By putting the above values of $\mu_i^u=0.86\,D$ and $\alpha_i^u=163.1\times10^{-25}$ cm^3 into Eq. 1, the author has calculated the solvation energies and transition energies of acetone in all the solvents except acetonitrile; they are listed in Table II. The calculated frequency shifts in Table II are in good agreement with the observed shifts in Table I. The differences between the theoretical and the observed values are greater for the polar solvents than for the non-polar solvents. This is probably due to the use of Onsager's approximate expression[14] for the polar-solvent dipole moments. Table II shows that the excited states of acetone are more stabilized than the ground states in the non-polar solvents. These results are contrary to those obtained by Bayliss and McRae's theory.[3,4] According to their theory, the solvation energy in the excited state of acetone is less than the ground-state energy in a non-polar solvent, since the solute dipole moment decreases as a result of the transition. The discrepancy between the present results and Bayliss and McRae's theory seems to be due to the exclusion of the ground- and excited-state polarizabilities in their theory.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 939—944 (1966)

The Flotation of Cation by Cationic and Anionic Surfactants

By Norichika Aoki* and Tsunetaka Sasaki

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa-cho, Setagaya-ku, Tokyo

(Received September 11, 1965)

The ion flotation of a cation by a cationic surfactant with the aid of an anionic chelating agent was studied for the system of Fe^{3+} - ethylenediaminetetraacetic acid (EDTA) - octadecyldimethylammonium chloride (ODAC). The systems of Fe^{3+}-EDTA and Fe^{3+}-ODAC were also studied for purposes of comparison. The effects of the concentration of the above three components, the pH and the gas-flow time on the flotation efficiency were measured. The diagram of the flotation efficiency vs. the pH showed a W-shaped curve for the Fe^{3+}-EDTA-ODAC system, which was explained by the formation of Fe^{3+}-EDTA, Fe^{3+}-ODAC and Fe^{3+}-EDTA-ODAC complexes, each of which has a different optimum pH region of its formation. The flotation of a cation by an anionic surfactant was also studied using ferric, ferrous, silver and Malachite Green ions as cations and sodium dodecylsulfate (SDS) as an anionic surfactant. The flotation efficiency increased with the time of the gas flowing, except for the system of Fe^{3+}-SDS. Such an increase was explained by the relatively insoluble nature of the corresponding SDS salts.

* Present address: Technical Laboratory, Central Research Institute of Electric Power, 1229, Iwato, Komae-machi, Kitatama- gun, Tokyo.

Recently, the technique of the ion flotation or the foam fractionation** has been receiving increasing attention, from both the practical and the theoretical points of view,[1] due chiefly to their remarkable efficiency in ion separation and concentration in dilute aqueous solutions. In the usual practice of ion flotation, ions in a solution are collected by the foam produced by an ionic surfactant of the charge opposite to that of the ion to be floated.[2] Thus, metallic cations are floated, for instance, by sodium dodecylsulfate (SDS). However, the possibilities have not yet been fully studied of floating ions by an ionic surfactant of the same sign, with or without the addition of a chelating agent or "collector" electrolyte which has the electric charge opposite in sign to both of them and so acts as a bridging ion between the surfactant and the metallic ions.

The present paper will describe the results of an ion flotation study from such a point of view, a study chiefly of the Fe^{3+} - ethylendiaminetetraacetic acid (EDTA) - octadecyldimethylammonium chloride (ODAC) system. The ordinary ion flotation of a cation by an anionic surfactant will also be studied for the sake of comparison.

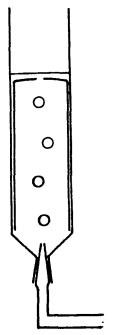

Fig. 1B. Ion flotation apparatus for unstable foam.

Experimental

Materials.—Cations used for separation: ferric and ferrous ions as sulfates, silver ion as nitrate, and Malachite Green ion as the corresponding dye salt.

Chelating agent used as a collector: ethylenediaminetetraacetic acid (EDTA).

Foaming agents: octadecyldimethylammonium chloride (ODAC) and sodium dodecylsulfate (SDS).

The ferric, ferrous and silver salts were purified by recrystallization, while the rest of the reagents of chemically-pure grade were used without purification.

Apparatus and Procedure.—The apparatus used in the foam separation experiment is shown in Fig. 1A. By means of a circulation pump, A, air moistened by passing it through the chamber, B, filled with wet cotton wool was introduced, at room temperature (20—25°C) into 50 cc. of the sample solution contained in the cell, D (32 cm. long and 2.5 cm. in diameter), from the the tip, C, about 0.3 mm. in diameter. The rate of gas flow was kept at 1.04 cc./sec. The gas-flow time was kept at 10 min. unless otherwise stated. The foam thus produced was made to overflow and was collected in the chamber, E, where it was cooled by a freezing mixture, F, to about −8°C and thus collapsed. The volume of the collapsed foam was usually about 0.7 cc. for 10 mins' foaming. The concentration of the cation in this solution was determined as follows.

Ferric and ferrous ions: Concentrated sulfuric acid and nitric acid were added to the liquid, and the mixture was heated to destroy the organic matter. The ferric ion was then reduced to the ferrous ion by hydroquinone, and after o-phenanthroline had been added, the ferrous ion concentration was determined at a pH value of about 4.5 by the light absorption at 508 Å, using a Beckmann spectrophotometer.

Malachite Green ion: The light absorption was measured at 615 Å, using a Beckmann spectrophotometer.

Silver ion: The concentration was determined by potentiometry using a cell consisting of a calomel electrode and a silver electrode. The foaming agent present did not interfere with the measurement.

The Efficiency of Ion Flotation.—The efficiency of ion flotation may be differently expressed according to whether we refer to the separation, the purification, the extraction or the concentration of ions in question. In the present case, we are chiefly interested in the concentration of cations. Therefore, the efficiency may be conventionally expressed by the ratio:

$$R = X/Y$$

where X is the concentration of ions in the solution obtained by collapsing the foam, and Y, the concentration of the same ions in the initial sample solution.

Results and Discussion

Numerous factors, such as the nature and concentration of the collector, the foaming agent, the ions to be floated and other additives, the time and rate of gas-flow, the temperature of the solution and the construction of the flotation cell, influence the efficiency of ion flotation. Of these,

** Some authors distinguish these two processes according to whether the separation or fractionation of the solutes occurs exclusively on bubbles in a solution or chiefly on films of foam upon a solution. In the present paper, however, the term "ion flotation" will be used for the sake of the brevity and convenience, though the process adopted is actually a case of foam fractionation.

several factors have been taken up and studied.

The Flotation of Ferric Ions by ODAC.—*The Effect of the Ferric Ion Concentration.*—Figure 2 shows the effect of the ferric ion concentration upon the flotation efficiency, R, for the Fe^{3+}-EDTA-ODAC system at constant ODAC and EDTA concentrations, and at a constant rate and time (10 min.) of gas-flow. It may be seen that R increased from 16 to 160 with the decrease in the ferric sulfate concentration from 7×10^{-5} mol./l. to 7×10^{-6} mol./l. This is in accord with the general trend of ion flotation.[3] By 10 mins' gas flowing, about 54% of the ferric ions in 50 cc. of the 7×10^{-6} mol./l. initial solution was removed and concentrated in about 0.17 cc. of foam.

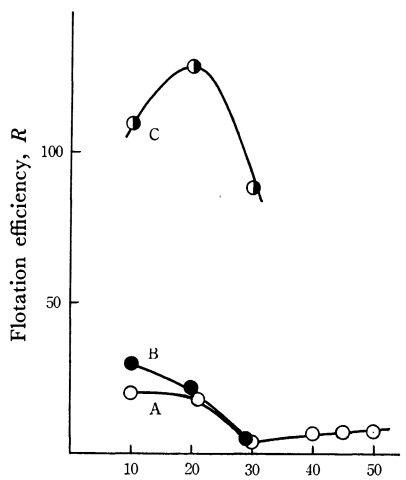

Fig. 3. Flotation efficiency vs. gas flowing time for Fe^{3+}-EDTA-ODAC system.

The Effect of the Time of the Gas-Flow.—Figure 3 shows the relation between the time of gas-flow and R at constant concentrations of ODAC, EDTA and ferric ions. We can see in this figure that the overall (integrated) value of R decreased with the increase in the gas-flow time. Further, a marked increase in R with the dilution of ferric ions can be confirmed. The value of $R=150$ for 20 mins' gas flowing in a 5×10^{-6} mol./l. ferric sulfate solution corresponds to a complete removal of ferric ions from the solution by foaming. These facts again agree with the general tendency of the ion flotation.[3]

The Effect of the Collector Concentration.—Figure 4 shows the effect of the collector concentration of

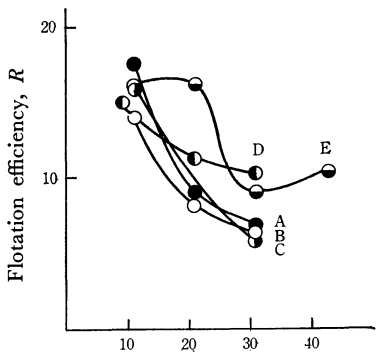

Fig. 4. Flotation efficiency vs. gas flowing time for Fe^{3+}-EDTA-ODAC system.
ODAC 3.3×10^{-4} mol./l., Fe^{3+} 6.4×10^{-5} mol./l.

R when the rest of the conditions were held constant. As may be seen in this figure, the effect of the EDTA concentration is not very distinct at 10 mins' gas flowing, while the increase in R can be confirmed with increasing concentrations of EDTA at 30 mins' gas flowing. Here, it should be noticed that no small value of R is confirmed even when the concentration of EDTA is zero. This is rather unexpected, since it is a case of cation flotation by a cationic surfactant, just the opposite of the usual case of ion flotation by an oppositely charged surfactant. This will be discussed in detail in a later section.

The Effect of the Surfactant Concentration.—Since the existence of EDTA did not seem to be essential, measurements were made for the effect of the surfactant concentration on the flotation of ferric

ions from the solution without the addition of EDTA. The results are shown in Fig. 5. We can see in this figure that R does not change appreciably over a wide range of ODAC concentration, except for a zero concentration, and presumably beyond the critical micelle concentration, where R steeply falls to a small value. In the case of the measurement at a zero concentration of ODAC, a flotation cell as is shown in Fig. 1B was used, since the foam produced was very unstable. This cell separated the surface zone of the solution from its bulk by a diaphragm with a small opening in its center which allowed the passage of bubbles. The bubbles bursted on the surface of the solution, leaving the surface layer rich in the solute, which was then prevented from mixing with the interior of the solution. After the gas had flowed, the surface layer was taken for the determination of the concentration,

and the R value was calculated. Thus the value of 1.5 was obtained. Strictly speaking, the value obtained here cannot be plotted on the same scale as those obtained by the former method, but it may be used for the purpose of comparison with other data as a whole.

The Effect of the pH.—In all the above experiments, the pH of the solution was not especially controlled: it was about 4. Now, aqueous ferric sulfate solutions containing ODAC and/or EDTA varying in pH value were studied. The results are shown in Fig. 6. In this experiment, the pH of the solution was controlled by using hydrochloric acid and sodium hydroxide.
The measurement of the R value for the Fe^{3+}-EDTA system was made by using the apparatus shown in Fig. 1B.

It may be seen in Fig. 6 that the systems containing both EDTA and ODAC show R values larger than those containing ODAC alone in the regions of pH higher than about 8 and lower than 6. Between pH 6 and 8, the difference in R value between both systems is not distinct. The latter system shows a maximum R value at about pH 6. This maximum may be explained as the optimum pH region of the formation of a coordination compound consisting of ferric ions and free octadecyldimethylamine, as was pointed out by Sebba.[4] The system containing EDTA alone shows a smaller value of R than these two systems, though the comparison is somewhat qualitative in this case.

Let us now attempt to explain the change in flotation efficiency with the pH value for the Fe^{3+}-EDTA-ODAC system. It can readily be seen from the coincidence of the maximum of R between the Fe^{3+}-ODAC system and the Fe^{3+}-EDTA-ODAC system in Fig. 6, that the flotation of Fe in the latter system near pH 6 is mainly due to the formation of the Fe^{3+}-ODAC complex, while the flotation of Fe in a low pH region is considered to be due to the formation of both Fe^{3+}-ODAC and Fe^{3+}-EDTA complexes, as is expected from the R values of these systems. As for the explanation of the large increase in R for the Fe^{3+}-EDTA-ODAC system in an alkaline region, the flotation of Fe by Fe^{3+}-ODAC and Fe^{3+}-EDTA interaction seems insufficient. Here, we may conceivably take account of Fe^{3+}-EDTA-ODAC linkage, since the interaction between EDTA and ODAC is expected to show a broad optimum in an alkaline region, considering the rather strongly basic nature of ODAC.

Thus, we can explain the total flotation effect of Fe over a wide range of pH by the above three interactions of Fe^{3+}-ODAC, Fe^{3+}-EDTA and Fe^{3+}-EDTA-ODAC. The so-called sublate salt formation insisted on by Sebba[4] is not marked in this system, since the interaction between Fe

and the surfactant is rather weak in a low pH region, contrary to his case. A slight increase in R in the acid region may be due to the formation of a simple compound of Fe^{3+}-ODAC, together with Fe^{3+}-EDTA, as has been mentioned above. The co-operating action of ODAC and EDTA in the flotation, especially in the alkaline region, would correspond to the action of polyaminopolycarboxylic acid, which is known to be effective in ion flotation.[5] This may suggest that the functional radicals of the collecting and frothing actions need not coexist in a single molecule, but that they can exist in separate molecules in a mixed solution, to show an effective ion flotation. This would open many possibilities in the practice of the choice of flotation agents.

The Flotation of Ferric, Ferrous, Silver and Malachite Green Ions by SDS.—The effect of the gas-flow-time on aqueous Fe^{3+}-SDS, Fe^{2+}-SDS, Ag^{+}-SDS and Malachite Green - SDS systems is shown in Figs. 7, 8 and 9. It may be seen in these figures that the values of R do not decrease, but rather increase, with time, except for the case of Fe^{3+}-SDS, which exhibits a decrease similar to that of the Fe^{3+}-ODAC system (cf. Fig. 4). This increase may come from the relatively insoluble nature of the corresponding SDS salts, the flotation of which is largely independent of the concentration of the cation to be floated. The increase in R with the gas-flow time is especially marked in the case of the Ag^{+}-SDS system, which forms an insoluble salt and an unstable foam. The effect of the concentration of the cation to be floated upon R was examined for ferric and ferrous ions, as may be seen in Figs. 7 and 8. The

results were somewhat irregular for ferric ions, but a trend similar to that in the case of the Fe^{3+}-EDTA-ODAC system was seen for ferrous ions.

The effects of the pH on Fe^{3+}-SDS and Fe^{3+}-SDS systems are shown in Fig. 10. The values of *R* for both systems are large in the region of low pH, but they decrease rapidly with an increase in the pH value, reaching zero near pH 4—5 in the former system and near pH 7 in the latter system. This fact was also inferred by Sebba.[6] It may be explained by the lower solubility of ferric than that of ferrous hydroxide. In fact, in the solutions near the above pH's, white precipitates appeared and the foam became very unstable.

The authors wish to express their thanks to Mr. M. Nakamura of our laboratory for his assistance in this work. They also thank the Ministry of Education for the Scientific Research Expenditure Grant given to facilitate the present work.

Photo-induced Reactions. III.[1),*1] The Synthesis of Biphenyls from Aromatic Bromo-Compounds

By Teruo MATSUURA and Kanji OMURA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September, 13, 1965)

Various bromobenzene derivatives were irradiated in benzene with a low-pressure mercury lamp. The corresponding biphenyl derivatives were formed as the main products. A mechanism for the reaction has been discussed.

In 1961, Wolf and Kharasch briefly reported that, when aromatic iodo-compounds were irradiated with ultraviolet light (2537 Å) in aromatic solvents, the corresponding biphenyl derivatives were obtained in synthetically useful yields.[2)] This reaction has since been applied to various iodo-compounds, including some aliphatic iodides. The primary reaction in the irradiation of iodo-compounds is now recognized to be a homolytic cleavage of the carbon-iodine bond.[3-7)] Such a homolytic cleavage also occurs in the photolysis of aromatic bromo-compounds.[7-10)] However, no synthetic applications have yet been undertaken.

We have carried out the photolysis of bromobenzene derivatives under conditions similar to those used by Wolf and Kharasch. When a 0.05 molar solution of bromobenzene in benzene was irradiated with a low-pressure mercury lamp (quartz) under bubbling nitrogen, biphenyl was obtained in a 40% yield, in addition to a non-volatile material which was assumed to be a mixture of polymers. Various bromobenzene derivatives were also photolyzed under the same conditions, and the products were either analyzed by vapor-phase chromatography or isolated. The results are summarized in Table I. In Experiments 1, 2, 5, 6, 7 and 10, the corresponding biphenyl derivatives were obtained in 30—40% yields, while *p*-bromoacetophenone (Exp. 9) gave 4-acetylbiphenyl in a lower yield. This is probably due to the presence of a carbonyl group which is photochemically reactive and which gives rise to side reactions.

The photolysis of *p*-bromoaniline (Exp. 8) and *m*- and *p*-bromonitrobenzene (Exps. 11 and 12) in benzene yielded no biphenyl derivative, but a large amount of the starting substance was recovered unchanged; also a small amount of a non-volatile material was formed.

The photolysis of *p*-bromophenol, *p*-bromoacetophenone and methyl *p*-bromobenzoate resulted in the reduction of the carbon-bromine bond, in addition to the formation of the corresponding biphenyls. Phenol, acetophenone, and methyl benzoate were respectively, detected in the reaction

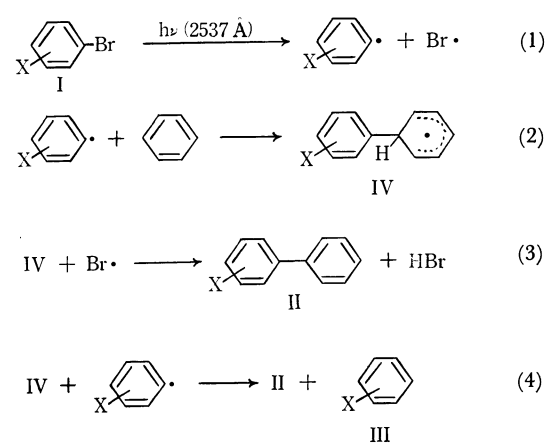
a) A solution of I (0.01 mol.) in benzene (200 ml.) was irradiated with a 40 W. low-pressure mercury lamp (quartz) under bubbling nitrogen, unless otherwise indicated.
b) Yields were based on the reacted I.
c) Irradiation was made with a 40 W. low-pressure mercury lamp (Vycor).
d) During irradiation oxygen was bubbled instead of nitrogen.
e) A solution of bromobenzene (0.02 mol.) in benzene (450 ml.) was irradiated with a 450 W. high-pressure mercury lamp with a pyrex jacket.

mixture. On the other hand, the corresponding reduction products could not be detected in the photolysis of bromobenzene, *p*-bromoanisole, or *p*-bromotoluene. In the case of bromobenzene the detection of benzene, which may be formed in the course of the reaction, is not possible. It is assumed that, in other cases, the corresponding reduction products might be formed in such small quantities that they could not be detected.

When the photolysis of bromobenzene in benzene was carried out with a low-pressure mercury lamp made of a Vycor tube in order to cut off short wavelength lights below about 220 mμ, biphenyl was obtained in a similar yield and the yield of the non-volatile products was slightly depressed. On the other hand, when the irradiation was made with a high-pressure mercury lamp using a pyrex filter which cut off lights below about 290 mμ, the reaction proceeded much more slowly and biphenyl was formed in only a small yield. The above results show that the reaction is initiated mainly by light near 2537 Å, which is known to be the most effective point of the light of a low-pressure mercury lamp.

A possible mechanism for the formation of biphenyls from bromobenzenes and benzene is shown by Eqs. 1—4.

The starting bromo-compound dissociates into a corresponding phenyl radical and a bromine atom by an ultraviolet light of 2537 Å (Eq. 1). The phenyl radical then attacks the solvent, benzene, to form a radical intermediate (IV) (Eq. 2). The last step of the reaction involves a hydrogen abstraction from the intermediate (IV) by either the bromine atom or the phenyl radical (Eqs. 3 and 4). Thus, a biphenyl derivative is formed simultaneously with the formation of a benzene derivative or hydrogen bromide respectively. This mechanism is supported by the findings that corresponding benzene derivatives were isolated in the photolysis of *p*-bromophenol (Exp. 5), *p*-bromoacetophenone (Exp. 9) and methyl *p*-bromobenzoate (Exp. 10), and that the liberation of hydrogen bromide was observed only when biphenyl derivatives were formed. In fact, hydrogen bromide was obtained in a 20% yield in the photolysis of bromobenzene in benzene.



Experimental

The melting points were determined in capillary tubes and were uncorrected. The infrared spectra were taken with a Nihon Bunko spectrophotometer, Model IR-S. The starting materials were commercially available, unless otherwise indicated, and their purities were checked by a melting point determination or by vapor-phase chromatography. The products were analyzed by vapor-phase chromatography under the following conditions: stationary phase, silicone DC 550 on celite; carrier gas, helium; gas pressure, 0.8 kg./cm^2.

The Photolysis of Bromobenzene.—Exp. 1.—A solution of 1.57 g. (0.01 mol.) of bromobenzene in 200 ml. of benzene was placed in a cylindrical vessel, into which a 40 W. low-pressure mercury lamp (quartz-made, unless otherwise indicated) was then inserted. During irradiation, a stream of nitrogen was bubbled through a sintered-glass disk jointed at the bottom of the vessel, which was cooled with tap water. The exhausted gas was then passed through ice-cooled water in order to trap the hydrogen bromide liberated from the reaction mixture. The aqueous solution was neutralized with 18.20 ml. of an aqueous 0.1 N sodium hydroxide solution. The yield of hydrogen bromide was calculated as 19.8% on the basis of the reacted bromobenzene. After being irradiated for 20 hr., the solvent was removed under reduced pressure and the residual liquid was distilled to yield 0.79 g. of a semi-solid, which boiled below 110°C/14 mmHg, and 0.39 g. of a non-volatile material. Vapor-phase chromatography of the semi-solid showed that it consisted of 0.13 g. (8.3%) of the starting material recovered, 0.57 g. (40%) of biphenyl, and 0.09 g. of an unknown product. The recrystallization of the semi-solid from methanol gave colorless crystals, m. p. 66—68°C, whose infrared spectrum was identical with that of an authentic sample of biphenyl.

Exp. 2.—Brombenzene was irradiated with a 40 W. low-pressure mercury lamp (Vycor), and the reaction mixture was treated in the way described in Exp. 1. The results are shown in Table I.

Exp. 3.—Bromobenzene was photolyzed as has been described in Exp. 1, except that the solution was bubbled with oxygen instead of nitrogen. The results are shown in Table I.

Exp. 4.—A solution of 3.14 g. (0.02 mol.) of bromobenzene in 450 ml. of benzene was irradiated for 10.5 hr. with a 450 W. high-pressure mercury lamp surrounded with a water-cooled pyrex jacket. The results are shown in Table I.

The Photolysis of *p*-Bromophenol (Exp. 5).—A solution of 1.73 g. of *p*-bromophenol in 200 ml. of benzene was photolyzed. The distillation of the products yielded three fractions; (i) 0.74 g. of a liquid, b. p. 40—78°C/28 mmHg, which was found by vapor-phase chromatography to consist of 0.68 g. of *p*-bromophenol and 0.06 g. of phenol; (ii) 0.33 g. of a solid, b. p. 90—110°C/16 mmHg, and (iii) 0.44 g. of a non-volatile material. The recrystallization of the fraction ii from benzene and cyclohexane gave 4-hydroxybiphenyl as crystals, m. p. 163—164°C. Lit. m. p. 163°C.[11]

The Photolysis of *p*-Bromoanisole (Exp. 6).—A solution of 1.88 g. of *p*-bromoanisole in 200 ml. of benzene was irradiated. The distillation of the products yielded three fractions: (i) 0.49 g. of a liquid, b. p. 30—70°C/6 mmHg, a preparative vapor phase chromatography of which, gave 0.16 g. of *p*-bromoanisole (ii) 0.64 g. of a solid, b. p. 72—105°C/6 mmHg, which showed only one peak in its vapor-phase chromatography and which was recrystallized from ethanol to give 4-methoxybiphenyl as colorless crystals, m. p. 86—87.5°C (lit. m. p. 89°C[12]), and (iii) 0.39 g. of a non-volatile material.

The Photolysis of *p*-Bromotoluene (Exp. 7).—A solution of 1.71 g. of *p*-bromotoluene in 200 ml. of benzene was irradiated. The distillation of the products yielded three fractions: (i) 0.32 g. of a liquid, b. p. 52—80°C/9 mmHg, which was found by vapor-phase chromatography to contain 0.27 g. of *p*-bromotoluene; (ii) 0.55 g. of a semi-solid, b. p. 82—102°C/9 mmHg, which was recrystallized from methanol to give 4-methylbiphenyl, m. p. 44—50°C (lit. m. p. 47.7°C[13]), and (iii) 0.36 g. of a non-volatile material.

The Photolysis of *p*-Bromoaniline (Exp. 8).—A solution of 1.73 g. of *p*-bromoaniline in 200 ml. of benzene was irradiated. During this irradiation brown materials were deposited on the surface of the lamp tube. The reaction mixture was then washed with an aqueous sodium hydroxide solution, dried over anhydrous sulfate, and evaporated. The distillation of the residual liquid yielded two fractions: (i) 0.99 g. of a solid, b. p. 90—106°C/15 mmHg, whose infrared spectrum was identical with that of *p*-bromoaniline, and (ii) 0.16 g. of a non-volatile material.

The Photolysis of *p*-Bromoacetophenone (Exp. 9).—A solution of 1.99 g. of *p*-bromoacetophenone in 200 ml. of benzene was irradiated. The distillation of the products yielded three fractions; (i) 0.24 g. of a semi-solid, which was found by vapor-phase chromatography to consist of 87 mg. of acetophenone and 105 mg. of *p*-bromoacetophenone; (ii) 0.44 g. of colorless crystals, which showed one peak in its vapor-phase chromatography and which were recrystallized from benzene and methanol to give 4-acetylbiphenyl as crystals, m. p. 119—121°C (lit. m. p. 120.5°C[14]), and (iii) 0.98 g. of a non-volatile material.

The Photolysis of Methyl *p*-Bromobenzoate (Exp. 10).—A solution of 1.50 g. (0.007 mol.) of the methyl ester[15] in 200 ml. of benzene was irradiated. The distillation of the products yielded three fractions: (i) 0.24 g. of a yellow liquid, whose infrared spectrum was identical with that of methyl benzoate; (ii) 0.52 g. of a solid, m. p. 98—114°C, which was recrystallized from ethanol to give methyl *p*-phenylbenzoate as colorless crystals, m. p. 115—116°C (lit. m. p. 117.5°C[16]), and (iii) 0.56 g. of a non-volatile material.

The Photolysis of *p*-Bromonitrobenzene (Exp. 11).—A solution of 2.02 g. of *p*-bromonitrobenzene in 200 ml. of benzene was irradiated. The distillation of the products yielded two fractions: (i) 1.48 g. of crystals, b. p. below 66°C/ca. 1 mmHg and m. p. 117—123°C, which were recrystallized from methanol to give

t-Amyloxycarbonyl as a New Protecting Group in Peptide Synthesis. II. Synthesis of a Hexapeptide Amide Related to Eledoisin by the *t*-Amyloxycarbonyl Method

By Shumpei SAKAKIBARA and Masahiko FUJINO*

Peptide Center, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received September 17, 1965)

The synthesis of a hexapeptide amide, L-lysyl-L-phenylalanyl-L-isoleucylglycyl-L-leucyl-L-methionine amide, has been carried out as a demonstration of the *t*-amyloxycarbonyl method. This peptide is known to possess strong biological activity which is similar to that of eledoisin and bradykinin. During the synthesis, no complication occurred involving the *t*-amyloxycarbonyl group, and the final product had the expected activity. Therefore, it is considered that the *t*-amyloxycarbonyl method is useful for the synthesis of complicated peptides.

In the preceding paper,[1] the syntheses and properties of *t*-amyloxycarbonyl (AOC) amino acids were reported, and it was suggested that the use of the AOC *N*-protecting group should be valuable in peptide synthesis, because this group has similar properties to the *t*-butoxycarbonyl (BOC) group and preparation of AOC-amino acids is as easy as that of carbobenzoxy derivatives. In the present work, a hexapeptide amide (X), L-lysyl-L-phenylalanyl-L-isoleucylglycyl-L-leucyl-L-methionine amide, was synthesized to test the efficiency of the AOC-method, and a part of the compound was also synthesized by the classical method for comparison.

The syntheses of eledoisin and its analogues have already been reported by many workers,[2,3] and the hexapeptide amide X was found by Bernardi et al.[3] to possess high biological activity. In those works, mentioned above, the BOC-method was used for the synthesis together with the carbobenzoxy group to avoid an undesirable side reaction with the methionine residue. In the present work, di-AOC-lysyl-phenylalanyl-isoleucyl-glycine (IV) was first prepared from glycine benzyl ester by the stepwise elongation method[4] as shown in Scheme 1.

Scheme 2.

During the synthesis shown in Scheme 1, no complications occurred in relation to the AOC-group; that is, removal of the AOC-groups with trifluoroacetic acid was almost quantitative, as was expected, and the crystallizability of the product at each step was quite satisfactory. On the other hand, trouble arose over the last stage of Scheme 2, and saponification of the ester group in the AOC-tetrapeptide ethyl ester (IIIb) gave only a colored product with a low melting point. Further, AOC-leucyl-methionine amide (VI) was prepared without any trouble by the active ester method, as shown in Scheme 3, and then compound VI was converted to leucyl-methionine amide (VII) using 2N hydrogen chloride in acetic acid. Condensation of the AOC-tetrapeptide IV with dipeptide amide VII was carried out using *p*-nitrophenyl trifluoroacetate as the condensing reagent according to the description of Sakakibara and Inukai.[5] In this case, AOC-tetrapeptide *p*-nitrophenylester was isolated and then coupled with compound VII (Scheme 3). Finally, the protected hexapeptide amide IX obtained was treated with 2 N hydrogen chloride in acetic acid to get the hexapeptide amide X, and it was confirmed that the removal of the AOC-groups was as smooth as that of BOC groups.

The homogeneity of the resulting hexapeptide amide X was judged by paper chromatography and by paper electrophoresis, and no contamination was detected by those procedures. The amino acid ratio in the acid hydrolyzate of compound X was determined using an automatic amino acid analyzer, and the result was also quite satisfactory. Furthermore, it was found that this compound was completely digestible by leucine aminopeptidase to give the expected amount of each amino acid, indicating that no racemization occurred during the synthesis. The biological activity of compound X was determined by the contraction test with guinea-pig ileum,[6] and the activity was 2.5 times higher than that of bradykinin which was prepared in this laboratory.[7] In conclusion, it can be asserted that the AOC method is useful in place of the BOC method for synthesis of complicated peptides.

Incidentally, during the course of the synthesis, carbobenzoxy-L-isoleucine was obtained as crystals for the first time in this laboratory.[8] Of the many carbobenzoxy derivatives of common L-amino acids, carbobenzoxy-L-leucine and this material were thought not to be crystallizable and, moreover, commercially available L-isoleucine used to be contaminated with *allo*-isoleucine and with leucine. Therefore, the crystallization of carbobenzoxy-L-isoleucine is a great advantage in the

purification of this compound. The purity of the crystallized product and an oily material which was obtained from the mother liquor after recrystallization were tested with an automatic amino acid analyzer after removal of the *N*-protecting group, and only a trace of contamination was detected in the crystallized product, whereas the *allo*-isoleucine and leucine contaminating the original material were both found to be concentrated in the oily residue.

Experimental*

Crystallization of Carbobenzoxy-L-isoleucine.[8] —Crude carbobenzoxy-L-isoleucine, which was prepared from L-isoleucine[9] (131 g., 1 mol.) by the usual procedure, was purified once by sodium bicarbonate extraction, and then the oily material was treated with petroleum ether (60—80°C) at −20°C. After each extraction the upper layer was discarded, and the inside-surface of the vessel was scratched with a glass bar under fresh petroleum ether at −20°C. Then the mixture was stored in a deep freezer for about one week and a small crop of crystals were obtained in the syrup. The remaining oil was then crystallized completely by triturating the crystals thoroughly and then storing them again in the deep freezer for two or three more days. If crystal-seed is available, crude material can be crystallized directly by triturating it with the seeds at −20°C. The crude crystals thus obtained were collected by filtration at −20°C using a pre-cooled funnel. Then, the product was dissolved in a mixture of toluene (250 ml.) and petroleum ether (250 ml.), and the solution was seeded with a few crystals and kept in a deep freezer. After one or two days, about 30% of the compounds separated as crystals, while the rest separated as an oil. Then, the mixture was gradually warmed to room temperature to re-dissolve the oily part, the crystals were triturated well, and the mixture was restored in the deep freezer. After two more days, this procedure was repeated, and finally the crystals formed were collected by filtration. Filtration, washing and drying procedures in vacuo were carried out at below 10°C, and the yield of dried crystals was about 60% (157 g.); m. p. 44—46°C, $[\alpha]_D^{26}$ +6.5° (*c* 6, ethanol).

Found: C, 63.48; H, 7.24; N, 5.25. Calcd. for $C_{14}H_{19}O_4N$: C, 63.38; H, 7.22; N, 5.28%.

***t*-Amyloxycarbonyl-L-isoleucylglycine Benzyl Ester (Ia).**—A solution of *t*-amyloxycarbonyl-L-isoleucine (4.92 g., 0.02 mol.) in tetrahydrofuran (40 ml.) was cooled to −5°C, and dicyclohexylcarbodiimide (4.12 g., 0.02 mol.) was added to the solution with stirring. After about 10 min., a solution of glycine benzyl ester tosylate (6.74 g., 0.02 mol.) and triethylamine (2.8 ml., 0.02 mol.) in chloroform (20 ml.) was added to the reaction mixture. The mixture was allowed to react for one hour at −5°C, and then for additional 10 hr. at 10°C. Dicyclohexylurea formed was removed by filtration, and the filtrate was concentrated to syrup which was dissolved again in ethyl acetate (100 ml.). Then, the solution was washed thoroughly with 0.5 N hydrochloric acid, 5% sodium bicarbonate and water, and the washed solution was dried over anhydrous sodium sulfate. The dried solution was then concentrated to syrup, and the residue was redissolved to a mixture of ethyl acetate (5 ml.) and petroleum ether (60—80°C, 40 ml.) to precipitate a small amount of insoluble materials which was filtered off. The final solution was concentrated to dryness, and the residue was crystallized gradually as colorless needles. Recrystallization from a mixture of ether (1 ml.) and petroleum ether (30 ml.) gave 5.0 g. (67%) of product; m. p. 68—70.5°C, $[\alpha]_D^{22}$ −25.7° (*c* 2.0, methanol).

Found: C, 64.28; H, 8.32; N, 7.09. Calcd. for $C_{21}H_{32}O_5N_2$: C, 64.26; H, 8.22; N, 7.14%.

Carbobenzoxy-L-isoleucylglycine Ethyl Ester (Ib).—Carbobenzoxy-L-isoleucine *p*-nitrophenyl ester[4] (3.86 g., 0.01 mol.) was dissolved in a solution of glycine ethyl ester hydrochloride (1.39 g., 0.01 mol.) and triethylamine (1.4 ml., 0.01 mol.) in chloroform (20 ml.), and the mixture was allowed to react at room temperature for 20 hr. The solvent was distilled off in vacuo, and the residue was dissolved in ethyl acetate. The ethyl acetate solution was washed well with N ammonia, N hydrochloric acid and water. After drying it over anhydrous sodium sulfate, the solvent was removed by distillation under reduced pressure and the product was obtained as crystals; wt. 3.20 g. (91%), m. p. 150—152°C. Recrystallization from ethyl acetate (25 ml.) gave 2.8 g. (87%) of product; m. p. 153.5—154.5°C, $[\alpha]_D^{24}$ −26.0° (*c* 1, acetic acid); Bernardi et al.[10] reported m. p. 156—159°C.

