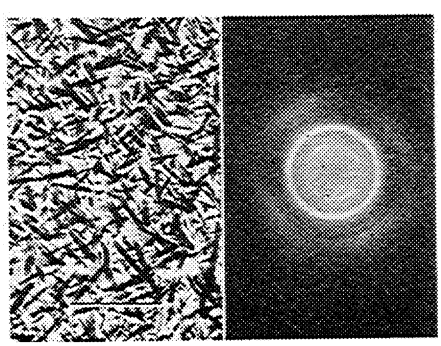
features in Fig. 2(b) are apparently composed of a number of small rectangular crystals assembled on the concentric circles. In the process of crystal growth, the difference in the way of the secondary aggregation of these elementary rectangular crystals gave rise to various shapes.

(b) Crystals on the Cleavage Face of Potassium Bromide.—When the cleavage face of potassium bromide was used as the substrate, the film vacuum-condensed on it was composed of small rectangular crystals and dendrites, as Fig. 5 shows, which were

Fig. 5. Electron micrograph of Cu-phthalocyanine vacuum-condensed onto a cleavage face of KBr.

similar to those formed on potassium chloride. The small crystals arranged in a row were distributed all over the surface, as were the dendrites.

(c) Crystals on the Cleavage Face of Sodium Chloride.—In contrast to the film formed on either potassium chloride or potassium bromide, the film on sodium chloride was composed of crystals with entirely different features, as Fig. 6(a) shows.



(a) (b)

Fig. 6. Electron micrograph (a) and diffraction pattern (b) of Cu-phthalocyanine vacuum-condensed onto a cleavage face of NaCl.

The laminar crystals grew in random directions, and the size of the crystals was apparently not uniform. No evident orientation was observed in the electron diffraction pattern, as may be seen in Fig. 6(b).

The Determination of the Crystal Orientation.—*(a) The Orientation of the Crystal Deposited*

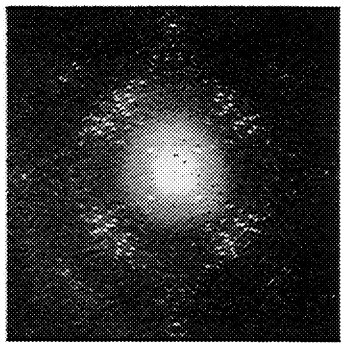


Fig. 7. High resolution electron diffraction pattern of Cu-phthalocyanine film vacuum-condensed onto a cleavage face of KCl. Crystals assume the standing b-axis orientation.

on Potassium Chloride.—Although the films condensed onto the cleavage face of potassium chloride were composed of crystals with various shapes, as has been described above, the electron diffraction patterns from those films, all gave the same pattern, as is shown in Fig. 7, this revealed that all the crystals assumed the same lattice orientation. The diffraction pattern consisted of four sets of identical cross-grating patterns, each of which was essentially the same as the single crystal pattern shown in Fig. 4(b). Therefore, it turned out that the film included eight groups of crystals, in each of which the orientation was the same. The total diffraction pattern is schematically reproduced in Fig. 8, in which the white circles represent the basic single crystal pattern associated with the two groups of the crystals which have a C_2 symmetry. Although the total pattern appeared to be complicated, it can be configurated

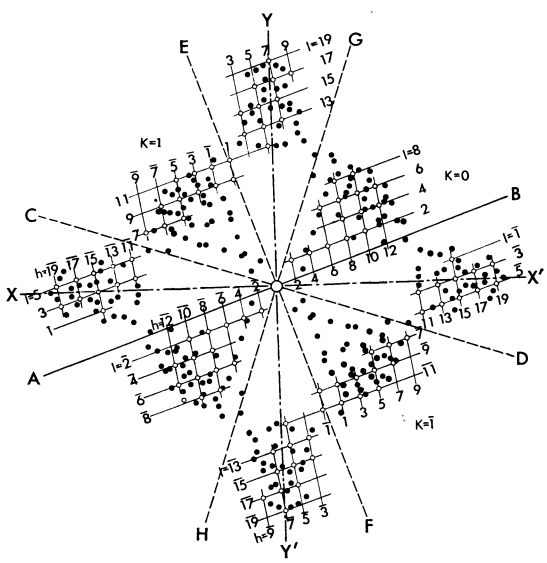

Fig. 8. The interpretation of the diffraction pattern shown in Fig. 7. White circles are the representation of the basic single crystal pattern.

by the systematic superposition of this elementary pattern, which is essentially the same as that shown in Fig. 4(b), with the major axes of C_{4v} symmetry, XX' and YY', which further coincide with the [100] and [010] directions of potassium chloride respectively.

Another result derived from the analysis of this elementary pattern is that the individual crystals have the $(31\bar{3})$ plane as the basal one facing parallel to the substrate crystal. As the AB line appears as the projection of the c* reciprocal axis in the elementary pattern, so other lines, CD, EF and GH, are similar projections of c* axes associated with individual crystal groups. The angle between the projection of each c* reciprocal axis and the nearest major axis of symmetry was found to be almost 20°.

(b) The Orientation of the Crystal Deposited on Potassium Bromide.—The films condensed onto potassium bromide were composed of crystals similar to those on potassium chloride, excepting that the high-resolution electron-diffraction pattern from the film revealed a somewhat different orientation of the deposited crystals. Figure 9 shows the

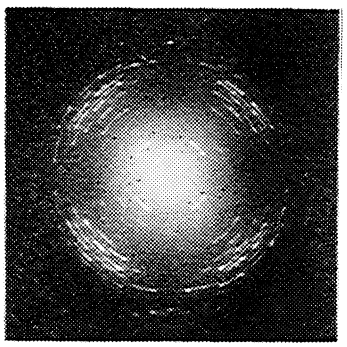

Fig. 9. High resolution electron diffraction pattern of Cu-phthalocyanine film vacuum-condensed onto a cleavage face of KBr.

electron-diffraction pattern obtained from the film. Also, in this case the crystals turned out to assume the standing b-axis orientation, in which the $(31\bar{3})$ plane of the crystal lies parallel to the cleavage face of potassium bromide. The pattern indicated that the orientation of crystals has a C_{4v} symmetry, the major axes of which again coincide with the [010] and [100] directions of potassium bromide. Therefore, the crystals may be classified into eight orientation groups, defined by two planes of symmetry which finally coincide with the (100) and (010) planes of potassium bromide; these planes are designated by XX' and YY'. The arc spots revealed that crystallites included in the individual groups were oriented with an azimuthal angular shift of about 12°. Thus, the projection of the reciprocal c* axis on the basal plane falls into an angular range defined,

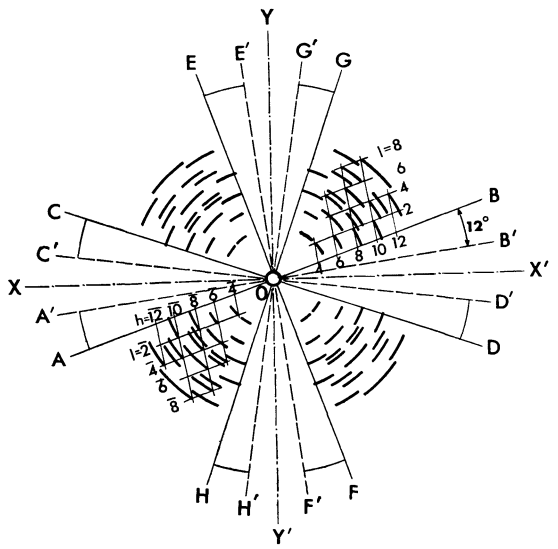

Fig. 10. The interpretation of the diffraction pattern shown in Fig. 9.

for instance, by AB and A'B' for one group of crystallites. Since the pattern has the C_{4v} symmetry, the angular ranges of the projection of the c* axis are defined by sets of CD:C'D', EF:E'F' and GH:G'H' for the other groups, as is shown in Fig. 10. Even in this case, each crystallite condensed onto potassium bromide again occurred in the standing b-axis orientation, which made the $(31\bar{3})$ plane parallel to the substrate surface.

Discussion

As has been described in the previous paper,[1] vacuum-condensed films of copper-phthalocyanine occur in the metastable form, the crystal structure of which is isomorphic with that of the platinum derivative. The a-, b- and c-axes of the copper-phthalocyanine crystal in the standing b-axis orientation are inclined to the normal of the substrate surface at angles of about 75°, 32° and 118° respectively. In the case of the platinum-phthalocyanine crystal with the standing b-axis orientation on muscovite, the main axes are inclined to the normal of the substrate face at angles similar to those of the copper derivative, and the molecular plane faces the substrate face.[2] Therefore, it seems that the molecular plane of copper-phthalocyanine in the alternative lattice rows in the basal face comes into parallel contact with the substrate face. The metastable form of copper-phthalocyanine has the following unit cell dimensions with a monoclinic space group $C2/c$: $a=25.82$ Å, $b=3.79$ Å, $c=23.72$ Å and $\beta=90.4°$.[5] As the

5) M. Ashida, N. Uyeda and E. Suito, This Bulletin, **39**, 2616 (1966).

axial angle, β, is nearly equal to a right angle, the a* and c* axes of the reciprocal lattice are approximated by the directions along the a- and c-axes of the real crystal respectively. Consequently, the projection of the reciprocal c* axis on the basal plane shown in Figs. 8 and 10 may be considered the projection of the c-axis on the substrate face.

The cleavage face of the potassium chloride crystal is the (001) plane, in which K^+ ions and Cl^- ions are alternatively located in the [100] and [010] directions at the distance of 3.14 Å, as is shown in Fig. 11. A phthalocyanine molecule

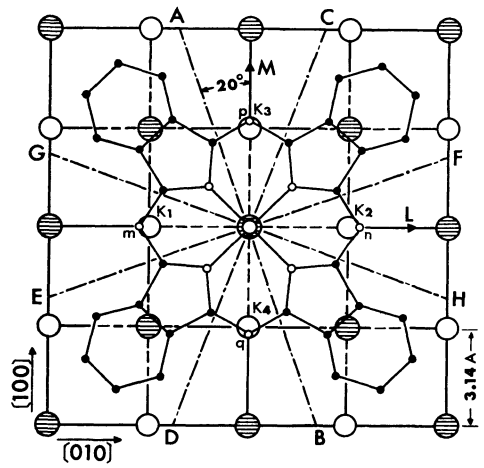

Fig. 11. The lattice structure of the cleavage face of KCl and the orientation relative to the deposited molecule of Cu-phthalocyanine.

is usually represented by a set of two molecular axes, L and M, which are defined through the center of the molecule through the bridge nitrogen atoms, as Fig. 11 shows. A projection of the c-axis of the crystal on a molecular plane makes an angle of about 20° with the M molecular axis, and the b-axis of the crystal is projected on a molecular plane in the direction of the M molecular axis.

According to Kobayashi,[6] the electrons in the phthalocyanine molecule are distributed on the bridge nitrogen atoms at the highest density; this causes an electrophilic effect to occur at these nitrogen atoms.[7] As the potassium ion has an electron-attractive force, the bridge nitrogen atoms of phthalocyanine possibly tend to come closer to the potassium ion. In the case of crystals deposited on potassium halides, it seems reasonable to consider that the bridge nitrogen atoms of the molecule which parallelly faces the (001) plane of the substrate crystal come into contact with the potassium ions on the cleavage plane. When it is tentatively assumed that four nitrogen atoms on the L and M molecular axes (e. g., m, n, p and q) are located on potassium ions (e. g., K_1, K_2, K_3 and K_4), the projection of the c-axis of the crystal on the substrate plane makes an angle of either $+20°$ or $-20°$ with the [100] direction of potassium chloride, as is shown by the line AB or CD; these lines give rise to two crystals with a plane of mirror symmetry, as is shown in Figs. 12 A and B. It should be noted that this angle coincides with that between the projection of the reciprocal c* axis of the phthalocyanine crystal and the [100] direction of potassium chloride as revealed by the electron-diffraction pattern. In addition to this choice of the c-axis, the above molecule parallel along the b-axis shifts in either the +M or −M direction depending upon the staggering of the overlapping molecule; this results in two different crystals by the axis of two-fold symmetry, as is shown in Figs. 12 A and C. The

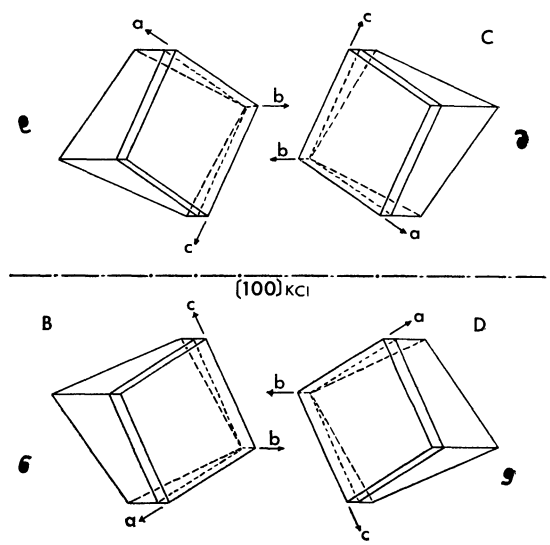

Fig. 12. Schematic diagram of the projection of crystals on the cleavage face of KCl.

M molecular axis can also lie parallel to the [010] direction of potassium chloride; that is, the staggering of the overlapping molecule may happen in four other ways in the [010] direction, thus forming a final crystal which has a projection of the c-axis like either EF or GH. Thus, the total film configuration involves a C_{4v} symmetry as far as the orientation of the individual crystallites is concerned.

Even though the same standing b-axis orientation appeared on potassium chloride, the crystal deposited onto potassium bromide showed an apparent azimuthal angular shift in the plane of the film. A cleavage face of potassium bromide is the (001) plane, in which K^+ ions and Br^- ions are located in the [100] and [010] directions at a

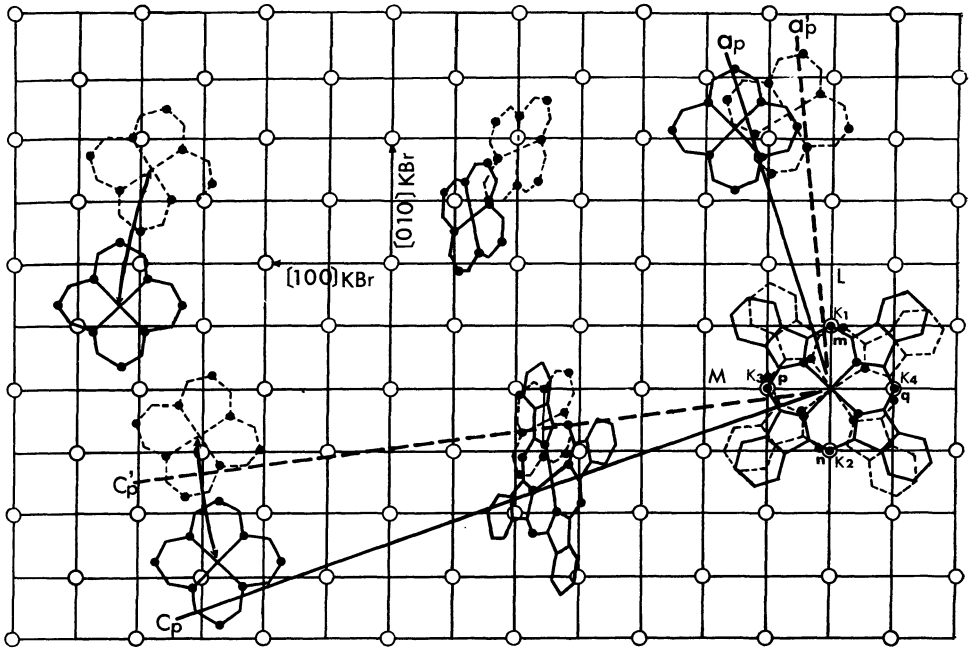

Fig. 13. The lattice structure of the cleavage face of KBr and the orientation relative to the deposited molecule of Cu-phthalocyanine.

distance of 3.29 Å, as is shown in Fig. 13. As has been described above, if four nitrogen atoms on the L and M molecular axes (e. g., m, n, p and q) of phthalocyanine, defined as the point of origin, are located on potassium ions (e. g., K_1, K_2, K_3 and K_4), the nitrogen atoms in the neighboring molecules are projected on the substrate face as is shown schematically in the figure. In this case, the projection of the c-axis, C_p, makes an angle of 20° with the [100] direction of potassium bromide. This angle coincides with that between the projection of the reciprocal c* axis of the phthalocyanine crystal, AB, and the [100] direction of potassium bromide as is revealed by the electron diffraction in Fig. 9. Since the orientation of the deposited crystals is distributed in an angular range of about 12° in azimuth, the projection of the c-axis lies between C_p and C_p'; that is, the molecules in the crystal may be rotated on the substrate face as is shown by the dotted line. The above characteristic orientation may plausibly be ascribed to the difference in misfitting between the deposit and the substrate crystal. The interaction betweeen the molecule and the substrate will also vary depending upon the differences in the negative ions.

The deposited crystals of phthalocyanine appeared in a C_{4v} symmetric orientation on the (001) planes of potassium chloride and potassium bromide. The planes of mirror symmetry corresponded to the (100) and (010) planes of potassium halides. On the contrary, phthalocyanine crystals deposited onto the (001) plane of muscovite, which apparently has a hexangonal symmetry, showed only a C_{2v} symmetry,[1,2] this symmetry was considered to be due to the influence of the staggering in the mica layer under the cleavage face. This suggestion was supported by the present finding that the orientation of the phthalocyanine crystal had the same symmetry as that of the substrate face in the case of alkali halide, which has no such staggering as muscovite.

The crystal growth of evaporated films consists of two factors, the rates of nucleation and its growth. A variation in the crystal shape is caused by the contribution of the two factors. When phthalocyanine is deposited onto a cleavage face of potassium chloride, the preferential nucleation occurs at steps on the substrate face. Fast nucleation causes a number of fine crystals at the steps. On the contrary, the deposited molecule can relatively freely move over the smooth parts of the surface; thus it collides with other deposited molecules to form a large aggregate, and the nuclei grow to a large dendrite on these parts. As the rate of sublimation is increased, the deposited molecules have more chance to collide, thus leading to the nucleation predominate in number. Therefore, fine crystals appeared all over the surface with uniform dimensions and formed a continuous film with a wave-like pattern, as is shown in Fig. 4. In contrast to the crystals deposited onto potassium chloride, the film formed on muscovite was composed of small rectangular crystals; dendrites

were not observed even when the film had the same standing b-axis orientation.[2] Since a cleavage face of muscovite is considered to be fairly smooth in an atomic scale over a limited area, this appearence is probably due to the difference in nucleation velocity. It seems that the molecules deposited onto muscovite have a lower mobility than those on potassium chloride, and that the difference in mobility depends upon the bonding force of the interface between deposit and the substrate.

Recently, Ino et al.[8] investigated the epitaxial growth of metal on a surface of sodium chloride which has been cleaved either in an ultrahigh vacuum of 10^{-7} to 10^{-9} mmHg or in a rather poor vacuum of 10^{-4} to 10^{-5} mmHg; they concluded that some gas molecule adsorbed on the sodium chloride surface is necessary for the epitaxial growth of a single crystal of f. c. c. metal. Furthermore, Mattews and Grünbaum[9] established that moist air modified the (001) plane of sodium chloride in such a way that f. c. c. metals tend to grow epitaxially upon it. In the present experimental results, the film condensed on sodium chloride has a random orientation. Phthalocyanine as well as condensed polycyclic aromatic compounds repulse water rather strongly. Since adsorbed water molecules could not be removed from the cleavage face of sodium chloride under the present experimental conditions, it is reasonable to postulate that the orientation overgrowth of copper-phthalocyanine on sodium chloride is disturbed by the adsorbed water molecules. This assumption was further confirmed by the use of sodium chloride cleaved in vacuo. In this case, the deposited crystals were found to have the standing b-axis orientation. The results will appear in detail in a future report.

The author is very grateful to Professor Eiji Suito of the Institute for Chemical Research, Kyoto University, for his interest and support; he wishes also to thank Dr. Natsu Uyeda of the same Institute for his many helpful discussions and suggestions during this work. Moreover, he is indebted to Professor Wasaburo Jono and Professor Teizo Watanabe of Kobe University for their encouragement in this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2638—2642 (1966)

The Mechanism of the Catalytic Hydrogenation of Propene on Nickel, Palladium, and Platinum (The Application of Microwave Spectroscopy to Isotopic Analysis)[1]

By Kozo Hirota and Yoshie Hironaka[2]

Faculty of Science, Osaka University, Toyonaka, Osaka

(Received May 6, 1966)

The catalytic hydrogenation of propene with deuterium gas and its isotopic exchange reaction with deuterium oxide have been carried out at room temperature, and the remaining propene has been subjected to microwave spectroscopic analysis so as to determine the isotopic isomer-distribution of propene-d_1 and -d_2. From the results, the following conclusions have been drawn: (1) the rate-determining step in the hydrogenation on platinum as well as nickel and palladium catalysts is the addition of hydrogen to the half-hydrogenated species; (2) the kinds of chemisorbed species and their distribution prior to the rate-determining step are not always the same, but depend on the metals, and (3) the life-time of the chemisorbed propene is shorter than the successive time interval of its exchange process on nickel, but this is not the case on platinum nor, probably, on palladium.

In previous reports,[3,4] the chemisorbed states of propene on nickel and palladium catalysts were investigated on the basis of the subspecies-distributions[5] of propene-d_1 in the products of the exchange and hydrogenation reaction with deuterium gas and deuterium oxide:

1) Presented at the 19th annual meeting of the Chemical Society of Japan, April 1, 1966.

2) Present address: Research Institute of Science and Industry, Osaka University.

3) J. Hirota and Y. Hironaka, *J. Catalysis*, **4**, 602 (1965); K. Hirota, Y. Hironaka and E. Hirota, *Tetrahedron Letters*, **1964**, 1645.

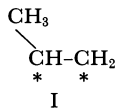
4) Y. Hironaka and K. Hirota, This Bulletin, **38**, 1558 (1965).

5) Subspecies may be called "isotopic isomers."

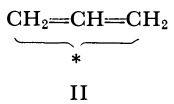
$$C_3H_6 + nD_2 \rightarrow C_3H_{8-y}D_y, \text{ and } C_3H_{6-x}D_x, \quad (1a)$$

$$C_3H_6 + nD_2O \rightarrow C_3H_{6-x}D_x. \quad (1b)$$

It has been proposed that the main chemisorbed states of propene are the associative-type I on nickel and the π-allyl-type II on palladium. In addition, both reactions were found to occur with the half-hydrogenated state, C_3H_7, as an intermediate.



I



II

Since these findings are very important to a discussion of the mechanism of catalytic hydrogenation, a similar investigation was made of platinum, using the mass spectrometric and microwave-spectroscopic methods in the analysis, as adopted in previous reports. The object of the present paper is not only to report the new knowledge obtained and to discuss it from the standpoint of the mechanism of catalytic hydrogenation in general, but also to report the superiority of microwave spectroscopy for isotopic analysis.

Experimental

The platinum catalyst was prepared from chloroplatinum acid by reduction with formaldehyde.

The other materials and procedures were the same as those in the cases of nickel and palladium.[3,4] The subspecies distribution of propene-d_2 in the product was determined, as was that of propene-d_1, by applying the microwave spectroscopic method to the samples, without any separating procedure.

The reaction times in both reactions were selected in such a way that the parameter, $\phi=\frac{1}{6}\sum_x xd_x$, an indication of the exchange degree, took a value similar to that of nickel and palladium (about 10%). (Cf. Table I (A))

Results

Table I (B) shows the isotopic distribution of the deuteropropenes remaining after the reactions. Deuteropropenes with higher x values can be observed, because d_5 and d_6 were negligibly small in the cases of most nickel and palladium catalysts.

The distribution of deuterium in the propene-D_2 system was slightly wider than that in the propene-D_2O system when Ni and Pd were used as catalysts, but, according to the present research, the deuterium-distribution of the proepene-D_2O system is, on the contrary, wider than that of the propene-D_2 system.

In the subspecies distrubtion of propene-d_1, shown in Table II, the characteristic differences of the three catalysts are obvious. There is a tendency for the methylene group to be most exchangeable on platinum, though only the methine group was easily exchanged in the case of nickel; there is also a difference in the case of palladium, by which all the three groups were exchanged with nearly equal probabilities. However, it is

Table I. Experimental conditions and deuterium-distribution of reaction products

Table III The subspecies distribution of propene-d_2 in the products of the metal/D_2O systems

Subspecies		Ni		Pd		Pt	
		Obs.	(Calcd.)	Obs.	(Calcd.)	Obs.	(Calcd.)
CHD_2-CH=CH_2	3,3-d_2	10.0	(11.3)	25.4	(43.6)	25.5	(6.4)
CH_2D-CD=CH_2	2,3-d_2	38.7	(39.6)	19.0	(14.8)	12.1	(24.3)
	*trans*-1,2-d_2	15.8	(17.1)	5.4	(3.5)	8.7	(4.0)
	*cis*-1,2-d_2	17.1	(17.1)	5.6	(3.5)	18.4	(32.4)
CH_3-CH=CD_2	1,1-d_2	4.9	(2.8)	7.5	(3.4)	15.8	(6.8)
	*trans*-1,3-d_2	6.9	(6.8)	18.7	(15.6)	15.9	(23.1)
	*cis*-1,3-d_2	7.1	(6.8)	18.4	(15.6)	3.7	(2.8)

important in the case of platinum that the exchange degree of $CH_3CH{=}CHD$ is not the same as between its cis- and trans-forms, irrespective of which is used, deuterium gas (No. 5505) or deuterium oxide (No. 41017). Considering this, the same tendency may exist in the case of the Pd/D_2O system,[3] though it is at present difficult to derive such a conclusion because the difference lies within the limits of experimental error.

The above findings can also be confirmed qualitatively by the clear difference in the infrared spectra of the products obtained by the use of the the three catalysts.

In Table III, the subspecies distribution of propene-d_2 is shown in addition to the data on Ni and Pd, which have already been mentioned.[3] The discrepancies among the distributions of the three catalysts and the calculated values shown in brackets will be discussed below.

Discussion

The Half-hydrogenated State. — In view of the similarity between the two reactions, 1a and 1b, in the substancies distribution of C_3H_6-d_1 (Table II), it can be said that the catalytic hydrogenation proceeds on platinum via the half-hydrogenated state, C_3H_7, in the same scheme as on nickel and palladium, making the step A rate-determining at room temperature. In other words, the exchange reaction occurs by the back ward process of the step B

$$\underset{*}{C_3H_6} \underset{-H}{\overset{H}{\rightleftarrows}} \underset{*}{C_3H_7} \xrightarrow{H} C_3H_8 \qquad (2)$$

(B) (A)

$$\underset{* \ *}{C_3H_6} + D \rightarrow \underset{*}{C_3H_6D} \rightarrow \underset{* \ *}{C_3H_5D} + H \qquad (3)$$

because the coincidence of No. 5505 and No. 41017 in the subspecies distribution of propene-d_1 is too close for the other reaction schemes to be possible.

However, in deriving this conclusion, it must be remembered that the water molecule is, as usual, assumed to exist dissociatively on the metal surface.

$$H_2O \longrightarrow \underset{*}{HO} + \underset{*}{H} \qquad (4)$$

Though the non-dissociative adsorption of water molecule is also possible on some parts of metal surfaces,[6] the state seems to be indifferent to the present exchange reaction in view of the above results.

Such being the situation, the scheme of Eq. 3 may be justified, and the so-called Rideal mechanism, Eq. 5, seems to be implausible; i. e., the possibility that the half-hydrogenated state is formed only by the reaction of the hydrogen molecule and chemisorbed propene in one step[7] is of less importance.

$$\underset{* \ *}{C_3H_6} + H_2 \longrightarrow \underset{*}{C_3H_7} + \underset{*}{H} \qquad (5)$$

However, the scheme of the exchange reaction, Eq. 1b, proposed on nickel may not necessarily be derived. The scheme of the reaction may be different on palladium and on other metals. The chemisorbed states[8] of propene are not always the same; rather, they may differ according to the metals as well as according to the reaction conditions. These points will be investigated below.

The Distribution of the d_1 Subspecies.— The characteristic features of the activity of platinum, clarified by the subspecies distribution of propene-d_1, suggest that some new chemisorbed species is produced from propene on platinum simultaneously with the associative state which is

6) G. C. Bond, "Catalysis by Metals," Academic Press, New York (1962), p. 219.

7) G. H. Twigg, *Discussions Faraday Soc.*, **8**, 152 (1950).

8) Besides, there is a possibility that the associative state, $\underset{* \ *}{C_3H_6}$, is π-bonded rather than σ-bonded to the surface on some metals.

	Calcd.[a]	Obs.[b]
$CH_3CD=CH_2$	50%	58.1%

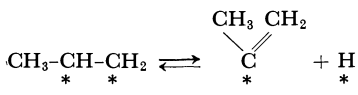
$CH_2=CH-CH_2D$	30%	22.5%

Fig. 1. Scheme of the associative mechanism of the exchange reaction.

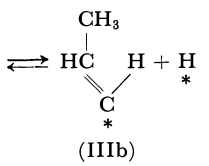
a) Percentage of the products on the right side are calculated by neglecting the isotopic effect during hydrogenation and dehydrogenation.

b) The result of Ni/D_2O system (No. 3513) is shown for the sake of the comparison.

predominant on nickel. In explanation of this, the existence of a dissociative state may be suggested; such a state would especially explain the predominance of the trans-form over the cis-form of CH_3–CH=CHD in the product. Such a suggestion is not new, because the state has already been mentioned on platinum by Farkas[9] and has been proposed by Burwell,[10] who expressed the states as follows:

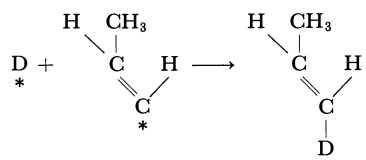


(IIIa) (6a)



(IIIb) (6b)

Both dissociative states, IIIa and IIIb, are convenient in explaining the broad distribution of deuterated propenes. Of the two dissociative states, however, the state IIIb, CH_3–CH=$\overset{*}{C}$H, would be more abundant, because less CH_3CDCH_2 is produced than the sum of *trans-* and *cis*-CH_3-CHCHD. The chemisorbed species may lie on the metal plane perpendicularly because of the steric hindrance of the methyl group. Therefore, the exchange occurs as follows:



(7)

On the other hand, an alternative explanation on the basis of the associative chemisorbed state is possible; i. e., because of the presence of the methyl group, the propene may not be chemisorbed parallel to the metal plane, but may take an inclined state. However, the production of the trans-form from such a state is hard to explain without introducing another assumption into the exchange process.

Parallel with the dissociative process, the exchange reaction on platinum may be realized by the associative process proposed for on nickel; it is shown diagramatically in Fig. 1. According to this scheme, the production of 3-d_1, 2-d_1 and, t- and c-1-d_1 can be explained quantitatively, because the isotopic effect can be neglected, and the subspecies distribution of propene-d_1 can be given by Eq. 8 on the assumption that the addition of D to $CH_3\overset{*}{C}H-\overset{*}{C}H_2$ occurs at an equal rate:

$$3\text{-}d_1 : 2\text{-}d_1 : (t+c)\text{-}1\text{-}d_1 = 3 : 5 : 2 \qquad (8)$$

The application of Eq. 8 to the data of nickel gives a semi-quantitative coincidence between theory and experiment. However, the Pt/D_2O system (No. 41017) gives a different result. By assuming the associative mechanism on platinum, the amounts of c-1-d_1 and t-1-d_1 are made equal to be 5.8% and the percentages of other subspecies are calculated (cf. Table IV). It is evident from the table that, except for t-1-d_1, the amounts agree well with the calculated values.

Table IV. The isotopic distribution of the propene-d_1 produced on platinum catalysts (%)
(Run: No. 41017)

	c-1-d_1	t-1-d_1	3-d_1	2-d_1
Obs.	5.8	47.8	19.5	27.3
Calcd.	(5.8)	(5.8)	19.4	29.0

This indicates that the difference between 47.8 and 5.8% (i. e., 42.0%) in t-1-d_1 results from the occurrence of the dissociative mechanism, while the residual 5.8% results from that of the associative mechanism.

Finally, it must be mentioned that, by the associative mechanism, the d_1-distribution of Pd/D_2O cannot be explained at all. Judging from the above reasoning, the dissociative mechanism may possibly play some role in the exchange reaction in the case of palladium as well as in those of platinum.

Distribution of Propene-d_2.—In Table III, the calculated subspecies distribution of propene-d_2 is shown in parentheses. Those values have been obtained on the assumption that the second exchange occurs independently and in the same way as that of the first. In the case of nickel, the values coincide well, indicating that the second exchange occurs independently of the first exchange. This finding, already reported by Morino and Hirota,[11] can be explained by the fact that the desorption of the propene-d_1 produced occurs at a faster rate than the second exchange process at the same chemisorbed state. However, since no such tendency is indicated in the case of platinum, the chemisorbed state on this metal may have a life-time sufficient to allow both processes to have some correlation. Of course, it cannot be said, from the results shown in Table III alone, that the lifetime of chemisorbed propene on platinum is longer than that on nickel.

As for palladium, an intermediate property of nickel and platinum is suggested in the present distribution, as it is in the propene-d_1 distrubtion. Such a result may be brought about from the adsorbed state on palladium, which is of the π-allyl type, as has been suggested in a previous paper.

Conclusion

As far as the reaction conditions in the present paper are concerned, the following conclusions are obtained: (i) the rate-determining step in the catalytic hydrogenation on nickel, palladium and platinum is the addition of hydrogen to the half-hydrogenated species, C_3H_7; (ii) the kinds of chemisorbed species and their distribution prior to the rate-determining step, however, vary with the metal, and (iii) the life-time of the chemisorbed propene is shorter than the successive interval of its exchange process so far as nickel is concerned, while this may not be true in the case of platinum and probably in that of palladium as well.

It must be mentioned, however, that further investigations are now going on in order to investigate if the above conculsions, especially Eq. 2, are applicable to these metals irrespectively of their methods of preparation and the presence of carriers.

We wish to express our sincere thanks to Professor Yonezo Morino and Dr. Eizi Hirota, the University of Tokyo, for their discussions and help in performing the present research.

Studies of the Aqueous Solution of a Surface Active Substance by Means of an Ultrasonic Interferometer. III. Determinations of Ionic and Nonionic Hydrations of Sodium Alkyl Sulfate

By Koji SHIGEHARA*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received May 13, 1966)

The amounts of water of ionic and nonionic hydration were calculated for sodium alkyl sulfate in the state of molecular dispersion from the data obtained by the author and under the assumptions usually adopted: (a) the solution, as a whole, consists of several volume elements of different compressibilities; (b) the ionic radical together with its hydration water is incompressible; (c) the compressibility of the water of nonionic hydration for the CH_2 group of the hydrocarbon chain is the same as that of ordinary ice; (d) the compressibility and the molar volume of the CH_2 radical in the state of molecular dispersion are the same as those in the micellar state. The water of hydration was calculated to be 2.1 mole per mole of the CH_2 radical, and 4.9 mole per mole of the ionic radical, the latter value being the same as that of the solute in the micellar state previously reported. The molar volume of the water of nonionic hydration is found to be slightly less than that of free water, in accordance with the prediction of others. The dehydration of sodium alkyl sulfate caused by the addition of inorganic electrolyte has also been observed.

In previous papers,[1,2] it has been shown that differential ultrasonic interferometry is one of the most useful methods for the study of aqueous solutions of surface active substances. The sound velocity measurement by this method, together with the density measurement, makes possible the calculation of the compressibility and the critical micelle concentrations (CMC) of aqueous solutions of several alkyl sulfates with or without the addition of inorganic electrolytes, and from these data the compressibility, the molar volume and the hydration number of ionic micelle were determined. It has been inferred therefrom that the hydrocarbon interior of the ionic micelle is liquid-like rather than solid-like; the nonionic hydration of CH_2-chain is also one of the most important factors responsible for the dissolution of the surface active substance, and the builder action of the inorganic electrolyte is due not only to the decrease in the mutual repulsion of the ionized head group of the surface active substance caused by the gegenion attachment to this group, but also to the decrease in the amount of nonionic hydration of the CH_2-chain of the surface active substance. However, no quantitative discussion of the nature and the amount of the nonionic hydration of the CH_2-chain of a surface active substance has yet been reported. The present paper will give an estimation of the nonionic hydration of the CH_2-chain of the surfactant molecule.

Calculation

A solution (total volume, V; compressibility, β) is assumed to consist of several volume elements, v_1, v_2,$\cdots$, of different compressibilities, β_1, β_2,$\cdots$, in such a manner as:[1]

$$V = v_1 + v_2 + \cdots \quad (1)$$

$$V\beta = v_1\beta_1 + v_2\beta_2 + \cdots \quad (2)$$

Then, for a solution of an alkyl sulfate below CMC, we have:

$$V = V_1(n_1 - nn_x - nn_yN) + V_2nn_yN + V_3nN + V_4n \quad (3)$$

$$V\beta = V\beta_1 + V_2nn_yN(\beta_2 - \beta_1) + V_3nN(\beta_3 - \beta_1) + V_4n(\beta_4 - \beta_1) \quad (4)$$

where n_1 and n denote the mole numbers of the solvent and the solute in the solution of the volume (V) respectively; n_x, the mole number of the water of ionic hydration per mole of the SO_4Na radical; n_y, the mole number of the water of nonionic hydration per mole of the CH_2 radical of the alkyl chain; N, the number of carbon atoms in a solute molecule; V_1 and V_2, the molar volume of free water and the water of nonionic hydration respectively; V_3, the molar volume of the CH_2 radical of the solute molecule; V_4, the molar volume of the SO_4Na radical together with its n_x moles of

hydration water; and β, β_1, β_2, β_3 and β_4, the compressibility of the solution as a whole and of the parts which have the molar volumes of V_1, V_2, V_3 and V_4 in the solution respectively. Thus, the terms of the right hand side of Eq. 3 indicate the volumes of free water, the water of hydration of the hydrocarbon chain, the hydrocarbon chain, and the hydrated ionic head respectively in that order. From Eqs. 3 and 4, we obtain:

$$\overline{V} = (-n_y V_1 + n_y V_2 + V_3)N + V_4 - n_x V_1 \quad (5)$$

$$d\beta/dC = [V_2(\beta_2 - \beta_1) + V_3(\beta_3 - \beta_1)]N + V_4(\beta_4 - \beta_1) \quad (6)$$

where $\overline{V}$ denotes the partial molar volume of alkyl sulfate, and C, the molarity of the solute ($C=n/V$).

It is assumed that such ionic radicals as HSO_4^- and $-SO_4^-$ (alkyl sulfate), and its hydration water, are incompressible, as has been accepted by many authors,[3] that V_3 and β_3 are equal to the molar volume (V_m) of CH_2 in the micelle and the compressibility (β_m) of the hydrocarbon parts in the micelle respectively, and that β_2 is equal to the compressibility (β_{ice}) of ordinary ice, as was accepted by Sasaki and Yasunaga[4] and by Shiio et al.[5] The last assumption is also in accordance with the view that the water molecule is oriented towards the CH_2 radical and that they form an ice-like structure by means of H-bonds between them, thus producing a microscopic "iceberg" around dissolved molecules of hydrocarbon.[6,7] The following equations can then be obtained for the solution of alkyl sulfates below CMC:

$$\overline{V} = (-n_y V_1 + n_y V_2 + V_m)N + V_4 - n_x V_1 \quad (7)$$

$$d\beta/dC = [V_2(\beta_{ice} - \beta_1) + V_m(\beta_m - \beta_1)]N - V_4\beta_1 \quad (8)$$

where the values of β_1, β_{ice}, β_m, V_1 and V_m are 44.082,[1] 11.1,[8] 70.1[1] (all in 10^{-12} cm^2/dyn.), 18.094[9] and 17.1[1] (both in cc./mol.) respectively.

In his previous papers,[1] the author has reported empirical equations* corresponding to those of Eqs. 7 and 8:

$$\overline{V} = 15.9N + 46 \quad (9)$$

$$d\beta/dC = -0.776\times10^{-12}\times N - 5.94\times10^{-12} \quad (10)$$

where $\overline{V}$ and $d\beta/dC$ are expressed in cc./mol. and (cm^2/dyn.)/(mol./l.) respectively.

By comparing Eq. 7 with Eq. 9, and Eq. 8 with Eq. 10, with due consideration of the difference in units, the n_x, n_y, V_2 and V_4 values are calculated to be as shown in Table I.

TABLE I

Radical	Amount of hydration water of (mol./mol.)	Molar volume of hydrated (cc./mol.)	Molar volume of hydration water of (cc./mol.)
SO_4Na	4.9	135	—
CH_2	2.1	—	17.5

The mole number of the water of ionic hydration per mole of the SO_4Na radical, $n_x=4.9$, and the molar volume of the hydrated SO_4Na radical, $V_4=135$ (cc./mol.), are consistent with those of the solute in the micellar state, determined independently in previous papers.[1] The mole number of the water of nonionic hydration per mole of the CH_2 radical, $n_y=2.1$, agrees with Butler's assumption,[6] which he adopted to calculate the heat of hydration of a homologous series of alcohols. There he considered that two hydrogen atoms of the CH_2 radical give rise to two H-bonds around it. The molar volume of the water of nonionic hydration, $V_2=17.5$ cc./mol., is slightly less than that of free water. This fact agrees with those reported by other authors.[7] All these facts lead us to the conclusion that the assumptions used in the calculation are permissible.

In a preceding paper,[2] the present author has reported that the $\overline{V}$ value of alkyl sulfate is not affected by the addition of inorganic electrolyte, that $d\beta/dC$ below CMC increases with the concentration of the added electrolyte, and that the extrapolated value of $d\beta/dC$ to $N=0$ shows the same value independently of the presence of the added electrolyte (Fig. 1). From these results and from Eqs. 7 and 8, the n_x, n_y, V_2 and V_4 values in the presence of inorganic electrolytes are obtained by a calculation similar to that mentioned above. It was confirmed that the values of n_x, V_2 and V_4 thus obtained were not affected by the addition of inorganic electrolytes. On the other hand, as is shown in Fig. 2, the mole number of the water of nonionic hydration per mole of the CH_2 radical, n_y, decreases with the increase in the concentration of inorganic electrolytes until it reaches a minimum value which is about 80% of the n_y value in the absence of electrolytes. This

confirms the view inferred in the former report[2] that the addition of inorganic electrolytes not only serves to increase the gegenion attachment, as is generally believed, but may also remove water of hydration from the hydrophobic chain of surface active substances. Both of these factors may be considered to decrease the CMC of the surface active substance.

The Physical Properties and Crystal Structure of 2-Bromo-1, 1, 1-trichloro-2-methylpropane

By Tsutomu KOIDE, Tsutomu ODA, Osamu WASHIO* and Kazuo FUJITA**

Laboratory of Chemistry, Osaka University of Liberal Arts and Education, Tennoji, Osaka

(Received May 16, 1966)

2-Bromo-1, 1, 1-trichloro-2-methylpropane gives a plastic crystal, named by Timmermans (*J. Chim. Phys.*, **35**, 331 (1938)), which is optically isotropic and which has a density of 1.97 g./cc. at 25°C. The X-ray data can be interpreted with a body-centered cubic lattice, with 7.42 Å for the unit cell length containing two molecules. The symmetry interpretation gives a crystal structure of a disordered orientation of molecules. It was found, by means of optical measurements and differential thermal analysis, that there is a phase transition at about −62°C, below which the crystal is in a lower symmetry.

In our previous papers,[1-5] several hexasubstituted ethane derivatives expressed by the formula

$X_{3-n}(CH_3)_nC\text{-}C(CH_3)_mX_{3-m}$ were studied from the point of view of crystal chemistry. It was observed that all the investigated substances undergo a phase transition in the solid state and that their high temperature modifications belong to the cubic structure, in which the molecular arrangement is in a disordered state.

It seems that it would be interest to see what effect may occur in the molecular behavior in the crystal, when substitution is extended to three species of atoms and groups such as chlorine, bromine and methyl groups, since they have nearly equal van der Waals radii.[6] In the present paper, the authors have studied 2-bromo-1, 1, 1-trichloro-2-methylpropane by means of X-ray diffraction, differential thermal analyses and optical measurements.

Experimental and Results

Material.—2-Bromo-1, 1, 1-trichloro-2-methylpropane was prepared by the bromination of chloreton with phosphorus pentabromide, following the method of Willgrerodt and Dürr.[7] The material obtained was purified by fractional melting and further by recrystallization three times from ether. The final purification was effected by fractional sublimation in a high vacuum (about 10^{-5} mmHg). The crystal shows plasticity and high volatility, its fumes irritating the eyes and nose.

Physical Properties.—The melting point was to be 160°C, and it sublimes at almost the same temperature. The density was found to be 1.97 g./cc. at 25°C by the flotation method using an aqueous solution of zinc chloride.

Optical Observation.— Under a polarized microscope, the optical properties of the crystal were observed at room and at lower temperatures. The cryostat used for the low-temperature measurements is described in Ref. 5. In the temperature range between room temperature and about −60°C, the crystal was found to be optically isotropic, indicating that the crystal is cubic. At about −60°C, it was suddenly transformed into a birefrigent polycrystal.

X-Ray Study.—A single crystal was sealed in a thin-walled Pyrex glass capillary tube. Within the capillary tube, a Pyrex glass rod almost filling the space was inserted to prevent the loss of crystal by sublimation.

Using Cu$K\alpha$ radiation ($\lambda=1.54$ Å) filtered through a nickel foil and adjusting [110] as the axis of rotation, we prepared a series of 30° oscillation photographs, covering a range of about 90°.

Laue photographs were also taken with X-rays parallel to [100], [110] and [111]. They show that the point-group symmetry of the crystal is T_d-$\bar{4}3m$ or O-43 or O_h-$m3m$. All the spectra appearing in oscillation photographs were extinguished except those of $h+k+l=2n$, they can be indexed with a body-centered cubic lattice with a unit cell of the side of $a=7.42$ Å.

The density indicates that two molecules are present in the unit cell, giving the calculated density to be 1.59 g./cc.

Differential Thermal Analysis (D. T. A.).—The apparatus and procedure of D. T. A. have been described elsewhere.[2] The investigated temperature range was from about −80°C to the melting point, 160°C. Two thermal anomalies were observed. One of them occurs at about −62°C on cooling, and at −35°C on heating. It is in accordance with the anomlies observed by a polarized microscope. Another anomaly was found at 160°C, corresponding to the melting point.

Discussion

The unit cell length of the cubic crystal of 2-bromo-1, 1, 1-trichloro-2-methylpropane, 7.42 Å, is comparable with the value of 7.43 Å given for hexachloroethane and that of 7.46 Å given for 1, 1, 1, 2-tetrachloro-2-methylpropane, even though the substance under investigation contains a bromine atom which has a larger van der Waals radius, 1.9 Å, than that of the chlorine atom, 1.8 Å.[6]

Since the unit cell contains two molecules, it is reasonable to place the centers of the mass of molecules at the lattice points, 0, 0, 0 and 1/2, 1/2, 1/2. The proper symmetry of these points is T_d-$\bar{4}3m$ or O-43, or O_h-$m3m$, so that the molecular symmetry in the crystal should have one of these cubic point groups. On the other hand, if we consider that the free molecule has the skew configulation (Fig. 1), the highest symmetry that the molecule

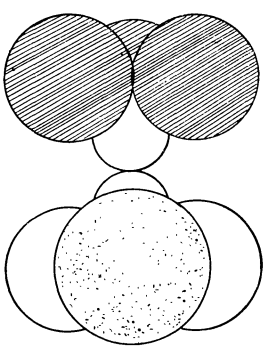

Fig. 1. The assumed skew configuration for the free molecule of 2-bromo-1, 1, 1-trichloro-2-methylpropane, $Br(CH_3)_2C\text{-}CCl_3$. The small circles represent carbon atoms, the larger circles the methyl groups, the dotted circle the bromine atom and the hatched one the chlorine atoms.

could have is C_s-m. In order for such a molecule of low symmetry to aquire an apparent high symmetry, it is necessary to take into consideration some statistical arrangements of molecules, as we have done in the cases of several other plastic crystals.[1-5,8]

Such a statistically-disordered molecular arrangement may disappear at lower temperatures. Thus the phase transition occuring at about $-62°C$ is perhaps the extreme temperature, below which the arrangement of the molecule is in an ordered state. The optical observation indicates that the crystal below the transition point possesses a lower crystal symmetry.

The authors wish to express their hearty thanks to Professor Isamu Nitta and Professor Tokunosuke Watanabé for their interest during this study.

Szilard-Chalmers Reaction of Anionic Cobalt Complex Ions on Ion-Exchange Resins*[1]

By Tatsuo MATSUURA

Institute for Atomic Energy, Rikkyo University, Sajima, Yokosuka

and Tetsuo HASHIMOTO*[2]

Faculty of Science, Kanazawa University, Kanazawa

(Received November 15, 1965)

The recoiling behavior of $[Co(C_2O_4)_3]^{3-}$, $[Co(NO_2)_6]^{3-}$ and $[Co(CN)_6]^{3-}$ ions on in anion-exchanger was studied both by the dynamic and the static methods under various conditions. As the stability of the complex decreases, the separable yield increased as a general trend, and the effectiveness of the dynamic method in obtaining higher yield than the static method was clearly demonstrated. On the other hand, specific activity increased with increasing stability of the complex, i. e., with decreasing G values. The increase of pH generally decreased the separable yield and increased the specific activity. The effects of mesh size of resin and preirradiation by gamma rays were also studied. Since the observed tendency that the separable yield decreased with increasing stability constant of the complex ion seems to be a general one, a theoretical interpretation for this relationship was attempted.

Extensive studies have been made of the recoil chemistry of cobalt complexes, possibly because of the availability of stable complexes of this element and of the ease in activating the element and in measuring its activity. One of the authors has recently introduced a "dynamic method" using a complex-loaded ion-exchanger, as a new technique for elucidating the recoil process as well as for enriching radioisotopes; and this method has an advantage in obtaining a yield higher than the usual static method in the cases of $[Co(NH_3)_6]^{3+}$, $[Co\,en_3]^{3+}$,[1] and $[Cr(C_2O_4)_3]^{3-}$ ions.[2]

In this paper, a few anionic cobalt complex ions, $[Co(C_2O_4)_3]^{3-}$,[3] $[Co(NO_2)]^{3-}$,[4] and $[Co(CN)_6]^{3-}$,[5] were chosen as the target resin form, and the yield and specific activity of the separable fraction were estimated both by the dynamic and the static methods. Since it is already known that there are many factors affecting these quantities, this study was also performed under various experimental conditions: different irradiation positions in a reactor,[1,6] different pH of the eluent,[2,7] differing mesh size of resin,[8] and pre-irradiation by gamma rays.[6,9] The G values of the complexes adsorbed on the resin by gamma rays were also

determined in this work in order to determine the interrelation of this value with the stability of complex and specific activity.[10]

Since the dependence of the yield on the nature of the complexes i. e. on their relative stability is one of the main concerns of this paper, and since the tendency that the higher the stability the lower the separable yield is what we have already observed with the two cationic cobalt complexes, $[Co(NH_3)_6]^{3+}$ and $[Co\,en_3]^{3+}$,[1,6] a theoretical consideration was attempted also in this paper as a first approach to a more rigorous treatment.

Experimental

Preparation of the Samples.—The complex salt, $K_3[Co(C_2O_4)_3]$, $Na_3[Co(NO_2)_6]$ and $K_3[Co(CN)_6]$, were prepared by the method described in "Inorganic Syntheses," and were purified by repeated crystallization. Ion exchange resin, Dowex 1X8, was sieved in the dry condition and beads of 120—150 and 40—50 mesh size were chosen as the sample resins.

After the resin was well-conditioned, it was converted into these complex ion forms by treating with an excess amount of about 0.1 N solution of the complex salts, and washed thoroughly with water. The resin was then treated with nitric acid solutions of known pH, which were to be used for elution of the separable species. The complex ion form of the resin was prepared as late as possible prior to the irradiation.

Irradiation and Separation.—In static irradiation experiments, about 2 ml. of the sample resin was taken into a polyethylene vial with about 0.5 ml. of the digesting liquid mentioned above and irradiated batchwise in the rotary specimen rack* and in the thermal column (with lead shield)* of the Rikkyo University TRIGA reactor. After being irradiated for 20 min. and 2 hr. in the respective irradiation positions, each sample was transferred into a glass column with a filter on which about 1 ml. of acetate-ion form resin was bedded, and then nitric acid of a definite pH was passed through the resin as an eluent of the enriched cobalt species at a flow rate of about 2—4 ml./min. The effluent was sampled in seven 25 ml. portions with a fraction collector.

In experiments by the dynamic method, the simultaneous separation of the recoiling species during irradiation was carried out in the thermal column or in the central thimble* as reported previously.[1,2] The volumes of the complex-ion form of resin irradiated were 10 ml. and 2 ml. for the respective irradiation positions, while the volume of the bed resin was fixed at 1 ml. throughout the experiment. The irradiations were done for two hours during the reactor operation and for an additional one and half hours after the shutdown of the reactor, and the elution was continued at a constant flow rate of 4 ml./min.[8] The effluent was collected with a fraction collector as in the static method.

It should be reported that in the case of the oxalatocomplex (green colored), a pink colored anionic species with relatively high specific activity was observed in the bed resin as an intermediate between the parent species and the completely aquated one. The species is considered to be $[Co(C_2O_4)_2]^{2-}$,[11] and it was eluted by 0.02 N nitric acid. Likewise, with the nitrocomplex (yellowish brown), a yellow colored anionic species with a relatively low specific activity appeared in the bed, and it was eluted in later portions of effluents when nitric acid of more than 0.01 N was used as an eluent. This species has not yet been identified.

Measurements.—The activity of the aliquots of effluent and of the resin was determined with a well type NaI(Tl) scintillation detector connected to a single channel analyzer. The measurements of specific activities for static runs were made for the most enriched, first two or three fractions of the eluents. Activation analysis using ^{60m}Co measured with a multichannel analyzer, or colorimetry by the nitroso-R salt method was employed in the determination of the non-active cobalt in the eluents.[1,6]

Determination of the *G* Values.—The G values of decomposition of the complex ion adsorbed on the ion-exchange resin were measured as follows. After 1 ml. of the sample resin which had been digested in a small amount of water or nitric acid of pH 2.0 was irradiated with gamma rays of a cobalt 60 source for 2—24 hr. at a dose rate of $(2—5)\times10^5$ r./hr., the decomposed cobalt species were eluted with about 100 ml. of nitric acid of pH 2.0 and their amount was determined as before. The calculation is based on the assumption that 1 r. of gamma rays deposits 6.08×10^{13} eV./(g. water) multiplied by the density of resin, i. e., 7.30×10^{13} eV./(ml. resin).[10]

Results and Discussion

Separable Yield.—The results obtained are shown in Tables I—IV, from which the following conclusions can be drawn.

The dynamic method was found to give higher separable yield than the static method as a general trend, especially in cases of $[Co(C_2O_4)_3]^{3-}$ and $[Co(NO_2)_6]^{3-}$ ions (except the case of the former complex ion irradiated in the central thimble as stated below) and under the condition of low pH of the eluent. As was observed already in the $[Cr(C_2O_4)_3]^{3-}$ study,[2,7] the separable yield, irrespective of whether dynamic or static method was used, increased with decreasing pH of the eluent. As to the effects of irradiation position, exact conclusions cannot be drawn because the irradiation and storage times were different for the static irradiations in the two different positions.

The order of increasing separable yield with the three complexes in the same pH region is $[Co(C_2O_4)_3]^{3-} < [Co(NO_2)_6]^{3-} < [Co(CN)_6]^{4-}$, i. e., it is approximately in the order of decreasing stability of the complex ion. Since this dependence of the separable yield on the stability of the complex ion

Table III. Effect of pre-irradiation by gamma ray

(Total gamma exposure is $(4.4—4.8)\times10^6$ r.; irradiations were done in the thermal column for 2 hr.)

Resin form	pH of eluent	Yield %	Specific activity μc./mg.
$[Co(C_2O_4)_3]^{3-}$	6*	13.6	0.04
$[Co(NO_2)_6]^{3-}$	2.0	39.4	0.1
$[Co(CN)_6]^{3-}$	2.0	6.4	5

* See Table I.

is the same as was already observed with $[Co(NH_3)_6]^{3+}$ and $[Co\,en_3]^{3+}$ under a variety of experimental conditions[1,6] and since it seems to be a general tendency, a theoretical interpretation is presented in a later section.

Table IV. Approximate G values of the complex ions

(Total gamma exposure is $(1—5)\times10^6$ r. The eluent is nitric acid of pH 2.)

Resin form	Digesting liquid	G Value
$[Co(C_2O_4)_3]^{3-}$	H_2O	10.0
$[Co(NO_2)_6]^{3-}$	H_2O	>15
	HNO_3(pH 2)	>31
$[Co(CN)_6]^{3-}$	H_2O	0.004
	HNO_3(pH 2)	0.016

As were observed with $[Cr(C_2O_4)_3]^{3-}$,[7] and $[Co(NH_3)_6]^{3+}$,[1], an increase of the mesh size of the resin decreased the yield for the cases of $[Co(C_2O_4)_3]^{3-}$ and $[Co(NO_2)_6]^{3-}$ ions. It is inferred that in these cases the rate of recombination is comparable with the rate of diffusion of the separable species in the resin phase.

Pre-irradiation by gamma rays brought about only a small decrease in yield in the $[Co(CN)_6]^{3-}$ case, although it was found that this treatment caused very large decreases in yield of the $[Co(NH_3)_6]^{3+}$ and $[Co\,en_3]^{3+}$ cases.[6,9]

Specific Activity.—Table I shows that the specific activity is almost unchanged whether the dynamic or static method is employed. This was anticipated from the previous work.[1,2,6,7] It can be seen from the data that the values for the dynamic method in the thermal column and of the static method in the rotary specimen rack are almost equal, but those of the static method in the

thermal column are a little smaller than the above two methods. This is probably due to the difference of standing time after irradiation. The tendency of the specific activity to decrease with decreasing pH of the eluent is the same as was observed in the case of $[Cr(C_2O_4)_3]^{3-}$.[2,7]

While the separably yield decreased with increasing stability of the complex ion, the specific activity increased with the stability.[6] As can be seen from Table IV, this order is the same as the decrease in G values.[10] Although the value of the specific activity of about 400 μc./mg. in the case of cyano-complex was the largest one yet obtained in this laboratory for the cobalt compound,[1,6] it is smaller than those reported in the solid state irradiation of this complex salt.[5]

Anomalous Results for the Trioxalato Ion Case in Irradiation at High Exposure Rate.—Table II shows that the separable yield in the case of the $[Co(C_2O_4)_3]^{3-}$ ion form which had been dynamically irradiated in the central thimble was considerably lower than those of other irradiation conditions, with an anomalous elution diagram as shown in Fig. 1. Since this unexpected decrease of yield is the first case encountered in experiments by the dynamic method, it seems worthwhile to consider this in detail.

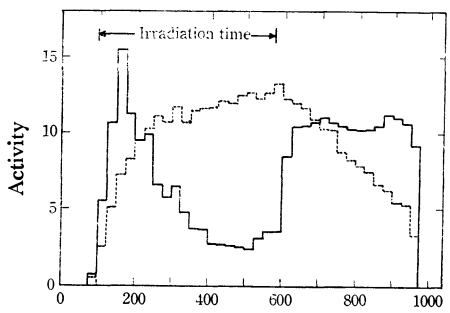

Fig. 1. Elution diagram of $[Co(C_2O_4)_3]^{3-}$ ion form.
—— Irradiated in the central thimble (pH 6, 120—150 mesh).
—— Irradiated in the the thermal column (pH 6, 40—50 mesh).
* Unit of ordinate: 10^4 c.p.m./5 ml. for solid line. 10^3 c.p.m./5 ml. for broken line.

As this anomaly occurred only in the case of $[Co(C_2O_4)_3]^{3-}$ ion irradiated in the central thimble, it can be inferred that the radiation decomposition products of this complex at the high exposure rate may play some role, and that they are probably the same species which are formed by the following photochemical decomposition of this complex ion:[12]

$$\begin{cases} 2[Co(C_2O_4)_3]^{3-} \xrightarrow{h\nu} 2Co(C_2O_4) + 3C_2O_4^{2-} + 2CO_2 \\ C_2O_4^{2-} + H_2O \xrightarrow{h\nu} HCO_2^- + CO_2 + OH^- \end{cases}$$

During irradiation, these fragments and the carbonate ion therefrom may combine with the primary elutable species such as $Co^*(C_2O_4)$ and Co^{*2+} ion into the non-elutable anionic species, such as $[Co^*(C_2O_4)(CO_3)]^{2-}$, $[Co^*(CO_3)_2]^{2-}$, $[Co^*(C_2O_4)(HCO_3)]^-$, etc. These complexes are supposed to be unstable from the analogy of the tricarbonate complex ion in aqueous solution[13] and to exist only in high concentration of the carbonate, which is the situation in the high exposure rate. Following the supposed decrease of carbonate centration after the shutdown of the reactor, these temporary complexes will immediately dissociate into the original elutable species.

Theoretical Discussion of the Dependence of Yield on the Stability of Complexes.—Although the increase of the separable yield with decreasing stability of the complex ion seems to be a general trend, this view has not been reported before. The authors believe this is because too many parameters, especially in batch irradiation experiments, have vitiated a knowledge of the true initial yield.[14] In fact, in this laboratory it has also been observed that the yield of $[Co\ en_3]^{3+}$ on the resin, for example, varied widely from more than ninety percent to as small as a few percent, depending on the irradiation conditions;[6] nevertheless, the yield was always lower than that of $[Co(NH_3)_6]^{3+}$ for all irradiation conditions. However, the fact that the dynamic method which has been developed gave large yield values even under the most disadvantageous conditions for the batch results[1,6] suggests that this method can generally provide nearly the highest, so to speak, initial separably yield,[8] except with the anomalous case mentioned above. The term initial or inherent yield is used to describe the radiochemical yield of the chemical entities into which the energetic recoiling atoms become finally incorporated immediately after they are thermalized through the epithermal reaction in that chemical environment.[7]

Thus, accepting the observed tendency to be generally true, the following theoretical interpretation for the dependence of the inherent separable

yield on the stability of the complex ion has been made as a first approach to a more rigorous treatment. For the sake of simplicity, the following assumptions were made.

1) The chemical forms of the parent complex ion and the separable species are $[CoL_6]^{3-}$ and $[Co(H_2O_6)]^{2+}$, respectively, and the formation of the intermediate complex is negligible.

2) The energy state of the parent and the separable species is regarded to be schematically as shown in Fig. 2. Here, ΔF_0 and F_a are the standard free energy change and the activation energy of the following reaction, respectively:

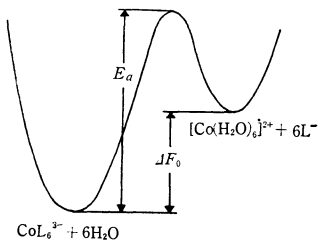

Fig. 2. Assumed energy state of the radioactive cobalt species after thermalization.

$$[CoL_6]^{3-} + 6H_2O + e^- = [Co(H_2O)_6]^{2+} + 6L^- \quad (1)$$

3) Because the central atom or whole molecule of the complex ion upon neutron-capturing becomes very much excited by recoiling compared with the activation energy, the final products which are formed after their thermalization are immediately distributed irrespective of the excited state in such a proportion that reaction 1 is in equilibrium at room temperature.

4) The complexing ability of the free ligand is assumed to be constant irrespective of pH, and, the effects of the concentration of the coexisting solute, of the complexing constant of the solute and of its acid dissociation constant on the equilibrium of Eq. 1 are negligible.

Reaction 1 can be divided into the following two processes:

$$[CoL_6]^{3-} + 6H_2O = [Co(H_2O)_6]^{3+} + 6L^- \quad (2)$$

$$[Co(H_2O)_6]^{3+} + e^- = [Co(H_2O)_6]^{2+} \quad (3)$$

The standard free energy change for each reaction is correlated with the stability constant of the complex ion (K) and the reduction potential of cobaltic ion (E_{red}) as follows:

$$\Delta F_s = -\boldsymbol{R}T \ln (1/K) \quad (4)$$

$$\Delta F_{red} = -FE_{red} \quad (5)$$

where $\boldsymbol{R}$, T and F are the gas constant, absolute temperature, and the Faraday constant, respectively. The overall standard free energy change for reaction 1 is

$$\Delta F_0 = \Delta F_s + \Delta F_{red} = \boldsymbol{R}T \ln K - FE_{red} \quad (6)$$

By using assumption 3, the distribution of the species involved in the reaction 1 can be expressed by

$$(N_a)(N_1)^6/(N_c)(N_w)^6 = [(Z_a)(Z_l)^i/(Z_c)(Z_w)^6] = \exp(-\Delta F_0/\boldsymbol{R}T) \quad (7)$$

where N_a, N_l, N_c and N_w are the number of molecules involved in the reaction 1 for $[Co(H_2O)_6]^{2+}$, L^-, $[CoL_6]^{3-}$ and H_2O, respetively, and Z_a, Z_l, Z_c and Z_w are the partition functions of these species. Assuming $N_l/N_a = N_w/N_c$ for every six-coordinated complex, Eq. 7 is expressed by

$$(N_a/N_c)^7 = [\exp(-\Delta F_0/\boldsymbol{R}T)] \quad (8)$$

On the other hand, the initial separable yield (Y) obtained by the experiment can be represented by

$$Y = N_a/(N_a + N_c) \quad (9)$$

Combining Eqs. 8 and 9

$$Y = 1/[\exp(\Delta F_0/7\boldsymbol{R}T) + 1] \quad (10)$$

Inserting the Eq. 6 into 10

$$Y = 1/[K^{1/7} \exp(-FE_{red}/7\boldsymbol{R}T) + 1] \quad (11)$$

$$(1/Y - 1) = K^{1/7} \exp(-FE_{red}/7\boldsymbol{R}T)$$

$$\ln(1/Y - 1) = (1/7) \ln K - (FE_{red}/7\boldsymbol{R}T) \quad (12)$$

Converting into common logarithms,

$$\log(1/Y - 1) = (1/7) \log K - 0.4343(FE_{red}/7\boldsymbol{R}T) \quad (13)$$

Equation 13 shows that $\log(1/Y - 1)$ should increase linearly with an increase in $\log K$ of the complex ion and should have a slope of (1/7) and an ordinate constant of $-0.4343\ FE_{red}/7\boldsymbol{R}T$ ($= -4.45$)[15] respectively.

The experimental values at pH 2 for these complexes obtained by the dynamic method are plotted against $\log K$[12a,15,16] in Fig. 3. Although the $[Co(C_2O_4)_3]^{3-}$ ion cannot be rigorously treated in this way, it is shown as a reference value. (The value at pH 6 was used for this case, because the yield at pH 2 was found to be almost the same as that at pH 6 by a preliminary experiment.)

The values for the cationic cobalt complexes, $[Co(NH_3)_3]^{3+}$ and $[Co\,en_3]^{3+}$, are not shown in this figure, because there are no values for the experimental conditions corresponding to the anionic complexes. However, since the initial yields for these cases should be very small in spite of the large $\log K$ values,[6] it is evident that they deviate much from this theoretical curve. It can be inferred that this discrepancy might be due to

(The line is the theoretical slope.)

the differing behavior of the intermediate complexes; while the intermediate ammine complexes are labile and elutable as bivalent cations and thus usually can be classified as the separable species,[6] the anionic intermediates may be considerably stable and resistant to aquation or elution and thus the separable yield will be considerably low.

At any rate, the present theory agrees with the experimental data only qualitatively. However, if the main reasoning is correct, the authors believe this theory can further be refined by introducing additional parameters, such as the pH value, acid dissociation constant of the ligand, the concentration of the coexisting solute, and its complexing and acid dissociation constants, and by considering the existence and the behavior of the intermediates mentioned above.

The authors wish to thank IAEA, which supported this work through the research contract (No. 221/RB). They also wish to thank Professor Masanobu Sakanoue of Kanazawa University for his kind encouragment on this work.

On the Preparation of Cadmium Sulfoselenide by the Wet Processes

By Koshiro HASHIMOTO,* Goro YAMAGUCHI** and Yoshitomo TODA*

* *Department of Industrial Chemistry, Chiba Institute of Technology, Yatsu, Narashino-shi, Chiba*
** *Department of Industrial Chemistry, The University of Tokyo, Hongo, Tokyo*

(Received December 1, 1965)

The super-homogeneous coprecipitation method, in which the binary solution reactants made to mix and react in a moment, thus reducing a super-homogeneous precipitate, has been used recently in the preparation of catalysts. The coloring temperature of the cadmium sulfoselenide red pigment can be lowered to 350°C by this method, while, when the usual wet method is used, the temperature is between 450 and 650°C. This is because a very homogenous solid solution can be formed by the super-homogeneous coprecipitation method. This method is also effective in making an anionic solid solution of A(X, Y) with different anions of X and Y. Spectral reflectance measurements and X-ray analysis in the present work have shown that the coloring temperature has been considerably lowered and the transformation of the β-Cd(Se, S) into the α form has been accelerated by the method.