Found: C, 62.01; H, 7.38; N, 8.06. Calcd. for $C_{18}H_{26}O_5N_2$; C, 61.70; H, 7.48; N, 8.00%.

***t*-Amyloxycarbonyl-L-phenylalanyl-L-isoleucylglycine Benzyl Ester (IIa).**—Compound Ia (4.32 g., 0.011 mol.) was dissolved in anhydrous trifluoroacetic acid (10 ml.) and the solution was allowed to stand at room temperature for 20 min. The trifluoroacetic acid was then evaporated off in vacuo, and the remaining oil was dried by flushing with toluene followed by storage over sodium hydroxide in vacuo. The residue was dissolved in dimethylformamide (25 ml.), neutralized with triethylamine (1.6 ml., 0.011 mol.) and subjected to reaction with AOC-L-phenylalanine *p*-nitrophenyl ester[1] (4.4 g., 0.011 mol.). After standing overnight at room temperature, the solution was diluted with water (60 ml.) to precipitate the product as crystals which were separated by filtration, washed well with N ammonia and with water, and dried; wt. 5.84 g. (98%). The crude material was recrystallized from 60% methanol; wt. 4.85 g. (81%), m. p. 142—144°C, $[\alpha]_D^{22}$ −13.8° (*c* 1.9, dimethylformamide), −33.3° (*c* 2, methanol.)

Found: C, 66.65; H, 7.82; N, 7.87. Calcd. for $C_{30}H_{41}O_6N_3$: C, 66.77; H, 7.66; N, 7.79%.

Carbobenzoxy-L-phenylalanyl-L-isoleucylglycine Ethyl Ester (IIb).—Compound Ib (3.5 g., 0.01 mol.) was treated with 31% hydrogen bromide in acetic acid (10.8 g.) for 40 min., and the product was precipitated by adding dry ether (150 ml.) to the reaction mixture. The separated product was washed with ether by decantation, and dried over sodium hydroxide in vacuo.

* All melting points given are uncorrected.

9) This material was obtained from Tanabe Pharmaceutical Co., Ltd., Osaka.

10) L. Bernardi, G. Bosisio, R. De Castiglione, O. Goffredo and F. Chillemi, *Gazz. Chim. Ital.*, 853 **94**, (1964).

The dried powder was dissolved in dimethylformamide, and triethylamine (1.80 ml.) was added to the solution. The triethylamine hydrobromide formed was filtered off, and the filtrate was subjected to reaction with carbobenzoxy-L-phenylalanine *p*-nitrophenyl ester (4.0 g., 0.01 mol.) for 24 hr. at room temperature. Water (100 ml.) was added to the mixture, and crystalline precipitates which appeared were filtered, washed well with N ammonia, and dried. The product was recrystallized from ethanol; wt. 3.9 g. (78%), m. p. 179.5—180.5°C, $[\alpha]_D^{24}$ −21.0° (*c* 1.7, acetic acid). Bernardi et al.[10] reported m. p. 175—176°C.

Found: C, 65.31; H, 6.90; N, 8.31. Calcd. for $C_{27}H_{33}O_6N_3$: C, 65.44; H, 6.71; N, 8.48%.

Di-*t*-amyloxycarbonyl-L-lysyl-phenylalanyl-L-isoleucylglycine Benzyl Ester (IIIa).—Compound IIa (3.78 g., 0.007 mol.) was dissolved in anhydrous trifluoroacetic acid (8 ml.), and the solution was allowed to stand at room temperature for 25 min. The trifluoroacetic acid was then evaporated to dryness in vacuo, and the residue was treated with a mixture of ether and petroleum ether to obtain crystals. The supernatant was removed by decantation, and the product was dried over sodium hydroxide in vacuo at room temperature; wt. 3.75 g., m. p. 202—203°C. This material was dissolved in dimethylformamide (30 ml.), neutralized with triethylamine (0.93 ml.) and then subjected to reaction with di-AOC-L-lysine *p*-introphenyl eater[1] (3.22 g., 0.0065 mol.). After standing overnight at room temperature, the solution was diluted with water (50 ml.) to precipitate the product, which was separated by filtration, washed well with N ammonia and with water, and dried. The product was recrystallized from 60% ethanol; wt. 4.47 g. (88%), m. p. 151—152°C, $[\alpha]_D^{22}$ −17.5° (*c* 2, dimethylformamide).

Found: C, 64.78; H, 8.13; N, 8.85. Calcd. for $C_{42}H_{63}O_9N_5$: C, 64.50; H, 8.12; N, 8.95%.

Di-*t*-amyloxycarbonyl-L-lysyl-L-phenylalanyl-L-isoleucylglycine Ethyl Ester (IIIb).—Compound IIb (1.25 g., 0.0025 mol.) was treated with 31% hydrogen bromide in acetic acid (2.6 g.) for 40 min., and the product was precipitated by adding dry ether (70 ml.) to the reaction mixture. It was separated by decantation, washed well with dry ether and dried over sodium hydroxide in vacuo. The dried powder was dissolved in dimethylformamide, and then triethylamine (0.38 ml.) was added to the solution. The triethylamine hydrobromide formed was filtered off, and the filtrate was subjected to reaction with di-*t*-amyloxycarbonyl-L-lysine *p*-nitrophenyl ester[1] (1.24 g., 0.0025 mol.) for 24 hr. at room temperature. Water (40 ml.) was added to the reaction mixture, and the precipitate which appeared was filtered, washed well with N ammonia and dried; wt. 1.64 g. (91%). This material was recrystallized from 60% ethanol; wt. 1.31 g. (73%), m. p. 162—163°C, $[\alpha]_D^{21}$ −18.5° (*c* 1.5, dimethylformamide).

Found: C, 61.71; H, 8.46; N, 9.75. Calcd. for $C_{37}H_{61}O_9N_5$: C, 61.72; H, 8.54; N, 9.73%.

Di-*t*-amyloxycarbonyl-L-lysyl-L-phenylalanyl-L-isoleucylglycine (IV).—a) Hydrogen was passed through a solution of IIIa (3.13 g., 0.004 mol.) in methanol (150 ml.) containing a small amount of palladium black for about 3 hr. The catalyst was then removed by filtration, and the filtrate was concentrated to dryness under reduced pressure. The residue was dissolved in a mixture of methanol and ethyl acetate (30 ml. each), and the product was precipitated as crystals by adding petroleum ether (60—80°C, 60 ml.). Recrystallization of the crude product from 50% methanol gave 2.74 g. (98%) of product which was dried over phosphorus pentoxide in vacuo at 60°C for 8 hr.; m. p. 127—133°C (decomp.), $[\alpha]_D^{21.5}$ −17.2° (*c* 2, dimethylformamide).

Found: C, 59.93; H, 8.48; N, 9.98. Calcd. for $C_{35}H_{57}O_9N_5 \cdot 1/2\ H_2O$: C, 59.99; H, 8.34; N, 9.99%.

b) A solution of IIIb (0.94 g., 0.0013 mol.) in pyridine (5 ml.) was treated with N sodium hydroxide solution (1.5 ml.) at room temperature for 3 hr., and then the solution was neutralized with N hydrochloric acid (1.5 ml.). The solvent was evaporated out under reduced pressure, and the residue was washed with ether and then with water. Then, the residue was dissolved in hot ethanol (10 ml.) and reprecipitated by adding water (30 ml.). It was collected by filtration and reprecipitated again from hot 50% methanol: wt. 0.74 g. (82%) after drying in vacuo at 60°C for 8 hr., m. p. 123—131°C (decomp.).

Found: C, 60.48; H, 8.41; N, 10.29. Calcd. for $C_{35}H_{57}O_9N_5 \cdot 1/2H_2O$: C, 59.99; H, 8.34; N, 9.99%.

***t*-Amyloxycarbonyl-L-leucyl-L-methionine Methyl Ester (V).**—Triethylamine (1.1 ml.) was added to a solution of L-methionine methyl ester hydrochloride (1.39 g., 0.007 mol.) in dimethylformamide (15 ml.), and the crystals formed were filtered off. The *p*-nitrophenyl ester of *t*-amyloxycarbonyl-L-leucine[1] (2.56 g., 0.007 mol.) was added to the filtrate prepared as described above, and the mixture was allowed to stand at room temperature for 20 hr. Water (120 ml.) was then added to the reaction mixture, and an oil separated which was extracted well with ethyl acetate (about 100 ml.). The ethyl acetate extract was washed thoroughly in succession with N ammonia, 0.5 N hydrochloric acid and water, and dried over anhydrous sodium sulfate. On removal of the solvent a crystalline residue was obtained, which was recrystallized from a mixture of ethyl acetate and petroleum ether; wt. 2.73 g. (89%), m. p. 92—93°C, $[\alpha]_D^{22}$ −39.5° (*c* 2.1, methanol).

Found: C, 55.53; H, 8.89; N, 7.29; S, 8.15. Calcd. for $C_{18}H_{34}O_5N_2S$: C, 55.35; H, 8.78; N, 7.17; S, 8.21%.

***t*-Amyloxycarbonyl-L-leucyl-L-methionine Amide (VI).**—A solution of V (2.0 g., 0.0051 mol.) in methanol (50 ml.) was saturated with dry ammonia gas at 0°C, and the solution was allowed to stand for 24 hr. at room temperature. The reaction mixture was concentrated to dryness under reduced pressure, and the residue was crystallized from a mixture of aqueous ethanol and acetone. The yield of product was 1.38 g. (72%); m. p. 104—106°C, $[\alpha]_D^{22}$ −37.8° (*c* 1.1, methanol).

Found: C, 54.50; H, 8.90; N, 11.36; S, 8.53. Calcd. for $C_{17}H_{33}O_4N_3S$: C, 54.37: H, 8.85; N, 11.19; S, 8.53%.

Di-*t*-amyloxycarbonyl-L-lysyl-L-phenylalanyl-L-isoleucylglycyl-L-leucyl-L-methionine Amide (IX).—Compound IVa (1.038 g., 0.0015 mol.) was dried over phosphorus pentoxide in vacuo at 80°C for 8 hr. and then dissolved in dry pyridine (3.0 ml.). *p*-Nitrophenyl trifluoroacetate (0.494 g., 0.0021 mol.) was added to the solution and the mixture was allowed to react overnight at room temperature. Then ice-cold water (20 ml.) was added to the mixture, and the precipitate

formed was separated by filtration. The product was then resuspended in water (20 ml.), collected by filtration, and dried in vacuo over phosphorus pentoxide; wt. 1.20 g. (98%), m. p. 171—173°C (decomp.). This material VIIIa was used in the following reaction without further purification. The same type compound VIIIb was prepared from IVb in 90% yield; m. p. 165—168°C (decomp.) which had to be recrystallized from 60% methanol for the following reaction; yield 65%, m. p. 176—179°C (decomp.). Compound VI (0.563 g., 0.0015 mol.) was treated with 2 N hydrogen chloride in acetic acid (5 ml.) at room temperature for 40 min., and then the reaction product was precipitated by adding ice-cold ether (30 ml.). The precipitate was collected by filtration, washed well with ether and dried over sodium hydroxide in vacuo. The product which corresponded to leucylmethionine amide hydrochloride VII (0.44 g.) was added to a solution of VIIIa (1.2 g., 0.0015 mol.) in dimethylformamide (5 ml.) together with triethylamine (0.21 ml.), and the mixture was allowed to react overnight at room temperature. Water was added in the reaction mixture to precipitate the product, which was then collected by filtration, washed well with N ammonia and with water, and dried. Repeated precipitation from dimethylformamide - ethyl acetate and then from dimethylformamide-water gave 1.16 g. (82%) of product; m. p. 233—234°C, $[\alpha]_D^{21.5}$ −26.5° (*c* 1, dimethylformamide).

Found: C, 58.91; H, 8.36: N, 12.10; S, 3.24. Calcd. for $C_{46}H_{78}O_{10}N_8S$: C, 59.07; H, 8.41; N, 11.98; S, 3.43%.

Compound VIIIb was also subjected to the same reaction with VII, and the same product was finally obtained in 85% yield; m. p. 233—234°C, $[\alpha]_D^{21.5}$ −25.9° (*c* 0.9, dimethylformamide).

L-Lysyl-L-phenylalanyl-L-isoleucylglycyl-L-leucyl-L-methionine Amide Dihydroc hloride Dihydrate (X).—Compound IX (0.2 g.) was dissolved in 2 N hydrogen chloride in acetic acid (5 ml.), and the solution was allowed to react at room temperature for 40 min. The product was precipitated by adding ice-cold ether (20 ml.) at 0°C, and the precipitate was collected by filtration washed well with ether and dried over sodium hydroxide in vacuo. The residue was dissolved in 60% methanol (4 ml.), and insoluble material was filtered off. The filtrate was concentrated to dryness over phosphorus pentoxide in vacuo to obtain the final product; wt. 0.17 g., m. p. 240—243°C (decomp.), $[\alpha]_D^{23}$ −16.8° (*c* 0.8, acetic acid); Bernardi et al. reported[3] m. p. 240—243°C (decomp.), $[\alpha]_D^{21}$ −17° (*c* 0.8, 95% acetic acid).

Found:* C, 50.00; H, 7.96; N, 13.63. Calcd. for $C_{34}H_{58}O_6N_8S \cdot 2HCl \cdot 2H_2O$: C, 50.05; H, 7.91; N, 13.73%.

The R_f values of the product in *n*-butanol : acetic acid : water (4 : 1 : 1) and *n*-butanol : pyridine : water (1 : 1 : 1) were 0.62 and 0.74 respectively (R_f values of an authentic leucine in the same solvent systems were 0.61 and 0.54 respectively); paper electrophoresis showed this compound to be homogeneous at pH 2.3 and 4.75, respectively. The amino acid ratios in the acid hydrolyzate were Lys 1.03, Phe 1.00, Ileu 0.98, Gly 1.06, Leu 1.01, Met 0.87. The amino acid ratios in the leucine-aminopeptidase digest were Lys 1.06, Phe 0.97, Ileu 0.98, Gly 1.06, Leu 1.00,Met 1.00. The biological activity, determined by the contraction test with guineapig ileum[6] was 2.5 times more than that of bradykinin prepared in this laboratory.[7]

The authors wish to express their thanks to Professor Tomoji Suzuki for determining the biological activity of the synthetic material.

* This material was dried over phosphorus pentoxide in vacuo for 10 hr. at 80°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 951—955 (1966)

The Radiolysis of Aqueous Solutions of Potassium Iodide

By Takeshi SAWAI, Yoshiharu SHINOZAKI and Gisuke MESHITSUKA

Tokyo Metropolitan Isotope Research Center, Fukazawa-cho, Setagaya-ku, Tokyo

(Received September 17, 1965)

The radiolysis of potassium iodide aqueous solutions has been studied in order to elucidate the contribution of the hydrated electrons to the radiolysis mechanisms. The deaerated and aerated solutions were irradiated by ^{60}Co γ-rays under various conditions, and the yields of iodine, hydrogen peroxide, hydrogen and oxygen were determined. The pH dependences of the initial yields of iodine and hydrogen peroxide in the deaerated solutions are different from the results obtained in the aerated solutions. These results can be reasonably explained by assuming the hydrogen atoms and hydrated electrons to be the reducing species. From an examination of the results, the radiolysis mechanisms of the potassium iodide aqueous solutions have been discussed. The rate constant of the reaction of hydrated electrons for iodine has been calculated to be 5.9×10^{10} M^{-1} sec^{-1}.

The radiolysis of aqueous solutions containing iodide ions has already been studied by several

workers,[1-5] and it is known that the yields of the products, iodine, hydrogen peroxide, hydrogen and oxygen, depend upon the concentrations of iodide ions, hydrogen ions and oxygen in the solution. Allen et al.[3] observed that the yield of iodine from the radiolysis of the deaerated iodide solution was very low in a neutral and high in a 0.8 N sulfuric acid solution. The radiolysis of an iodide ion solution is known to be an oxidation-reduction reaction, but this system has not yet been completely examined.

Most of the radiation chemical reactions of aqueous solutions have been explained by assuming hydrogen atoms and hydroxyl radicals as the primary intermediates. Recently the existence of two forms of the reducing species has been reported by many authors, and it has been shown that one is a hydrogen atom and the other, a hydrated electron.[6-19]

In the present work, the radiolysis of potassium iodide aqueous solutions has been investigated under various conditions in order to elucidate the contribution of the hydrated electrons to the radiolysis mechanisms.

Experimental

The Preparation of Samples and the Irradiation.—All the materials used were of GR grade, and the solutions were prepared using triply-distilled water. The aerated and deaerated solutions (20 ml.) of various concentrations of potassium idodide, from 5×10^{-4} to 0.1 M, and of various pH values, from 0.5 to about 7, were irradiated by ^{60}Co γ-rays at room temperature. The air-free neutral solutions were obtained by bubbling in nitrogen gas filtered with triply-distilled water and by degassing them using the standard freezing-pumping technique. For the determination of the variation in the oxygen concentration in the irradiated aerated solutions, an irradiation vessel similar to one described by Boyle[20] was used. The pH value was controlled with sulfuric acid and was measured in a nitrogen stream by using a Horiba, model 3, pH meter.

To avoid the thermal oxidation of iodide ions at low pH values, the irradiations were made immediately after mixing the degassed potassium iodide solution with the degassed sulfuric acid solution.

The doses employed were from 1.0×10^{18} to 1.5×10^{19} eV./ml. Dosimetry was carried out by using an aerated solution of 5×10^{-3} M ferrous ammonium sulfate in 0.8 N sulfuric acid.

Analysis.—Iodine was determined from the absorption of tri-iodide ions at 305 mμ by using a Shimadzu QR-50 spectrophotometer and hydrogen peroxide, by Ghormley's method.[21] The gaseous products were collected by means of a Toepler pump, and hydrogen and oxygen were analyzed by gas chromatography (Shimadzu GC-2B) by using a Molecular Sieve 13X column at room temperature. As a carrier gas, argon or hydrogen was used. The hydrogen was also determined by a mass spectrometer (Hitachi RMU-5G).

Results

The Yields of Products in Air-free Neutral Potassium Iodide Solutions.—The formation of iodine, hydrogen peroxide, hydrogen, and oxygen in deaerated neutral solutions of potassium iodide (pH 6.5—6.7) is shown in Fig. 1. The

concentrations of iodine and hydrogen peroxide increase with an increase in the dose and reach the steady-state concentrations at about 2×10^{18} eV./ml. The initial G-values of iodine and hydrogen peroxide are 0.10 and 0.13 respectively. The amount of hydrogen produced increases linearly with the dose, and $G(H_2)$ is calculated to be 0.45, which is in good agreement with the "molecular hydrogen yield." Oxygen is formed at doses higher

than 1×10^{18} eV./ml., and the $G(O_2)$ value is 0.17. In the deaerated solution of pH 5.3, the G-values of iodine, hydrogen peroxide, and oxygen are 0.14, 0.27, and 0.22 respectively.

The Effects of the Potassium Iodide Concentration on the Initial Yields of Iodine and Hydrogen Peroxide.—The initial G-values of iodine and hydrogen peroxide in the aerated and deaerated solutions are shown in Fig. 2 as a function of the potassium iodide concentration. With an increase in the iodide ion concentration, the yield of iodine increases and the hydrogen peroxide yield decreases, the formation of hydrogen peroxide reaches a very low steady-state concentration ($\sim1\times10^{-6}$ M) at the higher concentration of iodide ion ($\sim$0.1 M).

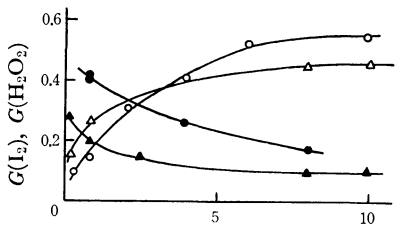

Fig. 2. Effects of potassium iodide concentrations on the initial yields of products in aerated and deaerated solutions at pH 5.3.

○ : I_2 in aerated, ● : H_2O_2 in aerated,
△ : I_2 in deaerated, ▲ : H_2O_2 in deaerated

The Dependence of the Initial Yields on the pH Values.—The pH dependences of the initial yields in the deaerated and aerated iodide solutions of 8.5×10^{-3} M are shown in Figs. 3 and 4. In the deaerated systems, the hydrogen yield decreases with an increase in the pH and becomes constant at about pH 2.5. The iodine yield shows a minimum in the range of pH 2.0—2.5. On the contrary, the yield of hydrogen peroxide shows a maximum in the same pH range. From the results in Fig. 3, it can be seen that, at pH values lower than 2, the change in the $G(I_2)$ with the pH is equal to the sum of the changes in $G(H_2O_2)$ and $G(H_2)$, and that in the higher pH range the change in $G(I_2)$ is equal to the change in $G(H_2O_2)$.

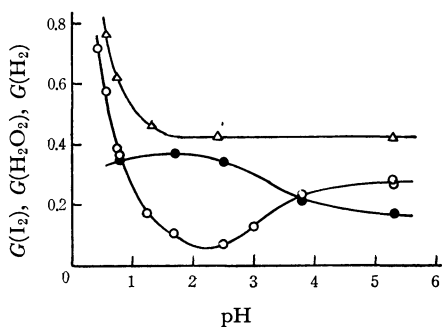

Fig. 3. Effects of pH on the initial yields of I_2, H_2O_2 and H_2 in the radiolysis of deaerated aqueous potassium iodide solutions.

[KI] : 8.5×10^{-3} M
△ : H_2, ○ : I_2, ● : H_2O_2

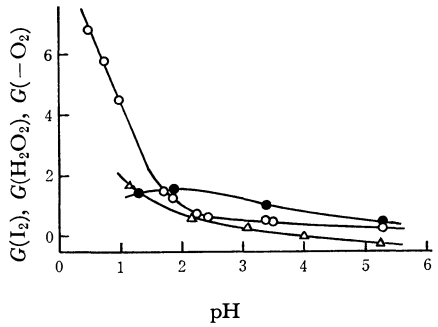

Fig. 4. Effects of pH on the initial yields of I_2, H_2O_2 and $-O_2$ in the radiolysis of aerated aqueous potassium iodide solutions.

[KI] : 8.5×10^{-3} M
○ : I_2, ● : H_2O_2, △ : $-O_2$

In the aerated systems, $G(I_2)$ decreases smoothly with an increase in the pH, as is shown in Fig. 4. $G(H_2O_2)$ shows behavior similar to that of the deaerated systems. With irradiation, the amount of dissolved oxygen increases at pH 5.3 but decreases at pH values lower than 4, while $G(-O_2)$ increases with a decrease in the pH.

Discussion

The Dependence of Initial Yields on the pH.—The radiolysis mechanisms of the aerated iodide solution were proposed by Allen.[22] For the deaerated system, however, no definite mechanisms have been given. In the radiolysis of aqueous solutions, hydrogen atoms and hydroxyl radicals have so far been assumed to be the primary intermediates, but the results obtained in these experiments, for example, the pH dependence of $G(I_2)$ or $G(H_2O_2)$, can not be explained only in terms of hydrogen atoms and hydroxyl radicals.

As to the formation of iodine from iodide ions, the following reactions can be postulated:

$$OH + I^- \rightarrow OH^- + I \quad (1)$$

$$2I^- + H_2O_2 \xrightarrow{H^+} 2I + 2H_2O \quad (2)$$

$$I + I \rightarrow I_2 \qquad I + I^- \rightarrow I_2^- \quad (3)$$

$$I_2^- + I_2^- \rightarrow I_3^- + I^- \qquad I_2 + I^- \rightleftarrows I_3^- \quad (4)$$

By assuming a hydrated electron as an intermediate, the results can be explained by the following competitive reactions:

22) A. O. Allen, "The Radiation Chemistry of Water and Aqueous Solutions," D. Van Nostrand Co., New York (1961).

$$e^-_{aq} + H^+ \rightarrow H \quad (5)$$

$$e^-_{aq} + H_2O_2 \rightarrow OH + OH^- \quad (6)$$

$$e^-_{aq} + I \rightarrow I^- \quad (7)$$

In a strongly acidic medium, hydrated electrons are converted to hydrogen atoms by the reaction 5, followed by the reaction 8, which forms hydrogen and iodine:

$$H + I^- + H^+ \rightarrow H_2 + I \quad (8)$$

As the pH increases, the reaction 8 decreases and the reaction 5 is followed by the reaction 9, and thus $G(I_2)$ and $G(H_2)$ decrease:

$$H + I \rightarrow H^+ + I^- \quad (9)$$

From the fact that $G(H_2)$ shows an almost constant value at pH higher than 2.5, it is clear that the reaction 8 is negligible in this pH range and that the hydrogen atoms produced reduce iodine atoms by means of the reaction 9. These facts agree with the results of the reaction of iodide ions with atomic hydrogen presented by Stein et al.[23] The oxidation reaction by hydrogen peroxide, which can occur in a strongly acidic medium, also decreases with an increasing pH, resulting in a slight increase in $G(H_2O_2)$:

$$2I^- + H_2O_2 \xrightarrow{H^+} 2I + 2H_2O \quad (2)$$

With a further increase in pH, the reaction 6 becomes important in giving more iodine by the reaction of the hydroxyl radical produced by the reaction 6, and thus $G(I_2)$ increases and $G(H_2O_2)$ decreases. From these mechanisms, the relations between the changes in $G(I_2)$ and $G(H_2O_2)$ with the pH (Fig. 3) can be explained reasonably.

In the aerated solutions, the following reactions are added to the reactions in the deaerated solutions:

$$e^-_{aq} + O_2 \rightarrow O_2^- \quad (10)$$

$$O_2^- + I \rightarrow O_2 + I^- \quad (11)$$

$$O_2^- + H^+ \rightarrow O_2 + H \quad (\text{or } HO_2) \quad (12)$$

$$H + O_2 \rightarrow HO_2 \quad (13)$$

$$HO_2 + I^- + H^+ \rightarrow H_2O_2 + I \quad (14)$$

$$HO_2 + HO_2 \rightarrow H_2O_2 + O_2 \quad (15)$$

With an increasing pH, the reactions 10 and 11 increase and 12, 13, and 14 decrease; thus $G(I_2)$, $G(H_2O_2)$, and $G(-O_2)$ fall smoothly, as is shown in Fig. 4. At pH 5.3 oxygen is formed, as will be described later.

The Dependence of Hydrogen Peroxide Formation on the Potassium Iodide Concentration.—From the dependence of $G(I_2)$, $G(H_2O_2)$ and the stationary concentration of iodine and hydrogen peroxide on the iodide ion concentration, it may be concluded that the hydrogen peroxide oxidizes iodide ions, presumably by the reaction 2. The fact that in the aerated solutions $G(H_2O_2)$ and the steady concentration of hydrogen peroxide are higher than those in the dearated solution, may be explained by the reactions 10, 12, 13, and 14.

Reactions in Deaerated Neutral Solutions.—The reactions 1, 5, 6, 7, and 9 can be assumed in the deareated neutral solution of potassium iodide 5×10^{-4} M, because the concentrations of hydrogen ion and iodide ion are very low. The oxidation reaction by hydrogen peroxide can be neglected in the low concentration range of potassium iodide in a neutral solution.

Oxygen is formed secondarily by the reaction of hydrogen peroxide with iodine. The following mechanisms were suggested by Anbar et al.[24] for the formation of oxygen in the radiolysis of potassium iodide solutions saturated with nitrous oxide:

$$I_2^- + H_2O_2 \rightarrow 2I^- + H^+ + HO_2 \quad (16)$$

$$I_3^- + H_2O_2 \rightarrow 3I^- + 2H^+ + O_2 \quad (17)$$

$$I_2 + HO_2 \rightarrow I_2^- + H^+ + O_2 \quad (18)$$

$$I_2^- + HO_2 \rightarrow 2I^- + H^+ + O_2 \quad (19)$$

Since the pK of HO_2 is 4.5 ± 0.2,[25] oxygen may also be produced by the following reactions:

$$HO_2 \rightleftarrows O_2^- + H^+ \quad (20)$$

$$O_2^- + (I, I_2, I_2^-, I_3^-) \rightarrow O_2 \quad (11')$$

The iodine produced is present in the forms of I_2 and I_3^-. If hydrogen peroxide is oxidized by I_2 or I_3^- to oxygen, the variations in the concentrations of hydrogen peroxide and iodine have to be observed as post-irradiation effects. However, the effects do not occur in dilute solutions. The iodine which can oxidize hydrogen peroxide to give oxygen seems to be I or I_2^-. Under the experimental conditions, all the hydroxyl radicals are scavenged by iodide ions and the following reactions, 21 and 22, do not occur, because the rate constants of these reactions are relatively slow (k_{21} and $k_{22}=4\times10^7$ M^{-1} sec^{-1}):[26,27]

$$OH + H_2O_2 \rightarrow HO_2 + H_2O \quad (21)$$

$$H + H_2O_2 \rightarrow OH + H_2O \quad (22)$$

From the results of the stationary concentrations of iodine and hydrogen peroxide in Fig. 1 and from the mechanisms proposed above, the following equations can be derived. As to the stationary state of iodine concentration:

$$G_{OH} + G e^-_{aq} \frac{k_6[H_2O_2]}{k_5[H^+]+k_6[H_2O_2]+k_7[I_2]}$$

23) G. Czapski, J. Jortner and G. Stein, *J. Phys. Chem.*, **63**, 1769 (1959).

24) M. Anbar, D. Meyerstein and P. Neta, ibid., **68**, 2967 (1964).

25) G. Czapski and L. M. Dorfman, ibid., **68**, 1169 (1964).

26) H. A. Schwarz, ibid., **66**, 255 (1962).

27) J. K. Thomas, ibid., **67**, 2593 (1963).

$$= G_{H} + Ge^{-}_{aq}\frac{k_5[H^+]+k_7[I_2]}{k_5[H^+]+k_6[H_2O_2]+k_7[I_2]} + 2G(O_2) \quad (23)$$

As to that of hydrogen peroxide:

$$G_{H_2O_2}=Ge^{-}_{aq}\frac{k_6[H_2O_2]}{k_5[H^+]+k_6[H_2O_2]+k_7[I_2]} + G(O_2) \quad (24)$$

From Eqs. 23 and 24, the following relations can be obtained:

$$G_{OH} + 2G_{H_2O_2} = G_{H} + Ge^{-}_{aq} + 4G(O_2) \quad (25)$$

In the potassium iodide solution of 5×10^{-4} M, most of the iodine produced is present in the form of I_2:

$$I_2 + I^- \rightleftarrows I_3^- \qquad (K = 7.2\times10^2)^{28)}$$

The values of k_5 and k_6 reported by Hart et al.[29] and $Ge^{-}_{aq}=2.8$ being used,[13,14,30] the rate constant of the reaction of hydrated electrons with iodine, $k_{e^-_{aq}+I_2}$, can be calculated from Eq. 24 to be 5.9×10^{10} M^{-1} $sec.^{-1}$ a value which is in good agreement with the value obtained by Hart et al.[31] using the pulse radiolysis technique.

On the other hand, in the deaerated solution of pH 5.3, $G(I_2)$ $G(H_2O_2)$ and $G(O_2)$, and the stationary concentrations of iodine and hydrogen peroxide are a little higher than those in the neutral solution. This may be due to the additional reaction of carbon dioxide with hydrated electrons.

$$CO_2 + e^-_{aq} \rightarrow CO_2^- \quad (26)$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 955—960 (1966)

Radical Yields in the Radiolysis of Neutral Aqueous Solutions

By Takeshi SAWAI

Tokyo Metropolitan Isotope Research Center, Fukazawa-cho, Setagaya-ku, Tokyo

(Received September 17, 1965)

The determination of the yields of the two reducing species and the OH radical in the radiolysis of neutral aqueous solutions was undertaken, using deaerated 2-propanol aqueous solutions containing potassium nitrate or hydrogen peroxide as electron scavengers. Irradiation was carried out with ^{60}Co γ-rays, and the hydrogen, nitrite ion, acetone, hydrogen peroxide and pinacol so produced were analyzed. The hydrogen yield decreases upon the addition of hydrogen peroxide or nitrate ions. The yield of hydrogen atoms is found to be 0.61 ± 0.03 by subtracting the molecular yield of hydrogen from the total hydrogen yield in the solutions containing enough scavengers. The yield of nitrite ions increases with an increase in the concentration of nitrate ions, and decreases with an increase in the concentration of acetone and with a decrease in the pH value. The acetone yield increases sharply with an increase in the quantity of nitrate ions and reaches a plateau value in the concentration range of nitrate ions higher than 1×10^{-2} M. In the presence of potassium nitrate of 1×10^{-2} M, pinacol is not formed, and the yield of hydrogen peroxide is less than the molecular yield of hydrogen peroxide. On the basis of these results, radiolysis mechanisms are elucidated and the yields of the hydrated electron and the OH radical of a neutral solution are found to be 2.77 ± 0.03 and 3.0 respectively. The relative rate constants, $k_{H+NO_3^-}/k_{H+(CH_3)_2CHOH}$ and $k_{e^-_{aq}+(CH_3)_2CO}/k_{e^-_{aq}+NO^-_3}$, are found to be 0.18 and 0.78.

Recent experimental evidence obtained by many investigators[1-5] in radiation chemical studies of dilute aqueous solutions has indicated that two forms of reducing species are produced in irradiated aqueous solutions. From chemical

and physical investigations[6-17] it has been established that the major part of the reducing species is a hydrated electron, which is referred to as e^-_{aq}. The other reducing species is presumed to be a hydrogen atom. The yields of the two reducing species, $G e^-_{aq}$ and G_H, have been measured using different aqueous systems.[6,8,10] Allan and Beck,[11] using deaerated 2-propanol solutions containing nitrous oxide, found the yields to be 2.80 ± 0.1 and 0.6 ± 0.1. More recently, however, from the radiolysis of aqueous methanol - sodium nitrate solutions, Allan[12] obtained $G e^-_{aq}=2.80\pm0.15$ and $G_{OH}=2.95$, while Adams et al.,[13] calculating the primary radical yields in neutral and alkaline solutions from the results of the pulse radiolysis of ferrocyanide solutions, obtained $G_{OH}=3.2$, $G_{e^-_{aq}}=3.16$, and $G_H=0.6$ to 0.8.

The present investigation was undertaken in order to determine the yields of the two reducing species and of the OH radical under neutral conditions in the gamma radiolysis of deaerated 2-propanol aqueous solutions containing potassium nitrate or hydrogen peroxide.

Experimental

The Preparation of Samples and the Irradiation.—2-Propanol was distilled, and the middle fraction was checked by gas chromatography prior to use. Other reagents of the GR grade were used without further purification. Solutions were prepared using water triply-distilled from acidic permanganate, dichromate and alkaline permanganate. The pH of the solutions was in the range between 5.6 and 5.7. In some experiments the pH of solutions was varied by adding sulfuric acid, sodium bicarbonate or sodium hydroxide. Solutions (20 ml.) degassed by the standard freezing-pumping technique were irradiated by ^{60}Co γ-rays at room temperature. The meansurements were made at least three times. The dose rate mainly employed was 2.42×10^{17} eV./ml.hr. Dosimetry was carried out with a usual ferrous dosimeter.

Analysis.—The hydrogen was analyzed by gas chromatography (Yanagimoto GCG-220) by using a molecular sieve 5A column (2m.) at room temperature and by using argon as the carrier gas. The acetone was determined by the spectrophotometric method[18] (Shimadzu QR-50 and Cary Model 14). The analysis of nitrite ion was made on the basis of the absorption at 525 mμ by using the method of sulfanilic acid and α-naphthylamine.[19] For the 2-propanol - hydrogen peroxide system, hydrogen peroxide was determined by the method developed by Ghormley,[20] while for the potassium nitrate - 2-propanol system the reduction of ceric ion was used for the determination of hydrogen peroxide. Pinacol was identified by a hydrogen-flame ionization detector using glycerol and PEG-6000 columns, and was determined from acetone obtained by the reaction with lead tetraacetate.[21]

Results

Deaerated 2-Propanol Aqueous Solutions Containing Hydrogen Peroxide.—Deaerated aqueous solutions containing various concentrations of hydrogen peroxide were irradiated and the amounts of hydrogen, acetone and hydrogen peroxide produced were determined. As for the organic product, only acetone was determined.

The formation of hydrogen is linear with the dose, as is shown in Fig. 1. Figure 2 shows the plots of the production of acetone and the disappearance of hydrogen peroxide versus the dose. They are dependent on the hydrogen peroxide concentration below 1×10^{-4} M. The variations in G-values with hydrogen peroxide concentration are given in Fig. 3. As the hydrogen peroxide

○: H_2, ●: acetone, △: $-H_2O_2$

concentration increases, the hydrogen yield decreases and the yields of acetone formation and of the disappearance of hydrogen peroxide increase, while at higher concentrations of hydrogen peroxide, these yields reach constant values. The constant $G(H_2)$ is 1.06 ± 0.02, a value which is in agreement with the results obtained by Allan et al.[6,11] and Stein et al.[10]

Deaerated 2-Propanol Aqueous Solutions Containing Potassium Nitrate.—The deaerated 2-propanol aqueous solutions containing nitrate ions were irradiated under various conditions, and the amounts of hydrogen, nitrite ion, acetone, pinacol and hydrogen peroxide produced were determined.

The formations of the H_2, NO_2^- and $(CH_3)_2CO$ are linear with the dose up to 2.5×10^{17} eV./ml. Above this dose, however, the rate of nitrite ion formation becomes slightly slower. The initial yields were obtained from the slopes of the straight lines.

The effects of potassium nitrate, 2-propanol and pH on the yields of hydrogen, nitrite ion and acetone are shown in Fig. 4 and in Tables I and II.

As the potassium nitrate concentration increases, the hydrogen yield decreases from 2.05 to 0.79 at the nitrate concentration of 6×10^{-2} M, while, on the other hand, the nitrite yield increases from 2.20 to 2.89. The acetone yield increases sharply at first and then decreases slowly. At the constant concentration of nitrate of 1×10^{-2} M, the nitrite yield slightly decreases with an increase in the amount of 2-propanol and reaches a constant value at 2.77 ± 0.03. These yields are independent of

Discussion

Deaerated 2-Propanol Aqueous Solutions Containing Hydrogen Peroxide.—The radiolysis of water can be expressed as follows:

$$H_2O \longrightarrow H,\ e^-_{aq},\ OH,\ H_2,\ H_2O_2, \quad (1)$$

In the presence of 2-propanol, H atoms and OH radicals react with the solute, mainly according to 2 and 3:

$$(CH_3)_2CHOH + H \rightarrow (CH_3)_2COH + H_2 \quad (2)$$

$$(CH_3)_2CHOH + OH \rightarrow (CH_3)_2COH + H_2O \quad (3)$$

The rate constant for the reaction of the H atom with 2-propanol is 2×10^7 M^{-1} sec^{-1},[22] and that of OH is 1.74×10^9 M^{-1} sec^{-1}.[23] Acetone is formed by the following reactions:[10,11]

$$(CH_3)_2COH + H_2O_2 \rightarrow (CH_3)_2CO + OH + H_2O \quad (4)$$

$$2(CH_3)_2COH \rightarrow (CH_3)_2CO + (CH_3)_2CHOH \quad (5)$$

Dimerization was also suggested by Stein et al.[10] as the possible disappearance reaction of the organic radical.

It is well known that hydrogen peroxide is a good electron scavenger. In the presence of hydrogen peroxide, it reacts with the hydrated electron in competition with the hydrogen ions:

$$H_2O_2 + e^-_{aq} \rightarrow OH + OH^- \quad (6)$$

$$H^+ + e^-_{aq} \rightarrow H \quad (7)$$

Both reactions, 6 and 7, are very fast; the rate constants of these reactions have been determined by Hart et al.[24] to be 1.2×10^{10} M^{-1} sec^{-1} and 2.3×10^{10} M^{-1} sec^{-1} respectively. On the other hand, hydrogen peroxide reacts with the hydrogen atom and the hydroxyl radical according to:

$$H_2O_2 + H \rightarrow OH + H_2O \quad (8)$$

$$H_2O_2 + OH \rightarrow HO_2 + H_2O \quad (9)$$

Both reactions, however, are relatively slow, and the rate constants, k_8 and k_9, are 4×10^7 [25] and 4.5×10^7 M^{-1} sec^{-1} [26] respectively. Therefore, the reactions 7, 8 and 9 can be ignored in systems which contain 2-propanol of 2.5×10^{-2} M and hydrogen peroxide of the 1×10^{-3} M-5×10^{-3} M range, and the hydrogen yield can be expressed by the following equation:

$$G(H_2) = G_{H_2} + G_H \quad (10)$$

The yield of the hydrogen atom, G_H, in the radiolysis of water can be calculated from the values of the total hydrogen yield, $G(H_2)$, and the molecular yield of hydrogen, G_{H_2}. From the results of Fig. 3, G_H is caluculated to be 0.61 ± 0.02 by using the value of $G_{H_2}=0.45$.[27,28]

The G values of acetone formation and of the disappearance of hydrogen peroxide are higher in the presence of higher concentrations of hydrogen peroxide. It seems that the chain reactions 3 and 4 occur, as suggested by Rabani et al.[10] The decrease in the rates of acetone formation and of hydrogen peroxide disappearance in the dilute solutions of hydrogen peroxide may be due to the competition of the reactions 4 and 5.

Deaerated Aqueous 2-Propanol Solutions Containing Potassium Nitrate.—*Hydrogen Yield.*—It is known that nitrate ion is a good electron scavenger; the rate constant of the scavenging was found by Hart et al.[29] to be 1.1×10^{10} M^{-1} sec^{-1}.

22) $k(H+NO_3^-)=1\times10^7$ M^{-1} sec^{-1} (G. Navon and G. Stein, *J. Phys. Chem.*, **69**, 1384 (1965)), k(H+2-propanol)/k(H+NO_3^-) =2 (Ref. 31).

The nitrate ion is reduced to the nitrite ion by reaction with the hydrated electron, but the details are not clear:

$$e^-_{aq} + NO_3^- \rightarrow NO_2^- \quad (11)$$

The hydrated electron reacts also with the hydrogen ion to give the H atom (reaction 7). In the presence of higher concentrations of nitrate ions, on the other hand, the reaction of the H atom with NO_3^- should be considered. It has been proposed that the H atom reduces the nitrate ion to the nitrite ion by the reactions 12 and 13:[30]

$$H + NO_3^- \rightarrow NO_2 + OH^- \quad (12)$$

$$2NO_2 + H_2O \rightarrow NO_3^- + NO_2^- + 2H^+ \quad (13)$$

The decrease in $G(H_2)$ with an increase in the nitrate ion concentration (Fig. 4) can be explained by the competition of the reactions 7, 11, 2 and 12.

The hydrogen yield in this system will be given by:

$$G(H_2) = G_{H_2} + \left(G_H + Ge^-_{aq}\frac{k_7[H^+]}{k_7[H^+]+k_{11}[NO_3^-]}\right) \times \frac{k_2[ROH]}{k_2[ROH]+k_{12}[NO_3^-]} \quad (14)$$

In the range of $k_7[H^+] \ll k_{11}[NO_3^-]$,

$$G(H_2) = G_H + \frac{G_H}{1+\dfrac{k_{12}[NO_3^-]}{k_2[ROH]}} \quad (15)$$

According to the Eq. 15, $G(H_2)$ is plotted versus $(G(H_2)-G_{H_2})[NO_3^-]/[ROH]$ in Fig. 7. A straight

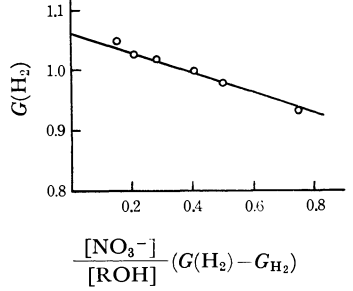

Fig. 7. Dependences of KNO_3 concentration on $G(H_2)$ in the radiolysis of deaerated aqueous solutions of 2×10^{-2} M 2-propanol at pH 5.6.

line is obtained, and from the intercept $G_H + G_H$ is found to be 1.06 ± 0.03, a value in good agreement with the results in the 2-propanol-hydrogen peroxide system. The ratio of the rate constants, k_{12}/k_2, is also calculated from the slope to be 0.18; this value is a little lower than the value, 0.5, given by Scholes et al.[31]

Nitrite Yield.—The radiolysis of aqueous nitrate solutions has been studied, but the reaction mechanisms are not clear.[30,32,33] As for the reaction of the hydrated electron with the nitrate ion, the following reactions, 16 and 17, have been examined:

$$e^-_{aq} + NO_3^- \rightarrow NO_2 + 2OH^- \quad (16)$$

$$e^-_{aq} + NO_3^- \rightarrow NO_2^- + OH + OH^- \quad (17)$$

If the reaction 16 is predominant, $G(NO_2^-)$ has to be approximately equal to 1/2 Ge^-_{aq}. However, the present result shows $G(NO_2^-)=2.8$, which is near the reported values of Ge^-_{aq} instead of half of them. From the studies of the radiolysis of sodium nitrate ice, Kevan[34] has shown that NO_2 is not formed via a reaction with the electron. If a nitrite ion is produced directly by the reaction 17, the increase in $G(H_2)$ and the decrease in $G(NO_2^-)$, with the decrease in pH equal one other. As Table II shows, however, this is not the case.

As possible reactions, the followings were suggested by Allan:[12]

$$e^-_{aq} + NO_3^- \rightarrow NO_3^{2-} \quad (18)$$

$$NO_3^{2-} + (CH_3)_2COH \rightarrow (CH_3)_2CO + NO_2^- + OH^- \quad (19)$$

The NO_3^{2-} radical ion has been tentatively identified by electron paramagnetic resonance studies of the radical species produced in the irradiated potassium nitrate crystal.[35]

In neutral solutions containing high concentrations of 2-propanol and nitrate ions, all hydrated electrons are scavenged by nitrate ions and the reaction 12 can be ignored; $G(NO_2^-)$ is equal to Ge^-_{aq}, on the basis of the reactions 18 and 19. From the results noted in Table I, the value of the hydrated electron yield is given as $Ge^-_{aq}=2.77\pm0.03$, which is in good agreement with the finding of Allan et al.[11,12] $G(NO_2^-)$ does not change with the pH value from 5.0 to 9.5; therefore, Ge^-_{aq} is constant in this pH range. The changes in $G(NO_2^-)$ with the variation in the nitrate ion concentration is about half that of $G(H_2)$, as is shown in Table IV. The nitrite ion formation by the

35) J. Cunningham, ibid., **66**, 972 (1962).

reaction of the H atom with nitrate may arise via the reactions 12 and 13.

In the presence of acetone, $G(NO_2^-)$ decreases by the following competitive reactions:

$$e^-_{aq} + NO_3^- \rightarrow NO_3^{2-} \quad (18)$$

$$e^-_{aq} + (CH_3)_2CO \rightarrow (CH_3)_2CO^- \quad (20)$$

In terms of the reaction kinetics, the yield of nitrite is written as follows:

$$G(NO_2^-) = Ge^-_{aq}\frac{k_{18}[NO_3^-]}{k_{18}[NO_3^-]+k_{20}[R_2CO]} + 1/2\,G_H\frac{k_{12}[NO_3^-]}{k_{12}[NO_3^-]+k_2[ROH]} \quad (21)$$

By introducing the numerical values of $G_H=0.6$, $k_{12}/k_2=0.18$, $[NO_3^-]=1.0\times10^{-2}$ M, and $[ROH]=2.0\times10^{-2}$ M, one can obtain the following relation:

$$\frac{1}{G(NO_2^-)-0.02} = \frac{1}{Ge^-_{aq}}1+\left(\frac{k_{20}[R_2CO]}{k_{18}[NO_3^-]}\right) \quad (22)$$

In Fig. 8, $1/G(NO_2^-)-0.02$ is plotted as a function of $[R_2CO]$, and $G(NO_2^-)$ and k_{20}/k_{18} are found from the intercept and the slope of the straight line to be 2.8 and 0.78 respectively. The ratio of the rate constants, k_{20}/k_{18}, is in agreement with the results obtained using the pulse radiolysis technique.[36,37]

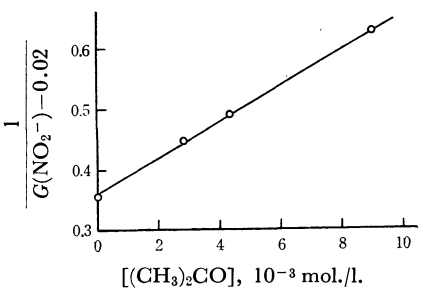

Fig. 8. Variations of $G(NO_2^-)$ with $(CH_3)_2CO$ concentration in the radiolysis of deaerated aqueous solutions of 2×10^{-2} M 2-propanol, 1×10^{-2} M KNO_3.

Acetone Yield.—In the potassium nitrate 1×10^{-2} M-2-propanol 2×10^{-2} M system, all the H atom and OH radicals react with 2-propanol to give organic radicals, and all the hydrated electrons are scavenged by nitrate ions. The yield of hydrogen peroxide is slightly lower than that of the molecular hydrogen peroxide in water radiolysis (Fig. 5); the results of Fig. 6 indicate that the dimerization of organic radicals can be neglected.

The mechanisms of the acetone formation can be written as follows:

$$(CH_3)_2COH + NO_3^{2-} \rightarrow (CH_3)_2CO + NO_2^- + OH^- \quad (19)$$

$$(CH_3)_2COH + H_2O_2 \rightarrow (CH_3)_2CO + OH + H_2O \quad (4)$$

$$2(CH_3)_2COH \rightarrow (CH_3)_2CO + (CH_3)_2CHOH \quad (5)$$

On the basis of the reactions, 2, 3, 4, 5 and 19, G(acetone) is given by:

$$\begin{aligned} G(\text{acetone}) &= G(NO_2^-)+G_{H_2O_2}-G(H_2O_2)+ \\ &\quad 1/2[G_H+G_{OH}+G_{H_2O_2}-(G(NO_2^-)+ \\ &\quad G_{H_2O_2}-G(H_2O_2))] \\ &= 1/2[G(NO_2^-)+G_H+G_{OH}] \\ &\quad +G_{H_2O_2}-G(H_2O_2) \end{aligned} \quad (23)$$

By using the numerical values of $G_{H_2O_2}-G(H_2O_2)=0.2$, $G(NO_2^-)=2.8$, $G_H=0.6$ and G(acetone)$=3.4$, G_{OH} can be calculated from Eq. 23 to be 3.0.

Radical Yields.—From the radiolysis of the deaerated neutral solutions of 2-propanol containing hydrogen peroxide or potassium nitrate, the primary radical yields have been obtained:

$$G_{OH}=3.0,\ Ge^-_{aq}=2.77\pm0.03,$$
$$G_H=0.61\pm0.03$$

These values are relatively high. Recently Hayon[14] obtained $G_{OH}=2.25$, $Ge^-_{aq}=2.3$ and $G_H=0.55$ from the radiolysis of dilute solutions containing various solutes, and suggested that the radical scavenger concentration was important in the measurement of the radical yields. Since relatively higher concentrations of scavengers were used in the present experiments, the higher values obtained may be due to reactions similar to those postulated by Dainton et al.[38] to account for the increase in radical yields at high and low pH values:

$$(H_2O^+ + H_2O^-) + NO_3^- \rightarrow NO_3^{2-} + OH + H^+ + H_2O \quad (24)$$

Organic Sulfur Compounds. II. The Formation and Thermal Decomposition of Carboxylic Sulfurous Anhydrides

By Michio KOBAYASHI and Asami YAMAMOTO

Department of Chemistry, Yokohama City University, Mutsuura-machi, Kanazawa-ku, Yokohama

(Received November 1, 1965)

Mixed anhydrides of carboxylic acids and monoalkyl sulfites have been prepared, and their thermal decomposition has been studied. Some of these mixed anhydrides can be distilled without decomposition. Disproportionation to carboxylic anhydride and dialkyl sulfite is the main pathway of the thermal decomposition.

A mixed anhydride of carboxylic acid and sulfurous acid (I) has been postulated as an intermediate in the reaction of carboxylic acid salts and chlorosulfites to form the carboxylic esters,[1-3] but it has not been isolated or identified. The formation of the carboxylic esters by the above method has been thought to proceed by the following reaction sequence:

$$RCO_2Na + ClSOOR' \rightarrow R\text{-}\underset{\underset{O}{\|}}{C}\text{-}O\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}OR' + NaCl \quad (1)$$

(I)

$$I \rightarrow RCO_2R' + SO_2 \quad (2)$$

In the analogous decomposition of carboxylic carbonic anhydride (II),[4] the disproportionation reaction 4 takes place along with the reaction 3, which has a formal similarity to the reaction 2:

$$R\text{-}\underset{\underset{O}{\|}}{C}\text{-}O\text{-}\underset{\underset{O}{\|}}{C}\text{-}OR' \rightarrow RCO_2R' + CO_2 \quad (3)$$

(II)

$$II \rightarrow {}^1/_2(RCO)_2O + {}^1/_2(R'O)_2CO + {}^1/_2CO_2 \quad (4)$$

On the other hand, the nitric ester formation is the sole decomposition mode in the pyrolysis of the nitric carbonic anhydride (alkyl nitratocarbonate) (III):[5]

$$R'O\text{-}\underset{\underset{O}{\|}}{C}\text{-}ONO_2 \rightarrow R'ONO_2 + CO_2$$

(III)

In the present paper, the preparation of several compounds of this little known class of carboxylic sulfurous anhydride and studies of their reactions, including thermal decomposition, will be described.

Results and Discussion

Methyl chlorosulfite was found to react with the anhydrous sodium acetate to give methyl acetoxysulfinate (Ia) (I: $R=R'=CH_3$) as a colorless mobile liquid which can be distilled without decomposition in vacuo. This anhydride is extremely sensitive to moisture, by which it is decomposed to acetic acid and sulfur dioxide. The determination of sulfur by oxidation with hydrogen peroxide as barium sulfate indicated the presence of approximately the calculated amount of sulfur atoms in this compound. Its infrared spectrum exhibited a strong carbonyl band at 1757 cm^{-1} which disappeared in contact with moisture, to be replaced by the absorption of acetic acid at 1712 cm^{-1}.

In a similar manner, ethyl acetoxysulfinate (Ib) (I: $R=CH_3$, $R'=C_2H_5$) was prepared from ethyl chlorosulfite and sodium acetate. The observed value of the sulfur content was close to the calculated figure. The high sensitivity of these anhydrides to moisture made the analysis very difficult. In the infrared spectrum, a strong carbonyl band at 1752 cm^{-1} and a S–O stretching band at 1190 cm^{-1} were observed.

Both the methyl ester and the ethyl ester were rather more stable than expected; they could be stored in a refrigerator for several days without any appreciable decomposition, provided strict caution was taken to avoid moisture.

The carbon tetrachloride solution of Ib was also stable; no change of its infrared spectrum was observed after one day. When refluxed for several hours, this solution produced acetic anhydride and ethyl sulfite, while it produced ethyl acetate on prolonged boiling. There was estimated to be a 40% decomposition in 3 hr. and a 55% decomposition in 6 hr.

When triethylamine was added to a solution of

benzoic acid and ethyl chlorosulfite in carbon tetrachloride, an exothermic reaction took place, with the precipitation of triethylamine hydrochloride. The filtered solution showed strong infrared absorptions at 1724 cm^{-1} (C=O) and at 1222 cm^{-1} (S–O) (Fig. 1). The concentration of this solution under reduced pressure gave a pale sirup. The infrared spectrum of this liquid was the same as that of the carbon tetrachloride solution, suggesting the formation of ethyl benzoyloxysulfinate (Ic) (I: $R=C_6H_5$, $R'=C_2H_5$). This compound was also very sensitive to moisture, which caused its decomposition to benzoic acid.

The reaction mixture of sodium benzoate and ethyl chlorosulfite was extracted with carbon tetetrachloride after the initial vigorous reaction had finished, and the insoluble powder was then filtered off. The infrared spectrum of the filtrate was superimposable upon that of the specimen obtained by the triethylamine method, showing the formation of Ic in this reaction, too. This fact seems to justify the postulation in the literature[2] which assumed the formation of I in the reaction 1.

The carbon tetrachloride solution of Ic was stable; 61% of it remained unchanged after 18 days. When this solution was heated under reflux in the presence of benzoic acid, a 42% decomposition in 6 hr. and a nearly complete decomposition in 14 hr. were observed. The products were benzoic anhydride and ethyl sulfite, both in yields 98% of the theoretical, and 2 mol. % of ethyl benzoate. Ether or benzene can be used as the solvent instead of carbon tetrachloride in the preparation of the mixed anhydride Ic.

n-Butyl benzoyloxysulfinate (Id) (I: $R=C_6H_5$, $R'=n\text{-}C_4H_9$) was obtained as a solution from sodium benzoate and *n*-butyl chlorosulfite by a manner similar to that which produces Ic. In its infrared spectrum (Fig. 2), strong C=O and S–O absorption bands appear. This anhydride gave ethyl *n*-butyl sulfite in a 54% yield when treated with anhydrous ethanol at room temperature, but no ethyl benzoate. This seems to indicate the preferable attack on sulfinyl sulfur by the anionoid reagent (reaction 5) rather than to the carbonyl group (reaction 6).

$$C_6H_5\text{–}\underset{\underset{O}{\|}}{C}\text{–O–S–}OC_4H_9 + C_2H_5OH \rightarrow$$

(Id)

$$C_6H_5CO_2H + C_2H_5O\text{–}\underset{\underset{O}{\downarrow}}{S}\text{–}OC_4H_9 \qquad (5)$$

$$Id + C_2H_5OH \rightarrow C_6H_5CO_2C_2H_5 + SO_2 + C_2H_5OH \qquad (6)$$

When a solution of Id in carbon tetrachloride was refluxed, a slow decomposition took place with the evolution of sulfur dioxide. This reaction was accelerated in the presence of triethylamine, resulting in a complete decomposition within a few hours. The products were benzoic anhydride and di-*n*-butyl sulfite, both in yields 98% of the theoretical; there was only a 2% yield of *n*-butyl benzoate.

So far, no carboxylic sulfurous anhydride has been obtained in the pure crystalline state. In an attempt to get one, we attempted to prepare *p*-nitrobenzoyloxysulfinate (Ie) (I: R = *p*-nitrophenyl, $R'=C_2H_5$) repeatedly. The reaction of *p*-nitrobenzoic acid, ethyl chlorosulfite, and pyridine in ether, and the reaction of sodium *p*-nitrobenzoate with ethyl chlorosulfite, were examined. Both gave a solution whose infrared evidence strongly suggested the presence of the expected mixed anhydride (Fig. 3). However, the separated crystals, after the evaporation of the solvent in a vacuum at room temperature, exhibited almost the same infrared spectrum as that of *p*-nitrobenzoic acid in a KBr disk, although the melting point of the product was 85—90°C (with decomposition), far below the 242°C of *p*-nitrobenzoic acid. Probably this compound was so sensitive to the presence of moisture that a complete hydrolysis by atmospheric moisture took place during the preparation of the KBr disk. When these crystals were shaken with carbon tetrachloride and the insoluble powder (*p*-nitrobenzoic acid) was filtered off, the infrared spectrum of the filtrate was superimposable upon Fig. 3, indicating the presence of Ie in this specimen.

Although the formation of the carboxylic ester over the postulated mixed anhydride I in a good yield has been reported in the literature,[1,2] most of the thermal decomposition of the carboxylic sulfurous anhydrides studied in this paper in carbon tetrachloride proceeded according to the disproportionation reaction 7, analogous to the reaction 4 observed in the carboxylic carbonic anhydride (II):

$$R\text{–}\underset{\underset{O}{\|}}{C}\text{–O–S–OR}' \rightarrow$$

(I)

$$^1/_2(RCO)_2O + {}^1/_2(R'O)_2SO + {}^1/_2SO_2 \qquad (7)$$

The pyrolysis of I without a solvent was also investigated. When the reaction of sodium benzoate and ethyl chlorosulfite was carried out without the solvent and when the resulting mixture was distilled under reduced pressure, the main products were again benzoic anhydride (50% of the theoretical yield) and ethyl sulfite (42% of the theoretical), while the yield of ethyl benzoate was only 5%. The pyrolysis of the reaction mixture of sodium benzoate and *n*-butyl chlorosulfite at 140—160°C gave benzoic anhydride and di-*n*-butyl sulfite as the main products, plus *n*-butyl benzoate in a 5% yield. With a 2 molar equivalent of butyl chlorosulfite, the yield of butyl benzoate was 10%, in comparison to yield of 43% for benzoic anhydride

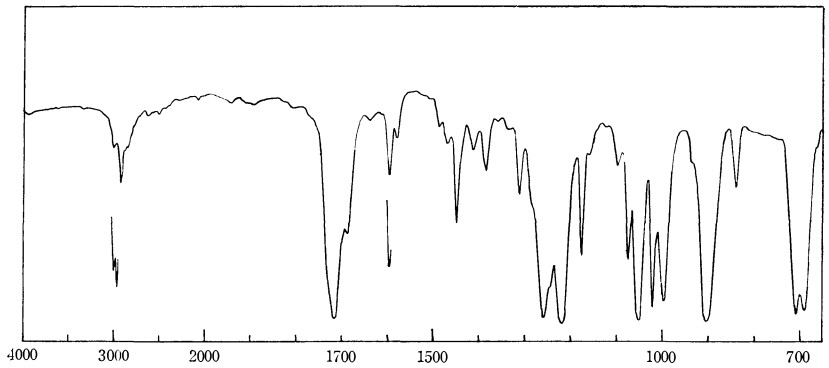

Fig. 1. Infrared spectrum of ethyl benzoyloxysulfinate (Ic) in CCl_4.

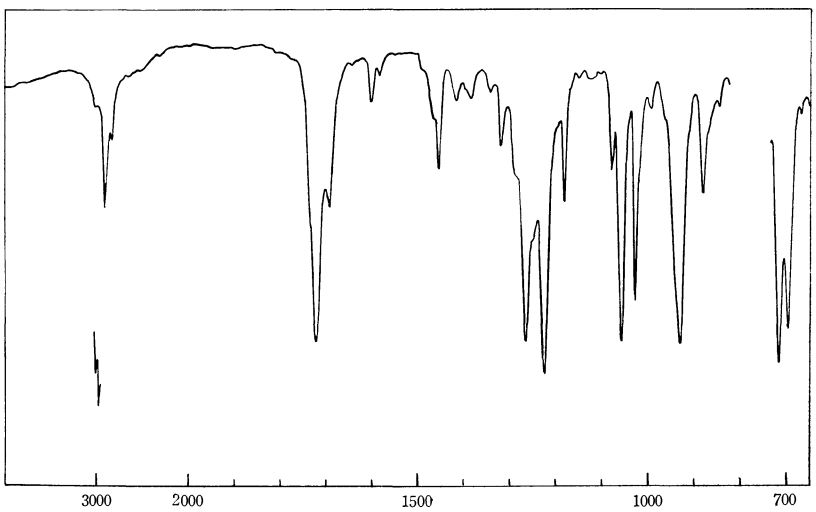

Fig. 2. Infrared spectrum of *n*-butyl benzoyloxysulfinate in CCl_4.

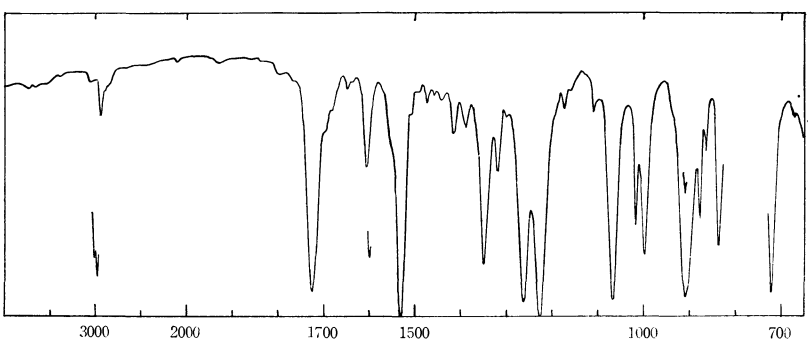

Fig. 3. Infrared spectrum of ethyl *p*-nitrobenzoyloxysulfinate (Ie) in CCl_4.

and 56% for di-*n*-butyl sulfite. When the reaction mixture of sodium *p*-nitrobenzoate and ethyl chlorosulfite was heated at 125°C for one hour and treated with water and ether, an insoluble powder remained in either solvent; it was identified as *p*-nitrobenzoic anhydride. The yield was 17% of the theoretical. No ethyl nitrobenzoate was detected.

In conclusion, the thermal decomposition of the carboxylic sulfurous anhydride at a comparatively low temperature results in the disproportionation 7 as the main reaction. With elevation of the reaction temperature, the yield of the carboxylic ester shows a tendency to increase, but it is rather doubtful whether this ester is the direct result of the reaction 2. There is a good chance that this

carboxylic ester is formed by the interaction of carboxylic anhydride with dialkyl sulfite, both being the main products of the primary reaction 7. Several examples of this type of the reaction 8 have been reported[6]:

$$(RCO)_2O + (R'O)_2SO \rightarrow 2RCO_2R' + SO_2 \quad (8)$$

In the case of Ib in carbon tetrachloride, ethyl acetate appeared only in the later stage of the reaction, in cost of acetic anhydride, clearly indicating the occurrence of the reaction expressed by the formula 8.

Mixed anhydride I could be formed from acyl chloride and sodium monoalkyl sulfite, besides the reaction 1. For example, Ic may be prepared by the interaction of benzoyl chloride and sodium ethyl sulfite (IV), as shown below:

$$C_6H_5COCl + NaO\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}OC_2H_5 \rightarrow Ic + NaCl \quad (9)$$

(IV)

When IV, prepared from sodium ethylate and sulfur dioxide, was treated with benzoyl chloride without the solvent, the reaction proceeded very slowly at room temperature. At a higher temperature, benzoic anhydride in a 53% yield, ethyl sulfite in a 50% yield and ethyl benzoate in a 10% yield were obtained, suggesting the expected formation of the intermediate Ic according to the reaction 9. When both reactants were left in carbon tetrachloride at room temperature for 3 days, 80% of the starting materials remained unchanged. Benzoic anhydride was formed in an amount 20% of the theoretical yield, while no indication of Ic itself was observed, even in the infrared spectrum. Only a slight amount of ethyl benzoate was there at first, but about 12 mol. % of it was detected when the filtrate from the unchanged IV was kept at room temperature for one week. Most probably it arises from the interaction of benzoyl chloride and ethyl sulfite, one of the primary products. This type of the reaction, 10, has also been known to occur with some acyl chlorides[6]:

$$2RCOCl + (R'O)_2SO \rightarrow 2RCO_2R' + SO_2 \quad (10)$$

The failure to detect the intermediate Ic may be attributable to the slowness of the reaction 9, during which the disproportionation 7 of the once-formed Ic proceeds (probably by a catalytic acceleration of IV itself as a base).

The disproportionation (7) may be concluded to be a base catalytic from the effect of triethylamine to accelerate the decomposition of Id, as has been described above, and also on the basis of the following evidence. Ethyl chlorosulfite was added to a solution of benzoic acid in pyridine, and the reaction mixture was warmed at 70°C for half an hour, diluted with water, and extracted with ether to give benzoic anhydride in a 55% yield, ethyl sulfite in a 27% yield, and a trace of ethyl benzoate. This experiment showed that Ic was decomposed even under these mild conditions, while refluxing for more than 10 hr. was necessary to complete the decomposition of Ic in carbon tetrachloride in the absence of a base. The above experiment also suggests that the rate of the reaction between the carboxylate anion and alkyl chlorosulfite is very fast, since the chlorosulfites are known to be decomposed by pyridine to form alkyl chlorides and sulfur dioxide with great ease.[7]

On the other hand, the decomposition of Ic in the presence of benzoic acid in carbon tetrachloride caused the disproportionation 7, although at a much slower rate than the base-catalytic one.

The following mechanism may be proposed for the disproportionation 7, where B means base catalyst:

$$R\text{-}\underset{\underset{O}{\|}}{C}\text{-}O\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}OR' + :B \longrightarrow$$

I

$$RCO_2^- + \left[B\text{----}\underset{\underset{O}{\|}}{S}\text{-}OR'\right]^+ \quad (11)$$

$$I + RCO_2^- \longrightarrow (RCO)_2O + \left[RO'\text{-}S\overset{O}{\diagdown\!\diagup}O\right] \quad (12)$$

$$[R'O\text{-}SO_2^-] \longrightarrow R'O^- + SO_2 \quad (13)$$

$$R'O^- + I \longrightarrow (R'O)_2SO + RCO_2^- \quad (14)$$

The anionoid attack on I occurred on the sulfinyl sulfur preferentially, not on carbonyl, as shown in the reaction of Id with ethanol. The attraction of an anionoid reagent to the positive center on sulfur atom, the linkage of which to the sulfinyl oxygen bears a strong semipolar character,[8] may be the reason for this difference in reactivity. The attack by the carboxylate anion on I also could take place on the sulfur atom, but it would form another I (15), with the net result of no apparent reaction:

$$I + RCO_2^- \longrightarrow RCO_2^- + I \quad (15)$$

Therefore, the only fruitful attack is the one expressed in 12, giving acyl anhydride.

Decomposition in the presence of the carboxylic acid was considered to proceed as is shown below:

$$I + RCO_2H \longrightarrow \left[R\text{-}\underset{\underset{O}{\|}}{C}\text{-}O\text{-}\underset{\underset{O}{\|}}{S}\text{-}OR'\right]^+ + RCO_2^- \quad (16)$$

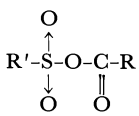
Infrared Spectra of the Carboxylic Sulfurous Anhydride.—The wave numbers of the C=O and S-O stretching bands of several derivatives of I are shown in Table I.

Table I

R	R'	Peak position[a] C=O, cm^{-1}	S-O, cm^{-1}
Methyl	Methyl	1757	1196
Methyl	Ethyl	1752	1190
Phenyl	Ethyl	1724	1222
Phenyl	*n*-Butyl	1723	1223
Phenyl	Phenyl[b]	1729	1230
p-Nitrophenyl	Ethyl	1730	1227

a) In CCl_4.
b) In ether. This compound will be described in detail later.

The wave numbers of the C=O absorptions of these compounds are close to those of the carboxylic carbonic anhydrides (for example, 1755 cm^{-1} for II: R=methyl, R'=ethyl; 1739 cm^{-1} for II: R=phenyl, R'=ethyl,[9] and they lie in a lower frequency region than that of the carboxylic sulfonic anhydride V[10] (1780 cm^{-1} for V: R=phenyl, R'=phenyl; 1800 cm^{-1} for V: R=ethyl, R'=phenyl).



(V)

Experimental

1. Methyl Acetoxysulfinate (Ia).—When, to 4.5 g. of a fine powder of sodium acetate (VI) which had been dehydrated at 200°C in vacuum for a few hours, there was added 6.5 g. of methyl chlorosulfite drop by drop, with constant shaking and good cooling, the reaction started at once, and heat was evolved. After 5 hr. at room temperature, the jelly-like reaction mixture was distilled in vacuo to give 4.5 g. of a colorless, mobile liquid at 37—39°C/1 mmHg in a 60% yield of the theoretical; infrared spectrum, 1752 (C=O), 1210 (S-O), 940, and 690 cm^{-1} (neat). This compound reacted with water very rapidly. In a small vial with a ground glass stopper there was weighed 365.0 mg. of this ample, which had been stored for 2 weeks in a refrigerator; the sample was then hydrolyzed with a solution of 2 g. of sodium hydroxide in 20 ml. of water in a closed vessel. The oil dissolved in less than one minute, thus forming a clear solution, which was then oxidized with 6 ml. of 30% hydrogen peroxide for 2 hr. Diluted hydrochloric acid was added to this solution, and the sulfate anion was precipitated as barium sulfate (551.9 mg.).

S: Found: 20.8%. Calcd. for $C_3H_6O_4S$: 23.3%.