Cadmium red is a substantial inorganic pigment with a clear tone; it is used in ceramics, glasses, enamels, and resins. This pigment has been considered to be a cadmium sulfoselenide which was a continuous solid solution of cadmium sulfide and cadmium selenide. However, the relation between the compositions and the color has hardly been discussed at all.[1-3] There are various combination of starting materials and processes used in the preparation of cadmium sulfoselenide. The processes are classified into wet and dry methods. In the wet method, the pigment is obtained by sintering the coprecipitate, which has been prepared by treating an aqueous solution of sodium sulfoselenide an aqueous solution of cadmium sulfide; the coloring temperature has been reported to be between 470 and 640°C by Stuckert,[4] between 450 and 650°C by Yamanouchi,[1] between 550 and 650°C by Eroles and Friedberg.[5] In this case, the binary solution is made to mix and react

in a moment, and then a super-homogeneous coprecipitate can be obtained. This is the super-homogeneous coprecipitation method which has been used recently in the preparation of catalysts.[6-8]

The authors will report in this paper the results of an examination of the thermal transformation of the coprecipitate (the β-Cd(Se, S) into the α form) by spectral reflectance measurements and by X-ray diffraction analysis.[2,9]

Experimental

The Preparation of Solutions.—Table I shows the effect of selenium upon the color. The poorer the selenium content, the more yellowish the color; the richer, the darker.[1] The lattice dimensions, a_0 and c_0 increase with a rise in the cadmium selenide content. Since the linearity between the lattice dimension and the content is almost complete, the concentration of cadmium sulfide or cadmium selenide in a pigment can be exactly determined by means of the X-ray diffraction patterns.[5,10] E-3 is the best color tone among them; the procedure for obtaining it is follows (the chemicals used in this experiment are commercially-available chemically-pure reagents). A cadmium salt solution (sp. gr. 1.4) is made by dissolving 98.42 g. of cadmium sulfate ($CdSO_4 \cdot 8/3H_2O$) in 102 cc. of distilled water. A sodium sulfoselenide solution is made by dissolving 85.7 g. of sodium sulfide ($Na_2S \cdot 9H_2O$) into 200 cc. of water, and by then dissolving 11.05 g. of metallic selenium into it with heating; the solution is used after filtration (sp. gr. 1.13). When cadmium sulfide is made, of course, metallic selenium is not added. In order to carry out a sudden and homogeneous reaction in a mixer, an intermediate aqueous solution such as a sodium sulfate solution (sp. gr. 1.21) is required.

The Preparation of Coprecipitates.—a) The usual method consists of adding a sodium sulfate solution to a cadmium sulfate solution and by then pouring a sulfoselenide solution into it, then obtaining a coprecipitate by stirring, as usual. The reason why a sodium sulfate solution is added is to set up the same conditions as in the following new method. The precipitate is filtered, washed by warm water, and dried at 100°C.

b) In the new method, at first, the double amount of a cadmium sulfate solution mentioned above is put into a 1.8 l. mixer, and then a sodium sulfate solution is slowly added along the wall of the container by means of a separating funnel. The two aqueous solutions easily separate into two layers as a result of the difference in specific gravity. A sodium sulfoselenide solution added by the same method makes the triple layers. The state is shown in Fig. 1. When switched on, the solution suddenly becomes homogeneous, and a precipitate is formed uniformly every part of the solution.

The samples obtained by the a) method (the usual method) are said to form the A-system, and those by the b) method (the new method), the B-system. In order to establish the characteristics of the new coprecipitative method, the authors also made CdS precipitates

by these two methods.

Sintering.—A dried precipitate (25 g.) is powdered in an agate motor; then it is put into a vitreous quartz Tamman tube (35 mm. in internal diameter) supplied with nitrogen gas (1 l./min.) and heated in the vertical electric furnace, taking care that every part of the sample is equal in temperature. Each sample is heated quickly, kept at the given temperature (350, 400, 450, 500 or 550°C) for 30 min., and then cooled in air. Again it is powdered in the agate motor.

Measuring Apparatus.—The Shimadzu Hardy-type photoelectric colorimeter is used for the spectral reflectance measurements. Color measurements are carried out by determining x, y, and z by the 30-division method, and Y, P_e and λ_d, according to the indications of the C. I. E. method.

The Shimadzu X-ray apparatus is used; the characteristic X-ray is Cu$K\alpha$=1.539 Å. MgO is used as the internal standard.

Results and Discussion

The Preparation of Samples.—Precipitates obtained from liquid-liquid reactions are not always homogeneous microscopically in their compositions. This fact has been reported in the field of gravimetric analysis, and attempts have recently been made to get homogeneous precipitates. In the formation of a solid solution of the A(X, Y) type, the diffusion velocities of X and Y across the boundary membranes are different, and so it is impossible that compositions of every particle of precipitate are A(X, Y) exactly. Furthermore the phenomenon of the crystallization of precipitates is not chemical equilibrium but chemical kinetics. The initial precipitate may differ from the following precipitate in composition. By the use of the method in mixing two solutions uniformly during the induction period in the formation of nuclei, a precipitate of the same composition and size may be formed from a supersaturated solution. This is especially very effective in a supersaturated solution of slightly soluble salt, for its induction period is momentary. Thus, the precipitate obtained by the new method (the B-system) may be thought to be highly homogeneous compared with the precipitate formed by the usual coprecipitation method (the A-system). The differences between these two systems will be discussed below.

The Results of Color Measurement.—The spectral reflectance curves of the precipitates of cadmium sulfoselenide sintered at the given temperatures are shown in Fig. 2 and Table II. The precipitates of both the A-system and the B-system are amorphous and hardly change at all up to 300°C. The B-system begins to show a reddish tone at 350°C, but the A-system does so at 400°C. Therefore, the B-system is more reddish than the A-system at the same temperature. This may be ascertained from the dominant wavelength. At 500°C the A-system develops the same color as that of B-system sintered at 450°C. This difference is also found in the results of X-ray diffraction analysis.

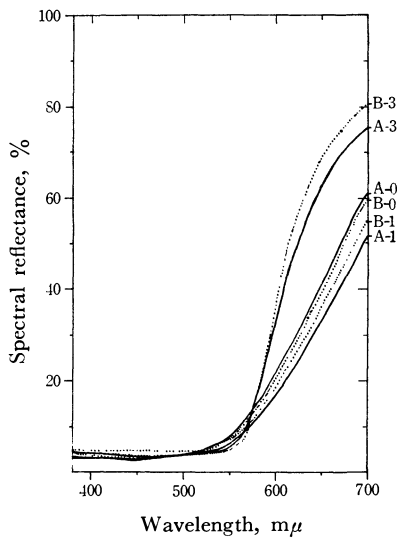

Fig. 2. The spectral reflectance curves of A- and B-system coprecipitates sintered at 350 and 450°C and without heat-treatment.

TABLE II. CHANGE OF COLOR THROUGH SINTERING
A: A-system (usual method)
B: B-system (new method)

Sample	Sintering temp. °C	Lightness %	Excitation purity %	Dominant wavelength mμ
A-0		13.0	65.9	596.2
A-1	350	10.6	57.7	598.3
A-2	400	12.9	60.2	603.0

B-3	450	16.0	65.2	607.3
B-4	500	16.0	62.3	608.0
B-5	550	16.5	60.1	608.0

X-Ray Diffraction Patterns.—The X-ray diffraction patterns of α-CdS obtained from cadmium sulfide precipitates of A- and B-systems sintered at 450°C; a typical one is shown in Fig. 3. These patterns show the conversion of the amorphous precipitate of cadmium sulfide into α-CdS (the wurtzite structure) by heating, because the broad peak splits into three characteristic peaks, which correspond to (100), (002) and (101) in the wurtzite structure. The thermal transformation of Cd(Se, S) can be studied qualitatively from these peaks, as is shown in Fig. 4. Up to about 300°C no change can be found in these patterns, but at 350°C the spilt peaks in the B-system become observable. This fact shows that the crystallization process corresponds exactly to the coloring process. At 450°C both are transformed into the substance of the wurtzite structure. The A-system develops a color as if it contained a smaller amount of selenium. From this fact, the A-system precipitate may be more inhomogeneous than the B-system and part of the selenium may be lost by the difference between the diffusion velocity of the solid and the missing velocity of the vapor at a low temperature. The diffusion velocity may be faster than the missing velocity of vapor above 500°C; in this case selenium can form a solid solution with CdS. There is no difference in the transformation temperature between the A- and the B-systems in the case of a cadmium sulfide precipitate consisting of only A(X). From this fact, the transition may have no close relation to the defect in the crystalline structure or the particle size of the precipitate, but rather a close relation to the homogeneity of the precipitate. Such a process would be effective in the precipitation of uniform solid solution. It may be possible to contain traces of impurities uniformly in the precipitate.

Conclusions

1) The optimum temperature of the cadmium sulfoselenide red pigment can be lowered by utilizing the super-homogeneous coprecipitation method.

2) The super-homogeneous coprecipitation method is an important way to obtain the precipitate of a uniform constitution of A(X, Y)-type solid solutions.

3) When selenium is partially substituted for sulfur, the transition to the wurtzite structure occurs at a lower temperature.

4) A precipitate of cadmium sulfoselenide showing the amorphous X-ray diffraction patterns can be transformed, even at 350°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2656—2665 (1966)

The Catalytic Hydrolysis of Oligophosphates by Ethylenediamine-Copper(II) and Poly-L-lysine-Copper(II) Complexes

By Yoshiki MORIGUCHI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received December 29, 1965)

The hydrolysis of some oligophosphates (tetra-, penta- and hexaphosphates) has been studied at 45°C in the absence and in the presence of a metal complex, and the relation between the nature of the complex catalyst and the composition of the degradation products has been investigated on oligophosphates as substrates, especially on pentaphosphate. In the presence of the Cu(II)-en (1 : 1) complex, the intermediate chain of pentaphosphate is attacked to produce trimeta- and pyrophosphates as the main products; the hydrolytic reaction is apparently of a first-order kinetics which depends on the concentration of the catalyst. The Cu(II) - Poly-Lys complex shows a strong catalytic activity and attacks pentaphosphate exclusively, thus producing orthophosphate as the main product. The optimum conditions for the catalytic effect on the hydrolysis of pentaphosphate are as follows: 1) the ratio of the NH_2 repeat unit of Poly-Lys to a mole of pentaphosphate ($[-NH_2]_i/[P_5]_i$) is about 1.6 at pH 8, the concentration of Cu(II) being constant; 2) the molar ratio of Cu(II) to the NH_2 repeat unit of Poly-Lys ($[Cu]_i/[-NH_2]_i$) is 1.0: 3) the activity reaches a maximum at about pH 10. Attempts have been made to explain these results on the basis of the structure of the Cu(II) - Poly-Lys complex.

The catalytic action of various metal chelates on the hydrolysis of Sarine and DFP (diisopropyl phosphofluoridate) has been studied by Martell and his co-workers.[1-3] The catalytic hydrolysis of polyphosphates by metal ions and chelates has also been studied by several workers.[4-6] In view of the fact that metal ions play a significant role in the catalytic action of the natural enzyme, metal complexes are some of the most interesting catalysts. Previous investigations of the metal complex catalysts have almost exclusively been kinetic studies; little attention has been paid to such peculiarities in the catalytic action as the action of the natural enzyme.[7,8] The present work was undertaken to investigate the relation between the nature of the metal complex catalyst and the kind of degradation products of the substrate as described in a previous report.[9] Polyphosphates with the 4—6 degree of polymerization, i. e., oligophosphates, were used as substrates for the purpose described above.

The ethylenediamine-copper(II) (Cu(II)-en) and poly-L-lysine - copper(II) (Cu(II) - Poly-Lys) complexes were used as catalysts. Though both of the ligands are similar in N-coordination to copper, Poly-Lys is a polypeptide and may be expected to have some catalytic effect on the ability to form higher-order structures (e.g. the α-helix configuration).

Experimental

Reagents.—Oligophosphates were prepared by the same method as has been reported previously.[10] Trimetaphosphate was prepared by the pyrolysis of sodium dihydrogenphosphate containing ^{32}P.[11] Ethylenediamine and cupric nitrate, $Cu(NO_3)_2 \cdot 3H_2O$, were both of the G. R. grade and were used without further purification. The concentrations of cupric ion and ethylenediamine were standardized by means of chelatometric[12] and potentiometric titrations respectively. Poly-L-lysine was of the pure hydrobromide form with a molecular weight of 85000.

Procedure.—The pH of the sample solution, which was made up of an oligophosphate and a catalyst, was adjusted by adding nitric acid or tetramethylammonium hydroixde. The ionic strength of the solution was maintained at 0.1 by adding tetramethylammonium nitrate. The pH of the solution was readjusted within ±0.5 pH unit at regular intervals. The solution (2.5—3.0 ml.) was kept at 45°C in a small test tube coated by silicone and was shaken vigorously at intervals. A part of the solution (0.05—0.1 ml.) was taken out at regular intervals, and the degradation products were identified and quantitatively determined by ion-exchange chromatography. Each degradation product was separated in response to the degree of polymerization by ion-exchange chromatography using ^{32}P as a tracer.[9,13] Its quantity, which was recorded on a chart by a linear count-rate meter, was determined by measuring the area of the separated peak on the chart by means of a planimeter. The H-form of Dowex 1 X4 (100—200 mesh) was used as the ion-exchange resin. The eluent used in the ion-exchange chromatography was an aqueous solution of sodium chloride, the concentration of which was continuously changed from 0.22 M to 0.6 M during elution. The pH of the eluent was adjusted to 9.2 by an ammonia-ammonium chloride buffer.

As a precipitate was formed in the oligophosphate-Poly-Lys system, it was separated by means of a centrifuge. A part of the supernatant solution was used for ion-exchange chromatography, and another part was used for the estimation of the ratio of the ^{32}P in the supernatant solution to that in the precipitate.

Results and Discussion

The experimental conditions and the results of hydrolytic degradation are summarized in Table I. A part of these results are quoted from Otani's data[13] for reference. As may be seen in Table I, the degradation ratio increases with the increase in the the chain length of oligophosphate and with the decrease in the pH of the sample solution. Cupric ion or its complexes show a catalytic action on the hydrolysis; this action is especially remarkable in the presence of the Cu(II)-Poly-Lys complex.

The Degradation in the Absence of Metal Ions and Complexes.—The hydrolytic degradations of tetra- and hexaphosphates at pH 8 and those of pentaphosphate at pH 4 and 8 are shown in Fig. 1 as a function of the reaction time. The ordinate of the figure, "Number of phosphorus atoms (%)," is expressed by the percentages of the total ^{32}P contained in the substrate and the degradation products. Each value of the degradation products is shown by the vertical distance between neighboring curves. These results, which are represented in Fig. 2a, can be expressed by the following equation:

$$k_1 t = 2.303 \log (100/P_n) \quad (1)$$

where P_n is the percentage of oligophosphate with the n degree of polymerization at the reaction time, t, and k_1, the first-order rate constant.

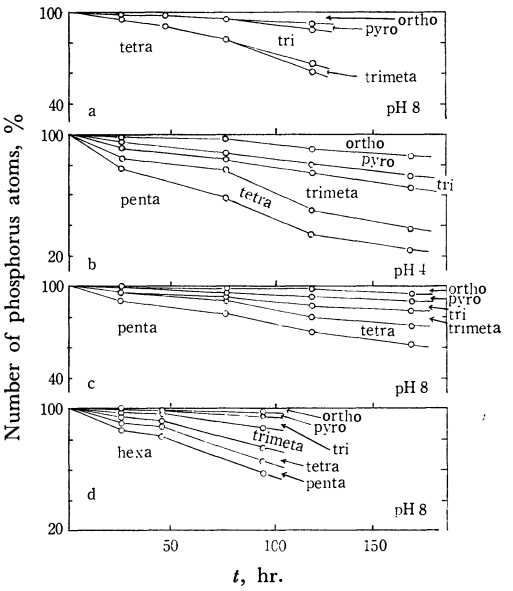

Fig. 1. The relation between the composition of degradation products and the reaction time in the absence of metal ion and complex. Initial concentration of oligophosphates, $[P_n]_i$; a: $[P_4]_i = 6.85 \times 10^{-3}$ M, b, c: $[P_5]_i = 4.07 \times 10^{-3}$ M, d: $[P_6]_i = 1.07 \times 10^{-2}$ M.

13) S. Otani, M. Miura and T. Doi, *J. Chem. Soc. Japan, Ind. Chem. Sect. (Kogyo Kagaku Zasshi)*, **66**, 593 (1963).

It has been found from several studies[13,14] that the hydrolysis of oligophosphates is of the first-order at low concentrations of substrate. This may also be confirmed as in Fig. 2a.

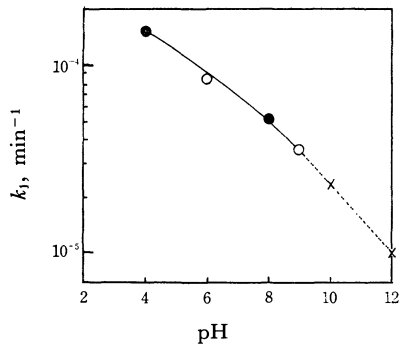

Fig. 3. The relation between the first-order rate constant in the hydrolysis of pentaphosphate and the pH in the absence of Cu(II) and complex.
●: Values obtained by the author (cf. Figs. 1b and 1c).
○: Values obtained by Otani et al.[13]
×: Extrapolated values.

The pH dependence of the first-order rate constant in the hydrolysis of pentaphosphate is shown in Fig. 3. Several stuides have been done on the pH-effect on the hydrolysis of polyphosphates,[6,13,15,16]; it can be concluded from these results that the hydrolysis rate increases with the decrease in pH because the hydrogen ion behaves as a catalyst, and that the terminal chain of polyphosphates is mainly attacked in the higher pH region, whereas the intermediate chain is also attacked in the lower pH region. These conclusions have been confirmed in the present study as may be seen in Figs. 1b, 1c and 3 and Table I; that is, the hydrolysis rate is greater at pH 4 than at pH 8, and the type of degradation is the terminal (a) and intermediate (b) chain attacks at pH 4, while it is the terminal chain attack (a) at pH 8.

$$\text{pentaphosphate} \rightarrow \text{tetra-} + \text{ortho-} \qquad \text{(a)}$$

$$\text{pentaphosphate} \rightarrow \text{trimeta-} + \text{pyro-} \qquad \text{(b)}$$

The dependence of the rate constants at pH 4 and 8 on the degree of the polymerization of oligophosphates is shown in Fig. 4. A part of the data are quoted from Otani's paper.[13] A similar study has been done at 60°C by Wieker.[17] The relation between the rate constant and the degree of polymerization can be expressed by Eq. 2, when the polyphosphate chain is attacked at random and the attack depends only on the statistical factor with relation to the degree of polymerization:

$$k_{P_n} = (n-1)k_{P_2} \qquad n > 2 \rightarrow n \geqq 2 \qquad (2)$$

where k_{P_n} is the rate constant of polyphosphate

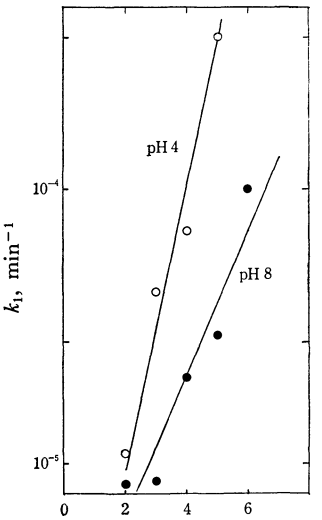

Fig. 4. The relation between the first-order rate constant and the degree of polymerization of oligophosphates.

with the degree of polymerization, n, and k_{P_2}, the rate constant of pyrophosphate. Though the rate constant in Fig. 4 increases linearly with the degree of polymerization, neither of the two straight lines agrees with Eq. 2. This may indicate that the hydrolytic degradation of oligophosphates depends on the electrostatic effect caused by the charge on the polyphosphate chain.

The Formation of Trimetaphosphate.— As may be seen in Figs. 1a, 1c and 1d, the formation of trimetaphosphate increases with the degree of polymerization when the pH is kept constant. The formation of trimetaphosphate from tetraphosphate has recently been reported by Otani et al. of our laboratory.[13] In view of the fact that crystalline Kurrol's salt, which is a kind of polyphosphate, has a spiral structure with four tetrahedra, $-PO_3-$, per pitch,[18] trimetaphosphate may be formed from the polyphosphate chain by such a mechanism as that the polyphosphate chain is constricted to form some spiral structure like Kurrol's salt, with trimetaphosphate then being formed from such a part, as is shown in Fig. 17.[19]

19) E. Thilo, "Advances in Inorganic and Radio Chemistry," Vol. IV, Academic Press Inc., New York (1962).

It may, therefore, be concluded that the probability of spiral formation to give trimetaphosphate increases with the increase in the degree of polymerization, and that even the tetraphosphate with four tetrahedra will probably form trimetaphosphate.

The Degradation in the Presence of Copper(II).—The results of hydrolytic degradation are shown in Fig. 5, where the molar ratio of cupric ions to oligophosphate is 1.0. The pH of the solution was kept at 4 or 8 for pentaphosphate and at 8 for tetra- and hexaphosphates. It has been reported[4-6] that the transition metals and a large quantity of alkali metals have a catalytic effect on the hydrolysis of polyphosphates. A comparison of Figs. 5a, 5c and 5d with Figs. 1a, 1c and 1d will indicate that the cupric ion acts as a weak catalyst that it seems to accelerate the formation of trimetaphosphate by the intermediate chain attack. The acceleration of the formation of ortho- and trimetaphosphates in the presence of alkali metals and alkaline earth metals has also been reported in the hydrolysis of polyphosphates with a high degree of polymerization by Wieker et al.[6] The results in Fig. 2b indicate that the hydrolytic reaction is of the first-order in the presence of cupric ions in not too high a concentration.

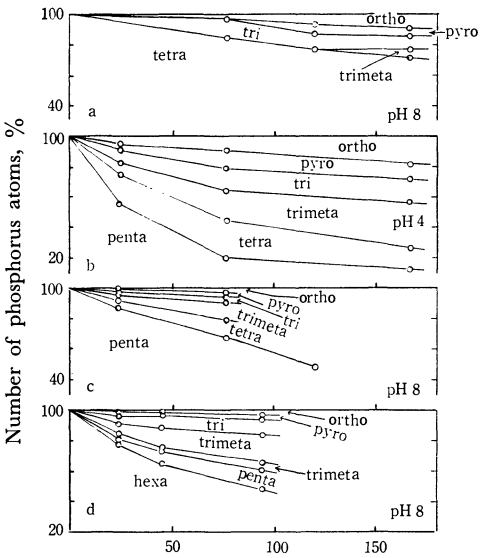

Fig. 5. The relation between the composition of degradation products and reaction time in the presence of Cu(II). Initial concentrations of oligophosphates, $[P_n]_i$, and Cu(II), $[Cu]_i$; a: $[P_4]_i=6.60\times10^{-3}$ M, $[Cu]_i=6.60\times10^{-3}$ M, b, c: $[P_5]_i=4.40\times10^{-3}$ M, $[Cu]_i=4.40\times10^{-3}$ M, d: $[P_6]_i=1.03\times10^{-2}$ M, $[Cu]_i=1.03\times10^{-2}$ M.

The Degradation in the Presence of the Cu(II)-en Complex.—The relation between the composition of degradation products and the reaction time for pentaphosphate at pH 4 and 8 are shown in Figs. 6b and 6c, and those for tetra- and hexaphosphates at pH 8, in Figs. 6a and 6d. The molar ratio of cupric ions and that of ethylenediamine to oligophosphate were 1.0 in each experiment. As may be seen in these figures, the Cu(II)-en complex has a considerable catalytic effect on the hydrolysis of oligophosphates at pH 8; the main products are pyro- and trimetaphosphates for the pentaphosphate substrate and tri- and trimetaphosphates for the hexaphosphate substrate. These results suggest that the Cu(II)-en complex catalyst attacks exclusively the intermediate chain of oligophosphates, thus forming trimetaphosphate.

As may be seen in Figs. 5b and 6b at pH 4, the hydrolysis rate (cf. Table I) and the composition of degradation products when both ethylenediamine and cupric ions are present are similar to those when cupric ions alone are present. These results indicate that in both cases the same catalyst species acts in the hydrolysis of pentaphosphate. The species seems to be hydrated cupric ions

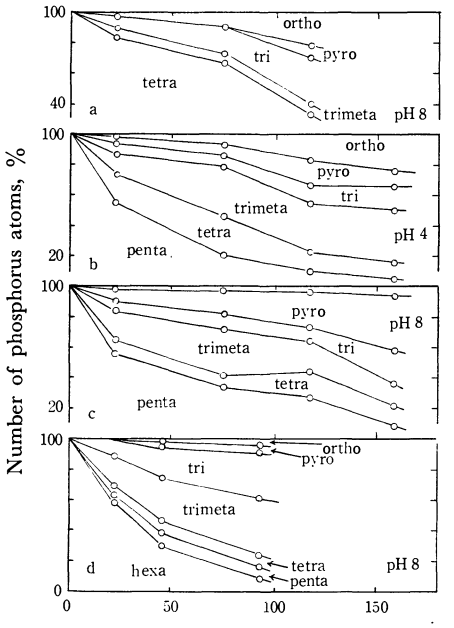

Fig. 6. The relation between the composition of degradation products and the reaction time in the coexistence of Cu(II) and ethylenediamine. Initial concentrations of oligophosphates, $[P_n]_i$, Cu(II), $[Cu]_i$ and ethylenediamine, $[en]_i$; a: $[P_4]_i=6.20\times10^{-3}$ M, $[Cu]_i=6.20\times10^{-3}$ M, $[en]_i=6.20\times10^{-3}$ M, b, c: $[P_5]_i=4.07\times10^{-3}$ M, $[Cu]_i=4.07\times10^{-3}$ M, d: $[P_6]_i=1.06\times10^{-2}$ M, $[Cu]_i=1.06\times10^{-2}$ M, $[en]_i=1.06\times10^{-2}$ M.

*2 Number of repeat unit of Poly-Lys (side chain amino group $-NH_2$) or that of amino group of en per phosphorus atom of oligophosphate.

*3 Percentage of substrate degradated at the reaction time 22 hr. except ( )$_{70}$ which is the one at 70 hr.

*4 Ratio of the degradation ratio in the presence of catalyst to that in the absence of catalyst at the same pH.

*5 First-order rate constants (hydrolysis rate) estimated from Eq. 1. (†: quoted from Otani's data[13]).

(aquo-complex), since little Cu(II)-en 1 : 1 chelate exists at pH 4. On the other hand, the form of the Cu(II)-en complex, which predominantly has a catalytic effect at pH 8, seems to be monohydroxo, Cu en(OH)(H_2O), or dihydroxo, Cu en-$(OH)_2$, chelate.[2]

The degradation ratio at the reaction time of 70 hr. and the apparent rate constant are plotted against the concentration of Cu(II)-en in Fig. 7. The initial concentration of pentaphosphate and the molar ratio of copper(II) to ethylendiamine were kept constant. The degradation ratio and the apparent first-order rate constant, k_{obs}, estimated by using Eq. 5, increase linearly with the concentration of catalyst. The simplest kinetics which is applicable to the results seems to be represented by Eqs. 3—6:

$$\text{pentaphosphate} \xrightarrow{{}^1k_1} \text{degradation products} \quad (3)$$

$$\text{pentaphosphate} + \text{catalyst} \xrightarrow{{}^2k_1} \text{degradation products} + \text{catalyst} \quad (4)$$

$$k_{obs}t = 2.303 \log (100/P_5) \quad (5)$$

$$k_{obs} = {}^1k_1 + {}^2k_1C \quad (6)$$

where k_{obs} is the apparent first-order rate constant (observed value) and C, the concentration of the metal complex catalyst. The value extrapolated to the zero concentration of the catalyst, ${}^1k_1$, does not agree with the value observed in the absence of the Cu(II)-en complex, k_{obs}. This may show that the catalytic effect of hydrogen ions and that of the Cu(II)-en complex on the hydrolysis of pentaphosphate are not always independent, but correlate with each other.

The dependence of the composition of degradation products at half-life on the catalyst concentration is shown in Fig. 8. The molar ratio of copper(II) to ethylenediamine in each experiment was kept

Initial concentration of pentaphosphate, [P$_5$]$_i$: [P$_5$]$_i$: 4.07×10^{-3} M, molar ratio of Cu(II) to ethylenediamine: 1.0.

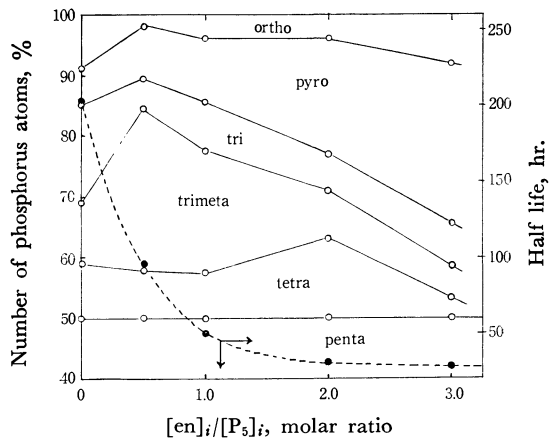

Fig. 8. The dependence of the composition of degradation products at half left on the Cu(II)-en catalyst concentration (life ordinate scale) and the dependence of the half life in the hydrolytic degradation of pentaphosphate on the Cu(II)-en catalyst concentration (right ordinate scale) at pH 8 (cf. Fig. 7).

constant at 1.0. The formation of pyrophosphate increases with the concentration of Cu(II)-en, as may be seen in Fig. 8. From the fact that the pyrophosphate and the triphosphate are hardly degraded in the presence of the Cu(II)-en complex (cf. Table I), it seems reasonable to conclude that the reaction shown in Eq. 7 becomes predominant with an increase in the concentration of the Cu(II)-en complex.

$$\text{pentaphosphate} \longrightarrow 2\ \text{pyro-} + \text{ortho-} \quad (7)$$

The Degradation in the Presence of the Cu(II)-Poly-Lys Complex.—The catalytic effect of the Cu(II)-Poly-Lys complex on the hydrolysis of oligophosphates was studied by using pentaphosphate; the results are shown in Figs. 9—16. Figures 9—11 show the dependence of the ^{32}P

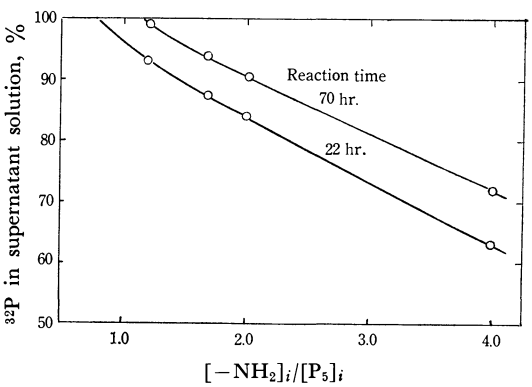

Fig. 9. The dependence of ^{32}P percentage in the supernatant solution of pentaphosphate-Poly-Lys-Cu(II) system on the Poly-Lys concentration (repeat unit molar concentration, [$-NH_2$]) at pH 8.

percentage in the supernatant solution on the concentrations of Poly-Lys, hydrogen ions and cupric ions respectively. These experiments were carried out at 45°C for 22 hr.; all the ^{32}P in the precipitate was assumed to be of the pentaphosphate form in estimating the degradation ratio.** Figure 12 shows the relation between the composition of the degradation products and the reaction time. The molar ratios of cupric ions to pentaphosphate are 0.71 and 1.0 in Figs. 12a and 12b respectively. The repeat unit of Poly-Lys per pentaphosphate is 1.43 in Fig. 12a and 2.0 in Fig. 12. The pH dependence of the hydrolysis of pentaphosphate in the presence of the Cu(II) - Poly-Lys complex is shown in Fig. 13, where all the experimental conditions except the pH value are the same as those in the case of Fig. 12a. Figure 14 shows the dependence of the degradation ratio on the concentration of the Cu(II)-Poly-Lys complex, the ratio of cupric ions to the repeat unit of Poly-Lys being kept constant at 1 : 2. Figure 15 shows the relation between the concentration of cupric ions and the degradation ratio, where the ratio of the repeat unit of Poly-Lys to pentaphosphate is kept constant at 1.43. Figure 16, obtained from the experiments in Fig. 14, shows the relation between the composition of the degradation products and the concentration of the Cu(II)-Poly-Lys complex. All of the initial concentrations of pentaphosphate in Figs. 9—15 are kept constant at 1.60×10^{-3} M.

Although the catalytic action of various amino-acids and synthetic polypeptides has been studied in the hydrolysis of DFP[3,20] and *p*-nitrophenyl-acetate[21,22] as substrates, the peculiar action of

** It could not be determined in this case whether or not all ^{32}P in the precipitate remained in the pentaphosphate form; therefore, in practice, it seems probable that the degradation ratio of pentaphosphate is somewhat greater than the value obtained in the present paper.

the catalyst on the substrate has not been investigated, probably because the substrates are too simple. As may be seen in Table I and Figs. 6 and 12, the catalytic action of the Cu(II) - Poly-Lys complex is very remarkable and differs from that of the Cu(II)-en complex in the main product of the hydrolytic degradation. The main product in the former case is orthophosphate, while those in the latter are pyro- and trimetaphosphates. Though ethylenediamine and Poly-Lys are both N-coordination ligands to copper(II), the catalytic effects in the hydrolysis of pentaphosphate differ from each other in the main products. This is probably due to the specific structure of Poly-Lys and to the remarkable catalytic action to be decribed below.

Orthophosphate may be formed from pentaphosphate by the following reactions:

pentaphosphate ⟶ tetra- + ortho-

tetra- ⟶ tri- + ortho-

tri- ⟶ pyro- + ortho- (8)

pentaphosphate ⟶ tri- + pyro-

tri- ⟶ pyro- + ortho- (9a)

pentaphosphate ⟶ trimeta- + pyro-

trimeta- ⟶ pyro- + ortho- (9b)

As may be seen in Figs. 12a, 12b and Table I, pyrophosphate does not degrade at all practically and the degradation ratios of tri- and trimetaphosphates are much less than that of pentaphosphate. From these facts in the presence of the Cu(II) - Poly-Lys complex, it seems reasonable to assume that the predominant reaction in bringing about the remarkable formation of orthophosphate in the initial stage of the reaction is not the intermediate chain attack represented by Eq. 9a or 9b, but the terminal chain attack, Eq. 8.

The composition of the precipitate which is formed by the interaction between a part of pentaphosphate and the Cu(II) - Poly-Lys catalyst can not be determined in the present work. Although the precipitate may also contain the degradation products from the reaction (8), (9a) or (9b), it is probable that most of the oligophosphates in the precipitate are pentaphosphate because the ^{32}P contained in the precipitate decreases with an increase in the reaction time (cf. broken lines in Figs. 13a and 12b) and in the degradation products in the supernatant solution. From the facts that there is remarkable difference between the degradations in the presence and in the absence of the precipitate and that the degradation ratio decreases upon the separation of the precipitate (Table II) it is found in the initial stage of the reaction that a great portion of the Cu(II) - Poly-Lys catalyst exists in the precipitate with a part of pentaphosphate and that the catalyst is liberated with the degradation of pentaphosphate from the precipitate to a bulk solution. The formation of precipitates by the interaction between polyphosphate and Poly-Lys depends on the pH, the concentration of Poly-Lys and that of cupric ions (Figs. 9—11), and the interaction seems to be considerably electrostatic in character.[23]

As may be seen in Figs. 13—15, there are three optimum conditions for the catalytic effect of the Cu(II) - Poly-Lys complex: 1) the remarkable catalytic effect appears only when the molar ratio of Poly-Lys to pentaphosphate, $[-NH_2]_t/[P_5]_t$, reaches a value which is larger than about 1.2 and attains a maximum at about 1.6; 2) the catalytic activity increases with the molar ratio of copper(II) to the NH_2 repeat unit of Poly-Lys, $[Cu]_t/[-NH_2]_t$, and attains a maximum at 1.0, and 3) the catalytic activity reaches a maximum at about pH 10. These results lead us to the following conclusions: 1) when the concentration of Poly-Lys is much lower than that of pentaphosphate, hardly any catalytic activity appears because the cupric ions which play an important role in the catalytic effect are masked by the complexation with pentaphosphate; 2) although copper(II) complexes with various compositions and structures may exist in the pentaphosphate - Poly-Lys - Cu(II) system, some of these species have the most remarkable catalytic activity; that is, the Cu(II)-Poly-Lys complex with 2 : 1 composition ratio of the side chain amino group to copper(II) or the hydroxo-complex with a 1 : 1 composition ratio acts on pentaphosphate and forms a mixed chelate such as that shown in Fig. 18a or 18b, so that the pentaphosphate is liable to suffer decomposition by the Cu(II) - Poly-Lys chelate[4], and 3) in view of the fact that the configuration of Poly-Lys becomes α-helix in the pH region above 10.5,[24] the results shown in Fig. 13 may indicate that there is some relation between the α-helix configuration of Poly-Lys and its catalytic activity.

It may be assumed from the variation in the color of the precipitate of the pentaphosphate-Poly-Lys - Cu(II) system that the complex species at pH 8—10 is different from that at 12. The

copper(II) atom in the light blue-green complex at pH 8—10 may be coordinated with one or two nitrogen atoms of the amino group of Poly-Lys (e. g. Fig. 18a or 18b), while that in the red-purple complex at pH 12 may be coordinated with the nitrogen atom of the peptide bond, –CONH–, in the main chain of Poly-Lys as well as the nitrogen atom of the side chain (e. g. Fig. 18c). As may be seen in Figs. 13 and 14, the former complex is catalytically more active than the latter because the active sites of copper(II) for pentaphosphate are occupied by nitrogen atoms of Poly-Lys. The color of the latter complex may be due to the biuret reaction from the interaction between cupric ions and polypeptides at high pH values. The chelate shown in Fig. 18a, 18b or 18c is an example of the conceivable structures; the structure with relation to the α-helix configuration can not be discussed in detail in this report for lack of data of the optical rotatory dispersion.

The oligophosphate - Poly-Lys - Cu(II) system is not suitable for the kinetic investigation because the precipitate is formed in this system. Kinetic studies of the oligophosphate - Poly-α, L-glutamate - magnesium(II) and -copper(II) systems are in progress.

The author whishes to express his sincere gratitude to Professor Masaji Miura for his kind guidance and constant encouragement throughout this work. He also wishes to thank Professor Keihei Ueno of Kyushu University for his understanding of this work, Dr. Kiwamu Yamaoka of the National Institutes of Health (U. S. A.) for supplying the Poly-L-lysine and Miss Fumiko Sakiue for her technical assistance.

Studies of Some Telluro-Vanadomolybdates

By Sarju PRASAD and K. C. PATHAK

Chemical Laboratories, Banaras Hindu University, Varanasi-5, India

(Received January 11, 1966)

Ammonium telluro-vanadomolybdate, $6(NH_4)_2O \cdot TeO_3 \cdot 3V_2O_5 \cdot 4MoO_3 \cdot 15H_2O$, has been synthesized, its properties studied, and its composition determined by analytical methods. Copper, silver, calcium, strontium, barium and lead salts have then been prepared from the ammonium salt. D. T. A. of ammonium and strontium salts have been carried out to investigate the thermal changes. The infrared spectra of the ammonium salt and its dehydrated product have been recorded, and the characteristic frequencies assigned.

A large number of condensation products of molybdenum and vanadium have been reported.[1] Gibbs[2] prepared two heterotriammonium phosphovanadomolybdates, $8(NH_4)_2O \cdot P_2O_5 \cdot 8V_2O_5 \cdot 14MoO_3 + 50H_2O$ and $7(NH_4)_2O \cdot 2P_2O_5 \cdot V_2O_5 \cdot 48MoO_3 + 30H_2O$, by boiling ammonium phosphomolybdate with an ammonium vanadate solution. Later Blum[3] confirmed Gibbs by showing the possibility of the condensation of vanadium, molybdenum and phosphorus and by isolating $5(NH_4)_2O \cdot P_2O_5 \cdot 11V_2O_5 \cdot 11MoO_3 \cdot 50H_2O$.

Telluric acid has been condensed to form heteropoly salts with molybdic acid,[4-6] and a series of vanadotellurites have been reported by Jena.[7]

The formation of heteropoly salts of tellurium with molybdic acid[8] and vanadium pentoxide[9] to form various salts has been studied in this laboratory. A heterotritellurovanadotungstate series[10] has also been investigated. This work is now extended to a study of the heterotrisalt formation of tellurium, vanadium and molybdenum. This paper will report the preparation of ammonium telluro-vanadomolybdate and its salts with copper, silver, calcium, strontium, barium and lead. The differential thermal analysis technique has been applied to a study of the thermal changes in the case of ammonium and strontium salts and the infrared spectra of the ammonium salt and its dehydrated product (the compound heated above 300°C) recorded in the KBr phase.

Experimental and Results

Ammonium Telluro-vanadomolybdate. — A mixture of telluric acid and 18.72 g. of ammonium metavanadate was refluxed in an ammoniacal medium for four hours. Twenty-six grams of molybdic acid dissolved in a sufficient quantity of aqueous ammonium was then added to the above solution, and the mixture was refluxed for another 8 hr. The solution was then evaporated to a small bulk and kept in a refrigerator for crystallization. The crystalline ammonium telluro-vanadomolybdate which was obtained was recrystallized and analyzed. Found: $(NH_4)_2O$, 15.98; TeO_3, 9.63; V_2O_5, 28.45; MoO_3, 31.08; H_2O, 14.86. Calcd. for $6(NH_4)_2O \cdot TeO_3 \cdot 3V_2O_5 \cdot 4MoO_3 \cdot 15H_2O$: $(NH_4)_2O$, 16.61; TeO_3, 9.346; V_2O_5, 29.06; MoO_3, 30.65; H_2O, 14.37%.

A yellow crystalline substance highly soluble in water, the compound is decomposed by acids and alkalies.

Copper Salt.—A greenish-yellow compound was precipitated when a dilute solution of copper sulfate was added to the ammonium salt solution. Found: CuO, 24.82; TeO_3, 9.53; V_2O_5, 28.62; MoO_3, 31.08; H_2O, 5.95. Calcd. for $6CuO \cdot TeO_3 \cdot 3V_2O_5 \cdot 4MoO_3 \cdot 6H_2O$: CuO, 25.36,; TeO_3, 9.33; V_2O_5, 29.01; MoO_3, 30.60; H_2O, 5.738%.

Silver Salt.—This is an orange yellow compound obtained by adding a dilute silver nitrate solution to the ammonium salt solution. The salt is blackened when exposed to light. Found: Ag_2O, 49.08; TeO_3, 6.62; V_2O_5, 18.92; MoO_3, 21.48; H_2O, 3.90. Calcd. for $6Ag_2O \cdot TeO_3 \cdot 3V_2O_5 \cdot 4MoO_3 \cdot 5H_2O$: Ag_2O, 50.02; TeO_3, 6.32; V_2O_5, 19.65; MoO_3, 20.72; H_2O, 3.239%.

Calcium Salt.—When a dilute solution of calcium acetate is added to the ammonium salt solution, a yellow compound is separated. It is

decomposed by acids. Found: CaO, 18.48; TeO_3, 9.64; V_2O_5, 31.08; MoO_3, 32.96; H_2O, 7.84. Calcd. for $6CaO \cdot TeO_3 \cdot 3V_2O_5 \cdot 4MoO_3 \cdot 8H_2O$: CaO, 18.93; TeO_3, 9.88; V_2O_5, 30.73; MoO_3, 32.41; H_2O, 8.104%.

Strontium Salt.—This a yellow compound obtained by adding a dilute solution of strontium acetate to the ammonium salt solution. The compound was filtered after some time and analyzed. Found: SrO, 30.86; TeO_3, 8.28; V_2O_5, 26.22; MoO_3, 28.86; H_2O, 5.78. Calcd. for $6SrO \cdot TeO_3 \cdot 3V_2O_5 \cdot 4MoO_3 \cdot 7H_2O$: SrO, 30.40; TeO_3, 8.586; V_2O_5, 26.70; MoO_3, 28.16; H_2O, 6.162%.

Barium Salt.—When a dilute solution of barium chloride was added to the ammonium salt solution, a yellow compound began to separate. It was kept for few hours to settle, and then filtered, dried and analyzed. The compound is decomposed by acids. Found: BaO, 38.34; TeO_3, 7.12; V_2O_5, 23.53; MoO_3, 24.62; H_2O, 6.39. Calcd. for $6BaO \cdot TeO_3 \cdot 3V_2O_5 \cdot 4MoO_3 \cdot 8H_2O$: BaO, 38.95; TeO_3, 7.437; V_2O_5, 23.13; MoO_3, 24.39; H_2O, 6.099%.

Lead Salt.—A heavy yellow precipitate was obtained by adding a solution of lead nitrate to the ammonium salt solution. Found: PbO, 50.02; TeO_3, 6.12; V_2O_5, 19.48; MoO_3, 21.47; H_2O, 2.91. Calcd. for $6PbO \cdot TeO_3 \cdot 3V_2O_5 \cdot 4MoO_3 \cdot 5H_2O$: PbO, 49.12; TeO_3, 6.442; V_2O_5, 20.03; MoO_3, 21.13; H_2O, 3.301%.

Estimations. — Tellurium was estimated as metallic tellurium[11]; ammonia, as has been described earlier[8]; molybdenum, by precipitating it as molybdenum sulfide and igniting to molybdenum(VI) oxide, and vanadium, by titrating it against a standard potassium permanganate solution at 70°C in a dilute sulfuric acid medium. The other metals were estimated by standard methods. The water content was determined by difference as not all the water molecules were removed at 120°C.

The differential thermal analysis of ammonium and strontium salt was carried out by the method described in an earlier communication.[9] The infrared spectra of the ammonium salt and its dehydrated product (the compound heated at 300°C) was recorded between 2 and 15 μ on a Perkin-Elmer infracord in a potassium bromide medium by the disc-technique method.

Discussion

The composition of ammonium telluro-vanadomolybdate has been determined by analytical methods. Its anionic nature has been confirmed by passing a freshly-prepared solution of the ammonium salt through a cation exchange resin (Amberlite IR 120); in this case the tellurium, vanadium and molybdenum contents of the solution remained unchanged. In precipitated copper, silver, calcium, strontium, barium and lead salts, the anion has the same composition in all cases.

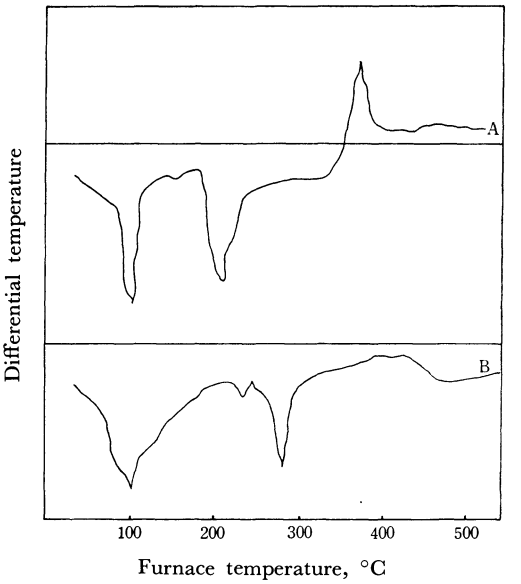

Fig. 1. Differential thermal analysis curves.
A. Ammonium telluro-vanadomolybdate
B. Strontium telluro-vanadomolybdate

The D. T. A. curve of the ammonium salt reveals two endotherms, at about 105 and 210°C, and a characteristic exotherm at about 370°C. The two endothermic peaks correspond to the dehydration of the compound; 6 water molecules are removed at 105°C, and the rest at about 210°C. The characteristic exothermic peak at 370°C is due either to the oxidation or to the decomposition of ammonia at the surface of molybdenum(VI) oxide or vanadium(V) oxide serving as a catalyst. The characteristic exotherm around this temperature has been observed while studying the D. T. A. of ammonium molybdate[12] and ammonium vanadate.[13] The oxidation of ammonia in the last stage of decomposition may be suggested as a possible source of exothermic heat.

In the case of strontium salt the water molecules are removed in two different temperature ranges, first at 105°C and the others at about 280°C, resulting in two endothermic peaks.

In the infrared spectrum of ammonium telluro-vanadomolybodate a broad band is observed in the region of 3400 cm^{-1} which is due to the intermixing of the N–H vibration of ammonium ions with the O–H stretching vibration of water. A sharp peak at 1650 cm^{-1} is observed; it represents

13) M. Taniguchi and T. R. Ingraham, *Can. J. Chem.*, **1964**, 2467.

the bending mode of the O–H vibrations of water. The spectrum of the above salt was recorded after heating it to 300°C; it was thus observed that the above bands are eliminated and that the overall spectrum is considerably altered. A strong peak at 1400 cm^{-1} is due to the hydrogen bonding of the constitutional water molecules held in the interstices of the crystal lattice; this has also been confirmed by the D. T. A. curve. These water molecules are firmly bound, but they are released at quite a higher temperature, one which may be sufficient to break the bonds.

The broad band in the 840—900 cm^{-1} region indicates the predominant character of V–O valence vibrations in conjunction with Mo–O vibrations; this character has been confirmed by a study of the spectrum of the heated salt, in which the complexity arising from the different bond has vanished and two distinct peaks at 910 and 980 cm^{-1} are observed.

The sincere thanks of the authors are due to the authorities of the Banaras Hindu University for providing facilities. One of the authors (K. C. P.) is also thankful to the Council of Scientific and Industrial Research, New Delhi, for a Fellowship. We are also thankful to Professor C. N. R. Rao, I. I. T., Kanpur, for infrared spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2668—2671 (1966)

Stability Constants of Uranyl Chelates with Nuclear-Substituted Salicylic Acids

By J. Mohan Rao and U. V. Seshaiah

Department of Chemistry, Osmania University, Hyderabad (Dn), India

(Received January 25, 1966)

The formation of an orange-red coloured water soluble chelate between uranyl ion and *p*-aminosalicylic acid with maximum absorption at 460 mμ is reported. The colour of the complex is fairly stable and attains maximum intensity at a pH 4.5. The composition of the complex has been evaluated by Job's and mole ratio methods employing absorbance data and has been found to be 1 : 1 with respect to metal and ligand. The stability constants of the uranyl chelates of certain nuclear substituted salicylic acids, such as, 3-nitrosalicylic, 5-sulphosalicylic, β-resorcylic and *p*-aminosalicylic acids have been determined and the validity of the linear relationship between ligand basicity and the metal chelate stability studied. Based on pH and adsorption studies, tentative structures for the above uranyl chelates have also been proposed.

The complex formation of substituted salicylic acids, such as amino-, alkyl-, chloro-, and nitrosalicylic acids, has been studied in detail with ferric and aluminium ions. It was observed by Foye et al.[1] that the sequence of stabilities with both the metals was parallel to the ionisation constants of the ligands. However, no such studies of the stability constants of uranyl chelates with nuclear-substituted salicylic acids have been carried out.

Baiulescu[2] has introduced a new method for the colorimetric determination of *p*-aminosalicylic acid based on the facts that the above ligand develops a characteristic orange-red colour with uranyl ions and that the complex obeys Beer's law. However, no details regarding the stoichiometry and stability constant have been reported. Recently, Rajam and Martell[3] have studied the formation of a 1 : 1 uranyl-5-sulphosalicylate employing the pH-titration technique; they reported its stability constant ($\log K$) to be 10.62. The formation of a red water-soluble chelate between uranyl ions and β-resorcylic acid[4] with a metal-ligand ratio of 1 : 1, which is also confirmed by the present authors, has been studied by spectrophotometric methods, but no data regarding the stability constant have been presented. While studying the chelate formation of 3-nitrosalicylic acid with ferric ions, the present authors have observed spectrophotometrically and potentiometrically that 3-nitrosalicylic acid forms a 1 : 1 chelate with uranyl ions.[5]

The present communication will describe the

studies in the complex formation of uranyl ions with *p*-aminosalicylic acid in some detail, as well as the evaluation and comparison of the stability constants of uranyl *p*-aminosalicylate, β-resorcylate and 3-nitrosalicylate chelates. Spectrophotometric, pH and ion exchange methods were employed in the studies of the above systems. pH titrations of the uranyl ion-5-sulphosalicylic and salicylic acids with the metal-ligand ratio of 1 : 1 were also carried out, and the stability constants were evaluated for purposes of comparison.

Experimental

A standard solution of uranyl nitrate was prepared from a B. D. H. Analar sample by direct weighing; the uranium content was gravimetrically confirmed as uranium oxide. For spectrophotometric studies, an uranyl perchlorate solution was prepared by dissolving the uranium hydroxide, precipitated from a known volume of a standard uranyl nitrate solution, in dilute perchloric acid. Fresh solutions of ligands, *p*-aminosalicylic (PAS), β-resorcylic (RA), 3-nitrosalicylic (NSA), 5-sulphosalicylic (5-SSA), and salicylic (SA) acids were prepared by direct weighing and were standardised potentiometrically and titrimetrically.

All the spectrophotometric measurements were carried out by means of a UNICAM SP 600 spectrophotometer. pH titrations were carried out with the help of a Ludwig pH meter, type-12.

Results and Discussion

The development of an orange-red colour when sodium *p*-aminosalicylate was mixed with uranyl ions is almost instantaneous and is pH-dependent. The absorbance of the mixture containing uranyl perchlorate and *p*-aminosalicylic acid in the ratio of 1 : 3 attains a maximum intensity at pH=4.5.

The Composition of the Complex.—The method of Voshburg and Cooper[6] was employed to determine the nature of the complex formed in the solution. All the mixtures, containing metal-ligand in ratios of 1 : 1, 1 : 2, and 1 : 3, showed a maximum absorption at 460 mμ; this isoabsorptive point suggests the formation of only one complex in solution. Job's continuous variation[7] and mole ratio methods[8] were employed to establish the stoichiometry of the complex.

In Job's continuous variation method, equimolecular aqueous solutions (1×10^{-3} M) of the metal and ligand were mixed in complementary quantities and the absorption was measured at 460 mμ and at pH=4.5. The Job curve (Fig. 1, curve A) obtained by plotting the optical densities against the composition of the coloured solutions has shown a peak at the mole fraction of 0.5 of the metal to the ligand, indicating the formation of 1 : 1 complex.

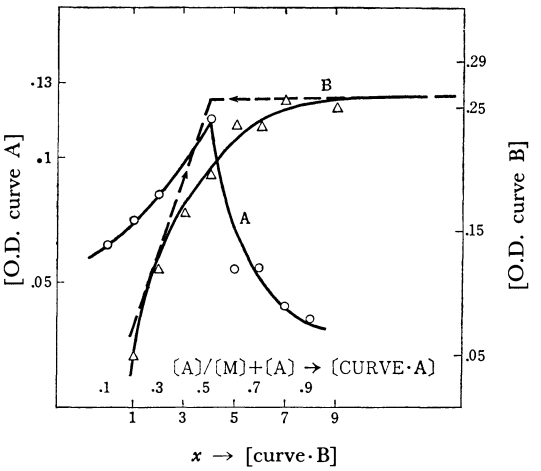

Fig. 1. Composition of the complex by Job's method and mole ratio methods.
A, [A]/([M]+[A])=mole fraction; B, x=ml. of 5×10^{-3} M ligand added to 4 ml. of 5×10^{-3} M uranyl solution. Total volume=20 ml. pH=4.5; λ=460 mμ

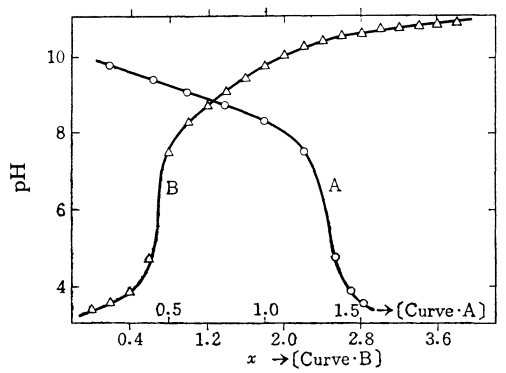

Fig. 2. Curve A, Formation of β-resorcylic acid.
$\bar{n}$=Average number of protons held per mole of anion residue; ($x=\bar{n}$)
Curve B, Potentiometric titration of resorcylic acid in 0.10 M KNO_3 at 28°C with 0.05 M NaOH. ($x=a$, equivalents of base added.)

In the mole ratio method too, the plot of the optical densities against the amount of ligand added to the metal shows a clear break at one equivalent of the ligand, confirming the 1 : 1 ratio of the metal to the ligand in the complex.

The Interaction of Uranyl Ions with Nuclear-Substituted Salicylic Acids.—Potentiometric titrations for the 1 : 1 ratio of uranyl ions to various ligands were performed at the same ligand concentration. The results of the experimental measurements are presented in Fig. 3, curves A, B, C, D, and E. The titration curves indicate qualitatively the relative magnitudes of the stabilities of

the uranyl chelates. Precipitations were found at the end of the titrations; they were probably caused by disproportionation to the metal hydroxide or by the hydrolysis of the 1 : 1 chelate.

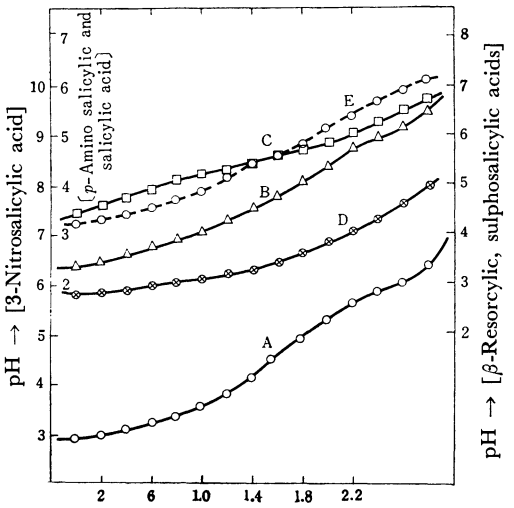

Fig. 3. Potentiometric titration of uranyl chelates of substituted salicylic acids in 0.10 M KNO_3 at 28°C with molar ratio 1:1 of ligand to uranyl ions.

Acid Dissociation Constants of β-Resorcylic Acid.—The step-by-step ionisation of β-resorcylic acid with its step constants can be expressed as follows:

$$H_3A \rightleftharpoons H_2A^- + H^+; \quad k_1 = \frac{(H_2A^-)(H\cdot)}{(H_3A)}$$

$$H_2A^- \rightleftarrows HA^{2-} + H^+; \quad k_2 = \frac{(HA^{-2})(H\cdot)}{(H_2A^-)}$$

$$HA^{2-} \rightleftarrows A^{3-} + H^+; \quad k_3 = \frac{(A^{3-})(H\cdot)}{(HA^{2-})}$$

where the parentheses indicate the concentrations of the respective ions.

The values of k_1 and k_2, the first and the second acid dissociation constants, of the β-resorcylic acid (H_3A) were determined by titrating the free acid in the presence of mineral acid (HNO_3) with standard, carbon dioxide-free sodium hydroxide (Fig. 2B). Various values of $\bar{n}$, the average number of protons held per anion residue, calculated from the following equations[9] have been plotted against the pH (Fig. 2A):

$$\bar{n} = \frac{(H_2A^-) + 2(H_3A)}{C_A}; \quad (H_2A^-) = aC_A + (H\cdot)$$

and $(H_3A) = C_A - (H_2A^-)$ in low-buffer regions and $(H_2A^-) = (a-1)C_A - (OH^-)$; $(HA^{2-}) = C_A - (H_2A^-)$ in higher buffer regions.

where a = equivalents of base added, and
C_A = total anion concentration.

The third dissociation constant, k_3, has been evaluated from the potentiometric data, using the algebraic method of Schwarzenbach et al.[10]:

$$(HA^{2-}) = (a-2)C_A - (OH^-);$$

$$(A^{3-}) = C_A - (HA^{2-}); \quad k_3 = \frac{(A^{3-})(H\cdot)}{(HA^{2-})}$$

The present value of $k_1 = 2.2 \times 10^{-4}$ slightly differs from the reported value of 4.73×10^{-4} [11] obtained conductometrically. The values of k_2 and k_3 have been worked out to be 4.5×10^{-10} and 1.16×10^{-11} respectively. The literature, however, does not reveal any values for these two constants for purposes of comparison.

The Stability Constants of the Chelates.—The equilibrium involved in the metal chelate formation of a 1 : 1 system (metal-ligand) may be expressed as:

$$UO_2^{2+} + A^{2-} \rightleftarrows UO_2A; \quad K = \frac{(UO_2A)}{(UO_2^{2+})(A^{2-})}$$

where K is the stability constant of the chelate. The stability constants of the complexes have been evaluated employing Bjerrum's method as modified by Chaberek and Martell.[12] In the case of a 1 : 1 complex, the various factors involved in the K of the chelate are obtained by using the following equations:

$$(A^{2-}) = \frac{(2-a)C_A - (H\cdot) + (OH^-)}{\frac{2(H\cdot)^2}{k_1k_2} + \frac{(H\cdot)}{k_2}}$$

$$K = \frac{C_A - x(A^{2-})}{(A^{2-})[C_M + x(A^{2-}) - C_A]}$$

where

$$x = \frac{(H\cdot)^2}{k_2k_1} + \frac{(H\cdot)}{k_2} + 1$$

where k_1 and k_2 are the suitable acid dissociation constants of the ligands, and where C_M = the total metal ion concentration.

The values of the stability constants of the uranyl chelates (Table I) indicate a gradual increase in the stability of the chelates as the basic nature of the donor group of the ligand increases. The stabilities of the uranyl chelates were found to increase in the sequence; 3-nitrosalicylic < 5-sulphosalicylic < β-resorcylic < salicylic < *p*-aminosalicylic acids. Moreover, as was predicted by the thermodynamically-derived equation of Ernst and

* The values of the acid dissociation constants have been abstracted from earlier works.

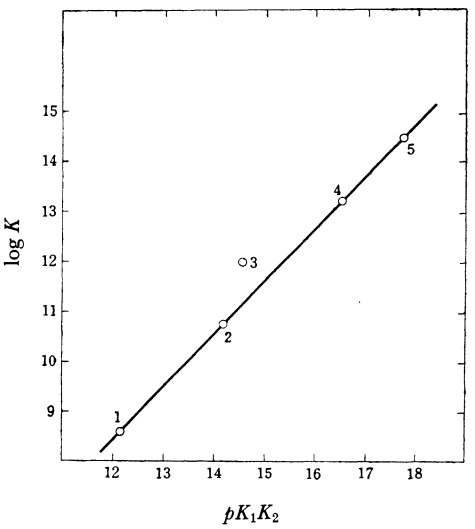

Fig. 4. Linear relationship of log K vs. $p(K_1K_2)$.
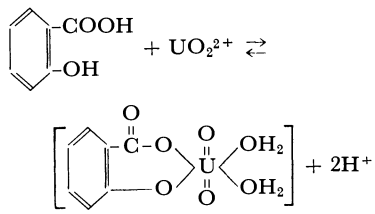
(1) 3-nitrosalicylic acid (2) sulphosalicylic acid (3) β-resorcylic acid (4) salicylic acid (5) p-aminosalicylic acid.

Menashi,[13] and as has been proposed by many workers,[14-16] the plot of $\log_{10}K$ against $p(k_1k_2)$ yields a straight line, as is shown in Fig. 4, for the complexes of the uranyl ions with both salicylic and substituted salicylic acids.

Under the experimental conditions, it seems that all the above ligands react with uranyl ions in 1 : 1 ligand-metal ratio, liberating two protons; the adjacent carboxylic and the phenolic groups seem to be responsible for the binding of the metal atom in the complexes. The structure with the reactive moiety may be tentatively represented as:



Similar structures have been assigned to the ferric complexes of p-aminosalicylate,[17] 5-sulphosalicylate,[18] β-resorcylate[19] and o-cresotate[20] by earlier workers. Further, the non-ionic nature of all the chelates, uranyl-3-nitrosalicylic, β-resorcylic and p-aminosalicylic acids was confirmed by their non-adsorption on both cation exchange resin, Rexyn 102(H), and anion exchange resin, Rexyn AG-7(Cl-SO_4).

Summary

1) The composition of the uranyl p-aminosalicylic acid chelate was found by spectrophotometric methods to be 1 : 1 with respect to the metal-ligand ratio.

2) The stability constants of uranyl-salicylate and substituted salicylate chelates were determined, and the validity of the linear relationship between the ligand basicity and the metal chelate stability was studied.

3) The second and third acid dissociation constants of β-resorcylic acid were determined from potentiometric data.

4) The stabilities of uranyl chelates were found to increase in the sequence:

3-nitrosalicylic acid < 5-sulphosalicylic < β-resorcylic < salicylic < p-aminosalicylic acids.

5) Substituents were found to play an important role in this case.

The authors are grateful to Professor N. V. Subba Rao for his keen interest in their investigations.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2672—2677 (1966)

Electrode Processes Followed by Chemical Reactions Involving Electroactive Species. II. A Study on the Substitution Reaction Involving Chromium(II)

By Kazuko OGINO (née EBATA) and Nobuyuki TANAKA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received March 30, 1966)

The one-electron reduction wave of hexamminechromium(III) ions at the dropping mercury electrode splits into two steps by the presence of manganese(II) and ethylenediaminetetraacetatomanganate(II) (MnY^{2-}; Y^{4-} represents a quadrivalent ethylenediaminetetraacetate anion) ions. The limiting current of the first step was considered to depend on the rate of the formation of CrY^{2-} by the substitution reaction of MnY^{2-} and chromium(II) ions which were produced at the electrode by the reduction of the chromium(III) complex ions. From the change in the limiting current of the first step by the change of the concentrations of Mn^{2+}, MnY^{2-} and H^+, the rate constants of the complex-forming reaction

$$Cr^{2+} + HY^{3-} \underset{k_{1b}}{\overset{k_{1f}}{\rightleftharpoons}} CrY^{2-} + H^+$$

were obtained to be $k_{1f}=8\times10^7$ l.mol^{-1}sec^{-1}, $k_{1b}=4\times10^4$ l.mol^{-1}sec^{-1} (ionic strength 1.0, 25°C).

In the previous papers[1,2] the mechanisms of the electrode reaction of hexamminechromium(III) in the presence of ethylenediaminetetraacetate (EDTA) was reported. The one-electron reduction wave of hexamminechromium(III) is affected by the presence of ethylenediaminetetraacetatomanganate(II) ions. The mechanism of this phenomenon is considered to be one similar to that observed in the presence of EDTA; chromium(II) ions produced at the electrode by the reduction of the chromium(III) complex react with manganese(II)-EDTA to form chromium(II)-EDTA complexes, which are oxidized at the electrode as long as the potential is sufficiently positive, resulting in a decrease of the net cathodic current. The reactions can be expressed as*

$$Cr(NH_3)_6^{3+} + e \rightarrow Cr^{2+} + 6NH_3 \quad (1a)$$

$$Cr^{2+} + MnY^{2-} \rightleftharpoons CrY^{2-} + Mn^{2+} \quad (1b)$$

$$CrY^{2-} \rightleftharpoons CrY^{-} + e \quad (1c)$$

where Y^{4-} represents a quadrivalent EDTA anion.

The determination of rate constants by means of the analysis of the limiting kinetic current due to the following chemical reaction seems to be convenient for reactions involving unstable substances, though it has been applied to the actual reaction only in a few cases involving organic substances.[3-5] Equations giving the relation between the current at a constant potential and the rate constants of the following chemical reaction were given by Alberts and Shain.[4] In this paper, these equations are applied to the determination of the rate constants of Reaction 1b, a substitution reaction of chromium(II) and manganese(II)-EDTA complex ions.

Experimental

Hexamminechromium(III) chloride was prepared according to the method of Mori.[6] The solution of manganese(II) chloride was standardized amperometrically against the solution of disodium ethylenediaminetetraacetate, which in turn was standardized against a standard copper(II) nitrate solution.

Solutions containing manganese(II) and manganese(II)-EDTA complex ions were obtained by adding appropriate amounts of the manganese(II) chloride and the ethylenediaminetetraacetate solutions before each measurement. The pH of the solution was adjusted with acetate buffer solution and the ionic strength was adjusted to be 1.0 with sodium chloride. Gelatin was added as a maximum suppressor by 0.005 %.

2) K. Ebata, *Sci. Repts. Tohoku Univ. Ser. I*, **47**, 191 (1964).

* It was shown previously[1] that the aquation of hexamminechromium(II) ions is more rapid than the direct substitution with EDTA. Since the reaction of chromium(II) with manganese(II)-EDTA is much slower than that with EDTA, it may be considered that the reaction of chromium(II) with manganese(II)-EDTA takes place via an aquo complex.

The current-time curves during the life of a mercury drop were recorded using a Rikadenki ERJ1 recorder with an RLDC-201 preamplifier. In the following sections of this paper, the word "current", denoted by i, means the instantaneous current observed 4 seconds after the beginning of the mercury drop growth, unless otherwise stated. The dropping mercury electrode used had an m value of 1.42 mg./sec. and a drop time, t_d, 5.54 sec. in a deaerated 0.1 M sodium perchlorate solution at −0.5 V. vs. SCE and 60 cm. mercury height. A saturated calomel electrode (SCE) with a large surface area served as an anode. All measurements were carried out at 25°C.

Results

When manganese(II) and manganese(II)-EDTA complex ions are present in the solution in a large excess over chromium(III) complex ions, Eqs. 1a to 1c can be symbolyzed as

$$A_1 + n_1e \rightarrow A_2 \quad (2a)$$

$$A_2 \underset{l_b}{\overset{l_f}{\rightleftharpoons}} A_3 \quad (2b)$$

$$A_3 + n_2e \rightleftharpoons A_4 \quad (2c)$$

where A_1, A_2, A_3 and A_4 correspond to $Cr(NH_3)_6^{3+}$, Cr^{2+}, CrY^{2-} and CrY^- in Eqs. 1a to 1c respectively, and l_f and l_b are the forward and the backward first-order rate constant of Reaction 2b. Symbols n_1 and n_2 represent numbers of electrons involved in electrochemical reactions; positive and negative values of n's correspond to the reduction and the oxidation process respectively. In the system given by Eqs. 2a to 2c, the case $n_1n_2<0$ is physically impossible if A_1 is a substitution-labile complex. For Reactions 1a to 1c, where A_1 is a substitution-inert complex ion, the value of n_1 is 1 and that of n_2 is −1.

Substances A_1, A_2 and A_3 in Eqs. 2a to 2c obey the following equations when the mass transfer process is controlled by the linear diffusion.

$$\frac{\partial[A_1]}{\partial t} = D_1\frac{\partial^2[A_1]}{\partial x^2} \quad (3a)$$

$$\frac{\partial[A_2]}{\partial t} = D_2\frac{\partial^2[A_2]}{\partial x^2} - l_f[A_2] + l_b[A_3] \quad (3b)$$

$$\frac{\partial[A_3]}{\partial t} = D_3\frac{\partial^2[A_3]}{\partial x^2} + l_f[A_2] - l_b[A_3] \quad (3c)$$

where $[A_j]$ and D_j are the concentration and the diffusion coefficient of species A_j, respectively. The initial and the boundary conditions are

$$t = 0,\ x>0:\ [A_1]=[A_1]_0,\ [A_2] = [A_3] = 0 \quad (4)$$

$$t>0,\ x = 0:\ [A_1] = [A_3] = 0 \quad (5a)$$

$$D_2\frac{\partial[A_2]}{\partial x} = -D_1\frac{\partial[A_1]}{\partial x} \quad (5b)$$

$$t>0,\ x\rightarrow\infty:\ [A_1]=[A_1]_0,\ [A_2] = [A_3] = 0 \quad (6)$$

where $[A_1]_0$ is the concentration of A_1 in the bulk of the solution. The boundary condition 5a expresses that, in the potential region in question, the rates of electrochemical reactions 2a and 2c are much greater than the rate of diffusion.