2. Ethyl Acetoxysulfinate (Ib). — *2.1. Reaction without a Solvent.* — From 12.5 g. of ethyl chlorosulfite (VII) and 8.0 g. of VI, 8.3 g. of Ib was obtained as a colorless liquid (b. p. 44°C/1 mmHg) by a manner similar to that used for Ia. The yield was 56% of the theoretical. This sample (169.7 mg.) gave 249.5 mg. of barium sulfate.

S: Found: 20.2%. Calcd. for $C_4H_8O_4S$: 21.1%.

2.2. Reaction in Carbon Tetrachloride.—A solution of 3.0 g. of VII in 50 ml. of carbon tetrachloride was added to 2.2 g. of VI, shaken well for 30 min., and filtered through a fritted glass funnel. The infrared spectrum of the filtrate was almost entirely superimposable upon that of the specimen obtained in 2.1. IR: 1752, 1190, 1000, 898, 700 cm^{-1}. After one day, no change was observed in the infrared spectrum.

2.3. The Decomposition of Ib.—A carbon tetrachloride solution of Ib (4.7×10^{-1} mol./l.) was refluxed to produce acetic anhydride in a 40% yield in 3 hrs, and in a 55.5% yield in 6 hr. When it was boiled for another 6 hr., the concentration of acetic anhydride was decreased to 11% and replaced by ethyl acetate in a 27.5% yield. (The determinations were made by the infrared spectroscopic method.)

3. Ethyl Benzoyloxysulfinate (Ic).—*3.1. Preparation.*—Benzoic acid (6.9 g.) and VII (7.3 g.) were dissolved in 180 ml. of carbon tetrachloride; no change was observed. When 6.8 g. of triethylamine was added drop by drop to this solution cooled in an ice bath, a vigorous reaction occurred, with the precipitation of white crystals; these crystals were identified as triethylamine hydrochloride. The infrared spectrum of the filtrate is shown in Fig. 1. When this filtrate was evaporated under reduced pressure at room temperature, with precaution taken to avoid moisture, it gave a pale sirup which solidified to a glassy mass at −70°C. When it came in contact with moisture, this sirup formed crystals of benzoic acid rapidly. After a carbon tetrachloride solution of Ic (3.14×10^{-1} mol./l. as 100% pure) had been refluxed for 6 hr., an aliquot of it was washed with a diluted potassium carbonate solution and water successively, and then dried over magnesium sulfate. By its infrared spectrum the presence of 5.73 $\times10^{-2}$ mol./l. of benzoic anhydride and 5.72×10^{-2} mol./l. of ethyl sulfite was detected. At this stage of the reaction, the yield of two products was 34% of the theoretical and in an equimolecular ratio. The main portion of the solution of Ic was refluxed for another few hours and finally evaporated to expel the solvent, after which the residue was heated in an oil bath for one hour to complete the decomposition. After it had been diluted with carbon tetrachloride, this residue was analyzed by infrared spectroscopy and so found to contain benzoic anhydride and ethyl sulfite in a 1.15 : 1.00 molar ratio. A few grams of aniline were added to this solution to remove benzoic anhydride as almost insoluble

9) D. S. Tarbell and N. A. Leister, *J. Org. Chem.*, **23**, 1149 (1958); 4b.
10) C. Overberger and E. Sarlo, *J. Am. Chem. Soc.*, **85**, 2446 (1963).

benzanilide (identified by melting point and infrared spectrum); The filtrate was then washed repeatedly with a potassium carbonate solution and dried over magnesium sulfate. The infrared spectrum of this solution revealed the presence of a small amount of ethyl benzoate, which was masked by benzoic anhydride before the treatment with aniline. The yields of benzoic anhydride, ethyl sulfite and ethyl benzoate were 94%, 82%, and 6% of the theoretical yield respectively.

3.2. The Decomposition of Ic in the Presence of Acid. When a solution of Ic (1.90×10^{-1} mol./l.) and benzoic acid (8.45×10^{-2} mol./l.) in carbon tetrachloride was refluxed, the yield of benzoic anhydride was 42% of the theoretical in 3 hr, and 98% in 14 hr. The corresponding yield of ethyl sulfite was also 98% in 14 hr. By treatment with aniline as described in 3.1, the yield of ethyl benzoate was estimated to be 2.4%. Therefore, 98% of the decomposition of Ic in this condition was shown to proceed according to the reaction 7, leaving only 2% at most for the reaction 2. The slightly higher yield of ethyl benzoate in 3.1 may be attributable to the high reaction temperature in the last stage of the reaction without the solvent, during which stage some of benzoic anhydride may react with ethyl sulfite to give ethyl benzoate following the reaction 8.

3.3. Formation from Sodium Benzoate.—Two grams of sodium benzoate and 1.7 g. of VII were mixed and extracted with 100 ml. of carbon tetrachloride after the initial exothermic reaction was over. The infrared spectrum of this extract was almost identical with that shown in Fig. 1, indicating the formation of the same mixed anhydride Ic. After 18 days, this solution was found by infrared analysis still to contain 61% of original Ic.

3.4. Decomposition without a Solvent.—Nine grams of VII was added to 10.0 g. of sodium benzoate, and the resultant gel-like mixture was distilled under reduced pressure. The redistillation of the total distillate gave the forerun, consisting of 2.0 g. of ethyl sulfite (42% of the theoretical yield), 0.5 g. of ethyl benzoate (4.8 mol.%), and 4.0 g. of benzoic anhydride (51% of the theoretical yield), b. p. 170—171°C/5 mmHg.

3.5. Reaction with Ethanol.—To a reaction mixture of 5.5 g. of sodium benzoate and 5.0 g. of VII 5 ml of ethanol (absolute) was added, after the initial vigorous reaction had subsided. The work-up of this mixture gave 2.0 g. of ethyl sulfite (38%), with no ethyl benzoate. The amount of benzoic acid recovered was 4.0 g. (82%). Therefore, ethanol attacked Ic on the sulfur atom, not on carbonyl.

3.6. The Reaction in Pyridine.—Benzoic acid (6.5 g.) was dissolved in 20 ml. of dry pyridine and cooled in an ice bath. When 7.0 g. of VII was added to this solution, no gas evolved and no precipitate appeared. After it had been heated in an oil bath for 30 min. at 70°C, the solution was diluted with a lot of water, made acidic with hydrochloric acid, and extracted with ether. The usual work-up gave 0.7 mol. % of ethyl benzoate, ethyl sulfite in 27.2% of the theoretical yield, and benzoic anhydride in a yield 55% of the theoretical.

4. *n*-Butyl Benzoyloxysulfinate.—*4.1. Preparation in Carbon Tetrachloride.*—When 2.5 g. of triethylamine was added to a solution of 2.8 g. of benzoic acid and 3.5 g. of *n*-butyl chlorosulfite (VIII) (b. p. 70°C/13 mmHg) in 62 ml. of carbon tetrachloride, triethylamine hydrochloride was precipitated at once. The infrared spectrum of the filtrate is shown in Fig. 2; it has a close similarity to that of the ethyl analog. (i) Anhydrous ethanol (5 ml.) was added to 10 ml. of this solution, and the mixture was warmed, washed with water and aqueous sodium hydrogen carbonate successively, and dried over magnesium sulfate. The infrared spectrum of the filtrate coincided with that of ethyl *n*-butyl sulfite. The yield was estimated by infrared analysis to be 54% of the theoretical. No ethyl benzoate was detected. (ii) Triethylamine (0.5 g.) was added to the remaining solution of the mixed anhydride Id; this mixture was then refluxed for a few hours, during which the evolution of sulfur dioxide was completed. The formation of benzoic anhydride and di-*n*-butyl sulfite, each in a 98% yield of the theoretical, was confirmed by the infrared spectroscopy. After treatment with aniline, *n*-butyl benzoate in a 2.1% yield was detected.

4.2. Reaction without a Solvent.—(i) A reaction mixture of 7.5 g. of sodium benzoate and 10.0 g. of VIII (equimolecular) was heated at 140—160°C for 2 hr. and diluted with water. The deposited oil was washed with aqueous sodium hydrogen carbonate, dried over magnesium sulfate, and distilled under reduced pressure to give a forerun consisting of 1.5 g. (31% of the theoretical yield) of di-*n*-butyl sulfite and 0.5 g. of butyl benzoate (5%) at 119—126°C/26 mmHg and 1.5 g. of benzoic anhydride (26% of the theoretical yield) at 207°C/25 mmHg. (ii) The reaction of 6.0 g. of sodium benzoate and 12 g. (1.9 mol.) of VIII was carried out as above. After they had been heated at 140—180°C for one and a half hours, the products were extracted with ether. Vacuum distillation gave 2.2 g. of di-*n*-butyl sulfite (56% of the theoretical yield), 0.7 g. of butyl benzoate (10 mol.%) and 2.0 g. of benzoic anhydride (43% of the theoretical yield).

5. Ethyl *p*-Nitrobenzoyloxysulfinate (Ie). — *5.1. Formation in Carbon Tetrachloride.*—VII (3 g.) was added to a suspension of 4.5 g. of sodium *p*-nitrobenzoate, which had been finely ground and dehydrated in a vacuum at 140°C for 3 hr., in 50 ml. of carbon tetrachloride. The reaction mixture was shaken occasionally and filtered, after 1.5 hrs., through a fritted glass funnel. The infrared spectrum of the filtrate (Fig. 3) exhibited strong C=O and S–O absorptions. With caution taken to avoid moistrue, this filtrate was concentrated under reduced pressure; this left almost colorless crystals (m. p. 85—90°C) (with decomposition). Its infrared spectrum in a KBr disk was almost the same as that of *p*-nitrobenzoic acid. When 2.7 g. of this specimen was shaken with 20 ml. of carbon tetrachloride, 2 g. remained undissolved, and the filtrate showed an infrared spectrum identical with that in Fig. 3, indicating the presence of Ie in the above specimen, probably contaminated with nitrobenzoic acid.

5.2. Formation in Toluene.—Sodium *p*-nitrobenzoate (10.0 g.) was suspended in 40 ml. of toluene, which had been dehydrated by boiling it over molten sodium, and treated with 8.5 g. of VII. The gel-like white precipitate was filtered off, and the filtrate was cooled in a dry ice - ethanol bath at −66°C to deposit pale crystals. About 50 ml. of petroleum ether was then added to decrease the solubility, and the supernatant was removed by decantation, thus leaving 5 g. of crystals (m. p. 85—90°C). Its infrared spectrum in

a KBr disk again coincided with that of *p*-nitrobenzoic acid.

5.3. Decomposition without a Solvent.—A reaction mixture of 7.3 g. of sodium *p*-nitrobenzoate and 10.5 g. of VII (2.1 molar equivalent) was heated in an oil bath at 125°C for one hour. Ether and water were added to the mass after it had been cooled. One gram of the white powder, identified as *p*-nitrobenzoic anhydride, remained undissolved. The yield was 17% of the theoretical yield. A lot of nitrobenzoic acid was recovered, but no ethyl *p*-nitrobenzoate was detected. The low yield of the acid anhydride may be attributed to the too mild reaction conditions, insufficient to bring about the complete decomposition of the mixed anhydride Ie.

6. Reaction between Benzoyl Chloride and Sodium Ethyl Sulfite.—*6.1. Without a Solvent.*—Sodium ethyl sulfite (IV) was prepared by passing dry sulfur dioxide into sodium ethoxide in ethanol and by evaporating the mixture to dryness under reduced pressure; it was finally dried in a vacuum for 3 hr. To 6.5 g. of this salt there was then added 7.0 g. of benzoyl chloride. After one hour at room temperature, the mixture was subjected to vacuum distillation to recover most of the starting materials unchanged. When the same amounts of the reactants were, in another experiment, heated at 120°C for few hours, 500 ml. of sulfur dioxide (about 40 mol.%) evolved. The vacuum distillation of the remaining mass gave 3.0 g. of the forerun at 50—70°C/80 mmHg and 3.0 g. of benzoic anhydride (52% of the theoretical yield), m. p. 41°C. The forerun was found by the infrared analysis to contain 1.75 g. of ethyl sulfite (50% of the theoretical) and 0.75 g. of ethyl benzoate (10 mol.%).

6.2. *Reaction in Carbon Tetrachloride.*—To a suspension of 1.5 g. of IV 1.5 g. of benzoyl chloride was added; the mixture was kept in a desiccator and occasionally shaken over a 4-day period, and then filtered from the insoluble powder. The infrared specturm of the filtrate showed that 10.1 mol.% (20.2% of the theoretical yield) of benzoic anhydride was produced, although a large part of the benzoyl chloride remained unaltered. The key bands of ethyl benzoate were weak in this filtrate at first, and those of ethyl sulfite were masked by benzoyl chloride. After 6 days, benzoyl chloride and benzoic anhydride were decomposed by aniline to benzanilide and filtered off. The filtrate was washed by diluted hydrochloric acid, aqueous potassium carbonate and water successively, and found by the infrared spectroscopy to contain 12.2 mol.% of ethyl benzoate and 4.3 mol.% of ethyl sulfite. If the same molar (10.1 mol.%) of ethyl sulfite as benzoic anhydride was assumed to have existed in the first filtrate, the difference (5.8 mol.%) may be considered to have converted into 11.6 mol.% of ethyl benzoate, in accordance with the observed value, probably by the reaction 9.

Organic Sulfur Compounds. III. The Reactions of Toluenesulfinic Acid with Acyl Chlorides

By Michio KOBAYASHI

Department of Chemistry, Yokohama City University, Mutsuura-machi, Kanazawa-ku, Yokohama

(Received September 21, 1965)

Sodium *p*-toluenesulfinate reacts with acetyl chloride to form acetic anhydride, *p*-toluenesulfinyl chloride, thiolsulfonate, and sodium *p*-toluenesulfonate. A reaction with benzoyl chloride gives benzoic anhydride in a good yield. A mixed anhydride of sulfinic acid and carboxylic acid is postulated as an intermediate, one which survives for a few hours at −60°C. The reaction mechanism is discussed.

The literature contains three reports on the reactions between arylsulfinic acid and carboxylic chloride. The reaction of sodium *p*-toluenesulfinate (I) and benzoyl chloride has been claimed[1] to form a ketosulfone, $C_6H_5COSO_2C_6H_4CH_3$, but this was questioned in a later paper.[2] The reaction of the same salt as a dihydrate with benzoyl chloride was reported in the second paper to give benzoic acid in a quantitative yield and *p*-tolyl *p*-toluenethiolsulfonate (IVa) in 20 mol.%,[2] but the exact material balance was not examined, nor was the reaction mechanism considered. On the other hand, the reaction of the anhydrous salt (I) and benzoyl chloride in xylene or in ether gave sodium *p*-toluenesulfonate, IVa, and an oil, which reacted with aniline to form benzanilide. A reaction mechanism involving a mixed anhydride of sulfinic acid and carboxylic acid was suggested.[3]

In this paper, studies of the mechanism of the reaction of *p*-toluenesulfinic acid with acetyl chloride and benzoyl chloride will be described.

Results and Discussion

The reaction of anhydrous sodium *p*-toluenesulfinate (I) with an equimolar amount of benzoyl chloride (II) was carried out at room temperature, and the reaction mixture was extracted with carbon tetrachloride. Infrared analysis revealed the formation of about 50 mol.%, namely 100% of the theoretical yield, of benzoic anhydride (III), and thiolsulfonate (IVa) in a 20 mol.% yield. The insoluble products in carbon tetrachloride contained sodium *p*-toluenesulfonate (25 mol.%). Therefore, the fate of the 100% portion of the benzoyl group and that of the 65% portion of $CH_3C_6H_4S$ group were clarified. The formation of benzoic anhydride was confirmed by the preparation of benzanilide in a yield 84% of the theoretical. The amount of the unchanged sulfinic acid was very small.

When the reaction mixture of I and acetyl chloride (V) was treated with anhydrous methanol, methyl *p*-toluenesulfinate was obtained in a low yield.

In another experiment, I was treated with acetyl chloride, and the reaction mixture was distilled in a vacuum to give acetic anhydride in a yield 68% of the theoretical. The residue gave 15.8 mol.% of the thiolsulfonate (IVa) and 14.2 mol.% of *p*-toluenesulfonate as *S*-benzylthiuronium salt (VI). The fact that sulfonic acid existed in the original residue as sodium salt was confirmed by the infrared spectrum in KBr disk, where a by-product, sodium chloride, did not interfere at all.

There remained at least one-fourth of the sulfur atoms, which fate had still not been explained. Since sulfonic acid was formed as sodium salt, it was clear that not all the chlorine atom could exist as sodium chloride in equimolar reaction conditions. This suggests that some of the sulfur compounds might be formed as chloride, such as sulfonyl chloride or sulfinyl chloride.

The reaction mixture of I and V was subjected to vacuum distillation as in the foregoing experiment. After the acetic anhydride had been collected, the distillation was continued and an orange-yellow high-boiling distillate was obtained. By its infrared spectrum and by the rapid reaction with water to give *p*-toluenesulfinic acid, this liquid was identified as *p*-toluenesulfinyl chloride, VII. The yield was 18.3 mol.% From the residue, 22.2 mol.% of *p*-toluenesulfonic acid was again isolated as VI.

On the basis of the above results, it was concluded that almost 100% of the acyl group was converted into the acyl anhydride, and that about 1/4 of the sulfur was recovered as sulfonic acid salt, another 1/4 as sulfinyl chloride, and 1/2 as thiolsulfonate. This means that the overall reaction can be expressed by the following formula 1:

$$\begin{aligned} RSO_2Na + R'COCl \rightarrow\ & {}^1/_2(R'CO)_2O + {}^1/_4\ RSO_2SR \\ & + {}^1/_4\ RSO_3Na + {}^1/_4\ RSOCl \\ & + {}^3/_4\ NaCl \end{aligned} \quad (1)$$

The formation of methyl *p*-toluenesulfinate in the reaction of methanol with the reaction mixture between I and V is explained by the interaction of methanol with the VII produced in reaction 1.

As the first step of the reaction of sulfinic acid salt with carboxylic chloride, either of the following two reactions could take place:

$$RSO_2Na + R'COCl \rightarrow R\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}O\text{-}\underset{\underset{O}{\|}}{C}\text{-}R' + NaCl \quad (2)$$

(VIII)

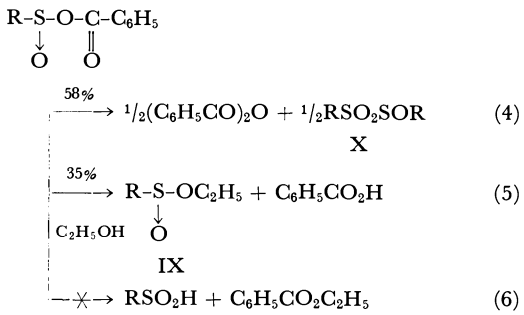
$$RSO_2Na + R'COCl \rightarrow R\text{-}\overset{\overset{O}{\uparrow}}{\underset{\underset{O}{\downarrow}}{S}}\text{-}\underset{\underset{O}{\|}}{C}\text{-}R' + NaCl \quad (3)$$

Although the usual alkyltion of sulfinate anion results in the formation of a *S*-alkyl derivative, not of a *O*-alkyl compound, the formation of carboxylic sulfurous anhydride[4] indicates the possibility of the formation of the VIII type. This class of compound, a mixed anhydride of sulfinic acid and carboxylic acid has been suggested[3] as described above, but never been isolated, and not expected to be stable compound.

The following experiments were carried out to determine whether the transitory formation of VIII in the reaction between sulfinate and acyl chloride could be verified.

A solution of free sulfinic acid and II in ether was cooled at −66°C and treated with triethylamine. An aliquot of the reaction mixture was then filtered, and its infrared spectrum was measured at once, in order to determine if any carbonyl band was present which could be attributed to VIII. Surprisingly, there was already strong absorption of benzoic anhydride; its yield was estimated to be almost theoretical. This must mean that the reaction is completed at −66°C or within several minutes at room temperature, the time interval needed to filter the solution and to inject the filtrate into the infrared cell. Anhydrous ethanol was added to the main portion of the above reaction mixture kept at −66°C. The usual work-up of this mixture gave benzoic anhydride in 29 mol.% yield, not in the 50 mol.% estimated above, and ethyl *p*-toluenesulfinate (IX) in a 35 mol.% yield, with a slight amount of ethyl benzoate. Therefore, the intermediate VIII may be considered to survive at a low temperature such as −66°C for some time, and to be converted into sulfinic ester by reaction 5, which proceeds along with the disproportionation 4:

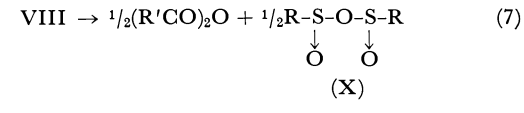
4) Part 2 of this series.



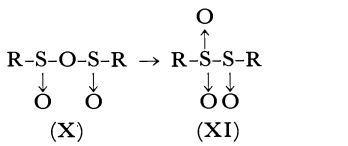
Ethyl sulfinate IX could be formed by the reaction of sulfinyl chloride (VII), which might be formed in a reaction analogous to reaction 1, with ethanol, but in such a case the yield would not exceed 25 mol.%. The preferential attack of ethanol on VIII on the sulfur atom (reaction 5), rather than on the carbonyl group of VIII (reaction 6), may be explained by the attraction of the nucleophilic reagent to the positive center of the sulfinyl sulfur.

The fact that the sulfinyl anion rapidly reacted with benzoyl chloride, even at −66°C, suggested the possibility of preparing IX by reacting I with II in the presence of ethanol; here the sulfinyl anion would react with II ahead of ethanol to form VIII, and then this VIII would react with ethanol according to the reaction 5 prior to the decomposition by the disproportionation 4. Indeed, I suspended in absolute ethanol reacted with II at 0°C to give the mixture, which consisted of IX in a 74 mol.% yield, III in a yield 19% of the theoretical, and ethyl benzoate in a 6 mol.% yield. These results showed that the rate of the reaction 5 was slightly higher than that of the disproportionation 4. It should be noticed that no thiolsulfonate (IVa) was detected in this experiment, although III was formed in yields as high as 10 mol.%. This indicated that thiolsulfonate was not the primary product of the disproportionation 4.

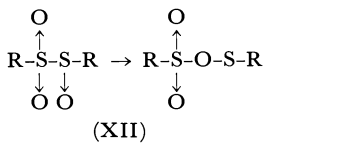
The variety of the products formed in the overall reaction 1 implies the complicated nature of this reaction. After the first step 2, the disproportionation 7 of VIII could proceed by the following mechanism 8 and 9:



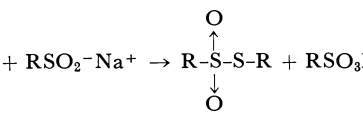
The sulfinic anhydride (X) has been considered to be very unstable, and it is expected to be isomerized to the sulfinyl sulfone XI, which has been prepared from the sulfinic acid by the dehydration with acetic anhydride.[5-7]



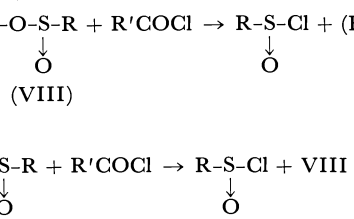
XI would further rearrange to a mixed sulfenic sulfonic anhydride XII[8]:



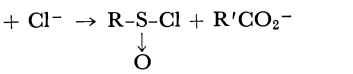
The formation of the thiolsulfonate IV could be explained by the reaction 12, which is similar to the proposed reaction for the formation of IV in the disproportionation of the sulfinic acid under acidic conditions.[8]



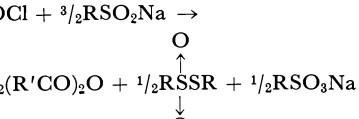
The formation of the sulfinyl chloride would then be the result of one of the following two reactions, of which the former is our choice:



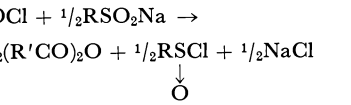
Therefore, the following reaction sequences would lead to the net reaction 13:



By combining (2), (7), $^1/_2$(11) and $^1/_2$(12), the following formula 17 was obtained:



while, by combining $^1/_2$(2) and $^1/_2$(13), Formula (18) was given:



5) H. Bredereck, A. Wagner, E. H. Beck, H. Herlinger and K. G. Kottenhahn, *Angew. Chem.*, **70**, 268 (1958).
6) F. Knoevenagel and L. Polack, *Ber.*, **41**, 3323 (1908).
7) H. Bredereck, A. Wagner, H. Beck and R. J. Klein, *Chem. Ber.*, **93**, 2736 (1960).
8) J. L. Kice and K. W. Bowers, *J. Am. Chem. Soc.*, **84**, 605 (1962).

Finally, we get the overall reaction formula 1 by adding 17 to 18 and by dividing by 2.

Experimental

The Reaction of Sodium *p*-Toluenesulfinate and Benzoyl Chloride without a Solvent.—To 7.0 g. of II there was added 9.0 g. (equimolecular) of a fine powder of I (dried in a vacuum at 140°C for a few hours) with cooling; exothermic reaction then started. After 30 min., 80 ml. of carbon tetrachloride was added to the jelly-like reaction mixture, and the insoluble white powder was filtered off. An aliquot of the filtrate was taken, diluted to 10 times of its volume, and its infrared specturm was measured. The formation of 50 mol.% of III, and 19.8 mol.% of IVa was observed, and trace of the II was unchanged. Into the main portion of the filtrate 6 g. of aniline were then stirred in order to precipitate the white crystals of benzanilide, 4.2 g. (84% of the theoretical yield), which was identified by its infrared spectrum. The filtrate of benzanilide was evaporated, and the residue was recrystallized from petroleum ether to give 2.3 g. of IVa (16.6 mol.%). The mother liquid was chromatographed through an alumina column, and 0.2 g. (4 mol.%) of *p, p'*-ditolyl disulfide was obtained as colorless crystals from the first eluant. A part of the white powder, insoluble in carbon tetrachloride, was examined by means of the infrared spectrum in a KBr disk and so found to contain *p*-toluenesulfonic acid as sodium salt, not as a free form. The main part of the salt residue was taken up in water, where a negligible amount remained undissolved. The addition of *S*-benzylthiuronium chloride gave 4.0 g. (25 mol.%) of the precipitate of *S*-benzylthiuronium *p*-toluenesulfonate (VI). To a part of the aqueous solution there was then added a ferric chloride solution, where the characteristic red color of ferric sulfinate was observed but no precipitate[9] was separated after one night.

The Reaction of *p*-Toluenesulfinic Acid with Benzoyl Chloride in Ether.—*p*-Toluenesulfinic acid was liberated from its sodium salt and dried in a vacuum. A solution of 3.0 g. of this acid in 70 ml. of anhydrous ether was then cooled in a dry ice - ethanol bath at −66°C. Three grams of the freshly-distilled II were dissolved in 20 ml. of ether, added to the above solution, and cooled; most part of the sulfinic acid was crystallized out. A solution of 2.0 g. of triethylamine in 20 ml. of ether was then added to the above suspension drop by drop over a 20 min. period. When the white precipitate filled the solution, one milliliter of the reaction mixture was taken out by suction, filtered through a fritted-glass funnel, and its infrared spectrum measured at once. The strong C=O absorption bands of benzoic anhydride were observed at 1790 and 1728 cm^{-1}; from their intensities, the yield of III was estimated to be 49.5 mol.%. To the main portion of the reaction mixture, kept at −66°C, 10 ml. of anhydrous ethanol was added in small portions. The mixture was cooled for 2 hr. at this temperature, allowed to warm to room temperature, and left overnight. The precipitate was filtered off and identified as triethylamine hydrochloride. The filtrate was washed by water, aqueous sodium carbonate and water successively, and dried over magnesium sulfate. On the evaporation of the filtrate, 3.2 g. of a colorless oil was obtained as a residue. Infrared analysis showed that this oil contained 1.3 g. of III (29 mol.%) and 1.3 g. of IX (35 mol.%). Actually, on vacuum distillation, 0.8 g. of IX (b. p. 115—117°C/4 mmHg) and 1.1 g. of III (b. p. 170°C/4 mmHg) were isolated. Ethyl benzoate was detected by infrared analysis, but its yield was too low to allow its isolation.

The Reaction of *p*-Toluenesulfinate with Benzoyl Chloride in Ethanol.—A suspension of 9.0 g. of I in 100 ml. of anhydrous ethanol was boiled once and cooled in ice water, whereby most of the I was separated as a fine powder. Into this ice-cooled suspension, 7.0 g. of II was stirred, and the reaction mixture was kept for 2 hr. in an ice bath. A lot of water was added to the mixture, and the heavy oil precipitated was extracted with 40 ml. of carbon tetrachloride. The infrared analysis of this extract showed the presence of 73.8 mol.% of IX, 9.6 mol.% of III and 6.1 mol.% of ethyl benzoate, with no thiolsulfonate IVa.

The Reaction of Sodium *p*-Toluenesulfinate with Acetyl Chloride (V).—i) To 9.0 g. of I 13.0 g. of freshly-distilled V were added with cooling. Heat was evolved, and a gel-like mixture resulted. After one hour, the whole mixture was vacuum-distilled to give 1.7 g. of a low boiling liquid, which was identified as acetic anhydride. Ether (40 ml.) was added to the residue, and an insoluble powder (3.4 g.) was filtered off. Ether was expelled from the extract, and 3.7 g. of the residue was treated with petroleum ether to give 1.7 g. of IVa. A white powder, insoluble in ether, was taken up in water and the insoluble matter was removed by filtration. The latter was also identified as IVa, the total yield of which reached 2.2 g. (63% of the theoretical). The yield of *p*-toluenesulfonic acid in the aqueous solution was determined as VI to be 14.2 mol.% (56.8% of the theoretical). A part of this aqueous solution again showed a red color with a ferric chloride solution, but it gave no precipitate of ferric sulfinate.

ii) To 5.3 g. of I 3.0 g. of V were added; then, after the initial exothermic reaction was over, 1 ml. of anhydrous methanol was added to the jelly-like mixture, whereby heat was evolved again. The mixture was diluted with water and extracted with petroleum ether to give 0.3 g. of methyl *p*-toluenesulfinate (6%).

iii) The reaction mixture of 9.0 g. of I and 5.0 g. of V was vacuum-distilled as in i). Three milliliter of a low boiling fraction was collected; it was found to contain 1.6 g. (63% of the theoretical) of acetic anhydride on redistillation. After it, a trace of a green-colored liquid came out, and finally 1.6 g. of an orange-yellow liquid at 100—110°C/3 mmHg (mostly at 110°C) was obtained. This oil formed colorless crystals of *p*-toluenesulfinic acid upon coming in contact with water. The infrared specturm of this liquid also confirmed it to be *p*-toluenesulfinyl chloride. The yield was 18 mol.% (73% of the theoretical yield, based upon formula 1). When the residue in the vacuum distillation was treated with water, the yield of *p*-toluenesulfonic acid was estimated to be 22.2 mol.% (89% of the theoretical yield) by precipitation as VI (3.63 g.).

The Liquid-Liquid Extraction of Alkaline Earth Metals with TTA (2-Thenoyltrifluoroacetone)

By Ikuko AKAZA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received September 21, 1965)

The liquid-liquid extraction of alkaline earth metals was investigated with a TTA-MIBK solvent and a NH_4OAc-AcOH-NH_4OH aqueous solution in the presence of relatively large amounts of the metals. The extractability of the metal ions was in the decreasing order of magnesium, calcium, strontium and barium, while their distribution ratios were too close to one another for them to be separated from each other. Critical studies were made on several factors affecting the distribution of each metal, such as the amount of metal in the aqueous solution, the concentration of TTA in the organic solvent, and the pH of the solution. It was noticed that the concentration of TTA in MIBK played a principal role in this extraction and that the log *D*-log(TTA) relation was shown as a curve, not a straight line. The relation in other similar cases had usually been shown as a straight line, but the new results were obtained by compensating pH-change, the extent of which was variable with the concentration of TTA in the system. Among the metal ions, calcium and magnesium could be separated from each other by carrying out the extraction from their solution in the presence of EDTA. A further extention of this extraction to a reversed-phase partition chromatography will be undertaken and reported on in another paper.

The chelating agent 2-thenoyltrifluoroacetone (usually abbreviated as TTA) has proved to be a valuable reagent for the solvent extraction of many metal ions. It has the property of accomplishing the extraction from stronger acid solutions than other chelating agents. Thus, there is a wide range of metal ions that may be extracted without interference from hydrolysis. A considerable amount of work has been done on the use of TTA[1] alone or with other chelating agents.[2] However, there have been few works on the extraction of alkaline earth metal ions except for the determination of the stability constant of their chelates with TTA.[3] Khym, Tompkins and Cohen[4] have reported the separation of the calcium-45 produced by the Sc(d, 2p) reaction from the target by solvent extraction with 0.5 M TTA in benzene from a solution of pH 9. Kiba and Mizukami[5] have studied the rapid separation of radioactive strontium by solvent extraction with 0.05 M TTA in methyl isobutyl ketone (abbreviated as MIBK) from a solution of pH 8. Although TTA was believed to cleave to trifluoroacetic acid and acetylthiophen when the pH of its aqueous solution was in excess of 9,[6] their intuitive choice of the solvent surmounted a difficulty of using TTA in a basic medium, for MIBK was later proved as to be a good retardent for the decomposition of TTA,[7] as well as a good polar solvating agent to facilitate the chelate formation and extraction. After this study, alkaline earth metals and heavier alkali metals such as cesium became the objects of quantitative extraction with TTA in MIBK from their aqueous solutions of higher pH values, especially in the preparation of radio-isotopes, the processing of irradiated reactor fuel, and the analysis of fission products.[8] However up to the present there have been no systematic studies of the liquid-liquid extraction of alkaline earth metals with TTA-MIBK in relatively large amounts of the metals.

The present author studied critically the extraction from aqueous solutions over a wide range of pH values, and determined the distribution ratio of each individual ion with relation to the concentration of TTA in the solvent and the pH of the aqueous phase. It was noticed that the distribution ratio between two phases varied remarkably with the concentration of TTA in the organic phase, and that the extraction mechanism is not as simple as it had been considered to be. As a result, the distribution ratios of the metals are too close together for them to be separated easily. The author aims to separate these metal ions by later extending this extraction method to the reversed-phase partition chromatography, which will be described in another paper.

Experimental

Reagents and Apparatus. — *TTA (2-Thenoyltrifluoroacetone).*—Dotite TTA, prepared by the Dōjindō Research Laboratories, was used without further purification. It was dissolved in MIBK (methyl isobutyl ketone) of an analytical reagent grade to make a 0.2 M TTA-MIBK solution in most cases.

Buffer Solution.—A buffer solution consisting of ammonium acetate - ammonia - acetic acid was employed to keep constant the pH of the aqueous solution. In consideration of its buffer capacity, a 6 M-solution was usually employed for adding to the sample solution, and the final concentration of the buffer solution was made 3 M by diluting the test solution to twice the volume of the initial buffer solution. Sometimes a 1.0 M buffer solution was also used to make the final concentration of the test solution 0.5 M.

Salt Solution.—Barium chloride dihydrate, strontium nitrate tetrahydrate, calcium nitrate tetrahydrate, and magnesium chloride hexahydrate, all of analytical grades, were dissolved in water to make solutions containing 10^4 p. p. m. of the metal ion. The concentration of each solution was standardized by titration with EDTA (ethylenediaminetetraacetic acid disodium salt). The stock solutions thus prepared were diluted with water to suitable concentrations before use.

Radioactive strontium-90 - yttrium-90 as nitrate and barium-140 - lanthanum-140 as chloride were employed in order to examine their behavior in the extraction, after their daughter nuclides had been separated by the usual method.

EDTA Solution.—Analytical-grade disodium salt of ethylenediaminetetraacetic acid (Dotite 2 Na) was dissolved in water to make a 0.01 M solution, the concentration of which was then standardized with standard calcium carbonate.

Buffer Solution of pH 10.—The buffer solution used for titration by EDTA was prepared by dissolving 7 g. of ammonium chloride in 57 ml. of aqueous ammonia and then diluting it to 100 ml.; it was adjusted to pH 10 by adding an ammonium chloride solution or aqueous ammonia.

Eriochrome Black T, the indicator, and a 0.1 M magnesium-EDTA solution were prepared as usual.

Separating Funnel.—A 85 ml., spindle-type separating funnel was used.

pH Meter.—A pH meter with a glass electrode and a saturated calomel electrode, Model M-3 Horiba Manufacturing Co., was employed.

Flame Photometer. — A spectrophotometer, Hitachi Model EPU-2A, provided with an accessory flame burner, H-2, was used to determine the quantity of metal ions in a solution, using hydrogen gas as the fuel.

Radioactivity Counter.—A G-M counting set of the Kōbe Kōgyō Co., consisting of a No. 131-G-M tube and a "100 scalor," was used for β-counting.

Shaker.—The shakng of the separating funnel was effected by a vertical electric shaker, Iwaki Model 3, operating at 300 strokes per minute.

Experimental Procedure. — In the separating funnel 10 ml. of a 0.2 M TTA-MIBK solution, 5 ml. of a sample solution and 5 ml. of a 6 M buffer solution were put together. The funnel was then shaken for ten minutes with the electric shaker. After the two phases had separated the aqueous solution was taken out through the stem and its pH was measured. The sample solution adhering to the glass electrode of the pH meter and to the inside wall of the funnel was washed down into a beaker. On the other hand, the organic phase remaining in the funnel was treated with 5 ml. of 1 M hydrochloric acid in order to back-extract the metal ion in the organic phase. The back extraction was repeated twice, and the acid washing was submitted to the determination of the metal ions contained in the organic phase. The original aqueous phase was also submitted to the determination, according to the following methods.

Titration Method.—The aqueous solution was nearly neutralized with a 1 M sodium hydroxide solution or 3 M aqueous ammonia, and 2 ml. of a buffer solution with a pH of 10 was added; then 2 ml. of a magnesium-EDTA solution was pipetted into the solution. The solution was titrated with a 0.01 M EDTA solution and two or three drops of a BT indicator solution. The acetate ion, which interferes with the clear exhibition of this color change, should be completely eliminated by evaporating the aqueous solution to dryness with a strong acid before the titration.

Flame Photometry. — The original aqueous phase contained various amounts of acetate, so it was difficult to re-establish the same conditions in a series of reference solutions and so draw the working curve. Therefore, the back-extract was submitted to flame photometry. However, in the solution some acetic acid, ammonia and TTA - methyl isobutyl ketone were present, together with the metal ion to be tested. These substances were removed by the following treatment before the flame-photometric determination. A half-volume of ethyl ether was added to the solution in a separating funnel, and the contents shaken for a while; then the aqueous phase was transferred into another funnel and shaken with ether again. The aqueous solution separated from ether was warmed to 50°C, and air was passed through the solution for about thirty minutes in order to expel the ether. Then the solution was submitted to the determination. As references for the determination a series of solutions were prepared containing definite amounts of the respective metals in 1 N hydrochloric acid.

Results and Discussion

Preliminary Experiments.—*The Behavior of Individual Ions.*—In order to examine the behavior of individual ions in larger amounts, some preliminary experiments were undertaken under the same conditions as had been done in its trace scale by Kiba and Mizukami.[5] In a separating funnel there were placed together 5 ml. of a 1.0 M buffer solution of pH 8.0, 5 ml. of a 0.02 M solution of the metal ion, and 10-ml. of a TTA-MIBK solvent of varying concentrations, from 0.05 M to 0.5 M. The recovery of each ion in the organic phase is shown in Fig. 1, from which it may be found that the percent extraction decreases in the order of magnesium, calcium, strontium and barium, and increases with the concentration of TTA in methyl isobutyl ketone. Extraction was also carried out with strontium and barium in varying amounts

from a trace to 0.005 M; the recovery is shown in Figs. 2 and 3.

In each case the increase in the concentration of TTA promoted the extraction of metal ions, and the larger the quantity of metal ion present, the lower was the percentage of extraction. When the quantity of metal ions was minute, methyl isobutyl ketone containing 0.2 M or more of TTA was very useful in effecting a satisfactory recovery of the metal. The extraction behavior was much the same in these four metals, as is shown by the closeness of the extraction curves in Fig. 1.

The Use of a Mixed Solvent.—Because of the similar behavior of the metal ions, the separation from one another seemed to be very difficult. Therefore, the mixed solvent was used in an attempt to effect a separation of the metals. Ten milliliters

of a mixed solvent consisting of 0.1 M TTA - benzene and 0.1 M TTA - MIBK in various ratios was used for extraction from a solution composed of 5 ml. of a 1.0 M buffer solution of pH 8.0 and 5 ml. of a 0.02 M solution of metal ions. The results obtained with mixed solvents of various compositions are shown in Fig. 4, which reveals that though the percentage extraction of each metal increases with the volume of TTA-MIBK, no better separation from one another can be expected. It also reveals that benzene does not play any role in the attainment of selectivity. Thereafter, MIBK was exclusively employed in this method.

Organic phase: 10 ml. of mixed solvent of 0.1 M TTA - MIBK and 0.1 M TTA - Benzene

The Change in pH During Extraction.—When a 1.0 M buffer solution was used in an aqueous phase, the pH, which was 8.0 initially, became 6.8 after the extraction. Since TTA can be considered to be a weak acid, its dissolution into the aqueous phase during the extraction and the release of protonized hydrogen from it by the metal ion may have caused the increase in hydrogen ions in the aqueous phase. In order to keep the pH nearly constant during the extraction, a 6 M buffer solution was preferred because of its large buffer capacity. In the subsequent experiments 5 ml. of the buffer solution was taken and diluted to 10 ml. with the sample solution and water in order to make the buffer concentration in the aqueous phase 3 M. The concentration of TTA in MIBK was also kept at 0.2 M in the subsequent experiments.

The Mechanism of Extraction.—The equation for the extraction of a metal ion with the charge $+z$, M^{z+}, and with a monobasic chelating agent, HT, can be simply written as:

$$M^{z+}_{(a)} + zHT_{(o)} \rightleftharpoons MT_{z(o)} + zH^{+}_{(a)}$$

where the subscripts a and o refer to the aqueous and organic phases respectively. A thermodynamic extraction constant for this process can be written most simply as:

$$K=(MT_z)_o(H^+)_a^z/(M^{z+})_a(HT)_o^z$$

and:

$$K=D(H^+)_a^z/(HT)_o^z$$

where D is the extraction coefficient (the total concentration of metal in the organic phase/the total concentration of metal in the aqueous phase).

Org. phase: MIBK containing varying amounts of TTA

D can also be written as:

$$D=K(\mathrm{HT})_o^z/(\mathrm{H}^+)_a^z \quad (1)$$

Therefore, the distribution ratio depends on the activity of both the chelating agent and the hydrogen ions. The values of D, determined in various concentrations of the chelating agent while the pH is kept constant, and at varying pH values at a definite concentration of the chelating agent, may clarify the extraction mechanism.

First the dependence of D on the pH of an aqueous solution after the extraction was examined by the following experiments. The distribution ratios were estimated in a series of extractions between 10-ml. portions of organic and aqueous phases, the former being 0.2 M TTA - MIBK and the latter consisting of various amounts of a metal ion in a 3 M buffer solution of varying pH values. The relations between log$D$ and pH after the extraction are shown as straight lines having slopes of unity to two for magnesium, calcium, strontium and barium, respectively, in Figs. 5, 6, 7 and 8. The slope becomes sharper as the quantity of the metal ions decreases and as the stability of the metal chelate increases.[1] The dependence of D on the concentration of TTA in methyl isobutyl ketone was also examined in the extraction between 10-ml. portions of organic and aqueous phases, the former being MIBK containing various amounts of TTA, and the latter consisting of 5 ml. of a 0.025 M solution of calcium ion and 5 ml. of a 6 M buffer solution of varying pH values. The results are summarized in Fig. 9, in which the pH noted is, of course, that of the aqueous phase after the extraction.

Next, the author attempted the extraction at a constant pH value of 7.0 of the aqueous phase and at the constant concentration of calcium of 0.125 mmol. between 10 ml. of the aqueous phase and 10 ml. of MIBK containing varying amounts of TTA. However, the author failed in the attempt to make the pH of the solution exactly 7.0 after each extraction, since the pH of the aqueous phase was liable to be made lower by mere contact with the organic phase, probably because of the partial transfer of the TTA from the organic to the aqueous phase. Even when a buffer solution with a higher capacity, such as a 6 M solution, is used, the pH of the aqueous solution cannot be guaranteed to remain strictly constant. Moreover, when an organic solvent containing a still larger amount of TTA is employed, the distribution of calcium is enormously affected by even a slight change in the pH, as is shown in Fig. 9. The proper distribution ratio should be estimated at the constant pH, but it is difficult to maintain the constant pH over all the estimation of log D - log(TTA). Therefore, the relation of the distribution ratio to the concentration of TTA at pH 7.0 was constructed from the data in Fig. 9. A noteworthy fact was thereby

found about the extraction mechanism. As Fig. 10 shows, the concentration of TTA, noted as (TTA) in the figure, has the relation with the distribution ratio given in the curve of log D vs. log(TTA). The curve seems to illustrate the true behavior of the extraction at pH 7.0. Nevertheless, a number of researchers who investigated the extraction of the TTA-chelates of other metals have described how the relation between log D and log(TTA) is usually represented by a straight line with a slope of an integral value, the integer being the number of TTA molecules attached to the metal. In many cases they seem to have overlooked the facts that the pH of the aqueous solution is lowered not only by the hydrogen ion exchanged with the metal, but also by the dissociation of TTA in the aqueous phase; that a lowering of the pH is remarkable when the concentration of TTA is high, and that, therefore, the higher the concentration of TTA, the larger the decrease in the extent of the distribution ratio. Such a change in the pH will be slight in an acidic solution, but it will be remarkable in a neutral or alkaline solution.

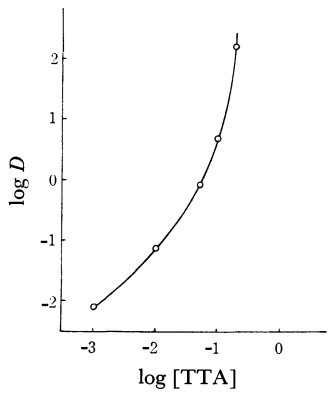

Fig. 10. Dependence of log [TTA] at pH 7.0, same data as in Fig. 9.

The curve drawn by the present author appears as a smooth one in Fig. 10, but it is suspected that it is really composed of a large number of short lines, with their slopes increasing from unity to large integers. This suggests that various species of metal-chelate are formed with the increase in the concentration of TTA in the organic phase. When the concentration of TTA is large, the number of TTA radicals attached to the calcium atom increases and, as a matter of fact, the distribution of the metal into the organic phase is enhanced. In addition, the distribution of metal usually depends upon the following factors: the time required for the attainment of equilibrium, the temperature, the kind and concentration of the metal ion and of the chelating agent, the pH of the aqueous phase, the other chelating agents present, the adduct-forming agent, and the organic solvent used.[9]

9) G. K. Schweitzer, *Anal. Chim. Acta*, **30**, 68 (1964).

The extraction between an aqueous phase containing a divalent ion as calcium and an organic phase containing TTA can be written as follows:

$$M^{2+}_{(a)} + 2HT_{(o)} \rightleftharpoons MT_{2(o)} + 2H^{+}_{(a)} \quad (2)$$

$$D = K(HT)^2_o/(H^+)^2_a \quad (3)$$

Therefore, D is inversely proportional to the square of (H^+). As has been described above, the author has found that the relation between log D and pH is linear, with the slope between unity and two. Therefore, Eq. 3 can explain the phenomenon where the slope is two, but not where it is unity. Similar behavior of alkaline earth metals has already been cited in the description by Cerrai et al.,[10] who investigated the liquid-liquid extraction of alkaline earth metals with di-(2-ethylhexyl)orthophosphoric acid (abbreviated as HDEHP). In their study they considered that this fitful phenomenon was caused by the acetate ions present. Thorium has been proved to be a metal subject to the same effect of acetate,[11] even in extraction with TTA from acidic solutions. The present author wishes to take this effect into account in clarifying the above phenomenon.

If a divalent metallic cation, M^{2+}, is present in a large excess of acetate ions in the buffer solution, a competition may occur between HT and the acetate ion for co-ordinating to the metal ion in the following manner:

$$M(CH_3COO)^{+}_{(a)} + HT_{(o)} \rightleftharpoons M{\cdot}CH_3COO{\cdot}T_{(o)} + H^{+}_{(a)} \quad (4)$$

In this case the dependence of the distribution ratio of metal on the hydrogen ion concentration may be written as a first-power dependence. On the

Table I. Some aspects of the behavior of the extraction of calcium

pH	TTA in organic phase, initial m	Metal ion in aqueous phase, initial, n	x	m/n calcd.	m/n tangent of the curve in Fig. 10
	M	M			
7.0	0.2	0.0125	1.74	16	8.7
7.0	0.1	0.0125	0.81	8	3.1
7.0	0.05	0.0125	0.36	4	1.95
7.0	0.01	0.0125	0.24	0.8	1.15

other hand, the methyl isobutyl ketone used as an extracting solvent may also participate in the extraction mechanism, because of its polarity. Log D and log(MIBK) have a linear relation with a slope of unity, as is shown in Fig. 11, when methyl isobutyl ketone of various concentrations in benzene is used in the extraction of alkaline earth metal from an aqueous solution kept at pH 8 by a 1.0 M buffer solution. This shows that methyl isobutyl ketone can co-ordinate to the alkaline earth metal as a monodentate ligand; therefore, Eqs. 2 and 4 should be revised to 5 and 6, respectively, in such a case:

$$M^{2+}_{(a)} + 2HT_{(o)} + L_{(o)} \rightleftharpoons MT_2 \cdot L_{(o)} + 2H^+_{(a)} \quad (5)$$

$$M(CH_3COO)^+_{(a)} + HT_{(o)} + L_{(o)} \rightleftharpoons MT \cdot CH_3COO \cdot L_{(o)} + H^+_{(a)} \quad (6)$$

where L is methyl isobutyl ketone as a non-charged ligand.

From these equations, the dependence of the distribution ratio on the concentration of TTA is considered to be only linear or quadratic, but the phenomena shown in Fig. 10, in which the distribution ratio increases with the concentration, even by the power of three, cannot be explained unless undissociated TTA is regarded as participating in the equilibrium. Equations 5 and 6, then will become 7 and 8 respectively:

$$M^{2+}_{(a)} + (2+m-2)HT_{(o)} + L_{(o)} \rightleftharpoons MT_2(HT)_{m-2} \cdot L_{(o)} + 2H^+_{(a)} \quad (7)$$

$$M(CH_3COO)^+_{(a)} + (1+m-1)HT_{(o)} + L_{(o)} \rightleftharpoons MT(HT)_{m-1} \cdot CH_3COO \cdot L_{(o)} + H^+_{(a)} \quad (8)$$

where m is the mole number of TTA in the organic phase participating in the extraction and varies with the concentration of TTA added to the system. These equations show the general scheme of the extraction with TTA from an aqueous solution containing metal ions; they satisfactorily explain the phenomena show in Fig. 10. The numerical value 2 noted in Eq. 7 resulted from the extractions carried out in the range of 0.2 M TTA - MIBK and 0.125 mmol. of calcium (cf. Figs. 5—9). Under different conditions each term in Eqs. 7 and 8 may vary with the circumstance and other types of metal chelates may be formed.

In higher concentrations of TTA, the molecules are supposed to associate around the chelate and the distribution of metal may increase remarkably. The acetate ion and methyl isobutyl ketone may be displaced from the chelate by TTA as its concentration increases. For all that, the concentration of TTA plays a principal role in the extraction.

If all of the TTA added in the system reacts with the metal, the equilibrium may be written as follows:

$$nM + (xn+m-xn)HT \rightleftharpoons n(NT_x \cdot (HT)_{m/n-x}) + nxH^+ \quad (9)$$

where n is the moles of metal ion, m is the moles of HT added in the system, and x is the moles of hydrogen ion displaced by the combined HT. From the experimental data on which Figs. 9 and 10 are based, some systematic relations can be derived for the equilibrium of the extraction. These relations are shown in Table I. If all of the TTA present in the system (m) participates in the extraction of all the metal ions (n), the m/n value shown in the fifth column will indicate the number of TTA attachable to a metal ion schematically, but the tangent at any point on the curve in Fig. 10 will indicate the actual number of TTA radicals participating in the extraction of the metal ion at the definite concentrations of TTA and metal ions (sixth column). The number of TTA radicals combined by their ionic linkage in the chelate is given in the column under x. It can be obtained from the slope of the line in the log$D$-pH graph. The conspicuous difference between the values in the fifth and sixth columns from the assumption arbitrarily made in calculating the m/n (the fifth column) that all the TTA is capable of attaching to the metal ion. Therefore, the m in Eq. 9 is not the total concentration of TTA in the system; rather, it should be m, that of the TTA participating in the extraction with the metal. Therefore, the TTA molecules other than those functionally attached seem to be left out of the extraction process. Then, however, the distribution ratio will reach a steady value when the concentration of TTA exceeds some definite value.

However, the distribution ratio shown in Fig. 10 increases boundlessly with the increase in TTA. Therefore, it may be assumed that all the TTA added to the system participates in the extraction in various forms. Then, another equilibrium may be present between the total amount of TTA and the functional amount:

$$\text{total (HT)} \rightleftharpoons m(\text{HT}) \qquad (10)$$

To confirm the above assumption, the following experiment was undertaken. Methyl isobutyl ketone containing 1.48 mol. of TTA per liter was equilibrated with a 0.5 M buffer solution of pH 5.5 of the same volume. The buffer solution thus treated was then used to prepare a solution containing a definite amount of calcium. Each variation in the volume of this solution was taken in a separating funnel, and the total volume was made up to 7.3 ml. with the pre-equilibrated buffer solution. The extraction was carried out between 7.3 ml. of this aqueous solution and the methyl isobutyl ketone pre-equilibrated as above. After the extraction, the amount of calcium ion remaining unextracted was determined by flame-photometry. The ratio of the amount of TTA to that of calcium in the organic phase was calculated from the data obtained over all the range. It was found that when the amount of calcium in the aqueous solution was increased, the calcium in the organic phase reached a saturation point with the molar ratio of calcium to TTA at 1 : 34. In other words, at least thirty-four molecules of TTA were required to extract an ion of calcium. Even this minimum number is larger than the number evaluated from the tangents of the curve of log D-log(TTA) obtained under the same conditions as in this experiment. The number obtained from the curve is considered to be the number of TTA molecules attached to the chelate; apparently, no additional molecules seem to be necessary for the extraction. This is, however, not correct. Since the saturation of calcium occured in the organic solvent when it contained 34 molecules of TTA to one calcium ion and since the distribution ratio of calcium increased boundlessly with the increase in the concentration of TTA, the extra TTA molecules must be regarded as necessary for the extraction. Therefore, it may be supposed that a relatively large number of TTA molecules besides those attached to the chelate are required for the complete extraction of calcium. Consequently, Eq. 10 seems to hold for the equilibrium of the extraction system.

The Separation of Magnesium from Calcium, Strontium and Barium.—The distribution ratios of alkaline earth metals are so close to one another that it seems difficult to separate one from the others, even by multiple-batch extraction. However, if another chelating agent such as EDTA is present in an aqueous solution, calcium may be separated from the others by taking advantage of the greater stability of its EDTA-chelate.

The Behavior of Individual Ions in the Extraction in the Presence of EDTA.—The extraction procedure is based on the principle of competition between TTA and EDTA in the formation of the chelate. To an aqueous solution containing magnesium, calcium, strontium and barium ions and a suitable amount of EDTA, aqueous ammonia was added to make the solution almost neutral; then extraction with TTA-MIBK was carried out as has been previously described. After the extraction the aqueous phase was transferred to a beaker and evaporated nearly to dryness. The residue was dissolved in a mixture of 2 ml. of 6 N hydrochloric acid and 10 ml. of 30% hydrogen peroxide, and then the solution was evaporated nearly to dryness. In order to destroy the EDTA completely, the successive additions of 10 ml. of 30% hydrogen peroxide and evaporations were repeated. After the treatment, some water was added to dissolve the residue; the solution thus obtained was neutralized with sodium hydroxide and then titrated with a standard solution of EDTA, using BT as an indicator, at pH 10.

The extraction with 0.2 M TTA - MIBK was carried out for solutions containing about 0.5 mmol. of each metal ion at varying pH values, in the presence of EDTA in an amount equivalent to the metal. The recovery of the metals, especially calcium and magnesium, in the organic phase is shown in Fig. 12. The result shows that magnesium is very easily extractable, but calcium is not, their separation factor, β, being 139. Further experiments were made in order to examine the behavior of each alkaline earth metal in the presence of as much as four equivalents of EDTA. Table II shows the results obtained in the extraction of magnesium, calcium, strontium and barium at varying pH values. This method was found suitable for separating magnesium from other alkaline earths. EDTA-chelate of calcium has a large stability, but the other metals have a smaller stability. From this fact it may be expected that magnesium, strontium and barium can be extracted all together with TTA; however, this is not the case except for magnesium. This anomalous behavior of strontium and barium may come from the fact that their TTA-chelates have a relatively lower stability than that of magnesium.

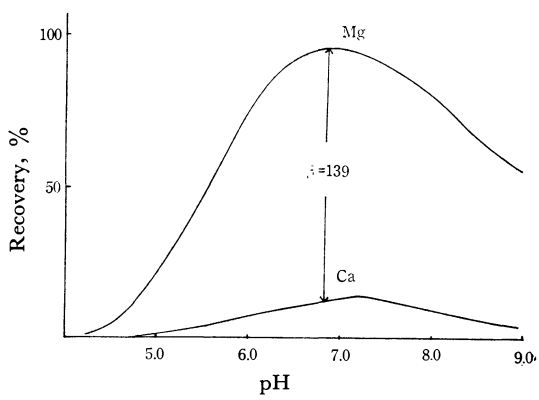

Fig. 12. Behavior of calcium and magnesium in extraction in presence of EDTA.

The Separation of Magnesium from Calcium by Extraction with TTA in the Presence of EDTA.—An aqueous solution containing a total amount of magnesium and calcium of 0.5 mmol. was subjected to extraction with 0.2 M TTA - MIBK in the presence of four equivalents of EDTA. The extraction was then repeated two more times with new batches of the organic solvent in order to make a satisfactory separation. The organic phases were then put together into another separating funnel. The back extraction of the organic phase was carried out with 1 N hydrochloric acid. The solution thus obtained was evaporated with the addition of 30% hydrogen peroxide in order to decompose the EDTA. The hydrochloric acid solution was first adjusted to pH 10 by adding a buffer solution of aqueous ammonia and ammonium chloride; then it was titrated with a standard solution of EDTA, using BT as an indicator. The volume of the EDTA solution required was equivalent to the sum of the amounts of calcium and magnesium extracted in the organic phase. Then, another part of the back-extracted solution was treated in the same way, and its pH was adjusted to 12 by adding potassium hydroxide and it was titrated with a standard solution of EDTA, using Dotite NN (calcon) as an indicator. The volume of the EDTA solution required in the latter titration represented the amount of calcium extracted in the organic phase. The recovery of calcium and magnesium from their mixture in various ratios is shown in Table III, from which it may be found that magnesium can be separated largely in the organic phase, while calcium remains in the aqueous phase, although there is some mutual contamination.

Table III. Separation of calcium from magnesium by extraction with TTA-MIBK in presence of EDTA

Ca alone	—	6.2

Summary

The liquid-liquid extraction of alkaline earth metal ions with 2-thenoyltrifluoroacetone dissolved in methyl isobutyl ketone has been investigated with a view of separating them. The extractability of the ions decreases in the order of magnesium, calcium, strontium and barium; moreover, the distribution ratios between the organic solvent and the aqueous solution are too close to one another for a satisfactory separation. Critical studies have been made on some factors affecting the distribution ratio (hereafter denoted by D) of each metal, such as the amount of metal ion in the aqueous solution, the concentration of TTA in the organic solvent, and the pH of the solution. Among these factors the concentration of TTA in MIBK was found to play a principal role in this extraction, and the relation between $\log D$ and log(TTA) was shown as a curve, not a straight line, in the range of TTA concentration from 0.001 to 0.2 M in MIBK, while another investigators had previously stated that the relation could be shown in many other cases as a straight line with a slope of 2. The slope of the straight line representing the relation between $\log D$ and log (TTA) had usually been believed to show the number of molecules of the chelating agent attached to the metal extracted, i. e., the extracted species; however, the curve obtained by the present author indicates that the extraction process is not so simple but is, rather, very complicated. The difference may be caused by a fact overlooked by the other investigators: the pH of the aqueous solution is lowered enormously by contact with the organic phase, and the distribution ratio is thereby remarkably decreased.

In the author's experiment with 1.48 M TTA-MIBK, the number of TTA molecules attached to a calcium ion is enormously large, at least thirty-four. This phenomenon can be explained

by assuming that, in a lower concentration of TTA, the metal ion is bonded not only by TTA but by the acetate ion present in the buffer solution or by MIBK, a polar solvent, while, on the other hand, in a higher concentration of TTA, the acetate ion and the MIBK do not participate the chelate formation but only the TTA can be attached to the metal, and a network of TTA, which will increase the distribution of metal into the organic solvent, may be produced surrounding the metal.

Among the metal ions, calcium and magnesium could be separated from each other by carrying out the extraction in the presence of EDTA, by virtue of the competition between EDTA and TTA for chelate formation. The author has extended this extraction method to a reversed-phase partition chromatography in a column; this will be described in a following paper.

The author wishes to express her thanks to Professor Toshiyasu Kiba for his kind advice and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 980—989 (1966)

The Separation of Alkaline Earth Metals as Their TTA-Complexes by Reversed-Phase Partition Chromatography

By Ikuko AKAZA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received September 21, 1965)

The author's preceding work, the liquid-liquid extraction of alkaline earth metals with TTA-MIBK, has now been extended to a reversed-phase partition chromatography in order to attain a good separation of the metal ions. The method was carried out with relatively large amounts of the metals through a column of Kel-F on which the organic phase of 1.5 M TTA - MIBK was supported. Elution was performed with 0.5 M buffer solutions, of various pH values, consisting of acetic acid, ammonium acetate and aqueous ammonia. The actual separation of each metal ion from the mixture of alkaline earth metals was achieved; the results are shown in several figures. The dependence of the distribution ratio on the pH of the solution and on the concentration of TTA in the stationary phase was examined from the elution curves; it might be considered that the same relation held as in the case of the liquid-liquid extraction system. Other experiments were then carried out in order to clarify the behavior of the TTA-chelates in the presence of a large amount of TTA; it was found that all of the TTA in the system participated in the effective extraction of the metal ion. The steps in the formation of the higher TTA-chelate in the column are depicted by the break-through curve of the chromatographic process.

Previously the present author studied the liquid-liquid extraction of alkaline earth metal ions with TTA (2-thenoyl trifluoroacetone) in methyl isobutyl ketone (abbreviated as MIBK); the details of that investigation have been described in a preceding paper.[1] As a consequence of that study it was found that the separation of alkaline earth metals from one another by batch extraction was very difficult because the distribution ratios of the TTA-chelates of the metals between methyl isobutyl ketone and an aqueous solution of a different pH value were so close together. The lower separation factors among the metal ions induced the author to seek other more convenient and efficient methods based upon extraction with TTA - MIBK. Reversed-phase partition chromatography is closely related to liquid-liquid extraction, except that in the former the water-immisible extractant is immobilized on a stationary inert support. In the column extraction of this type an aqueous solution containing the solute to be extracted is always in contact with the fresh organic solvent on the column, and multiple extraction may be carried out throughout the process; therefore, effective separation may be achieved between the substances of a lower separability. Moreover, a larger quantity of metal ions may be treated by this method.

In this investigation Kel-F (polytrifluorochloroethylene), presented by Hamlin et al.,[2] was chosen as the inert solid support from among the

various kinds of material that had been recommended. Reversed-phase partition chromatography has never been applied for the separation of alkaline earth metals in the column method, excepting the work by O'Laughlin and Banks[3] who separated barium, magnesium and calcium from each other using bis(di-*n*-hexyl-phosphinyl)-methane. Recently, however, Cerrai and Ghersini[4] attempted the paper chromatographic method with di-(2-ethylhexyl)orthophosphoric acid, HDEHP; the R_f value for each metal showed a capability of separation.

This paper will describe a column method of reversed-phase chromatography in which the stationary phase is a solution of TTA in MIBK supported on Kel-F, and the mobile phase is a 0.5 M buffer solution consisting of acetic acid, ammonium acetate and aqueous ammonia. The results of the liquid-liquid extraction of TTA-chelates of alkaline earth metals described in a preceding paper[1] will be fully utilized. The elution of the individual ions and the isolation of each metal could be achieved successfully by the column method. The relation of the chromatography to the liquid-liquid extraction will be discussed in detail.

Experimental

Apparatus.—The column, the fraction collector and the flame photometer were the same as those described in previous paper,[6] but the inner diameter of the column tube was 1.2 cm. and the length was 20 cm.

Reagents and Materials.—Kel-F (polytrifluorochloroethylene), TTA (2-thenoyltrifluoroacetone) and MIBK (methyl isobutyl ketone) were the same as those used by the author in previous investigations.[1,6]

The Organic Solvent Solution Used for The Stationary Phase.—In 20 ml. of MIBK placed in a separating funnel, dissolve 8.888 g. of TTA; the volume of the solution thereby becomes 27 ml. Adjust the pH of a 0.5 M ammonium acetate solution saturated with MIBK to the value which is preferred for each eluting process. Put 27 ml. of this solution into the separating funnel, and shake the vessel until the two phases are equilibrated enough. Use the organic phase for adsorbing on Kel-F powder, as will be described below. This method of preparation was employed in many cases in this research and is referred to as the 1.48 M TTA-MIBK solvent solution. In some cases, however, MIBK solutions with different amounts of TTA were also used.

Eluting Solution.—The eluting solution in each case should have a composition similar to that of an aqueous solution which has been equilibrated with the organic solvent solution it comes in contact with in the column. To save the trouble of actually equilibrating the two phases, the following method should be employed: First, prepare a solution containing a definite amount of TTA in MIBK. Next, prepare a 0.5 M ammonium acetate - acetic acid or aqueous ammonia buffer solution of a definite pH which is saturated with MIBK. Place equal volumes of the TTA-MIBK solution and the buffer solution in a separating funnel, and equilibrate the two phases by shaking. Take out a definite volume of the organic phase and pour it on the Kel-F powder in order to prepare a stationary phase of the column. Determine the amount of TTA present in the aqueous phase by the author's method.[5] Weigh the appropriate amount of TTA as calculated from the value and dissolve it in the buffer solution in the manner shown below.

Eluting Solution of pH 5.5.—Put into a 1-l. separating funnel 3.15 g. of a TTA reagent and 900 ml. of a 0.5 M ammonium acetate solution which has been saturated with MIBK; then shake the vessel for 30 min. in order to dissolve the reagent completely. Then adjust the pH of the solution to 5.5 by adding 0.5 M acetic acid. Make the total volume of the solution to 1 l. with a solution of 0.5 M ammonium acetate saturated with MIBK. Employ this solution for elution.

The amounts of TTA in the various buffer solutions which have been determined are as follows; the same amount of TTA should be dissolved for the preparation of each eluting solution:

Organic phase contacted	pH of the buffer solution	TTA g./l.
1.48 M TTA - MIBK	5.5	3.15
1.48 M TTA - MIBK	6.5	3.2
0.2 M TTA - MIBK	5.5	0.2
0.2 M TTA - MIBK	6.5	0.42
0.2 M TTA - MIBK	7.5	0.59

These eluting solutions can be stored without decomposition for a month in a dark place between 0°C and 3°C.

In the above case the amount of TTA to be dissolved in each eluting solution differs with the temperature, so the temperature during the preparation of the eluting solution and the elution of a solute from the column should be kept constant. Changes in temperature affect the solubility of MIBK in the eluting solution; therefore, the solubility of TTA also varies.

Sample Solution.—Barium chloride dihydrate, strontium nitrate tetrahydrate, calcium chloride dihydrate, and magnesium chloride hexahydrate, all of which are analytically-pure reagent grade materials, were employed. It is desirable, but not in all cases, that the sample solution have a composition like to that of the eluting solution. Three-milliliter portions of the sample solution were used for the column experiment.

Experimental Procedure.—*Preparation of the Stationary Phase.*—In a glass-stoppered Erlenmyer flask, put 8.0 g. of the Kel-F powder which has been dried at 80°C and stored in a calcium chloride desiccator; pour on it 7.3 ml. of an organic solvent solution prepared as above. After stoppering the flask, shake it by hand in order to homogenize the contents, and leave it in an ice-box for at least three hours. Add a small volume of a suitable eluting solution, and pour the slurry little by little into the chromatographic column, taking care not to let any air bubbles in, and gently pressing the slurry down with a glass rod each time. After pouring in all

the slurry, press the column bed with a glass rod in order to make it height about 18 cm. The upper surface of the column should be covered by the eluting solution.

The Elution, Separation and Determination of Metals.—Pour 3 ml. of the sample solution on the upper surface of the column and allow it to percolate into the column at the rate of 0.2 ml. per minute; then twice pour in little portion of the eluting solution in order to wash inside of the glass tube above the upper surface of the column, letting it flow down the column at the same rate. Set on the top of the glass tube a separating funnel from which the eluting solution of a definite composition is allowed to flow through the column, and carry out the elution at the rate of 0.5 ml. per minute. Collect the effluent in suitable fractions by a fraction collector, and determine the amount of metal in each fraction by flame-photometer. In order to get a satisfactory separation of an ion from the others with reasonable speed, a different eluting solution should be used for each ion.

Results and Discussion

The Characteristic Behavior of the Column.—*The Choice of Column Material.*—The author preferred Kel-F moulding powder for the same reason as was stated in a preceding paper.[6]

The Amount of Methyl Isobutyl Ketone that can be adsorbed by Kel-F.—In a glass-stoppered Erlenmyer flask 10 g. of Kel-F powder was placed; 50 ml. of MIBK was then poured on the powder, and the vessel was put aside for overnight after having been gently shaken. The unadsorbed solvent was drained through a small glass filter into a measuring cylinder under a slight suction. The inside wall of the flask was washed with 1 ml. of a fresh solvent in order to transfer all the Kel-F powder to the filter. The difference between the volume taken and that measured in the cylinder indicated the volume of the solvent adsorbed on Kel-F. It came to 9.0 ml. of the solvent for 10 g. of Kel-F powder.

The Volume of the Mobile Phase in the Column.—The column bed was prepared as follows: On to 8.0 g. of Kel-F powder, 7.2 ml. of MIBK saturated with water was poured. The ratio of these amounts was fixed at that obtained in the above experiment. The powder was then allowed to adsorb the liquid by standing overnight. A 0.1 M sodium chloride solution saturated with MIBK was added to the powder, and the resulting slurry was poured into the glass tube in order to make a column bed 18 cm. deep. Plenty of 0.1 M sodium chloride solution-saturated MIBK was allowed to flow down until the effluent showed the same concentration of sodium chloride as the original solution. After careful washing, with water, the inside of the tube below the fritted glass filter, water-saturated MIBK was poured on the column in order to wash down the 0.1 M sodium chloride solution occupying the pores of the column. The amount of sodium chloride was determined in the washing liquor by titrating it with a 0.1 M silver nitrate solution as usual; the volume of the pores of the column was then obtained from this value. That turned out to be 7.27 ml; hence, the volume ratio of the stationary phase to the mobile phase was found to be 1 : 1 in this case. This showed that the elution process consisted of multiple extractions between equal volumes of the two phases.

The pre-equilibration between the organic solvent and eluting solution of equal volumes, described in the preceding section, was necessary to maintain the condition of actual equi-volume extraction. However, they were not always prepared by the actual equilibration of the two phases, but usually by putting a calculated amount of the reagent in an aqueous solution.

Column Life and Stability.—After loading 0.09 mmol. of calcium on the column, elution with a solution of pH 5.5 was carried out; the elution curve was thus obtained as usual. The same experiment was repeated three more times in succession with the same column. The volume of eluent spent before the emergence of the calcium ion at a maximal concentration, as denoted by E, in each case is shown in Table I. In these experiments the temperature was kept at about 12°C, and the column was kept covered with black paper in order to exclued sunlight. In each elution about 420 ml. of the eluent was used, so the total volume came to as much as 1.7 l. On the other hand, two elutions carried out under the same conditions with the same column at an interval of two weeks gave a satisfactory result each time. Therefore, the column seems to remain capable of satisfactory use for a week, if the temperature is kept below 12°C and if light is excluded.