The solution to the equations was given by Alberts and Shain[4] under the assumption that $D_2=D_3$. The kinetic part of the current, i_k, is given by one of Eqs. 8, 12 and 13, according to the magnitude of the equilibrium constant of Reaction 2b*:

$$K = \frac{l_f}{l_b} = \frac{[A_3]_e}{[A_2]_e} \quad (7)$$

where $[A_j]_e$ is the concentration of A_j at equilibrium.

(a) For $K > 1$:

$$i_k = i_d\frac{n_2}{n_1}\frac{K}{K-1}\left\{1 - \exp(-lt) - 2\theta\exp(-K^2\theta^2)\int_\theta^{K\theta}\exp(\lambda^2)d\lambda\right\} \quad (8)$$

where

$$l = l_f + l_b \quad (9)$$

$$\theta = \sqrt{\frac{lt}{K^2-1}} \quad (10)$$

and i_d is the diffusion current observed in the absence of Reaction 2b:

$$i_d = n_1Fq[A_1]_0\sqrt{\frac{D_1}{\pi t}} \quad (11)$$

where q is the area of the electrode surface.

(b) For $K = 1$:

$$i_k = i_d\frac{n_2}{n_1}\left[1 - \frac{1}{lt}\left\{1 - \exp(-lt)\right\}\right] \quad (12)$$

(c) For $K < 1$:

$$i_k = i_d\frac{n_2}{n_1}\frac{K}{1-K}\left[\theta\sqrt{\pi}\exp(K^2\theta'^2)\times\left\{\mathrm{erf}(\theta') - \mathrm{erf}(K\theta')\right\} - \left\{1 - \exp(-lt)\right\}\right] \quad (13)$$

where

$$\theta' = \sqrt{\frac{lt}{1-K^2}} \quad (14)$$

$$\mathrm{erf}(\lambda) = \frac{2}{\sqrt{\pi}}\int_0^\lambda \exp(-y^2)dy \quad (15)$$

When $K^2\ll1$ is satisfied, θ' can be simplified as

$$\theta' = \sqrt{lt} \quad (16)$$

Thus, when the value of K is known, rate constants l_f and l_b can be computed from the value of i_k/i_d which is obtained experimentally.

The addition of manganese(II) chloride to the solution of hexamminechromium(III) caused a

* More simplified solutions of Eqs. 3a to 3c, obtained at several limited conditions, are given in Ref. 2.

small positive shift (2—3 mV. by 0.1 M $MnCl_2$) in the half-wave potential of hexamminechromium-(III) without changing the shape of the wave. When both manganese(II) and manganese(II)-EDTA complex ions were present, the wave showed a decrease in the current in the potential region more positive than about -1.25 V. as shown in Fig. 1, where the diffusion current observed in the absence of manganese(II)-EDTA is denoted by i_d, and the decrease in current by the addition of manganese(II)-EDTA, by i_k. The value of i_k was found to be proportional to the concentration of hexamminechromium(III) chloride. Table I gives the relation between the mercury height and i_k observed just before the mercury drop detaches the capillary. That i_k is independent of the mercury height indicates a kinetic nature of i_k. The value of i_k/i_d was dependent on the pH

and concentrations of manganese(II) and manganese(II) - EDTA complex ions.

As manganese(II) and manganese(II)-EDTA complex ions are present in a large excess under the experimental condition, the apparent equilibrium constant of Reaction 1b is given as

$$K = \frac{l_f}{l_b} = \frac{[CrY^{2-}]_e}{[Cr^{2+}]_e} = \frac{K_{CrY}}{K_{MnY}} \frac{[MnY^{2-}]}{[Mn^{2+}]} \quad (17)$$

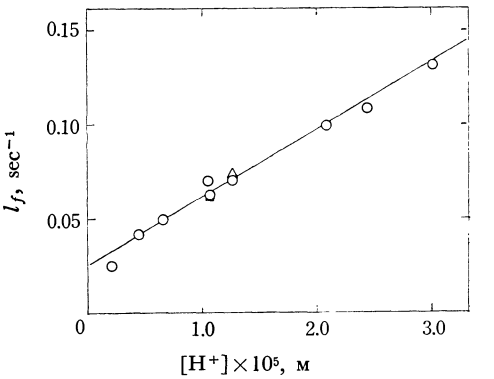

Fig. 2. Values of l_f as a function of the hydrogen ion concentration* in solutions of ionic strength 1.0 (NaCl) containing 0.4 mM $Cr(NH_3)_6^{3+}$, 0.1 M acetate buffer, 0.005% gelatin, a M Mn^{2+} and b M MnY^{2-}.

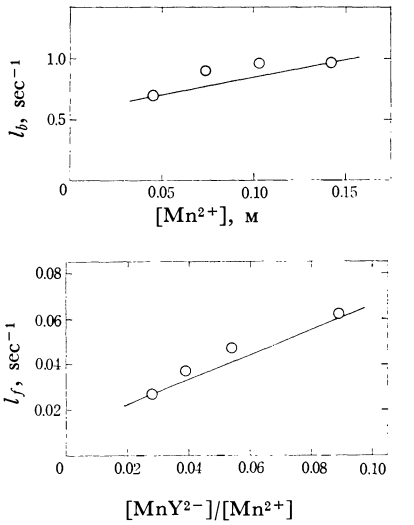

Fig. 3. Variation of l_f and l_b with the change of $[Mn^{2+}]$ in solutions of ionic strength 1.0 (NaCl), pH 4.94 containing 0.4 mM $Cr(NH_3)_6^{3+}$, 0.0039_8 M MnY^{2-}, 0.1 M acetate buffer and 0.005% gelatin.

* The hydrogen ion concentration was assumed to be equal to antilog(-pH).

where K_{CrY} and K_{MnY} are the stability constants of CrY^{2-} and MnY^{2-} respectively. The values of the stability constants at ionic strength 0.1 at 20°C were reported to be $10^{13.61}$ for CrY^{2-} [7] and $10^{13.58}$ for MnY^{2-} [8], respectively. When it is assumed that the ratio K_{CrY}/K_{MnY} does not vary considerably with changes of ionic strength from 0.1 to 1.0 and of temperature from 20°C to 25°C, Eq. 17 becomes

$$K = 1.07[MnY^{2-}]/[Mn^{2+}] \quad (18)$$

As the ratio $[MnY^{2-}]/[Mn^{2+}]$ was less than 0.1 under the experimental condition, Eqs. 13 and 16 were employed for the calculation of the rate constants of Reaction 1b.* Rate constants l_f and l_b obtained at various pH's and concentrations of manganese(II) and manganese(II)-EDTA complex ions are plotted in Figs. 2 and 3.

Discussion

The following reaction paths can be assumed for Reaction 1b:

$$(I)\quad MnY^{2-} + jH^+ \rightleftharpoons Mn^{2+} + H_jY^{(j-4)+} \text{ (fast)} \quad (19a)$$

$$(j = 0, 1, 2, \cdots)$$

$$Cr^{2+} + H_jY^{(j-4)+} \underset{k_{Ijb}}{\overset{k_{Ijf}}{\rightleftharpoons}} CrY^{2-} + jH^+ \text{ (slow)} \quad (19b)$$

$$(II)\quad MnY^{2-} + jH^+ \rightleftharpoons MnH_jY^{(j-2)+} \text{ (fast)} \quad (20a)$$

$$Cr^{2+} + MnH_jY^{(j-2)+} \underset{k_{IIjb}}{\overset{k_{IIjf}}{\rightleftharpoons}} CrH_jY^{(j-2)+} + Mn^{2+} \text{ (slow)} \quad (20b)$$

$$CrH_jY^{(j-2)+} \rightleftharpoons CrY^{2-} + jH^+ \text{ (fast)} \quad (20c)$$

In Path I, Reaction 19a, the dissociation reaction of manganese(II)-EDTA, was assumed to be in equilibrium for the following reason. If Reaction 19a is rate-determining in Path I, it is expected that the rate of chromium(II)-EDTA formation, and hence i_k, is governed by the rate of Reaction 19a and is independent of the concentration of hexamminechromium(III). This is against the experimental result which showed a proportionality between i_k and the chromium(III) concentration.

When Reaction 1b proceeds via Paths I and II, the first-order rate constants of Reaction 1b with respect to Cr^{2+} and CrY^{2-} are given by

$$l_f = \frac{1}{K_{MnY}} \frac{[MnY^{2-}]}{[Mn^{2+}]} \sum_{j=0} \{k_{Ijf}[H^+]^j (\prod_{\nu=0}^{j} K_\nu)\} + [MnY^{2-}] \sum_{j=0} (k_{IIjf} K_{MnH_jY}[H^+]^j) \quad (22)$$

$$l_b = \sum_{j=0} (k_{Ijb}[H^+]^j) + [Mn^{2+}] \sum_{j=0} (k_{IIjb} K_{CrH_jY}[H^+]^j) \quad (23)$$

where K_{MnH_jY} and K_{CrH_jY} are the stability constants of protonated complexes, e. g.,

$$K_{MnH_jY} = \frac{[MnH_jY^{(j-2)+}]}{[MnY^{2-}][H^+]^j} \quad (24)$$

It is defined that K_{MnH_jY} and K_{CrH_jY} are equal to 1 for $j=0$. For $j=1$, the following values were reported at ionic strength 0.1 at 20°C: $K_{MnHY}=10^{3.1}$;[8] $K_{CrHY}=10^{3.00}$.[7] The symbol K_ν in Eq. 22 denotes a reciprocal of the acid dissociation constant of $H_\nu Y^{(\nu-4)+}$, and is defined to be equal to 1 for $\nu=0$; for $\nu=1, 2, 3$ and 4, the values of K_ν were reported to be $10^{10.26}$, $10^{6.16}$, $10^{2.67}$ and $10^{1.99}$ respectively at ionic strength 0.1 at 20°C.[9]

That l_f and hence l_b change linearly with the change in hydrogen ion concentration as shown in Fig. 2 indicates that j in Eqs. 22 and 23 takes only the values 0 and 1.

The first terms of Eqs. 22 and 23 correspond to rate constants for Path I and the second terms to those for Path II. Equations 22 and 23 indicate that if Path II is the predominant path of Reaction 1b, l_f should be constant as long as $[MnY^{2-}]$ is kept constant, and that l_b should be proportional to $[Mn^{2+}]$. They also indicate that, when Path I is predominant, l_b should be independent of concentrations of both manganese(II) and manganese(II)-EDTA complex ions, and l_f should be independent of $[Mn^{2+}]$ and $[MnY^{2-}]$ as long as the ratio $[MnY^{2-}]/[Mn^{2+}]$ is constant. The values of l_f and l_b obtained at different concentrations of manganese(II) and manganese(II)-EDTA complex ions with the same ratio of $[MnY^{2-}]/[Mn^{2+}]$ are given in Fig. 2, where all the values lie near a single straight line. Figure 3 shows that l_f is not constant by the change of $[MnY^{2-}]/[Mn^{2+}]$, but that it varies almost proportionally with the change of $[MnY^{2-}]/[Mn^{2+}]$, when $[MnY^{2-}]$ is kept constant. It is also shown that l_b is not proportional to $[Mn^{2+}]$. It may be concluded from these that the predominant path of Reaction 1b under conditions where the ratio $[MnY^{2-}]/[Mn^{2+}]$ is considerably large and pH is low is

$$MnY^{2-} + H^+ \rightleftharpoons Mn^{2+} + HY^{3-} \text{ (fast)} \quad (25a)$$

$$Cr^{2+} + HY^{3-} \underset{k_{1b}}{\overset{k_{1f}}{\rightleftharpoons}} CrY^{2-} + H^+ \text{ (slow)} \quad (25b)$$

The rate constants of Reaction 25b are obtained

Values in parentheses are those calculated from values of k_{1f} or k_{1b} and the equilibrium constant of Reaction 26[18] by the present authors.

from the plots in Figs. 2 and 3, and are given in Table II. Rate constants of other paths are not determined because of the rather large error.

The rate constants of Reaction 25b obtained here are compared with those of reactions similar to Reaction 25b involving other bivalent metal ions.

$$M^{2+} + HY^{3-} \underset{k_{1b}}{\overset{k_{1f}}{\rightleftharpoons}} MY^{2-} + H^{+} \qquad (26)$$

The values of k_{1f} and k_{1b} for several metal ions are also given in Table II. The dissociation rate constant k_{1b} for chromium(II) is larger than any of those for other metal ions given in the table.

It was reported by Eigen[19,20] that the rate-determining step of the complex-forming reaction of many metal ions is the substitution of a water molecule from the coordination sphere of the metal ions.

$$M(H_2O)_x\cdots L \overset{k_{H_2O}}{\rightleftharpoons} ML\cdot(H_2O)_{x-1}\cdots H_2O \qquad (27)$$

The values of k_{H_2O} for many bivalent metal ions are given in references 19 and 20. Reaction 26 can be considered to proceed in several consecutive steps

$$\begin{aligned} M(H_2O)_x{}^{2+} + HY^{3-} &\overset{K_{ass.}}{\rightleftharpoons} M(H_2O)_x{}^{2+}\cdots HY^{3-} \\ &\overset{k_{H_2O}}{\rightleftharpoons} M(HY)(H_2O)_{x-1}{}^{-}\cdots H_2O \\ &\rightleftharpoons \cdots \rightleftharpoons MY(H_2O)_y{}^{2-} + (x-y)H_2O + H^{+} \end{aligned} \qquad (28)$$

The first step, an outer-sphere association, and the steps following the substitution of a water molecule are more rapid than the substitution step, and hence the overall rate constant, k_{1f}, can be written as

$$k_{1f} = K_{ass.}k_{H_2O} \qquad (29)$$

The outer-sphere association constant, $K_{ass.}$, is not considered to vary considerably with different metal ions of the same charge according to the theory of the ion association by Bjerrum,[21] and therefore, a parallelism is expected to exist between values of k_{1f} and k_{H_2O}. Actually the order of Ni(II) $<$ Co(II) $<$ Cd(II) $<$ Cu(II) $<$ Pb(II) and that of Co(II) $<$ Zn(II) for k_{1f} are the same as those for k_{H_2O} reported by Eigen. These orders can be

understood when the crystal field activation energies for the dissociation mechanism and the Jahn-Teller effect are considered.[20] Though the k_{H_2O} value for chromium(II) has not been reported, it is expected that k_{H_2O} for chromium(II) which has four d electrons is larger than those for nickel(II) and cobalt(II) from the view points of the crystal field activation energies and of the Jahn-Teller effect. Thus, it may be considered to be valid that the value of k_{1f} for chromium(II) obtained in this study is larger than those for cobalt(II) and nickel(II).

Polarographic and Potentiometric Studies of Indium(III)- and Europium(III)-Iminodiacetate Complexes

By Seizo MISUMI and Makoto AIHARA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received March 31, 1966)

The successive chelate formation constants for In(III)- and Eu(III)-IDA complexes were obtained by potentiometric titration and calculation by Bjerrum's method. The values of $\log K_1$ and $\log K_2$ for the In(III)-IDA complex are 9.54 and 8.87, and those for the Eu(III)-IDA complex are 6.22 and 4.72, respectively. The electrode reactions of these complexes were studied polarographically and found to be irreversible and diffusion-controlled. The ionic states of these complexes before reduction in the vicinity of the electrode surface were estimated to be $[InY_2(OH)]^{2-}$ or InY_2^- and $Eu(H_2O)_x^{3+}$. The rate constant, $(k_f^\circ)_B$, of the electron transfer for the Eu(III)-IDA complex was calculated to be 1.3×10^{-20} cm.sec^{-1}.

The polarography of complexes of some metal ions (e. g., zinc(II) and cadmium(II)[1]) with iminodiacetic acid (IDA) and the chelate formation constants of IDA complexes of rare earths[2] and some other metal ions[3] obtained by potentiometric titration have been investigated by serveral workers. In this paper, polarographic studies of indium(III)- and europium(III)-IDA complexes, of their electrode reaction, the rate constant, and the ionic state in the vicinity of electrode surface, are presented. The chelate formation constants for these complexes have also been determined by using Bjerrum's method.

Experimental

Reagents.—Stock solutions of indium(III) and europium(III) were prepared by dissolving metal perchlorates (more than 99.9% pure in distilled water; they were standardized volumetrically. The concentration of each stock solution was 0.01 M. Reagent-grade IDA (made by Wako Pure Chemical Industries) was used without any further purification.

A stock solution of monopotassium iminodiacetate (IDA-1K salt) was prepared by neutralizing IDA with a potassium hydroxide solution, and the concentration of IDA was adjusted to 0.5 M. A borate buffer (H_3BO_3-KCl-KOH) was used to adjust the pH of the solution. The ionic strength (μ) was adjusted with potassium chloride. A carbonate-free potassium hydroxide solution was prepared by the ion-exchange method.[4] All the other chemicals used were of an analytical reagent grade.

Apparatus.—A Yanagimoto PA-102 pen-recording polarograph was used to record the current-voltage curves. An H-type cell connected with a saturated calomel electrode (SCE) was used. The capillary used had a flowing weight, m, of mercury of 1.474 mg. sec^{-1} and a drop time, t_d, of 4.97 sec. drop^{-1} at the applied potential of -1.1 V. vs. SCE in an air-free 0.05 M IDA solution at a corrected height ($h_{corr.}$) of the mercury column of 68.41 cm. The measurement of the pH was made with a Hitachi pH meter, EHM-1 type. A titration apparatus consisting of a Horiba pH meter, P type, a titration vessel, and a thermostat was used. The titration vessel was a 150 ml. beaker fitted with a rubber stopper with holes for electrodes, a microburet, a thermometer, a gas inlet and outlet tubes; it was enveloped with a water jacket to maintain the solution at 25.0 ± 0.1°C during the measurements.

Procedure. — *Potentiometric Titration.*—Solutions of 1 : 1, 1 : 2, 1 : 3 and 1 : 5 ratios of metal ion to IDA were used. A sample solution was made up to 50 ml. or 100 ml., where the ionic strength was kept at 0.3 by the addition of potassium chloride. Purified nitrogen

gas was passed through the solution; the solution was meanwhile being stirred in order to remove any carbon dioxde from the solution. Then the solution was titrated with 0.1 N potassium hydroxide, and the pH was measured. All experiments were carried out at a constant temperature of 25.0±0.1°C.

Polarography.—To a solution indium(III) or europium-(III) containing an appropriate quantity of IDA, a borate buffer solution was added in order to adjust the pH to the required value. Potassium chloride was also added to keep an ionic strength of 0.3. The solution was prepared at 25.0±0.1°C, and purified nitrogen gas was passed through the solution for about 30 min. in order to remove any dissolved oxygen before a polarogram was recorded.

Results and Discussion

Potentiometric Titration.—The acid dissociation constant and the chelate formation constant were determined by the method outlined by Chabereck and Martel.[3]

The Dissociation Constant of IDA. — The dissociation constant of IDA was calculated by a direct algebraic method, using a titration curve. The values obtained were $pk_1=3.01$ and $pk_1=9.60$* at 25.0±0.1°C and $\mu=0.3$(KCl).

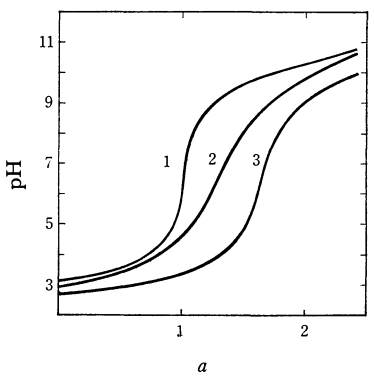

Fig. 1. Titration curves.
1) IDA, 2) $[Eu^{3+}]/[IDA]=1/3$,
3) $[In^{3+}]/[IDA]=1/5$
a=moles of base added per mole of acid.

The Chelate Formation Constant. — The chelate formation constant was calculated by using Bjerrum's method. In a solution with a 1 : 1 ratio of metal(III) to IDA, a hydrolytic buffer region appeared. However, from the solution with a 1 : 5 ratio of indium(III) to IDA or a 1 : 3 ratio of europium(III) to IDA, it disappeared, as Fig. 1 shows. The formation functions for In(III)- and Eu(III)-IDA complexes, plotted in Fig. 2, give a clear indication of the formation of

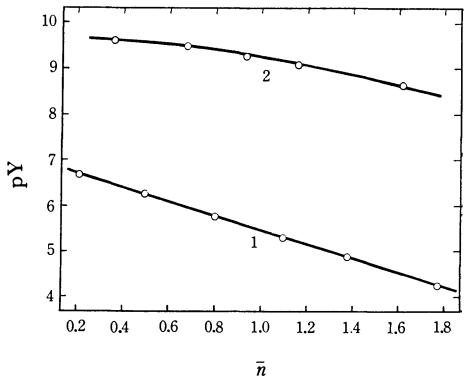

Fig. 2. Formation functions.
1) Eu(III)-IDA complex, 2) In(III)-IDA complex. $\bar{n}$=average number of donor groups bound per metal ion present. pY=negative logarithm of anion concentration, Y^{2-}.

the 1 : 1 and 1 : 2 complexes. The values of the successive chelate formation constants obtained are as follows:

	$\log K_1$	$\log K_2$
In^{3+}	9.54	8.78
Eu^{3+}**	6.22	4.72

Polarography.—Typical polarograms of In(III)- and Eu(III)-IDA complexes in borate buffer solutions are shown in Fig. 3.

Each complex ion shows a single reduction wave. The half-wave potentials for In(III)- and Eu(III)-IDA complexes shifted to the more negative side than that of the reduction wave of the corresponding metal aquo ion.

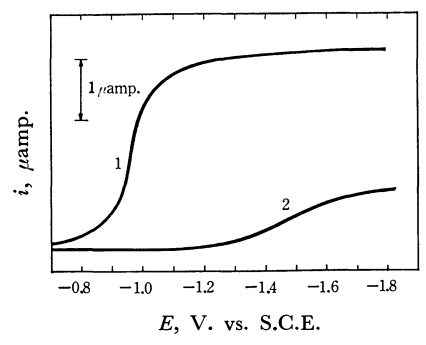

Fig. 3. Current-voltage curves of indium(III) and europium(III) in 0.05 M IDA solution.
1) $[In^{3+}]=0.5$ mM, pH=9.2; 2) $[Eu^{3+}]=0.5$ mM, pH=11.0

The Dependence of the Limiting Current on the Pressure of the Dropping Mercury Electrode.—The relation between limiting currents and various heights of the mercury column is shown in Table I.

* L. C. Thompson reported that $pk_1=2.58$ and $pk_2=9.33$ at 25°C and that $\mu=0.1$ (Ref. 2).

** L. C. Thompson: $\log K_1=6.73$ and $\log K_2=5.38$ (Ref. 2).

Table I. Dependence of limiting current on the height of mercury column

a) In(III)-IDA complex

$h_{corr.}$, cm.	i_l, μamp.	$i_l/\sqrt{h_{corr.}}$
53.41	2.828	0.395
63.41	3.144	0.395
73.41	3.372	0.394

0.5 mM In^{3+} in 0.05 M IDA medium, pH=9.2

b) Eu(III)-IDA complex

$h_{corr.}$, cm.	i_l, μamp.	$i_l/\sqrt{h_{corr.}}$
58.20	0.578	0.0757
63.21	0.604	0.0759
68.21	0.626	0.0758

0.5 mM Eu^{3+} in 0.05M IDA medium, pH=11.4

The values of $i_l/\sqrt{h_{corr.}}$ were found to be 0.395 ±0.001 μamp. $cm^{-1/2}$ for the In(III)-IDA complex and 0.0758±0.0001 μamp. $cm^{-1/2}$ for the Eu(III)-IDA complex. These results obviously indicate that the limiting currents for both In(III)- and Eu(III)-IDA complexes are diffusion-controlled.

Reversibility.—The reversibility of the electrode reaction for the In(III)- or the Eu(III)-IDA complex was verified by plotting log $i/(i_d-i)$ vs. E. As is shown in Table II, the mean values of the reciprocal slope for the In(III)-IDA complex and that for the Eu(III)-IDA complex were found to be 0.041 V. and 0.079 V. respectively. The mean values of αn were, therefore, 1.4 and 0.75 respectively, where α is the transfer coefficient and n, the number of electrons associated with the electrode reaction. Consequently, the electrode reactions for In(III)- and Eu(III)-IDA complexes were irreversible; three electrons change in the former, while one electron changes in the latter.

The Effects of the pH on Reduction Waves.—Polarograms were recorded with 0.5 mM Eu(III) or In(III) in 0.05 M IDA solutions at various pH's. The results are shown in Table II. The half-wave potential for the In(III)-IDA complex shifted to the more negative side as the pH increased from 9.2 to 10.6, whereas the half-wave potential for the Eu(III)-IDA complex was independent of the pH in the pH range from 9.2 to 12.0. The values of $d(-E_{1/2})_c/d\log C_{OH^-}$ calculated from the experimental data are as follows:

$$d(-E_{1/2})_c/d \log C_{OH^-} = 0.054$$

for the In(III)-IDA complex

$$d(-E_{1/2})_c/d \log C_{OH^-} = 0$$

for the En(III)-IDA complex

where $(E_{1/2})_c$ is the half-wave potential of complex ions and C_{OH^-} the concentration of hydroxyl ions.

The diffusion current for the In(III)-IDA complex decreased with an increase in the pH. It was supposed that the decrease in the diffusion current was caused by the precipitation of basic substances on the electrode. The diffusion current for the Eu(III)-IDA complex, on the other hand, was almost the same in the pH range from 10.0 to 12.0.

Table II. Effects of pH on reduction wave

a) In(III)-IDA complex

pH	$(E_{1/2})_c$ V. vs. SCE	i_d μamp.	Reciprocal slope mV.	αn
9.2	−0.977	3.244	39	1.5
9.5	−0.997	3.188	42	1.4
9.8	−1.020	3.032	42	1.4
10.2	−1.035	2.716	42	1.4
10.6	−1.057	1.744	42	1.4
		mean value	41	1.4

0.5 mM In^{3+} in 0.05 M IDA medium μ=0.3

b) Eu(III)-IDA complex

pH	$(E_{1/2})_c$ V. vs. SCE	i_d μamp.	Reciprocal slope mV.	αn
9.2	−1.427	0.552	74	0.80
9.8	−1.425	0.576	70	0.84
10.0	−1.425	0.620	82	0.72
11.0	−1.424	0.614	84	0.70
12.0	−1.426	0.616	83	0.71
		mean value	79	0.75

0.5 mM Eu^{3+} in 0.05 M IDA medium μ=0.3

The Effects of the Concentration of IDA on the Reduction Wave.—Polarograms were recorded in the range of the concentration of IDA from 5 mM to 50 mM at pH 9.2 for the In(III)-IDA complex and from 30 mM to 60 mM at pH 11.4 for the Eu(III)-IDA complex. The results are shown in Table III.

Table III. Effects of concentration of IDA on reduction wave

a) In(III)-IDA complex

Concn. of IDA mM	$(E_{1/2})_c$ V. vs. SCE	i_d μamp.	Reciprocal slope mV.	αn
5	−0.983	2.960	41	1.4
10	−0.987	3.188	42	1.4
25	−0.981	3.208	42	1.4
50	−0.980	3.224	40	1.5
		mean value	41	1.4

In^{3+}: 0.5 mM, pH=9.2 μ=0.3

b) Eu(III)-IDA complex

Concn. of IDA mM	$(E_{1/2})_c$ V. vs. SCE	i_d μamp.	Reciprocal slope mV.	αn
30	−1.378	0.630	77	0.77
40	−1.393	0.628	75	0.79
50	−1.411	0.604	76	0.78
60	−1.422	0.630	79	0.75
		mean value	77	0.77

Eu^{3+}: 0.5 mM, pH=11.4. μ=0.3.

The half-wave potentials for the In(III)-IDA complex were independent of the IDA concentration, but that for the Eu(III)-IDA complex shifted to the more negative side with an increase in the IDA concentration. Thus:

$$d(-E_{1/2})_c/d\log C_{IDA}=0 \text{ for the In(III)-IDA complex at pH 9.2}$$

and:

$$d(-E_{1/2})_c/d\log C_{IDA}=0.150 \text{ for the Eu(III)-IDA complex at pH 11.4,}$$

where C_{IDA} was the concentration of the complexing agent, IDA. The diffusion current for the In(III)-IDA complex increased with increasing IDA concentrations, while that for the Eu(III)-IDA complex was almost constant.

The Electrode Process and the Species of Complex in the Vicinity of the Electrode Surface. — If an irreversible electrode process for the metal M(III) complex takes place according to the following scheme:

$$MX_p^{3-pb} \rightleftarrows MX_q^{3-qb} + (p-q)X^{b-}$$
$$MX_q^{3-qb} + ne \rightarrow MX_q^{(3-qb-n)} \qquad (1)$$

where p is the maximum number of ligands (X^{b-}) attached to a metal ion in the bulk solution; q, the number of ligands attached to a metal ion in the vicinity of the electrode surface, and n, the number of electrons associated with the electrode reaction, an equation derived by Matsuda and Ayabe[5] for the current-voltage curve due to an irreversible electrode reaction of a complex ion is applicable. Therefore, as the electrode reaction of In(III)- or Eu(III)-IDA complex is irreversible and diffusion-controlled, the half-wave potential, $(E_{1/2})_c$, is given by Eq. 2[5]:

$$(E_{1/2})_c=2.3\frac{RT}{\alpha nF}[\log(k_f^0)_B f_{MX_p}/\sqrt{D_{MX_p}} + 0.5\log t_d - 0.053 - (p-q)\log(f_x D_x)] \qquad (2)$$

where $(k_f^0)_B$ is the forward reduction rate constant of the electron transfer process at the potential of the normal hydrogen potential; D_{MX_p}, the diffusion coefficient of the complex metal ion, MX_p^{3-pb}; t_d, the drop time; C_x, the concentration of the complexing agent, and f_{MX_p} and f_x, the activity coefficients of the complex metal ion and the complexing agent respectively. From Eq. 2, a plot of $-(E_{1/2})_c$ vs. $\log(f_x C_x)$ should produce a straight line with a slope equal to $(p-q)\ 2.3\ RT/\alpha n F$; the value of the tangent for $-(E_{1/2})_c$ vs. $\log f_x C_x$ is given by:

$$d(-E_{1/2})_c/d\log f_x C_x=(p-q)\ 0.0591/\alpha n$$

As the electrode reaction for the In(III)-IDA complex is an irreversible three-electron change ($n=3$) and is independent of the IDA concentration between 5 mM to 50 mM, the value of $(p-q)$ for OH in the case of the In(III)-IDA complex was calculated to be about 1, by using the observed value, 1.4, of αn in the pH range from 9.2 to 10.6. On the assumption that $p=2$ or $p=1$ for OH, for example, the $[InY_2(OH)]^{2-}$ or InY_2^- species would participate in the electron transfer process, where H_2Y indicates IDA. On the other hand, as the electrode reaction for the Eu(III)-IDA complex is irreversible, of a one-electron change ($n=1$), and independent of pH values from 9.2 to 12.0, the value of $(p-q)$ for IDA was calculated to be about 2, by using the observed value, 0.77, of αn in the range of the IDA concentration from 30 mM to 60 mM. Therefore, if it is assumed that $p=2$ for IDA, for example, the $Eu(H_2O)_x^{3+}$ species would participate in the electron transfer process, the transfer coefficient, α, being equal to 0.77.

The value of the forward rate constant, $(k_f^0)_B$, of the electron transfer process for the Eu(III)-IDA complex was calculated for the IDA concentration of 0.05 M with the value of the half-wave potential of -1.178 V. vs. NHE; a diffusion coefficient of the Eu(III)-IDA complex, D_{MX_p}, of 1.16×10^{-6} cm^2 sec^{-1}, and a drop time of 3.91 sec., provided that $f_{MX_p}=f_x=1$. The value obtained was:

$$\log(k_f^0)_B=-19.9 \quad (k_f^0 \text{ cm. sec}^{-1})$$

In conclusion, the above results indicate that the species which participate directly in the electron transfer process are mainly $[InY_2(OH)]^{2-}$ or InY_2^- and $Eu(H_2O)_x^{3+}$.

Studies of Scandium in Various Solutions. III. The Solvent Extraction and Complex Formation of Scandium(III) with Acetylacetone and Thenoyltrifluoroacetone

By Tatsuya SEKINE, Akira KOIZUMI and Mitsuo SAKAIRI

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received April 13, 1966)

The distribution of scandium(III) at a tracer concentration was determined between chloroform with acetylacetone or thenoyltrifluoroacetone and 0.1 M aqueous perchlorate solutions at 25°C. The change in the distribution ratio of the metal ion with the change in the chelating acid concentration or with the change in the hydrogen-ion concentration was explained in terms of the extraction of the tris chelate complexes into the organic phase and the formation of the primary complexes in the aqueous phases. The equilibrium constants in these systems were determined graphically, by a curve-fitting method to be as follows:

$$K_{ex}=[ScA_3]_{org}[H^+]^3/[Sc^{3+}][HA]^3_{org}$$

$$K_1=[ScA^{2+}]/[Sc^{3+}][A^-]$$

HA	Acetylacetone	Thenoyltrifluoroacetone
$\log K_{ex}$	−6.35	−1.30
$\log K_1$	8.3	7.1

Acetylacetone (AA) and thenoyltrifluoroacetone (TTA) in various organic solvents have been used for the extraction of scandium(III) in aqueous solutions.[1-5]

For the present paper, the authors studied the distribution of trace amounts of scandium(III) between chloroform solutions of AA or TTA and aqueous solutions of 0.1 M (Na, H)ClO_4 at 25°C; they also determined the extraction constants and the stability constants of scandium(III) aqueous complexes with these β-diketones.

Statistical Treatment

The distribution equilibrium of scandium(III) in an aqueous phase into an immiscible organic phase with an organophilic chelating acid, HA, may be described as follows:

$$Sc^{3+} + 3HA(org) \rightleftarrows ScA_3(org) + 3H^+ \quad (1)$$

$$K_{ex} = [ScA_3]_{org}[H^+]^3/[Sc^{3+}][HA]^3_{org} \quad (2)$$

In the equations, the subscript *"org"* denotes a species in the organic phase, while the absence of a subscript denotes a species in the aqueous phase.

The concentration of scandium in the two phases may be determined radiometrically, and the net distribution ratio may be defined as:

$$D = [Sc(III)]_{org,total}/[Sc(III)]_{total} \quad (3)$$

When it is assumed that (i) scandium(III) exists in the aqueous phase only as Sc^{3+} or as the chelate complexes, ScA^{2+}, ScA_2^+,⋯, and that (ii) scandium(III) exists in the organic phase only as the neutral tris chelate complex, ScA_3, the net distribution ratio in Eq. 3 may be described as:

$$D = [ScA_3]_{org}/([Sc^{3+}]+[ScA^{2+}]+[ScA_2^+]+\cdots) \quad (4)$$

The statistical treatment of the distribution ratios may then be carried out by applying the law of mass action.[6]

The complex formation equilibria in the aqueous phase may be described as:

$$Sc^{3+} + nA^- \rightleftarrows ScA_n^{3-n} \quad (5)$$

$$\beta_n = [ScA_n^{3-n}]/[Sc^{3+}][A^-]^n \quad (6)$$

By introducing Eqs. 2 and 6 into Eq. 4, the following equation is obtained:

$$D[H^+]^3[HA]^{-3}_{org} = K_{ex}/(1+\beta_1[A^-]+\beta_2[A^-]^2+\cdots) \quad (7)$$

The chelating acid is distributed between the two phases as:

$$HA \rightleftarrows HA(org) \quad (8)$$

$$K_D = [HA]_{org}/[HA] \quad (9)$$

6) J. Rydberg, *Acta Chem. Scand.*, **4**, 1503 (1950).

The chelating acid may dissociate in the aqueous phase as:

$$HA \rightleftarrows H^+ + A^- \quad (10)$$

$$K_a = [H^+][A^-]/[HA] \quad (11)$$

When a certain volume of an organic phase with the chelating acid at an initial concentration, $[HA]_{org,initial}$ is equilibrated with an aqueous phase of the same volume, the following equation holds:

$$[HA]_{org,initial} = [HA]_{org} + [HA] + [A^-] \quad (12)$$

From Eqs. 9, 11 and 12, the following equations can be introduced:

$$[A^-] = [HA]_{org,initial}/(1+K_a^{-1}[H^+] + K_D K_a^{-1}[H^+]) \quad (13)$$

$$[HA]_{org} = [HA]_{org,initial}/(1+K_D^{-1} + K_D^{-1}K_a[H^+]^{-1}) \quad (14)$$

Thus, the values $[A^-]$ and $[HA]_{org}$ at the equilibrium can be calculated from the initial concentration of the chelating acid in the organic phase, the hydrogen ion concentration, and the two equilibrium constants, K_D and K_a. The extraction constant and the stability constants of the scandium complexes may then be determined by introducing these values into Eq. 7.

Experimental

Reagents.—Scandium-46 was obtained from the New England Nuclear Co., U. S. A., as a hydrochloric acid solution. This was diluted with 0.1 M perchloric acid and used as the stock solution. All of the reagents were of a reagent grade. Acetylacetone and thenoyltrifluoroacetone were obtained from Dojindo & Co., Ltd. The sodium perchlorate was recrystallized two times from water. The chloroform was washed three times with water. The other reagents were used without further purification.

Procedures.—All of the procedures were carried out in a thermostatted room at 25±0.5°C. Stoppered glass tubes (volume: 20 ml.) were employed to equilibrate the two phases. The tracer solution, a buffer solution, a 0.1 M sodium perchlorate solution, and finally a chloroform solution of acetylacetone or thenoyltrifluoroacetone were placed in the tubes. Sulfanilate or pyridine (the initial concentration was 0.01 M) was used as the buffer. In some experiments, the scandium tracer in the aqueous phase was first extracted with the chelating acid into the organic phase and the scandium in the organic phase was back-extracted into fresh aqueous solutions. The initial volume of the two phases was always 5.0 ml., and the initial concentration of scandium in either the aqueous or the organic phase was 6×10^{-5} M.

The two phases in the tubes were agitated by a mechanical rotator for more than one hour and centrifuged at 2000 r. p. m. for three minutes. A 2-ml. portion was then pipetted from both the phases and transferred into small test tubes. The γ-radioactivity of the solutions was measured with a well-type (NaI) scintillation counter. A small portion was also taken from the aqueous phase, and the hydrogen ion concentration was measured potentiometrically, using 0.010 M perchloric acid +0.09 M sodium perchlorate as the standard of $-\log [H^+]=2.000$.

Results

Figures 1 and 2 give the distribution ratio of scandium(III) in the acetylacetone (AA) systems or the thenoyltrifluoroacetone (TTA) systems at various hydrogen ion concentrations. Figure 1 shows the log$D$ vs. $-\log [H^+]$ plot when the initial concentration of the chelating acids in the organic phase is 0.100 M while Fig. 2 gives the log$D$ $[H^+]^3$ vs. log $[HA]_{org}$ plot when the initial concentration of the chelating acid is different. In Fig. 1, the open circles give the data obtained when the tracer was initially added to the organic phase. The straight line of slope three in the figures are the calculated distribution curves obtained from the extraction constants, K_{ex}, in Table II.

The K_D and K_a values for AA and TTA which appear in the literature were introduced into Eqs. 13 and 14. The equations thus obtained are given in Table I.

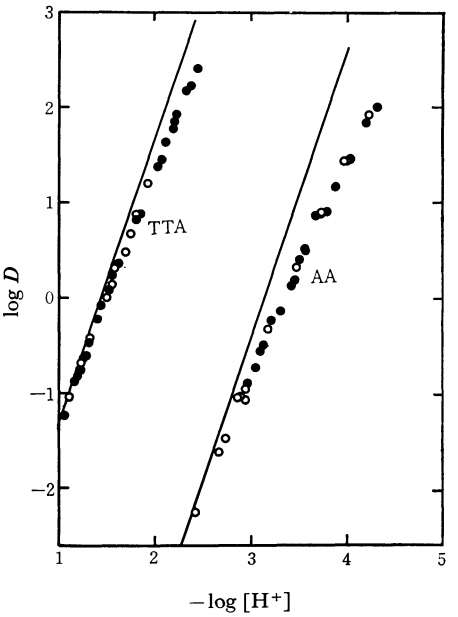

Fig. 1. Distribution of Sc(III) between chloroform with 0.1 M (initial concentration) chelating acid and 0.1 M (Na, H)ClO_4 at 25°C as a function of $-\log [H^+]$.
Open circles; extraction of Sc(III) in the aqueous phase into the organic phase.
Closed circles; back-extraction of Sc(III) in the organic phase into the aqueous phase.
The straight line for the TTA plot is $\log D = -3\log [H^+] - 4.32$ and that for the AA plot is $\log D = -3\log [H^+] - 9.44$.

$\log K_1$	8.3_2	7.1_4

7) J. C. Reid and M. Calvin, *J. Am. Chem. Soc.*, **72**, 2948 (1950).

Figures 3 and 4 give $\log D\,[H^+]^3[HA]^{-3}_{org}$ vs. log[A⁻] plot calculated from the data in Figs. 1 and 2 and Table I.

From Eq. 7, the following equation is obtained:

$$\log D[H^+]^3[HA]^{-3}_{org} = \log K_{ex} - \log(1+\beta_1[A^-] + \beta_2[A^-]^2+\cdots) \quad (15)$$

Equation 15 shows that the $\log D\,[H^+]^3[HA]^{-3}_{org}$ vs. log[A⁻] plot will be found to fit one of the family of standard curves[8-10]:

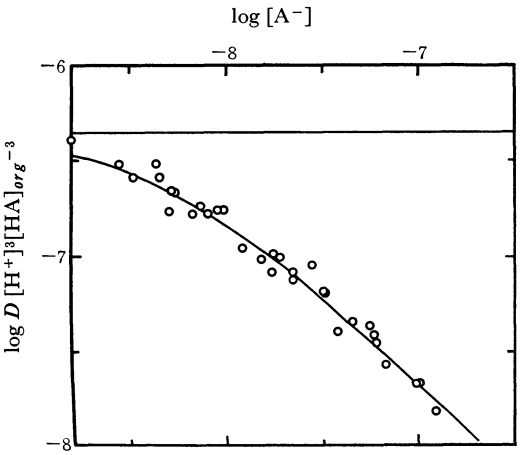

Fig. 3. Change in the extraction constant of Sc(III) with AA as a function of the concentration of the dissociated chelating acid in the aqueous phase.
The solid curve shows $\log D\,[H^+]^3[HA]^{-3}_{org}$ vs. $-\log(1+2.0\times10^8[A^-])$.

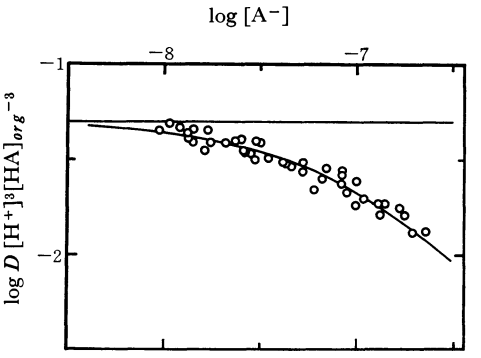

Fig. 4. Change in the extraction constant of Sc(III) with TTA as a function of the concentration of the dissociated chelating acid in the aqueous phase.
The solid curve shows $\log D\,[H^+]^3[HA]^{-3}_{org}$ vs. $-\log(1+1.3\times10^7[A^-])$.

10) T. Sekine and Y. Hasegawa, This Bulletin, **39**, 240 (1966).

$$\left.\begin{aligned} X &= \log v \\ Y &= -\log(1+\sum_{n=1}^{n} p_n v^n) \end{aligned}\right\} \quad (16)$$

After several trials, it was found that both of the plots in Figs. 3 and 4 fit the standard curve $X=\log v$; $Y=\log(1+v)$. The best-fit constants obtained from the curve-fitting are listed in Table II. The solid curves in Figs. 3 and 4 show the statistical curves calculated from these constants.

Discussion

In the present study, the aqueous phase was always 0.1 M (Na, H)ClO_4, and the hydrogen ion concentration was larger than 10^{-4} M. Therefore, the hydrolysis of Sc^{3+} in the aqueous phase may not be very much, because the hydrolysis constant of scandium in 0.1 M ($NaClO_4$) at 25°C was reported to be $[ScOH^{2+}][H^+][Sc^{3+}]=10^{-4.74}$.[11] The formation of polynuclear complexes may be negligible because the total concentration of scandium in the aqueous phase is less than 6×10^{-5} M; thus, Assumption i described in the previous section, may be valid in the present systems. The scandium complexes in the organic phase may be in the ScA_3 form in both the AA and TTA systems, because no remarkable deviation of the plot in Figs. 2 to 4 is observed even when the organic concentration of the chelating acid is larger or smaller than 0.1 M (cf. Ref. 5). Thus, it may be concluded that Assumption ii is also valid in the present systems. The distribution ratios obtained both by the extraction from the aqueous phase and by the back-extraction from the organic phase agree within the range of experimental error; this may indicate that the distribution equilibrium of scandium is established under the present experimental conditions.

The plots in Figs. 3 and 4 scatter somewhat from the fitted curve given by a solid curve, and as a result the limit of the error of the constants will be rather large. Therefore, the $\log K_{ex}$ are given to three figures, while the $\log\beta_1$ are given to only two figures.

Starý[12] listed the extraction constants of scandium(III) into benzene with AA ($\log K_{ex}=-5.83$) and TTA ($\log K_{ex}=-0.77$).

Wakahayashi, Oki, Omori and Suzuki[13] studied the distribution of scandium(III) chelate into various solvents. They reported that the net distribution ratio of scandium(III) between chloroform and 0.1 M (Na, H)ClO_4 was $\log D=0.41$ for the AA chelate and $\log D=-0.54$ for the TTA chelate when $-\log[A^-]=7.80$. Their figure for the TTA chelate seems to agree with the present results, but their value for the AA chelate seems to be a little higher. They did not give any constants for the complex formation in the aqueous phase.

Izatt and his co-workers[14] gave the stability constants for the AA complexes of scandium(III) at zero ionic strength and at 30°C as $\log K_1=8.0$ and $\log K_2=7.2$ ($\log\beta_2=15.2$). The $\log K_1$ in their work is of the same order as that in the present work, but the formation of a secondary complex of the $\log\beta_2$ around 15 can not be concluded from the present results (cf. Fig. 3).

No stability constant for scandium TTA complexes seems to have been reported.

Part of this work was carried out at the Laboratory of Nuclear Chemistry, the Institute of Physical and Chemical Research, Tokyo. The authors are very grateful to Professor Nobufusa Saito, the head of that Laboratory. The authors are also very grateful to Mr. Ichiro Kobayashi and Mr. Ichiro Sakamoto of the present laboratory for their experimental aid.

Faculty of Science, The University of Tokyo, Hongo Tokyo

(Received April 14, 1966)

The excitation curve for the $^{14}N(p, \alpha)^{11}C$ reaction was measured up to a proton energy of 15 MeV.; the reaction was found to have a fairly high cross section for a sensitive determination of nitrogen by radioactivation. A convenient technique was developed for the rapid quantitative conversion of the irradiated graphite into carbonate within a closed system. This technique makes possible the determination of a trace (down to several p.p.b.) of nitrogen in pyrolytic graphite. Discussions of the possible interference (i. e., that of boron by the $^{11}B(p, n)^{11}C$ reaction) will also be given. The nitrogen content of the pyrolytic graphite sample was found to vary markedly according to the starting material and to the preparation conditions.

The development of reliable methods for determining an ultra-trace quantity of nitrogen has been required because of its ultimate importance in the physicochemical study of hyper-pure substances, especially of semiconductor materials. Previously, we reported, in a short communication,[1] that radioactivation analysis by means of the $^{14}N(p, \alpha)^{11}C$ reaction is useful for determining a trace quantity of nitrogen in pyrolytic graphite for semiconductors. In this paper, the excitation curve for the $^{14}N(p, \alpha)^{11}C$ reaction, a detailed description of the chemical process, and some results of the determination will be given, along with a discussion of the possible interferences.

Pyrolytic graphite is prepared by the thermal decomposition of an organic vapor, the carbon from the organic substance depositing onto a heated substrate to give gradually a crystalline, lustrous plate with profitable semiconductor characteristics. The pyrolytic graphite prepared from pyridine was found to have fascinating semiconductor properties.[2] The presence of a trace quantity of nitrogen is considered to give it these properties.

As is shown in Table I, all previously-reported methods are unsatisfactory for determining a trace of nitrogen in graphite; they are either inapplicable to the matrix or are of insufficient sensitivity. Further, since nitrogen is abundant in air, the sample surface, the analytical reagents and apparatus are always contaminated with it. The present method is of a very high sensitivity (a few p.p.b. of nitrogen) and is free from the contamination effect. Further, because of its extreme thermal stability, pyrolytic graphite is a suitable matrix to be analyzed by charged-particle activation; a sample with less thermal stability is apt to melt or decompose during the irradiation.

A chemical process involving a rapid quantitative decomposition of the irradiated graphite is necessary, as will be explained later. Since pyrolytic graphite is quite resistant to chemical attack, some ingenuity is required for the decomposition. The technique described in this paper is not only suitable for the present purpose, but is useful also for the rapid quantitative decomposition of many kinds of substances within a closed system.

The Excitation Curve for the $^{14}N(p, \alpha)^{11}C$ Reaction, and a Discussion of Possible Interferences

The excitation curve for the $^{14}N(p, \alpha)^{11}C$ reaction up to 15 MeV. was measured by the stacked-foil method; the results are given in Fig. 1. Because of the possible error involved in the proton-beam monitoring and in the absolute activity measurements, the absolute value of the cross section is less certain than the shape of the excitation curve, although the uncertainty must be within 20%. The mean recoil range of the ^{11}C produced by 14.2 MeV. protons was also measured by inserting a recoil catcher in the stack; it was found to be 0.36 mg./cm^2.

The irradiation of carbon itself with 15 MeV.

protons gives no ^{11}C, since the threshold for the $^{12}C(p, pn)^{11}C$ reaction is 20.2 MeV. There is, however, another reaction, namely, $^{11}B(p, n)^{11}C$, which gives ^{11}C on the proton irradiation.[3] Figure 2 shows the thick-target saturation activity of ^{11}C produced by irradiating carbon containing 1 p.p.m. (by weight) of nitrogen or of boron (natural isotopic composition) with a 1 μamp. proton beam. Figure 3 shows the ratio of the ^{11}C activity formed from nitrogen to that formed from boron, when a thick matrix containing equal amounts (weight fraction) of the two elements is irradiated with protons. The thick-target yield varies with the nature (the stopping power) of the matrix, but the ratio is almost independent of it.

As is evident from Fig. 2 and Fig. 3, in the presence of boron nitrogen cannot be determined by proton activation in a single irradiation. Alternately, two irradiations at different proton energies, followed by the solution of the pair of simultaneous equations thus obtained, do not seem to

3) M. Furukawa, Y. Ishizaki, Y. Nakano, T. Nozaki, Y. Saji and S. Tanaka, *J. Phys. Soc. Japan*, **15**, 2167 (1960).

give accurate results. By radioactivation analysis using the $^{10}B(d, n)^{11}C$ reaction, an ultra-trace quantity of boron can be determined in the presence of nitrogen. However, this method is not suitable for the graphite matrix because of the simultaneous formation of a very high activity of ^{13}N due to the $^{12}C(d, n)^{13}N$ reaction.

Fortunately, however, the determination of a trace of boron in graphite has been well studied because of its importance in nuclear engineering. Both direct spectrography[4] and spectrography or spectrophotometry after ashing the sample in the presence of calcium oxide or lanthanum oxide[5,6] are useful. In the latter process, the methods developed for determining an ultra-trace quantity of boron in transistor-grade silicon[7] or in germanium are also applicable with slight modifications. Hence, it appears preferable to determine boron by one of the above method prior to the proton activation.

It was certain, however, that most of our present samples contained much less boron than nitrogen, because they were prepared from pyridine. Hence, without the prior determination of boron, their nitrogen content could be determined reliably.

The Elimination of the Surface Contamination

Surface contamination is easily eliminated by removing a surface layer of a suitable, uniform thickness after the irradiation. The layer thickness depends on the recoil range of the radio-nuclide and on the roughness of the initial surface. It has been shown previously that a surface layer of about 5 times the thickness corresponding to the recoil range should be removed.[8] Hence, for the present case, a surface layer about 1.8 mg./cm^2 thick should be removed. However, since the uniform removal of such a thin surface is difficult and since the initial surface roughness is not precisely known, it is considered preferable to grind off a surface layer of a greater thickness (5 to 10 mg./cm^2).

Chemical Process

The nuclide ^{11}C has a 20.4 min. half-life and emits positrons but no γ-rays. The proton irradiation of carbon gives a high activity of ^{13}N by the $^{13}C(p, n)^{13}N$ reaction,[9] the abundance of ^{13}C being 1.1%. ^{13}N also emits positrons and has a 10.0 min. half-life. Many kinds of impurities also give positron emitters on proton irradiation. Therefore, a trance of nitrogen in graphite cannot be determined by nondestructive γ-ray spectrometry; a chemical purification of the ^{11}C involving a rapid decomposition of the sample is required. In the purification, the matrix graphite itself is the carrier of ^{11}C.

After the irradiation with charged particles, the radionuclide formed is not distributed uniformly in the sample, and the radiation effect might have changed the chemical reactivity of the irradiated portion. Therefore, a quantitative treatment of the pyrolytic graphite involving its oxidation under drastic conditions is required until a homogeneous phase containing all of the carbon is obtained.

Wet oxidation in a mixture of sulfuric and condensed polyphosphoric acid provided a useful method of decomposing the sample. Kiba and his associates[10] describe the stoichiometrical oxidation of charcoals and naturally-occurring graphite with potassium iodate in condensed polyphosphoric acid. For the present purpose, the technique they described should, however, be slightly modified, because pyrolytic graphite is more resistive to oxidation than charcoals and graphites of other sources, and because a larger quantity (up to 1 g.) of the sample should be oxidized. The following modifications proved to be convenient: (1) a mixture of sulfuric and condensed polyphosphoric acid was used as the oxidation medium[11]; (2) a small quantity of perchloric acid was added near the end of the oxidation; and (3) the reaction temperature was raised slowly but continuously in the course of the reaction. Without these modifications, the oxidation was often incomplete with the formation of the so-called graphitic acid, which was still less oxidizable than the graphite itself. The fine pulverization of the sample with the aid of added alumina or silica[10] was of ultimate importance for the smooth oxidation. The perchloric acid, oxidizing the deep-colored molecular iodine formed in the reaction, was effective also in facilitating the observation of the reaction from outside.

The equipment shown in Fig. 4 was devised for oxidizing the graphite and absorbing quantitatively the carbon dioxide formed to yield a homogeneous phase. The oxidation and the absorption were carried out in a closed system. The absorbed carbon dioxide was further purified, because it probably contained such radiochemical impurities as were distilled from an oxidizing medium.

It was then converted into barium carbonate for activity and recovery measurements. The details concerning the operation of the equipment are given in the Experimental Section.

It took 40 to 50 min. for the barium carbonate to be obtained after the irradiation. Its radiochemical purity was so high that a satisfactory decay curve was obtained by measuring the annihilation radiation with a simple scintillation counter.

The Calculation of the Nitrogen Content

For a sample of a given nitrogen content (e. g., 1 p. p. m.), the absolute ^{11}C-activity induced in it can be calculated by the use of the integral excitation curve (Fig. 2) when the sample thickness, the initial proton energy, the proton-beam current, and the irradiation duration are known. Also, the absolute ^{11}C-activity contained in the analyzed sample (at the end of the irradiation) can be calculated by the use of the measured activity and recovery and of the counting efficiency. The above two calculations were made for each sample, and its nitrogen content was obtained from the resultant values.

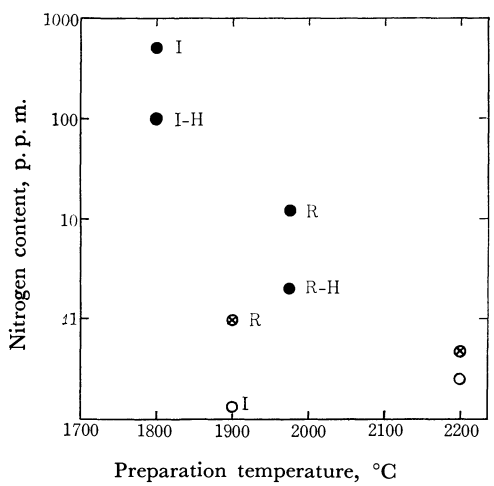

Fig. 5. Nitrogen content of the pyrolytic graphite.
●: Prepared from pyridine ; ○: Prepared from propane; ⊗: Prepared from propane in nitrogen atmosphere.
I : By induction heating ; R : By resistance heating ; −H: Heat-treated.

The Results of the Analysis

Some of the analytical results are given in Fig. 5. Figure 6 shows the decrease in nitrogen content on heat treatment, in which samples prepared from pyridine at 2150°C were kept at 2300°C in a nitrogen atmosphere (ca. 10 cmHg). Although the interference of boron should be taken into account for the sample with a low nitrogen content, the following facts can be derived unambiguously:

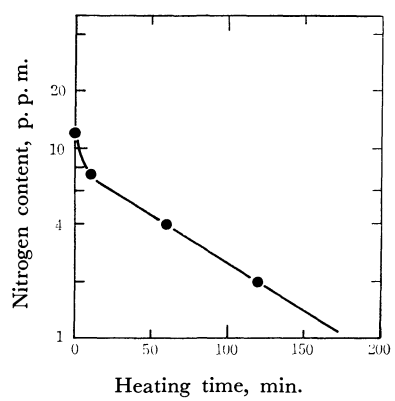

Fig. 6. Escape of the nitrogen on heat treatment.

(1) the sample from pyridine contains much more nitrogen than that from propane; (2) the presence of nitrogen gas in the preparation of pyrolytic graphite from propane does not make the nitrogen concentration in the product markedly higher; (3) the nitrogen concentration in the sample from pyridine depends on the temperature of the preparation—the higher the temperature, the lower the content; and (4) when the sample from pyridine is heated, the nitrogen content decreases.

Experimental

The Measurement of the Excitation Curve.—Nylon films of a known thickness (ca. 20 mg./cm^2) with thin aluminum foils (also of a known thickness) on both sides of each film were stacked. The stack was bombarded with a proton beam (15 MeV., 0.1 μamp.) from the cyclotron of the Institute for Nuclear Study, The University of Tokyo, for 1 min., the integrated beam current being read by an integrator. Each of the nylon films with the aluminum foils was sandwiched between bronze plates (ca. 3 mm. thick) for counting. The annihilation radiation from each sandwich was measured by a scintillation counter with a single channel analyzer, whose counting efficiency was calibrated with a standard ^{22}Na source. By following the decay, the sample activity was found to consist only of ^{11}C and ^{13}N. Thus, after the analysis of decay curve, the cross section of the ^{14}N(p, α)^{11}C reaction was calculated for each of the films.

The energy loss[12] (in MeV.·cm^2/g.) of charged particles in a compound is regarded as the sum of that in each element making up the compound in proportion to its weight fraction (the additivity rule). However, when the proton energy at each of the nylon films was calculated by the use of the additivity rule, an unreasonable result was obtained: the reaction appeared to have a considerably large cross section for proton energies below its threshold. There are two possible explanations of this result: (1) an incorrectness in the additivity rule for compounds consisting of light elements, especially for those containing hydrogen, or (2) a change in the thickness of the films in the course of the irradiation. No apparent thickness change, however, was observed in the irradiated part of the film. Hence, the value given by the additivity rule was slightly modified and used for the present calculations.

A more reliable experiment was undertaken by the use of a stack consisting of aluminum nitride films and aluminum foils. Fine powder of aluminum nitride was suspended in acetone, and allowed to deposit onto an aluminum foil of a known thickness to form a uniform film with the aid of a small, known quantity of polyvinyl acetate as a binder. The thickness of film was determined from its weight and area. Two stacks were bombarded with proton beams of different initial energies. The excitation curves obtained by the use of the stack material and of the additivity rule for the proton energy loss are of a reasonable form, agreeing with Blaser's result in the low-energy region.[13]

12) R. M. Sternheimer, *Phys. Rev.*, **115**, 137 (1959).

The Preparation of the Pyrolytic Graphite.—In a stream of propane or pyridine vapor (4 to 7 mmHg), a substrate plate was heated (1800 to 2200°C) by direct current (resistance heating) or by induction. The pyrolytic graphite grew at a rate of 50 to 300 μ/hr. The sample preparation from propane was also carried out in the presence of nitrogen (6 to 10 mmHg).

Irradiation, and the Removal of the Surface Contamination.—A rectangular window (10 mm.× 20 mm.) was cut in a metal plate thick enough to stop the protons. A graphite plate (0.4 to 2.0 mm. thick) slightly larger than the window was placed between a water-cooled target holder and the window of the metal plate, well in contact with both. It was then irradiated with a deflected proton beam (14 MeV., 10 μamp., 10 min.), the beam current being recorded. Since a part of the beam impinged on the metal plate at the edges of the window, the activity induced in it was measured and compared with that obtained on irradiating the metal plate without a window under the same conditions. Thus, the beam flux received by the sample itself was determined.

The sample surface was removed as uniformly as possible by grinding on a flat plate with the aid of fine alundum powder (both sides for a thin sample, one side for a thick sample). The thickness of the surface layer removed was determined by measuring the surface area and the loss of weight. The sample was then pulverized in a tall iron mortar in the presence of alumina powder (ca. 1 g.).

The Chemical Process.—In Fig. 4, A and B were for supplying a suitable pressure, while C was for generating nitrous fumes (gas formed on treating sodium nitrite with sulfuric acid).

Condensed polyphosphoric acid convenient for the present purpose was prepared by heating orthophosphoric acid up to 300°C during 40 min. and keeping it at 300°C for 20 min. The condensed polyphosphoric acid (50 ml.), sulfuric acid (35 ml.) and potassium iodate (25 g.) were added into D (500-ml. three-necked flask), and the mixture was heated gently. Into E (1-l. three-necked flask) were added carbon tetrachloride (300 ml.), carbonate-free sodium hydroxide solution (1.5 N, 200 ml.), and petroleum benzine (a few milliliters) to form three layers. When the temperature of the mixture in D reached 160°C, the air in D and E was replaced by nitrous fumes streaming from P1 to P4. After P1 and P4 had been closed, the stopper of the central neck of D was momentarily opened, and the pulverized sample was quantitatively added through the neck. Gentle heating was continued.

When oxidation began, a part of the carbon tetrachloride was pushed into F. Then E was shaken from outside to remove the petroleum benzine layer by being absorbed in the carbon tetrachloride beneath the sodium hydroxide solution. When the evolution of carbon dioxide became feeble even at 230°C, perchloric acid (60%; less than a few milliliters) was carefully dripped into D. A gentle shaking of D and E was necessary throughout to cause the oxidation process to proceed smoothly. When all of the sample had been oxidized, P1 was opened and the carbon dioxide remaining in D was carried into E with nitrous fumes.

13) J. P. Blaser, P. Marmier and M. Sempert, *Helv. Phys. Acta*, **25**, 442 (1952).

Without A and B, neither the sulfuric acid not the perchloric acid could be added smoothly. Without the replacement of air by nitrous fumes, the air expelled most of the sodium hydroxide solution into F before the carbon dioxide came into E. The nitrous fumes also served as a hold-back carrier for ^{13}N. Without the benzine layer, nitrous fumes were freely absorbed by the sodium hydroxide before the commencement of oxidation, and air entered E from F. The determination of the carbonate in E proved that the quantitative conversion of the graphite sample into the carbonate had taken place.

Hydrazine hydrate (60%; 20 ml.) and hydrochloric acid (2 N; 200 ml.) were successively added to E from F, with P3 open and P2 closed. The carbon dioxide thus evolved was caught by carbonate-free sodium hydroxide solution (1.5 N; 100 ml.) in G. The heat of neutralization evolved in E effectively caused the carbon dioxide to be forced into G, the vapor of benzine and carbon tetrachloride filling the vacancy in E. The solution in G was added to a hot solution of barium chloride (0.5 N, an amount equivalent to the sample carbon), and the barium carbonate was filtered off with suction and washed with hot water. The recovery of the sample carbon was determined gravimetrically after the activity measurement.

The Activity Measurement.—The annihilation radiation of ^{11}C in the barium carbonate was measured by a calibrated scintillation counter with a single channel analyzer. The decay of the barium carbonate activity was followed to ascertain the radiochemical purity. Also, the γ-ray spectra of some of the barium carbonate samples were measured by a multi-channel analyzer to ascertain the absence of γ-rays other than the annihilation radiation.

The authors wish to express their gratitude to Professor Ken-ichi Takeya and Dr. Kazuhiko Yazawa of the University of Electrocommunication for their kind encouragement. They are also indebted to members of the Semiconductor Research Group of the same university for their aid in the analytical practice, and to the cyclotron crew of the Institute for Nuclear Study, The University of Tokyo, for help in the cyclotron irradiation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2690—2695 (1966)

A Geochemical Study of Iodine in Volcanic Gases

By Fumihiro HONDA, Yoshihiko MIZUTANI, Tsutomu SUGIURA and Shinya OANA

Institute of Earth Science, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received May 20, 1966)

Volcanic gases from several active volcanoes in Japan have been analyzed for iodine and chlorine: Showashinzan (I=0.025—0.20 mg.I/kg.H_2O, Cl=238—1830 mg.Cl/kg.H_2O), Iwatesan (I=0.053—0.19, Cl=2720—3360), Issaikyoyama (I=0.030—0.087, Cl=104—213), Nasudake (I=0.16—3.9, Cl=188—9460), Yakedake (I=0.58—0.93, Cl=1250—1730), Kuju-Ioyama (I=0.13—1.3, Cl=266—8000), Kirishima-Ioyama (I=0.036—0.84, Cl=200—4200), and Miharayama (I=0.45—1.5, Cl=1640—2180). Each volcano has a characteristic I/Cl ratio. Analyses have also been made of hot-spring waters from the environs of Nasudake, Kuju-Ioyama, and Kirishima-Ioyama. It is indicated that the hot-spring waters are similar in I/Cl ratio to the volcanic gases from the same area.

In a previous paper,[1] the abundance and the behavior of halogens in the volcanic gases were investigated. As to the iodine, however, some uncertainties remained because of the paucity of analytical data. For this paper, the iodine and chlorine contents of volcanic gases from eight active volcanoes in Japan (Showashinzan, Iwatesan, Issaikyoyama, Nasudake, Yakedake, Kuju-Ioyama, Kirishima-Ioyama, and Miharayama) have been investigated.

The iodine and chlorine contents of some hot-spring waters around Nasudake, Kuju-Ioyama, and Kirishima-Ioyama have also been investigated in order to examine the similarity in I/Cl ratio between hot-spring waters and volcanic gases from the same area.

Experimental

The Sampling of Volcanic Gases.—Through a glass tubing inserted into the fumarole, volcanic gases were introduced into a cold trap, in which the water vapor in the gases was condensed; the halogens were completely dissolved in the condensed water.[1] The solution was then subjected to the following analyses.

The Determination of Iodine and Chlorine.—The methods for the determination of these elements are:

* These samples were given by K. Noguchi at Tokyo Metropolitan University.

Cl Mercuric thiocyanate[2]

I The catalytic oxidation of $FeSCN^{2+}$ [3]

Most of the samples contained an appreciable amount of sulfide which interferes with both chlorine and iodine analyses. Accordingly, samples were heated with sodium carbonate and hydrogen peroxide in order to oxidize the sulfide to sulfate.[2] The solution was then subjected to the above-mentioned analyses.

Continuous Observation of the Iodine and Chlorine Contents of Volcanic Gases.—Continuous observations over a short period (3—5 hr.) were made in order to examine the constancy in iodine and chlorine contents of volcanic gases from several fumaroles of Showashinzan and Nasudake. Samples were collected from a fumarole at about 20-min. intervals. In each sampling time, each about 15 min. long, about 100 ml. of condensed water was collected.

Results

The analytical results are listed in Tables I to III, while the sampling sites of the volcanic gases and hot-spring waters are shown geographically in Fig. 1.

Discussion and Conclusion

The following facts may be seen in Tables I to III:

1) The I/Cl ratio (in weight) of volcanic gases ranges from 10^{-3} to 10^{-5}. Most of the samples, however, have values from 10^{-3} to 10^{-4}. This value agrees with that given in the previous paper[1].

2) The I/Cl ratio of volcanic gases differs in different volcanoes, while the gases show a comparatively constant Br/Cl ratio.[1] The average I/Cl ratios are: Showashinzan (1.2×10^{-4}), Iwatesan (0.44×10^{-4}), Issaikyoyama (3.5×10^{-4}), Nasudake (temp. >300°C: 10.7×10^{-4}; temp.< 300°C: 6.7×10^{-4}), Yakedake (5.4×10^{-4}), Kuju-Ioyama (1.4×10^{-4}—two values were excluded from the average), Kirishima-Ioyama (temp.> 200°C: 3.0×10^{-4}; temp. <200°C: 2.3×10^{-4}), and Miharayama (6.0×10^{-4}).

3) The I/Cl value of volcanic hot-spring waters nearly agrees with that of the volcanic gases to which the hot-spring waters are believed to be related genetically.

4) The constancy in the I/Cl value is fairly good at each fumarole over a period of 2 to 3 hr. The results of continuous observations at the A-1 fumarole of Showashinzan show that the gases have a constant I/Cl value, while the iodine and chlorine contents vary widely. At Nasudake, it is observed that each of the fumaroles shows a constant I/Cl value with respect to the time change, though their values differ considerably from one fumarole to the other (Tables I and III).

The Behavior of Iodine in Volcanic Gases.— The gases of Kuju-Ioyama show a constant I/Cl value, though they show no clear relationship between the halogen content and the gas temperature. The gases of Showashinzan show a linear relationship between the iodine content and the gas temperature, as Fig. 2 shows. In addition, the gases have a conspicuously constant I/Cl ratio over a wide range of gas temperatures (187—759°C). This implies that the cause of the variation in iodine content is probably the same as that of the variation in chlorine.