Table I. Column life revealed by the shifting of elution peak

Experiment in order	Date	Volume of effluent before peak of maximum elution
1	April 22	158.9 ml.
2	April 23	161.9 ml.
3	April 24	174.9 ml.
4	May 1	126.8 ml.

The Recovery of Kel-F.—The Kel-F powder could be recovered from the degraded column by the following method: The powder used was washed with water repeatedly, and with 1 M hydrochloric acid several times. It was then put in water containing 40% alcohol, which had been found to be a good wetting solvent for Kel-F, and stirred well in order to remove the MIBK from the powder. This treatment was repeated several times until the solution became neutral and the powder, pure white. The powder was

then washed again with 99% alcohol and the washings were removed with a glass filter under suction. Some ethyl ether was poured on the powder. The powder was dried under strong suction in order to remove the ether completely. The powder of Kel-F thus treated could be used again after drying at 80°C for one hour.

Column Capacity.—The capacity of the column prepared as described in the procedure was estimated by loading it with a calcium salt of a known concentration. The breakthrough curve obtained was not as sharp nor as smooth as usual. This may be due to the mechanism of the extraction described in a foregoing paper[1]; the meaning of an irregular curve will be discussed later.

The Chromatographic Behavior of Alkaline Earth Metals.—The chromatographic behavior of each alkaline earth metal ion can be predicted from the previously-descrived results obtained in the liquid-liquid extraction of their TTA-chelates with MIBK.[1] Their distribution ratios were found to depend on the hydrogen ion concentration of the aqueous phase, the concentration of TTA in the organic phase, and the quantity of metal ion to be treated. At any definite pH value of the aqueous phase, the distribution ratio of each metal ion was in the desending order: magnesium, calcium, strontium and barium. From these results it was expected that, in the column chromatography, barium could be eluted from the column faster than the others. Taking each extraction curve obtained previously into account, the elution curves of each metal ion were obtained at pH 6.5 and 5.5.

The Elution Curve of Individual Ions.—To examine quantitatively the retention on, and the elution from, the column, 0.025 mmol. of each metal ion was placed in the column and eluted with an eluting solution of pH 6.5. The results are shown in Fig. 1, which shows that the elution at this condition may be useful for the separation of the two metals. When a similar elution was carried out at pH 5.9, the two curves overlapped with each

other. The elution curves of strontium and calcium at pH 5.5 are shown in Fig. 2. They show the possibility of using this condition for the separation of the above two metals. Magnesium, however, was precipitated as the insoluble TTA-chelate over the pH range mentioned above.

The Separation of Metal Ions.—a) The Separation of Barium and Strontium.—Various amounts of

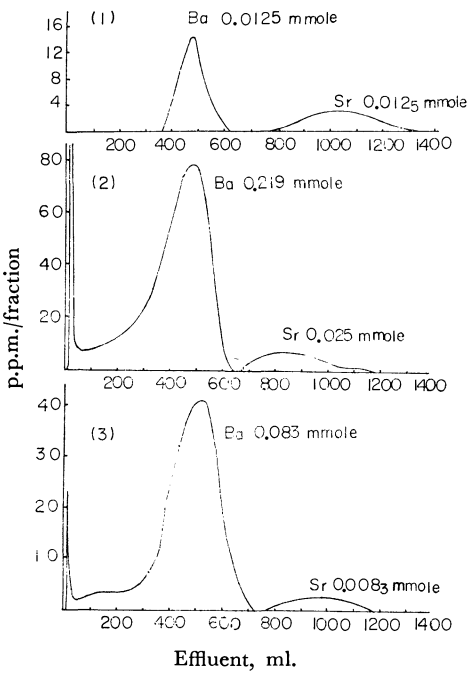

Fig. 3. Separation of barium from strontium.
Loaded: (1) 0.0125 mmol. Ba and 0.0125 mmol. Sr
(2) 0.219 mmol. Ba and 0.025 mmol. Sr
(3) 0.083 mmol. Ba and 0.008_3 mmol. Sr
Eluting solution: pH 6.5

barium and strontium ions were mixed in an eluting solution of pH 6.5 to make three kinds of a sample solution: (i) 0.0125 mmol. barium and 0.0125 mmol. strontium; (ii) 0.219 mmol. barium and 0.025 mmol. strontium and (iii) 0.083 mmol. barium and 0.0083 mmol. strontium, each in 3 ml. portions. Three milliliters of each sample solution were placed in the column, and the elution was carried out with the eluting solution of pH 6.5. The results obtained are shown in Fig. 3, from which it may be seen that the two metals could be separated from one another, even if they were present in widely different ratios.

b) The Separation of Strontium and Calcium.—In the column prepared as described in the procedure there was placed 3 ml. of a sample solution containing 0.333 mmol. strontium and 0.005 mmol. calcium and then another 3 ml. containing 0.005 mmol. strontium and 0.15 mmol. calcium. The elution was carried out with an eluting solution of pH 5.5. A satisfactory separation could be achieved, as is shown in Fig. 4.

c) The Separation of Barium, Strontium, Calcium and Magnesium.—A 3 ml. sample solution containing 0.0125 mmol. barium, 0.0125 mmol. strontium, 0.025 mmol. calcium and 0.0125 mmol. magnesium was employed. The TTA was left out, for it would precipitate magnesium as the chelate. Elution was carried out at first with an eluting solution of pH 6.5 until the volume of the effluent reached 700 ml. During the elution barium was eluted down as is shown in Fig. 5. Then the elution was continued with 400 ml. of an eluting solution of pH 5.5. Strontium and calcium

appeared in the effluent. At last the magnesium retained on the column was eluted down with 0.1 M hydrochloric acid. Thus the separation of alkaline earth metals from their mixture was achieved.

A Blank Test with the Solvent without TTA.—If the absence of the chelating agent TTA in MIBK causes a retention of alkaline earth metal ions by the stationary phase on the column, the method will be unsatisfactory for the separation of these ions. To test whether such retention really occurs, 7.3 ml. of MIBK which had been equilibrated with a 0.5 M buffer solution of pH 6.5 saturated with MIBK was allowed to be adsorbed on 8.0 g. of Kel-F powder and then the column was prepared. The elution of calcium ions was then carried out. Calcium ions appeared as early as in the first fraction of the effluent, and reached a maximum in the third. Therefore, the calcium ions placed in the column could not be retained at all without the presence of TTA in the organic solvent.

Some Relation to the Liquid-liquid Extraction.—*The Dependence of the Distribution of Metal Ions on the pH of the Solution.*—In a preceding paper[1] the present author stated that the dependence of the distribution ratio upon the hydrogen ion concentration of the aqueous phase could be represented by a straight line with a slope of about one to two in the graph of log$D$ vs. pH. The slope of the line was sharper when the quantity of metal ions was smaller, as well as when the stability of the chelate of the metal was higher; a higher concentration of TTA in the organic phase also made the slope sharper. In the present study, the relation between the distribution ratio of metal and the pH was investigated in the extraction process in the column. Each 3-ml. portion of sample solutions of varying pH values contained 0.005 mmol.

of strontium. This 3 ml.-portion was placed in the column; elution was then carried out with eluting solutions of the same pH. The elution curve was obtained as usual, and the distribution ratio of the metal in each case was calculated by Eq. 1, which is identical with the one generally used in partition chromatorgraphy:

$$D = (E - F)/B \qquad (1)$$

where

D: distribution ratio; E: the volume of the effluent before the emergence of the solute in a maximal concentration; B: the volume of the stationary phase, and F: the volume of the mobile phase, viz., the pores in the column.

The value of D calculated in each case is plotted in a graph of log D vs. pH in Fig. 6. In these experiments the pH of the eluting solution scarcely varied from the initial value. The relation between log D and pH is shown as a straight line with a slope of 2.3.

For comparison with the above results, a series of liquid-liquid extractions was carried out with 7.3 ml. of the same organic solvent as had been adsorbed on Kel-F powder and 21.9-ml.* portions of several eluting solutions containing 0.1 mmol. of calcium ions; the calcium ion content in the aqueous phase was determined by flame-photometry. This was repeated with samples of different pH values; the distribution ratio of calcium was calculated as usual. The data obtained are shown

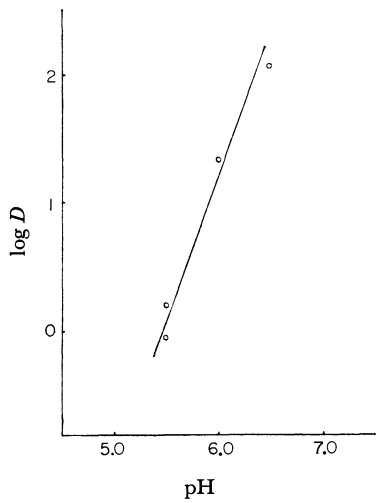

Fig. 6. Dependence of distribution ratio upon pH of the solution.
The values of D were calculated from respective elution curves.

* The reason for taking 21.9-ml. portions of the solution is as follows: If equal volumes (7.3 ml. each) of the solution and the organic solvent were used, the volume would be too small to separate the aqueous phase from the extraction system in the batch extraction with the organic solvent adsorbed on Kel-F described below. The author carried out the extraction at the volume ratio of 3 : 1.

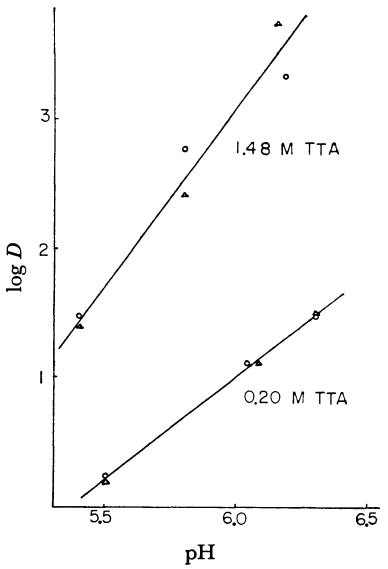

Fig. 7. Dependence of distribution ratio of calcium upon pH of the solution. Obtained from a batch extraction between each 7.3 ml. of solvent and 21.9 ml. of aqueous solution.
Loaded 0.1 mmol. Ca
△ Liq.-liq.(on Kel-F) batch extraction
○ Liq.-liq. batch extraction

in Fig. 7 as a graph of log D vs. pH.

Another series of extractions was carried out with the organic solvent solution adsorbed on Kel-F powder. The organic solution and the aqueous solution, as well as their volumes, were identical in this experiment and in that described just above. In a 100-ml. glass-stoppered Erlenmyer flask 8.0 g. of Kel-F powder was placed, and then an organic solvent solution was poured in. After the vessel had stood for more than three hours, each eluting solution containing calcium ions was introduced into it. The vessel was gently shaken for a while under tightly-stoppered conditions. The content was poured on a coarse glass filter, and the aqueous phase was allowed to drain by gravity into another vessel. The calcium ion content in the solution was determined by flame-photometry. The data obtained are shown in Fig. 7, in which the pH is that of the aqueous solution after the extraction.

The data obtained from the liquid-liquid batch extraction and those from the batch extraction between the liquid and a stationary phase on Kel-F are in good agreement. This shows that Kel-F did not affect the extraction. The slope of the line in log D vs. pH is 2.7 in the case of 1.48 M TTA-MIBK and 1.5 in the case of 0.2 M TTA. As in Fig. 9 of a preceding paper,[1] in which similar behavior of the relation log D vs. pH had been shown in this case the slope of the line increased with the concentration of TTA.

The column extraction and the batch extraction of metal ions were found to give lines of the same

slope, as is shown in Fig. 6 and Fig. 7, though the ion treated was strontium in the former and calcium in the latter. However, the slopes of the lines were 2.3 and 2.7 respectively; that is, they were larger than the slope (2.0) of the lines illustrated in a preceding paper,[1] in which a 0.2 M TTA solvent solution was used. Since the number of TTA attachable to a calcium ion with ionic linkage is two, the slope must also be two. In this case, however, the excess over two seems to indicate the formation of some anionic species of chelate in a higher concentration of TTA, such as 1.48 M.

The Dependence of the Distribution Ratio on the Concentration of TTA in the Solvent.—The relation of log$D$ to log(TTA) was obtained by the column chromatographic method, with a stationary solvent phase containing varying amounts of TTA. A definite volume of MIBK containing various amounts of TTA was equilibrated with an equal volume of the eluting solution of pH 5.5. The organic phase was used for the stationary phase on Kel-F powder. Several eluting solutions were prepared in accordance with the amounts of TTA in the organic phase in each case. Then, 0.02 mmol. of the calcium ion was loaded to the column and elution was carried out with the proper eluting solution. The dependence of log D on log (TTA) was obtained from the effluent volume of E. The results are shown in Fig. 8.

In a glass-stoppered centrifugal tube, liquid-liquid extraction was carried out with 7.3 ml. of the same organic solvent used in each stationary phase in the column chromatography, and with 21.9 ml. of the same eluting solution, which contained 0.1 mmol. of calcium ion. After centrifugation in order to separate the phases, the aqueous phase was taken out for the determination of calcium. The distribution ratio of calcium was calculated as usual.

Another batch extraction was carried out with the same organic solvent placed on Kel-F powder and with each eluting solution used in the above extraction. In a 100 ml.-Erlenmyer flask 7.3 ml. of the organic solvent solution was poured onto 8.0 g. of Kel-F powder. After the vessel had stood more than three hours, 21.9 ml. of the eluting solution, containing 0.1 mmol. of calcium ion, was poured onto the powder. The vessel was then stoppered and shaken gently for ten minutes. Calcium ion content in the aqueous phase was determined. This was repeated with solvents containing different amounts of TTA. The data obtained are shown in Fig. 9 as a graph of log$D$ vs. log(TTA). The data obtained from the liquid-liquid extraction and those from the batch extraction with the stationary phase placed on Kel-F are found to be in good agreement on the curve. This shows again that Kel-F powder does not affect the extraction mechanism.

○: D was obtained from liq.-liq. extraction.
▲: D was obtained from batch extraction with Kel-F.
Taken: 7.3 ml. of organic solvent, 21.9 ml of aqueous solution of pH 5.5, and 0.1 mmol. Ca

The column extraction and batch extraction resemble each other, as is shown in Figs. 8 and 9. In the former, however, the distribution ratio is a little lower in the low concentration of TTA. Because when the concentration of TTA is low the rate of chelate formation may be very small, in the column fresh eluting solution seems to be running through without reaching a satisfactory

equilibrium. But in the batch extraction complete equilibrium of the two phases is achieved upon longstanding contact.

The Variation in the Elution Curve due to the Variation in the Quantity of Metal Ions in the System.—It was described in a preceding paper[1] that, in the liquid-liquid extraction of the TTA-chelate of metal, the distribution of the metal ion decreases with the increase in the metal-ion content in the aqueous phase. Now the author has tried to ascertain if this is also the case in column extraction.

A sample solution, 3 ml., of pH 5.5, containing a known quantity of calcium ions, was placed on the column, and elution was carried out with the same eluting solution. This was then repeated with different amounts of calcium. The results are summarized in Table II, which shows that the

Table II. Distribution ratio obtained from the elution curves at various concentration of calcium

Amount of calcium loaded mmol.	Effluent volume before maximum elution, ml. (E)	Distribution ratio calculated (D)	Number of plates (N)
0.0125	220.0	29.1	39.6
0.03	204.7	27.0	22.2
0.09	174.9	22.9	20.1
0.15	170.9	22.4	19.2

peak of the elution curve is displaced forward with the increase in the quantity of metal ions loaded. This phenomenon seems to be caused by the decrease in the distribution ratio of the metal, as has been described previously.[1] The number of theoretical equivalent plates, N, was also calculated from the usual equation:

$$N = E(E - F)/s^2 \qquad (2)$$

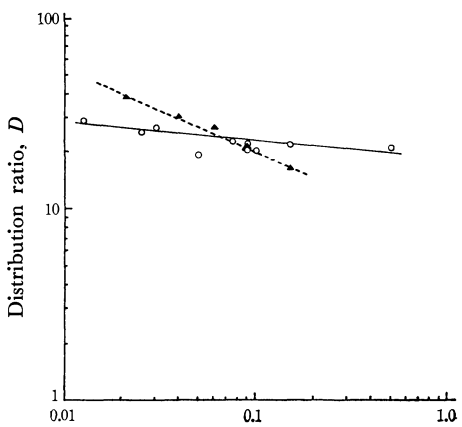

Fig. 10. Dependence of distribution ratio of calcium upon the concentration of calcium taken.
○ Obtained from elution through the column
▲ Obtained from liq.-liq. extraction

For comparison with the above column extraction, batch extraction was carried out between 7.3 ml. of the organic solvent and eluting solutions of pH 5.5 containing various quantities of calcium ions. The organic solvent was exactly the same as that held on Kel-F powder in the column. The relation observed in the batch extraction is shown in Fig. 10 with ▲ marks. In the batch extraction the decrease in the distribution ratio due to the increase in metal ion content appeared remarkably larger than in the column extraction. This inequality may be caused by the differences in the contact times of the two phases.

The Breakthrough Curve and the Capacity of the Column.—A column was prepared as described in

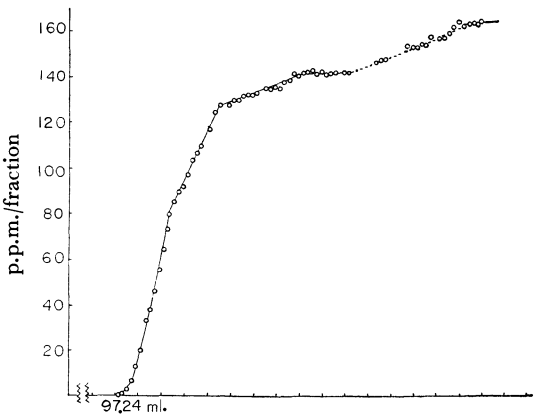

Fig. 11. Breakthrough curve of calcium.
With eluting solution of pH 5.5 containing 0.0040_6 mmol. Ca per ml.

the procedure; 500 ml. of a feed solution containing 0.00406 mmol. of calcium per ml. was also prepared by diluting 8 ml. of a stock solution of calcium salt with an eluting solution of pH 5.5 in a 500-ml. measuring flask. The solution was then fed on the column continuously at the rate of 0.05 ml. per minute. The breakthrough curve obtained is very irregular, as is shown in Fig. 11. It is neither sharp nor smooth over the whole range of the effluent, unlike most other breakthrough curves. The part of the curve shown by the dotted line merely shows the tendency of the curve, because the deviation of the measured results was too large for a perfect curve to be drawn. Let us attempt to account for the irregularity of the breakthrough curve. The calcium ion coming into the column at first forms its lowest TTA-chelate on the stationary phase, and then it changes to a higher TTA-chelate, which has a higher distribution ratio. Therefore, the increase in the amount of calcium in the effluent becomes slower, and the curve becomes less steep. When the stationary phase is saturated with calcium chelate of the highest distribution ratio, higher chelates begin to be degraded

to lower ones by the influx of new calcium ions into the phase, followed by a gradual decrease in the distribution ratio. The curve thus begins to become steeper again, and eventually the concentration in the calcium ion in the effluent reaches the constant value possessed by the initial feed solution. It may be assumed that in the column process, unlike as in the batch extraction, a solution passes through the column without reaching a satisfactory state of phase-equilibrium because of the small formation rate of the higher TTA-chelate. Consequently, the breakthrough curve may be thought to depict the steps of the formation of TTA-chelates as they really are. The amount of calcium retained on the column from the beginning to the breakthrough point was estimated to be 0.36 mmol., while the amount of calcium retained on the column throughout the interval represented in the curve was estimated to be 0.58 mmol.

In order to clarify the above picture, liquid-liquid extraction was carried out. In particular, the saturation of calcium in the organic phase was examined under conditions similar to those used in the column process. Each 7.3 ml. of an organic solution and an aqueous solution of pH 5.5 containing various amounts of calcium ion were shaken for ten minutes and then centrifuged. The amount of calcium remaining unextracted in the aqueous phase was then determined. The ratio of the amount of calcium extracted from each sample to the amount of TTA in the organic phase was plotted against the total amount of calcium taken. In this case the amount of TTA had been estimated to be 10.7 mmol. by the author's method.[5] The relation is shown in Fig. 12, in which the graph is a curve, not a straight line. This may be due

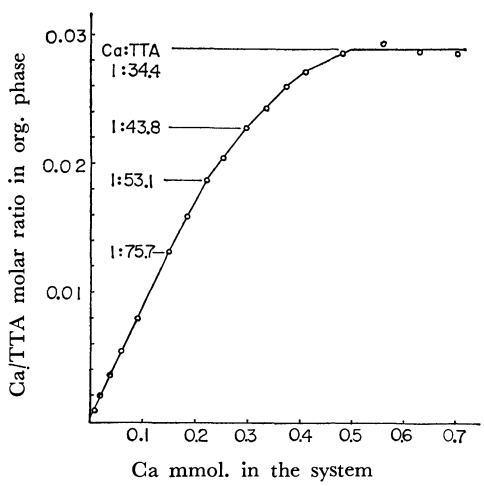

Fig. 12. Saturation of calcium in the organic phase.

Shown in the relation between the composition of the phase and the amount of calcium taken in the system.

to the step-by-step change in the species of metal-chelate with varying amounts of metal ions, followed by the variation in the distribution ratio. With the increase in the amount of calcium taken into the system, the quantity of TTA attached to a calcium ion decreases steadily. The distribution ratio of the metal-chelate formed at that time may be assumed to be lower. Finally, the organic phase is saturated with calcium, and the calcium chelate begins to separate out. This behavior of saturation corresponds to that of the breakthrough curve in Fig. 11; moreover, the saturation of calcium ion is maintained when about 0.5—0.6 mmol. of calcium is present in the system, while the amount of calcium in the organic phase is estimated to be 0.31 mmol.

When the elution is carried out, the amount of calcium loadable may be estimated to be approximately 0.3 mmol., that is, the value of the breakthrough point, though it is dependent on the flow rate, the concentration of metal ions, the particle size of Kel-F, the temperature, and so on. When 0.5 mmol. of calcium ion is fed into the column, the ion makes its appearance as early as in the first fraction, as has been confirmed by the author's experiment.

The picture of the process taking place in the column seems to be endorsed by these experiments.

Some Consideration of the Mechanism of the Extraction on the Column.—In liquid-liquid extraction the distribution ratio of alkaline earth metals depends upon the pH of the aqueous phase and on the concentration of TTA in the organic phase, as has been described in a preceding paper.[1] The behavior of the column extraction seems to be similar to that of the liquid-liquid extraction described in the same paper, in view of the group of facts clarified by the author's experiments. In the column extraction, as well as the other experiments described in this paper, an organic solvent containing as high a concentration of TTA as 1.48 M was used. At higher concentrations of TTA, calcium ions combine substantially with TTA, but not with acetate ions or MIBK. Among these, the number of TTA molecules involved in the ionic linkage is two; the number attached to calcium, including the above number, increases remarkably, as shown in Figs. 8 and 9, with the increase in the concentration of TTA in the solvent. However, as is shown in Fig. 12, the molar ratio of TTA to a calcium ion is thirty-four at the saturation of calcium in the organic phase; this number is the minimum ratio of TTA to calcium ion. Even this minimum number seems to be far larger than the number of TTA molecules which, we may expect from the relation of $\log D$ vs. $\log(\mathrm{TTA})$, are required by a calcium ion. Almost all the TTA in the system should be considered to participate in the extraction of calcium ions directly or indirectly, just as was described in a preceding paper.[1]

Summary

The author has extended the liquid-liquid extraction process of alkaline earth metal ions to a reversed-phase partition column chromatography, taking advantage of the results described in a preceding paper.[1] In the column, a methyl isobutyl ketone solution of TTA held on Kel-F powder has been used as a stationary phase. The separation of each metal ion from its mixture has been successfully achieved by carrying out the elution with eluting solutions of various pH values. It is noteworthy that as large an amount as several milligrams of a sample can be treated by this method. The relation between the method and the liquid-liquid extraction has been examined; no fundamental difference could be discovered between them. However, in the column chromatography, as well as in the batch extraction, described in this paper the organic phase contains a higher concentration of TTA than it does in the batch extraction in the liquid-liquid extraction described in a preceding paper. The experiments have also confirmed several facts which the batch method of the liquid-liquid extraction in a preceding paper[1] had seemed to suggest, regarding the behavior of TTA chelates in the presence of large amounts of TTA. Since the formation of TTA-chelate usually seems to require considerable time, in the column the eluting solution may pass through each plate while in an incomplete state of extraction equilibrium. The total distribution ratio of a metal ion as calculated from an elution curve is not much affected by the concentration of the metal in the system. The breakthrough curve of the column is thought to reflect the process taking place on the column.

The author wishes to express her thanks to Professor Toshiyasu Kiba for his kind advice and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 989—994 (1966)

The Intramolecular Hydrogen Bond of the Diol Ethers as Model Compounds of the Diols*[1]

By Hazime SAITÔ,*[2] Teijiro YONEZAWA, Shinichi MATSUOKA† and Kenichi FUKUI

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto
† *Faculty of Science, Kanazawa University, Kanazawa*

(Received September 24, 1965)

The intramolecular and intermolecular hydrogen bonds of the diol ethers are examined as model compounds of the diols by means of a study of their infrared and NMR spectra. The hydrogen bond shift and the intramolecular hydrogen bond shift are obtained. The value of the intramolecular hydrogen bond shift is discussed in terms of the electric field effect due to lone-pair electrons of the proton acceptor.

In a previous paper,[1] the free OH proton shifts of the diols have been estimated from a theoretical treatment, and their hydrogen bond shifts have been determined using both experimental and theoretical OH proton shifts. It has been pointed out that the hydrogen bond shift obtained arises predominantly from the intermolecular hydrogen bond, but the contribution of the intramolecular hydrogen bond can not be ignored.

The intramolecular hydrogen bond of the diols was investigated by Kuhn and others[2-9] with infrared spectra. Kuhn reported[2] that its strength is related to the number of methylene groups between two hydroxyl groups. That is to say, 1, 4-butanediol, which has four methylene groups, forms the strongest intramolecular hydrogen bond of the diols, making a stable seven-membered ring. Trimethylene glycol, which has three methylene groups, forms a stronger intramolecular hydrogen bond than ethylene glycol, with two methylene groups, and a weaker one than 1, 4-butanediol.

For the investigation of the intramolecular hydrogen bond with NMR, the measurements

a) Results by L. P. Kuhn.[2]
b) In our experiment, this value is not obtained. Values in parenthesis are results by M. St. C. Flett.[5]
c) The value assumed that free OH stretching is 3640 cm^{-1} as same as the value of trimethylene glycol monomethyl ether and 1,4-butanediol monomethyl ether.

should be carried out with as low a concentration as possible in a non-polar solvent such as carbon tetrachloride. The solubility of the diols in carbon tetrachloride, however, is lower than 0.005 mol./l., and NMR spectra cannot be obtained at such a low concentration.

Therefore, the diol monoalkyl ethers (diol ethers) are used as model compounds to investigate the natures of intramolecular hydrogen bond of the diols. The intramolecular hydrogen bond of the diol ether has also been studied, by means of infrared spectra, by Kuhn and Wires[10]; they reported the energy of the intramolecular hydrogen bond.

As model compounds for the diols, 1, 4-butanediol monomethyl ether, trimethylene glycol monomethyl ether, ethylene glycol monomethyl ether, ethylene glycol monoethyl ether, and ethylene glycol monobuthyl ether are used. From the measurement of the NMR spectra, the hydrogen bond shift due to the formation of an intramolecular hydrogen bond is obtained. The hydrogen bond shift is about 4.8 p. p. m. for the diol ethers; this value is found to be smaller than those of the diols and alcohols.

The intramolecular hydrogen bond shift referred to the free OH shift is 1.21 p. p. m. for ethylene glycol monomethyl ether and larger than 1.65 p. p. m. and 1.67 p. p. m. for trimethylene glycol monomethyl ether and 1, 4-butanediol monomethyl ether, respectively. This value is interpreted in terms of the electrostatic nature of the hydrogen bond using the Marshall-Pople formula.[11]

Experimental

Ethylene glycol monomethyl ether, ethylene glycol monoethyl ether, ethylene glycol monobutyl ether and carbon tetrachloride of guaranteed-grade reagent are used. Trimethylene glycol monomethyl ether and 1, 4-butanediol monomethyl ether are prepared from the corresponding diols by Smith's method.[12] The diol ethers are used after vacuum distillation after having been dried over barium oxide.

The NMR spectra are usually measured with a JNM-3 40 mc spectrometer; however, a Varian DP-60 60 mc spectrometer is used for lower concentrations, and a sample tube 15 mm. in diameter is used for the lowest concentration. Benzene is used as an external standard.

The infrared spectra for the diol ethers are measured with a Perkin-Elmer 12-C spectrometer equipped with a LiF prism and using a 3 mm.—20 mm. cell.

Results and Discussion

Infrared Spectra.—The infrared spectra for the diol ethers were measured in carbon tetrachloride (0.005 mol./l.) in order to compare the strength of the intramolecular hydrogen bond of the diol ethers with that of the diols. Table I gives our results, together with those of Kuhn,[2] on the diols.

Since no free OH stretching bands of ethylene glycol monomethyl- monoethyl- and monobutyl-ethers are observed in this concentration, the free OH proton may be said not to be present.

Then the shift of the OH stretching frequency, $\Delta\nu$, due to the intramolecular hydrogen bond in the infrared spectra of the diols is compared with that of the corresponding diol ethers, there is a distinct parallelism between the $\Delta\nu$ values of the diols and those of the diol ethers, though the $\Delta\nu$ values of the diol ethers are about twenty percent greater than those of the diols.

Therefore, it may be reasonable to adopt the diol ethers as a model compound of the diols so long as the fact that the $\Delta\nu$ values in the diol ethers are larger than those of the diols is kept in mind. In order to obtain information on the intramolecular hydrogen bond, the results of infrared spectra measured at various concentrations are shown in Fig. 1. Figure 1 shows that there is no free OH proton of ethylene glycol monomethyl ether in the range of the concentration between 0.005 to 0.5 mol./l., and that all OH protons make intramolecular hydrogen bonds

forming five-membered rings (Fig. 2 (I)). Now, in the concentration near 0.05 mol./l., the absorption band due to the intermolecular hydrogen bond is present in addition to the intramolecular bond itself, so it seems that there is an equilibrium between the monomer and the dimer, as is shown in Fig. 2 (II). The structure shown in Fig. 2 may be adequate, though we can consider other structures. This consideration is confirmed by the fact that no free OH absorption is observed in the infrared spectra of the diol ethers. Of the three structures, II-b is expected to be preferable.

Figure 3 is obtained by making the plot of the molecular extinction coefficient, $\varepsilon=(1/cd)\log(I_0/I)$, vs. the mole fraction of ethylene glycol monomethyl ether, where c is the concentration (mol./l.) and d, the thickness of the cell. If we use the ε_0 value, which is the value obtained by extrapolating the curve to an infinite dilution, the $\varepsilon/\varepsilon_0$ value is the fraction of the OH group which makes the intramolecular hydrogen bond. As is shown in Fig.

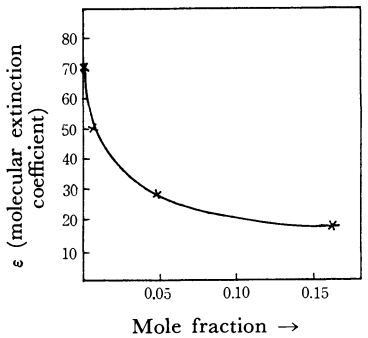

Fig. 3. A plot of ε vs. mole fraction of ethylene glycol monomethyl ether.

3, the OH shift of ethylene glycol monomethyl ether in an infinitely-diluted solution seems to indicate the intramolecular hydrogen bond shift. However, in trimethylene glycol monoethyl ether and 1, 4-butanediol monomethyl ether, there are free OH protons at the concentration of 0.005 mol./l., and so the value obtained by the extrapolation of the curve to an infinite dilution cannot always be expected to correspond with that resulting from a completely intramolecular hydrogen-bonded state. Namely, there seems to be an equilibrium in the infinite dilution as is shown in Fig. 4. It seems curious at first sight that trimethylene glycol monomethyl ether and 1, 4-butanediol monomethyl ether, which make stable

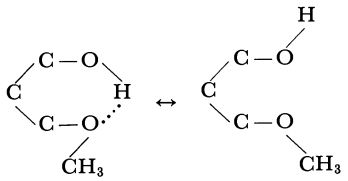

Fig. 4. Equilibrium between free and intramolecular hydrogen bonded state in infinitely diluted solution.

six- and seven-membered rings, respectively, in the intramolecular hydrogen bond, are in the equilibrium shown in Fig. 4, while ethylene glycol monomethyl ether, which makes a weaker hydrogen bond than they, is not in such an equilibrium. Because of the hindered rotation around the C-C and C-O bond axes, the probability of breaking the OH···O intramolecular hydrogen bond might increase as the number of C-C and C-O bonds between two hydroxyl groups becomes greater. Therefore, it may be understood that a free OH proton exists in 1, 4-butanediol monomethyl ether and trimethylene glycol monomethyl ether.

NMR Spectra.—NMR spectra at various concentrations of a carbon tetrachloride solution were measured, using benzene as an external standard. The plots of the OH proton shift vs. the mole fraction of the diol ethers are given in Fig. 5 and Fig. 6 for concentrations lower than 0.03 mol./l. The same plot for ethanol, as reported by Becker et al.,[13] is reproduced in Fig. 5 using the same scale. It may be seen in Fig. 5 that the change in the OH proton shift against the concentration in the diol ethers is smaller than that in ethanol. This is probably because there are a number of intramolecular hydrogen bonds in place of free OH protons in the ethanol at these concentrations.

The Hydrogen Bond Shift and the Intramolecular Hydrogen Bond Shift.—*Free OH Proton Shift.* — The free OH proton shift was calculated by the procedure reported in the previous paper,[1] using a simple LCAO MO method for the sigma electron system reported. The parameters used are the same as those in the previous paper. The sigma electron density for the OH proton of the diol ethers is given in Table II. The observed OH proton shifts referred to the benzene proton are shown in Table III. The bulk susceptibility correction is made in a usual way. The volume susceptibility needed for the correction is measured by Gouy's balance.

TABLE II. σ-ELECTRON DENSITY OF THE DIOL ETHERS

* As the term "hydrogen bond shift" corresponds to the maximum hydrogen bond, measurements must be carried out just above freezing point. However, we here extend the definition of this term to the measurement at room temperature in comparison to the hydrogen bond between the diols and the diol ethers.

	OH proton shift (extrapolated to infinite dilution)	OH proton shift (corrected)	Free OH proton shift (calcd.)	Intramolecular hydrogen bond shift
$HOCH_2CH_2OCH_3$	5.44	5.56	6.77	1.21
$HOCH_2CH_2CH_2OCH_3$	5.00	5.12	6.77	>1.65
$HOCH_2CH_2CH_2CH_2OCH_3$	4.98	5.10	6.77	>1.67

by the bulk susceptibility correction and subtraction from the calculated free OH proton shift. The results are given in Table III. Table III shows that the hydrogen bond shift of the diol ethers is smaller than that of ethanol, 4.8 p. p. m., and that of the diols, about 5.4 p. p. m.** The reason why the hydrogen bond shift of the diol ethers is smaller than that of the diols may be that the diols have two hydroxyl groups and both of them may be both proton acceptors and donners, while in the diol ethers the methoxy group replaced by the hydroxyl group may only be a proton acceptor. Therefore, the association of the diols is easier than that of the diol ethers.

It may be found by comparing Table III with Table I that the hydrogen bond shift of the diol ethers becomes larger as the intramolecular hydrogen bond is stronger.