It has already been reported by Mizutani[4] that the chlorine content of Showashinzan gases decreases linearly with a lowering of the temperature, and that the dilution effect of mixing water vapor into original gases is responsible for the variation in the chemical composition of the gases during

their effusion process. On the contrary, in the gases of Nasudake and Kirishima-Ioyama, iodine behaves differently from chlorine. In the cases of Nasudake, the I/Cl ratio of the gases varies widely with the gas temperature, as Fig. 3 shows. Gases with temperatures above 300°C show values of $(10—13)\times10^{-4}$, while gases with temperatures between 100°C and 300°C have values of $(0.8—12)\times10^{-4}$.

The gases of Kirishima-Ioyama are similar in this respect to those of Nasudake. The I/Cl value given for the gases with temperatures above 200°C shows $(2.8—3.1)\times10^{-4}$, while for the gases with temperatures below 200°C the value is $(0.35—3.9)\times10^{-4}$. The change in I/Cl ratio implies that the deposition and/or the addition of iodine and chlorine occurs in the gases as the temperature falls. Some evidence for the addition of some chemical components, including chlorine, to volcanic gases were suggested in the investigations

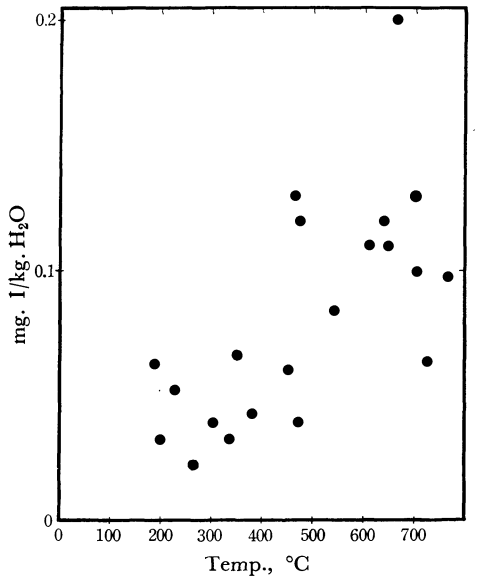

Fig. 2. Corelation between gas temperature and the iodine content of the gases of Showashinzan.

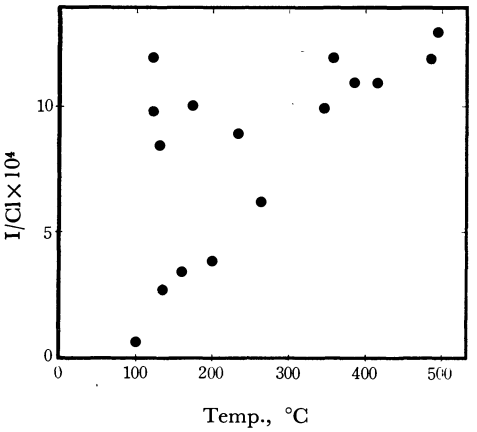

Fig. 3. Corelation between gas temperature and the I/Cl ratio of the gases of Nasudake.

by Mizutani et al.[5] and Suzuoki[6] of the chemical nature of the gases of Nasudake.

Both of these studies agree that the increase in chlorine in the gases is possibly caused by the contribution of the chlorine compounds which have accumulated in the subsurface during past effusion processes. Yoshida et al.[7] studied the halogen compounds sublimed from powdered volcanic rocks on heating; they showed that iodine behaves differently from chlorine during the volatilization and sublimation processes. Actually, volcanic sublimates, particularly alkali and ammonium chlorides, have lower I/Cl values (10^{-5}—10^{-6}),[7-9] than volcanic gases. If an appreciable quantity of halogens is supplied from such a deposit to the volcanic gases, the I/Cl value of the gases may be decreased, while the halogen content of the gases increases. It seems reasonable to explain the difference in I/Cl ratio with the decrease in the temperature as being caused by the increasing contribution of halogens from a secondary source, such as volcanic sublimates, though a problem remains as to the process of the discharge of halogens in deposits.

The authors express their gratitude to Dr. Nobuyuki Nakai for his helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2696—2702 (1966)

The Effects of the Temperature on the γ-Radiation-Induced Polymerization of Ethylene*

By Sueo MACHI, Miyuki HAGIWARA, Masao GOTODA and Tsutomu KAGIYA

Japan Atomic Energy Research Institute, Takasaki Radiation Chemistry Research Establishment, Takasaki, Gunma

(Received January 18, 1966)

The gamma-radiation-induced polymerization of ethylene was carried out/over the wide range of temperature from 30 to 200°C at pressure ranging from 100 to 400 kg./cm^2 and at dose rates from 2×10^3 to 4×10^5 rad./hr. It was shown that the rate of polymerization is rapidly accelerated at 30°C, that the degree of acceleration decreases with an increase in the reaction temperature, and that above 100°C the rate is independent of the time. It was correspondingly shown that the molecular weight of the polymer increases with the reaction time, at 30°C, that its increment for a unit of time decreases with an increase in the temperature, and that the molecular weight is independent of the time above 100°C. By means of a kinetical discussion it was concluded that the rate of the termination reaction, which is almost eliminated at 30°C, increases with the temperature and attains a value comparable to that of initiation above 100°C. The dose rate exponents of the polymerization rate and molecular weight were shown to vary with the reaction temperature. Namely, the exponents were evaluated as 0.9 and 0 at 30°C, 0.8 and −0.1 at 100°C, and 0.7 and −0.2 at 140 and 200°C, for the polymerization rate and the molecular weight respectively. It was assumed from these high exponents that the termination may occur above 100°C in a first-order reaction to a considerable extent. Under a constant pressure, the polymer yield was shown to decrease with the temperature from 30 to 60—80°C, and then to increase at high temperatures from 80 to 200°C. On the other hand, the molecular weight of the polymer simply decreases with the temperature from 30 to 200°C. The chain transfer reaction is considered to be almost negligible at 30—70°C. The number of polymer chains for a constant reaction time and monomer concentration is independent of the temperature from 30 to 70°C, while it increases with the temperature from 70 to 200°C. The effects of pressure on the polymer yield and molecular weight were also investigated at 140°C.

In previous papers[1,2] the γ-radiation-induced bulk polymerization of ethylene at normal temperatures was characterized by a steady increase in the polymerization rate and in the molecular weight of polymer with the reaction time. From the kinetic study,[2] the existence of a long-lived radical has been suggested; this has been confirmed by the results of the experiments of the two-stage irradiation method.[3] On the other hand, it was recently shown that the phenomena of the rate acceleration and the increase in the molecular weight with the time vanish, and that the molecular weight is considerably lowered at high reaction temperatures, as has previously been reported briefly.[4] This paper attempts to elucidate the specific influences of the reaction temperature on the γ-radiation-induced polymerization of ethylene in bulk.

Experimental

The reaction vessel, the irradiation facilities, and the experimental procedures are the same as have been reported in a previous paper.[2] The ethylene used was commercially available and 99.9% pure (free of CO and H_2S), containing 21 p. p. m. of acetylene and 0.3 p. p. m. of oxygen. Polymerizations were carried out to low conversion in order to maintain the pressure essentially constant, and the temperature was constant within ±1°C for the duration of the experiment.

Results and Discussion

The Effect of the Temperature on Chain Termination.—A marked acceleration in rate and an increase in the number-average molecular weight with the reaction time have been reported in the γ-radiation-induced polymerization of ethylene at normal temperatures.[1,2] On the other hand, in the polymerization at high temperatures (above 100°C), no increase in the polymerization rate and molecular weight were observed, as has already been reported briefly.[4]

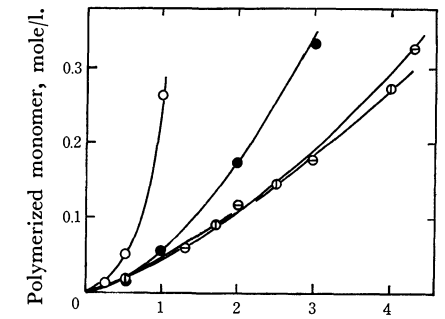

Fig. 1a.

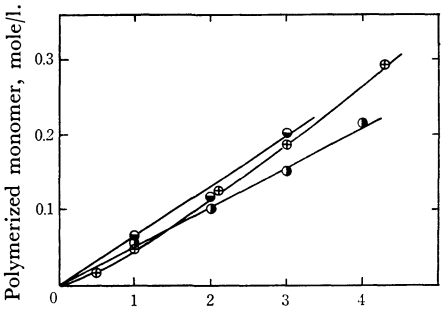

Fig. 1b.

Fig. 1. The amount of polymerized monomer vs. reaction time at various reaction temperatures. (Reaction pressure, 400 kg./cm²; dose rate, 2.5×10^4 rad./hr.; reaction temperature, 30 (○), 58 (●), 62 (⊖), 70 (⊕), 86 (⊕), 100 (◑), 140°C (◒))

The results of the experiments which were carried out at various reaction temperatures from 30 to 200°C, at a dose rate of 2.5×10^4 rad./hr. and at a pressure of 400 kg./cm², are summarized in Table I. Figures 1a and 1b show the relation between the amount of the polymerized monomer (i. e., the polymer yield) and the reaction time. They show that the amount of the polymerized monomer increases rapidly with the time at lower temperatures and less rapidly at higher temperatures. In order to show the time dependency of the amount of the polymerized monomer, it is plotted on a logarithmic scale in Fig. 2. The slopes of the line are the time exponents of the polymer yield, which are listed in Table II. It is found that the time exponent at 30°C is 2.1 and that it decreases with the increase in the temperature to unity at temperatures of 100°C and above. In other words, the rate of polymerization increases almost proportionally with the time at 30°C, the increase in the rate for unit time becomes less with an increase in the temperature, and finally the rate becomes independent of the time. Namely, the rate acceleration is observed at 30 to 86°C, its degree decreases with the temperature, and it is not observed at 100 and 140°C.

Reaction pressure, 400±5 kg./cm²; dose rate, 2.5 ×10⁴ rad./hr.

The effect of the reaction temperature on the increase in the molecular weight with the reaction time is shown in Fig. 3. The molecular weight of polymer formed at 30°C is shown to be proportional to the time. This feature, together with the rate acceleration, have been explained[2] on the assumption that the termination and transfer do not take place to any appreciable extent. It has been also suggested that the life of the polymer radical is long and that the accumulation of polymer radicals causes the rate acceleration. In the polymerization from 58 to 86°C, it is observed that the molecular weight increases with the time and that the increment for the unit of time decreases with a rise in the temperature. This corresponds to the above fact, i. e., the degree of rate acceleration decreases with temperature. These corresponding facts may indicate that the rate of chain termination increases with rise in the temperature, the average life-time of the polymer radical, therefore, becomes shorter, and the extent of radical accumulation decreases.

Above 100°C the polymerization rate and molecular weight are shown to remain constant, independently of the reaction time, in Figs. 1b and 3. This suggests that the rate of the termination becomes comparable to that of the initiation. The life of the radical is not long, but normal, and the stationary state is realized.

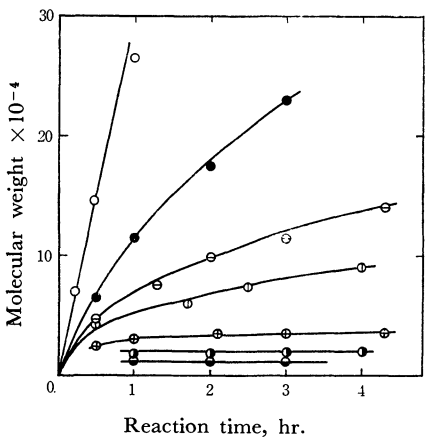

Fig. 3. Molecular weight vs. reaction time at various temperatures. (Notes and reaction conditions are the same as shown in Fig. 1.)

The Order of the Termination Reaction.— In order to elucidate the termination reaction, the dependence of the polymerization rate and the molecular weight on the irradiation dose rate was investigated at various temperatures from 30 to 200°C, the results are summarized in Table III. The rate and the molecular weight are plotted on logarithmic scales against the dose in Figs. 4 and

Table III. Effects of dose rate on polymer yield and molecular weight at various temperatures

Reaction temp. °C	Dose rate rad./hr. ×10⁻⁴	Reaction time hr.	Polymer yield g.	Molecular weight $\bar{M}_n$ ×10⁻⁴

(Notes and reaction conditions are the same as shown in Fig. 4.)

5 respectively. Here, since the rate and the molecular weight increase with the time at 30°C, the data in these figures have been normalized to a fixed reaction time of one hour. The dose rate exponents of the rate and the molecular weight evaluated from the slope of these lines are shown in Table IV. The dose rate exponents for both the rate and the molecular weight are shown to decrease with a rise in the temperature from 30 to 140°C; they remain constant at temperatures from 140 to 200°C.

TABLE IV. DOSE RATE EXPONENTS OF POLYMERIZATION RATE AND MOLECULAR WEIGHT AT VARIOUS TEMPERATURES

Reaction temp., °C	Dose rate exponent of rate	Dose rate exponent of molecular weight
30	0.9	0.0
100	0.8	−0.1
140	0.7	−0.2
200	0.7	−0.2

Reaction conditions are the same as shown in Table III.

It has already been shown in a previous paper[2] that the exponents at 30°C of 0.9 (approximately unity) for the rate and 0 for the molecular weight coincide with the reaction scheme at normal temperatures; i. e., we may assume no termination reaction. The exponents for the polymerization above 100°C (i. e., 0.8 and 0.7 for the rate, and −0.1 and −0.2 for the molecular weight) are higher than the common exponents of 0.5 and −0.5 for the rate and molecular weight in the case of second-order termination with respect to the polymer radical. These high exponents may indicate that first-order termination with respect to the polymer radical is predominant. The first-order termination is assumed to be brought about by a reaction between the polymer radical and the radical of a low molecular weight which has little effect on the molecular weight of high polymers.

The fact that these exponents decrease with a rise in the temperature indicates that the contribution of the second-order termination, i. e., the mutual termination of the polymer radicals, increases with the temperature from 100 to 200°C.

The Evaluation of the Rate of Termination.—The rates of termination at various temperatures from 58 to 76°C are evaluated by means of the analysis[5] of the data on the polymer yield on the basis of the following elementary reactions, which have been proposed[2] for the γ-radiation-induced polymerization of ethylene in bulk:

1. Initiation

$$M \xrightarrow{k_i} R_1 \qquad R_i = k_i \rho_M I \qquad (1)$$

2. Ethylene excitation and dimerization

$$M \rightleftarrows M^*$$
$$M + M \overset{K_e}{\rightleftarrows} M_2^* \qquad f_{M_2^*} = K_e f_M^2 \qquad (2)$$

3. Propagation

$$R_1\cdot + M_2^* \xrightarrow{k_p} R_3\cdot$$
$$\cdots\cdots \qquad R_p = k_p[R\cdot] f_{M_2^*} \qquad (3)$$
$$R_{n-2}\cdot + M_2^* \xrightarrow{k_p} R_n\cdot$$

4. Termination

$$R_n\cdot + Z \xrightarrow{k_{t1}} P_n \qquad R_t = k_{t_1}[R\cdot][Z] +$$
$$R_m\cdot + R_n\cdot \xrightarrow{k_{t2}} P_{m+n} \qquad k_{t_2}[R\cdot]^2 \qquad (4)$$

5. Transfer

$$R_n\cdot + Y \xrightarrow{k_{tr}} P_n + Y\cdot$$
$$R_{tr} = k_{tr}[R\cdot][Y] \qquad (5)$$

where M represents the ethylene monomer; $R_n\cdot$, an active polymer chain composed of n monomers; $[R\cdot]$ total concentration of all active polymer chains irrespective of size; M*, the excited monomer; M_2^* the excited dimer; Y the substance with which the activity of the radical is transferred; Z, the substance by which the radical is deactivated; P_n, the dead polymer composed of n monomers; R_i, R_p, R_{tr}, and R_t, the rates of initiation, propagation, transfer, and termination; k_i, k_p, k_{tr}, and k_t, the rate constants of these reactions; ρ_M the density of ethylene; I, the dose rate; f_M, the fugacity of ethylene; $f_{M_2^*}$, the fugacity of the excited dimer, and K_e the equilibrium constant of the 2nd step.

5) T. Kagiya, M. Izu, S. Machi and K. Fukui, paper presented at the 14th Polymer Symposium, Kyoto, October, 1965.

The rate of polymerization, R, is written:

$$R = k_p K_e [\mathrm{R}\cdot] f_M^2 \quad (6)$$

where R represents the overall polymerization rate. [R·] is given in the non-stationary state;

$$[\mathrm{R}\cdot] = \int R_i dt - \int R_t dt \quad (7)$$

Since no second-order termination in the polymer radical takes place below 100°C, Eq. 7 is:

$$[\mathrm{R}\cdot] = \int k_i \rho_M I dt - \int k_{t_1} [\mathrm{R}\cdot][\mathrm{Z}] dt \quad (8)$$

Here, [R·] on the right side being replaced by Eq. 6,

$$[\mathrm{R}\cdot] = k_i \rho_M I t - (k_{t_1}[\mathrm{Z}]/k_p K_e f_M^2) \cdot \int R dt \quad (9)$$

where $\int R dt$ corresponds to the amount of the polymerized monomer, M_p. By substituting [R·] in Eq. 6 with Eq. 9, R is written:

$$R = k_i k_p K_e \rho_M f_M^2 I t - k_{t_1}[\mathrm{Z}] M_p \quad (10)$$

By integrating Eq. 10 with time,

$$\int R dt = M_p = (1/2) \cdot k_t k_p K_e \rho_M f_M^2 I t^2 - k_{t_1}[\mathrm{Z}] \int M_p dt \quad (11)$$

$$M_p / \int M_p dt = (1/2) \cdot k_i k_p K_e \rho_M f_M^2 I t^2 / \int M_p dt - k_{t_1}[\mathrm{Z}] \quad (12)$$

According to Eq. 12, $(M_p/\int M_p dt)$ is plotted in Fig. 6 against $(t^2/\int M_p dt)$, where $\int M_p dt$ is calculated from Fig. 1 by a graphical method. The values of $k_{t_1}[\mathrm{Z}]$, i. e., the rate of termination, are determined from the intercept on the axis of

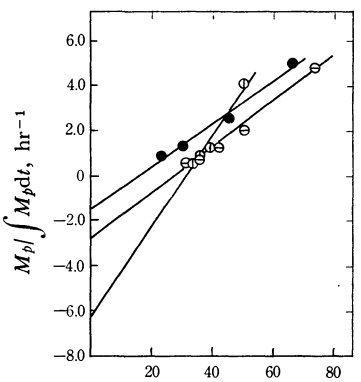

Fig. 6. $M_p/\int M_p dt$ vs. $t^2/\int M_p dt$.
(Notes and reaction conditions are the same as shown in Fig. 1.)

TABLE V. RATE OF CHAIN TERMINATION AT VARIOUS TEMPERATURES

Reaction temp. °C	Rate of termination $k_{t_1}[\mathrm{Z}]$ hr^{-1}
58	1.5
62	2.8
70	6.1

Reaction pressure, 400±5 kg./cm²; dose rate, 2.5 ×10⁴ rad./hr.

$M_p/\int M_p dt$; they are summarized in Table V. The rate of termination is shown to increase with the reaction temperature.

The Effects of the Temperature on the Polymer Yield and the Molecular Weight.— As is shown in Figs. 1 and 3, the effects of the temperature on the polymer yield and molecular weight are complicated because of their time dependency. Figure 7 shows how the polymer

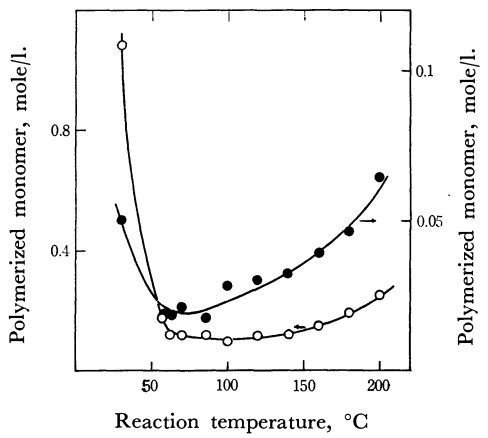

Fig. 7. Effect of reaction temperature on the amount of polymerized monomer.
(Reaction pressure, 400 kg./cm²; dose rate, 2.5 ×10⁴ rad./hr.; reaction time, 0.5 (●), 2.0 hr. (○). Data at 100, 200°C for 0.5 hr., and 62, 70°C for 2.0 hr. are calculated from those at other reaction time.)

yield at the reaction times of 0.5 and 2.0 hr. varies with reaction temperature. It is shown that the polymer yield decreases rapidly with the temperature from 30 to 60°C, remains almost constant from 60 to 80—100°C, and increases in the higher temperature region (to 200°C). Figure 8 indicates that the molecular weight of the polymer formed at 0.5 and 2.0 hr. under the constant pressure of 400 kg./cm² simply decreases with a rise in the reaction temperature, and that it is very sensitive to the temperature from 30 to 100°C. The effect is shown to become larger as the polymerization proceeds.

The Effects of the Temperature on Chain Initiation and Transfer.—The number-average

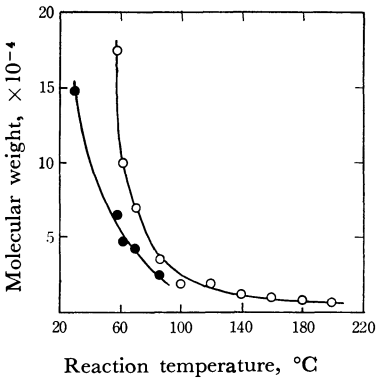

Fig. 8. Effect of reaction temperature on the molecular weight.
(Notes and reaction conditions are the same as shown in Fig. 7. Data at 62, 70°C. for 2.0 hr. are calculated from those at other reaction time.)

degree of polymerization at a given reaction time is written for the polymerization in the non-stationary state, assuming no termination by the recombination of polymer radicals, which is almost realized below 100°C:

$$1/\overline{DP}_n = \int R_i dt / \int R_p dt + \int R_{tr} dt / \int R_p dt \quad (13)$$

where $\overline{DP}_n$ represents the number-average degree of polymerization. From the above reaction scheme, Eq. 13 is, then,

$$1/\overline{DP}_n = k_t \rho_M I(t/M_p) + (k_{tr}/k_p)[Y]/K_e f_M^2 \quad (14)$$

According to Eq. 14, $1/\overline{DP}_n$ is plotted in Fig. 9 against t/M_p to give an almost linear relation. The fact that the lines in Fig. 9 pass through the point of origin indicates that the transfer reaction does not take place at temperatures from 30 to 70°C.

The relation between the number of moles of polymer chains (N_p) for a unit of ethylene concentration and the reaction time is shown in Fig. 10, where N_p is evaluated as the ratio of the amount of the polymerized monomer to the number-

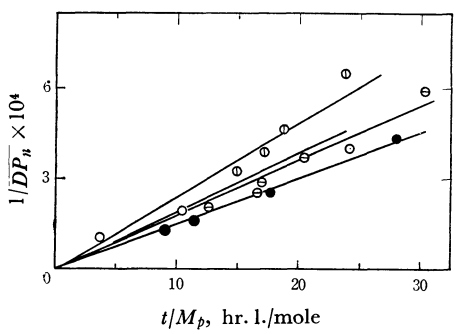

Fig. 9. $1/\overline{DP}_n$ vs. t/M_p.
(Notes and reaction conditions are the same as shown in Fig. 1.)

(Notes and reaction conditions are the same as shown in Fig. 1.)

average molecular wight of the polymer, i. e., $M_p/\overline{M}_n$. It is observed that N_p/ρ_M (i. e., the number of moles of polymer chains formed divided by the concentration of ethylene) increases almost proportionally with the time at the respective temperatures because of successive initiation by continuous radiation. The number of moles of polymer chains formed per unit of reaction time (i. e., N_p/t, the rate of the increase in number of polymer chains) is shown in Table VI and Fig. 11 for various reaction temperatures. It is shown

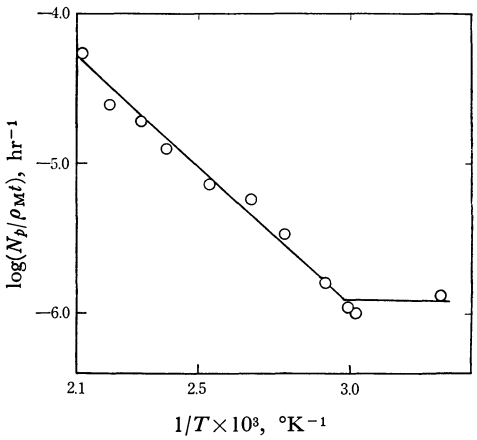

Fig. 11. Effect of temperature on the rate of increasing in the number of polymer chains.
(Reaction pressure, 400 kg./cm^2; dose rate, 2.5×10^4 rad./hr.)

TABLE VI. EFFECT OF REACTION TEMPERATURE ON THE RATE OF INCREASING IN THE NUMBER OF MOLES OF POLYMER CHAINS

that N_p/t is almost independent of the temperature from 30 to 70°C, where the chain transfer does not take place. The rate of initiation is, therefore, known to be independent from the temperature of this range. On the other hand, the higher temperature range, N_p/t is shown to increase with the temperature and an apparent activation energy of about 8 kcal./mole was observed. It is also noted that the polymer yield increases with the temperature over the same range (shown in Fig. 7). Since no evidence for the absence of chain transfer is given in this temperature range, the activation energy may be ascribed not only to the initiation reaction but also to the transfer reaction.

TABLE VII. EFFECTS OF REACTION PRESSURE ON POLYMER YIELD AND MOLECULAR WEIGHT AT 140°C

350	228	11.1	2.0	0.33	1.2
400	261	11.8	listed in Table I		

Dose rate, 2.5×10^4 rad./hr.; volume of reaction vessel, 100 ml.

The Effect of the Pressure on the Polymer Yield and the Molecular Weight at 140°C.— The results of experiments where ethylene pressure varies from 100 to 400 kg./cm^2 are summarized in Table VII. It is shown that the amount of polymerized monomers and the molecular weight per unit of reaction time increase with the ethylene pressure. The number of moles of polymer chains per unit of time is plotted in Fig. 12 against the concentration of ethylene for the polymerization at 140 and 30°C. The direct proportionality which was previously reported[6] is observed at 30°C. On the other hand, at 140°C with the same concentration of ethylene, N_p is greater than 30°C and is not proportional to the concentration of ethylene. This difference between 30 and 140°C may indicate that additional processes related to ethylene occur at 140°C to increase the number of polymer chains. They may be the additional initiation and/or the transfer with the monomer.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2703—2706 (1966)

Syntheses of Isomeric Methylpseudoionones and Isomeric Pseudoionones by Means of the Wittig Reaction

By Kazuhiro SASAKI

Ichikawa Works, Kobayashi Perfumery Co., Ltd., Ichikawa, Chiba

(Received February 18, 1966)

Four isomeric methylpseudoionones and two isomeric pseudoionones were separately synthesized by the Wittig reaction of citral a or citral b with the corresponding phosphonates. Two isomeric pseudoionones were also synthesized by the Wittig reaction of citral a or citral b with 2-oxopropylidenetriphenylphosphorane. The configurations and the conformations of the dienone systems in four methylpseudoionones and two pseudoionones were discussed on the basis of the infrared and ultraviolet absorption data.

Since butanone has an active methyl and an active methylene group, the condensation of citral (I) with butanone results in the formation of two pairs of methylpseudoionones, i. e., *n*-methylpseudoionones (II) and isomethylpseudoionones (III). The four isomers have been isolated as their semicarbazones or phenylsemicarbazones.[1,2] The direct synthesis of each isomer, however, has never been reported.

Recently, II, III, and pseudoionone (IV) were synthesized by the reaction of citral (an isomeric mixture) with the corresponding 2-oxoalkylidenetriphenylphosphoranes,[3] but the configurations and the conformations of the dienone systems were not described.

In the present experiment, the syntheses of each isomeric methylpseudoionone and pseudoionone were attempted by the use of the corresponding phosphonates, according to the modified Wittig reaction.[4] The phosphonates employed in the present investigation were prepared by the Michaelis-Arbuzov reaction.[5]

Diethyl 2-oxopropylphosphonate (V) was treated successively with sodium amide and with a 96 : 4 mixture of citral a (Ia) and citral b (Ib) (Ia-rich I) to afford a 95 : 5 isomeric mixture of *trans*-3, *trans*-5-pseudoionone (IVa) and its 5-*cis* isomer (IVb). The treatment of V with a 2 : 98 mixture of Ia and Ib (Ib-rich I) in the same way gave a 2 : 98 mixture of isomers, IVa and IVb. These products were confirmed by gas chromatographic identification with authentic samples obtained by the aldol condensation of Ia-rich I or Ib-rich I with acetone, by a study of the infrared spectra*1 of the products (Table I)*2, and by elementary analyses of the semicarbazones.*3 IVa and IVb were also prepared by the reaction of 2-oxopropylidenetriphenylphosphorane (VI) with Ia-rich I or Ib-rich I for the sake of comparison. The results (Table II) show that the phosphonate method gave better yields than the phosphorane method, and that the reaction proceeded substantially stereospecifically (only *trans* isomers were produced).

*1 The infrared spectra were measured through the courtesy of Dr. Yoshitaka Matsuoka and Mr. Kenya Sakaguchi of the Eisai Research Laboratories.

*2 The infrared and ultraviolet absorption spectra of the products (as mixtures) were measured without further purification.

*3 This conclusion might be supported by the following reports: Surber and his co-workers observed that the preparation of the α, β-*cis* form of methyl ketones unsaturated in the α, β- and γ, δ-positions with respect to the carbonyl group proves practically impossible (W. Surber, V. Theus, L. Colombi and H. Schinz, *Helv. Chim. Acta*, **39**, 1299 (1956)). Naves and his co-workers reported that the most probable configuration for III and IV is *trans*-3, *trans*-5 or *trans*-3, *cis*-5, while that for II is *trans*-4, *trans*-6 or *trans*-4, *cis*-6 (Ref. 2).

IIIb). Many authors have reported such a carbonyl splitting in the infrared spectra of *trans*-3-penten-2-one and its 5-alkyl homologs; they have ascribed the effect to an equilibrium between the *s-cis* and *s-trans* conformations.[12-15] On the other hand, it has been reported that no such carbonyl splitting is observed in the infrared spectra of 3-methyl-*trans*-3-penten-2-one and its 3-ethyl homolog, which have the same partial enone structure as that of isomethylpseudoionones (IIIa, IIIb); it has also been reported that the spectral properties of 3-methyl-*trans*-3-penten-2-one and its 3-ethyl homolog are very close to those of the ketones with a fixed *s-trans* conformation.[14] Although no definite evidence can be offered except the infrared spectral data, the conjugated enone systems of *n*-methylpseudoionones (IIa, IIb) and pseudoionones (IVa, IVb) seem to exist in an equilibrium between *s-cis* and *s-trans* conformations, while the systems of isomethylpseudoionones (IIIa, IIIb) may exist predominantly or exclusively in the *s-trans* conformation.

The infrared spectra of *n*-methylpseudoionones (IIa, IIb), isomethylpseudoionones (IIIa, IIIb), and pseudoionones (IVa, IVb) showed two absorption bands due to C=C stretching vibrations at 1630—1633 and 1588—1596 cm^{-1}. The intensities of both bands in the spectra of *n*-methylpseudoionones (IIa, IIb) and pseudoionones (IVa, IVb) were nearly equal, while the intensity of the band at 1592 or 1596 cm^{-1} in the spectra of isomethylpseudoionones (IIIa, IIIb) was weakened. This weakened intensity could be ascribed to an effect of the C-3 methyl group, which should polarize the C-3 double bond in the direction opposite to the effect of the carbonyl group.[14]

Experimental

Materials.—Citrals (Ia-rich I and Ib-rich I) were isolated from commercial lemongrass oil by the procedure described in a previous paper.[16] Ia-rich I: b. p. 66—68°C /0.7 mmHg, Ia : Ib=96 : 4. Ib-rich I: b. p. 61—63°C 10.7 mmHg, Ia : Ib=2 : 98. 2-Oxopropylidenetriphenylphosphorane (VI) was obtained by the reaction of chloroacetone and triphenylphosphine, followed by the treatment of the resultant 2-oxopropylidenetriphenylphosphonium chloride with 10% sodium carbonate.[17] Diethyl 2-oxopropylphosphonate (V) was prepared from triethyl phosphite and bromoacetone. B. p. 75—78°C/0.3 mmHg; yield 53%; $\nu_{C=O}$ 1714, $\nu_{P=O}$ 1259, ν_{P-O} 1165, ν_{C-O} 1025 cm^{-1}. Diethyl 2-oxobutylphosphonate (VII) was prepared from triethyl phosphite and bromomethyl ethyl ketone. B. p. 91—95°C/0.7 mmHg; yield 65%; $\nu_{C=O}$ 1713, $\nu_{P=O}$ 1256, ν_{P-O} 1167, ν_{C-O} 1026 cm^{-1}. Diethyl 1-methyl-2-oxopropylphosphonate (VIII) was prepared from triethyl phosphite and 1-bromoethyl methyl ketone. B. p. 70—73°C/0.25 mmHg; yield 11%; $\nu_{C=O}$ 1716, $\nu_{P=O}$ 1253, ν_{P-O} 1167, ν_{C-O} 1027 cm^{-1}.

The Reaction of a 96 : 4 Citral Mixture (Ia-rich I) or a 2 : 98 Citral Mixture (Ib-rich I) with 2-Oxopropylidenetriphenylphosphorane (VI).—A solution of 3.04 g. (0.02 mole) of Ia-rich I and 6.37 g. (0.0 2mole) of VI in 70 ml. of *n*-butyl ether was heated while being stirred on an oil bath. When the reaction has been completed the solvent was evaporated, a small amount of cold ether was added to the residue, and the crystallized triphenylphosphine oxide was filtered off and washed with ether. The combined filtrate and washings were then dried over anhydrous sodium sulfate. After the solvent had been removed, the residue was distilled off under reduced pressure to give 1.0 g. of a 95 : 5 mixture of IVa and IVb. The same procedure with Ib-rich I gave 0.8 g. of a 7 : 93 mixture of IVa and IVb. In the reaction with Ib-rich I, the prolongation of the reaction time by one half-hour at a refluxing temperature resulted in the formation of 1.4 g. of a 11 : 89 mixture of IVa and IVb.

The Modified Wittig Reaction with the Phosphonates.—To a suspension of 1.95 g. (0.05 mole) of sodium amide in 30 ml. of dry tetrahydrofuran (THF), there was added a solution of 9.71 g. (0.05 mole) of V in 20 ml. of dry THF with stirring and cooling. After the addition was complete, the temperature of the reaction mixture was gradually raised to −3—−1°C, after which the reaction was continued at that temperature until the evolution of ammonia had ceased. The reaction mixture was then again cooled below −10°C, and a solution of 7.61 g. (0.05 mole) of Ia-rich I or Ib-rich I in 20 ml. of dry THF was added. The reaction mixture was gradually warmed to room temperature and allowed to stand overnight. The solvent being evaporated under reduced pressure, the residue was poured into a large excess of water and extracted with ether. The ethereal extract was washed with water and dried over anhydrous sodium sulfate. After the solvent had been removed, the oily residue was distilled under reduced pressure to afford 4.7 g. of a 95 : 5 mixture, or 4.6 g. of a 2 : 98 mixture, of IVa and IVb.

The products rich in IIa, rich in IIb, rich in IIIa, and rich in IIIb, were prepared in a similar manner.

The author wishes to express his deep gratitude to Professor Masaki Ohta and Assistant Professor Rokuro Sudo of the Tokyo Institute of Technology and to Dr. Kazuyoshi Fujiwara of Tamura Veterinary Chemicals, Ltd., for their constant interest and encouragement. Thanks are also due to Mr. Kenjiro Kobayashi, President of Kobaysahi Perfumery Co., Ltd., and Mr. Mitsuhiro Takahashi, Director of the same company, for their permission to publish this work.

Studies of Poly-β-benzyl-L-aspartate Helix. I. The Synthesis and Rotatory Dispersion of Copolymers of β-*p*-Methyl, Chloro, Cyano, or Nitrobenzyl-L-aspartate with β-Benzyl-L-aspartate

By Masahisa HASHIMOTO and Jiro ARITOMI

Research Laboratory, Dainippon Pharmaceutical Co., Ltd., Ebie, Fukushima-ku, Osaka

(Received February 19, 1966)

β-*p*-Methyl, chloro, cyano and nitrobenzyl-L-aspartates were synthesized, and the respective homopolymers and copolymers of these β-(*p*-substituted benzyl)-L-aspartates with β-benzyl-L-aspartate were prepared. The introduction of a methyl, chloro, or cyano group into the para position of the aromatic ring in the side chain of poly-β-benzyl-L-aspartate (PBLA) also causes a reversal from the left- to the right-handed in the helical sense of the polypeptide in a chloroform solution, as in the case of the nitro group. The residue of the copolymers where the transition takes place contained: nitro, 20—30; cyano, 40—50; chloro, ca. 50; and methyl group, ca. 70 mol.-%. These values may indicate the relative stabilities between the PBLA helix and poly-β-(*p*-substituted benzyl)-L-aspartate helices. These series of copolymers had no absorption band in the longer wavelength region except for a nitrobenzyl series, which had an absorption band at around 330 mμ. The absence of an absorption band resulted in a normal b_0 value. The results suggest that the factors which determine the helical sense of the PBLA helix are not very simple and that the left-handed helix of PBLA is much less stable.

It has been shown that poly-β-benzyl-L-aspartate (PBLA) forms the left-handed α-helix in a chloroform solution.[1,2] Recently Goodman and his co-workers have reported that the introduction of a nitro group in the para position of the aromatic ring in the side chain of poly-β-benzyl-L-aspartate causes a reversal from the left- to the right-handed in the helical sense of the polypeptide in a chloroform solution.[3,4] It has also been suggested that the right-handed helix is stabilized by the nitro-aromatic groups in the side chain, which form an electronically-coupled side chain helix rigidly arrayed about the main chain helix.

These findings stimulated our interest in studying the helical sense of poly-β-benzyl-L-aspartate homologues which have other side chains. In this paper, we shall describe the synthesis of poly-β-(*p*-methylbenzyl)-L-aspartate (PMeBLA), poly-β-(*p*-chlorobenzyl)-L-aspartate (PClBLA), poly-β-(*p*-cyanobenzyl)-L-aspartate (PCNBLA), and also poly-β-(*p*-nitrobenzyl)-L-aspartate (PNBLA), together with the copolymers derived from these β-(*p*-substituted benzyl)-L-aspartates and β-benzyl-L-aspartate. It will be described as well how optical rotatory dispersion data show that the introduction of a methyl, chloro, or cyano group in the aromatic side chain also causes a reversal in helical sense of the polypeptide in a chloroform solution, as in the case of a nitro group.

Results and Discussion

Syntheses.—β-Benzyl-L-aspartate (BLA) has been prepared by the partial hydrolysis of α, β-dibenzyl-*N*-carbobenzoxy-L-aspartate[5] and by selective β-esterification using concentrated hydrochloric acid[6] or aqueous sulfuric acid[7]. Goodman et al.[4] have prepared β-*p*-nitrobenzyl-L-aspartate by the nitration of β-benzyl-L-aspartate with nitronium fluoroborate.

In the present study, β-(*p*-substituted benzyl)-L-aspartates were prepared by the direct β-esterification of L-aspartic acid with *p*-substituted benzyl alcohol. β-*p*-Methylbenzyl-L-aspartate (MeBLA) was obtained in only a trace amount by using concentrated hydrochloric acid, but it was prepared in a 10% yield by using *p*-toluenesulfonic acid as the catalyst. β-*p*-Chlorobenzyl-L-aspartate (ClBLA) and β-*p*-cyanobenzyl-L-aspartate (CNBLA) were obtained in better yields by using *p*-toluenesulfonic acid than by using concentrated hydrochloric acid as the catalyst. The esterification of L-aspartic

acid with *p*-nitrobenzyl alcohol, using *p*-toluenesulfonic acid as the catalyst, afforded a mixture of β-*p*-nitrobenzyl and α-*p*-nitrobenzyl-L-aspartates, with the former predominant. However, hydrochloric acid also gave a mixture, with the former predominant. It was more favorable to obtain the β-isomer of *p*-nitrobenzyl-L-aspartate by the reaction using concentrated hydrochloric acid than to use *p*-toluenesulfonic acid, since the repeated recrystallizations needed to separate the β-isomer lowered the yield.

In order to confirm that these synthesized esters were β-esters and L-isomers, these esters were treated with aqueous ammonia to convert them to asparagine, which was identified as L-asparagine monohydrate. The *N*-carboxyanhydrides (NCA) of these esters were prepared by a method similar to that of Karlson et al.[1] (method B). The polymerizations of NCA's were carried out in glass ampules, in which the air was replaced with dry nitrogen, using triethylamine[8] as an initiator ($A/I=100$).

Optical Rotatory Dispersion in a Chloroform Solution.—*1) The Poly-β-(p-methylbenzyl)-L-aspartate and Copolymers of β-p-Methylbenzyl-L-aspartate with β-Benzyl-L-aspartate.*—The values of b_0 derived from the Moffitt equation[9] have been empirically correlated with the sense of helix; the b_0 values of −630 obtained for poly-γ-benzyl-L-glutamate have been associated with the right-handed helix, and that of +600 for poly-β-benzyl-L-aspartate have been correlated with the left-handed one.[10]

The optical rotatory measurement of PMeBLA in a chloroform solution gave b_0 values ($\lambda_0=212$ mμ) of −680, which seem to indicate that PMeBLA exists in a right-handed helix. However, Fasman[11] pointed out that the sign is not always an indication of the helical sense. If PMeBLA exists in a right-handed helix, the copolymer of β-*p*-methylbenzyl-L-aspartate with β-benzyl-L-aspartate, which have been demonstrated to exist in a left-handed helix in a chloroform solution,[1,2] must exhibit a drastic change in b_0 values when the copolymer composition varies. Truly, b_0 values displayed a sharp change when they were plotted against copolymer composition (Fig. 1a). The values of λ_c and $[\alpha]_{546}$ also showed drastic changes (Table I). PMeBLA showed values of 256 for λ_c which are empirically correlated with a right-handed helix.[12] These typical drastic and abrupt changes in b_0, λ_c, and $[\alpha]_{546}$ indicate that a transition from the left-handed helix of PBLA to the right-handed helix of PMeBLA occurs at ca. a 70 mol.-% methyl residue content.

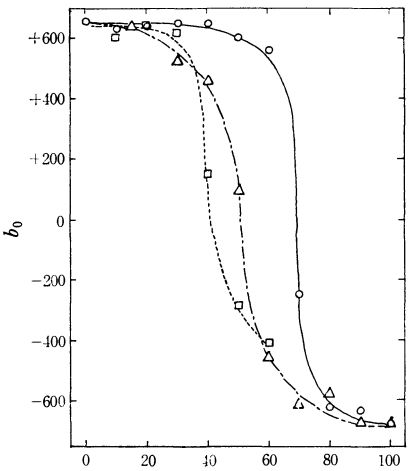

Fig. 1. Values of b_0 against copolymer composition; a) ○—○, copolymers of BLA and MeBLA, b) △-·-△, copolymers of BLA and ClBLA, c) □---□, copolymers of BLA and CNBLA.

2) The Poly-β-(p-chlorobenzyl)-L-aspartate and Copolymers of β-p-Chlorobenzyl-L-aspartate with β-Benzyl-L-aspartate.—Drastic changes in b_0, λ_c, and $[\alpha]_{546}$ similar to those shown above were observed for this series of copolymers (Fig. 1b, Table II). These results reveal that a reversal in the helical sense from the left-handed helix of PBLA to the right-handed helix of PClBLA takes place at a nearly equimolar composition of these residues.

3) The Copolymers of β-Cyanobenzyl-L-aspartate with β-Benzyl-L-aspartate.—Data are shown in Fig. 1c and Table III. Unfortunately, copolymers with cyano-residue contents greater than 60 mol.-%

were insoluble in chloroform. In this series a transition from the left-handed to the right-handed helix occurs at a 40—50 mol.-% cyano-residue content.

4) The Copolymers of β-Nitrobenzyl-L-aspartate with β-Benzyl-L-aspartate.—Goodman et al.[4] have reported that a transition from the left-handed helical sense of PBLA to the right-handed helical sense of PNBLA occurs at a 26—32 mol.-% nitro-residue content, and that copolymers with more than a 32% nitro-residue content have large negative b_0 values. In our series a transition takes place at a 20—30 mol.-% nitro residue, Moffitt's plots for copolymers containing 30 and 40 mol.-% nitro residues are non-linear, and those with nitro-residue contents greater than 40 mol.-% are insoluble in chloroform (Table IV).

*3 C=0.5%, dichloroacetic acid.

In the present study, as has been described above, the optical rotatory dispersion studies with series of copolymers of β-benzyl-L-aspartate and *p*-substituted esters are carried out. The introduction not only of a nitro group but also of a methyl, chloro, or cyano group in the para position of the aromatic ring in the side chain of poly-β-benzyl-L-aspartate causes a reversal from the left- to the right-handed in the helical sense of the polypeptide in chloroform.

Goodman and his co-workers[4] have proposed an explanation based on competitive hydrogen bonding between the carbonyls of the side-chain esters and the main-chain amides. They have suggested that if PBLA were in a right-handed helical conformation, normal intramolecular hydrogen bonding could be disrupted through the interaction of main-chain NH groups with suitably-placed side-chain ester groups. The stabilization of the right-handed conformation in the poly-β-*p*-nitrobenzyl-L-aspartate helix has been explained by assuming that nitroaromatic groups form an electronically-coupled side-chain helix; they have also suggested that when the nitro group is not present, certain $\pi-\pi^*$ transitions are absent, or that there is insufficient π-electron cloud density to allow side chains to overlap.

In our studies, PMeBLA, PClBLA, and PCNBLA have neither an asymmetric absorption band in the long wavelength region nor the enhanced b_0 values which have been reported on PNBLA.[4] Ultraviolet absorption spectra[13] show that these three have small molar extinction coefficients compared with that of PNBLA. Especially, PMeBLA and PClBLA have molar extinction coefficients associated with the aromatic groups which do not differ much from that of PBLA. Nevertheless, these polymers are in right-handed helices. It is remarkable that the helical sense is reversed even by a methyl group which is weakly electron-releasing in contrast with the strongly electron-withdrawing nitro group. Therefore, it is unlikely that stabilization forces of an electronically-coupled aromatic group in the side chain are the primary forces which bring about a reversal

13) Molar extinction coefficients are as follows: PBLA, $\lambda_{max}^{CHCl_3}$ 259 mμ (ε, 210); PMeBLA, $\lambda_{max}^{CHCl_3}$ 265 mμ (ε, 281); PClBLA, $\lambda_{max}^{CHCl_3}$ 268 mμ (ε, 254); PCNBLA, λ_{max}^{DMF} 274 mμ (ε, 825); PNBLA, λ_{max}^{DMF} 275 mμ (ε, 7770).

into a right-handed helix, just as Goodman et al. have proposed for PNBLA. The helix reversals found in the present study also can not be interpreted by the dipole properties of the *p*-substituted benzene rings, since the effects of the introduction of a methyl group on the dipole properties of the aromatic ring should be opposite to those of the other three groups. (The dipole moments of mono-substituted benzenes, Ph-X, are as follows[14]: CH_3, $-0.4(\times 10^{-18})$; Cl, 1.58; C≡N, 4.0; NO_2, 3.98, where the dipole moment of $\overrightarrow{Ph-X}$ is taken to be positive.)

However, in the series of nitro, cyano, chloro, and methyl groups, the transitions occur at 20—30, 40—50, ca. 50, and ca. 70 mol.-%. These values may indicate relative stabilities between PBLA helix and poly-β-(*p*-substituted benzyl)-L-aspartate helices. From these values, it is evident that the helix of PNBLA is the most stable and that that of PMeBLA is the most unstable among the homopolypeptides in the present study. However, the stabilities relative to the PBLA helix differ much less between PCNBLA and PClBLA, while the difference is significant between PMeBLA and PClBLA. These results can be interpreted neither by the electronic nor by the dipole properties of *p*-substituted benzene rings.

These results suggest that the factors which determine the helical sense of PBLA helix are not simple, and that the left-handed helix of PBLA is far less stable.

Experimental

Samples and Apparatus.—The optical rotatory dispersion was measured with a Rudolph photoelectric polarimeter, model 200-S, using a mercury lamp as the light source. Measurements were made at five wavelengths from 5780 to 3650 Å; the concentration was 0.5% w/v, and the path length was 2 dm. The chloroform used was refluxed over and distilled from phosphorus pentoxide.

The mole-per-cent residue content for each of the copolymers is given in a molar ratio in the polymerization mixture of NCA's.[15] The measurements of viscosity were made on solutions in dichloroacetic acid at a concentration of 0.5% w/v using an Ostwald viscometer (35°C) for a qualitative comparison of the relative molecular weights of the various preparations.

Preparation.[16]—*β-Benzyl-L-aspartate.*—The preparation was carried out according to the procedure of Hayakawa, Noguchi, et al.[7] A 32% yield of white powder was obtained; m. p. 221°C (decomp.) $[\alpha]_D^{24}$ +24.4 (*c* 1, 0.1 N HCl).

β-p-Methylbenzyl-L-aspartate. — A mixture of well-pulverized L-aspartic acid (10.0 g.), *p*-toluenesulfonic acid (14.4 g.), and *p*-methylbenzyl alcohol (9.2 g.), which had been prepared by the reduction of *p*-methylbenzaldehyde with sodium borohydride in a methanol solution, was heated at 80°C for 2 hr. with stirring; during the reaction water was removed three or four times under reduced pressure from a reaction vessel. After water (150 ml.) had been added to the reaction mixture and it had been washed with ether (150 ml.), the aqueous layer was neutralized by adding sodium bicarbonate; after the mixture had then stood in a cold place, the precipitate was filtered and recrystallized from water (300 ml.). After decoloring with Norit, β-*p*-methylbenzyl-L-aspartate was obtained (1.70 g. (9.5%)) as white leaflets; m. p. 225—226°C (decomp.) $[\alpha]_D^{25}$ +14.3 (*c* 1, glacial acetic acid).

Found: C, 60.46; H, 6.44; N, 6.02. Calcd. for $C_{12}H_{15}O_4N$: C, 60.75; H, 6.37; N, 5.90%.

β-p-Chlorobenzyl-L-aspartate.—A mixture of L-aspartic acid (1.2 g.), *p*-toluenesulfonic acid (1.5 g.), and *p*-chlorobenzyl alcohol (2.5 g.), which had been prepared by the hydrolysis of *p*-chlorobenzyl chloride in an aqueous sodium carbonate solution, was treated according to the same procedure as was used for β-*p*-methylbenzyl-L-aspartate; recrystallization from boiling water furnished 1.3 g. (58.5%) of the product as white leaflets, m. p. 208°C (decomp.), $[\alpha]_D^{23}$ +25.6 (c 1, glacial acetic acid).

Found: C, 51.35; H, 4.58; N, 5.32; Cl, 13.94. Calcd. for $C_{11}H_{12}O_4NCl$: C, 51.27; H, 4.69; N, 5.44; Cl, 13.76%.

A similar procedure but using concentrated hydrochloric acid instead of *p*-toluenesulfonic acid afforded the product in about a 15% yield.

β-p-Cyanobenzyl-L-aspartate. — The procedure was exactly the same as was used for β-*p*-methylbenzyl-L-aspartate (yield 10—15%); m. p. 187—188°C (decomp.), $[\alpha]_D^{25.5}$ +11.2 (*c* 1, glacial acetic acid).

Found: C, 57.88; H, 5.04; N, 11.60. Calcd. for $C_{12}H_{12}O_4N_2$: C, 58.06; H, 4.87; N. 11.29%.

p-Cyanobenzyl alcohol was prepared by the chlorination of *p*-methylbenzonitrile, followed by hydrolysis with aqueous·potassium carbonate.[17]

β-p-Nitrobenzyl-L-aspartate. — a) A mixture of *p*-nitrobenzyl alcohol (15 g.) and L-aspartic acid (7 g.) was stirred for 0.5 hr., with the temperature kept at 110°C; concentrated hydrochloric acid (3 ml.) was added. After the mixture had been stirred for 2 hr., concentrated hydrochloric acid (1 ml.) was added; then the mixture was stirred for another hour. During the reaction water was removed from the reaction vessel two or three times under reduced pressure. The reaction mixture was then diluted with water, neutralized with sodium bicarbonate, and filtered. Treatment with Norit and recrystallization from water afforded pale yellow crystals whose infrared spectra have two

14) C. P. Smyth, "Dielectric Behavior and Structure," McGraw-Hill, New York (1955), p. 253.

15) For almost these copolymers prepared, the results of their elementary analyses agreed, within ±0.35%, with the values calculated from the molar ratios of the NCA's in the polymerizations. The chloro-residue contents of the copolymers of ClBLA with BLA were determined by the ultraviolet spectra (utilizing the aromatic absorption bands) and by the infrared spectra (utilizing the out-of-plane deformation bands of the aromatic rings). These results agree, within 2 mol.%, with the mixing molar ratios of the NCA's in the polymerizations. For all the copolymers, their molar ratios may, therefore, not differ much from those of the NCA's in the polymerization mixtures.

16) All melting points are uncorrected.

17) J. N. Ashley, H. J. Barber, A. J. Ewins, G. Newberg and A. D. H. Self, *J. Chem. Soc.*, **1942**, 103.

ester-carbonyl stretching absorptions (1740 cm^{-1} and 1720 cm^{-1}). Repeated recrystallizations from hot water gave leaflets (2.7 g.); m. p. 190.5—191°C (decomp.), $[\alpha]_D^{19.5}$ +16.7 (*c* 2, glacial acetic acid), which have a single ester-carbonyl stretching absorption at 1720 cm^{-1} in the infrared spectrum; this was proved to be the β-ester by the conversion to L-asparagine to be described below.

Found: C, 49.17; H, 4.70; N, 10.31. Calcd. for $C_{11}H_{12}O_6N_2$: C, 49.26; H, 4.51; N, 10.44%.

On the other hand, the concentration of the mother liquor gave crystals which have an ester-carbonyl stretching absorption at 1740 cm^{-1}, with a weak shoulder at 1720 cm^{-1}. Repeated recrystallizations afforded α-*p*-nitrobenzyl-L-aspartate (m. p. 180—181.5°C (decomp.), ester νC=O 1740 cm^{-1}). The specimen was converted to L-isoasparagine monohydrate, which was identified by a comparison of its infrared spectrum with that of an authentic sample.[18]

b) The same procedure utilizing *p*-toluenesulfonic acid as was used for β-*p*-methylbenzyl-L-aspartate afforded a mixture which contained more α-esters than was obtained by the procedure of (a).

Conversions of p-Substituted Benzyl-L-aspartates to L-Asparagine.—To establish that these *p*-substituted benzyl-L-aspartates are β-esters and that no racemization takes place during the preparation of the products, these esters were converted as follows. β-*p*-Methylbenzyl-L-aspartate (0.517 g.) was treated with 28% aqueous ammonia at 100°C for 25 hr. in the sealed glass ampule. The solution was then heated to remove the ammonia and washed with ether, the aqueous layer was concentrated, and the residue was recrystallized from aqueous alcohol to give crystals (0.264 g.); m.p. 230°C (decomp.), $[\alpha]_D^{24.5}$ +31.0 (*c* 1, 6 N HCl); reported for L-asparagine monohydrate[2] $[\alpha]_D^{20}$ +31.2.

Found: C, 32.07; H, 7.00; N, 18.35. Calcd. for $C_4H_8N_2O_3 \cdot H_2O$: C, 32.00; H, 6.70; N, 18.66%.

Exactly the same treatments of β-(*p*-chloro, *p*-cyano and *p*-nitro)-benzyl-L-aspartates (0.49, 0.53, and 0.53 g.) as for β-*p*-methylbenzyl-L-aspartate were carried out to afford 0.18, 0.23 and 0.26 g. of L-asparagine monohydrate; their specific rotations were as follows: $[\alpha]_D^{24.5}$ +29.6, +33.7 and +30.7 (*c* 1, 6 N HCl) respectively.

β-Benzyl-L-aspartate-N-carboxyanhydride. — The procedure of Karlson et al.[1] (method B) utilizing the reaction of phosgene with β-benzyl-L-aspartate suspended in anhydrous dioxane[19] at 40°C and the recrystallization of the anhydride from ethyl acetate-*n*-hexane furnished the product as needles.

β-p-Methylbenzyl-L-aspartate-N-carboxyanhydride.—The same procedure as that described above for β-*p*-methylbenzyl-L-aspartate (10.0 g.) afforded the product (7.0 g.) as leaflets, m. p. 129—131°C, $[\alpha]_D^{27}$ −30.6 (*c* 2.6, ethyl acetate).

Found: C, 59.22; H, 5.09; N, 5.45. Calcd. for $C_{13}H_{13}NO_5$: C, 59.31; H, 4.98; N, 5.32%.

β-p-Chlorobenzyl-L-aspartate-N-carboxyanhydride.—The same procedure as has been described above for β-*p*-chlorobenzyl-L-aspartate (15.0 g.) gave the product (5.8 g.) as leaflets, m. p. 162°C (decomp.), $[\alpha]_D^{24}$ −30.1 (*c* 1.5, ethyl acetate).

Found: C, 50.81; H, 3.65; N, 4.74; Cl, 21.86. Calcd. for $C_{12}H_{10}O_5NCl$: C, 50.81; H, 3.55; N, 4.94; Cl, 12.50%.

β-p-Cyanobenzyl-L-aspartate-N-carboxyanhydride.—The same procedure as has been described above for β-*p*-cyanobenzyl-L-aspartate (8.0 g.) and the recrystallization of the anhydride from dioxane-*n*-hexane furnished the product (6.5 g.) as leaflets, m. p. 153—154°C (decomp.), $[\alpha]_D^{27}$ −53.6 (*c* 2.4, dioxane).

Found: C, 57.06; H, 3.95; N, 10.12. Calcd. for $C_{13}H_{10}O_5N_5$: C, 56.94; H, 3.68; N, 10.22%.

β-p-Nitrobenzyl-L-aspartate-N-carboxyanhydride.—M. p. 174—176°C (decomp.), $[\alpha]_D^{25}$ −48.5 (*c* 1.5, dioxane). (Found: C, 48.91; H, 3.67; N, 9.22%.)

Poly-β-benzyl-L-aspartate and Poly-β-p-methyl chloro, cyano or nitrobenzyl-L-aspartate.—A typical polymerization was carreid out as follows: to 7 ml. of dioxane[17] containing 0.4 ml. of a solution of 100 mg. of triethylamine in 10 ml. of dioxane, 1.0 g. of β-benzyl-L-aspartate-*N*-carboxyanhydride was added; A/I=100. The clear solution in a glass ampule[20] (dried for 7 hr. at 140°C) was sealed under an atmosphere of dry

nitrogen and allowed to stand for 3.5 days at 30°C. The solution was poured into 80 ml. of diethyl ether in order to precipitate the polymer, which was washed with ether and reprecipitated from a chloroform solution with ether and dried at 60°C in vacuo.

These β-*p*-methyl, chloro, cyano, and nitrobenzyl-L-aspartate-*N*-carboxyanhydrides were polymerized according to the same procedure as was used for β-benzyl-L-aspartate. The quantities used and the yields obtained for these polymers are summarized in Tables V—VIII. Poly-β-*p*-cyano and nitro benzyl-L-aspartates were reprecipitated from a dimethylformamide solution with ether.

PMeBLA; Found: C, 65.63; H, 6.11; N, 6.58. Calcd. for $C_{12}H_{13}O_3N$: C, 65.74; H, 5.98; N, 6.39%. PClBLA; Found: C, 55.08; H, 4.44; N, 5.77; X, 11.99. PNBLA; Found: C, 52.39; H, 4.26; N, 11.05. Calcd. for $C_{11}H_{10}O_5N_2$: C, 52.80; H, 4.03; N, 11.20%.

Copolymers of β-p-Methylbenzyl-L-aspartate with β-Benzyl-L-aspartate.—Tabel V summarizes the quantities used

and the yields obtained for these copolymers. A typical polymerization was as follows: 0.513 g. of β-*p*-methylbenzyl-L-aspartate-*N*-carboxyanhydride and 0.488 g. of β-benzyl-L-aspartate-*N*-carboxyanhydride (1 : 1 molar ratio) were dissolved in 7.0 ml. of dioxane. To a total of 14.3% w/v NCA's in a dioxane solution, 0.40 ml. of a solution of 100 mg. of triethylamine in 10 ml. of dioxane was added ($A/I=100$). The mixed solution in a glass ampule was sealed under an atmosphere of dry nitrogen and allowed to stand for 3.5 days at 30°C. The workup was the same as for poly-β-benzyl-L-aspartate described above.

Copolymers of β-p-Chlorobenzyl-L-aspartate with β-Benzyl-L-aspartate.—Table VI summarizes the yields obtained for these copolymers. Polymerizations were carried out in a manner similar to that employed for the copolymers of MeBLA with BLA. The NCA's were in a 5% w/v solution, and polymerizations were allowed to proceed for 7.5 days.

Copolymers of β-p-Cyanobenzyl-L-aspartate with β-Benzyl-L-aspartate.—Table VII summarizes the quantities used and the yields obtained for these copolymers. Polymerizations were carried out according to the procedure used for the copolymers of MeBLA with BLA. The NCA's were in a 10% solution for C4011—C4051 and in a 5% solution for C4061—C4091, and polymerizations were allowed to proceed for 5 days. The copolymers were dissolved in chloroform for C4011—C4061 and in dimethylformamide for C4075—C4091, and they were precipitated with ether.

Copolymers of β-p-Nitrobenzyl-L-aspartate with β-Benzyl-L-aspartate.—Table VIII summarizes the quantities used and the yields obtained for these polymers. Polymerizations were carried out according to the procedure used for the copolymers of MeBLA with BLA. The solutions of NCA's were 5% except C2101 (3%), and polymerizations were allowed to stand for 5 days.

The authors wish to express their gratitude to Professor Takehiko Shimanouchi and Professor Kazutomo Imahori, The University of Tokyo, for their encouragement throughout this work. They are indebted to Professor Tatsuo Miyazawa and Dr. Kozo Hamaguchi of Institute for Protein Research, Osaka University for the use of Rudolph photoelectric polarimeter. They are also grateful to Dr. Shinsuke Ose, Dr. Hideji Takamatsu and Dr. Kiyoshi Nakamura of this laboratory for their encouragement and valuable discussions and also greatly indebted to Mr. Satoshi Arakawa for his kind help in the course of their experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2713—2720 (1966)

Studies of Poly-β-benzyl-L-aspartate Helix. II. The Circular Dichroism and Optical Rotatory Dispersion of Copolymers of β-*p*-Methyl, Chloro, or Cyanobenzyl-L-aspartate with β-Benzyl-L-aspartate

By Masahisa HASHIMOTO

Research Laboratory, Dainippon Pharmaceutical Co., Ltd., Ebie, Fukushima-ku, Osaka

(Received February 19, 1966)

The observation of the circular dichroism (240—290 mμ) due to the aromatic side chain indicates that, in a chloroform solution, even the side-chain aromatic rings of the copolyaspartate chain in the right-handed helix are in a regular arrangement to form an outer helix. On the contrary, for the copolyaspartate chain in the left-handed helix, the aromatic rings are much less regular. The ORD measurements indicate that, in a dimethylformamide solution, the poly-β-benzyl-L-aspartate chain is essentially in a random coil form, whereas the para-substituted derivatives are essentially in a right-handed helix. Accordingly, for each series of copolymers, the transition from a random coil form to a right-handed helix is observed as the molar content of the para-substituent is increased. The copolypeptide chain of β-benzyl-L-aspartate and β-(*p*-methylbenzyl)-L-aspartate (molar ratio, 1 : 1) takes either the left-handed helix in a chloroform solution or the right-handed helix in a dimethylformamide solution. Accordingly, for this copolypeptide, the transition from the left to right-handed conformation is observed at the mixing volume ratio, 90 : 10, of the chloroform-dimethylformamide solution.

Goodman et al.[1] have reported that the left-handed helix of poly-β-benzyl-L-aspartate (PBLA) is reversed to the right-handed sense by the introduction of the nitro group in the para-position of the side-chain aromatic ring. They have proposed that this right-handed conformation is stabilized by an electronically-coupled nitroaromatic side-chain helix rigidly arrayed about the main chain helix. In the previous paper,[2] the present author and Aritomi have revealed that the helix reversal

1) M. Goodman, A. M. Felix, C. M. Deber, A. R. Brause and G. Schwartz, *Biopolymers*, **1**, 371 (1963).

2) Part I of this series: M. Hashimoto and J. Aritomi, This Bulletin, **39**, 2707 (1966).

is also brought about by the introduction of the methyl, chloro, or cyano groups at the para-position of the benzyl group. This is quite clear since, for each series of the copolymers of β-benzyl-L-aspartate (BLA) with β-(*p*-methyl, chloro, or cyanobenzyl)-L-aspartate (MeBLA, ClBLA, or CNBLA), a sharp change in b_0 values[3] has been observed with the variation in the molar contents of the para-substituent.

In this paper, the author will present; (1) the results of the optical rotatory dispersion (ORD) and circular dichroism (CD) measurements of the above copolymers in a chloroform solution, in the absorption region (around 240—290 mμ) of the side-chain aromatic rings, and (2) the results of the ORD measurements of the copolymers in a dimethylformamide solution in the visible and near-ultraviolet regions. The evidence obtained to establish the conformations of the side-chain aromatic rings of the copolymers in a chloroform solution will be presented, and the conformations of the copolymer chains in dimethylformamide will be discussed.

Experimental

The samples of the copolymers used in the present study are the same as those used in the previous report[2] except for PClBLA (C1102), which was synthesized in a similar way but by adopting anhydride to the initiator ratio, 50.

Chloroform obtained from E. Merck AG was treated with molecular sieves (4A, Tomoe Kogyo Co., Tokyo) to remove a small amount of ethanol. The dimethylformamide (DMF) used was purified by distillation, and the dichloroacetic acid (DCA) was purified by vacuum distillation.

Ultraviolet ORD and CD measurements were carried out through the courtesy of Professor Kazutomo Imahori of College of General Education, The University of Tokyo, on a JASCO, model ORD/UV5, optical rotatory dispersion recorder with a CD attachment equipped with a xenon light source at 30°C. The CD measurements were made at the minimum scanning speed (10 mμ/10 min.). Fused-quartz cells 10 mm. and 1 mm. long were used. Identical cells and solutions were used in both ORD and CD measurements; the solutions were prepared to be around 2 in optical density. ORD and CD data are expressed in terms of $[m']$ and θ respectively, and their units are both deg.cm²/decimole. The refractive index was estimated from the Sellmeir equation, using the indices of chloroform observed at 434 and 589 mμ.

The ultraviolet absorption measurements were carried on a Hitachi EPS-2U spectrophotometer.

Optical rotatory dispersion measurements in the near-ultraviolet and visible regions were carried through the courtesy of Professor Tatsuo Miyazawa and Dr. Kozo Hamaguchi of the Institute for Protein Research, Osaka University, on a Rudolph, model 200-S, photoelectric polarimeter using a mercury lamp as the light source. The values of b_0 and λ_c were calculated from measurements at five wavelengths, from 5780 to 3650 Å; the concentration was 0.5% w/v, and the path length was 2 dm. In the Moffitt plot, the dispersion of the refractive index is neglected, using the values at the sodium D line.

Results and Discussion

Ultraviolet Rotatory Dispersions and Circular Dichroisms of Copolymers of β-Benzyl-L-aspartate with β-*p*-Methyl, Chloro, and Cyanobenzyl-L-aspartate in a Chloroform Solution.—*a) Copolymers of BLA with CNBLA.*— The copolymer of BLA with CNBLA containing 60 mol.-% cyano residues had b_0 values of −401 in a chloroform solution.[2] The ORD curve (Fig. 1a) of the cpolymer showed a negative plain

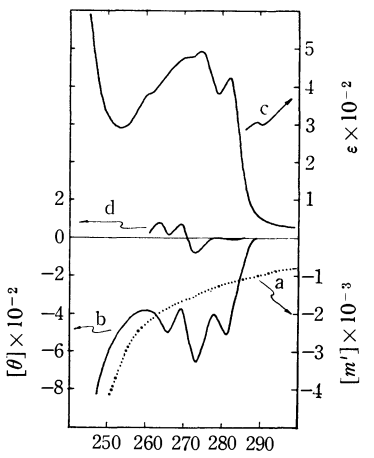

Fig. 1. Curves of ORD (a), CD (b), and UV (c) in chloroform, and CD (d) in chloroform containing 10%v/v dichloroacetic acid for the copolymer of BLA with CNBLA containing 60 mole per cent cyano residues.

curve, and no definite Cotton effect was found in the region from 260 to 290 mμ. However, the CD measurements for this copolymer gave, in this region, a distinct negative CD peak involving fine vibrational structures. This dichroism is evidently associated with the side-chain aromatic rings of the copolymer. This negative ellipticity decreased remarkably in a chloroform solution containing 10% dichloroacetic acid (Fig. 1d). Therefore, it is clear that the CD of this copolymer in a chloroform solution is not essentially due to an optically active chromophore, which still gives rise to CD in a random coil form. (For poly-L-tyrosine, it has been reported that one of the CD bands, observed at 245 mμ in a helical conformation, persists in a random conformation.[4]) Accordingly,

3) W. Moffitt, *J. Chem. Phys.*, **25**, 467 (1956); W. Moffitt and J. T. Yang, *Proc. Natl. Acad. Sci. U. S.* **42**, 596 (1956).

4) G. D. Fasman, E. Bodenheimer and C. Lindblow, *Biochemistry*, **3**, 1665 (1964); S. Beychok and G. D. Fasman, ibid., **3**, 1675 (1964).

the results may be attributed to the fact the negative CD curve involving fine vibrational structures evidently arises from a regular arrangement of the side-chain aromatic rings of this copolymer in a helical conformation. The increasing negative ellipticity with the decrease in the wavelength below 250 mμ observed for the copolymer may suggest that the copolymer has a negative ellipticity for the n-π^* transition near 220 mμ, which is associated with a right-handed α-helix.[5] The above results are consistent with the negative b_0 values (−401).[2]

The ORD and CD curves of the copolymer of BLA with CNBLA containing 30 mol.-% cyano residues are shown in Figs. 2a and 2b respectively. In the region from 250 mμ to 280 mμ, a very weak positive ellipticity was found. The increasing positive ellipticity with a decrease in the wavelength below 250 mμ suggests that this copolymer exists in a left-handed α-helix which is opposite in the helical sense to that of the copolymer containing 60 mol.-% cyano residues. This result is also consistent with the positive b_0 values (+626) observed for this copolymer.[2]

The CD curve of poly-β-benzyl-L-aspartate (PBLA) shows a small ellipticity involving fine structures (Fig. 3b). The magnitude of this ellipticity is rather small; however, the results were reproducible. The peaks in CD curves either in Figs. 2b or 3b do not correspond to those in UV spectra; however, these two CD curves are fairly similar to each other, both in their shape and in the position of the peaks. A comparison of the magnitude of their ellipticity may be meaningless because of the weakness in their ellipticity. However, the fact that the absolute magnitude of the ellipticity of PBLA associated with the aromatic

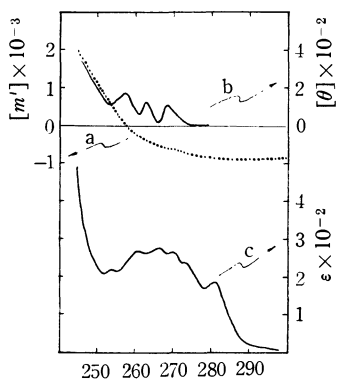

Fig. 2. Curves of ORD (a), CD (b), and UV (c) in chloroform for the copolymer of BLA with CNBLA containing 30 mole per cent cyano residues.

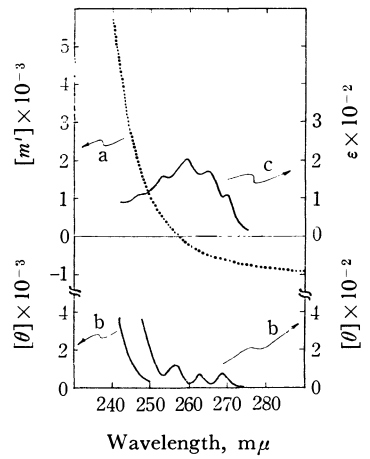

Fig. 3. Curves of ORD (a), CD (b), and UV (c) for PBLA in chloroform solution.

group is smaller than that of the copolymer in Fig. 1b may indicate that the side-chain aromatic rings of PBLA are packed with much less regularity. The same conclusion can be obtained for the side-chain of the copolyaspartate containing 30 mol.-% cyanobenzyl residues, since the magnitude of the CD peak is far less than that of the copolymer in Fig. 1b.

The CD curve of poly-γ-benzyl-L-glutamate (PBLG) may be seen in Fig. 4a. This polypeptide showed no significant ellipticity in the region of the absorption of the aromatic group. This finding indicates that the aromatic rings in PBLG are not in a regular orientation in a chloroform solution, although in oriented solid film Tsuboi has elucidated, from his infrared studies, that the aromatic rings of this polypeptide are held in a regular orientation.[6]

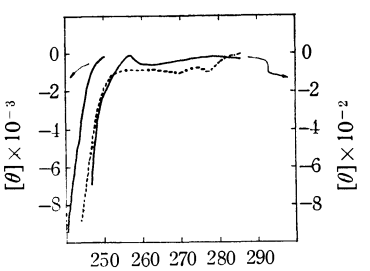

Fig. 4. CD of PBLG (a), ——, and the copolymer of BLA with ClBLA containing 50 mole per cent chloro residues (b), ·····, in chloroform.

b) Copolymers of BLA with MeBLA.—The UV, ORD, and CD curves of copolymers of BLA with MeBLA containing 80 and 60 mol.-% methyl residues in a chloroform solution are shown in Figs.

5) G. Holzwarth, W. B. Gratzer and P. Doty, *J. Am. Chem. Soc.*, **84**, 3194 (1962).

6) M. Tsuboi, *J. Poly. Sci.*, **59**, 139 (1962).

5 and 6 respectively, while the results concerning a homopolymer, poly-β-(*p*-methylbenzyl)-L-aspartate (PMeBLA), are shown in Fig. 7. The ellipticity observed for PMeBLA is to some extent larger than that of the copolymer containing 80 mol.-% methyl residues. The negative CD curves observed for these polypeptides are different in magnitude and in the wavelength of their maximum ellipticity. However, the wavelengths of the CD peaks of these polypeptides are in good agreement with the wavelengths of their UV absorption peaks. These results may indicate that both the methylbenzyl and benzyl groups are regularly arranged

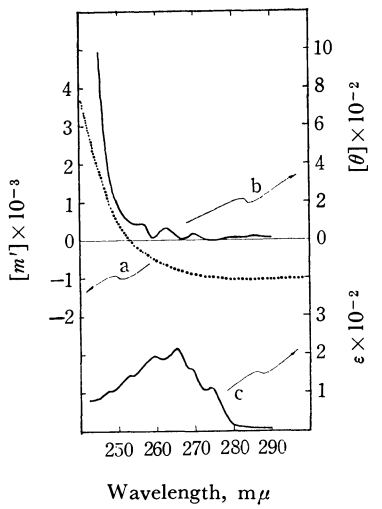

Fig. 6. Curves of ORD (a), CD (b), and UV (c) in chloroform for the copolymer of BLA with MeBLA containing 60 mole per cent methyl residues.

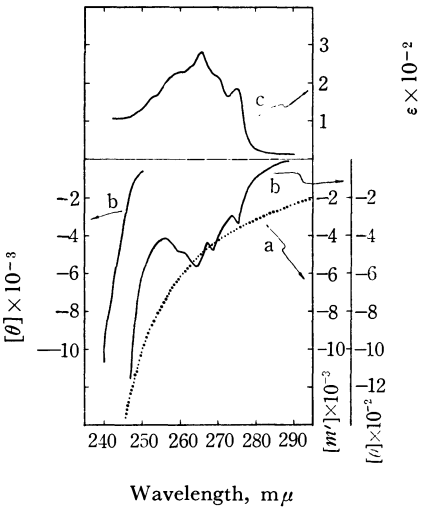

Fig. 7. Curves of ORD (a), CD (b), and UV (c) in chloroform for PMeBLA.

and contribute to the ellipticity. On the contrary, for the copolymer containing 60 mol.-% methyl residues the CD curve (Fig. 6b) is almost the same as that of PBLA (Fig. 3b). This result indicates that this copolymer exists in a left-handed helix and that the methylbenzyl group does not contribute to the ellipticity. Therefore, the side-chain aromatic rings of this copolymer may be said to be much less regularly packed as in PBLA.

c) Copolymers of BLA with ClBLA.—The UV, ORD, and CD curves in a chloroform solution of a copolymer of BLA with ClBLA containing 60 and 40 mol.-% chloro residues are shown in Figs. 8 and 9 respectively, while the results concerning a homopolymer, poly-β-(*p*-chlorobenzyl)-L-aspartate (PClBLA), are shown in Fig. 10. The

results may be interpreted similarly as in case of the BLA-MeBLA series described above. A copolymer of BLA with ClBLA containing 50 mol.-% chloro residues gave no significant CD curve in the region of the side-chain aromatic group (Fig. 4b). Judging from the b_0 value, −93, in a chloroform solution,[2] the copolymer exists essentially in a random coil. As is evident from Figs. 7b and 8b, the ellipticity associated with the aromatic rings is comparatively large in magnitude if the backbone is folded in the right-handed helix, while the left-handed helix exhibits a negligible amount of ellipticity for the side-chain chromophore. Thus, if equal amounts of the left- and right-handed helices exist, the CD value due to the right-handed helix would exceed that of the left-handed one, and the resulting CD curve should be one similar in shape to, and a half the magnitude of, that of the right-handed helix (Fig. 10). However, since no significant peak was detected in the CD curve of the copoly-(BLA-ClBLA) (50 : 50), as may be seen in Fig. 4b, the assumption of the mixture of the left- and right-handed helices for this copolymer should be discarded; rather, the copolymer has been proved to exist in a random coil. The amount and the sense of the helical conformation judging from CD measurements of PClBLA and three copolymers (chlororesidue contents; 40, 50, and 60 mol.-%) are consistent with those obtained from b_0 analysis.[2]

A pronounced increase in negative ellipticity and negative ORD with a decrease in the wavelength below 250 mμ was observed for both PMeBLA and PClBLA. This result indicates that both PMeBLA and PClBLA have a negative ellipticity for the n-π^* transition near 220 mμ; it leads to the conclusion that both polypeptides exist in the right-handed helix, although the ultraviolet absorption of chloroform prevents the direct measurement of the n-π^* transition around 220 mμ. On the other hand, a positive ellipticity and a positive ORD curve were observed for PBLA, which exists in the left-handed α-helix. In each series of copolymers, the transition from the left- to the right-handed helix, depicted by the change in the signs of ellipticity and optical rotation parameter, takes place in a narrow range of composition.

The ellipticities observed for PMeBLA and PClBLA at 250 mμ, are about twice as large as that observed for PBLG, although this comparison is only qualitative because their ellipticity steeply changes around 250 mμ. The ellipticity around 240 mμ observed for PMeBLA and PClBLA in chloroform is also about twice as large as that for poly-γ-methyl-L-glutamate, as estimated from the results of Holtzwarth et al.[7] The ORD curve of PBLA in chloroform in the present study is in accordance with that in methylene dichloride reported by Blout.[8] However, for PClBLA and PMeBLA the observed optical rotations at 250 mμ are about twice and one-and-a-half times as large, respectively, as that for poly-α, L-glutamic acid in a water solution (pH, 4.3; the helical form), as estimated from the results of Blout et al.[9] The above comparison indicates that, for PClBLA and PMeBLA, the CD and ORD around 240 mμ are both larger in magnitude than the ordinary polypeptides in the right-handed α-helix. These results may be due to the contributions to CD and ORD of the aromatic absorption band around

7) G. Holzwarth and P. Doty, *J. Am. Chem. Soc.*, **87**, 218 (1965).

220 mμ[10] and/or of the ester-carbonyl absorption around 220—230 mμ resulting from the regular arrangement of the side-chain group. However, qualitatively the above results do not change the conclusion obtained as to the helical sense of the polypeptides.

In the present study, the negative CD bands were found in the 250—290 mμ region, whereas no definite Cotton effect was observed in this region, for the polypeptide chains forming the right-handed helix. The Kronig-Kramers transform relating ellipticity to rotation has been shown to lead to the following relation when the circular dichroism is in a Gaussian form:[11]

$$[\theta^\circ] = \pm 0.82 \frac{n_\lambda^2 + 2}{3} ([m'_{max}] - [m'_{min}])$$

where $[\theta^\circ]$ is the maximum ellipticity of the band, and $[m']$ is the reduced mean residue rotation. This relation suggests that Cotton effects should be observed in the 250—290 mμ region for the present, right-handed polypeptides. (Even when the CD curve deviates from a Gaussian curve, the relation should hold qualitatively.) Furthermore, essentially the same selection rules hold on ORD and CD even in the case of a vibration-coupled optically active chromophore.[12] The largest observed ellipticity associated with the aromatic chromophore in the present study is −650 (Fig. 1b). The value of $(n_\lambda^2+2)/3$ in the above formula is about 0.7 in the region from 260 mμ to 290 mμ; thus, the value of the $0.82(n_\lambda^2+2)/3$ term, is about 1.2. Therefore, if this maximum ellipticity (−650) is completely due to a band, the above relation leads to an estimation that a trough, about 280 in magnitude, should appear in the ORD curve. However, as is evident from Fig. 1b, the three peaks of CD lie close together. In addition, the contribution of the large ellipticity (ca. -1.5×10^4) of the n-π^* transition around 220 mμ to this region cannot be excluded completely. Therefore, if one assumes that the net maximum ellipticity for the band is about a half of the observed value after the correction of the contributions from the other bands, this ellipticity may, practically speaking, not be so large as to give rise to a definite Cotton effect. This situation is less profound in the other polypeptides in the present study.

The results of the ORD and CD measurements described above indicate qualitatively but strongly that a reversal in the helical sense really takes place in each series of copolymers, and that PClBLA and PMeBLA in a chloroform solution exist in the right-handed α-helix. The results also lead to the conclusion that, in the right-handed helix, the side-chain aromatic rings of the copolyaspartate chain are arranged regularly to form an outer helix, whereas in the left-handed helix the aromatic rings are much less regular.

From the results in the present study, it can not be determined whether or not an outer helix formed by the side-chain aromatic rings contributes to the stability of the right-handed helix of the main chain.

The Optical Rotatory Dispersion in Dimethylformamide.—In a chloroform solution PBLA is known to exist in a left-handed α-helix,[13,14] whereas in a dimethylformamide (DMF) solution PBLA has been estimated to be essentially in a random conformation from the studies of the copolymers of BLA and *p*-nitrobenzyl-L-aspartate.[1]

The results of the ORD measurements in the present study of homopolymers and copolymers of BLA with CNBLA, ClBLA, or MeBLA are listed in Tables I—III respectively.

In the series of copolymers of BLA and CNBLA, the specific rotations at 546 mμ are ca. −100 for the copolymers containing cyanoresidues of more than 30 mol.-% (C4101—C4041); the value sharply decreases to ca. −40 with a decrease in the cyanoresidue content, as Table I shows. (PBLA itself and the copolymers up to a 30 mol.-% cyanoresidue content were less soluble in DMF, and 0.25% solutions were used for the measurements instead of a 0.5% solution.) The results indicate that there is a transition.

A similar change are found in the b_0 value, just as in case of specific rotation. The b_0 values of

−480——580 for the copolymers (C4101—C4041) become sharply less (ca. −300) for the rest of the copolymers (C4021—C0014). As has been reported in the previous paper,[2] the b_0 value of PBLA in a chloroform solution was +659 (left-handed helix), whereas the value of PClBLA or PMeBLA was −680 (right-handed helix). Karlson et al. have shown that the b_0 value of ca. −250 is attributable to the residual contribution for PBLA in a random chain.[13] If this residual contribution exists in the left- and right-handed helical conformations of poly-L-aspartate esters, the b_0 values should differ not only in sign but also in magnitude according to the sense of the helix. The small difference in b_0 value between the above-mentioned left- and right-handed poly-L-aspartate esters leads to the conclusion that the residual contribution to the b_0 value is small for these polypeptides in a helical solvent like chloroform. Therefore, the b_0 value of ca. −660 can possibly be expected for poly-L-aspartate esters in a DMF solution if they exist in the right-handed helix.

On the other hand, the b_0 values of PBLA were observed to be −315 and −280 in DMF and DCA solutions respectively. The similarity in the b_0 values of the two solvents suggests that PBLA exists essentially in a random coil in a DMF solution because DCA has been revealed as a random coil solvent for PBLA by Karlson et al.[13] This fact seems to be an exception for PBLA, because DMF is usually considered to be a helix-promoting solvent.

As for λ_c values observed for this series of copolymers in a DMF solution, no sharp change in λ_c was found as the molar content of the cyano residue varied. λ_c values of 251 and 285 were observed for PCNBLA and PBLA respectively, both in a DMF solution. These values are ordinally correlated with the right-handed helix,[15] since the constant, λ_c, usually has a value of 210 or less for the random-coil form (for poly-γ-benzyl-L-glutamate[16] and poly-γ-methyl-L-glutamate[17] in a DCA solution, 180 and 187 were reported as the respective λ_c values). The plot for λ_c of PBLA in a DCA solution was nonlinear, but it could roughly be estimated to be 280—310. Considering that both values of b_0 and λ_c obtained for PBLA in a DMF solution coincide with those for a DCA solution, it may be deduced that these unusually high values should be correlated with a random coil form. Another example of anomaly is found for poly-L-tyrosine (λ_c=330) in its coiled form.[18] Thus, both λ_c and b_0 strongly suggest that PBLA exists in a random form in a DMF solution.

On the other hand, the b_0 values of −580——480 observed for the copolymers of BLA and CNBLA containing cyano residues more than 30 mol.-% in a DMF solution are somewhat smaller than the value for PClBLA or PMeBLA in a chloroform solution, but considerably larger than the value for PBLA in a DMF solution. The evidence that some copolymer in a DMF solution is in a right-handed helix may be derived from the fact that a sharp change in b_0 value from ca. −600 to ca. +600 was found for a copoly-L-aspartate ester (BLA-MeBLA 1 : 1) in chloroform-DMF solutions, as will be described later. Consequently, the b_0 values of −580——480 indicate that the copolymers are mainly in a right-handed helix, and possibly partially in a random coil form also. The nonlinear change in b_0 and $[\alpha]_{546}$ values (Table I) observed for a series of copolymers of BLA and CNBLA in DMF solution reflect a transition from a right-handed helix to a random-coil form, a transition which occurs as the molar content of the cyano residue is decreased. There is a possibility that the transition also affects the solubilities of the copolymers in DMF.

The results of the ORD measurements of the copolymers of BLA with ClBLA and with MeBLA are shown in Tables II and III. For these series the results are essentially the same as with a series of copolymers of BLA and CNBLA; PClBLA and PMeBLA themselves exist mainly in a right-handed helix, and in the case of copolymers with BLA transitions, from a right-handed helix to a random-coil form, were found at 15—30 and 30—40 mol.-% of chloro and methyl residue contents respectively.

The above finding that poly-β-(*p*-substituted benzyl)-L-aspartates exist in a right-handed helix in a DMF solution was confirmed by another piece of evidence that PClBLA showed a helix-to-coil transition in a DMF-DCA solvent system (as is shown in Fig. 11). When DCA was added to the PClBLA solution in DMF up to a 24% v/v of DCA,

the solution became turbid; the further addition of DCA caused the precipitation of PClBLA. The same phenomenon occurred in the reversed procedure when DMF was added to a PClBLA solution in DCA up to a 70% v/v of DMF. The small magnitude of the observed optical rotation of PClBLA in DMF or DCA solutions resulted in the somewhat scattered b_0 plot of Fig. 11. However, the nonlinear change in the b_0 value in Fig. 11 evidently indicates that a helix-to-coil transition takes place as the DCA content in DMF increases.

Finally, a clear-cut transition from the left- to the right-handed helix should be mentioned for a copoly-BLA: MeBLA (molar ratio, 1 : 1). This

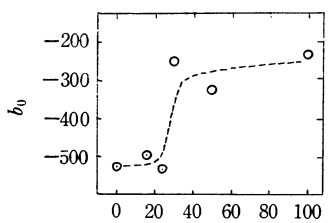

Fig. 11. b_0 Values of PClBLA versus solvent composition (DMF-DCA).

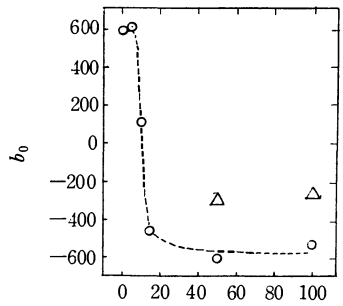

Fig. 12. b_0 Values of the copolymer of BLA with MeBLA containing 50 mole per cent methyl residues versus solvent composition (○ chloroform-DMF; △ DMF-DCA).

copolypeptide chain takes either the left-handed helix in a chloroform solution or the right-handed helix in a DMF solution (b_0 value; +602 in $CHCl_3$, −532 in DMF). For this copolymer in chloroform-DMF solutions, the observed b_0 values as a function of the solvent composition are illustrated in Fig. 12. The sharp change in b_0 value from ca. +600 to ca. −600 obviously indicates that the transition from the left- to right-handed helix occurs at the mixing volume ratio, 90 : 10, of the chloroform-DMF solution. Therefore, it may also be expected that a transition from the right-handed helix conformation to a random-coil form can be observed in the DMF-DCA solvent system. Such experiments were, indeed, attempted, but unfortunately the transition was not observed because of the precipitation of the copolymer when DCA was added in about a 10% v/v ratio to its DMF solution.

The author wishes to express his gratitude to Professor Takehiko Shimanouchi, The University of Tokyo, for his encouragement. He is also indebted to Professor Kazutomo Imahori and Dr. Masaru Shiraki, The University of Tokyo, for their useful discussions. Moreover, he is grateful to Dr. Shinsuke Ose, Dr. Hideji Takamatsu, and Dr. Kiyoshi Nakamura of this laboratory for their encouragement and valuable discussions, and also to Mr. Satoshi Arakawa for his kind help in the experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2721—2723 (1966)

A New Method for the Phosphorylation of Alcohols by Means of Bromine and Dibenzylhydrogen Phosphite

By Teruaki MUKAIYAMA, Hajime KOUDA and Kyoko KODERA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received March 12, 1966)

Various alkyldihydrogen phosphates were obtained in good yields by reacting alcohols, dibenzylhydrogen phosphite, and bromine in the presence of triethylamine, followed by catalytic hydrogenation. When benzyl alcohol and diethyl phosphite were used in the above reaction, only the oxidation of the latter took place, giving diethylhydrogen phosphate in an excellent yield. These results suggest that the above phosphorylation of alcohol proceeds through a quaternary phosphonium salt, i. e., dibenzyloxyalkyloxyhydroxy phosphonium bromide, which is then converted into an alkylbenzylhydrogen phosphate. The effect of tertiary amines on this type of phosphorylation was also examined.

The reactions of various phosphorous compounds with monobromocyanoacetamide and benzylalcohol, and the phosphorylation of alcohols and phenols by means of dibenzyl phosphite (or phosphorous acid) and monobromocyanoacetamide, have been studied in detail.[1-5]

This paper will describe an improved synthesis of monoesters of phosphoric acid, a method in which bromine in the presence of triethylamine is employed as an oxidizing reagent in place of the monobromocyanoacetamide mentioned in the above experiments. In this phosphorylation, it was found that bromine was a more reactive and effective oxidizing reagent than monobromocyanoacetamide, which was prepared from bromine and cyanoacetamide. When bromine was added to a mixture of ethanol, dibenzyl phosphite, and triethylamine in benzene under ice cooling, triethylamine hydrobromide was immediately separated. After the triethylamine hydrobromide (98%) and benzene had been removed and the benzylbromide had been fractionated (97%), the residue, benzylethylhydrogen phosphate, was hydrogenated without further purification.

Thus ethyldihydrogen phosphate was obtained in a 81% yield as its anilinium salt.

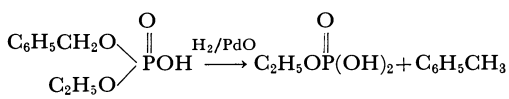
5) T. Obata and T. Mukaiyama, This Bulletin, in press.



In a similar fashion, *n*-propyl, isopropyl, *n*-butyl or bornyldihydrogen phosphate was obtained as the anilinium salt in a 98, 78, 82, or 30% yield respectively. Bromine is more reactive than monobromocyanoacetamide, and the phosphorylation of alcohols takes place rapidly at a lower temperature, resulting in the formation of the desired phosphates in good yields without the use of excess alcohols.

It has been reported that the phosphorylation of phenol by the use of dibenzylphosphate and monobromocyanoacetamide gave a 79% yield of phenyldihydrogen phosphate as the anilinium salt. In the present experiment, however, the phosphorylation of phenol failed, and only bromophenols were obtained. Apparently, the isolation of phosphorous acid (as anilinium salt) in a 72% yield, after catalytic hydrogenation, indicates that dibenzyl phosphite did not participate in this reaction and that the preferential bromination of phenol occurred.

There are two possible pathways for the formation of monoalkyl phosphate by this procedure: (A) Initially a quaternary phosphonium salt (I) is formod. The intermediate (I) is then converted into another quaternary phosphonium salt (II), which is in turn decomposed to alkylbenzyl phosphate and benzyl bromide. (B) Initially the $(C_6H_5CH_2O)_2(HO)PBr_2$ compound is formed. This compound is then converted to benzylbromophosphonate, $(C_6H_5CH_2O)(HO)\overset{\overset{O}{\|}}{P}Br$, by the elimination of benzyl bromide. The bromophosphonate thus formed reacts with an alcohol in the presence of triethylamine to yield the corresponding alkylbenzyl phosphate.

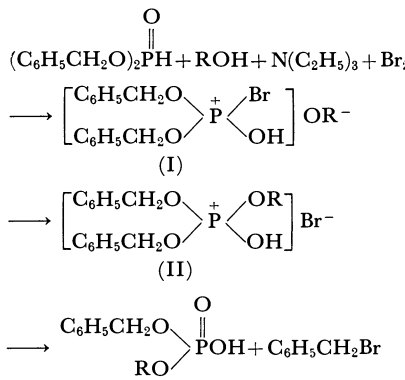
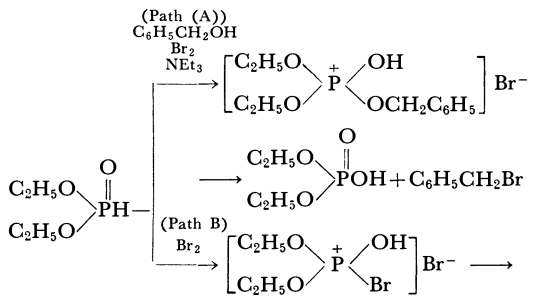
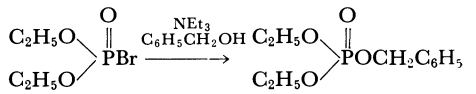
1) solvent system ; *n*-propanol - concentrated ammonium hydroxide - water, 6 : 3 : 1.



In order to differentiate the two alternatives, A and B, the reaction was tried using diethyl phosphite, benzyl alcohol, and bromine in the presence of triethylamine. In this case, since the ethyl group is not so easily eliminated as the benzyl group or hydrogen, it can be expected that diethyl phosphate will be formed according to the mechanism A, while diethylbenzyl phosphate will be formed according to the mechanism B. When the reaction was carried out at 0°C diethyl phosphate (68%), benzyl bromide (86%), and triethylamine hydrobromide (90%) were obtained. Therefore, it can be concluded that the key intermediate of the above-mentioned phosphorylation is the quaternary phosphonium salt (II), rather than benzylbromophosphonate.





In order to examine the effect of tertiary amines on this type of phosphorylation, the reaction of diethyl phosphite, bromine, and benzyl alcohol in the presence of triethylenediamine, *N*-methylmorpholine, pyridine, or hexamethylenetetramine was attempted under identical conditions (see Table II). The results show that the yield of diethyl phosphate is influenced by the basicity of amine, increasing with an increase in the basicity.

Concerning the phosphorylation of alcohol with phosphorous compounds and halogen, it has been reported by Kirby[6] that 4-hydroxy but-2-enyl phosphate was obtained in a 86.5% yield by treating butene-1, 4-diol with iodine, and phosphorous acid in the presence of triethylamine. In the present experiment, however, it was found that the reaction of iodine, dibenzyl phosphite,

and alcohols in the presence of triethylamine resulted in the formation of a large quantity of unidentified red tarry products.

Experimental

Reagents.—The solvents, alcohols, and amines were purified and dried by ordinary procedures. Diethyl phosphite[7] and dibenzyl phosphite[8] were prepared according to the procedures described in the literature.

The Phosphorylation of Alcohols by Means of Bromine and Dibenzyl Phosphite in the Presence of Triethylamine.—A solution of bromine (1.60 g.; 0.01 mole) in 10 ml. of benzene was vigorously stirred, drop by drop, into a solution of dibenzyl phosphite (2.70 g.; 0.01 mole), ethanol (0.50 g.; 0.01 mole), and triethylamine (1.01 g.; 0.01 mole) in 10 ml. of benzene under ice cooling. After stirring had been continued for 1 hr., the solution was heated at 40—50°C for an additional hour. The solution was then allowed to stand overnight and filtered to remove triethylamine hydrobromide (1.77 g.; 98%; m. p. 246—247°C). From the filtrate, benzene and benzyl bromide (1.68 g.; 97%; b. p. 75—82°C/23 mmHg) were fractionated, and the residue was dissolved in 50 ml. of 99% ethanol. The solution was then hydrogenated over palladium oxide (100 mg.) at room temperature under atomospheric pressure. After the absorption of quantitative amount of hydrogen, the catalyst was removed by filtration and the solution was concentrated to about 10 ml. under reduced pressure. Aniline (1.9 g.) was then added, giving anilinium ethyldihydrogen phosphate (1.76 g.; 81%; m. p. 155—157°C). The anilinium salt was purified by chromatography (cellose-*n*-butanol - water) and recrystallized from acetonitrile-water, m. p. 157—158°C. A mixed-melting-point determination with an authentic sample was not depressed.

Found: C, 42.23; H, 7.83; N, 6.48. Calcd. for $C_8H_{14}NO_4P$: C, 43.84; H, 6.39; N, 6.56%.

Ethyl phosphate itself was also identified with an authentic specimen by paper chromatography (R_f 0.37) *n*-propyl, isopropyl, *n*-butyl, and bornyldihydrogen phosphates were obtained as their anilinium salts by the phosphorylation of *n*-propanol, isopropanol, *n*-butanol and borneol respectively (see Table I).

The Reaction of Diethyl Phosphite with Benzyl-Alcohol and Bromine in the Presence of Triethylamine.—A solution of bromine (1.60 g.; 0.01 mole) in 10 ml. of benzene was vigorously stirred, drop by drop, into a solution of diethyl phosphite (1.38 g.; 0.01 mole), benzyl alcohol (1.10 g.; 0.01 mole), and triethylamine (1.01 g.; 0.01 mole) in 10 ml. of benzene under ice cooling. The mixture was then allowed to stand overnight and filtered to remove triethylamine hydrobromide (1.63 g.; 90%). From the filtrate, benzyl bromide (1.48 g.; 86%; b. p. 75—85°C/23 mmHg) and diethyl phosphate (1.05 g.; 68%; b. p. 114—117°C/0.02 mmHg) were obtained by fractionation. Diethyl phosphate was identified with an authentic sample by paper chromatography (R_f 0.70; solvent system, *n*-propanol - concentrated ammonium hydroxide - water 6 : 3 : 1).

The Reaction of Diethyl Phosphite with Bromine and Benzyl Alcohol in the Presence of Various Tertiary Amines.—A solution of bromine (1.60 g., 0.01 mole) in 10 ml. of benzene was vigorously stirred, drop by drop, into a solution of diethyl phosphite (1.38 g.; 0.01 mole), benzyl alcohol (1.10 g.; 0.01 mole) and triethylenediamine (0.60 g.; 0.005 mole) under ice cooling. The mixture was then allowed to stand overnight and filtered to remove triethylenediamine dihydrobromide (1.24 g.; 98% d. p. 347—348°C). From the filtrate, benzyl bromide (1.29 g.; 74% b. p. 70—84°C/6 mmHg) and diethyl phosphate (0.92 g.; 60%; b. p. 118—121°C/0.03 mmHg) were obtained by fractionation.

Similarly, diethyl phosphate was obtained in yields ranging from 68% to 36% by treating alcohol with diethyl phosphite and benzyl alcohol and bromine in the presence of various amines, such as pyridine, *N*-methylmorpholine and hexamethylenetetramine. The results are listed in Table II.

The Reaction of Phenols and Dibenzyl Phosphite with Bromine in the Presence of Triethylamine.—A solution of bromine (1.60 g.; 0.01 mole) in 10ml. of benzene was vigorously stirred, drop by drop, into a solution of dibenzyl phosphite (2.70 g.; 0.01 mole), phenol (0.95 g.; 0.01 mole) and triethylamine (1.01 g.; 0.01 mole) in 10 ml. of benzene under ice cooling. The mixture was allowed to stand overnight and then filtered to remove triethylamine hydrobromide (1.73 g.; 95%). From the filtrate, *o*-bromophenol (34%; it was identified by gas chromatography) was removed by distillation under reduced pressure. The residue was dissolved in 30 ml. of 99% alcohol and hydrogenated over palladium oxide (100 mg.) at room temperature under atmospheric pressure. After the absorption of hydrogen had ceased, the catalyst was removed by filtration and the solvent was removed under reduced pressure. The residue was dissolved in 10 ml. of 95% alcohol, and aniline (1.9 g.) was added to the solution. The anilinium salt of phosphorous acid (1.25 g.; 71.5%; m. p. 170—173°C) was obtained; recrystallization from acetonitrile-water raised the melting point to 173—175°C. It was identified by paper chromatography (R_f 0.31; an authentic sample, R_f 0.30; solvent system, *n*-propanol - concentrated ammonium hydroxide - water, 6 : 3 : 1).

Found: C, 41.21; H, 6.26; N, 8.32. Calcd. for $C_6H_{10}NO_3P$: C, 41.14; H, 5.71; N, 8.32%.

Similarly, phosphorous acid (m. p. 172—173°C) resulted as anilinium salt in the case of the reaction of *p*-nitrophenol, and no depression was observed in a mixed-melting-point determination with an authentic sample.

The authors wish to express their hearty thanks to Dr. Oyo Mitsunobu and Mr. Teisuke Obata for their kind help during the course of this experiment, and to Miss Keiko Nakamura for her microanalysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2724—2728 (1966)

The Chemistry of Polyazanes. V. The Mechanism of the Oxidation of Benzalphenylhydrazone

By Hiroshi MINATO, Hiroo TATENO* and Hiroshi YOKOKAWA*

Department of Chemistry, International Christian University, Mitaka, Tokyo

(Received March 18, 1966)

Benzalphenylhydrazone was oxidized with amyl nitrite and with sodium hypoiodite, and the products of the oxidation were analyzed. The products identified were dibenzaldiphenyltetrazone, α-benzilosazone and unoxidized benzalphenylhydrazone. The mechanism of the oxidation was discussed.

The oxidation of benzalphenylhydrazone (I) was investigated by several chemists many years ago, but the mechanisms proposed were not convincing, nor were the products of the oxidation quantitatively studied.

Minunni[1] oxidized the benzalphenylhydrazone with mercuric oxide, and obtained the compound II, dibenzaldiphenyltetrazone.

$$\underset{\text{(I)}}{C_6H_5CH{=}NNHC_6H_5} \xrightarrow[\text{or AmONO or NaOI}]{\text{HgO}}$$

(m. p. 158°C)

$$\underset{\text{(II)}}{\begin{matrix}C_6H_5CH{=}NNC_6H_5\\ |\\ C_6H_5CH{=}NNC_6H_5\end{matrix}} \quad \text{and/or} \quad \underset{\text{(III)}}{\begin{matrix}C_6H_5C{=}NNHC_6H_5\\ |\\ C_6H_5N{-}N{=}CHC_6H_5\end{matrix}}$$

(m. p. 186°C) (m. p. 202°C)

$$\text{and/or} \quad \underset{\text{(IV}_\alpha\text{)}}{\begin{matrix}C_6H_5C{=}NNHC_6H_5\\ |\\ C_6H_5C{=}NNHC_6H_5\end{matrix}}$$

(m. p. 208°C)

Pechmann[2] oxidized the benzalphenylhydrazone with amyl nitrite and also obtained compound II.

Ingle and Mann[3] repeated Pechmann's experiment and obtained a compound melting at 202°C as well as the compound II melting at 186°C. Ingle and Mann assigned the structure III to this new compound. Then Ingle and Mann, using sodium hypoiodite as a new oxidizing agent, obtained a compound melting at 208°C as well as the compound II. They assigned the structure IV, benzilosazone, to this compound. However, the benzilosazone formed by mixing benzil and phenylhydrazine melts at 225°C. Therefore, they named the oxidation product (m. p. 208°C) as α-benzilosazone, and called the osazone (m. p. 225°C) formed from benzil and phenylhydrazone β-benzilosazone.

$$C_6H_5CH{=}NNHC_6H_5 \xrightarrow{\text{NaOI}} \text{(II)}$$

$$+ \quad \underset{\text{(IV}_\alpha\text{) m. p. 208°C}}{\begin{matrix}C_6H_5{-}C{=}N\diagdown NHC_6H_5\\ |\\ C_6H_5{-}C{=}N\diagup NHC_6H_5\end{matrix}}$$

$$\begin{matrix}C_6H_5{-}C{=}O\\ |\\ C_6H_5{-}C{=}O\end{matrix} + 2C_6H_5N_2H_3 \rightarrow$$

$$\underset{\text{(IV}_\beta\text{) (m. p. 225°C)}}{\begin{matrix}C_6H_5{-}C{=}N\diagup NHC_6H_5\\ |\\ C_6H_5{-}C{=}N\diagdown NHC_6H_5\end{matrix}}$$

However, they did not mention anything about the reason why IV_α, not IV_β, was produced by the oxidation of benzalphenylhydrazone.

This investigation was undertaken in order to find out: 1) the products of the oxidation of benzalphenylhydrazone by amyl nitrite and sodium hypoiodite; 2) whether or not compound III was present in the oxidized mixture, and 3) a plausible mechanism for the oxidation of benzalphenylhydrazone.

Experimental

Benzalphenylhydrazone (I).—By mixing phenylhydrazine and benzaldehyde in ethanol, yellow crystals of benzalphenylhydrazone were produced. After the recrystallization from ethanol, they melted at 155—156°C. (Literature: 156°C).

β-Benzilosazone (IV_β). — A hot ethanol solution containing 4.5 g. of phenylhydrazine hydrochloride (0.032 mol.) and 11.3 g. of sodium acetate (0.1486 mol.) was added to an ethanol solution containing 3 g. of benzil (0.0142 mol.). Bright yellow crystals were recrystallized from a 2 : 1 mixture of benzene and ethanol. M. p. 224—225°C (Literature: 225°C).

The Oxidation of Benzalphenylhydrazone (I) by Amyl Nitrite.—Five grams of benzalphenylhydrazone (I) (0.0255 mol.) was dissolved in 100 ml. of ether, and 6.0 ml. (0.0403 mol.) of amyl nitrite was

added to this solution. The mixture was heated on a water-bath at 40—50°C for 6 hr. This solution was orange yellow at first, but on further heating it became darker, and yellow crystals precipitated. Brown nitrogen dioxide gas evolved for several hours.

The mixture was cooled, and the yellow crystals were filtered and washed with ethanol and ether; yield, 0.5690 g.; m. p. 184—186°C. This was identified as dibenzaldiphenyltetrazone (II) from its melting point and its infrared spectrum. The filtrate was evaporated to dryness to yield 5.114 g. of a yellowish-red residue. This residue was divided by repeated recrystallization from ether and ethanol into three fractions. The first fraction, weighing 0.0212 g., was identified as the benzalphenylhydrazone (I) by a study of its melting point and its infrared spectrum. The second fraction, weighing 3.990 g., was identified as α-benzilosazone, (IV_α) from a study of its melting point and its infrared spectrum. The third fraction, weighing 1.003 g., was an oily substance which was not identified.

The Oxidation of Benzalphenylhydrazone (I) by Iodine and Sodium Ethoxide.—Ten grams of benzalphenylhydrazone (I) (0.0510 mol.) in 200 ml. of ether were added to a solution of 1.59 g. of sodium (0.0650 mol.) in 20 ml. of ethanol. Then an ethereal solution of 6.57 g. (0.0510 mol.) of iodine was gradually stirred into this mixture over a 1.5 hr. period at room temperature. Then the solution was shaken with 50 ml. of a saturated solution of sodium sulfite in order to remove the last trace of iodine. Upon the evaporation of the ether, 10.773 g. of a brownish-red, somewhat resinous residue was obtained. This residue was divided into four fractions by repeated recrystallizations from ethanol, ethyl acetate, and/or benzene. The first three fractions were identified, by a study of infrared spectra and their melting points, as 0.296 g. of dibenzaldiphenyltetrazone (II) (0.71 mmol.), 4.943 g. of α-benzilosazone (IV_α) (12.67 mmol.), and 1.256 g. of benzalphenylhydrazone (I) (6.41 mmol.). It was not possible to identify the fourth fraction, which was viscous and resin-like.

An Attempt to Oxidize α-Methylphenylhydrazone of Benzaldehyde.—A solution of 1.008 g. of the α-methylphenylhydrazone of benzaldehyde (0.0048 mol.) in 12 ml. of diethyl ether and a solution of 0.15 g. of sodium (0.0066 mol.) in 2 ml. of ethanol was mixed; a solution of 1.67 g. of iodine (0.0066 mol.) in 10 ml. of ether was then stirred, drop by drop, into this mixture. The solution thus prepared was treated in a manner similar to that described above for the oxidation of benzalphenylhydrazone. The white crystals obtained was recrystallized from ethanol; yield, 0.892 g. The melting point (105—107°C) and the infrared spectrum of these crystals were identical with those of an authentic sample of the α-methylphenylhydrazone of benzaldehyde.

An Attempt to Reduce β-Benzilosazone.—To a mixture of 3.7 g. of β-benzilosazone (0.0095 mol.), 90 ml. of ethanol and 20 ml. of benzene, 82 g. of a 3% sodium amalgam (0.0107 mol.) was added, at one time, at 90°C, and in a carbon dioxide atmosphere; the mixture was then stirred for 9 hr. at 90°C. The yellow color of β-benzilosazone disappeared within 2 hr. of the stirring. After 9 hr., the reaction mixture became white and highly viscous. It was neutralized with a 10% hydrochloric acid solution to pH 7.2. The mercury was removed, and the solution was made strongly acid by the addition of concentrated hydrochloric acid. When the solution was concentrated by the evaporation of the solvents, a pale green solution was obtained. When diethyl ether was added to this solution, white crystals obtained; yield, 0.43 g.; m. p. 242—244°C. From the mother liquor, 0.30 g. of white crystals were obtained; m. p. 183—184°C. When the filtrate was further evaporated, a dark brown solution of a high viscosity remained.

Results and Discussion

The products of the oxidation of benzalphenylhydrazone (I) with amyl nitrite are summarized in Table I. Pechmann[2] oxidized benzalphenylhydrazone with amyl nitrite; he identified only the dibenzaldiphenyltetrazone (II), which was very little soluble in ethanol and was easily isolated. When Ingle and Mann[3] repeated Pechmann's experiment, they found a compound melting at 202°C as well as the tetrazone (II). They assigned the structure III to this compound, but the assignment was made without any convincing evidence. Our experiment did not indicate the presence of the compound III. Since our experiment did not account for 100% of the starting material, the production of the compound III was not completely excluded. However, our data seem to imply that the compound melting at 202°C was most likely an impure form of α-benzilosazone, which melted at 208°C.

Table I. Products of oxidation of benzalphenylhydrazone with amyl nitrite*

Product	g.	mmol.	mol./mol. I
$C_6H_5CH{=}NNHC_6H_5$	0.0212	0.108	0.004
$C_6H_5CH{=}N{-}N{-}C_6H_5$ | $C_6H_5CH{=}N{-}N{-}C_6H_5$	0.569	1.46	0.057
$C_6H_5C{=}N{-}NHC_6H_5$ | $C_6H_5C{=}N{-}NHC_6H_5$	3.990	10.2	0.400
	% Accounted for		92.8% of I

* Five grams of benzalphenylhydrazone (25.5 mmol.) was mixed with 40.3 mmol. of amyl nitrite in ethanol.

The products of the oxidation of benzalphenylhydrazone with sodium hypoiodite are summarized in Table II. Ingle and Mann[3] did the same oxidation; they reported the formation of II and IV_α, but did not give any quantitative data. A comparison of Tables I and II reveals that, in the case of the oxidation with sodium hypoiodite, the smaller percent of the starting material was accounted for and about 13% of I remained unoxidized, even though a stoichiometric amount of the oxidant was present. The residue, which was unidentifiable, was resinous. These facts seem to indicate that a part of the sodium hypoiodite

	% Accounted for		65.2% of I

* Ten grams of benzalphenylhydrazone (51.0 mmol.) in ether was mixed with an ethanolic solution of 1.59 g. of sodium (65.0 mmol.) and with an ethereal solution of 6.57 g. (51.0 mmol.) of iodine.

was used to oxidize some of the oxidation products to resinous substances. α-Benzilosazone possesses oxidizable hydrogens; a plausible scheme of this oxidation may be shown as follows:

$$\begin{array}{l} C_6H_5{-}C{=}N{-}NHC_6H_5 \\ \quad | \\ C_6H_5{-}C{=}N{-}NHC_6H_5 \\ \quad (IV_\alpha) \end{array} \xrightarrow{NaOI} \begin{array}{l} C_6H_5{-}C{=}N{-}N{-}C_6H_5 \\ \quad | \quad\quad | \\ C_6H_5{-}C{=}N{-}N{-}C_6H_5 \end{array}$$

$$+ \begin{array}{l} C_6H_5{-}C{=}N{-}NHC_6H_5 \\ \quad | \\ C_6H_5{-}C{=}N{-}N{-}C_6H_5 \\ \quad | \\ C_6H_5{-}C{=}N{-}N{-}C_6H_5 \\ \quad | \end{array} + \text{others}$$

As to the mechanism of the oxidation of benzalphenylhydrazone, neither Pechmann nor Ingle and Mann proposed anything. Minunni[1] proposed the following mechanism.

By the abstraction of a hydrogen atom attached to nitrogen, a radical, $C_6H_5CH{=}\dot{N}\dot{N}C_6H_5$ (A), is formed. This free radical, with a divalent nitrogen-atom, is unstable and rearranges to $C_6H_5\dot{C}{=}NNHC_6H_5$ (B) with a trivalent carbon atom.

$$\underset{(I)}{C_6H_5CH{=}NNHC_6H_5} \rightarrow \underset{(A)}{C_6H_5CH{=}\dot{N}\dot{N}C_6H_5} \rightarrow \underset{(B)}{C_6H_5\dot{C}{=}NNHC_6H_5}$$

The combination of A-A results in the tetrazone (II), while that of B-B results in the osazone (IV).

The mechanism proposed by Minunni seems to be unacceptable for two reasons. First, the radical B appears to be a more stable radical than the radical B. In the radical A, the odd electron is in resonance with the p-electrons of C=N and two benzene rings; hence, this radical is a rather well-stabilized radical. The radical B, on the other hand, is not so stable, since the odd electron is in resonance with the p-electrons of only one benzene ring. Therefore, it is unlikely that the radical A rearranges to the less stable radical B. Second, the combination of two B radicals should produce the thermodynamically more stable osazone, the β-form, not the α-form. In order, for the radical B to be stabilized, the p-orbital with the odd electron must be parallel with the p-orbitals of the benzene ring. When this rotation occurs, the radical becomes symmetrical, and the combination of B-B should yield the more stable β-osazone. For these two reasons, Minunni's mechanism seems to be unacceptable.

Sidgwick[4] explained this reaction by assuming the initial formation of two radicals; the radical A formed by the hydrogen-abstraction from the α-nitrogen of I, and the radical B formed by the hydrogen-abstraction from the α-carbon of I:

$$\underset{(A)}{C_6H_5CH{=}N{-}\dot{N}{-}C_6H_5} \leftarrow \underset{(I)}{C_6H_5CH{=}N{-}NHC_6H_5} \rightarrow \underset{(B)}{C_6H_5\dot{C}{=}NNHC_6H_5}$$

The combination of A-A will form II, while that of B-B will form IV. However, Sidgwick's explanation does not solve any of the difficulties mentioned above in connection with Minunni's mechanism. Since the radical A appears to be much more stable than the radical b, the hydrogen abstraction most likely will take place on the α-nitrogen, not on the α-carbon. The combination of two B radicals should yield the β-benzilosazone, but the osazone isolated by the experiment was the α-form.

We wish to propose and describe a plausible mechanism for the oxidation of benzalphenylhydrazone.

The abstraction of hydrogen takes place on the α-nitrogen atom of I and yields the radical A, which is stabilized by the resonance expressed by the limiting forms, A and C.

$$C_6H_5CH{=}NNHC_6H_5 \rightarrow [\underset{(A)}{C_6H_5CH{=}N{-}\dot{N}{-}C_6H_5} \leftrightarrow \underset{(C)}{C_6H_5\dot{C}H{-}N{=}N{-}C_6H_5}]$$

The combination of A-A results in the formation of II. The combination of C-C will yield the compound IV', which is then expected to tautomerize to IV_α:

$$(C) + (C) \rightarrow \underset{(IV')}{\begin{array}{l} C_6H_5CH{-}N{=}N{-}C_6H_5 \\ \quad | \\ C_6H_5CH{-}N{=}N{-}C_6H_5 \end{array}} \rightarrow \underset{(IV_\alpha)}{\begin{array}{l} C_6H_5{-}C{=}N\diagdown NHC_6H_5 \\ \quad | \\ C_6H_5{-}C{=}N\diagup NHC_6H_5 \end{array}}$$

The combination of A-A is a combination of electronegative nitrogen atoms, which must be less favorable than the combination of C-C. In the actual experiments, the benzilosazone (IV) was

4) N. V. Sidgwick, "Organic Chemistry of Nitrogen," Clarendon Press, Oxford (1937), p. 464.

found in a much greater quantity than the tetrazone (II).

In order to defend this mechanism, the following three conditions must be satisfied:

(1) The trivalent carbon radical B, $C_6H_5\dot{C}=NNHC_6H_5$, is not formed from the oxidation of I.

(2) The azo form IV′ should tautomerize to the hydrazone form IV under the experimental conditions.

(3) The tautomerism should yield the α-osazone, which is less stable than the β-osazone.

In an attempt to establish that the hydrogen atom of the α-carbon is not abstracted, the α-methylphenylhydrazone of benzaldehyde was prepared and was subjected to oxidation with sodium hypoiodite. After crystallization and washing, 90% of the α-methylphenylhydrazone was isolated as crystals; this fact indicates that the hydrogen atom on the α-carbon atom of the benzalphenylhydrazone will not be abstracted either.

The problem of the tautomerism from the azo form IV′ to the hydrazone form IV is rather complex. In 1961, Zollinger[5] wrote that "it has always been found that the hydrazone is the more stable species. Since the rate of rearrangement of the azo into the hydrazone form is in general very low, azo compounds can readily be isolated in spite of this. The reaction is favored by solvents able to provide protons and is catalyzed by acids and bases, but no exact investigations have yet been undertaken."

Brough et al.[6] prepared 1′-(*p*-chlorophenyl)-benzeneazomethane by the oxidation of the corresponding hydrazo-compound; they found that it was fairly stable at 0°C, but isomerized to the hydrazone in methanol at room temperature.

$$p\text{-Cl-}C_6H_4\text{-}CH_2\text{-N=N-}C_6H_5 \xrightarrow{CH_3OH} p\text{-Cl-}C_6H_5\text{-CH=N-NH-}C_6H_5$$

However, 1′,1′-diphenylbenzeneazomethane, C_6H_5-N=N-$CH(C_6H_5)_2$, is rather stable and melts at 73—75°C. Perhaps the compound IV′ resembles 1′-(*p*-chlorophenyl)-benzeneazomethane rather than 1′, 1′-diphenylbenzeneazomethane, and perhaps the compound IV′ easily isomerizes to IV_α.

In order to ascertain what actually happens, an attempt was made to reduce IV_β so as to prepare IV′. When the β-benzilosazone IV_β was subjected to reduction with an excess amount of sodium amalgam or lithium aluminum hydride in an inert atmosphere, a mixture of several compounds always resulted, and it was not possible to prepare the compound IV′. Although the attempt to ascertain the easy isomerism from IV′ to IV_α failed, it seems likely that the isomerization proceeds under experimental conditions which are either basic (sodium hypoiodite) or acidic (amyl nitrite).

Now the problem of the tautomerism to the α-osazone, not to the β-osazone, should be dealt with. When the azo form IV′ tautomerizes to the osazone, two types of transition state seem possible, as is illustrated in Fig. 1. The IV′ form may tautomerize to IV either by way of the transition state of a four-membered ring, as is shown in Fig. 1 (a), or by way of the transition state of a five-membered ring, as is shown in Fig. 1(b). The transition state of Fig. 1(b) seems more favorable than that of Fig. 1(a), since the nitrogen atom and the hydrogen atom are more closely situated in Fig. 1(b) than in Fig. 1(a). If the compound IV′ tautomerizes to IV by way of the five-membered transition state, the osazone formed must be the α-osazone. When a compound like 1′, 1′-diphenylbenzeneazomethane is to tautomerize to a hydrazone, it must go through a four-membered transition state. It is highly likely that the rate of the tautomerization of IV′ to IV_α is much faster than that of 1′, 1′-diphenylbenzeneazomethane.

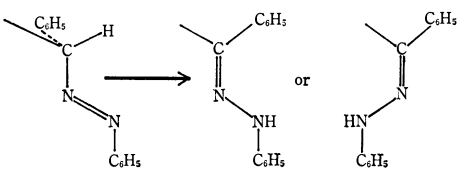

Fig. 1(a)

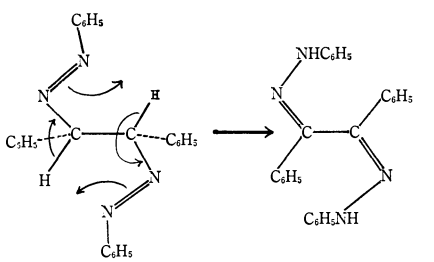

Fig. 1(b)

Thus, the mechanism proposed above as plausible seems to account for the available experimental data fairly well.

When Milligan and Minor[7] oxidized benzalphenylhydrazone with ammoniacal silver nitrate in dimethylformamide, they isolated two products, one melting at 201°C, and the other, at 187°C. They assigned the structure III to the former and the IV′ structure to the latter. Their assignment is surprising, especially in view of the existing experimental data.

7) T. W. Milligan and B. C. Minor, *J. Org. Chem.*, **27**, 4663 (1962).

The compound melting at 186°C was obtained from the oxidation of benzalphenylhydrazone with mercuric oxide,[1] amyl nitrite,[2,3] or sodium hypoiodite.[3] Minunni,[1] Pechmann,[2] and Ingle and Mann[3] assigned the structure II to this compound. Both Pechmann[2] and Ingle and Mann[3] reduced the compound melting at 186°C and obtained benzalphenylhydrazone, I. This fact is consistent with the structure II, but not with the structure IV', which was suggested by Milligan and Minor.

The compound melting at 186°C is "very insoluble in almost all solvents, and dissolves but sparingly in hot benzene and chloroform."[3] This solubility characteristic seems to go better with the structure II than with the structure IV'. Such azo compounds as $C_5H_5N{=}NCH(C_6H_5)_2$ and $(C_6H_5)_2CHN{=}NCH(C_6H_5)_2$ very readily dissolve in benzene and chloroform, and even in ligroin. It seems unlikely that the compound possessing the structure IV' is very insoluble in almost all solvents.

The only data which seems to favor the structure IV' is its NMR spectrum, which shows the aromatic multiplet at −436 c. p. s. and another signal at −343 c. p. s. (4.28 τ), the latter "corresponding in position and intensity to that expected for two protons on benzylic carbon atoms substituted by azo-unsaturation."[7] However, the compound melting at 186°C was only sparingly soluble in hot chloroform, and the NMR spectrum measured in deuteriochloroform may not be too reliable. It was not possible to prepare a 0.001 M solution of the compound in chloroform due to its small solubility. The reduction with phenylhydrazine and the solubility of the compound melting at 186°C seem to be more persuasive than the NMR spectrum.

The compound melting at 208°C was converted to β-benzilosazone (IV_β) (m. p. 225°C) by heating it with phenylhydrazine, or by heating it with ethyl succinate.[3] The compound yielded benzil and triphenylosotriazole,  , upon reaction with sulfuric acid and water. β-Benzilsazone yielded only benzil and no triphenylosotriazole upon reaction with sulfuric acid and water. On the basis of these findings, Ingle and Mann[3] assigned the structure IV_α to the compound melting at 208°C. Its infrared spectrum was very much similar to, but not superimposable upon, that of β-benzilosazone.

The compound melting at 202°C was assigned the structure III by Ingle and Mann[3] and by Milligan and Minor[7], but without any convincing evibence. Its ultraviolet spectrum ($\lambda_{max}^{CHCl_3}$ 298, 335 mμ: ε, 19400, 37000) and infrared spectrum (NH at 3330 cm^{-1} and ArC=N– at 1590, 1543, 1485 cm^{-1})[7] were very similar to those of α-benzilosazone melting at 208°C ($\lambda_{max}^{CHCl_3}$ 295 (18300), 340 mμ (33200); 3330, 1590, 1543, 1485 cm^{-1}). It seems that the compound melting at 202°C may be the impure α-benzilosazone (m. p. 208°C).

Grateful acknowledgment is made to the donors of The Petroleum Research Fund, administered by the American Chemical Society, for support of this research.

Syntheses of L-Sorbosylthymines and Related Compounds[1)]

By Kanji TOKUYAMA and Mitsuru KATSUHARA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received July 11, 1966)

1, 3, 4, 5-Tetra-*O*-acetylsorbopyranosylureas were prepared from sorbopyranosyl chloride via 1, 3, 4, 5-tetra-*O*-acetylsorbopyranosylisocyanates. 1-Ureido- and 6-ureidosorbofuranoses were obtained from the corresponding aminosorboses. The transformations of the ureas thus obtained into *N*-(sorbose)thymines were achieved, although with difficulty, by the direct condensation of halogeno- or tosylsorboses with metal salts of thymine.

A variety of nucleosides have received considerable interest in connection with their potential biochemical activities. However, synthetic studies have dealt almost exclusively with the preparation of aldose derivatives, such as ribosylpyrimidines or glucosylpurines. This paper will discuss the introduction of the thymine group into sorboses at the C-1, C-2, and C-6 positions through urea derivatives.

1) Sorboses. Part VIII. For Part VII, see K. Tokuyama, M. Kiyokawa and M. Katsuhara, *J. Org. Chem.*, **30**, 4057 (1965).

Mercuric salts of thymine or theophylline in inert solvents are generally employed for nucleoside synthesis.[2-5] The condensation of the salts with 1, 3, 4, 5-tetra-*O*-acetyl-α-L-sorbopyranosyl chloride (I)[6] in xylene did not give any of the expected nucleoside; instead, a colorless sirup with no chlorine and nitrogen was obtained. It showed a positive resorcin test (Seliwanoff test),[7] a strong band due to an enol acetate, a weak band due to a double bond in the infrared, and an ultraviolet maximum at 210 mμ. These facts suggested that the structure of the product was 2-deoxy-1, 3, 4, 5-tetra-*O*-acetyl-L-sorbopyranos-2, 3-ene (II) or -1, 2-ene. The NMR spectrum, showing a singlet (two protons) at τ 5.24 due to the $-CH_2-$ at the C-1 position and no signals at a lower field, was consistent with the structure of II. The condensation reaction in such a polar solvent as *N*, *N*-dimethylformamide (DMF) or nitromethane in the presence of mercuric cyanide[8,9] gave the same results. The formation of II was observed even in the absence of the salt to a small extent. Therefore, this type of reaction was thought to be not suitable for sorbose nucleoside synthesis.

Another promising route to sorbosylthymine utilizes urea derivatives[10-14] (for the scheme, see Charts 1 and 2). Thus I was treated with silver isocyanate in anhydrous toluene under heating. The sirup produced showed a strong band at 2245 cm^{-1} characteristic of the N=C=O stretching vibration.[15] Thin-layer chromatography revealed that the sirup was a mixture of the major α, β-anomers (III and IV) and the minor II.

The ammonolysis of the sirup mixture of the III and IV isocyanates was performed by adding methanolic ammonia at 0°C; the subsequent fractional recrystallization furnished *N*-(1, 3, 4, 5-tetra-*O*-acetyl-α-L-sorbopyranosyl)urea (V) and the β-anomer of V (VI). The ureas, V and VI, gave satisfactory analyses and revealed absorptions at 1659 and 1530 cm^{-1} characteristic of the -CO-NH- group. From the optical rotations, V was determined to have the α-configuration, and VI, the β-configuration.

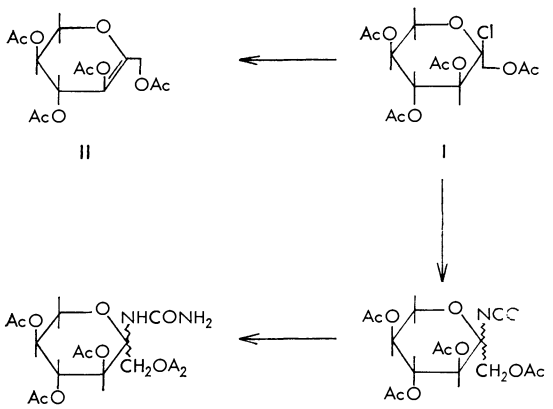

Chart 1

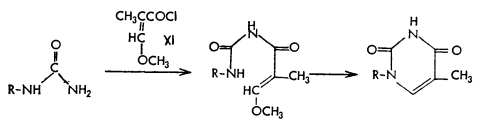
The α-urea V was condensed with 2-methyl-3-methoxyacryloyl chloride (XI) in pyridine.[12,16] After the reaction product had been purified by silica gel-column chromatography, 1-(1, 3, 4, 5-tetra-*O*-acetyl-α-L-sorbopyranosyl)-3-(2-methyl-3-methoxyacryloyl)urea (VII) was obtained as a colorless powder. This showed an ultraviolet absorption at 255 mμ. The ring closure and simultaneous deacetylation of this compound by



V ($R=R_1$) VII ($R=R_1$) VIII ($R=R_1'$)
VI ($R=R_2$) IX ($R=R_2$) X ($R=R_2'$)
XXIII ($R=R_3$) XXV ($R=R_3$) XXVII ($R=R_3$)
XXIV ($R=R_4$) XXVI ($R=R_4$) XXVIII ($R=R_4$)

treament with monomethylamine, followed by the purification of the reaction product by cellulose column chromatography, afforded a brown sirup (VIII). The sirup VIII showed analytical data corresponding to those of L-sorbosylthymine, a positive resorcin test, and the ultraviolet maximum at 303 mμ characteristic of thymine. Similarly, β-L-sorbopyranosylthymine (X), λ_{max}^{UV} 285 mμ, was prepared from the β-urea VI via 1-(1, 3, 4, 5-tetra-*O*-acetyl-β-L-sorbopyranosyl)-3-(2-methyl-3-methoxyacryloyl)urea (IX). The sorbopyranosylthymines thus obtained, VIII and X, were unstable; e. g., they released the thymine moiety upon mild acetylation.

The introduction of thymine into the C-1 and C-6 positions of L-sorbose was also studied. Previously we observed that the condensation of 1-*O*-tosyl-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (XII) with 2-thiouracil in DMF gave *S*-substituted (XIII) and *O*, *S*-disubstituted thiouracil (XIV).[1] The analogous condensation of XII with the sodium salt of thymine was attempted. However, the product formed was 1-deoxy-1-dimethylamino-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (XV), which was identified by comparison with an authentic sample prepared by the reaction of XII with dimethylamine. The formation of XV in this reaction is interesting, but we have no reasonable explanation for this finding at the present time. On the other hand, the treatment of XII with the sodium salt of theophylline in DMF gave the expected compound (XVI), which showed a band characteristic of theophylline in the infrared spectrum. Therefore, the introduction of the thymine group into the C-1 and C-6 positions of sorbose was carried out through ureidosorbose in a way similar to that used with VIII and X.

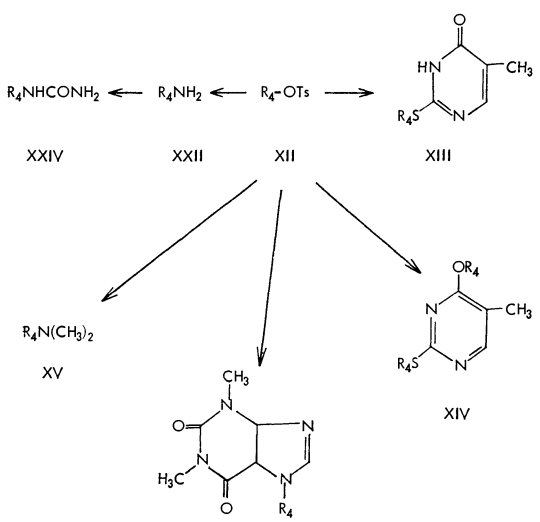

Chart 3

2, 3 : 4, 6-Di-*O*-isopropylidene-α-L-sorbofuranose (XVII)[17] was converted into 1-*O*-methyl-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (XVIII) with methyl iodide in the presence of sodium ethoxide in liquid ammonia. In the methylation of XVII, methyl iodide and sodium alkoxide in liquid ammonia were more satisfactorilly used than dimethylsulfate in an alkaline medium[18] or methyl iodide and potassium in liquid ammonia and an inert solvent.[19] The partial deacetonation of XVIII gave a monoacetonated compound (XIX), which was then converted into 6-tosylate (XX) on tosylation under cooling. The heating of XX with liquid ammonia led to 1-*O*-methyl-6-deoxy-6-amino-2, 3-*O*-isopropylidene-α-L-sorbofuranose (XXI).

When XXI (or the 1-deoxy-1-amino-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (XXII) previously reported[20]) in dilute alcohol was treated with potassium cyanate in the presence of one equivalent of acetic acid, the crystalline urea derivative XXIII (or XXIV), was obtained. This product XXIII (or XXIV) was then condensed with XI by a procedure similar to that used for V (see Chart 2); this produced an unstable intermediate XXV (or XXVI) which showed an ultraviolet absorption at 250 mμ. Without purification, XXV (or XXVI) was immediately treated with aqueous ammonia. There was thus isolated by thin-layer chromatography the desired thymine derivative XXVII (or XXVIII). The product XXVII (or XXVIII) gave analytical data corresponding to the structure and showed a positive resorcin test and the ultraviolet absorption at 270 mμ characteristic of thymine.

The thymine derivatives of L-sorbose obtained above, VIII, X, XXVII and XXVIII, were found to be unstable, and they were slowly converted into sorbose or aminosorboses at room temperature. The conversion was found to be more rapid in an aqueous solution.

Experimental[21]

1, 3, 4, 5-Tetra-*O*-acetyl-*α*-L-sorbopyranosyl Chloride (I).—A mixture of 1, 3, 4, 5-tetra-*O*-acetyl-*α*-L-sorbopyranose (6 g.)[6,22] and aluminum chloride (15.5 g.) in chloroform (90 ml.) was stirred at room temperature for 1 hr. The precipitates were removed by filtration and washed with ether (400 ml.), and the washings were combined with the filtrate. The combined solution was then washed with cold water, cold aqueous sodium bicarbonate, and cold water successively. The dried solution was evaporated under reduced pressure to leave a yellow sirup which was purified by silica gel-column chromatography with benzene and ether (9 : 1 v/v). The recrystallization of the thus-purified sirup from ether and petroleum ether gave needles (1.8 g.); m. p. 62—64°C, $[\alpha]_D^{25}$ −83.2 (*c* 1.027, chloroform).[6]

Found: C, 45.85; H, 5.22; Cl, 9.67. Calcd. for $C_{14}H_{19}O_9Cl$: C, 45.92; H, 5.32; Cl, 9.23%.

The Reaction of Mercuric Salt of Thymine with I.—To a suspension of mercuric salt of thymine (2.1 g.)[2] in dry xylene (150 ml.), there was added a dry xylene solution (25 ml.) of I (1.8 g.). Traces of water were removed by azeotropic distillation with xylene (50 ml.). After it had been refluxed for 1.5 hr., the solution was concentrated to a sirup which showed, on thin-layer chromatography, no spot with a positive resorcin test and ultraviolet absroption. The purification of the sirup on an alumina column (neutral) (25 g.) with benzene gave a colorless sirup (II) (220 mg.); $[\alpha]_D^{22}$ +217.6 (*c* 1.032, chloroform).

Found: C, 51.06; H, 5.81. Calcd. for $C_{14}H_{18}O_9$: C, 50.91; H, 5.49%.

1, 3, 4, 5-Tetra-*O*-acetyl-L-sorbopyranosyl Isocyanate (III and IV).—A solution of I (0.6 g.) in anhydrous toluene (6 ml.) was added to a suspension of silver isocyanate (0.45 g.)[23] in anhydrous xylene (10 ml.), and the mixture was heated at 100—110°C for 2.5 hr. under stirring. After it had been cooled, the precipitates (silver chloride and unreacted silver isocyanate) formed were removed by filtration and washed with toluene, and the washings were combined with the filtrate. The combined solution was then concentrated to about 1—2 ml. under reduced pressure, and to the residue there was added 10—20 ml. of petroleum ether (20 ml.). The upper organic layer was separated by decantation from a small amount of the yellow sirup precipitated. A yellow sirup (0.54 g.) was obtained on the removal of the solvent. IR cm^{-1} $\nu_{N=C=O}$ 2245 (liquid film). The thin-layer chromatogram (silica gel) showed two major spots (III and IV) and one minor spot (II).

***N*-(1, 3, 4, 5-Tetra-*O*-acetyl-L-sorbopyranosyl)urea (V and VI).**—Silver chloride was removed by filtration from a reaction mixture of I (9.4 g.) and silver isocyanate (7.2 g.) by a similar procedure to those used above for III and IV. When ammonia was bubbled into the filtrate under stirring at 0°C, crystals appeared immediately. After 5 min., the crystals (5.98 g.) were filtered, washed with ether, and dissolved in chloroform and methanol (20 : 1 v/v); petroleum ether was then added to the solution until crystals appeared again. The recrystallization of the resultant crystals from methanol gave colorless needles (VI) (1.53 g.); m. p. 194—195°C, $[\alpha]_D^{24.5}$ +65.1 (*c* 1.049, methanol).

Found: C, 46.05; H, 5.85; N, 7.40. Calcd. for $C_{15}H_{22}N_2O_{10}$: C, 46.15; H, 5.68; N, 7.18%.

From the mother liquor (chloroform-methanol-petroleum ether), the *α*-anomer (V) (1.49 g.) was obtained; this was recrystallized from methanol, m. p. 217—219°C, $[\alpha]_D^{23.5}$ −34.4 (*c* 0.973, chloroform).

Found: C, 46.35; H, 5.79; N, 7.34. Calcd. for $C_{15}H_{22}N_2O_{10}$: C, 46.15; H, 5.68; N, 7.18%.

1-(1, 3, 4, 5-Tetra-*O*-acetyl-*α*-L-sorbopyranosyl)-3-(2-methyl-3-methoxyacryloyl)urea (VII). — To a suspension of V (2.0 g.) in chloroform (20 ml.), XI (1.5 g.)[24] and pyridine (0.8 ml.) were added. The mixture was stirred for 2 days at room temperature. After the precipitates had been removed by filtration, the solvent was removed under reduced pressure and the residue was dissolved in chloroform (20 ml.), and washed with 5% sodium bisulfite, 5% sodium bicarbonate, and water successively. The dried solution was then evaporated under reduced pressure to leave a yellow sirup. This sirup was washed with petroleum ether. A plae yellow powder (2.05 g.) was thus obtained. λ_{max}^{UV} 255 mμ (ethanol).