The Intramolecular Hydrogen Bond Shift of the Diol Ethers.—In the case of ethylene glycol monomethyl ether, the intramolecular hydrogen bond shift is obtained by extrapolating the curve of the OH proton shift to an infinitely-diluted solution, as was described in the previous section. In the cases of 1, 4-butanediol monomethyl ether and trimethylene glycol monomethyl ether, however, the extrapolated values are not precisely correspondent to the intramolecular hydrogen bond shift, as has been mentioned in connection with the results of the infrared spectra. If free OH protons are present, the extrapolated value of the intramolecular hydrogen bond shift is smaller than the genuine intramolecular hydrogen bond shift, because the proton shift in an infinitely-diluted solution, δ, referred to the free OH proton shift is expressed as;

$$\delta = (1-\omega_f)\delta_{intra} \quad (1)$$

where δ_{intra} is an intramolecular hydrogen bond shift and ω_f the fraction of the free OH proton. Thus, $\delta < \delta_{intra}$ is concluded to hold in the case of $\omega_f > 0$. The intramolecular hydrogen bond shifts thus obtained are listed in Table IV.

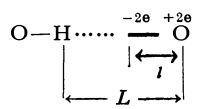
The hydrogen bond shift of the diols seems to be a little larger than that of the diol ethers, considering that the $\Delta\nu$ values of the diol ethers are somewhat larger than those of the diols, as is shown in Table I.

A Theoretical Consideration of the Intramolecular Hydrogen Bond Shift.—It was reported by Kuhn that there is the following relation between the bond length, L, of OH···O and the shift of the wave number, $\Delta\nu$, for the intramolecular hydrogen bond of the diols[2]:

$$\Delta\nu = 250/L - 74 \quad (2)$$

Assuming that the above relation is valid for the diol monomethyl ethers, the OH···O bond lengths of the intramolecular hydrogen bond of the diol ethers and the diols may be evaluated from the above equation.

By using the value obtained above and the electrostatic model for the hydrogen bond described by Pople,[14] the intramolecular hydrogen bond shift can be evaluated. The electrostatic model is shown below, where L is the length of H···O and l, the length of the lone-pair dipole of the oxygen atom.



The variation in shift due to the electric field, E, was found by Marshall-Pople[11] to be as follows:

** Values at room temperature; see Ref. 1.

14) J. A. Pople, "Hydrogen Bonding," Ed. by Hadzi, Pergamon Press, New York (1959), p. 71.

TABLE V. CALCULATED INTRAMOLECULAR HYDROGEN BOND SHIFT BASED ON THE MARSHALL'S FORMULA

	$\Delta\nu$ cm^{-1}	L Å	Intramolecular hydrogen bond shift p. p. m. Calcd. l=0.11Å	Calcd. l=0.29Å	Obs.
$HOCH_2CH_2OH$	32	1.99	0.06	1.39	
$HOCH_2CH_2OCH_3$	35	1.99	0.06	1.39	1.56
$HOCH_2CH_2CH_2OH$	78	1.64	0.18	2.00	
$HOCH_2CH_2CH_2OCH_3$	93	1.49	0.35	3.74	>1.65
$HOCH_2CH_2CH_2CH_2OH$	156	1.40[a]	0.52	5.70	>1.67
$HOCH_2CH_2CH_2CH_2OCH_3$	184				

a) As Eq. 2 is applied in the range of $1.6<L<3.3$, this value is estimated referring the crystal data.[16]

$$\delta_E = -\frac{881}{216}\frac{a^3}{mc^2}E^2 \qquad (3)$$

In this equation, the intramolecular hydrogen bond shift is calculated by using the E value due to the dipolar field of lone-pair electrons of the proton acceptor, where L is estimated by means of Eq. 2 and where l is assumed to be 0.11 Å[14] and 0.29 Å[15] in the two cases. The calculated bond lengths and intramolecular hydrogen bond shifts are listed in Table V, along with the hydrogen bond shifts of the diol ethers obtained in the experiments. The results of the calculation depend greatly on the length of the lone-pair dipole, l. The calculated values in the case of l=0.29 Å can explain the experimental value, while the values corresponding to l=0.11 Å are too small to explain it. Although the intramolecular hydrogen bond shift cannot be discussed precisely because of the uncertainty of our knowledge of the lone-pair dipole and the OH···O bond length, this hydrogen bond shift may be understood in terms of the electric field effect of the proton acceptor.*

The authors are grateful to Drs. Tanekazu Kubota and Yoshiki Matsui of the Shionogi Research Laboratory, Shionogi & Co., Ltd., for their measurements of the infrared spectra, and to Drs. BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 994—1002 (1966)

Nickel(II) and Copper(II) Complexes of β-Ketoamines Derived from β-Diketones and Aromatic Amines[1)]

By Shoichiro YAMADA, Hiroaki NISHIKAWA* and Emiko YOSHIDA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received September 24, 1965)

Nickel(II) and copper(II) complexes of β-ketoamines derived from acetylacetone or benzoylacetone and aromatic amines have been newly synthesized and characterized. The aromatic amines included aniline, *o*-, *m*- and *p*-toluidine, *o*, *o'*-dimethylaniline, *o*, *o'*-diethylaniline, *o*-, *m*- and *p*-chloroaniline, and α- and β-naphthylamine. The configurations of these complexes in pyridine have been examined and compared with those in non-donor solvents. All these complexes are considered to be square-planar in non-donor solvents and in the solid state. The nickel(II) complexes of the *o*, *o'*-disubstituted derivatives do not combine with pyridine molecules, whereas the corresponding copper(II) complexes readily combine with the pyridine molecule. The difference between nickel(II) and copper(II) ions is discussed in terms of the bonding nature of the metal ions. The β-ketoamines and salicylideneimines are also compared.

* Present address: Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa.

1) Presented in part at the 8th International Conference on Co-ordination Chemistry (8th ICCC), Vienna, September, 1964; The Proceedings, 8th ICCC (1964), p. 373.

Studies of nickel(II) and copper(II) complexes of Schiff bases derived from salicylaldehyde have so far been carried out by a number of investigators, yielding many conclusions which are of significance to the co-ordination chemistry of these metal ions. At that stage, it was thought to be interesting to compare the complexes of salicylideneimines with the corresponding complexes of β-ketoamines, such as acetylacetone- and benzoylacetoneamines (Fig. 1).[2,3] However, no systematic study has been carried out on the synthesis and characterization of these complexes.

In the present work, a series of new copper(II) and nickel(II) complexes have been synthesized with the β-ketoamines derived from aromatic amines and β-diketones. Then their configurations in pyridine have been examined and compared with the configurations in non-donor solvents, in order to establish the ability of the metal ions to combine with additional ligands at the residual co-ordination sites of the quadri-co-ordinate complexes. Copper(II) and nickel(II) have also been compared as the central metal ion, as the β-ketoamines and the salicylideneimines have been compared as the ligand. This kind of examination is particularly significant for the *N*-*o*, *o*'-disubstituted phenyl-derivatives, since these complexes might behave differently from the *N*-monosubstituted phenyl derivatives due to the steric condition, and so a comparison would yield important information about the co-ordination chemistry of these metal ions. Several new complexes of nickel(II) and copper(II) with salicylideneimines have also been synthesized in the present work.

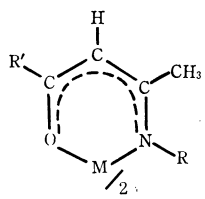

Fig. 1. Metal(II) complexes of β-ketoamines with R'=CH_3 or C_6H_5.

Experimental

Materials.—Bis(*N*-substituted acetylacetoneaminato)-nickel(II) complexes were prepared by the general method given below. Into a warm solution of nickel(II) acetate (0.01 mol.) and the ligand (0.012—0.013 mol.) in ethanol (15—20 ml.), a solution of potassium ethanolate was stirred drop by drop; this solution had been prepared, in advance, by adding potassium metal (0.022—0.024 g. atom) into ethanol (15—20 ml.). The reaction was then continued at about 70°C for two to six hours, depending upon the ligands used.

When the solution was cooled, crude crystals of the compound separated out. Pure crystals of the compound were obtained by the recrystallization of the crude product from suitable solvents. Prior to the above procedure, the ligand had generally been prepared by refluxing a mixed solution of the *β*-diketone and the amine on a water-bath for many hours. The elemental analyses of these compounds are given in Table I. These complexes are green.

Bis(*N*-substituted acetylacetoneaminato)copper(II) complexes were prepared in the same way as were the corresponding nickel(II) complexes, except that the reaction period with the copper(II) complexes was generally longer. The crystals which separated out were quickly filtered, washed, generally with ethanol, and dried in a vacuum desiccator. The elemental analyses of these compounds are shown in Table I. Most of these complexes are dark-brown or dark-green.

Bis(*N*-substituted phenyl-benzoylacetoneaminato)-nickel(II) complexes were prepared in a way similar to that used for the corresponding bis(acetylacetoneaminato)nickel(II) complexes. The elemental analyses are shown in Table II. These complexes are green or brownish green.

Bis(*N*-substituted phenyl-benzoylacetoneaminato)-copper(II) complexes were prepared in a way similar to that used for the corresponding bis(benzoylacetoneaminato)nickel(II) complexes. The elemental analyses are shown in Table II. These complexes are dark-brown.

The solvents used for the recrystallization of all the above complexes were mostly benzene and ethanol, although acetone and chloroform were occasionally employed.

The following complexes were reported previously[4]: Ni(Aca. *o*, *o'*-$(CH_3)_2C_6H_3)_2$, Ni(Bza. $C_6H_5)_2$, Cu(Aca. $C_6H_5)_2$, Cu(Aca. *o*, *o'*-$(CH_3)_2C_6H_3)_2$ and Cu(Bza. $C_6H_5)_2$. The methods of the preparation in the present work are different from that employed previously, except for that for the first complex. A paper has recently been presented describing the *N*-alkyl substituted β-ketoamine complexes of nickel(II).[5]

Bis(*N*-substituted phenyl-salicylideneiminato)complexes were prepared by reactions between the bis(salicylaldehyde)metal complex and one of the aromatic amines in ethanol or methanol. These complexes are dark-brown or dark-green.

For the preparation of *o*, *p*, *o'*-trichlorophenyl-substituted complexes of this series, a solution of the Schiff base, which had been prepared in advance, was added to copper acetate or nickel acetate in ethanol,

and then the solid sodium hydrogen carbonate was added. The reaction was continued at 60—70°C for several hours. The elemental analyses are shown in Table III. These complexes are all brown or green.

The other complexes discussed in the present paper were prepared according to the methods previously reported. Elemental analyses for carbon, hydrogen and nitrogen agreed with the formulae given previously.

Measurements.—The electronic absorption spectra of the complexes in solution were determined with a Shimadzu QR 50 spectrophotometer and a Beckman DU spectrophotometer. Pyridine for a solvent was purified by distillation after it had been boiled for some hours over barium oxide.

The diamagnetism of the nickel(II) complexes in the solid state was detected by Gouy's method.

Results and Discussion

The Nickel(II) Complexes of β-Ketoamines and Salicylideneimines Derived from Aromatic Amines.—Numerous new nickel(II) complexes of the ketoamines have been prepared in the present work; they are shown in Tables I, II and III, together with several new complexes of salicylideneimines. In general, the preparation of the metal complexes of the β-ketoamines was found to be more difficult in many ways than the preparation of the corresponding complexes of the salicylideneimines.

The fact that all these nickel(II) complexes of the β-ketoamines are diamagnetic in the solid state indicates the planar configuration of these complexes. It is now well known that the electronic spectrum of a nickel(II) complex varies remarkably according as the nickel(II) complex is square-planar, tetrahedral or octahedral.[6,7] Consequently, the spectrum may be regarded as symptomatic of the configuration of the nickel(II) complex. Thus, the present measurements clearly indicate that the electronic spectra of the complexes of $Ni(Aca.aryl)_2$ and $Ni(Bza.aryl)_2$ types in chloroform or benzene are characteristic of the square-planar nickel(II) complex (Figs. 2 and 3).[8] There is controversy about the assignment of the absorption bands of square-planar nickel(II) complexes,[9] but a tentative assignment may be ^1A_g—$^1B_{1g}$ and ^1A_g—$^1B_{3g}$ for the absorption bands at about 16.5 and 20.5×10^3 cm^{-1} respectively. These complexes show no absorption at about 900—1000 mμ, where the tetrahedral or the octahedral nickel(II) complexes are expected to absorb. Hence, both the presence of the monomeric, tetrahedral species and the association of the square-planar complexes may be excluded, at least near room temperature. The same conclusion was obtained with a solution of a very high concentration. Comparison clearly shows that the tendency of the square-planar complexes to form associated polymers in solution is much lower with the β-ketoamine complexes than with the corresponding salicylideneimine complexes, since the previous studies[6] have shown that bis(*N*-monosubstituted phenylsalicylideneiminato)-nickel(II) complexes in non-donor solvents consist of the square-planar monomer, the associated polymer with the sexa-co-ordinated nickel(II), and the tetrahedral monomer, the former two being in equilibrium with each other near room temperature. This difference between the β-ketoamine and the salicylideneimine complexes may be due to the stronger ligand field produced by the β-ketoamines, since the stronger ligand field will increase the energy difference between the $d_{x^2-y^2}$ orbital and the next highest orbital of the nickel(II) ion, making the highest $d_{x^2-y^2}$ orbital less readily occupied in the formation of the sexa-co-ordinated nickel-(II).[10]

In order to examine the effect of the two substituents at the *o*- and *o'*-carbon atoms on the residual co-ordination sites, the electronic absorption spectra of the compounds were examined in pyridine, and compared with the results for the corresponding complexes with monosubstituted radicals. With the exception of the *o*, *o'*-disubstituted complexes, all the nickel(II) complexes examined were found to take up two pyridine molecules, as may be seen from their electronic spectra (Figs. 2 and 3, and Tables IV and V). The absorption bands at about 10 and 16.5×10^3 cm^{-1} are tentatively identified as $^3A_{2g}\rightarrow{}^3T_{2g}$ and $^3A_{2g}\rightarrow{}^3T_{2g}$ (F) for the octahedral nickel(II) complexes. The spectra obtained, which are remarkably different from the spectra of the tetrahedral and the square-planar complexes of nickel(II), have the main features characteristic of the sexa-co-ordinated nickel(II) complexes.[6,7,11] Since Beer's law is generally obeyed, an equilibrium between the octahedral complex and another species may be excluded. It should be noted that even the *o*-monosubstituted complexes form sexa-co-ordinated complexes by taking up two pyridine molecules for the complexes of the $Ni(Sal.R)_2$, $Ni(Aca.R)_2$ and $Ni(Bza.R)_2$ types. This is also found to be the case with the complexes having α-naphthyl for R.

On the contrary, the spectra of the *o*, *o'*-disubstituted nickel(II) complexes of salicylideneimines, acetylacetoneamines and benzoylacetoneamines in pyridine are very similar to the spectra of the same compounds in chloroform (Figs. 2 and 3, and Tables IV and V). It is clear that

the square-planar configuration of these complexes is held in pyridine as well as in chloroform. Neither the sexa-co-ordinated form combining the two pyridine molecules nor the tetrahedral form is present, since there is no absorption in the frequency region lower than 700 mμ, except for a very feeble absorption band which may be ascribed to the singlet-triplet(spin-forbidden) transition of

the square-planar complex. The fact that no association of the square-planar complexes takes place may be interpreted on the basis of the steric hindrance due to the two methyl or ethyl groups at the *o*- and *o'*-positions.

of the β-ketoamines and salicylideneimines, which are shown in Tables I, II and III, have been prepared in the present work. The planar configuration is most likely for the copper(II) complexes, since the tendency of the copper(II) complex to take the square-planar configuration is known to be very great. The square-planar configuration can not be rejected, even for the *o*, *o*'-disubstituted complexes of copper(II), on the steric ground alone, since the corresponding complexes of nickel(II) have been found to be square-planar. It is reasonable to presume that the *o*, *o*'-disubstituted and the monosubstituted complexes of copper(II) take a square-planar configuration. This presumption seems to be consistent with the present observation that the *o*, *o*'-disubstituted and the monosubstituted complexes of copper(II) show ligand field bands at a nearly identical frequency, and that the whole pattern of the spectra is also quite similar among these complexes (Fig. 4). It was previously shown that the ligand field band was shifted toward a considerably lower frequency when the cupric complex was distorted appreciably from the square-planar configuration.[6,7]

The change in the ligand field band of these copper(II) complexes on going from chloroform to pyridine, the change shown in Figs. 4 and 5, is similar to the change observed previously when the quadri-co-ordinated complex of copper(II) takes up one or two additional ligands to form a quinque- or sexa-co-ordinated complex.[12] It may be concluded, therefore, that all the cupric complexes examined in the present work are combined with one or two pyridine molecules in the pyridine solution. The change in the spectrum of the complex on going from chloroform to pyridine is more pronounced for the salicylideneimine complexes than for the corresponding β-ketoamine complexes.

Judging from the steric effect due to the two substituents, it is most likely that the *o*, *o*'-disubstituted complexes are able to take only one molecule of pyridine to form a quinque-co-ordinated configuration. It should be noted that the spectral behavior of the *o*, *o*'-disubstituted complexes of copper(II) in pyridine is quite similar to that of the corresponding monosubstituted complexes, and that the monosubstituted complexes of copper(II) in pyridine show spectra almost superposable on those of the corresponding disubstituted complexes (Figs. 5 and 6). The spectral change on going from chloroform to pyridine is also similar for these complexes. It is most likely that all these copper(II) complexes, therefore, take an identical configuration in pyridine. This seems to be in agreement with a previous finding concerning the ability of bis(acetylacetonato)copper(II) to combine with another ligand such as pyridine.[13]

Comparison of Nickel(II) with Copper(II). —It has been found in the present work that, in the binding of the additional pyridine molecule, the *o*, *o*'-disubstituted complexes of copper(II) are different from the corresponding complexes of nickel(II); the nickel(II) complexes combine

with no additional pyridine molecule. This difference between copper(II) and nickel(II) may be interpreted in terms of the bonding nature of the metal ions and in terms of the steric condition of the ligands. In the complexes of copper(II) with a d^9 configuration, the copper-ligand bond distance along the z-direction is generally found to be appreciably longer, due to the Jahn-Teller effect, than the corresponding bond distance in the xy-plane, that is, the complex-plane. Moreover, quinque-co-ordinated complexes are not rare for the copper(II) ion. On the other hand, the six bonds between the nickel(II) ion and ligands are essentially equivalent in the sexa-co-ordinated complexes of nickel(II) with a d^8 configuration. It is, therefore, reasonable to expect that the two substituents at the o- and o'-positions may prevent the pyridine molecule from combining with the nickel(II) ion, whereas the copper(II) ion in the corresponding complex may combine with the pyridine molecule at a little farther distance in spite of the possible steric hindrance.

Infrared Spectra of Urea Complexes of Copper(II) *n*-Alkanoates

By Yoko KURODA, Akira SASANO and Masaji KUBO

(*Department of Chemistry, Nagoya University Chikusa, Nagoya*)

(*Received September* 25, 1965)

The infrared absorption spectra of various urea complexes of copper(II) carboxylates were recorded and the assignments of observed frequencies have been carried out to various modes of vibration. On the basis of comparison of the observed spectra with those of related compounds, it is concluded that copper(II) carboxylate monoureas and hemiureas form dimer molecules in crystals as in copper(II) acetate monohydrate, that copper(II) formate bisurea dihydrate has a crystal structure bearing resemblance to that of copper(II) formate tetrahydrate, and that urea molecules in these urea complexes are involved in bonding by electrostatic forces or hydrogen bondings instead of being bonded to copper atoms by coordination bonds.

Urea forms various addition compounds with copper(II) *n*-alkanoates.[1,2] The most general types of the urea complexes are copper(II) *n*-alkanoate monoureas, $Cu(C_nH_{2n+1}CO_2)_2\cdot(NH_2)_2CO$ (n=0—3, 5), and copper(II) *n*-alkanoate hemiureas, $Cu(C_nH_{2n+1}CO_2)_2\cdot 0.5(NH_2)_2CO$ (n=4—9). In addition, the hydrated urea complexes of copper(II) formate and acetate, $Cu(HCO_2)_2\cdot 2(NH_2)_2CO\cdot 2H_2O$ and $Cu(CH_3CO_2)_2\cdot(NH_2)_2CO\cdot H_2O$, can be prepared in the crystalline state. We have observed the magnetic moments of these copper(II) compounds and found that except for copper(II) formate bisurea dihydrate, they show subnormal magnetic moments, 1.40±0.03 Bohr magnetons, per copper atom at room temperature, suggesting the existence of paired copper atoms in crystals. Undoubtedly, urea molecules in the monourea complexes occupy the same positions about copper atoms as do water molecules in the crystals of copper(II) acetate monohydrate.[3] However, the structures of the hemiurea complexes and the hydrated urea complexes are open to speculation so long as the magnetic data alone are taken into account. The present investigation has been undertaken in order to gain some information from infrared spectroscopy about the role of urea molecules possibly participating in coordination on copper atoms.

Experimental

Materials tested were prepared by methods described in a previous paper.[2] Infrared absorptions were recorded over a wave number range from 4000 to 200 cm^{-1} using a Model DS-402G grating infrared spectrophotometer from Japan Spectroscopic Company. In the frequency range above 400 cm^{-1}, all samples were run as potassium bromide disks and checked in Nujol mulls. Below 430 cm^{-1}, spectra were obtained using Nujol mulls. Potassium bromide plates and thin polyethylene films were used as cell windows for Nujol mulls in the two regions, respectively.

with those of copper(II) acetate and copper(II) acetate monohydrate[4] in Table I. In the wave number range 1800—400 cm^{-1}, all absorption peaks characteristic of anhydrous copper(II) acetate, which shows practically the same spectrum as that of copper(II) acetate monohydrate in this frequency range, appear in the spectrum of copper(II) acetate monourea without any appreciable change in the position, the intensity, and the shape of absorption bands as shown in Fig. 1. Accordingly, additional absorptions appearing in the spectrum of copper(II) acetate monourea can be assigned to vibrations involving urea molecules. On the other hand, no such clear correspondence can be made below

400 cm^{-1}, probably because lattice vibrations, librations, etc. are involved in the spectra. In a region beyond 1800 cm^{-1}, only NH stretching vibrations are observable as intense bands.

Other copper(II) *n*-alkanoate monoureas were tested and yielded analogous results.

Copper(II) Caproate (*n*-Hexanoate) Hemiurea.—Table II shows the absorptions of copper(II) caproate, copper(II) caproate monourea, and copper(II) caproate hemiurea. In the region of band progressions (about 1350—1200 cm^{-1}), the spectra are complicated and no definite correspondence of absorption peaks can be found between the spectra of these compounds, presumably owing to difference in the interactions of methylene chains in crystals. However, major peaks of copper(II) caproate appearing in the wave number range 1800—400 cm^{-1} can be found in the spectra of the monourea and hemiurea complexes also without any appreciable shifts. In particular, a very strong peak at 1585 cm^{-1} is practically unaltered in its wave number and band shape. Below 400 cm^{-1}, no definite correspondence of absorption peaks can be made between these spectra for the same reason as given for copper(II) acetate and its derivatives. By taking into account relative intensities and band shapes, peaks attributable to urea molecules were selected from the spectra of copper(II) caproate monourea and hemiurea in the wave number range 1800—400 cm^{-1}.

The absorption spectra of other copper(II) carboxylate hemiureas were recorded and absorptions characteristic of urea molecules were determined.

Copper(II) Formate Bisurea Dihydrate and Copper(II) Formate Monourea.—The absorptions of copper(II) formate, copper(II) formate tetrahydrate, copper(II) formate bisurea dihydrate, and copper(II) formate monourea are shown in Table III. In the wave number range 1800—830 cm^{-1}, the spectrum of anhydrous copper(II) formate is practically identical with that of the tetrahydrate, although they differ markedly from each other below about 700 cm^{-1}. The absorptions of the tetrahydrate appearing in the wave number range 1800—400 cm^{-1} can be found in the

spectrum of copper(II) formate bisurea dihydrate also without any appreciable shift and change in the band contour as shown in Fig. 2.

Discussion

The absorptions characteristic of carboxylate ions appearing in the wave number range 1800—400 cm^{-1} are almost unaltered by the addition of urea to copper(II) carboxylates except for copper(II) formate and by the substitution of water in copper(II) acetate monohydrate with urea to form copper(II) carboxylate monoureas and hemiureas. In addition, the frequency of absorptions at about 1585 cm^{-1} attributable to the antisymmetric COO stretching vibration is shifted to some extent from the corresponding frequencies observed for sodium, potassium, and silver salts.[4,5] These facts lend additional support to the presumption already suggested by magnetic measurements[1,2] that copper(II) carboxylate monoureas and hemiureas form dimer molecules in crystals.

In the wave number range 1800—400 cm^{-1}, the spectrum of copper(II) formate bisurea dihydrate has all absorptions of copper(II) formate tetrahydrate without any appreciable change, in addition to bands attributable to urea molecules. This indicates that the compound forms crystals consisting of two-dimensional network structures as observed by X-ray crystal analysis for the tetrahydrate.[6] On the other hand, copper(II) formate monourea shows a spectral feature quite different from those of copper(II) formate tetrahydrate and bisurea dihydrate. In the first place, the antisymmetric COO stretching frequency at 1581 cm^{-1} is higher than the corresponding frequencies of the tetrahydrate and the bisurea dihydrate by about 20 cm^{-1}. Secondly, the COO scissoring vibration appearing at 779 cm^{-1} is lower by about 55 cm^{-1}. Lastly, marked splittings of bands are observed in the wave number region of 1389—1343 cm^{-1}. These results suggest that the structure of copper(II) formate monourea is basically different from those of copper(II) formate bisurea dihydrate and copper(II) formate tetrahydrate in conformity with a conclusion from magnetic studies[2] that among copper(II) formate and its derivatives, only copper(II) formate monourea forms dimer molecules analogous to those in copper(II) acetate monohydrate in crystals.

The normal vibrations of urea have been calculated and the assignment of observed frequencies has been made by Yamaguchi et al.[7,8] Kutzelnigg et al.[9] have discussed the vibrational spectra of urea molecules in pure crystals and solutions and those constituting the host lattice of urea adducts in relation to intermolecular forces. Based on the results of these investigations, frequencies observed for the urea complexes of copper(II) carboxylates have been assigned to various modes of vibration as shown in Table IV. The frequency observed for copper(II) carboxylate monoureas depends on the kind of carboxylate ions to some extent, whereas that of copper(II) carboxylate hemiureas is almost independent of the chain length of the carboxylate ions.

A urea molecule has an oxygen atom and two nitrogen atoms capable of being coordinated on a

metal atom. It is expected that coordination affects the vibrational frequencies of urea, especially those of NH_2 stretching and CO stretching vibrations. In fact, Penland et al.[10] have found that dichloro(bisurea)platinum(II) and dichloro(bisurea)palladium(II) show a decrease in the frequencies of NH_2 stretchings and antisymmetric CN stretching as well as an increase in the frequencies of CO stretching coupled with NH_2 scissoring and concluded that nitrogen is involved as donor atoms in coordination. On the other hand, Table IV shows that no marked differences can be found in the NH_2 stretchings, the CO stretching mixed with the NH_2 scissoring, the antisymmetric CN stretching, etc. between tetragonal or hexagonal urea and the urea complexes of copper(II) carboxylates. Accordingly, it is concluded that urea molecules in these urea complexes are not bonded to copper atoms by coordination bonds having a covalent character but that they are involved in bonding by electrostatic forces or hydrogen bondings as in the tetragonal or hexagonal crystals of urea. Penland et al.[10] have presumed that oxygen-to-metal bonds are formed in the dichloro(bisurea) complexes $M(NH_2CONH_2)_2Cl_2$ of zinc(II) and copper(II) showing no such marked shifts of bands as observed for the platinum(II) and palladium(II) complexes and that two chlorine atoms and two oxygen atoms occupy coordination sites at the corners of a square with a metal atom at its center. However, it is very likely that in dichloro(bisurea)-copper(II), for instance, all the coordination sites of copper are occupied by chlorine, the coordination squares being arranged in a one-dimensional array by sharing their edges as in the crystals of dichloro-(1, 2, 4-triazole)copper(II)[11] and that urea molecules are not directly involved in the square coordination of copper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1006—1008 (1966)

The NMR Signal Shape of Identical Nuclei Exchanging between Two Different Environments*

By Toshio NAKAGAWA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received September 28, 1965)

The Gutowsky-Holm equation has been transformed into a formula which expresses the signal as a function of dimensionless parameters ($a=2\pi\tau|\nu_A-\nu_B|$, $r=1/2\pi T_2|\nu_A-\nu_B|$ and p_B) and a dimensionless variable ($f=(\nu-\nu_A)/(\nu_B-\nu_A)$). The shape function in this form is convenient for graphic representation and can be easily calculated for a desired combination of the parameters by using a suitable computer. The exchange rate can be determined by searching for a theoretical curve that agrees with the shape of the experimental signal.

When an assembly of identical nuclei are exchanging in a random statistical manner between two environments with different chemical shifts, the signal takes on various shapes, depending on the exchange rate, the fractional populations, and the transverse relaxation times. In this report we shall neglect all coupling, and examine the signal shape observed under these circumstances.

This problem has already been solved mathematically by Gutowsky and Holm for the case where the two transverse relaxation times, T_{2A} and T_{2B}, are equal.[1] The equation thus obtained is, however, inconvenient for a general discussion of signal shape because it is formulated in terms of dimensional quantities. The main purpose of the present report is to transform it into a formula which expresses the shape of a signal as a function of dimensionless parameters, and then to discuss its application to the determination of exchange rates.

Theoretical Consideration

First of all we shall define the dimensionless parameters:

$$a = 2\pi\tau|\nu_A-\nu_B| = 2\pi p_B\tau_A|\nu_A-\nu_B| = 2\pi p_A\tau_B|\nu_A-\nu_B| \quad (1)$$

$$r = 1/2\pi T_2|\nu_A-\nu_B| = w/|\nu_A-\nu_B| \quad (2)$$

* Presented at the International Symposium on Nuclear Magnetic Resonance, Tokyo, September, 1965.

1) H. S. Gutowsky and C. H. Holm, *J. Chem. Phys.*, **25**, 1228 (1956).

and a dimensionless variable:

$$f = (\nu_A-\nu)/(\nu_A-\nu_B) = (\nu-\nu_A)/(\nu_B-\nu_A) \quad (3)$$

By substituting them into the Gutowsky-Holm equation, we get a general formula:

$$\begin{aligned} v = C\times[&(1+ar)\{-af(f-1)+r(1+ar)\} \\ &+a(f+p_B-1)(f+2arf-ar-p_B)] \\ &\div[\{-af(f-1)+r(1+ar)\}^2 \\ &+(f+2arf-ar-p_B)^2] \end{aligned} \quad (4)$$

where $C = -\gamma H_1 M_0/2\pi\,|\nu_A-\nu_B|$

Here v describes the transverse component of the resultant magnetic moment, which is perpendicular to the rotating field, H_1, and which is proportional to the absorption intensity. The same symbol, v, will be used hereafter to represent the absorption intensity. C is a constant, dependent on the apparatus sensitivity. The other notations, other than w, have their usual meanings. The parameter, r, is one half of the half-height-width of the A (or B) signal, w, divided by the separation between the A and B signals, in the absence of exchange effects and with no overlap of signals.

Equation 4 is convenient for graphic representation because this formula gives the relative intensity as a function of the relative position, f, with respect to the signal positions of the A and B states. The shape function can be easily calculated for a desired combination of a, r, and p_B by using a suitable computer. An IBM-1620 computer performed the calculation in a quarter of an hour. The Fortran program is shown in Table I. In this program, the maximum signal height is made equal to unity by choosing automatically a proper value of C.

In several limiting cases, Eq. 4 becomes simpler and is reduced to the familiar relations, 5 to 9.

$$v_{(p_B=0)} = C\times\{r/(r^2+f^2)\} \quad (5)$$

$$v_{(p_A=0)} = C\times[r/\{r^2+(f-1)^2\}] \quad (6)$$

$$v_{(a\to\infty)} = C\times[rp_A/(r^2+f^2)+rp_B/\{r^2+(f-1)^2\}] \quad (7)$$

$$v_{(a=0)} = C\times[r/\{r^2+(f-p_B)^2\}] \quad (8)$$

$$v_{(r\to\infty)}=0 \quad (9)$$

$$\begin{aligned} v_{(r=0)} &= C\times[ap_Ap_B/\{a^2f^2(f-1)^2+(f-p_B)^2\}] \\ &= C'\times[1/\{a^2f^2(f-1)^2+(f-p_B)^2\}] \end{aligned} \quad (10)$$

The last equation (10) has previously been derived by the author and presented graphically for many combinations of a and p_B.[2)]

A one-to-one correspondence can be shown to hold between the signal shape (expressed in the relative intensity as a function of f) and the set of parameters (a, r, and p_B). One important exception, however, is the case where r equals zero, and where a tends to infinity. In this case, two lines appear, at $f=0$ and at $f=1$. The ratio of their heights varies from p_A/p_B to p_A^2/p_B^2, depending on the product of a and r, or, in other words, on the ratio of τ to T_2. Both times are infinitely large compared with $1/|\nu_A-\nu_B|$, but their ratio may be finite.

$$v_{(\text{at } f=0)}/v_{(\text{at } f=1)} = p_A(p_A+ar)/p_B(p_B+ar) \quad (11)$$

The following two cases may also be considered as rather exceptions. As is shown by Eq. 9, no signal appears for an infinitely large r value, regardless of the values of a and p_B. The same Lorentzian curve is obtained for sets of parameters which have r's all equal, a's all different, and $p_B=0$ (or 1). A detailed discussion of these cases seems unnecessary, however, since no information of practical importance could be derived from such a discussion.

The most important application of Eq. 4 is probably to the case where $p_A=p_B=1/2$. Except for the last paragraph, we shall be concerned exclusively with this case in the remainder of this section. Equation 4 can be reduced to Eq. 12, which is symmetrical with respect to $f=1/2$:

$$\begin{aligned} v = C\times&\{a^2rf(f-1)+r(1+ar)^2+a(1+2ar)/4\} \\ &\div\{a^2f^2(f-1)^2+(1+2ar+2a^2r^2)f(f-1) \\ &+r^2(1+ar)^2+(1+2ar)^2/4\} \end{aligned} \quad (12)$$

The signal shapes have been calculated and presented graphically for all combinations of $a=\infty$, 32, 8, 4, $2\sqrt{2}$, 2, 1.7, $\sqrt{2}$, 1.2, 1, $1/\sqrt{2}$, 1/2,

2) T. Nakagawa, *Ann. Rept. Shionogi Lab.*, **13**, 60 (1963).

1/4, 1/16, 0 and $r=0$, 1/20, 1/10, 1/5, 1/3, 1/2.** Both the life-time, τ_A $(=\tau_B)$, and the transverse relaxation time, T_2, can be determined by searching for a figure that agrees with the shape of the experimental signal.

Provided one of the signal positions of the components, ν_A, or ν_B, is known on the chart by some means, the comparison is easy. The scale of f can be determined from the center of symmetry ($f=1/2$) and from the position of ν_A or ν_B ($f=0$ or 1). Because of the one-to-one correspondency, both a and r can be determined unequivocally.

In most cases, however, we cannot scale f by a glance at the chart. Equation 12 has two independent parameters, a and r; therefore, it is necessary to use at least two shape parameters in order to compare the experimental and theoretical curves. The ratios of maximum to minimum height, of quarter-height-width to half-height-width, of half-height-width to three-quarter-height-width, etc., may be used as such parameters. A more precise comparison can be achieved by dividing the signal peak into many equal heights, and by comparing the relative widths of the experimental and theoretical curves at corresponding heights.

Provided $a=0$, the signal displays a Lorentzian curve for any r value; the value of r cannot be determined from the signal shape. Even in this case, however, we are able to evaluate T_2 from the half-height-width ($T_2=1/2\pi w$), and deduct τ_A $(=\tau_B)=0$ from the Lorentzian shape of the signal. The signal position of the components, ν_A and ν_B, cannot be determined. For $a\neq 0$, there is only one theoretical curve that accurately coincides with the signal obtained experimentally, thus, a, r, ν_A, and ν_B can all be determined.