Found: C, 49.39; H, 5.85; N, 5.66. Calcd. for $C_{20}H_{28}N_2O_{12}$: C, 49.18; H, 5.78; N, 5.74%.

***N*-(*α*-L-Sorbopyranosyl)thymine (VIII).** — To a solution of VII (2 g.) in hot ethanol (10 ml.), 40% aqueous monomethylamine (12 ml.) was added in several portions within 4 hr. at 80—85°C. The mixture was concentrated under reduced pressure, and the residue was washed with chloroform, dissolved in ethanol (8 ml.), and subjected to column chromatography on cellulose (2.4×52 cm.). The column was eluted with *n*-butanol-ethanol-water (4-1-5, v/v), and 5 ml. portion of each of the effluents was taken. The fractions (tubes Nos. 43—47) which showed ultraviolet absorption were combined, and the solvent was evaporated to give a hygroscopic brown sirup (40 mg.). $[\alpha]_D^{23}$ −25.1 (*c* 0.987, water), λ_{max}^{UV} 303 mμ (water).

Found: C, 42.70; H, 6.42; N, 9.09. Calcd. for $C_{11}H_{16}N_2O_7 \cdot H_2O$: C, 42.99; H, 6.23; N, 9.12%.

1-(1, 3, 4, 5-Tetra-*O*-acetyl-*β*-L-sorbopyranosyl)-3-(2-methyl-3-methoxyacryloyl)urea (IX). — A suspension of VI (1.3 g.) in chloroform (12 ml.) was mixed with XI (1.0 g.) and pyridine (0.6 ml.), and then treated by a procedure similar to that used for VII. A pale yellow powder (1.33 g.) was obtained; λ_{max}^{UV} 255 mμ (ethanol).

Found: C, 49.13; H, 5.98; N, 5.42. Calcd. for $C_{20}H_{28}N_2O_{12}$: C, 49.18; H, 5.78; N, 5.74%.

***N*-(*β*-L-Sorbopyranosyl)thymine (X).**—IX (1.33 g.) was treated by a procedure similar to that used for VIII. Crude X was then purified from this by cellulose-column chromatography using *n*-butanol-ethanol-water in a way similar to that described above. The fractions (tubes Nos. 45—46) that showed ultraviolet absorption were combined and concentrated to dryness

21) Melting points were determined on a Kofler block. The NMR spectra were measured on a Varian A-60 spectrometer at 60 Mc. in deuteriochloroform at room temperature, using tetramethylsilane as an internal standard.

22) Y. Khouvine and M. G. Arragon, *Bull. soc. chim. France*, **1938**, 1404.

under reduced pressure. A brown sirup (0.05 g.) was thus obtained. $[\alpha]_D^{24}$ −9.6 (*c* 0.660, water), λ_{max}^{UV} 285 mμ (water).

Found: C, 41.57; H, 6.28; N, 8.15. Calcd. for $C_{11}H_{16}N_2O_7 \cdot 2H_2O$: C, 40.74; H, 6.22; N, 8.64%.

1-Deoxy-1-ureido-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (XXIV).—To a hot solution of XXII (3.8 g.) in ethanol (20 ml.) there was added a solution of potassium cyanate (1.6 g.) in water (20 ml.) and then glacial acetic acid (1.1 ml.). After it had been heated on a boiling water bath for 25 min., the solution was concentrated under reduced pressure. The recrystallization of the residual sirup from methanol and *n*-hexane gave colorless needles (2.4 g.); m. p. 180°C (decomp.), $[\alpha]_D^{28}$ −29.7 (*c* 1.060, chloroform).

Found: C, 51.20; H, 7.52; N, 9.51. Calcd. for $C_{13}H_{22}H_2O_6$: C, 51.64; H, 7.34; N, 9.27%.

***N*-(1-Deoxy-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose-1)thymine (XXVIII).**—The treatment of XXIV (1.51 g.) in chloroform (15 ml.) and pyridine (0.5 ml.) with XI (1.0 g.) in a way similar to that used for VIII gave an intermediate (XXVI) [1.67 g., λ_{max}^{UV} 250 mμ (ethanol)] as a yellow sirup. To a solution of XXVI (1.47 g.) in hot ethanol (4 ml.), aqueous ammonia was then added in several portions within 6 hr. at 80—90°C. After the solvent had been removed, a yellow powder was obtained; this was purified into a colorless powder by alumina thin-layer chromatography with chloroform and acetone (1 : 1, v/v). $[\alpha]_D^{24}$ −8.5 (*c* 1.017, chloroform), λ_{max}^{UV} 270 mμ (water).

Found: C, 55.52; H, 6.81; N, 7.51. Calcd. for $C_{17}H_{24}O_7N_2$: C, 55.43; H, 6.56; N, 7.61%.

1-*O*-Methyl-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (XVIII).—Small pieces of sodium (12.8 g.) were slowly added to a solution of XVII (135 g.) in liquid ammonia (300 ml.) at about −40°C. To the solution, ethanol (about 40 ml.) was added to discharge the blue color of sodium, and then methyl iodide (77 g.) was then added over a 1 hr. period. After 2 hrs.' stirring, the ammonia was allowed to evaporate, and the solution was extracted with benzene. The benzene solution was washed with water and dried, and the solvent was removed. The distillation of the residual sirupy crystals gave XVIII (165 g.); b. p. 111°C/2 mmHg; m. p. 53°C, $[\alpha]_D^{23}$ −11.1 (*c* 1.075, acetone).

Found: C, 57.09; H, 7.67. Calcd. for $C_{13}H_{22}O_6$: C, 56.95; H, 8.03%.

1-*O*-Methyl-2, 3-*O*-isopropylidene-α-L-sorbofuranose (XIX).—A solution of XVIII (41.8 g.) in 60% acetic acid (100 ml.) was warmed at 80°C for 1 hr. The reaction mixture was then cooled, made alkaline with sodium hydroxide, and extracted with chloroform. After the solvent had been removed, the residue was distilled to give a colorless sirup (25.35 g.); b. p. 140°C/2 mmHg, $[\alpha]_D^{23}$ +33.3 (*c* 1.191, chloroform).

Found: C, 51.58; H, 7.83. Calcd. for $C_{10}H_{18}O_6$: C, 51.28; H, 7.69%.

1-*O*-Methyl-6-*O*-tosyl-2, 3-*O*-isopropylidene-α-L-sorbofuranose (XX).—Into a solution of XIX (5.4 g.) in pyridine (15 ml.), tosyl chloride (3.76 g.) was stirred in small portions under cooling. After having been stirred at 0—−5°C for 7 hr., the reaction mixture was poured into a saturated sodium carbonate solution (100 ml.) and extracted with chloroform, which had previously been washed with water and dried; the solvent was then evaporated under reduced pressure. The recrystallization of the residue from benzene and *n*-hexane gave colorless needles; m. p. 37°C, $[\alpha]_D^{23}$ +21.4 (*c* 1.129, chloroform).

Found: C, 52.21; H, 5.73; S, 8.61. Calcd. for $C_{17}H_{24}O_8S$: C, 52.58; H, 6.19; S, 8.24%.

1-*O*-Methyl-6-deoxy-6-amino-2, 3-*O*-isopropylidene-α-L-sorbofuranose (XXI).—A solution of XX (150 g.) and liquid ammonia (150 ml.) in an autoclave was heated on a boiling-water bath for 20 hr. After the liquid ammonia had been removed, the residue was extracted with chloroform and the solvent removed. The distillation of the residue gave a colorless sirup (32 g.); b. p. 125°C/3 mmHg, m.p. 55°C, $[\alpha]_D^{24.5}$ +8.3 (*c* 1.074, methanol).

Found: C, 51.46; H, 8.32; N, 5.82; CH_3O, 13.11. Calcd. for $C_{10}H_{19}NO_5$: C, 51.50; H, 8.15; N, 6.01; CH_3O, 13.30%.

1-*O*-Methyl-6-deoxy-6-ureido-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (XXIII).—To a hot solution of XXI (1.8 g.) in ethanol (7 ml.), there was added a solution of potassium cyanate (0.8 g.) in water (7 ml.), and then glacial acetic acid (0.6 ml.). After being heated on a boiling water bath for 3 hr., the solution was concentrated and extracted with ethyl acetate, and the solvent was removed. The recrystallization of the residue from ethanol and *n*-hexane gave colorless rods; m. p. 184°C (decomp.), $[\alpha]_D^{25}$ −22.4 (*c* 1.006, ethanol).

Found: C, 47.58; H, 7.29; N, 9.89. Calcd. for $C_{11}H_{20}O_6$: C, 47.83; H, 7.25; N, 10.14%.

***N*-(6-Deoxy-1-*O*-methyl-2, 3-*O*-isopropylidene-α-L-sorbofuranose-6)thymine (XXVII).**—The treatment of XXIII (0.95 g.) in chloroform (10 ml.) and pyridine (0.6 ml.) with XI (0.6 g.) in a way similar to that used for VII gave an intermediate (XXV) [1.1 g., λ_{max}^{UV} 250 mμ (ethanol)]. The compound XXV thus obtained was treated by the procedure used for XXVIII. The crude product was purified by silica-gel thin layer chromatography. XXVII (0.049 g.) was obtained as a colorless sirup; $[\alpha]_D^{25}$ −34.9 (*c* 0.988, ethanol), λ_{max}^{UV} 270 mμ (water).

Found: C, 49.71; H, 6.66; N, 7.56. Calcd. for $C_{15}H_{22}N_2O_7 \cdot H_2O$: C, 49.99; H, 6.71; N, 7.77%.

7-(1-Deoxy-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose-1)theophylline (XVI).—Theophylline (1.8 g.) was dissolved in hot water (ca. 100 ml.) containing potassium carbonate (0.7 g.), and the water was removed under reduced pressure. The residue was well dried in a desiccator. The potassium salt of theophylline thus obtained was added to DMF (40 ml.) containing XII (3 g.). The solution was refluxed for 10 hr. After it had cooled, the solution was filtered, the filtrate was evaporated to dryness under reduced pressure, and the residue was extracted with chloroform. The solvent was removed, and the residue was recrystallized from ether to give colorless needles of XVI (0.62 g.); m. p. 181—183°C; $[\alpha]_D^{24}$ −2.7 (*c* 1.033, chloroform).

Found: C, 54.01; H, 6.35; N, 13.39. Calcd. for $C_{19}H_{26}N_4O_7$: C, 54.02; H, 6.20; N, 13.26%.

1-Deoxy-1-dimethylamino-2, 3 : 4, 6-di-*O*-isopropylidene-α-L-sorbofuranose (XV).—A mixture of XII (5 g.), 40% aqueous dimethylamine (25 ml.), and methanol (25 ml.) in an autoclave was heated on

a boiling water bath for 30 hr. After cooling, the solution was evaporated and extracted with chloroform, which had previously been washed with water and dried, and then evaporated. The distillation of the residue gave a colorless sirup (2.4 g.); b. p. 105—107°C/5 mmHg, $[\alpha]_D^{24}$ −1.5 (*c* 1.105, chloroform).

Found: C, 58.38; H, 8.89; N, 4.89. Calcd. for $C_{14}H_{25}NO_5$: C, 58.51; H, 8.77; N, 4.87%.

A mixture of the potassium salt of thymine (1 g.) and XII (3 g.) in DMF (50 ml.) was refluxed for 20 hr. After it had cooled, the solution was filtered, and the filtrate was evaporated under reduced pressure. The distillation of the residue gave XV (0.8 g.).

The authors wish to express their deep gratitude to Dr. Ken'ichi Takeda, Director of this Laboratory, for his encouragement.

Organic Sulfur Compounds. XIII. The Reactions of *p*-Toluenesulfinyl Chloride with Azides

By Michio KOBAYASHI* and (in part) Asami YAMAMOTO

Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama

(Received April 18, 1966)

Attempts to prepare a sulfinyl azide resulted in the formation of the sulfonyl azide, disulfide, and thiolsulfonate; of these products, the first two were considered to be disproportionation products of the intermediate, sulfinyl azide. The reaction of a sulfinic acid with hydrazoic acid gave a sulfonamide. No rearrangement similar to the Curtius or the Schmidt reaction was observed.

Recently a photochemical rearrangement of a sulfonyl azide has been reported,[1] although this class of compounds has been established as giving no intramolecularly rearranged products on thermal decomposition.[2-5] No sulfinyl azide (I) has, to the authors' knowledge, yet been prepared. Since the analogous carboxylic azides are known to decompose thermally to give nitrogen and the rearranged product, isocyanate (reaction 1), it seemed of interest to study the reactions which could proceed through the intermediate formation of a sulfinyl azide. If a sulfinyl azide was actually produced and then lost its nitrogen to generate a sulfinyl nitrene (II), an intramolecular rearrangement to a *N*-sulfinylamine (III) would be expected.

$$\underset{\underset{\|}{O}}{RC}\text{-}N_3 \rightarrow RN{=}C{=}O + N_2 \qquad (1)$$

$$\underset{\underset{O}{\downarrow}}{RS}\text{-}N_3 \rightarrow \underset{\underset{O}{\downarrow}}{R\text{-}S}\text{-}\underset{|}{N}\text{-} + N_2 \qquad (2)$$

(I) (II)

$$II \rightarrow R\text{-}N{=}S{=}O \qquad (3)$$

(III)

In this paper, the results of attempts to synthesize sulfinyl azides by several alternative routes will be described.

When sodium azide was treated with *p*-toluenesulfinyl chloride in benzene, only a small amount of nitrogen was evolved. After the reaction was quenched by water a considerable amount of *p*-toluenesulfinic acid was recovered, whereas there was no indication of the presence of *p*-toluidine, which should be formed by the hydrolysis of the expected product of the rearrangement, *N*-sulfinyl-*p*-toluidine. When methylene chloride was used as the solvent, the reaction was again sluggish, and the volume of the nitrogen evolved was only one-tenth of the calculated amount. Among the reaction products, 15 mol.% of *p*-toluenesulfonyl azide was detected by infrared spectroscopy.

On the other hand, the reaction in acetonitrile was rather rapid. After the reaction mixture had been let stand for 4 days at room temperature, the mixture was diluted with water and extracted with methylene chloride; the formation of a substantial amount of *p*-toluenesulfonyl azide was again observed, while there was no trace of sulfinyl-*p*-toluidine or *p*-toluidine in the products.

The reaction between silver azide and *p*-toluenesulfinyl chloride in benzene was also very slow and stopped halfway.

Sodium azide and silver azide are almost insoluble in the above solvents. This was considered to be the main reason for the slow rate of reaction.

1) W. Lwowski and E. Scheiffele, *J. Am. Chem. Soc.*, **87**, 4359 (1965).
2) O. C. Dermer and M. T. Edmison, ibid., **77**, 70 (1955).
3) J. F. Heacock and M. T. Edmison, ibid., **82**, 3460 (1960).
4) G. Smolinsky and B. I. Feuer, ibid., **86**, 3085 (1964).
5) J. E. Franz, C. Osuch and M. W. Dietrich, *J. Org. Chem.*, **29**, 2922 (1964).

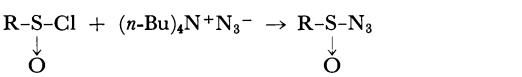
Indeed, when a solution of *p*-toluenesulfinyl chloride in *N*, *N*-dimethylformamide was slowly added to a solution of sodium azide in the same solvent, which could dissolve some sodium azide upon being warmed, the evolution of nitrogen started immediately and reached a total of 78 mol.%. From the reaction mixture, 40 mol.% of *p*-toluenesulfonyl azide and small amounts of *p*, *p*-ditolyl disulfide, *p*-toluenesulfonamide, and sodium *p*-toluenesulfonate were isolated. Again in this case, *p*-toluidine or *N*-sulfinyl-*p*-toluidine was not detected among the products.

Reactive *N*-sulfinylamines, such as sulfinyl sulfonamide, have been reported to react with dimethylformamide to give azomethine derivatives[6]; the reaction of *N*, *N*-diphenylformamide with sulfinyl sulfonamide has been also described.[7] Therefore, it is possible that the reaction of sodium azide with *p*-toluenesulfinyl chloride in dimethylformamide gave a sulfinylamine, which reacted further with the solvent to form a condensed product instead of *p*-toluidine. However, no reaction was observed between *N*-sulfinylaniline and dimethylformamide when these reactants were heated on a water bath for several hours. This suggests that if a *N*-sulfinylamine (III) was formed by the intramolecular rearrangement of a sulfinyl nitrene (II), the former would be stable under the reaction conditions and could, therefore, be isolated.

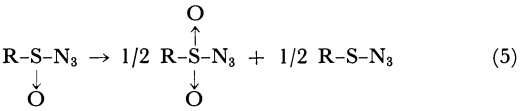
The material balance in the reaction of sodium azide with *p*-toluenesulfinyl chloride in dimethylformamide was far from satisfactory. Most probably, some reaction product other than the sulfinylamine reacted with the solvent to give volatile compounds, which could escape notice during the treatment of the reaction mixture.

Finally, the reaction of *p*-toluenesulfinyl chloride with a solution of tetra-*n*-butylammonium azide in benzene was examined. The reaction proceeded very rapidly at room temperature, accompanied by the evolution of about 75 mol.% of nitrogen. Among the products, *p*-toluenesulfonyl azide (38%), *p*-tolyl *p*-toluenethiolsulfonate (13%), and *p*, *p*-ditolyl disulfide were detected. A close examination of every fraction of the reaction mixture confirmed the absence of *N*-sulfinyl-*p*-toluidine and its hydrolyzed product.

Consequently, the reaction of *p*-toluenesulfinyl chloride with azide ions may be concluded to result not in the formation of the expected rearrangement product of the sulfinyl nitrene II, but in the formation of several other possible products; their formation can best be explained by assuming the disproportionation of the possible intermediate, a sulfinyl azide I, as is shown below:



(4)



(5)

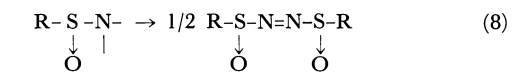
(IV)

(6)

(7)

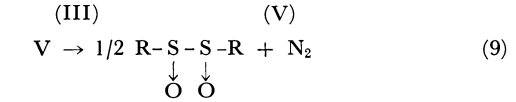
Although the existence of sulfenyl azides has not been established, Kharasch[8] has described how the reaction of sulfenyl chlorides with sodium azide gives the disulfide as the only isolatable product, probably via the reactions 6 and 7.

Although the mechanism of the formation of the thiolsulfonate is uncertain at present, the following reaction sequence may be tentatively presumed to be applicable:



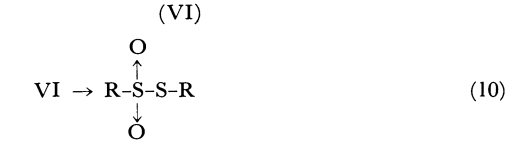
(8)

(III) (V)



(9)

(VI)



(10)

The reaction of *p*-toluenesulfinic acid with hydrogen azide in a benzene-water mixture was also attempted in order to find out whether any reaction similar to the Schmidt reaction of carboxylic acids occurs. The only product identified was *p*-toluenesulfonamide, and no toluidine salt was detected, showing the absence of the molecular rearrangement in this reaction also. The formation of sulfonamide could be attributed to the following reaction mechanism:

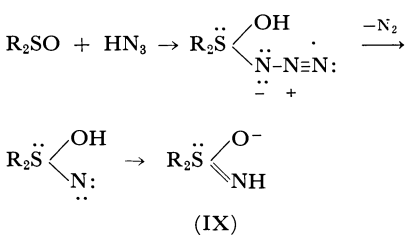
(VIII)

Although the proposed intermediate, the hydroxysulfoximine VIII, is not known, the related sulfoximine IX has been shown to be formed by the reaction of a sulfoxide with hydrazoic acid,[9] probably according to the following reaction mechanism:



(IX)

Experimental

Materials.—Tetra-*n*-butylammonium azide was prepared by distilling an aqueous hydrogen azide solution, collecting the distillate directly in a solution of tetra-*n*-butylammonium hydroxide in water, and evaporating the resulting salt solution to complete dryness under reduced pressure.[10]

The Reaction of *p*-Toluenesulfinic Acid with Hydrazoic Acid.—To a cooled mixture of 1 g. of sodium azide, 1 ml. of water, and 6 ml. of benzene, 0.7 g. of concentrated sulfuric acid was added. A solution of 1.5 g. of *p*-toluenesulfinic acid in benzene was added to the above solution under cooling. After one night, the benzene layer was separated and evaporated to leave 0.5 g. of *p*-toluenesulfonamide. The aqueous layer was made alkaline and extracted with ether in order to check for the presence of *p*-toluidine, but no residue remained after the evaporation of the solvent.

The Reaction of Sodium Azide with *p*-Toluenesulfinyl Chloride in Dimethylformamide.—When 1.5 g. of sodium azide was warmed with 200 ml. of dimethylformamide which had been dehydrated by calcium hydride and rectified, most of the salt dissolved. When a solution of 4.0 g. of sulfinyl chloride (23 mmol.) in 15 ml. of the same solvent was then added to the above azide solution at room temperature, the reaction started immediately, accompanied by a rapid evolution of gas; the total volume of gas was 450 ml. (18 mmol.) The solvent was removed from the reaction mixture under reduced pressure, and the residue was treated with methylene chloride. From the insoluble part, 0.59 g. (15 mol.%) of *p*-toluenesulfonamide and some sodium *p*-toluenesulfonate were isolated. The part soluble in methylene chloride was fractionated by column chromatography over alumina to obtain 0.16 g. of *p, p*-ditolyl disulfide (2.8 mol.%) and 1.8 g. of *p*-toluenesulfonyl azide (39 mol.%).

The Reaction of Tetra-*n*-butylammonium Azide with *p*-Toluenesulfinyl Chloride.—To a warm solution of 4.1 g. of the azide (14.4 mmol.) in 100 ml. of dry benzene, there was added, drop by drop, 2.5 g. of sulfinyl chloride (13.9 mmol.) in 30 ml. of benzene; a vigorous evolution of gas was observed, the volume totalling 245 ml. (75 mol.%). After one night, the reaction mixture was shaken with water, the benzene layer was dried, and subjected directly to infrared measurement; it was estimated that 1.04 g. of *p*-toluenesulfonyl azide (76% of the theoretical yield based on the reactions 4 and 5) and 0.52 g. of *p*-tolyl *p*-toluenethiolsulfonate (13 mol.%) were formed. The elution chromatography of the solute of the above solution with petroleum ether gave 0.43 g. of pure *p, p*-ditolyl disulfide (identified by its m. p. and infrared spectrum) (48% of the theoretical yield based on the reactions 5—7); its presence in the original benzene solution could not be detected by infrared spectroscopy because of the coincidence of the key bands of the disulfide with those of the other major products. The aqueous extract of the reaction mixture was evaporated to dryness under reduced pressure to give 4.0 g. of tetra-*n*-butylammonium chloride (14 mmol.); no *p*-toluenesulfonic acid nor amine compound was detected in this residue by means either of infrared spectroscopy or of such other characteristic reactions as the formation of *S*-benzylthiuronium sulfonate.

Organic Sulfur Compounds. XIV. The Reactions of Sulfinic Esters and Related Compounds with Hydrazine

By Michio KOBAYASHI* and Asami YAMAMOTO

Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama

(Received April 18, 1966)

Anhydrous hydrazine reacted with sulfinic esters under mild reaction conditions to give disulfides, which were in turn, upon prolonged heating, reduced by hydrazine to mercaptans. Aromatic thiolsulfonates and sulfonyl chlorides were also reduced by hydrazine, whereas aromatic sulfoxides and sulfinic acids were not reduced under comparable reaction conditions. A mixture of hydrazine with a sulfinic ester or another of the reducible sulfur compounds described above can hydrogenate carbon-carbon double bonds and triple bonds. A mechanism involving the intermediate formation of diimide is proposed.

The reactions of hydrazine hydrate with ethyl benzenesulfinate and methyl β-naphthalenesulfinate have been described by Curtius,[1] and the formation of nitrogen and disulfides has been observed. Although these reactions have been claimed to be expressed by the following equation, no details of the material balance have been given and no reaction mechanism has yet been discussed.

$$4\,\mathrm{R\text{-}\overset{\overset{\mathrm{O}}{\downarrow}}{S}\text{-}OR'} + 3\,N_2H_4\cdot H_2O \rightarrow 2\,(\mathrm{RS\text{-}})_2 + 4\,\mathrm{R'OH} + 7\,H_2O + 3\,N_2 \quad (1)$$

In an attempt to prepare the hitherto-unknown sulfinyl hydrazides, the reactions of anhydrous hydrazine with alkyl sulfinates and sulfinyl chlorides have been studied by the present authors. Ethyl *p*-toluenesulfinate and hydrazine reacted very slowly at room temperature, but vigorously at 60—80°C to form about one mole of gaseous product and *p*,*p*-ditolyl disulfide in an almost theoretical yield. Ethyl *p*-bromobenzenesulfinate reacted similarly to give 1.5 mole of gas and di-*p*-bromophenyl disulfide in a quantitative yield. Ethyl benzenesulfinate gave 1.25 mole of gas and diphenyl disulfide in good yields. The amounts of the gaseous product were always more than the calculated figures based on the equation 1.

Upon prologned heating, the reaction proceeded further to give the thiophenols. For instance, *p*-bromobenzenesulfinic ester gave *p*-bromothiophenol in a good yield.

The reaction between *p*-toluenesulfinyl chloride (I) and hydrazine was very vigorous, even at −60°C; di-*p*-tolyl disulfide was the major product. This reaction could be expressed by the following formula:

$$4\,\mathrm{CH_3C_6H_4\text{-}\overset{\overset{\mathrm{O}}{\downarrow}}{S}\text{-}Cl} + 7\,N_2H_4 \rightarrow 2\,(\mathrm{CH_3C_6H_4S\text{-}})_2 + 3N_2 + 4\,N_2H_5Cl + 4\,H_2O \quad (2)$$

(I)

In all the reactions described above, the formation of the desired sulfinyl hydrazide was not observed; this suggests the low stability of this class of compounds.

The reactions of several other organic sulfur compounds with anhydrous hydrazine were also examined. *p*-Toluenesulfinic acid did not react with hydrazine, and the acid was recovered unchanged upon the acidification of the reaction mixture. Diphenyl sulfoxide was also unreactive towards hydrazine.

p-Tolyl *p*-toluenethiolsulfonate (II) reacted very rapidly with hydrazine, in either the presence or absence of the solvent, to form a considerable quantity of gas, as well as di-*p*-tolyl disulfide and *p*-toluenesulfinic acid in good yields. When the reaction was carried out in ethanol for several hours at the boiling point, *p*-thiocresol and sulfinic acid were the products.

Many studies of the reactions between thiolsulfonates and anionoid reagents have been published.[2] For instance, with cyanide anions or hydroxide anions:

$$\mathrm{RSO_2SR'} + CN^- \rightarrow \mathrm{RSO_2^-} + \mathrm{R'SCN} \quad (3)$$

$$\mathrm{RSO_2SR'} + OH^- \rightarrow \mathrm{RSO_2^-} + \mathrm{R'SOH} \quad (4)$$

with thiolate anions[3]:

$$\mathrm{RSO_2SR'} + \mathrm{R''SH} \rightarrow \mathrm{RSO_2H} + \mathrm{R'SSR''} \quad (5)$$

with amines[4]:

$$\mathrm{RSO_2SR'} + \mathrm{R''NH_2} \rightarrow \mathrm{RSO_2H} + \mathrm{R'SNHR''} \quad (6)$$

* To whom inquiries should be addressed: Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo.

1) T. Curtius and F. Lorenzen, *J. pr. Chem.*, [2] **58**, 160 (1898).

2) N. Kharasch, *Chem. Revs.*, **59**, 583 (1959).

3) T. F. Parsons, J. D. Buckman, D. E. Pearson and L. Field, *J. Org. Chem.*, **30**, 1923 (1965).

4) B. G. Boldyrev and S. A. Kolensnikova, *Zh. obshch. khim.*, **35**, 198 (1965).

In all these reactions, the anionoid reagents attacked the thiolsulfonate on the sulfide sulfur. By analogy, the hydrazine molecule may be expected to react with the thiolsulfonate according to the following formula to give the sulfenyl hydrazide in the first stage:

$$RSO_2SR' + N_2H_4 \rightarrow RSO_2H + R'SNHNH_2 \quad (7)$$

The overall reaction may then be expressed by the following equation:

$$RSO_2SR' + 1/4\ N_2H_4 \rightarrow RSO_2H + R'SSR' + 1/4\ N_2 \quad (8)$$

As has been described above, the volume of the gaseous products in the reactions of hydrazine with sulfinate esters exceeded the volume of nitrogen calculated on the basis of the reaction 1. This suggests the formation of some hydrogen molecule according to the reaction shown below:

$$2\ R\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}OR' + 3\ N_2H_4 \rightarrow (RS\text{-})_2 + 3\ N_2 + 3H_2 + 2\ R'OH + 2\ H_2O \quad (9)$$

This idea has led us to examine the reaction of sulfinate esters, or other reducible organic sulfur compounds, with hydrazine in the presence of cyclohexene. If the hydrogen in the reaction 9 is formed in a reactive state, cyclohexene would be reduced to cyclohexane. Actually, when a mixture of cyclohexene (60 mmole), hydrazine (30 mmole), and methyl *p*-toluenesulfinate (12 mmole) in ethanol was warmed, 9 mole% per ester of cyclohexane was formed. In the presence of a large excess of hydrazine, the formation of 1.5 mole of cyclohexane, 0.9 mole of di-*p*-tolyl disulfide, and 1.2 mole of gas was observed. These results may be expressed by the following formula:

$$R\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}OCH_3 + 3/2\ N_2H_4 + 3/2\ C_6H_{10} \rightarrow 3/2\ C_6H_{12} + (RS\text{-})_2 + 3/2\ N_2 + CH_3OH + H_2O \quad (10)$$

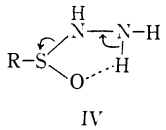
The reaction between di-*p*-tolyl disulfide, cyclohexene, and an excess of hydrazine also gave cyclohexane (75—87 mole% per mole disulfide). Cyclohexene was reduced by a mixture of *p*-tolyl *p*-toluenethiolsulfonate and hydrazine to give cyclohexane in a 50 mole% yield per thiolsulfonate and *p*-toluenesulfinic acid in a 83% yield. This reaction may be represented by the equation below:

$$2\ RSO_2SR + N_2H_4 + C_6H_{10} \rightarrow (RS\text{-})_2 + 2\ RSO_2H + N_2 + C_6H_{12} \quad (11)$$

A mixture of *p*-toluenesulonyl chloride and hydrazine reduced cyclohexene to give 1.3 mole of cyclohexane per mole of sulfonyl chloride; *p*-toluenesulfinic acid was another major product.

Acetylenic triple bonds can be hydrogenated, too. When a solution of tolan (3.3 mmole), ethyl *p*-toluenesulfinate (2.60 mmole), and a large excess of hydrazine in ethanol was refluxed for 5 hr., the formation of bibenzyl (65 mole%) and *trans*-stilbene (19 mole%) was observed.

As the common reactive hydrogenator in the above reductions, diimide (III) is considered the most plausible. In the reaction with sulfinate esters and sulfinyl chlorides, a sulfinyl hydrazide (IV) could be formed as an intermediate; this could in turn decompose to give the sulfenic acid and diimide:

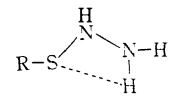


$$\longrightarrow RSOH + HN{=}NH \quad (12)$$

IV III

In the next step, the sulfenic acid could be reduced with excess hydrazine, not with diimide, to give the disulfide.

In the case of thiolsulfonates, the sulfenyl hydrazide formed in the reaction 7 would decompose to the sulfide and diimide:



$$\longrightarrow RSH + HN{=}NH \quad (13)$$

The disulfide could also give the sulfenyl hydrazide according to the reaction shown below:

$$RSSR + N_2H_4 \rightarrow RSH + RSNHNH_2 \quad (14)$$

By assuming the reactions 12—14, the amount of cyclohexane formed may be seen to correspond well with the calculated yield of diimide in these reactions. It has also been confirmed that no reduction of cyclohexene is observed, even upon prolonged boiling, with hydrazine in ethanol except when a sulfur compound is added.

Recently there have been many investigations on the reduction with diimide.[5-15] Diimide has

been produced by several methods, including the oxidation of hydrazine, the decomposition of hydroxylamine-*O*-sulfonic acid, and the decomposition of azodicarboxylate, but the methods particularly related to the present investigation are the decomposition of the sulfonylhydrazine[6a,11,15] and the alkaline decomposition of chloroacetylhydrazide.[14] The reaction of the sulfonylhydrazine in the presence of a base to give diimide and a sulfinic acid is especially reminiscent of the reactions investigated in this paper:

$$RSO_2NHNH_2 \rightarrow RSO_2H + NH{=}NH \qquad (15)$$

Most probably, in the reaction of sulfonyl chlorides with hydrazine described above, this sulfonylhydrazine is formed in the first stage of the reaction.

The steric course of the hydrogenation by diimide has been shown to be *cis*.[5b,6a,7] In the reduction of tolan with ethyl sulfinate and hydrazine described above, the formation of *trans*-stilbene, not the expected *cis*-stilbene, was observed. Considering that thiophenol is a powerful catalyst for the *cis-trans* isomerization of doulbe bonds, the above result may be explained in terms of the isomerization of the primary product, *cis*-stilbene, to the *trans* isomeride in the presence of *p*-thiocresol, formed as another main product.

In the literature, the reduction efficiency of sulfonylhydrazines has been reported to be rather poor; for instance, the amount of the alkene reduced was 0.2—0.3 mole per mole of sulfonylhydrazine.[15] On the contrary, the efficiency of the sulfinate esters or other sulfur compounds described in this paper in the reduction of cyclohexene is very good. This may be attributable to the presence of a large excess of hydrazine, in which the rate of the decay of diimide to nitrogen and hydrogen or to nitrogen and hydrazine[14] could be retarded.

Experimental

Materials.—Anhydrous hydrazine was prepared by boiling hydrazine hydrate with sodium hydroxide and barium oxide successively.

The Reaction between Ethyl *p*-Bromobenzenesulfinate and Hydrazine.—When 1.0 g. of the ester and 0.7 ml. of hydrazine were mixed at room temperature, the reaction proceeded very slowly at first, but after some time the exothermal reaction, accompanied by the evolution of gas, was started; the total gas volume was 150 ml. (1.6 mole). Upon the dilution of the reaction mixture with water, di-*p*-bromophenyl disulfide was obtained in a nearly quantitative yield.

The Reaction of *p*-Toluenesulfinyl Chloride with Hydrazine.—To a mixture of 4 g. of hydrazine and 1 ml. of anhydrous pyridine, cooled in a dry ice-acetone bath, 7 g. of sulfinyl chloride was added slowly; a very vigorous reaction, accompanied by the evolution of gas, occurred to give a solid mass, from which 2.5 g. of di-*p*-tolyl disulfide and 1 g. of *p*-toluenesulfinic acid were then isolated.

The Reaction of *p*-Tolyl *p*-Toluenethiolsulfonate with Hydrazine.—When 0.7 ml. of hydrazine was added, drop by drop, to 2 g. of the thiolsulfonate, a vigorous reaction started, and about 20 mole% of gas was evolved. After an hour, the mixture was diluted with water to leave 1 g. of di-*p*-tolyl disulfide.

The Reduction of Cyclohexene with Methyl *p*-Toluenesulfinate and Hydrazine.—A mixture of 2.0 g. of the methyl ester, 5.0 g. of cyclohexene, and 1.0 g. of hydrazine in 40 ml. of anhydrous methanol was warmed on a water bath for one hour. The reaction mixture was then diluted with water, and the organic layer was separated, dried, and analyzed by gas liquid chromatography (a 1 m. tricresyl phosphate column at 82°C), and found to contain 1.83% of cyclohexane. A similar reaction of 5.0 g. of ethyl *p*-toluenesulfinate, 5.0 g. of cyclohexene, and 5.0 g. of hydrazine in 40 ml. of ethanol at 70—80°C gave 750 ml. of gas in 8 hr. Analysis by gas chromatography revealed the formation of 1.48 mole of cyclohexane per mole of the sulfinate ester. The extraction of the water layer with methylene chloride gave 3.0 g. of di-*p*-tolyl disulfide.

The Reduction with Di-*p*-tolyl Disulfide.—A mixture of 3.0 g. of the disulfide, 5.0 g. of hydrazine, and 5.0 g. of cyclohexene in 40 ml. of ethanol was warmed at 65°C for 11 hr.; 180 ml. of gas was thus evolved. By treatment similar to that of the above reaction, the formation of 75 mole% cyclohexane (based on the disulfide) was indicated.

The Reduction of Tolan.—A solution of 585 mg. of tolan, 2 g. of hydrazine, and 480 mg. of ethyl *p*-toluenesulfinate in 15 ml. of absolute ethanol was refluxed for 5 hr. The reaction mixture was then diluted with water, extracted with *n*-hexane, and fractionated by elution chromatography over alumina with petroleum ether. Bibenzyl, di-*p*-tolyl disulfide, and *trans*-stilbene were eluted in this order. Since the separation of bibenzyl from the disulfide was incomplete, the yield of these compounds was estimated by infrared spectroscopy and found to be 401 mg. of bibenzyl and 127 mg. of the disulfide, whereas the yield of *trans*-stilbene was 113 mg. No *cis*-stilbene was detected.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2739—2744 (1966)

The Ionic Telomerization of Conjugated Diene Compounds. I. The Cationic Telomerization of Butadiene with Its Hydrochlorides at Low Temperatures

By Teruzo ASAHARA and Hideo KISE

Institute of Industrial Science, The University of Tokyo, Azabu-Shinryudocho, Minato-ku, Tokyo

(Received May 7, 1966)

The telomerization of butadiene with its hydrochlorides (1-chlorobutene-2 and 3-chlorobutene-1) at low temperatures in the presence of cationic catalysts was investigated. The aim of the present investigation is to explore methods to control the molecular weight of the products with various reaction conditions, and to determine the properties and structure of the telomers obtained. The activity of several cationic catalysts at −50——40°C, and the effects of the conversion and the ratio of chlorobutene to butadiene (RCl/Bu) on the yield and average molecular weights of the telomers were investigated. The products were divided into simple adducts and higher telomers by vacuum distillation. The fraction of the 1 : 1 adduct contained three isomers, one of which was 1-chlorooctadiene-2, 6. The structure and properties of the higher telomers were investigated by the aid of the infrared spectra, the average molecular weight, the iodine value, and elementary analysis. On the basis of the results, the reaction mechanism was discussed.

There is information in the literature about the cationic telomerizations of conjugated dinene compounds with compounds of the allyl halide type. For example, the reactions of isoprene and butadiene with their hydrochlorides in the presence of stannic chloride were investigated by Leets[1] and Petrov[2]; the adducts of a 1 : 1 ratio were thus isolated by vacuum distillation. It was found that the relative amounts of the simple addition products and higher telomers depend primarily on the degree of conversion of the reaction. It was also shown that the addition of allyl and alkyl halides to butadiene and isoprene goes in accordance with Markovnikov's rule and occurs at both the 1, 4 and 1, 2 positions. However, the higher telomers are very complex and have not previously been investigated, and knowledge about the reaction mechanism is lacking.

This paper will be concerned, in particular, with the comparison of the activity of several cationic catalysts in the telomerization of butadiene with its hydrochlorides at low temperatures, and with the effect of the initial ratio of the chlorobutene to butadiene on the degree of conversion of the reaction and on the average molecular weight of the resultant telomers. The structure of telomers will also be discussed.

Experimental

The Synthesis of Chlorobutene.—1-Chlorobutene-2 and 3-chlorobutene-1, which were used as telogens, were prepared according to the method described by Dolnick.[3] The two isomers were separated by the fractional distillation of the obtained products, which consisted of about 65% 1-chlorobutene-2 (b. p. 83—85°C), 32% 3-chlorobutene-1 (b. p. 63—66°C), and a trace of a third product with a lower boiling point. The total yield of chlorobutenes was about 85%. In the present experiments 1-chlorobutene-2 was used as a telogen.

Telomerization.—Butadiene was dried before use by passing it through a column of anhydrous calcium chloride and sodium hydroxide. The purity was found to be above 99.3%. Ethyl bromide was purified by washing it several times with chilled concentrated sulfuric acid and water, drying it on calcium chloride, and distilling it.

A 500-ml. round-bottomed glass flask, equipped with a sealed stirrer, a thermometer, a condenser, and an inlet for gas, was cooled in a dry ice-aceton bath under a nitrogen stream; then it was charged with known amounts of the telogen, butadiene, and ethyl bromide. After the temperature of the solution had reached −50——55°C, the catalyst, contained in a part of the ethyl bromide, was slowly added. The reaction is exothermic, and the temperature of the solution rises as the reaction proceeds. The rate of the addition of the catalyst solution was adjusted to keep the temperature of the solution under −35°C. After the telomerization, a small amount of pyridine was added to stop the reaction, and then *n*-hexane was added. The precipitated pyridine/catalyst complex was separated, and the solution was washed with a 5% sodium carbonate solution, a 5% hydrochloric acid solution, and then water, and dried on anhydrous calcium chloride. The solvent and the unreacted chlorobutene and butadiene were distilled off under a vacuum by a water jet pump, and the residue was subjected to vacuum distillation.

Analysis.—*Molecular Weight.*—The molecular weight of the products was measured in a toluene solution with a Mechrolab vapor-pressure osmometer, model 301A, at 37°C. Squalane was used as the standard material.

Infrared Spectra.—The spectra of the telomers were taken with a Hitachi-Perkin-Elmer double-beam grating spectrophotometer, model 125. The evaluation of the absorption intensity was made by the ordinary base-line method.

Gas Chromatography.—The adducts with a 1 : 1 ratio of butadiene to chlorobutene were analyzed by a Hitachi-Perkin-Elmer F6 gas chromatograph with a flame ionization detector. The separation column was a stainless steel tube packed with Diasolid S (Nihon Chromato Kogyo, Ltd.); the liquid phase was silicon grease (10%).

The Amount of Unsaturation.—The degree of the unsaturation of telomers was determined by the Wijs method in a carbon tetrachloride solution.

Results and Discussion

1) The Activity of Catalysts. — Several cationic catalysts were used in the telomerization of butadiene with 1-chlorobutene-2. The findings on their catalytic activities are shown in Table I. Zinc chloride is partially insoluble in the reaction solution. Table I shows that, under the present reaction conditions, aluminum chloride and ferric chloride have considerable catalytic ability, but the other catalysts investigated gave only a small amount of a product. Stannic chloride in dichloromethane was used as a catalyst at 15—20°C by Petrov[2]; it gave an appreciable amount of the 1 : 1 adduct and higher telomers. However, in the present experiment at low temperatures, stannic chloride in ethyl bromide gives only a very small amount of telomers with higher molecular weights, and scarcely any of the 1 : 1 adduct. All the products are yellow-brownish viscous liquids and contain little of the simple adduct, except for the ferric chloride being used as the catalyst.

Table I. Telomerization of butadiene with 1-chlorobutene-2 by cationic catalysts

Catalyst	C/Bu mole	EtBr/Bu vol.	Time min.	Yield %	Av. mol. wt.

$FeCl_3$	0.015	2.2	240	65.8	527
$SnCl_4$	0.020	1.5	420	2.6	394
$ZnCl_2$	0.029	1.5	1380	1.2	—
BF_3Et_2O	0.058	2.6	240	0.3	—
BF_3Et_2O*	0.106	1.8	240	3.0	1235

RCl/Bu, 1.0 (molar ratio);* RCl/Bu, 0.5 (molar ratio)

On the basis of these results, aluminum chloride and ferric chloride were employed in the following experiments.

2) Conversion and Molecular Weight.—The yield and the molecular weight of the products are plotted against the reaction time in Fig. 1. The reaction nears completion during a short period; therefore, the reaction must be stopped in the early stages if we are obtain lower telomers by the control of the conversion. Under these conditions, the average molecular weight of the telomer is limited to less than about 530; other conditions must be used to obtain the higher telomers.

RCl/Bu=1.0 (molar ratio); $AlCl_3$/Bu=0.01 (molar ratio); EtBr/Bu=1.5 (volume ratio)
○: Yield ●: Average molecular weight

3) Telomerization with Two Chlorobutene Isomers and the Polymerization of Chlorobutene.—As has previously been mentioned, two isomeric chlorobutenes are obtained by the addition of hydrogen chloride to butadiene. When it is used as a telogen under the same reaction conditions, 1-chlorobutene-2 gives a little higher yield and average molecular weight of telomers (Table II, Nos. 1 and 2). However, the analysis by gas chromatography shows that the 1 : 1 adducts of butadiene and each of these two chlorobutenes are composed of nearly the same proportions of isomers, and that the higher telomers from each of these two chlorobutenes have nearly the same infrared spectra. These results indicate that the carbonium cation shown below is formed by the interaction between chlorobutene and the catalyst in the initiation process:

$$CH_3-\overset{+}{C}H\cdots CH\cdots CH_2$$

The difference in the yield of telomers may be attributable to the difference in the rate of the initiation reaction.

Experiment No. 3 in Table II shows that the polymerization of 1-chlorobutene-2 by the action of aluminum chloride affords polymers with a low unsaturation. A small amount of dimer was isolated by distillation (21% of total product; b. p. 60—72°C/1 mmHg).

Found: C, 52.81; H, 7.64; Cl, 39.10. Calcd. for $(C_4H_7Cl)_2$: C, 53.05; H, 7.80; Cl, 39.15%.

No condensation product was found. Therefore, in the system which contains both butadiene and chlorobutene, the polymerization of chlorobutene and the grafting of a growing carbonium ion onto the preformed telomers are also plausible (see section 8).

TABLE II. TELOMERIZATION OF BUTADIENE WITH TWO CHLOROBUTENE ISOMERS AND POLYMERIZATION OF CHLOROBUTENE

Expt. No.	Telogen	Yield, % Soluble	Yield, % Insoluble	Av. mole wt.	Iodine value

2	3-Cl-But-1	37.7	—	419	216
3	1-Cl-But-2	60.3	—	466	25
4	—	0.5	38.0	—	—

No. 1—3: $AlCl_3$/RCl, 0.01 (molar ratio); RCl/Bu, 1.0 (molar ratio); EtBr/Bu, 1.5 (vol. ratio); Reaction time, 240 min.
No. 3: Reaction in the absence of butadiene.
No. 4: Polymerization of butadiene. $AlCl_3$/Bu, 0.02 (molar ratio); EtBr/Bu, 1.5 (vol. ratio); Reaction time, 100 min.

4) The Effect of the RCl/Bu Ratio.—As Figs. 2 and 3 show, the yield and the average molecular weight of telomers depend on the initial ratio of chlorobutene to butadiene. When aluminum chloride was used as a catalyst, the maximum yield of telomers is obtained at RCl/Bu=0.7. In the region where RCl/Bu is lower than 0.7, the insoluble product is obtained; it increases in amount with the decrease in the RCl/Bu ratio. Moreover, almost all the product obtained from the polymerization of butadiene in the absence of chlorobutene is insoluble in ordinary organic and inorganic solvents (Table II, No. 4). These products are probably caused by branching. As

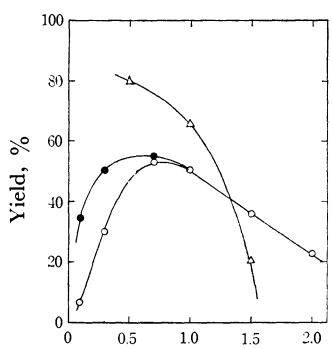

Fig. 2. Effect of the ratio of chlorobutene to butadiene on the yield of telomer.
Reaction time: 4 hr.
○: Catalyst: $AlCl_3$; $AlCl_3$/Bu=0.01 (molar ratio); ●: Insoluble telomor; △: Catalyst: $FeCl_3$; $FeCl_3$/Bu=0.015 (molar ratio)

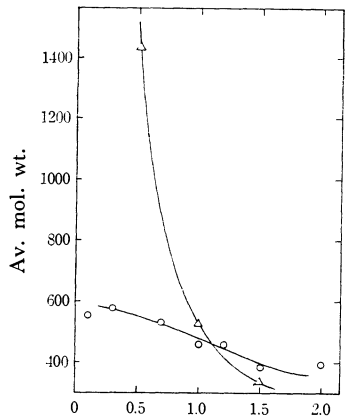

Fig. 3. Effect of the ratio of chlorobutene to butadiene on the average molecular weight of telomer.
Reaction time: 4 hr.
○: Catalyst: $AlCl_3$; $AlCl_3$/Bu=0.01 (molar ratio)
△: Catalyst: $FeCl_3$; $FeCl_3$/Bu=0.015 (molar ratio)

will subsequently be described, the total unsaturation of higher telomers is always low, and it is obviously due to the reactivity of the telomers preformed in side reactions. Grafting and cyclization are suggested, at least as contributory factors.

On the other hand, with ferric chloride as a catalyst, the yield of telomers increases monotonously with the decrease in the RCl/Bu ratio; in the low region of this ratio, the product is a very adhesive semisolid, only a small part of which is insoluble.

The increase in the RCl/Bu ratio causes a decrease in the average molecular weight of products when both aluminum chloride and ferric chloride are used as the catalyst. However, the decrease in the average molecular weight is larger when ferric chloride is used than when aluminum chloride is used.

On the basis of these results, it may be concluded that ferric chloride is the most convenient of the catalysts investigated for controlling the molecular weight of telomers in the telomerization of butadiene with 1-chlorobutene-2.

5) Lower Telomers.—The telomerization of butadiene with 1-chlorobutene-2 was carried out to various extents of the reaction. The increasing degree of reaction is accompanied by an increasing total yield of telomers and by a decrease in the yield of lower adducts (Table III). This agrees with the finding of Leets[1] that, in the telomerization of isoprene with prenyl chloride in dichloromethane in the presence of stannic chloride, the yield of monoterpene chloride increases in the early stages of the reaction, but then decreases

in the later stages; the increase in the yield of polyterpene chloride follows the opposite pattern. This may be due to the consumption of the preformed 1 : 1 adduct by some side reactions or by its addition to butadiene as a telogen, producing higher adducts.

TABLE III. CONVERSION AND LOWER TELOMERS

RCl/Bu mole	EtBr/Bu vol.	Time min.	Conversion %	Lower adducts in telomer, %
1.0	2.20	240	65.8	13.9
1.2	2.22	90	15.9	51.7
1.2	2.23	130	53.9	27.5
1.2	2.23	180	54.4	25.7
1.5	2.30	240	20.5	43.3

Telogen, 1-chlorobutene-2; Catalyst, $FeCl_3$

The fraction with a b. p. of 50—65°C/10 mmHg (I) was again divided into two fractions: 50—58°C/10 mmHg (II) and 58—65°C/10 mmHg (III).

II: Found: C, 64.99; H, 8.81; Cl, 23.43.
III: Found: C, 64.10; H, 8.73; Cl, 24.51.
Calcd. for $H(C_4H_6)_2Cl$: C, 66.43; H, 9.06; Cl, 24.51%.

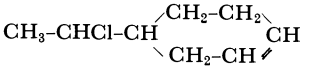
The gas chromatogram of II has two main peaks, which overlap one another, whereas that of III consists of only one peak. The III content in the fraction I is about 61%. The infrared spectrum of the fraction II (Fig. 4, curve 4) exhibits the characteristic stretching (1645 cm^{-1}) and deformation (910 cm^{-1}) bands of a vinyl group, together with the stretching (1665 cm^{-1}) and deformation (965 cm^{-1}) bands of the -CH=CH- grouping. The spectrum of the fraction III (Fig. 4, curve 3) has only the bands of -CH=CH- (965 and 1665 cm^{-1}). The cationic addition of chlorobutene to butadiene is known to abide by Markovnikov's rule; therefore, the structures of the 1 : 1 adducts may be shown as follows:

CH_3-CH=CH-CH_2-CH_2-CH=CH-CH_2Cl (A)

CH_3-CH=CH-CH_2-CH_2-$CHCl$-CH=CH_2 (B)

CH_2=CH-CH(-CH_3)-CH_2-CH=CH-CH_2Cl (C)

CH_2=CH-CH(-CH_3)-CH_2-$CHCl$-CH=CH_2 (D)



(E)

From the results mentioned above, the fraction III is determined to be A. The fraction II is considered, from the infrared spectrum, probably to be a mixture of B and C. The iodine values of II and III are 325 and 315 respectively, values which correspond to 92.8 and 90.0% of the theoretical value based on the assumption that two C–C double bonds are present in each molecule. Consequently, the amount of cyclic product (E) must be small.

6) The Infrared Spectra of Higher Telomers.—The infrared spectra of higher telomers, obtained from telomerizations under various conditions, were taken and the amounts of *trans*-1, 4, *cis*-1, 4 and 1, 2 linkages were determined by the method described by Richardson[4] and by Golub[5]. The *trans*-1, 4 linkage predominates, accounting for 80—85% of the total observed unsaturation. The contents of 1, 2 and *cis*-1, 4 linkages are determined to be 9—15% and 2—10% respectively. The structures of telomers vary with the RCl/Bu ratio, the conversion, the structure of chlorobutenes, and the catalysts, but the differences are small and no definite trend can be discerned.

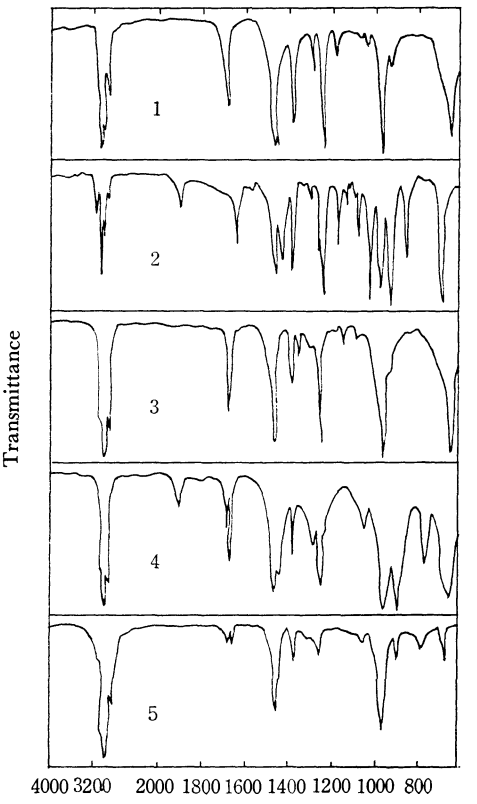


Fig. 4. Infrared spectra of telogens and telomers.
1: 1-Chlorobutene-2 2: 3-Chlorobutene-1
3: Fraction III 4: Fraction II
5: Higher telomer

7) The Unsaturation of Telomers.—The amount of the unsaturation of higher telomers was determined by the Wijs method in a carbon tetrachloride solution. According to Kemp,[6] the iodine value of polybutadiene depends on the

* Numbers are in common with Table IV.

reaction time and on the amount of excess iodine chloride. Therefore, the effects of the amount of iodine chloride and the reaction time on the iodine value of the telomer with a molecular weight of about 550 were studied; it was concluded that, in the presence of about a 60% excess of idoine chloride, the addition of iodine chloride to the C–C double bond in telomers nears completion after 3 hr. The results are shown in Table IV. The theoretical unsaturation is always low, and it may be taken as evidence of the occurrence of some side reactions. As will be shown below, various side reactions may possibly occur, particularly grafting and cyclization which involve the loss of unsaturation.

When aluminum chloride is used as a catalyst, the theoretical unsaturation of telomers decreases somewhat with the increase in the RCl/Bu ratio. However, in case of ferric chloride, an appreciable increase in the theoretical unsaturation is observed.

The amount of the residual unsaturation also depends on the conversion. It increases with the decrease in the conversion. This is considered to be due to the predominance of the side reactions as a result of the decrease in the butadiene concentration and the increase in the telomer concentration at the later stage of the reaction.

8) The Mechanism of the Reaction.—The reaction mechanism of the cationic telomerization of butadiene with chlorobutene is known to be as follows:

Initiation:

$$\left.\begin{matrix}CH_3\text{-}CH{=}CH\text{-}CH_2Cl\\ CH_3\text{-}CHCl\text{-}CH{=}CH_2\end{matrix}\right\} + AlCl_3 \longrightarrow$$

$$CH_3\text{-}\overset{+}{C}H\text{---}CH\text{---}CH_2 + AlCl_4^- \qquad (1)$$

Propagation:

$$CH_3\text{-}\overset{+}{C}H\text{---}CH\text{---}CH_2 + (n-1)CH_2{=}CH\text{-}CH{=}CH_2$$

$$\longrightarrow H(C_4H_6)_{n-1}CH_2\text{-}\overset{+}{C}H\text{---}CH\text{---}CH_2 \qquad (2)$$

Transfer reaction:

$$H(C_4H_6)_{n-1}CH_2\text{-}\overset{+}{C}H\text{---}CH\text{---}CH_2 + CH_3\text{-}CH{=}CH\text{-}CH_2Cl \longrightarrow$$

$$H(C_4H_6)_nCl + CH_3\text{-}\overset{+}{C}H\text{---}CH\text{---}CH_2 \qquad (3)$$

Termination:

$$H(C_4H_6)_{n-1}CH_2\text{-}\overset{+}{C}H\text{---}CH\text{---}CH_2 + AlCl_4^-$$

$$\longrightarrow H(C_4H_6)Cl + AlCl_3 \qquad (4)$$

The finding that the proportion of the 1, 4-1, 4 adduct in the mixture of the 1 : 1 adduct is about 61% suggests that the probability of finding the positive charge on the terminal carbon atom of a growing carbonium ion is about 78%. This is

compatible with the value in the butadiene polymerization.[7]

Several side reactions are also possible; they are shown as follows:

Grafting:

$$-CH_2-CH=CH-CH_2- + -CH_2^+ \longrightarrow -CH_2-\overset{+}{C}H-\underset{CH_2-}{CH}-CH_2- \quad (5)$$

Hydride-ion transfer from the telomer:

$$\begin{matrix}-CH-CH_2-\\ |\\ CH=CH_2\end{matrix} + -CH_2^+ \longrightarrow \begin{matrix}\overset{+}{C}-CH_2-\\ |\\ CH=CH_2\end{matrix} + -CH_3 \quad (6)$$

Proton transfer to the telomer:

$$-CH_2-CH=CH-CH_2- + -CH_2-CH=CH-CH_2^+ \longrightarrow -CH_2-\overset{+}{C}H-CH_2-CH_2- + -CH=CH-CH=CH_2 \quad (7)$$

Intramolecular tranfser reactions:

$$\begin{matrix}CH_2-CH\\ /\quad \|\\ -CH_2-CH\ \overset{+}{C}H_2-CH\\ \quad |\\ CH_2=CH\end{matrix} \longrightarrow \begin{matrix}-CH_2-\overset{+}{C}-CH_2-CH=CH-CH_3\\ \quad\quad |\\ \quad CH_2=CH\end{matrix} \quad (8)$$

$$\begin{matrix}\quad\quad CH_2-CH_2\\ -CH=CH\ \diagup \quad\quad \diagdown\\ \quad\quad \overset{+}{C}H_2-CH \quad\quad CH\\ \quad\quad\quad\quad\quad\quad \diagdown\quad /\\ \quad\quad\quad\quad\quad\quad CH_2-CH\end{matrix} \longrightarrow \begin{matrix}\quad\quad\quad\quad CH_2-CH_2\\ \quad\quad\quad\quad\quad\quad\quad\quad \diagdown\\ -\overset{+}{C}H-CH\quad\quad\quad\quad CH\\ \quad\quad\quad\quad\quad\quad\quad\quad /\\ \quad\quad\quad\quad\quad\quad CH_2-CH\end{matrix} \quad (9)$$

Reactions 5 and 9 cause a decrease in the average iodine value of telomer mixtutes. Reactions 5, 6 and 7 give telomers with more than one chlorine atom, but reactions 6 and 7 have no effect on the average chlorine contents in the telomer mixtures.

The telomers which are formed by reactions 1—4 can be represented by the general formula, $H(C_4H_6)_nCl$. However, the low amount of unsaturation, the formation of insoluble telomers, and the high chlorine contents in higher telomers suggest the presence of side reactions. Thus, telomers represented by the general formula $[H(C_4H_6)_\alpha Cl]_\beta$ are obtained. The values of α and β were calculated from the results of the elementary analysis and the average molecular weights (Table V).

If a telomer is formed by a times of propagation (Eq. 2), b times of grafting (Eq. 5), and c times of cyclization (Eq. 9), and if the reaction is initiated exclusively by Eq. 1, the following relations must hold:

$$\begin{aligned}\alpha\beta &= a + b + 1\\ \beta &= b + 1\\ F &= a - c + 1\end{aligned} \quad \text{(i)}$$

where F represents the average number of the residual C–C double bonds in a telomer and can be obtained from the iodine value determination. Equation i can then be rewritten as follows:

$$\begin{aligned}a &= \beta(\alpha - 1)\\ b &= \beta - 1\\ c &= \beta(\alpha - 1) + 1 - F\end{aligned} \quad \text{(ii)}$$

The calculated values of a, b and c are given in Table V. When aluminum chloride is used as the catalyst, the increase in the RCl/Bu ratio causes an increase in the proportion of grafting, with a decrease in the contribution of propagation. On the other hand, when ferric chloride is used as the catalyst, the proportion of propagation increases with the RCl/Bu ratio. The cyclization occurs almost independently of the RCl/Bu ratio. The high occurrence of cylization in Exp. 7 may be related to a very high conversion of the reaction.

Knowledge about reactions 6, 7 and 8 is lacking; there is no direct evidence for any of these reactions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2745—2749 (1966)

The Reactions of 1-Chloro-2-oximino-3-butanone

By Mitsuo MASAKI, Masatoshi SUGIYAMA, Suehiro TAYAMA, and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

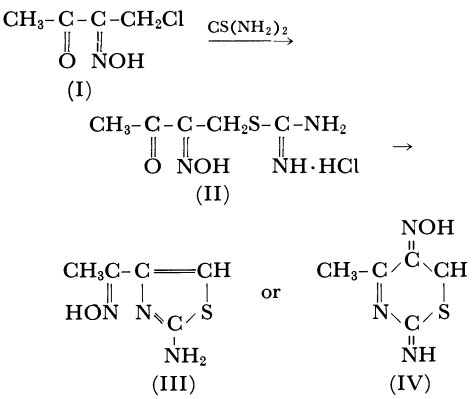
(Received May 9, 1966)

The reaction of 1-chloro-2-oximino-3-butanone (I) with thiourea at 50—60°C gave *S*-(2-oximino-3-oxobutyl)thioformamidine hydrochloride (II), which upon being heated in an aqueous solution, then gave 2-amino-4-(1-oximinoethyl)thiazole (III). The treatment of I with aminoacetonitrile gave a mixture of *N*-(2-oximino-3-oxobutyl)aminoacetonitrile (IV) and *N*, *N*-bis(2-oximino-3-oxobutyl)aminoacetonitrile (V), which were confirmed as the corresponding amidoxime and benzoyl or *p*-nitrobenzoyl derivatives respectively. The reaction of I or 3-chloro-2-oximinopropiophenone with barium thiocyanate gave the corresponding acyclic thiocyanates (VI), while the reaction of *anti*-bromoacetophenone oxime with barium thiocyanate yielded 2-amino-4-phenylthiazole-3-oxide. That the cyclization reaction between the oximino and the cyano groups of V or VI did not occur seemed to favor the *syn*-chloromethyl conformation of the oximino group in I, a mechanism for which is hereby proposed.

The reaction of halogenated biacetyl monooximes has received only scant attention, but they seem to be useful for some synthetic reactions because they have three functional groups. The reaction of 1-bromo-3-oximino-2-butanone with thioformamide or thiobenzamide has been known to give the corresponding thiazole derivatives.[1] Recently, Ogloblin and Potekhin reported the preparation of 1-chloro-2-oximino-3-butanone (I) and its reactions with hydroxylamine hydrochloride, phenylhydrazine, or diethylamine to give the corresponding carbonyl derivatives or substituted product.[2]

We have shown in a previous paper that the reaction of I with amino acid esters, as an example of primary amines, gave products formed not by the condensation of the carbonyl group, but by the displacement of chlorine in I.[3] In the present experiment, the reactions of I with thiourea, aminoacetonitrile, and barium thiocyanate were examined.

The reaction of I with thiourea in ethanol at 50—60°C gave *S*-(2-oximino-3-oxobutyl)thioformamidine hydrochloride (II), which was characterized by elementary analysis and by a study of the infrared spectrum of the free base. When II was boiled in an aqueous solution and then neutralized with ammonia, a crystalline product, m. p. 206—207°C, was obtained. The elementary analysis of the product indicated that the empirical formula, $C_5H_7N_3OS$, held, a formula compatible with the cyclic structure, 2-amino-4-(1-oximinoethyl)thiazole (III) or 2-imino-4-methyl-5-oximino-5, 6-dihydro-2*H*-1, 3-thiazine (IV).



Garreau reported the treatment of 1-chloro-2, 3-butanedione with thiourea to give a substance, m. p. 230°C, the structure of which he claimed to be 4-acetyl-2-aminothiazole (V), though the possibility of the thiazine structure (VI) could not be excluded.[4]

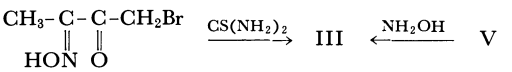
3) M. Sugiyama, M. Masaki and M. Ohta, This Bulletin, submitted for publication.

4) Y. Garreau, *Chem. Zentr.*, **1947**, 731; *Chem. Abstr.*, **51**, 12148 (1957).

The substance, m. p. 230°C, prepared from 1-bromo-2, 3-butanedione and thiourea was treated with hydroxylamine to give the corresponding oxime, which was confirmed to be identical with the substance, m. p. 206—207°C obtained above. The identical product was also obtained directly by the reaction of 1-bromo-3-oximino-2-butanone with thiourea.



On the basis of these results, as well as infrared and ultraviolet spectral data, the substance with a m. p. of 206—207°C was concluded to be 2-amino-4-(1-oximinoethyl)thiazole (III); accordingly, the substance with a m. p. of 230°C, obtained from 1-bromo-2, 3-butanedione and thiourea, must be 4-acetyl-2-aminothiazole (V).

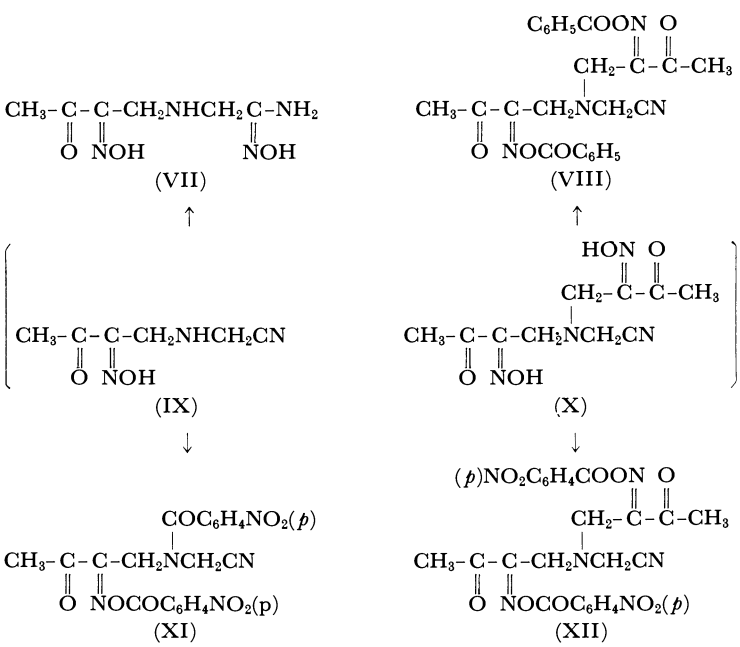
The infrared spectrum of III showed two absorption bands, at 3380 and 3305 cm^{-1}, which could be ascribed to asymmetric and symmetric NH_2-stretching vibrations, as the relationship of the wave numbers of the two bands accorded well with the equation of Bellamy-Williams.[5] The presence of the primary amine corresponded only with the III structure.

The ultraviolet spectrum of III showed two absorption maxima, at 224.5 and 270 mμ; this also supported the thiazole structure, since unsubstituted thiazole has an absorption maximum at 235 mμ[6] and the maximum bands of 2-amino-4-phenylthiazole were observed at 230.5 and 285 mμ.

A probable pathway for the formation of III from II would be the initial cyclization of II to give V and hydroxylamine, which then reacts to give III. A similar ring-closure by the loss of hydroxylamine was also observed in the reaction of bromoacetophenone oxime with thiourea; when bromoacetophenone oxime and thiourea were heated in an ethanolic solution for twenty minutes, 2-amino-4-phenylthiazole was obtained in a quantitative yield.

When I was treated with two equivalents of aminoacetonitrile in ethyl acetate at room temperature, an oily product was obtained with a quantitative amount of aminoacetonitrile hydrochloride. The oily product was soluble in water, and its purification was difficult. The treatment of the crude product with hydroxylamine afforded 2-(2-oximino-3-oxobutylamino)acetoamidoxime (VII), while treatment with benzoyl chloride gave *N*, *N*-bis(2-benzoyloximino-3-oxobutyl)amino acetonitrile (VIII). Thus, the oily product is probably a mixture of *N*-(2-oximino-3-oxobutyl)-aminoacetonitrile (IX) and *N*, *N*-bis(2-oximino-3-oxobutyl)aminoacetonitrile (X). Reaction with *p*-nitrobenzoyl chloride gave the corresponding di-*p*-nitrobenzoyl derivatives (XI, XII), from the yields of which the oily product appeared to include nearly equivalent amounts of IX and X (Scheme 1).

Sharp et al. described the reaction of α-oximino-



Scheme 1

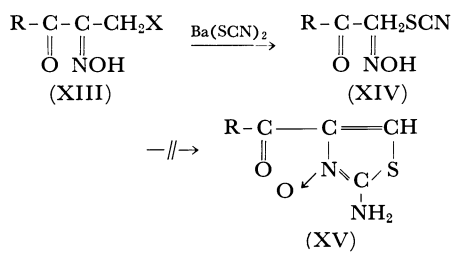
6) A. R. Katritzky, "Physical Methods in Heterocyclic Chemistry," Vol. II, Academic Press, New York and London (1963), p. 59.

carbonyl compounds with α-aminonitrile to give 2-aminopyrazine-1-oxides.[7] The analogous ring closure between oximino and cyano groups of IX was attempted by treatment in the presence of acids or by the conversion of the nitrile into the iminoether, but the corresponding cyclic compound was not isolated.

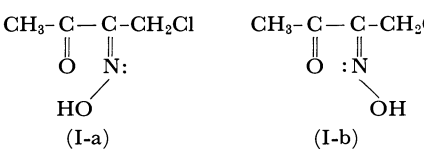
The reaction of 1-chloro-2-oximino-1-phenylpropane with barium thiocyanate has been reported to give 2-amino-4-methyl-5-phenylthiazole-3-oxide.[8] When 3-chloro-2-oximinopropiophenone (XIII, R=C_6H_5) was treated with barium thiocyanate, it gave not the corresponding cyclic compound (XV), but 2-oximino-3-oxo-3-phenylpropyl thiocyanate (XIV, R=C_6H_5), which was characterized by elementary analysis and by the presence of absorption bands near 2130 cm^{-1} (-SCN) in the infrared spectrum as well as by the negative ferric chloride reaction. The treatment of I with barium thiocyanate gave an oily product, which also had absorption bands near 2130 cm^{-1} in the infrared spectrum and did not show a color reaction with ferric chloride.



(XIII) (XIV) (XV)

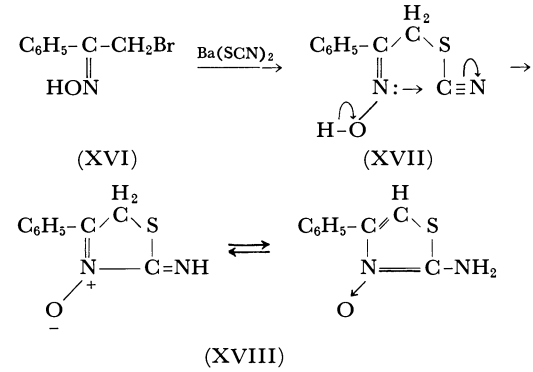
R=C_6H_5, CH_3

Although, in the case of the synthesis of aminopyrazine oxide[7] or aminothiazole oxide[8], neither the configuration of the oximes nor the mechanism of the cyclization reactions has been discussed, the pathways of those cyclization reactions probably involve an attack by the nitrogen of the oximino group on the carbon of the cyano group (see XVII). Therefore, if the hydroxyl group in the oxime of I has an *anti*-configuration to the chloromethyl group (I-a), IX or XIV may be expected to undergo ring closure readily, while if both groups are situated in the *syn*-configuration (I-b), the cyclization reaction of IX or XIV would not easily take place.



(I-a) (I-b)

When *anti*-bromoacetophenone oxime (XVI) was treated with barium thiocyanate, the cyclization reaction occurred expectedly, and 2-amino-4-phenylthizaole-3-oxide (XVIII), which shows a positive ferric chloride reaction, was obtained.



(XVI) (XVII)

(XVIII)

Thus, the fact that the cyclization reaction of IX or XIV did not occur may be ascribed to the *syn*-chloromethyl configuration (I-b) of the oxime in I.[9]

Experimental

***S*-(2-Oximino-3-oxobutyl)thioformamidine (The Free Base of II).**—A mixture of thiourea (1.5 g.) and I (2.7 g.) in ethanol (40 ml.) was heated at 50—60°C for 2 hr. and then left standing at room temperature overnight. The solution was evaporated under reduced pressure to give an oily residue, which was the hydrochloride (II). The oily residue (II) was dissolved in water (40 ml.) and treated with activated charcoal. A half of the solution was neutralized with sodium bicarbonate (1.7 g.) to separate yellow crystals (2.7 g.). (The remaining half of the solution was used for the cyclization reaction in the next section.) The product (1 g.) was dissolved in 0.5 N hydrochloric acid (15 ml.), treated with activated charcoal, and then reprecipitated by neutralizing it with a clear aqueous solution of sodium bicarbonate (0.6 g. in 9 ml. of water). After it had been washed twice with water and twice with ethanol, it was analyzed. Fine yellow crystals; m. p. 128—130°C (decomp.). IR: ν_{max}^{KBr} 3300 (-NH-), 3000—2200 (broad band), and 1650 cm^{-1} (-C=O).

Found: C, 34.91; H, 5.05; N, 24.12. Calcd. for $C_5H_9N_3O_2S$: C, 34.28; H, 5.18; N, 23.99%.

2-Amino-4-(1-oximinoethyl)thiazole (III).—*a) From II.*—The remaining half of the solution of II described above was heated on a boiling water bath for 3 hr. After it had then cooled to room temperature, the solution was neutralized with an aqueous ammonia to separate almost colorless crystals, which were recrystallized twice from water by using activated charcoal. Colorless needles; m. p. 205—206°C. The product showed no depression in mixing tests with the specimen obtained by either the b) or the c) method. UV: λ_{max}^{EtOH} 224.5 mμ (ε=15700) and 270 (sh., 7700). IR:

7) W. Sharp and F. S. Spring, *J. Chem. Soc.*, **1951**, 932; J. J. Gallagher, G. T. Newbold, W. Sharp and F. S. Spring, ibid., **1952**, 4870.

8) A. Dornow, H. H. Marquardt and H. Paucksch, *Chem. Ber.*, **97**, 2165 (1964).

9) The *syn*-chloromethyl conformation of I might be supported by the fact that the melting point of 1-diethylamino-2, 3-butanedione-2-oxime[2] derived from I is essentially identical with that of authentic *syn*-1-diethylamino-2, 3-butanedione-2-oxime.[10]

10) G. B. Bachman and D. E. Welton, *J. Org. Chem.*, **12**, 221 (1947).

ν_{max}^{KBr} 3380 (*asym*-NH_2), 3305 (*sym*-NH_2), and 1650 cm^{-1} (-C=O).

Found: C, 38.86; H, 4.55; N, 26.93. Calcd. for $C_5H_7N_3OS$: C, 38.22; H, 4.49; N, 26.74%.

b) From 4-Acetyl-2-aminothiazole.—When thiourea (1.9 g.) was added to a solution of 1-bromo-2, 3-butanedione (4.2 g.) in ethanol (20 ml.), the mixture became a clear solution with an exothermic reaction; then colorless crystals soon separated. The resultant mixture was heated under reflux for 30 min. The crystals were collected and recrystallized from water to yield 4-acetyl-2-aminothiazole hydrobromide as colorless needles; m. p. 248—250°C (decomp.). (Found: N, 12.24%). The treatment of the hydrobromide with aqueous sodium bicarbonate gave the free base with a m. p. of 229—231°C (decomp.) (lit.[4] 230°C). A solution of the free base (0.95 g.), hydroxylamine hydrochloride (0.5 g.), and potassium hydroxide (0.4 g.) in methanol (50 ml.) was heated under reflux for 4 hr., after which the solvent was removed under reduced pressure; the residual solid was recrystallized twice from water and once from *n*-butanol to give 0.5 g. of colorless needles; m. p. 207—208°C.

c) From 1-Bromo-3-oximino-2-butanone. — Thiourea (0.76 g.) was added to a solution of 1-bromo-3-oximino-2-butanone (1.8 g.) in ethanol (15 ml.). The mixture soon became a clear solution with exothermic reaction. The solution was heated under reflux for 30 min. and then cooled to room temperature to give a crystalline product. An aqueous solution of the product was treated with sodium bicarbonate to give colorless crystals (0.5 g.), which were recrystallized from the solvent described in a) and b) to give colorless needles; m. p. 206—207°C.

The Reaction of Phenacylbromide Oxime with Thiourea.—A mixture of phenacylbromide oxime (2.0 g.) and thiourea (0.75 g.) in ethanol (20 ml.) was heated on a boiling water bath for 20 min. and then allowed to stand at room temperature for 1 hr. After the solution had been concentrated under reduced pressure, the residue was treated with water. The crystals were washed successively with an aqueous solution of sodium bicarbonate and with water. Yield, 1.6 g. Recrystallization from ethanol gave colorless needles; m. p. 150—151°C (lit.[11] 151—152°C). UV: λ_{max}^{EtOH} 230.5 mμ (ε=22300) and 285 (7400).

The Reaction of I with Aminoacetonitrile.—To a solution of aminoacetonitrile (4.5 g., 0.08 mole) in ethyl acetate (70 ml.), I (5.4 g., 0.04 mole) was added. The solution was then allowed to stand at room temperature overnight. After the hydrochloride of aminoacetonitrile (3.7 g.; 94.6%) had been filtered off, the filtrate was evaporated under reduced pressure to give an oily product which was readily soluble in water and alcohol, but not in ether or benzene. In order to remove the impurities, the oily product dissolved in ethyl acetate was chromatographed on alumina. After elution with ethyl acetate, the elute was evaporated to give a reddish oil, "oily product A," which was used for the following reactions.

2-(2-Oximino-3-oxobutylamino)acetoamidoxime Hydrochloride (VII).—A solution of the oily product A (2 g.) and hydroxylamine (1 g.) in methanol (25 ml.) was allowed to stand at room temperature for two days. The solution was then evaporated under reduced pressure to give an oily product. A solution of the product in ethanol (20 ml.) was treated with dry hydrogen chloride and allowed to stand in a refrigerator overnight. The solvent was evaporated under reduced pressure, and the residual product was treated with activated charcoal in ethanol. Yield, 1.34 g. Recrystallization from ethanol-ether gave white crystals; m. p. 140°C (decomp). IR: ν_{max}^{KBr} 2900—2500 (broad band) and 1690 cm^{-1} (-C=O).

Found: C, 31.87; H, 5.65; N, 25.08. Calcd. for $C_6H_{13}N_4O_3Cl$: C, 32.04; H, 5.79; N, 24.92%.

***N, N*-Bis(2-benzoyloximino-3-oxobutyl)aminoacetonitrile (VIII).**—A solution of benzoyl chloride (4 g.) in ethyl acetate was slowly stirred at −10—−5°C into a solution of the oily product A (4.4 g.) and pyridine (2.25 g.) in ethyl acetate (100 ml.). After the addition was complete, stirring was continued at that temperature two more hours. The solution was then washed with water, an aqueous solution of sodium bicarbonate, and again with water, dried over anhydrous sodium sulfate, and then evaporated under reduced pressure. The oily product was treated with isopropyl alcohol (20 ml.) to give a crystalline product (1 g.). Several recrystallizations from isopropyl alcohol gave *N, N*-bis(2-benzoyloximino-3-oxobutyl)aminoacetonitrile.

Colorless needles; m. p. 140—141°C. IR: ν_{max}^{KBr} 1765 (-C=O), 1708 (-C=O), and 1230 cm^{-1} (-COO-).

Found: C, 62.28; H, 5.00; N, 12.29. Calcd. for $C_{24}H_{22}N_4O_6$: C, 62.33; H, 4.80; N, 12.12%.

The *p*-Nitrobenzoylation of the Product Derived from I and Aminoacetonitrile.—A solution of *p*-nitrobenzoyl chloride (7.4 g., 0.04 mole) in ethyl acetate (40 ml.) was stirred, drop by drop, at −10—−5°C into a solution of the oily product A, prepared from I (2.7 g., 0.02 mole), aminoacetonitrile (2.2 g., 0.04 mole), and pyridine (3.2 g.) in ethyl acetate (40 ml.). After the stirring had been continued at that temperature for 8 hr., the mixture was washed with water; thereby a crystalline product (1.5 g.) was separated. The recrystallization of the crystalline product from acetonitrile gave *N*-*p*-nitrobenzoyl-*N*-(2-*p*-nitrobenzoyloximino-3-oxobutyl)aminoacetonitrile (X) as fine yellowish needles; m. p. 187°C (decomp.). IR: ν_{max}^{KBr} 1770 (-COO-), 1710 (-C=O), 1655 (-CONH-), 1530 ($-NO_2$), 1350 ($-NO_2$), and 1230 cm^{-1} (-COO-).

Found: C, 53.03; H, 3.49; N, 5.65. Calcd. for $C_{20}H_{15}N_5O_8$: C, 52.98; H, 3.34; N, 15.45%.

The organic layer in the above reaction was dried over anhydrous sodium sulfate and evaporated under reduced pressure. The residual product was then treated with activated charcoal in chloroform. After the chloroform had been evaporated under reduced pressure, the oily residue was crystallized by teatment with isopropyl alcohol. The crystalline product (1.5 g.) was repeatedly recrystallized from a mixture of acetonitrile and ethanol (7 : 3) to give *N, N*-bis(2-*p*-nitrobenzoyloximino-3-oxobutyl)aminoacetonitrile (XII) as yellowish needles; m. p. 162—163°C. IR: ν_{max}^{KBr} 1765 (-COO-), 1710 (-C=O), 1530 ($-NO_2$), 1350 ($-NO_2$), and 1230 cm^{-1} (-COO-).

Found: C, 52.50; H, 3.80; N, 15.49. Calcd. for $C_{24}H_{20}N_6O_{10}$: C, 52.17; H, 3.65; N, 15.21%.

3-Chloro-2-oximinopropiophenone (XIII).— The

11) R. M. Dodson and L. C. King, *J. Am. Chem. Soc.*, **67**, 2242 (1945).

procedure for the preparation of 3-chloropropiophenone was modified from the method of Matsumoto and Hata.[12] The main modification was that chloroform was used as the solvent instead of tetrachloroethane. In this case, 3-chloropropiophenone was directly obtained without the isolation of phenyl vinyl ketone.

Benzoyl chloride (422 g.; 3 mole) was added, with stirring and ice-cooling, to a mixture of aluminum chloride (414 g.; 3.1 mole) and absolute chloroform (1000 ml.). Ethylene was then introduced into the stirred mixture at such a rate that all was absorbed, the internal temperature being kept between 10—15°C for 40 hr. The reaction mixture was poured into a mixture of hydrochloric acid (426 ml.) and ice (2.3 kg.). The organic layer was washed successively with dilute hydrochloric acid, an aqueous solution of sodium carbonate, and water, and dried over anhydrous sodium sulfate. After the chloroform had been evaporated under reduced pressure, the residual crystalline product was washed with petroleum ether and treated with activated charcoal in benzene or ether to give 3-chloropropiophenone (213 g.). On the concentration of the washings of petroleum ether, an additional product (72 g.) was obtained. The total yield was 285 g. (56.4%); m. p. 46—47°C (lit. 53—55°C[12]).

The nitrosation of 3-chloropropiophenone was carried out in a manner similar to that in the case of 1-chloro-3-butanone.[3] Colorless prisms with a m. p. of 111—112°C was obtained in a 83% yield (lit. 113—114°C[12]; 110—110.5°C[2]).

The Reaction of 3-Chloro-2-oximinopropiophenone with Barium Thiocyanate.—A solution of barium thiocyanate (3 g.) in ethanol (15 ml.) was gradually added to a solution of 3-chloro-2-oximinopropiophenone (4 g.) in ethanol (20 ml.), and then the mixture was refluxed for 1 hr. The precipitate was filtered off, and the filtrate was evaporated under reduced pressure to give an brown residue, which was treated with activated charcoal in benzene (20 ml.). After the benzene had been evaporated under reduced pressure, the residual red oil (4.5 g.) was allowed to stand at room temperature to crystallize. The crystalline product was purified by passing the methanolic solution through an alumina column. Recrystallization from benzene gave 2-oximino-3-oxo-3-phenylpropyl thiocyanate (XIV, $R=C_6H_5$) as colorless needles; m. p. 91—93°C. The product showed no color reaction with ferric chloride. IR: ν_{max}^{KBr} 2150 (-SCN) and 1670 cm^{-1} (-C=O).

Found: N, 12.79. Calcd. for $C_{10}H_8N_2O_2S$: N, 12.72%.

5-Phenyl-2-aminothiazole-1-oxide (XVIII). — A solution of barium thiocyanate (1.5 g.) in ethanol (15 ml.) was added, drop by drop, to a solution of *anti*-2-bromoacetophenone oxime[13] (XVI, 2 g.) in ethanol (20 ml.), and the mixture was warmed at 35°C for 1 hr. After the precipitated barium chloride was filtered off, the solution was concentrated under reduced pressure to give an oily product. The oily product was purified by means of unactivated-alumina column chromatography to yield a caramel (1.5 g.), which showed a blue color with ferric chloride and which had no infrared absorption in the region of the -SCN group. The picrate of XVIII was obtained by refluxing a solution of the caramel (0.5 g.) and picric acid (0.5 g.) in ethanol (40 ml.) for 1 hr., followed by the evaporation of the ethanol. Recrystallization from ethanol gave yellow plates; m. p. 171—172°C.

Found: C, 43.01; H, 2.82; N, 16.67. Calcd. for $C_{15}H_{11}N_5O_8S$: C, 42.76; H, 2.63; N, 16.63%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2750—2755 (1966)

Studies of the Hydrocracking of Lignin. I. The Hydrocracking of Desulfonated Sulfite Waste Lignin

By Motoyoshi OSHIMA, Kan KASHIMA, Teruo KUBO
Haruro TABATA and Hiroshi WATANABE

The Noguchi Institute, Kaga, Itabashi-ku, Tokyo

(Received November 15, 1965)

The raw material for the hydrocracking was prepared by treating alcohol fermented sulfite waste liquor with lime, desulfonating the thus-prepared slurry by heating, and deashing the precipitate with sulfur dioxide. The hydrocracking was run with a high-boiling fraction of lignin-hydrogenated oil as the solvent (pasting oil) and with Fe-promotor-sulfur as the catalyst. The yield of monophenols was 24% (based on klason lignin) with a 100% recovery of the pasting oil under reaction conditions of a temperature of 430°C, an initial hydrogen pressure of 130 kg./cm^2, and a catalyst dosage of 3% (based on the lignin). The higher reaction pressure resulted in a slight increase in the yield of monophenols. The formation of non-volatile pitch decreased with the increase in the initial pressure up to 130 kg./cm^2 but a further increase of the pressure exerted no effect. The higher reaction temperature gave more hydrogen absorption and a higher yield of monophenols, and less pitch formation and pasting oil recovery. However, it is essential to select reaction conditions where the highest yield of monophenols is obtained with a 100% recovery of the pasting oil.

Numerous studies of the hydrogenation of lignin have been reported since 1931.[1] Particularly from the end of the 1930's through the 1940's, Harris and Adkins,[2] Hachihama and Jodai,[3] and Lautsch[4] conducted energetic research, mainly for academic purposes. Although few studies were conducted with commercial applications in mind, the yield of phenols, the possible major commercial products, was low, and no particular consideration was paid to the recovery of the solvent, which was the most critical factor in considering the economic feasibility of the process.

Recently, Sakakibara et al.[5] hydrogenated wood-hydrolysis lignin (concentrated sulfuric acid process) with cyclohexanol as the solvent and with a CuCrO type catalyst, the yield of the acidic fraction was 38.9%.

Giesen[6] claimed in his patent that a 55% yield (lignin base) of the 150—325°C (6 mmHg) fraction could be obtained by hydrogenating wood-hydrolysis lignin (Scholler process) using xylenols as the solvent, of which a 100% recovery was claimed. The studies of lignin hydrogenation with phenol, cyclohexanol, tetralin, crude petroleum oil and other materials as the solvents have been reported by one of the present authors.[7] The solvent recovery was very low in the above work, and the low solvent recovery made the process economically unattractive.

In lignin hydrocarcking processes, it is usual to use a solvent in an amount from 1 to 3 times as great as that of lignin. Excellent solvents for the lignin hydrocracking process, such as phenols, sometimes react with lignin in the course of hydrocracking; this makes the analysis and evaluation of the process very complicated.

For the purpose of eliminating the above-mentioned complications and disadvantages, the present authors utilized as a solvent the high-boiling-point fraction of the lignin-hydrogenated product; a 100% recovery of the solvent was successfully achieved by the so-called pre-stabilization of the high-boiling-point fraction. The process proposed here is the one where monophenols are obtained from lignin. The effects of various reaction conditions were fully studied.

Although the present authors[8] have reported a fairly high liquefaction yield (yield of liquid material) and a high yield of monophenols, further detailed experimental work has proved that the

previously-published data should be rechecked because of the complicated effect of the solvent and the poor analytical techniques previously utilized. The work reported on here is the reinvestigation of the previous work and, hence, the conclusion of our work.

Experimental

The Preparation of Lignin (Desulfonated SWL).—Alcohol-fermented softwood sulfite waste liquor (solid content, 12%) (15 kg.) and calcium hydroxide (0.25 kg.) were mixed and agitated for 30 min. at 70°C, the precipitate thus formed was collected by a centrifugal seperater, 0.05 kg. of calcium hydroxide was added to the filtrate, it was heated for 30 min. at 70°C, and the precipitate was collected. The combined filter cake weighed roughly 3 kg. (containing approx. 50% water). The alcohol-fermented sulfite waste liquor (1.5 kg.) was mixed with the filter cake and heated for 1 hr. at 195°C. The precipitated desulfonated lignin (with 20—30% ash) was filtered, suspended in water, and acidified with SO_2 gas. The deashed lignin was filtered, washed, and dried. The lignin thus prepared will hereafter be referred to as desufonated SWL for the sake of simplicity. The lignin was analyzed and found to be as follows: lingin (klason lignin), 92.2%; ash, 4.7%; total sulfur; 2.4%. The moisture content ranged from 3 to 6%. The lignin sample used in this study was manufactured by the above-mentioned authors' process and supplied by the Crown Zellerbach Corporation, U. S. A.

The Preparation of the Catalyst.[9]—Reduced iron, copper powder, tin powder and sulfur (in an atomic ratio of Fe : Cu : Sn : S=10 : 1 : 1 : 12) were charged into a porcelain ball mill with three times as much water as the combined weight of the above ingredients and crushed and mixed for about one day. After the catalyst had settled, the water layer was discarded and the catalyst was stored wet. (The catalyst should always be wet in order to prevent the loss of its activity). The well-settled catalyst slurry contained approx. 50% water.

The catalyst will be referred to as the standard catalyst hereafter.

Pasting Oil (Solvent).—Pasting oil was the stabilized highboiling-point fraction (b. p.>247°C) of the hydrocracking product of lignin. The pasting-oil fraction was collected from several runs of a bench-scale pilot-plant unit. The authors named this fraction "green pasting oil."

When the green pasting oil was used as the solvent, an excessive degradation took place in it, thus a 100% recovery of the oil was very difficult, and the reproducibility of the data was very poor. The green pasting oil was pretreated as follows to make a so-called stabilized pasting oil. The green pasting oil was hydrogenated with the standard catalyst at a specified temperature. A fraction boiling above 247°C was recovered; this fraction, desulfonated SWL, and the standard catalyst were then mixed and hydrogenated again under same conditions. The fraction of the product boiling above 247°C was the pre-stabilized (or simply stabilized) pasting oil at the specified temperature. Unlike the green pasting oil, the stabilized pasting oil could be recycled with fairly reproducible results without excessive degradation.

Reaction Procedure.—Specified amounts of desulfonated SWL, stabilized pasting oil, a catalyst, and, for better agitation, a rod 13 mm. in diameter and 460 mm. long were charged into an autoclave (2.8 l.; externally-heated rotating type). Hydrogen was then charged in up to the specified pressure, the autoclave was rotated (23 r. p. m.) and heated to the specified temperature within 3 hr.,*1 kept at that temperature for 2 hr., and then left to cool while the autoclave was rotated and the final pressure was recorded.

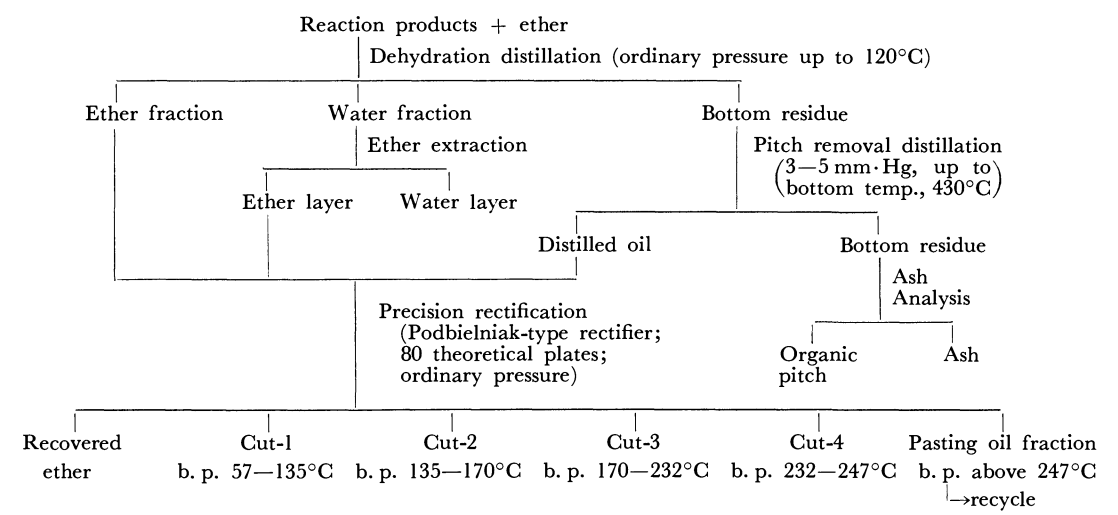

Fig. 1. The fractionation of the reaction products.

9) M. Oshima, Y. Maeda and K. Kashima, Can. Pat. 700210; U. S. Pat. 3223698; M. Oshima and K. Kashima, Japanese Pat. 405634 (1963).

*1 A faster heating-up time results in a poorer reproducibility of the results. Hence, no isothermal condition was obtained in the reaction. Therefore, the reaction temperatures and pressures are not exact in a strict sense.

After the gas had been purged, the autoclave was opened and the contents were washed out with ethyl ether.

The Fractionation and Analysis of the Reaction Products.—Cut-2 through cut-4 (Fig. 1) were analyzed by gas chromatography for the monophenol content. The apparent yield of monophenols was a little higher than the actual yield since some neutrals were contained in the phenol fractions of the gas chromatogram. For the sake of brevity, the monophenol yields in this paper are the figures calculated from the chromatogram without any alkaline extraction (see "Neutrals in Monophenols Fraction"). The weights of individual phenols were assumed to be proportional to the areas occupied on the chromatogram. This assumption had been verified in the authors' laboratory. For cut-2, containing large amounts of low-boiling materials, the inner standard method, with *p*-cresol as the standard, was used. The gas chromatograph was operated as follows: Stationary phase, dilaurylphthalate; column, 5 m. long, 0.6 cm. in diameter; temp., 170°C; carrier gas, H_2, 180 cc./min. An example of the gas chromatograms is shown in Fig. 2.

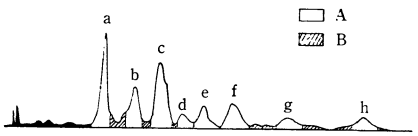

Fig. 2. Analysis of monophenols in the gas chromatogram of cut-3.

A identified phenols, B unidentified phenols
Monophenols = A + B

The Analysis of Neutrals in the Monophenol Fraction.—The different fractions of cut-3 were combined, and then 50 g. of this mixture was treated as is shown in Fig. 3.

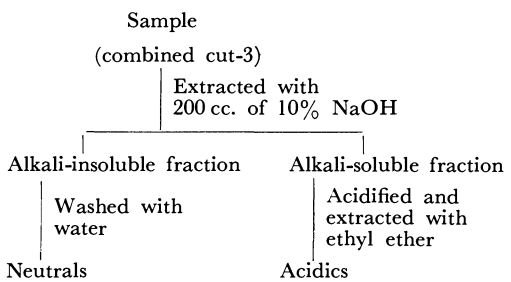

Fig. 3. The analysis of neutrals.

The neutral fraction thus obtained was gas chromatographed, and the relative areas on the chromatogram were subtracted from the areas of monophenols on the chromatogram (Fig. 2.) Thus the true amounts of the individual monophenols were obtained.

Definition of Terms.—Intitial pressure (I. press.): Gauge pressure of hydrogen gas charged into the autoclave at room temperature (kg./cm²). Maximum pressure (Max. press.): Maximum gauge pressure (kg./cm²) (it does not necessarily appear at the reaction temperature). Amount of catalyst (A. C.): (catalyst charged (dry basis))/(klason lignin charged) × 100(%). Pasting oil recovery (P. O. R.): (fraction boiling above 247°C recovered)/(oil boiling above 247°C charged) × 100(%).

Monophenols yield (M. P. Y.): (amount of monophenols analyzed by chromatogram)*2/(klason lignin charged) × 100(%). Liquefaction yield (L. Y.): (Total oil boiling above 57°C recovered-Pasting oil charged)/(klason lignin charged) × 100(%). Pitch yield (P. Y.): (organic pitch)/(klason lignin charged) × 100(%). Hydrogen absorption index (H. A. I.): this is not an accurate measure of the hydrogen absorption. See "Effect of Hydrogen Pressure." (Initial pressure − final pressure)/(klason lignin charged) × 100(%) (kg./cm²/100 g. room temp.).

Results and Discussions

The experimental results are tabulated in Table I.

The Effect of the Amount of Catalyst.—Figure 4 shows that a catalyst amount of 3% based on lignin is sufficient for the reaction.

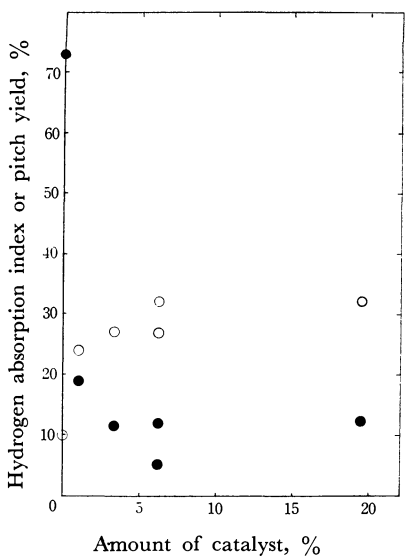

Fig. 4. Effects of amount of catalyst on hydrogen absorption index (○) and pitch yield (●).

The Monophenol Yield.—From the commercial point of view, the most valuable products from the lignin hydrocracking are monophenols; a 100% recovery of pasing oil should also be secured. Under too mild conditions, the pasing oil recovery exceeds 100%. By running with more severe reaction conditions, one can make the recovery of pasting oil lower and the yield of monophenols higher. As the reaction conditions giving a 100%

recovery of pasting oil must be used commercially, the yield of monophenols under those conditions is very important in considering the commercialization of the process.

Monophenol yields from several runs under identical reaction conditions, such as the reaction temperature and pressures, were compared, but no definite conclusion could be drawn because of the scattered data. However, very remarkable correlations between the monophenol yield and the pasting oil recovery were observed when the initial pressures were nearly equal. This is illustrated by Fig. 5, where monophenol yield are plotted for all the runs with catalyst amounts of between 3 and 7%, and at various temperatures. From the figure we can see that the monophenol yield at initial pressures from 90 to 100 kg./cm² is 26—27%, while at more than 130 kg./cm² it is 29—30%, when pasting oil is fully recovered. No effect of the blending ratio of lignin to pasting oil on the monophenol yield was observed.

The Effect of the Hydrogen Pressure.— As is shown in Fig. 6, generally speaking, the hydrogen absorption index tends to increase and the

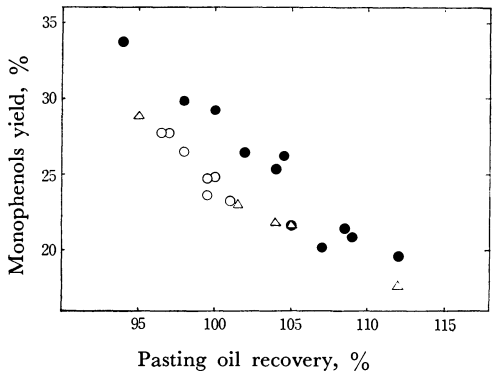

Fig. 5. Relation between pasting oil recovery and monophenols yield at initial pressures: of 90—100 kg./cm² (○, △), or above 130 kg./cm² (●),

pitch yield, to decrease with an increase in the initial hydrogen pressure up to approximately 130 kg./cm², but any further increase exerts no effect on the pitch yield.

Monophenol yields at 100% recovery of pasting oil tend to increase with the hydrogen initial pressure (Fig. 5).

The Effect of the Reaction Temperature.—The hydrogen absorption index, the pitch yield, the monophenol yield, and the pasting oil recovery as plotted against the reaction temperatures give a series of fairly scattered points on the graphs. As an example, relations between the reaction temperatures and the monophenol yield are shown in Fig. 7.

The statistical analysis of the data gave the results tabulated in Table II.

Table II shows that there are definite correlations between the temperature and the four variables with a 99% confidence level. That is to say,

higher reaction temperatures give a higher hydrogen absorption index and monophenol yield and a lower pitch yield and pasting oil recovery.

Neutrals in the Monophenol Fraction.— Neutrals in the monophenol fraction as defined in "Fractionation and Analysis of the Reaction Products" were quantitatively analyzed according to the procedures described in "Analysis of Neutrals in the Monophenol Fraction."

The neutrals content in the individual peaks of Fig. 2 are found to be as in Table III.

Table III shows that in the so-called monophenol, the yields shown in the figures and tables contain about 18% neutrals on the average. No complete analysis of the neutrals in monophenols fractions of individual runs has yet been made, however, and so the monophenol yield as defined by "Fractionation and Analysis of the Reaction Products" was used throughout this paper.

The authors would like to express their appreciation to the Noguchi Institute for the permission to publish this study, and to the Crown Zellerbach Corporation, U. S. A., for their cooperation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2755—2759 (1966)

Studies of the Hydrocracking of Lignin. II. The Components of Lignin Hydrocracking Products

By Motoyoshi OSHIMA, Kan KASHIMA, Teruo KUBO
Haruro TABATA and Hiroshi WATANABE

The Noguchi Institute, Kaga, Itabashi-ku, Tokyo

(Received November 15, 1965)

The components of the hydrocracking products of alcohol-fermented softwood sulfite waste lignin were identified by rectification, gas chromatography, and IR spectrophotometry. In the acidic fraction (b. p. 170—232°C) phenol, *o*-cresol, 2,6-xylenol, *m*-cresol, *p*-cresol, 2-ethylphenol, 2, 4-xylenol, 2, 5-xylenol, 4-ethylphenol, 3-ethylphenol, 3, 5-xylenol, 2-(*n*-propyl)phenol, 3, 4-xylenol, 4-(*n*-propyl)phenol and 3-(*n*-propyl)phenol were identified. In the neutral fraction (b. p. 170—232°C) naphthalene, 2-methylnaphthalene, and tetralin were identified. In the fraction (b. p. 135—170°C) ethylbenzene, *m*-xylene, *p*-xylene, *o*-xylene, and *n*-propylbenzene were found. In the fraction boiling between 57 and 135°C toluene was identified.

The preceding paper reported on our study of the reaction conditions of the hydrocracking process. In the analysis of monophenols in that paper, the component contents were determined merely by the retention time and the percentages of the areas of peaks in the gas chromatogram.

In this paper, a detailed investigation of the components of the products of the runs conducted with the refined lignin (desulfonated SWL) as the raw material and pre-stabilized pasting oil as the solvent will be reported. Precise rectification, alkaline extraction, gas chromatography, and infrared spectrophotometry techniques resulted in the identification of eleven acidic components and four neutral components, besides the compounds previously reported by some of the present authors. *p*-Cresol, *o*-cresol, 4-ethylphenol and 4-(*n*-propyl)-phenol had been reported to be obtained from the products of lignin hydrocracking with phenol solvent,[1] and *m*-xylene, *p*-xylene, *o*-xylene and ethylbenzene were obtained from the runs with a tetralin solvent.[2]

Experimental Procedures

Cuts-1—4 of all the runs reported in the previous paper[3] were collected and combined. Cut-1, an alkali-unextracted portion of cut-2, and alkali-extracted and unextracted portions of cut-3 were gas chromatographed; the peaks to be identified were numbered for the sake of convenience.

Cut-2 and cut-3 were rectified and separated into fractions with narrow boiling-point ranges. From each fraction, after the contaminating component had been removed by alkali extraction if necessary, the component to be identified was collected from the effluent of the gas chromatograph. (No rectification of cut-1 was conducted. Cut-1 was directly gas chromatographed, and the components desired were collected.)

The components were identified from their boiling points, retention times in the gas chromatogram,

and infrared spectra. The alkali-extraction procedure has been explained in a previous paper.[3]

Analysis and Collection by Gas Chromatograph.—A model GC-1B gas chromatograph manufactured by Shimadzu Seisaku-sho was used under the operating conditions as shown in Table I.

Infrared Analysis.—When the authentic material was available, the infrared spectrum of the authentic material was compared with that of the sample obtained from lignin. Infrared charts (IRDC Card)*1 were used instead of the standard spectrum when no standard sample was available.

Results and Discussions

Combined Cut-3.—A precision rectification was made with a 1 kg. sample of the combined cuts-3+4 (cut-3; 750 g., cut-4; 250 g.) as prepared by the procedure mentioned before. The fractions collected are shown in Table II.

Acidic Fraction.—The acidic fraction of combined cut-3 was gas chromatographed as shown in Fig. 1.

Individual peaks on the gas chromatogram were named PA-1 through PA-11; their relative retention times (RRT), like that of phenol as the standard, are listed in Table III.

The relative retention times of the standard phenolic reagents are shown in Table IV.

The fractions shown in Table II were extracted with alkali if necessary and gas chromatographed. From the effluent of the chromatograph, portions corresponding to the peaks to be identified were collected by cold trapping and were subjected to infrared analysis. Although some peaks were easily identified by simply comparing the infrared spectra of the components with those of the standards, while others were mixtures; some more comments will be given below.

4-(*n*-Propyl)phenol	3.8	3.8

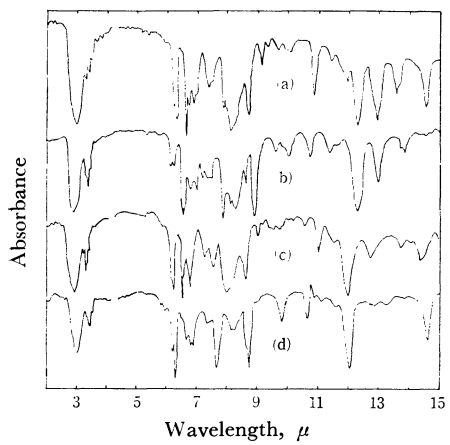

Fig. 2. IR spectra of PA-4 (a), PA-6 (b), PA-7 collected from fr-18 (c) and PA-7 collected from fr-19 (d). (Liquid film method)

The absorptions of PA-4 at 10.8 μ, 11.4 μ and 14.5 μ belong to *m*-cresol, and those at 11.9 μ and 12.3 μ, to *p*-cresol.

PA-6.—The infrared spectrum of PA-6, collected as before from the acidic fraction of fr-10, is shown in Fig. 2(b). Figure 2(b) shows that PA-6 was composed mainly of 2, 4-xylenol (7.9 μ and 13.0 μ). Weak absorptions of 2, 5-xylenol (10.0 μ, 10.7 μ and 13.8 μ) were also detected.

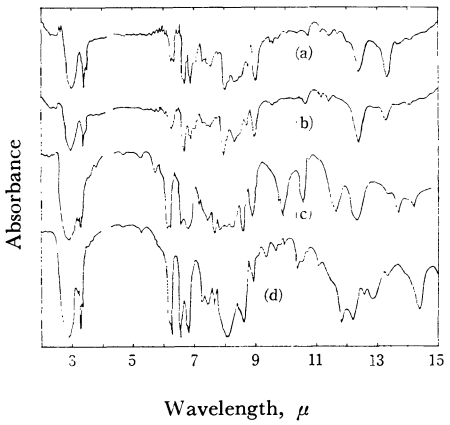

Fig. 3. IR spectra of PA-8 collected from fr-18 (a), from fr-19 (b) and from fr-23 (c), and PA-11 (d). (Liquid film method)

PA-7.—The infrared spectra of two PA-7 fractions collected from acidic fractions of fr-18, and fr-19 respectively, are shown in Figs. 2(c) and 2(d).

In the spectrum of PA-7 collected from fr-18, absorptions of 4-ethylphenol (12.1 μ) and those of 3-ethylphenol (11.0 μ, 12.8 μ and 14.4 μ) are observed. The PA-7 collected from fr-19 gave an infrared spectrum almost identical to that of 3, 5-xylenol.

PA-8.—Three PA-8 fractions were collected from fr-18, fr-19 and fr-23 separately.

As is shown in Figs. 3(a) and 3(b), the infrared

Table V. Identified components in acidic fraction of combined cut-3

Gas chromatographic Peak No.	Identified component

PA-2	*o*-Cresol
PA-3	2,6-Xylenol*
PA-4	*m*- and *p*-Cresols
PA-5	2-Ethylphenol
PA-6	2,4- and 2,5-Xylenols
PA-7	3-, and 4-Ethylphenols, 3,5-xylenol
PA-8	2-(*n*-Propyl)phenol, 3,4-xylenol and at least one unidentified compound
PA-9	Unidentified
PA-10	Unidentified
PA-11	4-(*n*-Propyl)phenol, 3-(*n*-propyl)phenol

* No IR spectrum was obtained because gas chromatographic collection of the peak was difficult.
The component was identified from RRT and boiling point.

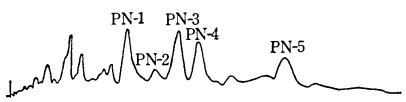
spectra of two PA-8 fractions resemble that of 2-(*n*-propyl)phenol very closely (12.3 μ, 13.3 μ and others), except that the absorption at 12.3 μ is stronger than that of the standard sample, indicating the presence of some unknown meterials in PA-8. The infrared spectrum of PA-8 (Fig. 3(c)) collected from fr-23 is identical with that of 3, 4-xylenol.

PA-11.—Figure 3(d) shows the infrared spectrum of PA-11, collected from the acidic fraction of fr-29.

Absorption of 4-(*n*-propyl)phenol (12.2 μ and 12.6 μ) and those of 3-(*n*-propyl)phenol (11.1 μ, 11.8 μ, 12.9 μ and 14.4 μ) are observed in the spectrum of PA-11.

The above results are summarized in Table V.

Neutral Fraction.—Figure 4 is a gas chromatogram of the alkali-insoluble portion of the combined cut-3. The major peaks in Fig. 4 were named PN-1 through PN-5.



Retention time

Wavelength, μ

Fig. 5. IR spectra of PN-1 (a), PN-2 (b) and PN-5. (Liquid film method)

PN-1.—The infrared spectrum of PN-1 collected from the neutral fraction of fr-10 is shown in Fig. 5(a) and is identical with that of tetralin.

PN-2.—The infrared spectrum of PN-2 collected from the neutral fraction of fr-10 is shown in Fig. 5(b); it indicates that PN-2 is 1, 2-dialkylbenzene. From its boiling point (approx. 200°C), PN-2 was estimated to be 2-methylbutylbenzene.

PN-3.—The alkaline extraction of fr-14 gave a white crystalline precipitate as an alkali-insoluble fraction. The melting point of the crystals was 79.5°C. Its gas chromatographic retention time, infrared spectrum, and mixed melting point showed that the compound was naphthalene.

PN-5.—PN-5 was collected from the neutral fraction of fr-29; it was found, from Fig. 5(c), to be composed mainly of 2-methylnaphthalene.

Table VI. Identified components in the neutral fraction of combined cut-3

Gas chromatographic peak No.	Identified component
PN-1	Tetralin
PN-2	2-Methylbuthylbenzene
PN-3	Naphthalene
PN-5	2-Methylnaphthalene

The results are summarized in Table VI.

Combined Cut-2.—Table VII shows the results of the rectification of the combined cut-2. The gas chromatogram of the neutral fraction of the combined cut-2, with the peak numbers of p-1 through p-19, is shown in Fig. 6.

16	173.2	11.1
17	175.0	7.6

*2 A small amount of phenol was present in the fractions because of the incomplete rectification.

Table VIII. Identified components in the combined cut-2

Gas chromatographic peak No.	Identified component
p-3	Toluene
p-9	Ethylbenzene
p-10	*m*-, and *p*-Xylenes
p-12	*o*-Xylene
p-16	*n*-Propylbenzene

the main components were gas chromatographically-collected*3 and the infrared spectra of the components were measured. The infrared spectra thus obtained were compared with those of standard samples, and the compounds listed in Table VIII were identified.

Further, the types of components were estimated by infrared analysis to be as follows; peak Nos. 5, 6, 7, 8, 11 and 18 were aliphatic hydrocarbons, while peak Nos. 14, 17 and 19 were aromatic hydrocarbons.

The combined cut-2 was thus found to be mainly composed of hydrocarbons.

Combined Cut-1.—A gas chromatogram of the combined cut-1, with the peak numbers p-1 through p-6, is shown in Fig. 7. The retention times (RT) of the peaks, and those of standard samples which were suspected to be components of cut-1, are shown in Tables IX and X respectively.

Table IX. Retention times of components of combined cut-1

Peak No.	RT, min.
1	3.2
2	3.5
3	8.0
4	13.0
5	16.0
6	18.6

*3 The gas chromatograph column temperature was changed from 100°C to 150°C depending on the vapor pressures of the fraction to be collected.

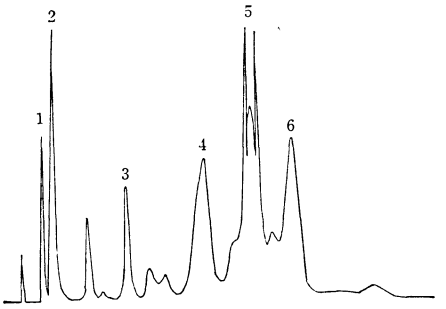

Fig. 7. Gas chromatogram of cut-1.
Column, DLP; Column temp., 100°C

Table X. Retention times of some standard

Sample	RT, min.
Acetone	3.2
n-Heptane	6.5
Cyclohexane	6.0
Methanol	2.3
Ethanol	2.9
n-Butanol	9.9
Methyl ethyl ketone	5.5
Toluene	16
Benzene	7.7

Among the peaks of cut-1, only p-1 and p-5 have identical retention times with those of the standard samples, i. e., acetone and toluene respectively. Acetone is used as a solvent in the treatment of lignin reaction products; hence, no conclusion can be drawn as to whether a part of the acetone originates from lignin or not.

Although many gas chromatographic peaks in the combined cuts-1 remain unidentified, it was concluded that substantial amounts of *n*-heptane, cyclohexane, ethanol, *n*-butanol, methyl ethyl ketone and benzene were not present in cut-1.

Studies of the Hydrocracking of Lignin. III. The Hydrocracking of Various Types of Lignin

By Motoyoshi OSHIMA, Kan KASHIMA, Hiroshi WATANABE
Haruo TABATA and Teruo KUBO

The Noguchi Institute, Kaga, Itabashi-ku, Tokyo

(Received November 15, 1965)

Three types of raw material for lignin hydrocracking were prepared and their reactivities were compared in relation to the refined lignin reported in the authors' previous paper (*Bull. Chem. Soc. Japan*, **39**, 2750 (1966)). The raw materials were prepared; 1) by autoclaving the alcohol-fermented sulfite waste liquor (heat-precipitated lignin); 2) by drying the liquor (dried SWL), and 3) by concentrating the liquor (concentrated SWL). Although these three types of lignin are less costly to prepare, they showed poor reactivities in the hydrocracking process. Heat-precipitated lignin gave a 16—20% monophenol yield [Analyzed by rectification and gas chromatography (no alkaline extraction was conducted).] at a 100% recovery level of pasting oil. No definite monophenol yield figures could be concluded in the runs with dried or concentrated SWL because of the scattered data. The poor reproducibility of data in the cases of these two types of lignin is discussed.

In the previous paper, the hydrocracking of the refined lignin (desulfonated SWL) was reported on in detail.[1] Although the yield of monophenols was high, the cost of the lignin was too high for the commercial success of the process.

In the present paper, several types of lignin which are less costly to prepare were investigated. The lignins studied here are; a lignin solid prepared by simply autoclaving the fermented sulfite waste liquor—heat-precipitated lignin, a lignin solid prepared by drying the same waste liquor—dried SWL, and a thick lignin paste containing a 50% solid from the same origin—concentrated SWL.

Experimental Procedures

Heat-precipitated Lignin. — Ten killograms of alcohol-fermented sulfite waste liquor (softwood) was heated to 210°C over a 3 hr. period, kept at that temperature for 1 hr., and then cooled overnight. The lignin solid precipitated was filtered, washed, and dried.

The analysis showed the solid contained lignin (Klason lignin) (83.5%) and inorganic ash (13.3%) (on a dry basis).

Dried SWL.—Alcohol-fermented sulfite waste liquor was concentrated to a 50% solid content and oven-dried at 110°C. This was prepared and supplied by the Crown Zellerbach Corporation, U. S. A. The content of the solid on the dry basis was; lignin (analyzed by the β-naphthylamine method) (56.8%) and inorganic ash (13.9%).

Concentrated SWL.—This was also supplied by the Crown Zellerbach Corporation, U. S. A. The content was: water (48.7%), lignin (analyzed by the β-naphthylamine method) (28.9%), and inorganic ash (7.2%).

The Preparation of the Catalyst.—The standard catalyst used in our previous paper[1] was used here; it consisted of reduced iron, copper powder, tin powder, and sulfur in an atomic ratio of 10 : 1 : 1 : 12.

The reaction procedures, the separation and the analysis of the reaction products have been described in the previous paper[1] and the terms have been defined there.

Results and Discussions

Tables I, II and III show the results of the runs with heat-precipitated lignin, dried SWL, and con-concentrated SWL as the raw materials respectively.

Monophenol Yield.—In considering the commercial feasibility of the process, the yield of monophenols at a 100% recovery of pasting oil is very important, as has been described in the previous paper.[1]

Figures 1 and 2 show the relations between the monophenol yield and the pasting-oil recovery in the runs with heat-precipitated lignin, dried SWL, and concentrated SWL respectively. The data points in Figs. 1 and 2 are distributed over a considerably wide range as compared with the case of refined lignin in the previous paper. The reason for the scattered data will be discussed later.

Table IV, correlation analysis, shows that, although the first-order regression may be concluded for the runs with heat-precipitated lignin with more than a 99% confidence level, no correlation can be assumed for the runs with dried SWL or concentrated SWL.

In the runs with heat-precipitated lignin as the raw material, the monophenol yield at 100% pasting

400°C	▲	△
440°C	●	○

Table IV. Correlation analysis:
Pasting oil recovery and monophenol yield

	Heat-precipitated lignin	Dried SWL	Concentrated SWL
No. of runs	22	10	9
First-order regression	635.4	99	6.8
Residual	306.6	420.3	43.8
F	41.5**	1.88	1.11

oil revovery level was 16—20%. In the case of dried SWL or concentrated SWL, no definite conclusions have been drawn as to the monophenol yield.

The Effect of the Reaction Temperature.—From Fig. 1, a general trend may be observed for higher reaction temperatures to result in higher monophenol yields and lower pasting oil recoveries in the case of heat-precipitated lignin. The same trend, though not so clear, may also be observed in the cases of dried and concentrated SWL. These results show that an excessive degradation of both lignin and pasting oil, even though stabilized, takes place at higher temperatures.

The relations between the pitch yield and the reaction temperature are analyzed in Table V.

Table V. Correlation analysis:
Pitch yield and reaction temperature

	Heat-precipitated lignin	Dried SWL	Concentrated SWL
No. of runs	22	10	9
First-order regression	365.2	1023	246.4
Residual	353	515.6	514.2
F	20.6**	15.9**	3.36

Higher reaction temperatures give lower pitch yields in the cases of heat-precipitated lignin and dried SWL. No clear correlation was obtained in the case of concentrated SWL because of highly-scattered data.

The Reactivities of Various Types of Lignin.—The monophenol yields from the runs of the refined lignin are much higher than those from the runs of the three types of lignin in this study.

A very marked difference in pasting-oil recovery was observed between the runs with dried SWL and concentrated SWL. In the case of dried SWL, it was extremely difficult to get a pasting-oil recovery of more than 100%. On the contrary, in the case of concentrated SWL, it was hard to obtain a pasting-oil recovery of less than 100%.

Such a difference between concentrated SWL and dried SWL was unexpected since these two types of lignin are very close in their structures and impurities. As reasons for the difference, the following three can be postulated: (1) In the drying operation, the condensation of the lignin structure took place. (2) Excess water in concentrated SWL exerted some unknown effects on the reaction. (3) In the runs with concentrated SWL, the ratio of pasting oil to lignin was kept low because of the limitation of reaction pressure. With dried SWL, the ratio was more than 2, but in the case of concentrated SWL, it was around 1. The solvent-lignin ratio might have had some effects. The true reason is yet to be determined.

Pitch yields in the runs with the three types of lignin were much higher than the 5—10% pitch yields in the runs with the refined lignin reported previously.

The effect of the reaction temperature is very significant in the cases of heat-precipitated lignin and dried SWL, but it was less in the runs with concentrated SWL. This may clearly be seen from Figs. 1 and 2 and Table V.

The Effects of Other Reaction Conditions.—No significant effects of the hydrogen initial pressure (30—170 kg./cm^2), the amount of catalyst (3—30% of the lignin), and the rate of revolution of the autoclave (23—80 r.p.m.) were observed. In order to improve the dispersion of the catalyst, attempts were made to prepare catalysts by ball-milling the ingredients in acetone or pasting oil instead of water, but no significant effect was observed.

The Reproducibility of the Data.—A poor reproducibility of data was encountered in the study of the three types of lignin in this paper as compared with the case of the refined lignin. This made the interpretation of data quite difficult. Various efforts to eliminate the poor reproducibility were all fruitless. Impurities present in the three types of lignin might have exerted some serious effects.

Especially in cases of dried SWL and concentrated SWL, the problem was critical. By closely observing the course of the reaction conducted in a vertical mechnaically-agitated autoclave, we found the following evidence to show that the mixture of lignin and pasting oil first changed to a soft pitch-like solid mass before it was degraded by hydrocracking:

(1) When the temperature of the autoclave reached 200°C, a rubbing sound was heard from the autoclave. (2) An exothermic reaction was observed around 200°C. (3) If the autoclave was opened as soon as the reaction temperature reached 200°C, it was found that the autoclave contained a soft pitchy solid.

In the cases of heat-precipitated lignin and refined lignin, both of which had been prepared by heat precipitation processes, the above phenomena were not observed. In the cases of dried and concentrated SWL, the possible poor dispersion of the solid and the non-uniformity of the temperature in the reaction mass might have resulted in the poor reproducibility of the data and the low yield.

The authors would like to express their appreciation to the Noguchi Institute for the permission to publish this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2763—2767 (1966)

Studies of the Hydrocracking of Lignin. IV. The Evaluation of the Catalysts

By Motoyoshi OSHIMA, Kan KASHIMA, Haruro TABATA
Hiroshi WATAMABE and Teruo KUBO

The Noguchi Institute, Kaga, Itabashi-ku, Tokyo

(Received November 15, 1965)

In order to find a more active catalyst than the standard catalyst (*Bull. Chem. Soc. Japan*, **39**, 2750) (1966)), some seventeen materials were tested in the hydrocracking reaction of lignin. Although no catalyst was found that would alter the economic picture of the process, several interesting pieces of information were obtained. Selenium and zinc iodide gave a very high hydrogen absorption, indicating their activities as the catalyst. The reaction mechanism with these catalysts, seemed, however, very different from that with the standard catalyst. They resulted in high neutral yields and poor phenol yields. Cobalt octacarbonl, cobalt sulfide, ammonium molybdate, Raney iron, iron pentacarbonyl, nickel oxalate, and Ni-S showed fair activities. A closer evaluation of some of the above catalysts revealed that the standard catalyst was, at least at present, the most preferable catalyst.

The standard catalyst discussed in previous papers,[1-3] consisted of iron, copper, tin and sulfur in an atomic ratio of 10 : 1 : 1 : 12. The catalyst was discovered by improving the Fe-S*-type catalyst, which was originally employed in the study of coal hydrogenation.[4]

* The expression, for example, Ni-S, shows that the catalyst was produced by the wet-ball milling of Ni and S powders.

4) E. Munekata, Japanese Pat. 152898 (1942).

Sulfur has been known to show a slight activity in the hydrocracking reaction. In this study, selenium and tellurium, belonging to the same group as sulfur in the periodical table, were examined as catalysts of the reaction.

Halogenated metals, such as ferric chloride, or stannous iodide, had been used in the hydrogenation of coal. This type of compound was suspected to be also active in the lignin hydrogenation. Zinc iodide was tested as an example of this type of catalyst.

Compounds of nickel, cobalt, or molybdenum have long been known as catalysts for various types of hydrogenation reactions. Studied in this paper were: nickel compounds such as Ni–S* and nickel oxalate, cobalt compounds such as cobalt sulfide and cobalt octacarbonyl, a molybdenum compound (ammonium molybdate), iron compounds such as iron pentacarbonyl, and Raney iron.

Experimental Procedures

Raw Material Lignin. — Three types of lignin, refined lignin (desulfonated SWL), heat-precipitated lignin, and dried SWL, were used in the present study. For a detailed explanation of the preparative procedures and an analysis see our previous papers.[1,3]

The Preparation of Catalysts. — Selenium and tellurium were commercial reagent of the metallic grade. Ammonium molybdate ($(NH_4)_6Mo_7O_{24}\cdot 4H_2O$), zinc iodide, nickel oxalate, zinc oxide, and cobalt sulfide were also commercial reagents (Extra Pure grade). Ni-S was prepared by milling a mixture of nickel and sulfur in an 1:1 atomic ratio in aqueous media using a porcelain ball mill. Iron aluminum alloy (Fe 44.36%, Al 50.2%) was treated with a caustic solution by the usual procedure to prepare Raney iron. The catalyst was stored in dry ethanol.

Cobalt octacarbonyl ($Co_2(CO)_8$) was prepared as follows. Cobaltous carbonate ($CoCO_3$) (13.7 g.) and petroleum ether (150 ml.) were charged into a stainless steel autoclave, pressurized to 250 kg./cm^2 with 1 : 1 mixture of hydrogen and carbon monoxide gas, and heated for 3 hr. at 150—160°C. The product was then filtered, and the filtrate cooled. The crystallized cobalt octacarbonyl was filtered and dried under a dry carbon monoxide atomosphere.

In order to prepare iron pentacarbonyl, pyrite cynder was reduced in a hydrogen stream for 5—6 hr. at 630—730°C; 80 g. of it was then charged in a 500 ml. stainless steel autoclave and pressurized to 170 kg./cm^2 with carbon monoxide gas and kept at 190—200°C for 3 hr. The autoclave was cooled, the remaining gas was purged, and the autoclave was pressurized again to 170 kg./cm^2 with fresh carbon monoxide gas and heated at 190—200°C for 3 hr. The iron pentacarbonyl ($Fe(CO)_5$) thus formed was separated from unreacted iron powder by filtration.

The standard catalyst was a ball-milled mixture of iron, copper, tin and sulfur with an atomic ratio of 10 : 1 : 1 : 12. The details of the preparative procedures have been given in a previous paper.[1]

Reaction Conditions.—The reaction conditions are tabulated in Table I.

Conditions A, C and D, where a xylenol mixture was used as the solvent, were for the preliminary evaluation of the catalyst, while B and E were the regular reaction procedures. The types of lignin used were the ones which were of particular interest at the time when the study was made, hence, there is no special meaning in the selection of lignin.

The activity of the catalysts were tested and compared with the standard catalyst under these conditions. First catalysts were evaluated preliminarily under the conditions A, C and D, only those with promising activities were subjected to full evaluation under the B and E conditions.

The reaction condition B is identical with the one used in Part III.[3] A lower reaction temperature was used in D and E in order to observed the activity at a lower temperature.

A commerially-available industrial-grade xylenol-mixture was distilled to remove a low-boiling fraction (b. p. below 205°C); the residue was then used as the solvent.

The stabilized pasting oil was prepared by a usual procedure fully described in a previous paper.[1]

The Separation and Analysis of the Product.—For A, C and D, the procedure described in Fig. 1 was used.

With the runs under B and E reaction conditions the analytical procedures were the same as in the previous paper.[1]

Definitions of Terms.—The terms used in this paper are as have been described in the previous paper[1] except for the following. In the preliminary runs;

Table I. A list of the reaction conditions

Reaction conditions	A	B	C	D	E
Autoclave	300 ml. Shaking	3 l. Rotating	3 l. Rotating	3 l. Rotating and agitating	3 l. Agitating
Solvent	Xylenols	Stabilized pasting oil	Xylenols	Xylenols	Stabilized pasting oil
Raw material	Refined lignin	Heat-precipitated lignin	Refined lignin	Dried SWL	Dried SWL
Reaction temp., °C	400	400	400	360	360

Results and Discussion

Selenium,[5] Tellurium and Zinc Iodide.—Table II shows the results of the preliminary runs with selenium metal as the catalyst under the condition A. A high hydrogen absorption of 21% (lignin charged) was observed when selenium was used. This cannot be explained by the consumption of hydrogen by selenium to form hydrogen selenide. As compared with the runs with a 10% standard catalyst, the run with 2% selenium gave more organic pitch, but the runs with selenium more than 7% the quantity of lignin gave an almost comparable pitch yield.

Selenium, suspected to be a peculiar catalyst in the preliminary runs, was fully evaluated under the B reaction condition, which is identical with that of Table I of Part III of a previous report.[3] As is shown in Table III, a remarkably high hydrogen absorption was observed, as had been expected. The neutral materials in the cut-3 fraction comprized, however, as much as 73% of the total.

The gasification was almost twice as much as the run with the standard catalysts and amounts of neutral materials and low boilers were high. Thus, the reaction mechanism seemed to be different from that with the standard catalyst. From a commercial point of view, the selenium catalyst was concluded to be less desirable than the standard catalyst. Tellurium was examined under the C reaction condition (Table IV). Tellurium showed a hydrogen absorption almost comparable to that of the standard catalyst, but the amount of organic pitch residue was exceptionally large. Tellurium was thus rejected.

Zinc iodide also gave a very high final-initial pressure difference. The product oil, however, was dark brown, tarry material and gave much non-distillable pitch (Table IV). The reaction mechanism seems to be different from the standard catalyst. A combination of zinc iodide and sulfur gave less pressure difference and a higher pitch yield than did zinc iodide without sulfur.

Other Miscellaneous Catalysts.—Although a vertical, mechanically-agitated autoclave and a horizontal, rotating autoclave were used (Table

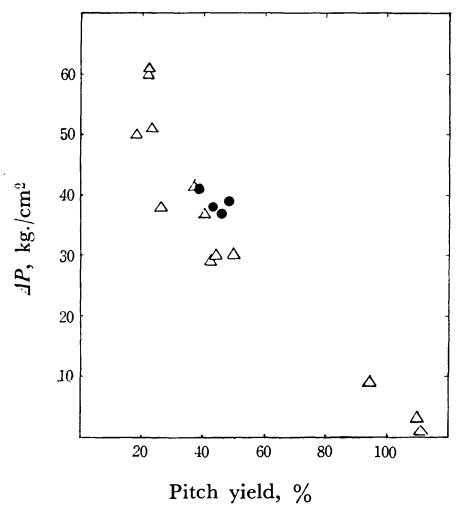

Fig. 3. Pressure difference between final-initial pressure against pitch yield.
● Standard catalyst

V), no difference was observed. These data gave the relation between the pitch yield and the liquefaction yield, and that between the pitch yield and the final-initial pressure difference, shown in Figs. 2 and 3 respectively.

Ni-S and nickel oxalate behaved almost identically as the standard catalyst. Raney iron was almost comparable to the above three. Cobalt sulfide and cobalt octacarbonyl showed a large final-initial pressure difference and a very low pitch yield. The two catalysts seemed to be better than the standard catalyst as far as the preliminary examination was concerned. Ammonium molybdate and iron pentacarbonyl showed a pressure difference comparable to that of the standard catalyst. They also showed a low pitch yield and a high liquefaction yield.

Zinc oxide unexpectedly showed a fair activity, though it was a little inferior to the standard catalyst. On the other hand, Zn-S showed no activity. Elemental sulfur showed very little activity.

Ammonium Molybdate and Iron Pentacarbonyl. — In the preliminary examination described in the previous section, cobalt sulfide, cobalt octacarbonyl, ammonium molybdate, and iron pentacarbonyl seemed to be a little more active than the standard catalyst. The former two are expensive and so are not attractive for the commercial process. The latter two, ammonium molybdate and iron pentacarbonyl, were studied in detail under the E reaction condition (Table VI).

Statistical analysis showed that no difference in pitch yield, pressure difference, and monophenol yield could be deduced between the standard catalyst and the iron pentacarbonyl catalyst. In the case of ammonium molybdate, a higher pressure difference and a lower pitch yield than in the case of the above two catalysts can be concluded with more than a 99% confidence level. However, as far as the monophenol yield and the pasting oil recovery are concerned, no clear differences could be concluded to exist among the three catalysts studied.

From the commercial point of view, the monophenol yield at a 100% recovery of pasting oil is a critical factor. From this point of view, three catalysts showed almost identical activities. Considering the cost of preparation, the standard catalyst is, at least at present, the most desirable catalyst for the hydrocracking of lignin.

The authors would like to express their appreciation to the Noguchi Institute for the permission to publish this study.

NOTES

The Synthesis of 3-*t*-Butyl-6-methyl-2-benzofurylacetic Acid

By the late D. S. DEORHA and Padma GUPTA

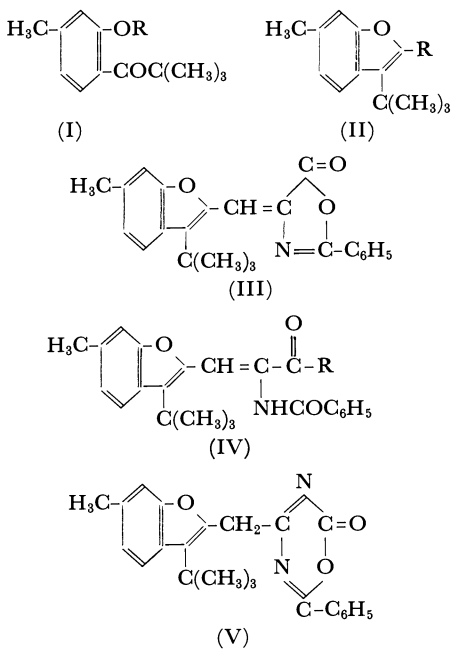
Chemistry Department, University of Rajasthan, Jaipur, India

(Received September 14, 1965)

Arylacetic acid is made from an aromatic aldehyde by the hydrolysis of derived azlactone to pyruvic acid and by subsequent oxidation. During the investigation it has been observed that the azlactones of a few 2-formylbenzofurans offer resistance to hydrolysis, which therefore sometimes results only in tars. Moreover, the derived pyruvic acids are so sensitive to oxidation by alkaline hydrogen peroxide that the reaction is hard to control and sometimes furnishes sticky intractable gums. The reaction explored by Jennings[1] for the conversion of *m*-nitrobenzaldehyde to *m*-nitrophenylacetic acid has been successfully used by Dean and coworkers[2]; it has now been extended to the preparation of 3-*t*-butyl-6-methyl-2-benzofurylacetic acid from 2-formyl-3-*t*-butylbenzofuran.

For this purpose 2-hydroxy-4-methylphenyl *t*-butyl ketone (I, R=H), and 5-methyl-2-pivaloylphenoxyacetic acid (I, R=CH_2COOH) have been prepared and converted into 3-*t*-butyl-6-methylbenzofuran (II, R=H), which, when dimethylformamide and phosphorus oxychloride[3] are employed, yields 2-formyl-3-*t*-butyl-6-methylbenzofuran (II, R=CHO) in a good yield. The orientation of the formyl group in it has been confirmed by its oxidation to the carboxylic acid (II, R=COOH), which is identical with that formed by the cyclisation of the phenoxyester (I, R=$CH_2COOC_2H_5$) and by subsequent hydrolysis (II, R=$COOC_2H_5$). Thus, 4-[(3′-*t*-butyl-6′-methyl-2′-benzofuryl)methylene]-2-phenyloxazolin-5-one (III), obtained from 2-formyl-3-*t*-butyl-6-methylbenzofuran (II, R=CHO) by heating it with hippuric acid and sodium acetate in acetic anhydride, reacts with hydrazine hydrate to yield α-benzamido-β-(3-*t*-butyl-6-methyl-2-benzofuryl)acrylohydrazide (IV, R=$NHNH_2$). The latter, with nitrous acid, forms α-benzamido-β-(3-*t*-butyl-6-methyl-2-benzofuryl) acryloazide (IV, R=N_3). Upon being refluxed in dry benzene this azide furnishes 4-[(3′-*t*-butyl-6′-methyl-2′-benzofuryl)methyl]-6-phenyl-2*H*-1, 3, 5-oxadiazin-2-one (V), which, with hydrochloric acid, yields 3-*t*-butyl-6-methyl-2-benzofurylacetic acid (II, R=CH_2COOH).

Though more steps are involved in this method, it gives purer products and all the reactions proceed quite smoothly.



Experimental

2-Hydroxy-4-methylphenyl *t*-Butyl Ketone.—Pivalyl chloride (13.0 g.) was added gradually to a solution of *m*-cresol (10.8 g.) in dry ether (50 ml.) containing dry pyridine (9 ml.), the temperature maintained below 10°C. After it had been kept for 18 hr. at room temperature, the mixture was treated with water and then extracted with ether. The ether extract was thoroughly washed with aqueous sodium bicarbonate and then with water. The evaporation of the ether left an oil which, on distillation (b. p. 130°C/20 mmHg), furnished 3-methylphenyl pivalate[4] (17 g.) as a colorless oil.

1) K. F. Jennings, *J. Chem. Soc.*, **1957**, 1512.
2) F. M. Dean, D. S. Deorha, J. C. Knight and T. Francis, ibid., **1961**, 327.
3) M. Bisagni, Ng. Ph. Buu Hoi and R. Royer, ibid., **1955**, 3688.
4) R. Batzly, W. S. Ide and A. P. Phillips, *J. Am. Chem. Soc.*, **77**, 2522 (1955).

To the above ester (5 g.) finely-powdered anhydrous aluminum chloride (5 g.) was added in small quantities at room temperature. The reaction commenced immediately. After the addition, the mixture was heated at 70°C for 12 hr. The complex was decomposed with ice and 10 ml. of concentrated hydrochloric acid. The product, which was isolated with ether in the usual way, was distilled, whereby hydroxy ketone (2 g.) was obtained as a viscous liquid, b. p. 150°C/0.3 mmHg.

Found: C, 74.82; H, 8.46. Calcd. for $C_{12}H_{16}O_2$: C, 75.00; H, 8.33%.

With hydroxylamine the ketone formed an oxime which separated from benzene as colorless crystals, m. p. 164°C.

Found: N, 6.88. Calcd. for $C_{12}H_{17}NO_2$: N, 6.76%.

Ethyl 5-Methyl-2-pivaloylphenoxyacetate. — A mixture of 2-hydroxy-4-methylphenyl *t*-butyl ketone (15.5 g.), anhydrous potassium carbonate (40 g.), ethyl chloroacetate (10.2 g.), potassium iodide (0.1 g.), and dry acetone (150 ml.) was refluxed on a water bath for 18 hr. and then filtered. The residue was washed with hot acetone, and the combined acetone filtrates were distilled. The residue was crystallized from ethanol as colorless plates (21 g., 91%), m. p. 63°C.

Found: C, 69.25; H, 8.10. Calcd. for $C_{16}H_{22}O_4$: C, 69.03; H, 7.97%.

Its 2, 4-dinitrophenylhydrazone separated from ethanol in the form of yellow needles, m. p. 152°C.

Found: N, 12.00. Calcd. for $C_{22}H_{26}N_4O_7$: N, 12.22%.

5-Methyl-2-pivaloylphenoxyacetic Acid. — The foregoing ester (10 g.) was heated with sodium hydroxide (5%, 100 ml.) and ethanol (15 ml.) until it dissolved (2 hr.). The acidification of the cooled and diluted solution furnished the *phenoxyacetic* acid, which crystallized from ethanol as needles (8 g., 90%), m. p. 143°C.

Found: C, 67.34; H, 7.40. Calcd. for $C_{14}H_{18}O_4$: C, 67.17, H, 7.25%.

Its 2, 4-dinitrophenylhydrazone was crystallized from ethanol in the form of orange plates, m. p. 230°C.

Found: N, 13.28. Calcd. for $C_{20}H_{22}N_4O_7$: N, 13.02%.

3-*t*-Butyl-6-methylbenzofuran.—The above phenoxyacetic acid (14.0 g.) was mixed with anhydrous sodium acetate (25 g.) and acetic anhydride (50 ml.), kept at 160°C (oil bath) for 3 hr., and then poured into cold water (200 ml.). After 24 hr. the product was extracted with ether in the usual way. The removal of the ether left an oil which was distilled under reduced pressure as a colorless liquid (7.5 g., 73%, b. p. 100°C/5 mmHg).

Found: C, 83.14; H, 8.70. Calcd. for $C_{13}H_{16}O$: C, 82.93; H, 8.57%.

2-Formyl-3-*t*-butyl-6-methylbenzofuran.—a) An ice-cold mixture of *N*, *N*-dimethylformamide (3.5 ml.) and freshly-distilled phosphorus oxychloride (3.5 ml.) was added to a solution of 3-*t*-butyl-6-methylbenzofuran (1.0 g.) in *N*, *N*-dimethylformamide (3.5 ml.). The mixture was then heated on a water bath for 4 hr., cooled, diluted with water, and neutralized with sodium bicarbonate. After 2 hr., the product was extracted with ether in the usual way, and recovered by the evaporation of the solvent. The residue was crystallized from ethanol, furnishing the 2-formylbenzofuran (1.0 g., 89%) in the form of colorless needles, m. p. 60°C.

Found: C, 77.90; H, 7.30. Calcd. for $C_{14}H_{16}O_2$: C, 77.71; H, 7.45%.

b) A solution of 3-*t*-butyl-6-methylbenzofuran (1.0 g.) in ether (10 ml.) containing hydrogen cyanide (0.7 ml.) and aluminum chloride (1.0 g.) was saturated at 0°C with hydrogen chloride, kept for 24 hr., and then evaporated in a current of air. The hydrolysis of the residue with 40 ml. of water at 0°C, and then on a boiling water bath for 1 hr., gave a low-melting solid. The product was isolated by ether in the usual way. The removal of the ether left a residue which, on crystallization from ethanol, furnished 2-formyl-3-*t*-butyl-6-methylbenzofuran (0.35 g., 30%) in the form of colorless needles, m. p. and mixed m. p. with the above sample under a), 60°C.

The 2, 4-dinitrophenylhydrazone separated from ethanol in the form of red crystals, m. p. 261°C.

Found: N, 14.40. Calcd. for $C_{20}H_{20}N_4O_5$: N, 14.14%.

4-[(3'-*t*-Butyl-6'-methyl-2'-benzofuryl)methylene]-2-phenyloxazolin-5-one.— A mixture of the above-mentioned formylbenzofuran (4.65 g.), benzoylglycine (7 g.), anhydrous sodium acetate (4.0 g.), and acetic anhydride (25 ml.) was heated on a water bath for 2 hr., cooled, diluted with ethanol (100 ml.), and kept overnight. The crystalline solid was then filtered and crystallized from ethanol as orange yellow needles (7.7 g., 72%), m. p. 195°C.

Found: N, 4.15. Calcd. for $C_{23}H_{21}NO_3$: N, 3.09%.

α-Benzamido-β-(3-*t*-butyl-6-methyl-2-benzofuryl) Acrylohydrazide. — To a suspension of the finely-powdered oxazolone (5.0 g.) in ethanol (150 ml.), 99% hydrazine hydrate (0.7 g.) was added. This mixture was vigorously stirred until the color had been discharged. The solid was then collected and crystallized from ethanol to furnish acrylohydrazide (5.4 g., 89%) in the form of light yellow needles, m. p. 187°C.

Found: N, 10.59. Calcd. for $C_{23}H_{25}N_3O_3$: N, 10.74%.

4-[3'-*t*-Butyl-6'-methyl-2'-benzofuryl)methyl]-6-phenyl-2*H*-1, 3, 5-oxadiazin-2-one.—An ice-cold solution of sodium nitrite (0.3 g.) in a minimum amount of water was added slowly to a solution of the α-benzamido-β-(3-*t*-butyl-6-methyl-2-benzofuryl) acrylohydrazide (1 g.) in glacial acetic acid (25 ml.), the temperature being kept below 10°C. After 30 min., the yellow crystalline precipitate was filtered, washed with water, and dried in air.

The crude azide (1 g.) (decomp. 136°C) was then extracted from a soxhlet thimble with benzene (50 ml.); when concentrated and cooled, the benzene extracts deposited a product which, on recrystallization from benzene, gave the oxidiazine (0.7 g., 85%) in the form of orange-yellow needles, m. p. 214°C.

Found: N, 7.20. Calcd. for $C_{23}H_{22}N_2O_3$: N, 7.48%.

3-*t*-Butyl-6-methyl-2-benzofurylpyruvic Acid. — A mixture of 4-[(3'-*t*-butyl-6'-methyl-2'-benzofuryl)-methylene]-2-phenyloxazolin-5-one (1.0 g.) and potassium hydroxide (20%, 20 ml.) was boiled under reflux until the oxazolone dissolved completely. The condenser was then removed, and the hydrolysis was completed by gentle boiling until ammonia could no longer be detected in the issuing vapors. During the latter part of the reaction, the volume of the solution was kept at 20ml. by the occassional addition of water.

The solution was then diluted with water (50 ml.) and filtered. The cold filtrate was acidified with concentrated hydrochloric acid, and then warmed on a steam bath to 60°C. In this form, the pyruvic acid separated in a granular form and was easily filtered. The benzoic acid formed in the reaction remained in solution. The pyruvic acid crystallized from benzene as colorless plates (0.25 g., 24%), m. p. 206°C.

Found: C, 70.20; H, 6.40. Calcd. for $C_{16}H_{18}O_4$: C, 70.01; H, 6.61%.

3-*t*-Butyl-6-methyl-2-benzofurylacetic Acid.—a) A suspension of the above-mentioned oxadiazine (3.74 g.) in acetic acid (40 ml.) and 5 N hydrochloric acid (5 ml.) was refluxed until its dissolution was complete and the color of the solution had been completely discharged, whereafter dilution with water precipitated the 2-benzofurylacetic and benzoic acids. The latter was leached out with water at 60°C, leaving the crude 2-benzofurylacetic acid, which was then crystallized from aqueous ethanol (1 : 1) in colorless plates (2.0 g., 85%), m. p. 130°C.

Found: C, 73.00; H, 7.95. Calcd. for $C_{15}H_{18}O_3$: C, 73.13; H, 7.83%.

b) A solution of the crude pyruvic acid (1.0 g.) in aqueous potassium hydroxide (5 ml., 10%) at 0°C was mixed with hydrogen peroxide (20 ml., 100 vol.), warmed until effervescence began, cooled to 0°C, diluted with ice water, and finally acidified with concentrated hydrochloric acid. The 3-*t*-butyl-6-methyl-2-benzofurylacetic acid thus precipitated crystallized from aqueous ethanol (1 : 1) as colorless plates (0.31 g., 35%), m. p. and mixed m. p. with the sample under a), 130°C.

Its methyl ester, prepared by diazomethane, crystallized from benzene in the form of colorless needles, m. p. 52°C.

Found: C, 73.96; H, 7.60. Calcd. for $C_{16}H_{20}O_3$: C, 73.79; H, 7.74%.

3-*t*-Butyl-6-methyl-2-benzofurylcarboxylic Acid.—a) Ethyl 5-methyl-2-pivaloylphenoxyacetate (1.08 g.) was dissolved in ethanol (10 ml.), and a solution of sodium ethoxide (0.2 g. of sodium in 10 ml. of dry ethanol) was added. The solution was heated on a water bath for 15 min. and then diluted with water (20 ml.). The clear solution was acidified with 5 N hydrochloric acid. The product was crystallized from ethanol in the form of colorless prisms (0.4 g., 40%), m. p. 234°C.

Found: C, 73.19; H, 7.18. Calcd. for $C_{14}H_{16}O_3$: C, 73.00; H, 7.00%.

b) 2-Formyl-3-*t*-butyl-6-methylbenzofuran (1.0 g.) was dissolved in purified acetone (50 ml.), and a solution of potassium permanganate (0.6 g.) in water (20 ml.) was added. The solution slowly deposited manganese dioxide; after 18 hr., this was removed by means of sulfur dioxide. The solution was then diluted with water, and the solid that separated was collected, dissolved in ether, and extracted with a sodium bicarbonate solution. The extract was acidified with 5 N hydrochloric acid to give the acid (0.5 g., 46%), which was crystallized from ethanol, m. p. and mixed m. p. with the above sample under a), 234°C.

The thanks of the authors are due to Professor R. C. Mehrotra, Head of the Chemistry Department, University of Rajasthan, Jaipur, for providing facilities, and to the Council of Scientific and Industrial Research, New Delhi, for awarding a fellowship to P. G.

Vibrational Analysis of Substituted and Perturbed Molecules. Direct Determination of Force Constants from the Coriolis Interaction

By C. David Bass* and Jack S. Margolis**

North American Aviation Science Center, Thousand Oaks, California

(Received September 22, 1965)

Molecular spectroscopists generally acknowledge the importance of obtaining the molecular force constants since there is much potential information contained in them if they can be determined accurately enough. For example, these force constants may be related to the chemical bonding and the electronic structure; they are useful to the spectroscopist for predicting the molecular frequencies beyond the range of his instruments and in interpreting the combination and overtone bands he observes. Also, determining accurate values of the anharmonic forces goes hand in hand with determing the harmonic forces. The analysis required to obtain molecular force constants using the $\boldsymbol{F}$-$\boldsymbol{G}$ matrix techniques rapidly becomes very complex as the molecular size increases and must proceed in a backward manner.

A great deal of the computational difficulties of the $\boldsymbol{F}$-$\boldsymbol{G}$ matrix procedure has been obviated by means of the molecular Green's function.[1)]

For XY_3 planar molecules, the Green's function method allows direct computation of the mixing parameter connecting two modes of the same symmetry type using only the observed frequencies as input data. The force constants can then be calculated directly from the mixing parameter. It is not necessary to make mathematical approximations in order to solve the equations and so computational errors are negligible. However, the number of molecular frequencies available to the computation are usually not more than just sufficient to determine the force constants, and since the off-diagonal components[2] of the force constant matrix are very sensitive to small variations of the frequencies there will remain large uncertainties in the values of these numbers. It is important to find measurable quantities which determine the force in a less sensitive way. One such quantity is the Coriolis coefficient. Mills,[3] Meal and Polo,[4] Kristiansen and Cyvin,[5] Boyd and Longuet-Higgins[6] have shown how to relate the Coriolis coefficient to force constants.

Calculations

The Coriolis coefficient, ζ_r, can be measured directly from the splitting of the degenerate frequencies of a molecular vibration. Following the procedure of Boyd and Lonquet-Higgins[6] we denote the two real normal coordinates of a degenerate vibration P_r, Q_r; these are written in a basis of mass adjusted cartesian coordinate u_k, v_k, w_k:

$$u_k=\sqrt{m_k}x_k;\quad v_k=\sqrt{m_k}y_k;\quad w_k=\sqrt{m_k}z_k.$$
$$P_r=\sum_j \alpha_{rj}S_j;\quad Q_r=\sum_j \alpha_{rj}S_j. \tag{1}$$

As an example of this we apply the method to the calculations of the mixing parameter for a molecule of type XY_3-planar. The normal coordinates for this molecule have been tabulated in Ref. 1b.

This leads to the following expression for the Coriolis coefficient ζ_3:

$$\zeta_3=\sum_k \begin{vmatrix} \frac{\partial P_r}{\partial u_k} & \frac{\partial P_r}{\partial v_k} \\ \frac{\partial Q_r}{\partial u_k} & \frac{\partial Q_r}{\partial v_k} \end{vmatrix}$$
$$=\frac{1}{A^2d_1{}^2d_2{}^2}[3r^2(a^2d_1{}^2-2ad_1+1)-d_2{}^2(2ad_1+3r^2)]. \tag{2}$$

This may be rewritten as an equation with a as the unknown:

$$d_1{}^2(3r^2-d_2{}^2\zeta_3)a^2-4d_1{}^3a-d_1{}^2(3r^2+d_2{}^2\zeta_3)=0. \tag{3}$$

As a specific illustration we shall consider the case of BF_3. From the potential constants $F_{33}=6.303\times10^5$, $F_{34}/d=-0.259\times10^5$, and $F_{44}/d^2=0.528\times10^5$ (all force constants are millidynes/Angstrom), Meal and Polo[4] calculated $\zeta_3=0.83$ for BF_3. Substitution of this value for ζ_3 into Eq. 3 gives a value -1.2761 for a, which compares with $a=-1.2765$ calculated from Eq. 12, Ref. 1b. The force field, calculated from the equations in 1c is: $F_{33}=6.310\times10^5$, $F_{34}/d=-0.3198\times10^5$, $F_{44}/d^2=0.528\times10^5$. The frequencies used to obtain the latter results appear in a publication of Ladd et al.[7] Aside from F_{34}/d, which is the potential constant most sensitive to observed frequencies, the results are in substantial agreement.

However, a different set of data, (Ref. 5) results in a quite different force field, as calculated by the Wilson method: $F_{33}=7.4068\times10^5$, $F_{34}/d=-0.6398\times10^5$, $F_{44}/d^2=0.50013\times10^5$. The value of ζ_3 calculated in Ref. 5 is 0.717. Abramowitz has recently measured ζ_3 and found a value 0.70.[8] Equation 2 gives $a=-1.0385$ for $\zeta_3=0.70$, and, using the frequencies of Ref. 5 with the equations of 1c: $F_{33}=7.5807\times10^5$, $F_{34}/d=0.7934\times10^5$, $F_{44}/d^2=0.5060\times10^5$. Equation 12, Ib gives $a=-1.1261$. There is substantial agreement within this last set of data, the largest discerpancy again appearing in F_{34}/d.

The new result of Abramowitz indicates that the BF_3 vibrational data of Kristiansen and Cyvin[5] is more reliable that other reported data. Utilizing the simple formalism of this paper, and our previous results (1a—1b) we have performed the calculations with much less effort than earlier investigators.

2) We are speaking of off-diagonal in the sense of a matrix constructed in a basis of internal coordinates. However, the Green's function analysis is most conveniently carried out in a basis of external cartesian coordinates which form an ortho-normal set. The advantage is that we deal with unitary matrices.

o-Methyl Proton Chemical Shifts in Sterically-much-hindered Aromatic Ketones

By Kazuhiro MARUYAMA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received February 16, 1966)

Proton chemical shifts of α-hydrogen atom in the aromatic side chain have theoretically been explained by the ring current model. Furthermore, it is known experimentally that *o*-carboxy, *o*-carbonyl, and *o*-nitro substituents cause a paramagnetic shift (i. e., a shift to a lower τ-value) of about 0.2—0.3 p. p. m. to the α-hydrogen atom of the methyl group on the aromatic ring.[1] The present author has found that *o*-methyl protons of sterically-much-hindered ketones, alkyl-substituted benzophenone derivatives and alkyl-substituted pivalophenone derivatives show, rather, a shift to a higher τ-value of about 0.2—0.3 p. p. m. The results are shown in Table I. NMR spectra for all compounds were obtained in a carbon tetrachloride solution using tetramethylsilane as the inner reference. Carbon tetrachloride solutions with concentrations from five to ten percent were used for all the measurements because there was no appreciable difference in chemical shifts within this concentration for these compounds. The values of the chemical shifts were corrected by the side-band method. A 60 Mc. 3H-60 spectrometer, manufactured by the Japan Electron Optics Laboratory, was used in these measurements.

Synthetic method and their physical constants of the compounds from No. 22 to No. 27 have been reported in this Bulletin.[2]

As one can easily see in Table I, methyl protons of the 2, 6-position and of the 2, 6, 2′, 6′-position of alkylated benzophenone derivatives (No. 14—No. 21) appear at a considerably higher field side than do methyl protons of sterically-less-hindered benzophenone derivatives (No. 7—No. 13). In methylated pivalophenone derivatives, again, methyl protons of the 2-position and of the 2, 6-position appear at a higher field side. Because the paramagnetic shielding effect of the *o*-carboxy, *o*-carbonyl, and *o*-nitro groups on the methyl group will be most effective if the benzene ring and these substituents have coplanarity, the observed effects (i. e., the shift to a higher field side) in sterically-much-hindered ketones might be due to the loss of coplanarity among two benzene rings, the carbonyl group, and methyl groups.* Methyl-proton chemical shifts of 2, 6, 2′-trimethylbenzophenone (No. 15) are likely to be typical and to show these circumstances most clearly: 2, 6-CH_3, $\delta(10-\tau)$: 2.04, 2′-CH_3, δ : 2.64. That is to say, 2, 6-CH_3 protons appear at a higher field side than do 2-CH_3 of 2-methylbenzophenone, and 2′-CH_3 appears at a far lower field side than that. Considering the molecular model, the two benzene rings in 2, 6, 2′-trimethylbenzophenone are exactly perpendicular to each other at the most strain-free average molecular state, and the 2′-methyl group may take the position which is affected most effectively by the magnetic deshielding effect of the carbonyl group (see Fig. 1). On

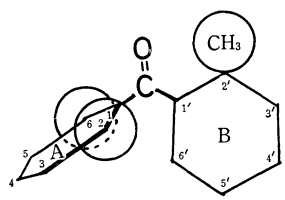

Fig. 1. Configuration of 2, 6, 2′-trimethylbenzophenone.

the other hand, 2- and 6-methyl groups must be under the influence of the magnetic shielding effect of the carbonyl group because the plane of the carbonyl double bond and the plane of the disubstituted benzene ring are perpendicular; then the signal moves upfield. Although two benzene rings in 2, 6, 2′, 6′-tetramethylbenzophenone are also able to be perpendicular to each other with a slight sterical repulsion of a methyl group (i. e., 6′-CH_3 on ring B) and a benzene ring (i. e., ring A), this state could not be the most strain-free molecular state. Two benzene rings and the carbonyl group should take a twisted position to each other in the more strain-free state, and then the four methyl groups may be non-equivalent in this state. Two of the four methyl groups can be near the other benzene ring, and the other two methyl groups near the

carbonyl. However, this state is interconvertible with a rotation of C_1—C—$C_{1'}$ bondings without

any appreciable sterical repulsion through the molecular state in which two benzene rings are perpendicular to each other. Thus, four methyl groups are supposed to become equivalent to the average molecular state. Recently, Mislow and co-workers[3] have observed the methyl proton chemical shifts of *o*, *o'*-bridged biphenyl derivatives and found that the signal moved upfield with an increase in the angle of torsion between the two benzene rings; they ascribed this effect to the magnetic shielding effect of the other benzene ring on which the methyl was not attached. Therefore, a part of the shielding effect might also be ascribed to that of the benzene ring in 2, 6, 2', 6'-tetramethylbenzophenone. Thus, four methyl groups may be supposed to be under the magnetic shielding effect of both the carbonyl group and the benzene ring, although it is not clear which is the more important of the said shielding effects.

A similar explanation may be applied to all the compounds examined here which show a shift to the upfield side of the methyl proton signal.

Extended Hückel Calculations Including the Outer Orbitals: Ethylene, Methyl Chloride and Related Compounds

By Hiroshi KATO, Hideyuki KONISHI and Teijiro YONEZAWA

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received March 7, 1966)

LCAO calculations including the outer atomic orbitals (AO) have been carried out for small molecules by several authors.[1,2] In this note, the extended Hückel method proposed by Hoffmann[3] is modified so that the molecular orbitals (MO) are constructed not only by the valence AO's but also by the outer AO's. The calculations are made for planar ethylene, twisted ethylene, methyl chloride, and the transient species, $(Cl\cdots CH_3\cdots Cl)^-$, appearing in S_N2-type reactions. The calculations are carried out by several methods. The following AO's are included in each method:

A: valence AO's

B: valence AO's + $3s_C$, $3p_C$ AO's,

C: valence AO's + $3s_C$, $3p_C$ AO's + $2s_H$, $2p_H$ AO's,

D: valence AO's + $3s_C$, $3p_C$ AO's + $3d_C$, $3d_{Cl}$ AO's,

where $3s_C$ and $3p_C$ refer to the 3s and 3p AO's of the carbon atom and so on.

The adopted values of the Coulomb integrals of the outer AO's are as follows: −3.75 eV. for the carbon 3s AO; −2.35 eV. for the carbon 3p AO's;[4] −3.40 eV. for the hydrogen 2s, 2p AO's, and −1.47 eV. and −1.60 eV. for the carbon and chlorine 3d AO's respectively.[5] The orbital exponents of these AO's, derived from the rule in Ref. 2, which are necessary in calculating the overlap integrals, are 0.500 for the hydrogen AO's, 0.483 for the carbon AO's, and 2.0333 for the chlorine AO's. The geometries of the treated compounds have already been given in our previous paper,[6,7] where the adopted configurations for the transient species, $(Cl\cdots CH_3\cdots Cl)^-$, were denoted by the notations b-IV and b-VI.[7]*

The calculated values of the total electronic energy, the highest occupied (HO), the lowest vacant (LV), and the next LV orbital energies of the normal and twisted ethylene molecules are listed in Table I (a), along with the methods adopted. The same quantities calculated for the methyl chloride and the transient species are given in Table I (b). Remarkable effects of the inclusions of the outer AO's are seen on the lowerings of the vacant MO energies. For normal ethylene, the first $\pi-\sigma^*$ transition energies are

Table I. The calculated total energies, E, the HO, LV and the next LV orbital energies (in eV.)

6) T. Yonezawa, H. Konishi, H. Kato, K. Morokuma and K. Fukui, *J. Chem. Soc. Japan, Ind. Chem. Sect. (Kogyo Kagaku Zasshi)*, **69**, 869 (1966).
7) H. Kato, K. Morokuma, T. Yonezawa and K. Fukui, This Bulletin, **38**, 1749 (1965).

* The configurations of these compounds are as follows: for the b-IV compounds, the C–Cl$^-$ distance is 2.4 Å; for the C–Cl, 1.95 Å and the Cl–C–H angle is 100°, and for the b-VI symmetrical configuration, the C···Cl is 2.05 Å, and the Cl–C–H angle, 90°.

21.4 eV. by Method A, and 7.4 eV. by Method C. As to the total energies, the lowerings in the twisted ethylene are larger than those in normal ethylene.

The same tendencies are found in the methyl chloride and its anions. Namely, the differences between the HO and LV orbital energies of methyl chloride are 15 eV. by Method A and 9 eV. Method D, whereas the corresponding observed value is about 8 eV.[7] The largest lowering of the total energy of the compounds in Table I (b) is found in the species with a symmetrical configuration, b-VI. Further, by population analysis of the above compounds it is shown that the carbon 3s AO participates in the C—Cl bondings while the 3pσ AO does not, as Table II shows. In other words, it may be suggested that the hybrids formed by the carbon 2pσ and 3s AO's take part mainly in the C—Cl bonding at the transition state of S_N2-type reactions. The contributions of the 3d AO's to the ground state of chlorinated compounds are found to be negligibly small.

Accordingly, it may be concluded that the inclusion of the outer AO's improves especially the excited states of the normal molecules and the ground states of the unstable compounds or of those containing atoms with unusual valencies. Hence, the improvement made in Methods B, C and D may be useful in discussing the σ-σ^* transition and the ^{13}C–H coupling constants in NMR of various compounds. Full details of these results will be published in the near furture.

The authors wish to thank Professor Saburo Nagakura and Dr. Haruo Hosoya for their kind advice.

The Reaction of Cuprous Ethanethiolate with 1, 2-Dibromoethylene

By Masuo MURAKAMI and Kozo TAKAHASHI

Central Research Laboratory, Yamanouchi Pharmaceutical Co., Ltd., Itabashi-ku, Tokyo

(Received March 28, 1966)

In 1959, Adams and Ferretti[1] reported that *S*-ethyl hydrogen thiocarbonate was formed by the oxidation of ethyl ethynyl sulfide, which had been obtained from the reaction between 1, 2-dibromoethylene and cuprous ethanethiolate, with hydrogen peroxide. It is generally accepted that the thiocarbonic acid and their primary esters are exceedingly unstable in the free state, but their derivatives, such as salts, neutral esters and amides, are sufficiently stable.

Since the observation of Adams and Ferretti about the stability of *S*-ethyl hydrogen thiocarbonate seems unusual, we have repeated their experiments; we have found that the reaction between 1, 2-dibromoethylene and cuprous ethanethiolate does not lead to ethyl ethynyl sulfide, but to 1, 2-bis-ethylthioethylene, which is subsequently converted to the corresponding sulfone by oxidation.

The reaction of cuprous ethanethiolate with commercial 1, 2-dibromoethylene*1 was carried out according to the reported procedure.[1] The product **I**, b. p. 104—108°C at 18 mmHg, was isolated in a 49% yield, while a large amount of tarry material remained:

$$Br\text{-}CH{=}CH\text{-}Br + CuSC_2H_5 \longrightarrow C_2H_5S\text{-}CH{=}CH\text{-}SC_2H_5 \quad (I)$$

The infrared spectrum of I was similar to that of Adams and Ferretti's product (b. p. 61°C at 1 mmHg), which they assumed to be ethyl ethynyl sulfide. It showed a strong band at 1260 cm^{-1}, but not those absorptions at 3300 cm^{-1} and 2100—2140 cm^{-1} which are characteristic of monosubstituted acetylenes. The results of elementary analysis (Found: C, 48.37; H, 8.06; S, 43.35), Calcd. for $C_6H_{12}S_2$: C, 48.63; H, 8.16; S. 43.25%. gas chromatography*2 and NMR spectrum (3.90 τ(s), 3.93 τ(s), 7.29 τ(q), 7.33 τ(q), 8.70 τ(t), 8.72 τ(t)) indicated that I was a mixture of about equal amounts of two stereoisomeric 1, 2-bis-ethylthioethylenes. When I was oxidized with hydrogen peroxide in acetic acid as reported before, two isomeric products were isolated; they were then purified by recrystallization from ethanol. The first product **II**, m. p. 145—146°C, is less soluble than the second product **III**, m. p. 90—91°C, which is easily soluble in water. The yields were 35% and 41% respectively. The analysis leads to identical empirical formulas ($C_2H_6O_2S$) for both products; the would-be *S*-ethyl hydrogen thiocarbonate, m. p. 145—146°C, prepared by

1) R. Adams and A. Ferretti, *J. Am. Chem. Soc.*, **81**, 4927 (1959).

*1 Infrared spectrum and NMR spectrum showed that the material is a mixture of about equal amount of cis and trans form.

*2 Gas chromatography on Silicon DC 550 column (1 m.) with hydrogen as carrier gas at 100°C showed two peaks with about equal peak-height.

Adams and Ferretti[1] also gives the same formula. These facts demonstrate that II is apparently identical with the Adams and Ferretti's product. Both of the isomers thus obtained are neutral substances, and they show two strong bands, at 1310 cm^{-1} and 1120 cm^{-1}, in the infrared spectrum, which can be assigned to the stretching vibration of a sulfone group.

When both isomers are hydrogenated over palladium-carbon, one mole of hydrogen was absorbed easily, yielding a theoretical amount of 1, 2-bis-ethylsulfonylethane, m. p. 137—139°C, which does not depress the melting point of the authentic sample.[2]

$\longrightarrow C_2H_5SO_2CH{=}CHSO_2C_2H_5 \longrightarrow$

(II): trans $C_2H_5SO_2CH_2CH_2SO_2C_2H_5$

(III): cis

2) Beckman, *J. Prakt. Chem.*, **17**, 469 (1878).

From these results, we may conclude that II and III are geometrical isomers[3] of 1, 2-bis-ethylsulfonylethylene.

Boonstra and Rinzema[4] reported that ethyl ethynyl sulfide[5] shows characteristic bands at 3330 cm^{-1} and 2040 cm^{-1} in the infrared spectrum. From these findings, it is evident that the Adams and Ferretti's products are 1, 2-bis-ethylthioethylene and *trans*-1, 2-bis-ethylsulfonylethylene, but not ethyl ethynyl sulfide and *S*-ethyl hydrogen thiocarbonate. It is also shown that the reaction of 1,2-dibromoethylene with cuprous ethanethiolate proceeds in the same way as that with cuprous thiophenolate.[1]

Complex Formation of Indium(III) with Oxalate Ion in 1M Sodium Perchlorate Media

By Yuko HASEGAWA and Tatsuya SEKINE

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received April 13, 1966)

Much work has been devoted to the complex formation of indium(III) in aqueous solutions with various ligands.[1] It has been shown that indium(III) is a good acceptor of various ligands, forming stable complexes in aqueous solutions.

The complex formation of some trivalent metal ions with oxalate ion has also been studied, and it has been reported[2] that lanthanum(III), europium(III), luthetium(III) and americium(III) form oxalate complexes, $MC_2O_4^+$, $M(C_2O_4)_2^-$ and $M(C_2O_4)_3^{3-}$, in 1 M sodium perchlorate media.

For the complex formation of indium(III), Lacroix reported[3] that a tripositive indium ion combines with two oxalate ions. Moreover, White, Tang and Li[4] reported that indium(III) forms a complex species, $InHC_2O_4^{2+}$. However, no quantitative data on the successive formation of indium(III) complexes seem to have been published.

For the present paper, the authors studied the complex formation of indium(III) with oxalate ions in 1 M $Na(ClO_4)$ at 25°C. A liquid-liquid distribution method was employed in conjunction with an indium-114 m tracer in order to keep the metal ion concentration very low and to avoid the formation of indium oxalate precipitates. The complex formation was determined from the decrease in the metal extraction with thenoyltrifluoroacetone. The stability constants were determined graphically by a curve-fitting method.

Experimental

Most of the reagents and procedures were the same as those described previously[5,6] except the following.

Tracer and Reagents.—Indium-114 (half-life; 50.0 days) was prepared by the irradiation of five-nine indium metal with thermal neutrons in the JRR-2 reactor of the Japan Atomic Energy Institute. The irradiated sample was dissolved in aqua regia and evaporated to dryness. The residue was dissolved in perchloric acid and used as the stock tracer solution. The chloroform was washed three times with water.

Procedures.—In the present study, sulfanilic acid-sulfanilate was used to buffer the aqueous phase between pH 3.0 to 3.4, and a chloroform solution of 0.01 M

thenoyltrifluoroacetone (TTA) was used as the organic phase. The initial concentration of indium(III) in the aqueous phase was always less than 3×10^{-7} M.

Results and Discussion

The dissociated oxalate ion concentration in the solutions at different hydrogen ion concentrations was calculated from the total oxalate concentration, using the acid dissociation constant. The details of the statistical treatment have been given in previous papers[2,5,6]; only the final equations will be given in Table I.

Table I. Abrribations and equations

D: Net distribution ratio

$$D=\frac{\gamma\text{-radioactivity per ml. org. phase}}{\gamma\text{-radioactivity per ml. aq. phase}} \quad (1)$$

D_0: Distribution ratio in the absence of ligands

$$D_0=[InA_3]_{org}/[In^{3+}]_{aq} \quad (2)$$

K_{ex_0}: Extraction constants

$$K_{ex_0}=D_0[H^+]^3[HA]_{org}^{-3} \quad (3)$$

$=10^{-3.83}$ (determined from the data in Fig. 1)

β_n: The stability constant for the "nth" complex

$$\beta_n=[InL_n^{3-2n}]/[In^{3+}][L^{2-}]^n \quad (4)$$

$$\log(1+\sum\beta_n[L^{2-}]^n)^{-1} = \log D[H^+]^3[HA]_{org}^{-3}/K_{ex_0} \quad (5)$$

Figure 1 gives the $\log D$ vs. $-\log[H^+]$ plot when the aqueous phase contains no oxalate. The plot in the figure falls on the straight line of slope 3 (cf. Eq. 3).

The stability constants of the oxalate complexes may be calculated by Eq. 5, and the stability constants may be determined by a "curve-fitting" method.[5,6]

The stability constants for the complex $InC_2O_4^+$ and $In(C_2O_4)_2^-$ species were determined by the curve-fitting method as $\log\beta_1=5.30$ and $\log\beta_2=10.52$. Figure 2 gives the $\log D[H^+]^3[HA]_{org}^{-3}/K_{ex_0}$ vs. $\log[C_2O_4^{2-}]$ plot, together with the curve calculated from the stability constants obtained by the curve-fitting method.

Under the present experimental conditions, the hydrolysis of indium(III) may be neglected (for the calculation of the stability constants) because the hydrolysis constants have been given as $10^{-4.4}=[InOH^{2+}][H^+]/[In^{3+}]$ and $10^{-3.9}=[In(OH)^{2+}][H^+]/[InOH^+]$.[7]

It seems that the experimental data can be explained by assuming only the primary and the secondary complexes within the present oxalate concentration range. No stability constants of indium(III) oxalate complexes have been reported which can be directly compared with the present

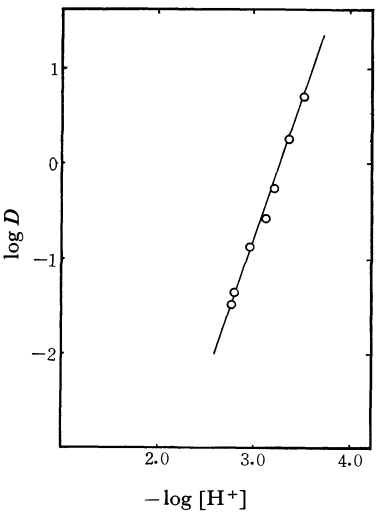

Fig. 1. Distribution ratio of indium(III) as a function of hydrogen ion concentration at 25°C when oxalate ion is absent in the aqueous phase.
Organic phase: 0.01 M TTA in chloroform
Aqueous phase: 1.0 M $NaClO_4$

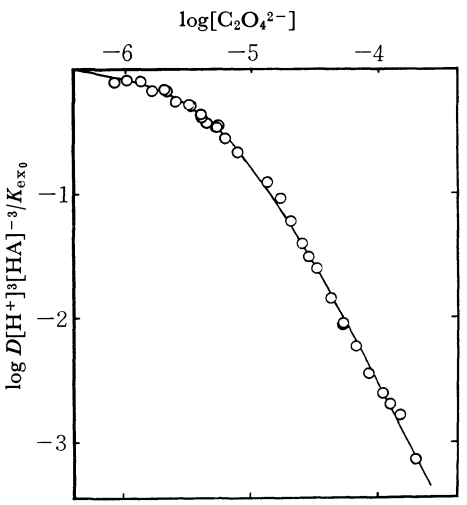

Fig. 2. Variation of $D[H^+]^3[HA]_{org}^{-3}$ of indium(III) as a function of the concentration of oxalate ion at 25°C.
Organic phase: 0.01 M TTA in chloroform
Aqueous phase: 1.0 M $Na(ClO_4)$
The solid curve shows $\log D[H^+]^3[HA]_{org}^{-3}K_{ex_0}^{-1} = -\log(1+2.0\times10^5[C_2O_4^{2-}]+3.3\times10^{10}\times[C_2O_4^{2-}]^2)$

results, nor have such constants been reported for the oxalate complexes of aluminum(III), gallium(III) or thallium(III) under similar experimental conditions except for those by Dutt and Sur[8] in 1 M potassium nitrate at 32°C. It may be

7) G. Biederman, *Arkiv Kemi*, **9**, 277 (1956); *Rec. Trav. Chim.*, **75**, 716 (1956).

8) N. K. Dutt and B. Sur, *Z. anorg. Chem.*, **293**, 195 (1957).

seen in their results that the K_2 of the aluminum(III) oxalate complex ($\log K_2 = 5.45$) is of the same order as that of the indium(III) complex in the present study ($\log K_2 = 5.22$).

The stability constants for the primary and the secondary oxalate complexes of lanthanum(III), europium(III), luthetium(III) and americium(III)[2] under the same experimental conditions are a little smaller than those of indium(III); the tertiary complex, such as was always found for these trivalent ions, was not found for indium(III).

Part of the present work was carried out at the Laboratory of Nuclear Chemistry, the Institute of Physical and Chemical Research, Tokyo. The authors are very grateful to Professor Nobufusa Saito, the head of the laboratory. The authors are also grateful to Dr. Tadashi Nozaki and Dr. Mariko Inarida for their experimental aid.

A Powerful New Aldol Condensation Agent, Ba_3N_4[1]

By Yoshiyuki OKAMOTO and J. C. GOSWAMI

Research Division, School of Engineering and Science, New York University, University Heights, New York

(Received April 26, 1966)

The thermal decomposition of many inorganic azides, especially those of heavy metals, proceeds explosively and results in the formation of the corresponding metal and nitrogen.[2] However, we have found that barium azide, $Ba(N_3)_2$, decomposes smoothly in organic solvents such as decalin or tetralin at the temperature of their respective boiling points to yield nitrogen and a fine black powder, barium pernitride, Ba_3N_4.[3,4]

Barium pernitride obtained was found to be exceedingly reactive with water and air. We now wish to report that this compound is also a highly active catalyst for an aldol condensation. Indeed, barium pernitride exhibits much greater reactivity than that of aluminum tri-*t*-butyl alcoholate, known as a powerful catalytic agent for this reaction.[5]

The typical results are described as follows. Barium azide (10 g.) and decalin or tetralin (50 ml.) were placed in a 100 ml. pyrex three-neck flask equipped with a Liebig reflux condenser. The air in the apparatus was replaced with dry nitrogen. The flask was heated slowly in an oil bath. The decomposition reaction started within 20 min. and after the solvents reached the boiling point, the mixture was refluxed for 30—40 min. to complete the reaction.

Upon cooling the system, the solvent was replaced with 50 ml. dried ether under a stream of dry nitrogen. Dried acetone (25 g.) was added dropwise into the suspension of Ba_3N_4 in ether with stirring at -15 to -20°C during 30 min. Mesityl oxide (14.2 g., b. p. 133°C/757 mmHg, 2, 4-dinitrophenylhydrazone m. p. 204°C) and diacetone alcohol (5.8 g., b. p. 160°C/757 mmHg, 2, 4-dinitrophenyl hydrazone m. p. 202°C) were obtained as the main products. When an excess of Ba_3N_4 was used, the dehydrate, mesityl oxide, was the only product formed (according to Eq. 1).

Ba_3N_4 (prepared from 12.2 g. $Ba(N_3)_2$) suspended in 60 ml. ether was reacted with 32 g. acetophenone at 30°C for 1 hr. Dypnone (25 g., b. p. 133°C/0.5 mmHg, 2, 4-dinitrophenylhydrazone m. p. 167°C, authentic compound m. p. 167°C[5]) was obtained.

$$R\text{-}\overset{\overset{O}{\|}}{C}\text{-}CH_3 + Ba_3N_4 \xrightarrow{\text{ether}} R\text{-}\overset{\overset{O}{\|}}{C}\text{-}\overset{\overset{H}{|}}{C}=\overset{\overset{CH_3}{|}}{C}\text{-}R + N_2 + NH_3 + Ba(OH)_2 \quad (1)$$

where $R=CH_3$ or C_6H_5.

Two Crystal Forms and the Fluorescence Spectra of 9, 10-Dichloroanthracene

By Harumitsu KUWANO and Michio KONDO

Central Research Laboratories, Sankyo Co., Ltd., Shinagawa-ku, Tokyo

(Received May 2, 1966)

It has been pointed out by Stevens[1] that the fluorescence spectra of aromatic hydrocarbons in the solid state have a close relationship to their crystal structures. According to him, aromatic hydrocarbons of type A show slightly red-shifted emission spectra, preserving molecular vibrational structures, whereas crystals of type B exhibit broad, structureless emission bands at considerably longer wavelengths than the corresponding molecular fluorescence in solutions.

Bock et al.[2] reported the fluorescence spectrum of 9, 10-dichloroanthracene (DClA) at various temperatures. They reported that, at room temperature, the spectrum exhibits a broad band with something of a structure and with peaks at about 470 and 490 mμ. On the other hand, Stevens and Dickinson[3] reported a single green-fluorescence band, with a peak about 540 mμ, for sublimed DClA. This fact has stimulated us to verify the existence of the two crystal forms of DClA.

Results and Discussion

Materials.—DClA was purified by column chromatography through alumina and recrystallized from benzene. Crystal-form α was obtained as long, yellow plates from benzene, alcohol or carbon tetrachloride. Form β was obtained as greenish-yellow plates on sublimation or by heating the α-form crystal above 180°C.

Lattice Constants and Crystal Structures.—The lattice constants of the α and β forms of DClA were determined by the usual X-ray technique. The crystal data for the α and β forms are summarized in Table I, together with the values reported by Trotter.[4]

The lattice constants of the α form agree excellently with those reported by Trotter. This leads to the conclusion that the α form is identical with that analyzed by Trotter.[5] According to his result, molecules are stacked along the a-axis, with their molecular planes nearly perpendicular to the a-axis. Adjacent molecules in the stacked column are separated by about 3.5 Å. In the projection along the a-axis, the long axes of two adjacent molecules are seen to be at an angle of about 60° to each other.

A crystal structure analysis of the β form is now in progress. Preliminary results reveal that the molecular stacking along the a-axis resembles the 9, 10-dibromoanthracene crystal, the structure of which has been analyzed by Trotter.[6] Namely, as can be seen from the value of the a-axis, the molecular planes are nearly parallel to the bc plane and the molecules in a stacking column are completely superposable on the bc plane when they are projected along the a-axis. In this regard, the β form is in sharp contrast to the α form, although both α and β forms belong to the type B.

Fluorescence Spectra. — The fluorescence spectra were recorded with a Shimadzu model SV-50 AL spectrophotometer equipped with an accessory for measuring the emission spectra of solid samples.

The fluorescence spectra measured on polycrystalline powders of the α and β forms of DClA at room temperature are shown in Fig. 1, together with that measured in a cyclohexane solution.

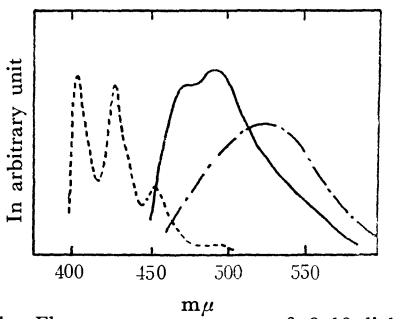

Fig. 1. Fluorescence spectrum of 9, 10-dichloroanthracene.
----: in cyclohexane ——: α form
— — —: β form

Emission bands in the crystalline state are at longer wavelengths than that in the solution. The α form exhibits a broad spectrum with peaks at about 470 and 490 mμ, whereas the β form shows a broad structureless band, with a peak at about

* A value recalculated from their lattice constants.

525 mμ.* The spectrum reported by Bock et al. resembles the present one on the α form, but the emission band reported by Stevens and Dickinson is located at a slightly longer wavelength than that of the β form reported herein.

As has been mentioned, the α and β forms of DClA both belong to the type B. These closely-stacked structures with interplanar distances of about 3.5 Å seem to be favorable for the formation of excimers. The broad structureless emission of the β form is separated from the 0–0 band of the emission spectrum in a cyclohexane solution by about 5800 cm^{-1}. For aromatic hydrocarbons in solutions, it has been pointed out that the excimer fluorescence spectra are located at positions lower than the 0–0 bands of monomer emissions by about 6000 cm^{-1}.[7] Furthermore, pyrene, a typical crystal with a dimer structure, shows a structureless emission band quite similar to the excimer fluorescence observed in solutions of moderately-high concentrations (10^{-2} mol./l.) as regards its shape and its position.[1] Therefore, the fluorescence spectrum of the β form can be regarded as being due to the excimer state.

On the other hand, it is not easy to explain the structure of the emission band of the α form. This band has a frequency lower than that of the 0–0 band of the monomer emission by about 3600 cm^{-1}. This band may be explained by; (a)"a weak excimer state" or (b) "a unimolecular degradation of an excited state strongly perturbed in crystals." Recently, it has been reported[8] that anthracene in cyclohexane at a low temperature (20°K) shows an excimer fluorescence with some structure located at a position lower than the 0–0 band of monomer emission by only about 2000 cm^{-1}. This fact seems to suggest the superiority of the explanation (a) over (b), but the possibility of (b) cannot be ruled out. Therefore, a more satisfactory explanation should be obtained from studies of the temperature dependence of the fluorescence spectra of the α and β forms of DClA.

Many theortical papers[9] have appeared on the excimer configuration, but no definite conclusion has yet been obtained. The present results will at least throw some light on this problem.

* The excitation spectra of the α and β forms were only a little different. This means that the absorption spectra of the α and β forms are essentially indentical.

A Correlation of Catalytic Activity for the Oxidation of Carbon Monoxide and the Adsorption of Carbon Dioxide on Nickel Oxide

By Junko KONDO, Toshio UCHIJIMA and Yukio YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received May 10, 1966)

Various kinds of physical or chemical properties of oxides have previously been discussed, e. g., semiconductivity,[1] the decomposition pressure of oxides,[2] reducibility,[3] the heat of the formation of oxides,[4] and the rate of isotopic exchange reaction in molecular oxygen,[5] in attempts to find a parameter which is capable of accounting for the oxidation activity of nickel oxide catalysts.

It is generally accepted that carbon dioxide is adsorbed on the oxygen atom of the nickel oxide surface in the form of the "CO_3-complex," the existence of which was ascertained by both infrared spectroscopic[6] and micro-calorimetric[7] studies. The nature of the surface oxygen would be made clear by the measurement of the interaction between carbon dioxide and the catalyst surface. The adsorption of carbon dioxide will be examined in this study by means of the gas chromatographic technique for the purpose of obtaining the parameter for the catalytic activity of the oxidation of carbon monoxide.

The apparatus was a conventional assembly used for gas chromatography, modified by an additional small reactor. The oxidation of carbon monoxide with oxygen, diluted with helium as a carrier gas, was performed on grayish-green nickel oxide, which had been prepared by calcining basic nickel carbonate in air at 700°C for 8 hr. Molecular Sieve 5A was packed in the analytical column.

In order to observe the behavior of the adsorbed carbon dioxide, a gas sample (0.1 ml.) of carbon dioxide, mixed with a small amount of argon, was injected at the top of the nickel oxide catalyst column and the values of the retention times of carbon dioxide and argon were measured. The true retention volume of carbon dioxide was calculated from the flow rate and the retention time of argon.

The extent of the oxidation of carbon monoxide by gaseous oxygen on nickel oxide was determined first, and then that by nickel oxide itself, that is, reduction rate of nickel oxide by carbon monoxide. The rate constant of the oxidation of carbon monoxide by gaseous oxygen, k_o, was obtained by injecting the stoichiometric reaction mixture of carbon monoxide (0.5 ml.), oxygen (0.25 ml.) and helium (0.25 ml.) as a pulse. The reduction rate constant of nickel oxide by carbon monoxide, k_r, was derived in the same way using a mixture of carbon monoxide (0.5 ml.) and helium (0.5 ml.). The conversion of carbon monoxide to carbon dioxide both by gaseous oxygen, x_o, and by nickel oxide, x_r, was obtained from the decrease in the gas chromatographic peak height of carbon monoxide. The reaction kinetics being assumed to be first order with respect to the total pressure, the rate constants, k_o and k_r, were calculated as

$$k_o = F/W\,[\ln\,(1-x_o)^{-1}] \qquad (1)$$

and

$$k_r = F/W\,[\ln\,(1-x_r)^{-1}] \qquad (2)$$

respectively, where F (ml./min.) is the flow rate of the carrier gas and W (g.) is the weight of the catalyst.

The relationship between x_r and the retention volume of carbon dioxide, $V(CO_2)$, is shown in Table I. Both the true retention volume and the reduction rate constant are large under oxidized conditions and small under reduced conditions.

Table I. Relationship between retention volume of CO_2 on nickel oxide column and amount of reduction of nickel oxide by CO

Amount of catalyst, 4 g. Temperature, 140°C

Pretreatment	$V(CO_2)$, ml.	x_r, %
Oxidation	14.9	31
Reduction	8.0	16
Reoxidation	10.8	26

As to the retention volume, this may coincide with the schematic model of the adsorption of carbon dioxide on the surface oxygen proposed by Stone.[7]

Correlation of the oxidation rate of carbon monoxide or the reduction rate of nickel oxide

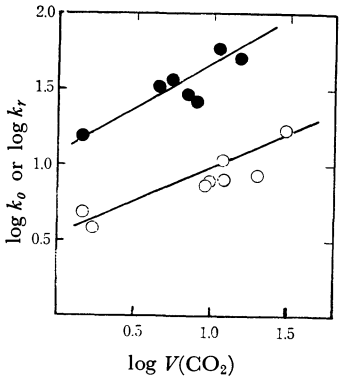

Fig. 1. Correlation between reaction rate constants and retention volume of CO_2 on nickel oxide at 120°C.

● Oxidation rate constant of carbon monoxide, k_o, in Eq. 1.
○ Reduction rate constant of nickel oxide, k_r, in Eq. 2.

with the retention volume of carbon dioxide over a nickel oxide catalyst is plotted in Fig. 1 for various conditions, such as oxidized or reduced, and fresh or poisoned. The oxidation rate of carbon monoxide by oxygen gas on nickel oxide is parallel to the reduction rate of nickel oxide by carbon monoxide. This correlation may reflect the fact that the more reactive surface oxygen for carbon monoxide the catalyst has, the more active is the catalyst for the catalytic oxidation of carbon monoxide.

By means of surface potential measurements, Chee and Yoneda[8] revealed recently that the surface state of nickel oxide during the oxidation of carbon monoxide is the oxidized one, irrespective of pretreatment and that the rate-determining step of this reaction is the process of the reaction between gaseous carbon monoxide and adsorbed oxygen.

A parallel correlation between the two kinds of rate constants and the retention volume of carbon dioxide seems to be reasonable, since the same surface oxygen may interact with carbon dioxide in both cases, and it may determine the catalytic activity as well.

On the basis of the above results and discussion, it may be concluded that the surface oxygen on which carbon dioxide is adsorbed can control the oxidation rate of carbon monoxide, and that the ability of carbon dioxide adsorption on nickel oxide is an important parameter for the catalytic activity of the oxidation of carbon monoxide. The value of the retention volume of carbon dioxide is the product of the number of adsorption sites and the equilibrium constant of the adsorption. In order to clarify the nature of the active center for the oxidation reaction of carbon monoxide on nickel oxide, it will be necessary to distinguish the amount of the adsorption of carbon dioxide from the adsorption strength. This problem will be dealt in another paper.

The authors wish to thank Dr. Yasukazu Saito and Dr. Dong Hyeon Chee for their many helpful discussions and suggestions during this work.

An Interpretation of Observed Long-range Couplings

By Kensuke TAKAHASHI*

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received June 4, 1966)

Long-range spin-spin interactions between protons separated more than three bonds in saturated and unsaturated compounds have recently become the subject of a number of reports.[1] With respect to this problem, the importance of the straight zig-zag path (the M- or W-rule) in saturated systems has been pointed out by Rassat et al.[2] A similar case holds with some aromatics.[3] In this note, we should like to point out the additivity of the coupling constants with respect to the paths across which the long-range couplings take place. Such an empirical rule has not yet been pointed out in the previous reports. It seems to fit especially the large long-range couplings observed. The decrease in the coupling constant with the increase in the number of the bonds between nuclei was pointed out by Aihara.[4] Therefore, when the

magnitudes of the coupling constants are first compared, the number of the bonds between nuclei must be taken into consideration. The notation of J^n_{ij} will be used here; n denotes the number of bonds between two nuclei, i and j, in series. The magnitude of the J^4 value between two protons is too small to be observed in usual saturated compounds, but it sometimes amounts to about 2 c. p. s. with one straight zig-zag path, as is shown by the examples of Nos. 1, 2, 3 and 4 in Table I. A theoretical approach to this problem was formulated by Barfield.[5] On the other hand, in bicyclo(2, 1, 1)hexanes (No. 5 in Table I), J^4 amounts to about 7 c. p. s., and, in this case, the number of paths connecting two protons is two; therefore, the magnitude of coupling may be expected to be approximately twice as much as is the case with only one path. No. 6 in Table I shows an abnormally large long-range coupling of 14 c. p. s.; this magnitude of coupling is considered to be about three times the magnitude of the examples with only one path. Recently, the J^5 value between protons has been observed with some 1, 3-dioxanes;[6] in this case the paths are also considered to be two. J^6 values between protons have been observed with some aromatics.[2] As can be seen from a comparison between the values of Nos. 10 and 11 and Nos. 8 and 9 in Table I, the cases with two paths show values of the coupling constants about twice as large as those in which only one path is effective. From the above-mentioned data, it may be concluded that the additive contribution of the effective coupling paths holds, to a good approximation, in the long-range couplings observed.

The Crystal Structure of Meso-pentane-2, 4-diol Borate

By Shunsuke KURIBAYASHI

Government Industrial Research Institute, Osaka, Midorigaoka, Ikeda

(Received August 19, 1966)

In the course of a structural investigation of the model substances of polyvinyl alcohol, we have analyzed the crystal structure of meso-pentane-2, 4-diol borate.[1] This compound crystallizes in a monoclinic form, with unit cell dimensions of $a=15.36$ Å, $b=13.39$ Å, $c=7.60$ Å, and $\beta=113.0°$ The systematic absences of the reflections show that the space group is $C2/c$ or Cc. As the statistical test of the intensity distributions suggests that there exists a center of symmetry in the crystal, it was decided that the space group was $C2/c$. As this compound is very hygroscopic and is easily dissolved in nearly all kinds of solvents, it was very difficult to determine the density of the crystal. However, from the fact that the crystal is a little heavier than water, it is reasonable to consider that there are 8 molecule in the unit cell.

Multiple film equi-inclination Weissenberg photographs about the c axis were taken with CuK_α radiation for layers from 0 up to 6, while the intensities were estimated visually against a standard scale.

The structure was analyzed mainly by the Patterson projection along the c axis. The positional and thermal parameters of each atom so obtained were then refined by the least-square method. The reliability index, R, for (hkl) reflections at this stage of analysis is 18%, omitting the unobserved reflections. The final electron density projection along the c axis is shown in Fig. 1.

Surrounding the center of symmetry, two molecules are hydrogen-bonded, as is shown in Fig. 2, the distance of the hydrogen bond being about 2.8 Å. The boron atom is surrounded by three oxygen atoms, which form an almost equilateral triangle about the boron; these four atoms are nearly coplanar. The two CH groups and the two oxygen atoms are almost on one plane; all the carbon atoms also form a plane. These three planes, namely, the plane containing all the carbon atoms, that containing two CH groups and two oxygen atoms, and that containing the BO_3 group, intersect to form a chair-like structure. The details of the structure analysis will be reported in the near future.

A Retentive S_Ni Hydrolysis in Aqueous Acrylonitrile and the Polymerization of Acrylonitrile Initiated by the S_Ni Hydrolysis Intermediate

By Kunio Okamoto, Kôichi Komatsu and Haruo Shingu

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received July 13, 1966)

As a result of continuation of our search[1] for the solvent systems in which the S_Ni solvolysis of simple alkyl derivatives involves retention of configuration, we found the water-acrylonitrile system being added to the examples of such retentive solvents. We also found that the acrylonitrile, used as the solvolytic solvent, concomitantly polymerizes, most probably being initiated by the S_Ni ion-pair intermediate.

The hydrolysis of α-phenylethyl chloride (2.61 g., α_D[2] +31.00°) was conducted in 97 wt.% aqueous acrylonitrile (90 cc.) in the presence of added triethylamine (0.201 M) at 90—91°C for 50 hr. Polyacrylonitrile[3] (16.1 wt.% of the starting nitrile), resulted in during the course of the reaction, was separated after treatment of the reaction mixture with ether and water; the ethereal solution was worked up in the usual way and then distilled in vacuo. The fraction A (0.842 g., b. p. 42—58°C/2.5 mmHg; the mixture of styrene, α-phenylethyl alcohol and unchanged α-phenylethyl chloride) and the succeeding fraction B (0.157 g., bath temp. 30—40°C/0.15 mmHg; almost pure α-phenylethyl alcohol) were respectively acetylated with acetic anhydride in pyridine to give α-phenylethyl acetates[4] with α_D +2.01° and α_D +2.02°. The content of the unchanged chloride (0.440 g.) in the fraction A was estimated from the chloride ion analysis of the water washings of the acetylation products; styrene (0.113 g.) was recovered from the acetylation products as a component eluted by *n*-hexane in the elution chromatography over basic alumina; α-phenylethyl acetate was eluted by benzene. The rotation of the unchanged chloride (α_D +0.264°) was calculated on the basis of the rotations of the fraction A and the α-phenylethyl alcohol,[5] contained in the fraction A. From the titrimetric chloride ion analysis of the washings of the reaction mixture the completion of the hydrolysis was estimated to be 58.1%.

These results indicate that 6.31%[6] of the optical activity of the starting chloride was retained in the acetate derived from α-phenylethyl alcohol, and that the acetate possesses the same configuration as that of the chloride. In other words, the hydrolysis to 58.1% completion gave α-phenylethyl alcohol with 6.31% of retention of the configuration, since the acetylation process gives no change to the optical purity and the configuration of the alcohol.[7] Although the titrimetric first-order rate constant for this hydrolysis showed appreciable decreasing tendency, the S_Ni-character of this hybrolysis seems to be undoubtful on the basis of the predominant racemization of the product (93.7%) and of the unchanged chloride (99.1%). The specific solvation of the acrylonitrile molecule to the S_Ni ion-pair intermediate would be responsible for this unusual steric course of the hydrolysis.

The rate of the concomitant polymerization of acrylonitrile, estimated from wt.% yield of polyacrylonitrile at intervals, was as high as about eight fold of the rate in the absence of α-phenylethyl chloride; this rate increased with the increasing initial concentration of α-phenylethyl chloride and decreased with the decreasing water content in aqueous acrylonitriles. The added triethylammonium chloride and styrene, in the absence of the chloride, were found to have no appreciable accelerating action on this polymerization. From these findings, we conclude that this polymerization is most probably initiated by the S_Ni ion-pair intermediate produced from α-phenylethyl chloride and that the specific solvation above mentioned may also be responsible for this initiation.

2) α_D signifies the rotation, neat, l dm., at 20—22°C.

3) The almost identical infrared spectrum with the authentic polyacrylonitrile. The inherent viscosity, 0.525 (DMF, 0.5%).

4) n_D^{25} 1.4931 and 1.4915, respectively. The acetate, the alcohol and styrene were identified by their infrared spectra.

5) The rotation of this alcohol, α_D +0.690°, estimated from that observed for the corresponding acetate. The maximum rotation of R-(+)-α-phenylethyl acetate, α_D 129° (lit. α_D^{28} 117°, H. R. Snyder and J. H. Brewster, *J. Am. Chem. Soc.*, **71**, 291, 4165 (1949)), determined from the results of the preliminary acetylation of the optically active α-phenyl ethyl alcohol. The maximum rotation of R-(+)-α-phenylethyl alcohol, α_D 44.2° (cf. Ref. 1b or 1c).

6) Calculated from the mean value of the rotations of the acetates obtained from the fraction A and B. The maximum rotation of R-(+)-α-phenylethyl chloride was taken as 125° (cf. Ref. 1b or 1c).

7) The second run (71% completion) afforded α-phenylethyl alcohol with 4.7% of retention of the configuration.

Circular Dichroism of Lanthanide(III) Complexes

By Sigeo KIDA

Department of Chemistry, Wakayama University, Masago-cho, Wakayama

and Toshiyuki ISOBE and Seizo MISUMI

(Received September 24, 1966)

There have been reported a number of studies on the circular dichroism (CD) of metal complexes with optically active ligands. However, these studies have been limited to the absorption bands due to the d-d transitions; no studies of the Cotton effect associated with the absorption due to the f-f transitions have ever been reported, except for magnetic optical rotation studies.[1] Katzin and Barnett[2] have suggested the appearance of the Cotton effect of the tartarato complexes of some lanthanide(III) ions in an alkaline aqueous solution, but they have not yet shown any experimental data. In this paper we will report the results of the CD measurements of some lanthanide (III) complexes with optically active ligands.

The measurements have been carried out on aqueous alkaline solutions of tartarato-, lactato-, alaninato-, serinato- and valinato complexes of neodymium(III) and propylen ediamine tetraacetato complexes of praseodymium(III), neodymium-(III) samarium(III), dysprosium(III) and erbium-(III). The circular dichroism was clearly observed in the region of each absorption band (one of which is shown in Fig. 1), even though the intensity is very weak compared with that of a d-complex. This is to be expected from the fact that the f-electrons in lanthanide(III) complexes are better shielded than d-electrons in ordinary transition metal complexes. In some cases the results were rather ambiguous because of too weak intensities.

As may be seen in Fig. 1, a few CD components

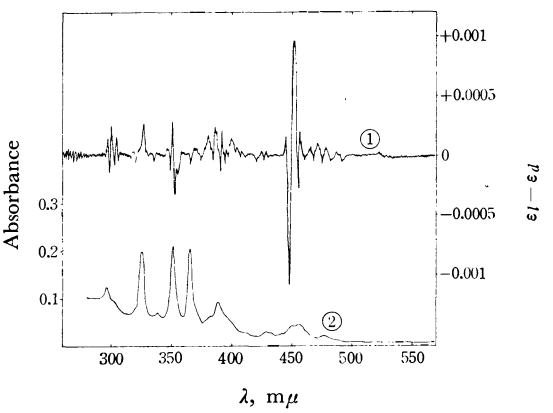

Fig. 1. CD and absorption spectra of levo-propylenediamine tetra acetato complex of dysprosium(III) in aqueous solution (0.1 F, pH= 10.63), 1 cm. cell. 25°C.
(1) CD spectrum (2) Absorption spectrum

are observed for each absorption band; these components may be attributable to the ligand-field splitting. It is interesting that the absorption bands due to f-f transitions can be resolved into so minute peaks by CD measurements.

A more detailed discussion will be reported later.

Nuclear Magnetic Resonance Spectra of Organophosphorus Compounds. I. Long-range Coupling between Phosphorus and Proton through Four Bonds

By Kensuke TAKAHASHI,* Taro YAMASAKI and Goh MIYAZIMA

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai
The Research Institute of Mineral Dressing and Metallurgy, Tohoku University, Naga-machi, Sendai

(Received September 28, 1966)

In this communication, we will compare the results of the coupling constants observed in some organophosphorus compounds of the type of $(EtO)_nPCl_{3-n}$ with those of $(EtO)_nPXCl_{3-n}$ (X=O or S, and n=3, 2 or 1). Some data were given in Table I and a typical proton spectrum of $EtOPOCl_2$ was shown in Fig. 1. The doubling

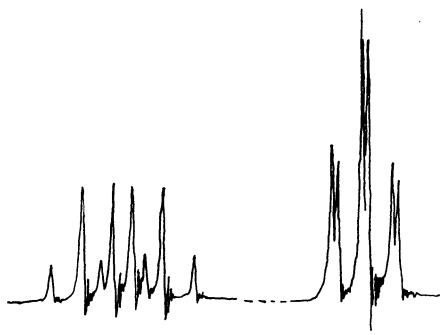

Fig. 1. The proton magnetic resonance spectrum of $EtOPOCl_2$ at 60Mc p. s. Applied magnetic field increases from left to right.

of the usual 3—4 pattern of the ethyl group is clearly observed in Fig. 1. This is ascribed to the coupling between phosphorus and protons in methyl and methylene groups. As has been shown in Table I, the long-range coupling between phosphorus and proton through four bonds was observed in six pentavalent compounds but unresolved one in three trivalent compounds. The magnitude of the long-range coupling, $^4J_{PH}$, seems to increase in the order of P, PS and PO, while that of the $^3J_{PH}$ increases in the order of P, PO and PS; the effect of the substitution of oxygen by sulfur in the $^4J_{PH}$ is opposite to that in the $^3J_{PH}$. The substitution of an ethoxy group by chlorine causes the increase of the coupling constants both between phosphorus and methyl protons and between phosphorus and methylene protons. This kind of effect caused by some electronegative groups has been discussed by Hendrickson et al.,[1] but the long-range coupling between phosphorus and proton through four bonds has not yet been reported except some acetylenic compounds.[2] The coupling constants between protons in these compounds are almost constant. Another point of interest is that we can determine the relative sign of the coupling constants in this system using the double resonance technique. Preliminary results show $^3J_{PH}$ and $^4J_{PH}$ in $EtOPOCl_2$ (No. 4 in Table I) have the same relative sign. This was determined by partial irradiation of the methylene protons. Spectra were examined on the liquid containing a small amount of TMS as an internal reference. The proton and phosphorus resonances were observed at 60 and 24.288 Mc. p. s. respectively, using a Hitachi H-60 type spectrometer system.

The π-Type Conjugation in the Cyclopropylmethyl Cation

By Teijiro YONEZAWA, Hiroshi NAKATSUJI and Hiroshi KATO

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 5, 1966)

The high conjugative ability of the cyclopropyl group with an adjacent π orbital has been established experimentally[1] and theoretically.[2-4] For the cyclopropyl derivatives, Walsh predicted that this conjugation would be most effective when these compounds were in a "bisected" conformation (I in Fig. 1). Recently his prediction has been confirmed by Pittman and Olah through their NMR measurements.[1]

In the present paper, we will treat quantitatively the electronic structures of the two conformers, "bisected" (I) and "non-bisected" (II) (see Fig. 1), of the cyclopropylmethyl cation with our newly-developed semi-empirical ASMO-SCF method.[5] The geometry chosen for the cyclopropyl group is the same as that in cyclopropane, while the C_1–C_5 bond distance (in Fig. 1) is assumed to be 1.50 Å.

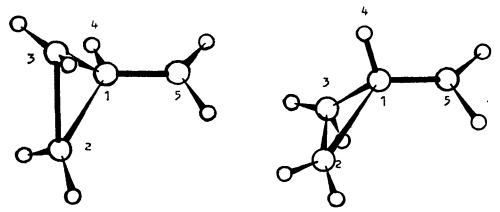

Fig. 1. The configurations of "bisected" (I) and "non-bisected" (II) conformers. In the I form, the atoms H_4, C_1 and the terminal CH_2 group are on the same plane, and in the II form the C_1–H_4 bond is perpendicular to the plane of the terminal CH_2 group.

TABLE I. THE ATOM AND AO BOND POPULATIONS IN CYCLOPROPYL GROUP

Compound	C_1–C_2	p_1–p_2	C_1–H_4	$p_{\sigma 1}$–h
Bisected (I)	0.585	0.309	0.847	0.523
Non-bisected (II)	0.650	0.378	0.785	0.464
Cyclopropane	0.651	0.367	0.839	0.539

The calculated total energies show that the I form is more stable than the II form by 0.813 eV. The π atomic orbital (AO) population of the C_5 atom is 0.443 in I and 0.280 in II. As to the atom bond population between the C_1 and C_5 atoms, the values are 1.015 in I and 0.924 in II, while the π AO bond populations are 0.203 in I and 0.113 in II; other π AO bond values obtained by the same method include 0.425 in ethylene, 0.114 in the ethyl cation, and -0.022 in ethane. Accordingly, it may be concluded that the π-conjugation in the I form is quite strong and that it contributes greatly to the stabilization of the I form.

The atom bond populations of C_1–C_2 and C_1–H_4 are collected in Table I, together with the corresponding values in cyclopropane. The table implies that the values of C_1–C_2 in the II form and of C_1–H_4 in the I form do not suffer much change, compared with the values in the cyclopropane, while remarkable changes do occur in C_1–C_2 in I and in C_1–H_4 in II. Further, in Table I, the sum of the AO bond populations between the three p AO's belonging to the C_1 and C_2 atoms, denoted by p_1–p_2 in Table I, and the value between the $p\sigma$ AO of the C_1 atom and the 1s AO of the H_4 atom ($p_{\sigma 1}$–h) are also indicated. Hence, the following conclusion may be drawn; the large changes in the atom bond population of C_1–C_2 in I and of C_1–H_4 in II are mainly caused by the changes in p_1–p_2 in I and in $p_{\sigma 1}$–h in II. As may be seen in Fig. 1, the p AO of the C_1 atom conjugating with the vacant π AO of the C_5 atom also participates in the C–C bonding in the I form and in the C–H bonding in the II form. Accordingly, the above-mentioned changes are largely due to the interactions between the p AO of the C_1 atom and the vacant π AO.

From the above discussions, it is clear that the stabilization in the I form arises mainly from π-type interaction between the vacant π AO of the sp^2 carbon and the π-like AO's in the ring carbons.

The transition energies for the first excitation may be evaluated as 6.60 eV. and 5.04 eV., and the oscillator strengths as 0.054 and 0.015, for I and II respectively. These transitions may be attributed to the intramolecular charge transfer from the cyclopropane ring to the vacant π AO of the sp^2 carbon.