** Duplicates are available on microfilm on request to the author.

Life-times have frequently been estimated by ignoring the effect of T_2. In more rigorous analysis, T_2 has been evaluated from the line width at high temperatures, where the signal narrows into a sharp peak. Then the life-time can be evaluated, for example, by comparing the peak separations at a temperature in the transition region and at a temperature sufficiently low to stop the exchange. The temperature independency of T_2, ν_A, and ν_B is assumed in this analysis.

The advantage of the present method is that it is free from these assumptions. At least in principle, τ, T_2, ν_A, and ν_B can be determined uniquely and simultaneously from a single experiment at any temperature in the transition region. The applicability to an actual system depends on the adequacy of the assumption that $T_{2A}=T_{2B}$, and on the accuracy of the apparatus used.

For the case where $T_{2A}\neq T_{2B}$[3] a more general formula:

$$v=C\times[\{(1+ar_Ap_B+ar_Bp_A)K+a(f+p_B-1)L\}/(K^2+L^2)] \quad (13)$$

where

$$K=(r_Ap_A+r_Bp_B)+a\{r_Ar_B-f(f-1)\}$$
$$L=f(1+ar_A+ar_B)-(ar_A+p_B)$$
$$C=-\gamma H_1M_0/2\pi\,|\nu_A-\nu_B|$$
$$a=2\pi\tau\,|\nu_A-\nu_B|$$
$$r_A=1/2\pi T_{2A}\,|\nu_A-\nu_B|$$
$$r_B=1/2\pi T_{2B}\,|\nu_A-\nu_B|$$
$$f=(\nu-\nu_A)/(\nu_B-\nu_A)$$

is derived. It is easy to design a program similar to that shown in Table I.

Studies of the Cage Effect of Solvents. V. The Photolysis of Azoethane in *n*-Heptane

By Sukeya KODAMA, Shin'ichi FUJITA, Junsuke TAKEISHI and Osamu TOYAMA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received September 29, 1965)

The effect of a solvent cage on the photolysis of azoethane in *n*-heptane was investigated at 366 mμ in the temperature range from −75 to 99°C. Among the gaseous products, nitrogen served as a measure of the azoethane decomposed. The other gaseous products were *n*-butane, ethane and ethylene; these three hydrocarbons accounted for ninety per cent of the decomposition at 0°C. The quantum yield of nitrogen was found to decrease with a lowering of the temperature. The value obtained at 0°C was 0.021. In the presence of a sufficient amount of styrene, which was used as a scavenger for ethyl radicals, the yields of the gaseous hydrocarbons were more or less reduced to constant values; from these the ratio of rate constants for the combination and disproportionation of the geminate ethyl radicals formed by the photolysis in a solvent cage was determined to be $k_{comb}/k_{disp}=11.5\exp(-371/\boldsymbol{R}T)$. The fraction of ethyl radicals that reacted in these ways in the solvent cage, before escaping it, was dependent on the temperature; it decreased from 0.838 at −75°C to 0.467 at 99°C. In the absence of styrene, the reactions for ethyl radicals that escaped the original solvent cages were inferred to be hydrogen abstraction, addition, combination and disproportionation.

In previous papers of the present series,[1] the effect of a solvent cage on the geminate methyl radicals formed by the photolysis of azomethane in various solvents was reported on. This paper will report on a similar study of the ethyl radicals obtained by the photolysis of azoethane in *n*-heptane.

The cage effect in the photolysis of azoethane in solution has been investigated by Szwarc and his co-workers[2] in an attempt to determine the ratio of disproportionation to combination of the geminate ethyl radicals in a solvent cage, and in an attempt to compare the results with those obtained in the gas phase. The present work will provide quantitative data that will enable us to discuss the reactions in the solvent cage in relation to the other reactions involved in the photolysis.

Experimental

Materials.—Azoethane was prepared by the thermal decomposition of the azoethane - cuprous chloride obtained from diethyl hydrazine di-hydrochloride and then purified and stored in a way similar to that used for azomethane.[1a] The solvent used in this work was *n*-hepane. It was chosen for various reasons: *n*-butane, a major product in the photolysis, is separated with ease from *n*-heptane by fractional distillation; the ethyl radicals formed in the photolysis would not be consumed in the addition reaction to solvent molecules if the latter had no double bonds; and the rate of the photolysis of azoethane would be reduced if the solvent were polar.[3] *n*-Heptane, obtained as a commercial sample, was found to be gas chromatographically pure. It was, however, further purified by vacuum distillation before use.

The scavenger used in this work for ethyl radicals was styrene, which was used in the previous work for methyl radicals. Commercial styrene was purified by vacuum distillation.

Apparatus and Procedure.—The photolysis was carried out with a solution of about 0.05 M azoethane in *n*-heptane at 366 mμ, using a high-pressure mercury lamp of 100 W. (Mazda SHL-100UV) and a glass filter (Mazda UV-Dl). In a few experiments, the filter was removed to obtain a high-intensity light. In experiments with varied light intensity, screens were used to reduce the light intensity. The reaction cell was a glass cylinder of 3.6 cm. in diameter and 1.0 cm. long, with a capacity of about 10 ml. The other details about the apparatus and the procedure have been described in a previous paper.[1a]

The gaseous products were nitrogen, ethylene, ethane and *n*-butane. These were separated from the solution by thrice-repeated bulb-to-bulb distillation at the dry ice - acetone temperature. For *n*-butane, an automatic fractional distillation vessel was used. Undecomposed azoethane, heptane vapor and by-products were separated by a column of cuprous chloride crystals at −120°C. This column reduced the vapor pressure of azoethane by forming an addition compound in the way opposite to that described above for preparing azoethane and enabled us to separate butane from azoethane at −120°C. The addition and release processes of azoethane on the column were reversible at a reduced pressure. *n*-Butane was condensed at

a) Without filter

−165°C, while ethane and ethylene were condensed at −210°C. The noncondensed nitrogen was determined by a Toepler gauge. The ethane and ethylene were determined by the Toepler gauge and a gas chromatograph with a column of 2% squalane on activated alumina (2 m.) and ethylene glycol saturated with silver nitrate on celite (2 m.) at room temperature. The Toepler gauge was also used to determine the *n*-butane.

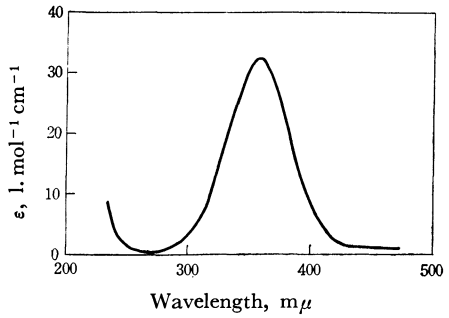

Fig. 1. Absorption curve of azoethane in *n*-heptane.

The molecular extinction coefficient of azoethane in *n*-heptane was determined to be as shown in Fig. 1. The quantum yield of nitrogen formation was measured by using a potassium ferrioxalate actinometer[4] and a quartz reaction cell. The value obtained at 366 mμ was 0.021 at 0°C.

Results

Table I summarizes the results obtained. The rates of the formation of the various products given in the table refer to the initial conversion of a small percentage. The $[1/2(C_2H_4+C_2H_6)+C_4H_{10}]/N_2$ column represents the material balance which takes only these products into account, since one molecule of azoethane gives one molecule of nitrogen and two ethyl radicals, the latter of which combine to butane or produce ethylene and ethane. The $[(C_2H_4+C_4H_{10})/N_2]_s$ column represents the sum of the yields of ethylene and butane relative to that of nitrogen in the presence of a sufficient amount of styrene; it gives, as is shown below, the fraction of ethyl radicals that undergo cage reactions.

Figure 2 shows the dependence of the yields of butane, ethane and ethylene and the material balance on the rate of photolysis, i. e., on the light intensity, in the absence of styrene at 0°C. Figure 3 shows the effect of the addition of styrene in increasing amounts at 0°C. Figures 2 and 3 both show that the result of photolysis is scarcely influenced at all by removing the light filter. This indicates that the most effective mercury line is 366 mμ, as would be expected from the absorption curve given in Fig. 1 and from the absorption property of the glass reaction cell.

drawn by comparing the rates of nitrogen formation at various temperatures, keeping the azoethane concentration and light intensity constant and normalizing them to the quantum yield value of 0.021 at 0°C.

Discussion

Primary Processes.—Previous studies of the photolysis of azoethane in the gas phase[5] and of azomethane in solution[1] suggest that the probable processes in the initial stage of the present photolysis may be:

$$C_2H_5N_2C_2H_5 + h\nu \rightarrow C_2H_5N_2C_2H_5^* \quad (1)$$

$$C_2H_5N_2C_2H_5^* + M \rightarrow C_2H_5N_2C_2H_5 + M \quad (2)$$

$$C_2H_5N_2C_2H_5^* \rightarrow [2C_2H_5 + N_2] \quad (3)$$

Here the asterisk denotes the excited state; M, a solvent molecule, and the bracketed species, those formed together in a solvent cage.

Cerfontain and Kutschke[5c] have shown that, in the gas phase photolysis of azoethane as well as in that of azoisopropane, the excited molecules of the substrate are deactivated by collision, while such deactivation is absent in the case of azomethane. Reaction 2, therefore, cannot be omitted in the present case, though a corresponding deactivation process was previously neglected in the photolysis of azomethane in solution.[1]

Reaction 2 appears to account for the result that the quantum yield of nitrogen is considerably less than unity. However, the quantum yield falls off with a lowering of the temperature, as is shown in Fig. 5, while the studies of the yield of fluorescence in solution show that the quenching by deactivation usually increases with the temperature.[6] If reaction 2 is the only process involved in reducing the quantum yield, the decomposition of the excited azoethane must require an appreciable energy of activation.

The decomposition of the excited molecules of azoethane is represented in reaction 3 as a one-step act. If, however, they decompose in two stages, as $C_2H_5N_2C_2H_5^* \rightarrow C_2H_5N_2 + C_2H_5$ followed by $C_2H_5N_2 \rightarrow C_2H_5 + N_2$, the recombination reaction, $C_2H_5N_2 + C_2H_5 \rightarrow C_2H_5N_2C_2H_5$, in a solvent cage may provide an alternative explanation for the low quantum yield of nitrogen. Such a possibility can not be ruled out, though the decomposition of the $C_2H_5N_2$ radicals has been inferred to be considerably exothermic[7] and the flash photolysis technique has as yet given no evidence for the formation of this species as a transient intermediate.[5d,5f]

The short-lived $C_2H_5N_2$ radicals, if formed, would not survive to take part in reactions other than the decomposition and recombination considered above. So far as the secondary reactions to be discussed below are concerned, therefore, the decomposition of the excited azoethane may virtually be represented by reaction 3.

Cage Reactions.—In view of the reactions between ethyl radicals in the gas phase, the probable reactions for the geminate ethyl radicals formed by reaction 3 may be :

$$[2C_2H_5 + N_2] \rightarrow C_4H_{10} + N_2 \quad (4)$$

$$\rightarrow C_2H_6 + C_2H_4 + N_2 \quad (5)$$

$$\rightarrow 2C_2H_5 + N_2 \quad (6)$$

Reactions 4 and 5 are, respectively, the combination and disproportionation of the geminate ethyl radicals in the original solvent cage, while reaction 6 represents the separation of the radicals from each other by their escaping the cage before they combine or disproportionate.

Figure 3 shows that, in the presence of a sufficient amount of styrene as a scavenger for ethyl radicals, almost all the butane, ethane and ethylene are formed by the cage reactions 4 and 5.[8] However, in Fig. 3 as well as in Fig. 4, the yield of ethane in the presence of styrene is slightly higher than that of ethylene, whereas they should be equal to each other according to reaction 5. It seems possible that this slight difference arises from the hydrogen atom abstraction by hot ethyl radicals from the solvent molecules constituting the cages, since the excess energy released by the decomposition of azoethane amounts to 62 kcal./mol. at 366 mμ.

The fraction of the geminate ethyl radicals that react in the solvent cage as represented in reactions 4 and 5 may be computed from the sum of the

relative yields $(C_4H_{10}+C_2H_4)/N_2$ in the presence of styrene. Figure 4 shows that this fraction is greater than 0.8 below $-50°C$, but that it decreases with a rise in the temperature, reflecting the fact that the escape of the ethyl radical from the solvent cage by diffusion is favored at high temperatures.

The Reactions of Ethyl Radicals That Have Escaped the Original Cages.—The results obtained in the present work, together with those obtained previously in the photolysis of azomethane in solution,[1] suggest that the probable reactions for the ethyl radicals that have escaped the original cages are:

$$C_2H_5 + C_2H_5 \rightarrow C_4H_{10} \quad (7)$$

$$C_2H_5 + C_2H_5 \rightarrow C_2H_6+C_2H_4 \quad (8)$$

$$C_2H_5 + RH \rightarrow C_2H_6+R \quad (9)$$

$$C_2H_5+(C_2H_5)_2N_2 \rightarrow (C_2H_5)_3N_2 \quad (10)$$

RH in reaction 9 represents a molecule of *n*-heptane, the solvent. The hydrogen atom abstraction from azoethane molecules by ethyl radicals may not be important, because its rate constant may be of the same order of magnitude as that for reaction 9, while the concentration of azoethane in the present experiment is as low as 0.05 mol./l.

The difference between the results obtained with and without styrene is accounted for by reactions 7—10. Figures 2 and 3 show that ethane formed in other ways than reaction 5 is largely due to reaction 9. Figure 2, however, shows that, as the rate of nitrogen formation increases, i. e., as the concentration of ethyl radicals increases, the yield of ethane falls off, while those for butane and ethylene increase. These observations may be explained as follows. As the concentration of ethyl radicals increases, the rates of combination and disproportionation increase; both of these rates are second-order with respect to ethyl radicals and have very low activation energies. This, in turn, reduces the fraction of ethyl radicals consumed in reaction 9, which is first-order in the ethyl radical and which has a considerable activation energy.[9] For a similar reason, the fraction of ethyl radicals consumed in reaction 10 is also reduced; this improves, though slightly, the material balance given in Fig. 2 as the concentration of ethyl radicals increases.

It cannot be concluded from the present work that only reaction 10 is responsible for the material balance less than unity, represented by $[1/2(C_2H_4+C_2H_6)+C_4H_{10}]/N_2$. Another possibility may be $C_2H_5+R\rightarrow C_2H_5R$. However, a combination $R+R\rightarrow R_2$ is also a probable reaction for the solvent radical R. It will, however, be tentatively assumed below that the loss in material balance arises mostly from reaction 10.

In the previous studies with azomethane,[1] the combination of methyl radicals corresponding to reaction 7 was found to be negligible compared to the hydrogen atom abstraction reaction similar to reaction 9. This difference probably reflects the lower ability of ethyl radicals in solution to abstract hydrogen atoms from solvent molecules.

The Evaluation of the Rate Constant Ratios.—A steady-state treatment of reactions 1—3, combined with the dependence of the quantum yield of nitrogen on the temperature (Fig. 5), yields:

$$k_3/k_2 = 0.5 \exp(-650/\boldsymbol{R}T)\,\text{mol.}\,l^{-1} \quad (I)$$

A corresponding expression for the gas-phase photolysis has been obtained as:[10]

$0.25 \exp(-2000/\boldsymbol{R}T)\,\text{mol.}\,l^{-1}$

Reactions 4—6, when regarded as ordinary elementary steps, lead to:

$$k_4/k_5 = (C_4H_{10})_s/(C_2H_4)_s \quad (II)$$

$$k_6/k_4 = [(N_2)_s - (C_4H_{10})_s - (C_2H_4)_s]/(C_4H_{10})_s \quad (III)$$

$$k_6/k_5 = [(N_2)_s - (C_4H_{10})_s - (C_2H_4)_s]/(C_2H_4)_s \quad (IV)$$

where the suffix s denotes the presence of styrene. The Arrhenius plots of these rate constant ratios are shown in Fig. 6. The plot for Eq. II is linear and yields:

$$k_4/k_5 = 11.5 \exp(-371/\boldsymbol{R}T) \quad (V)$$

The rate constant ratio for the disproportionation and combination of ethyl radicals as given

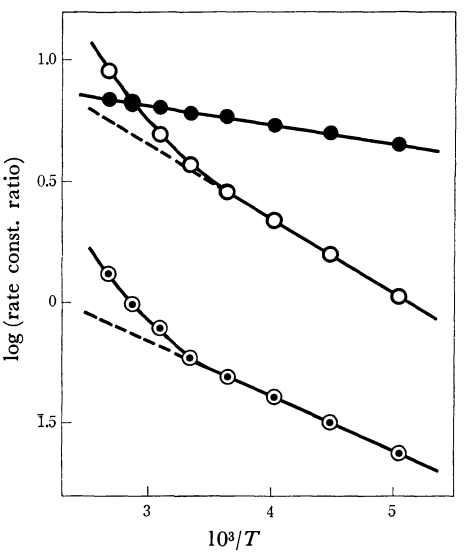

Fig. 6. Arrhenius plots of rate constant ratio.
●, k_4/k_5; ○, k_6/k_5; ⊙, k_6/k_4

9) A reported value in the gas phase is 10.6 kcal./mol. (D. G. L. James and E. W. R. Steacie, *Proc. Roy. Soc.*, **A244**, 289 (1958)).

10) Calculated from the results obtained by Cerfontain and Kutschke (Ref. 5c).

by the C_2H_4/C_4H_{10} ratio of yields has been investigated by many workers in the gas phase. The most reliable value given by these studies is 0.13 ± 0.02; it is independent of the temperature in the 50—250°C range.[2b,5f] All the values of $(C_2H_4)_s/(C_4H_{10})_s$ given in Table I are greater than 0.13, and Eq. V shows that k_4/k_5 is slightly dependent on the temperature. Similar results have been obtained and discussed in detail by Szwarc and his co-workers.[2]

Figure 6 shows that the plots for Eqs. III and IV are not linear above room temperature. Similar deviations at high temperatures were observed in the photolysis of azomethane in solution.[1d] The Arrhenius plots for the self-diffusion in such liquids as *n*-pentane and *n*-heptane also show anomalies at high temperatures.[11] As was described in a previous paper on the photolysis of azomethane,[1d] the crude representation for the escape of a radical from a solvent cage given in reaction 6 seems to break down at high temperatures, giving rise to these deviations.

The linear portions of the plots for k_6/k_4 and k_6/k_5 below room temperature yield:

$$k_6/k_4 = 3.40 \exp(-1050/\boldsymbol{R}T) \quad \text{(VI)}$$

$$k_6/k_5 = 39.0 \exp(-1420/\boldsymbol{R}T) \quad \text{(VII)}$$

The significance of these expressions will be discussed in a later paper, together with the results obtained in the photolysis of $CH_3N_2C_2H_5$ in solution.

The yields of butane, ethane and ethylene formed by reactions 7—9 are given by comparing each yield in the presence of and in the absence of styrene. The yield for reaction 10 is obtained as $2-(2C_4H_{10}+C_2H_6+C_2H_4)/N_2$. By combining these quantities, we obtain the following values at 0°C:

$$k_9/k_7^{1/2} = 1.2\times 10^{-4}\ l^{1/2}\ mol^{-1/2}\ sec^{-1/2}$$

$$k_{10}/k_7^{1/2} = 1.1\times 10^{-2}\ l^{1/2}\ mol^{-1/2}\ sec^{-1/2}$$

$$k_{10}/k_9 = 93$$

The Synthesis of Deoxyaspergillic Acid and Tetrahydrodeoxyaspergillic Acid

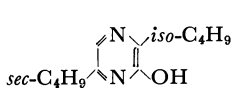
By Yasuhiro CHIGIRA, Mitsuo MASAKI and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Tokyo

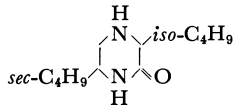
(Received September 30, 1965)

Deoxyaspergillic acid (I) and tetrahydrodeoxyaspergillic acid (II) were synthesized. 1-Chloro-3-methyl-2-pentanone was directly oximinated with hydroxylamine, and then the oxime was treated with L-leucine ethyl ester to yield *N*-(3-methyl-2-oximinopentyl)-L-leucine ethyl ester (III), which, on alkali-hydrolysis, followed by acid-hydrolysis, gave *N*-(3-methyl-2-oxopentyl)-L-leucine (IV). The treatment of the methyl ester of IV with ammonia gave I, and the hydrogenation of III on Raney nickel gave II.

The antibiotic aspergillic acid has been concluded to be 1-hydroxy-3-isobutyl-6-*sec*-butyl-2-pyrazinone or its tautomeric 1-oxide of the 2-hydroxypyrazine.[1] The reduction of aspergillic acid with hydrazine yields deoxyaspergillic acid, i. e., 3-isobutyl-6-*sec*-butyl-2-hydroxypyrazine (I), while reduction with zinc in acetic acid gives tetrahydrodeoxyaspergillic acid, i. e., 3-isobutyl-6-*sec*-butyl-2-piperazinone (II).[2]



(I)



(II)

Two routes for the synthesis of racemic deoxyaspergillic acid have been reported. The first, reported by Newbold et al.,[1] consists of the reaction of 3-methyl-2-oximinovaleraldehyde with leucine nitrile to give 2-aminopyrazine-1-oxide derivative, which is then converted into I by treatment with sodium dithionite, followed by hydrolysis. The second synthesis consists of the treatment of DL-leucyl-DL-isoleucine anhydride with phosphoryl chloride.[3] On the other hand, tetrahydrodeoxyaspergillic acid has never been synthesized. The present paper will describe an alternative route for the synthesis of racemic deoxyaspergillic acid and the synthesis of racemic tetrahydrodeoxyaspergillic acid.

It has been previously reported in our laboratory that 3, 6-disubstituted 2-hydroxypyrazines[4] and 2-piperazinones[5] can be synthesized starting from

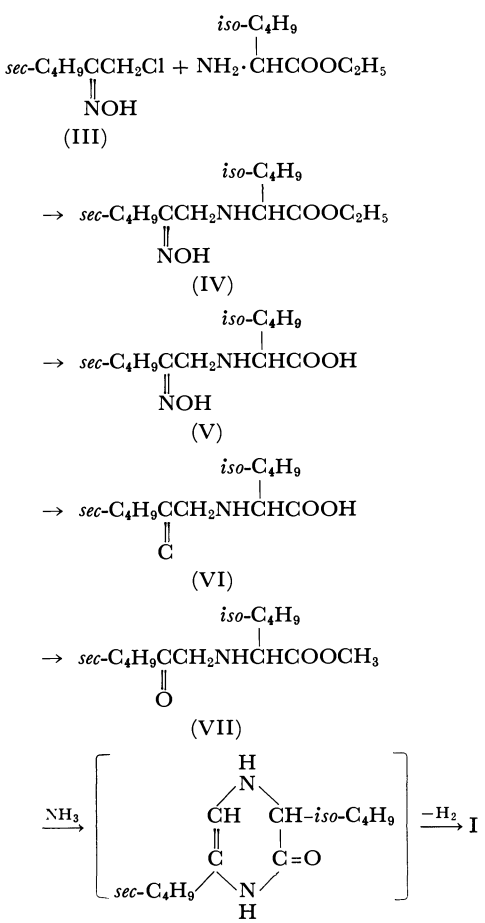
5) M. Masaki and M. Ohta, ibid., **36**, 922 (1963).

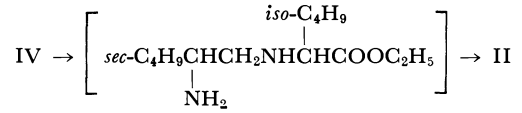
N-(2-oximinoalkyl)-amino acid esters. In an application of this method to the synthesis of I and II, however, 1-chloro-3-methyl-2-pentanone oxime (III) is required. Aliphatic α-halooxime is generally prepared by the reduction of nitroolefine with stannous chloride.[6] The direct oximination of aliphatic α-haloketones with hydroxylamine has been successfully reported only in the case of α-bromo- and α-chloro-acetone,[7] because the reaction of α-haloketone with amines is very complex.[8]

The reaction of 1-chloro-2-pentanone with hydroxylamine was, therefore, studied under various conditions; finally a 43% yield of 1-chloro-2-pentanone oxime was obtained by stirring a suspension of the ketone in an aqueous hydroxylamine solution at 0°C for 4 hr. In a similar manner, 1-chloro-3-methyl-2-pentanone was converted into the corresponding oxime (III) in a 50% yield.

The treatment of 1-chloro-3-methyl-2-pentanone oxime (III) with L-leucine ethyl ester in ether at room temperature yielded *N*-(3-methyl-2-oximinopentyl)-L-leucine ethyl ester (IV) as a yellow oil which was characterized by saponifying it to the corresponding carboxylic acid (V). *N*-(3-Methyl-2-oximinopentyl)-L-leucine (V) was treated with benzaldehyde in hydrochloric acid - methanol to give *N*-(3-methyl-2-oxopentyl)-L-leucine (VI), which was then converted into the methyl ester hydrochloride (VII) by esterification with methanol and hydrogen chloride. When treated with ammonia in methanol, this ester hydrochloride yielded 3-isobutyl-6-*sec*-butyl-2-hydroxypyrazine (I). The last stage of this reaction involves air oxidation, which is common to most pyrazine syntheses.[4] The product was confirmed by a comparison of its melting point, as well as its infrared and ultraviolet absorption spectra, with those of the deoxyaspergillic acid derived from aspergillic acid[2] or that synthesized by Newbold et al.[1,3]



The oximino ester (IV) was hydrogenated in the presence of Raney nickel at 80°C in an autoclave; thereby the initially-produced amino ester cyclized spontaneously to yield 3-isobutyl-6-*sec*-butyl-2-piperazinone (II), which was isolated as its hydrochloride. The hydrochloride showed the same melting point as that of tetrahydrodeoxyaspergillic acid hydrochloride and showed the absorption bands at 3200, 1660 and 1470 cm^{-1} characteristic of 3, 6-disubstituted 2-piperazinones.[5] These data, as well as the results of the elementary analysis, support the assigned structure.



Experimental

The Oximination of 1-Chloro-2-pentanone.—An aqueous solution of hydroxylamine [from the hydrochloride (3 g.) in water (2.5 g.) and sodium carbonate decahydrate (6 g.) in water (10 ml.)] was stirred, drop by drop, into 1-chloro-2-pentanone (5.0 g.) at 0°C; then, after the addition was complete, the stirring was continued for another 4 hr. The mixture was extracted with ether, and the ethereal layer was washed twice with water and dried over anhydrous sodium sulfate. The evaporation of the ether and the distillation of the residue yielded 2.3 g. of 1-chloro-2-pentanone oxime, b. p. 62—70°C/3 mmHg (lit.[5] 78—82°C/7 mmHg.)

Found: N, 10.32. Calcd. for $C_5H_{10}NOCl$: N, 10.33%.

1-Chloro-3-methyl-2-pentanone Oxime (III).—In an analogous manner to that used for 1-chloro-2-pentanone, 1-chloro-3-methyl-2-pentanone[9] (20 g.) was treated with an aqueous solution of hydroxylamine hydrochloride (10 g.) and sodium carbonate decahydrate (20 g.); 1-chloro-3-methyl-2-pentanone oxime (12 g.) was thus obtained as a colorless oil, b. p. 74—78°C/2.5 mmHg.

Found: C, 48.06; H, 8.19; N, 9.20. Calcd. for $C_6H_{12}NOCl$: C, 48.16; H, 8.13; N, 9.36%.

6) A. Dornow, H. D. Jordan and A. Müller, *Chem. Ber.*, **94**, 67 (1961).
7) R. Scholl and G. Matthaiopoilos, ibid., **29**, 1552 (1896).
8) C. L. Stevens, P. Blumbergs and M. Munk, *J. Org. Chem.*, **28**, 331 (1963).
9) G. T. Newbold and F. S. Spring, *J. Chem. Soc.*, **1947**, 375.

The reaction of the product with piperidine afforded 1-piperidino-3-methyl-2-pentanone oxime as a colorless oil, b. p. 108—110°C/0.15 mmHg.

Found: N, 14.41. Calcd. for $C_{11}H_{22}N_2O$: N, 14.14%.

***N*-(3-Methyl-2-oximinopentyl)-L-leucine Ethyl Ester (IV).**—To a solution of leucine ethyl ester (15.5 g.) in absolute ether (50 ml.) there was added a solution of 1-chloro-3-methyl-2-pentanone oxime (6.4 g.) in absolute ether (25 ml.); the mixture was then allowed to stand at room temperature for a week. After the crystals of leucine ethyl ester hydrochloride (4.5 g.) had been removed, the ethereal solution was washed several times with water and extracted with 3 N hydrochloric acid (3×50 ml.). The combined extracts were neutralized with an aqueous solution of sodium carbonate to give a yellow oil, which was then extracted with ether. The ethereal extracts were washed twice with water and dried over anhydrous sodium sulfate. The evaporation of the ether yielded IV as a yellow oil (10 g.), which was characterized by saponifying it to the corresponding carboxylic acid (V), as is shown below.

***N*-(3-Methyl-2-oximinopentyl)-L-leucine (V).**—The crude IV (4.5 g.) was added to a solution of potassium hydroxide (4.5 g.) in water (20 ml.). When the mixture was allowed to stand at room temperature overnight, the mixture became nearly clear. The solution was diluted with water (20 ml.), treated with activated charcoal, and then neutralized with a 20% aqueous acetic acid to give colorless needles, which were recrystallized from methanol, m. p. 168—169°C (decomp.). Yield, 2.2 g.

Found: N, 11.18. Calcd. for $C_{12}H_{24}N_2O_3$: N, 11.47%.

***N*-(3-Methyl-2-oxopentyl)-L-leucine (VI).**—To a mixture of V (2 g.) and 3 N hydrochloric acid (20 ml.), benzaldehyde (2 g.) and methanol (20 ml.) were added the resultant clear solution was allowed to stand at room temperature. After a week the mixture was concentrated to about 20 ml. under reduced pressure. The residue was washed three times with ether and neutralized with a saturated solution of sodium carbonate. The precipitated crystals (0.9 g.) were recrystallized from methanol to yield colorless microscopic needles, m. p. 164.5—165.5°C (decomp.).

Found: N, 6.41. Calcd. for $C_{12}H_{23}NO_3$: N, 6.11%.

***N*-(3-Methyl-2-oxopentyl)-L-leucine Methyl Ester Hydrochloride (VII).**—A suspension of VI (0.8 g.) in methanol was refluxed for 2 hr., while dry hydrogen chloride was passed continuously through the mixture; then the mixture was allowed to stand overnight. The solution was evaporated under reduced pressure to give an oily residue, which was dried in a desiccator over potassium hydroxide under reduced pressure. Crystallization from ethyl acetate afforded colorless plates, m. p. 145°C (after half melting at 134°C). Yield, 0.4 g.

Found: N, 5.24. Calcd. for $C_{13}H_{25}NO_3 \cdot HCl$: N, 5.01%.

3-Isobutyl-6-*sec*-butyl-2-hydroxypyrazine (I).—A solution of VII (0.3 g.) in methanol (20 ml.) was saturated with ammonia. After three days the solution was evaporated to afford a brown oily residue, to which ethyl acetate (5 ml.) was then added. After the insoluble ammonium chloride had been removed, the filtrate was again concentrated under reduced pressure, and the residue was extracted with 6 N hydrochloric acid. After treatment with activated charcoal, the solution was neutralized with 2 N sodium hydroxide, yielding pale brown crystals (0.1 g.). Recrystallization from aqueous methanol gave colorless needles with a m. p. of 99.5—100.5°C. λ_{max}^{EtOH} 228 mμ (ε=7900) and 325 (8400). (Found: C, 69.22; H, 9.98; N, 13.68).

These constants are essentially identical with those of the racemic deoxyaspergillic acid derived from aspergillic acid [m. p. 103—104°C, λ_{max}^{EtOH} 228 mμ (ε=7000) and 325 (8400)][2] or that synthesized by Newbold et al. [m. p. 100.5—101.5°C, λ_{max}^{EtOH} 227 mμ (ε=8000) and 324 (8000)].[1] The infrared spectrum of the product was also essentially identical with that[10] of deoxyaspergillic acid.

3-Isobutyl-6-*sec*-butyl-2-piperazinone (II) Hydrochloride.—A solution of crude IV (4 g.) in ethanol (150 ml.) was shaken with Raney nickel (2 g.) at an initial pressure of 90 kg./cm² of hydrogen at 80°C. After the hydrogen absorption had ceased, the catalyst was removed and the solution was concentrated under reduced pressure. The residue was dissolved in ether (100 ml.) and treated with dry hydrogen chloride to give a yellow oil, which was, after being washed several times with ether, left in absolute ether in a refrigerator. After two days, small needles crystallized out. They were collected and recrystallized twice from *n*-butanol to yield 0.5 g. of colorless needles, which melted at 260°C (decomp.) after darkening at 230°C. ν_{max}^{KBr} 3200, 2950, 1660, 1470, 1280 and 1000 cm⁻¹. (Found: C, 58.15; H, 9.95; N, 11.26.)

According to Dutcher,[2] the tetrahydrodeoxyaspergillic acid hydrochloride derived from aspergillic acid by reduction with zinc and acetic acid melts at 260°C after darkening at 235°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1017—1019 (1966)

The Surface Adsorption of Sodium Alkyl Sulfates from Dioxane-Water Mixtures

By Keishiro SHIRAHAMA, Kiyoshi NAKAO, Hiroko ENDO and Ryohei MATUURA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki

(Received October 4, 1965)

The surface adsorptions of three sodium alkyl sulfates (C_{12}, C_{14}, C_{16}) from dioxane-water mixtures have been measured by using ^{35}S-labeled surfactants; it has been found to decrease with an increase in the dioxane concentration. This decrease has been explained in terms of the following factors; (1) the variation in the standard chemical potential of the surfactant in the bulk phase, or the free energy of transfer, (2) the surface tension of the solution, and (3) the dielectric constant of the solvent. In a solvent containing more dioxane than 40 wt.%, it has been shown, both by experiment and by theory, that these alkyl sulfates lose their surface activities.

The air/solution interface reflects the properties of the bulk phase. Thus, in the case of a surfactant solution, the surface excess may be correlated to the chemical potential of the surfactant in the solution by Gibbs' equation.

If the nature of a solvent in the bulk phase is changed by adding to it a third substance, the surface properties should correspondingly be altered; therefore, it is informative to study the surface phenomena in relation to the nature of the solvent in the bulk phase.

The surface adsorption of an ionic surfactant from an aqueous solution has been shown to be affected very much by the addition of extraneous salts, and this has been explained by considering only the electrical double layer produced just below the surface.[1]

In a previous paper, such properties as the micelle formation and solubility of sodium alkyl sulfates in the dioxane-water mixed solvent were discussed in detail.[2]

The present work will describe the surface adsorption of sodium hexadecyl (SHS), tetradecyl (STS) and dodecyl (SDS) sulfates from their solution in a dioxane-water mixture, and will attempt to explain the decrease in the surface adsorption in terms of the variation, with the dioxane concentration, of the standard chemical potential of the surfactant, of the dielectric constant of the solvent, and of the surface tension of the solution.

Experimental

The surfactants used, i. e., SHS, STS and SDS, were synthesized and purified as described in the previous work.[2] The surface adsorption measured by the radiotracer method in the same way as has already been reported.[3] The surface tension of the solutions was measured by the drop-weight method with the Harkins-Brown corrections applied.[4] The solvents used were the same as were used in the previous work.[2] The experiments were carried out at 25°C.

Results and Discussion

The surface adsorption of the three alkyl sulfates is shown in Fig. 1 as a function of the dioxane concentration. The general feature is the decrease in the adsorption with the increase in the dioxane concentration; the adsorption becomes undetectable when the dioxane concentration increases beyond 30 wt.% for SDS and STS, and 45 wt.% for SHS. This trend may be explained in the following manner.

The chemical potential of the surfactant ion in the surface phase is expressed as:

$$\mu^s = \mu^{os} + \boldsymbol{k}T \ln a^s - \gamma A + e\psi \qquad (1)$$

and that in the bulk phase as:

$$\mu = \mu^o + \boldsymbol{k}T \ln a \qquad (2)$$

where the superscript s refers to the surface, μ^o and a are the standard chemical potential and the activity, respectively, of the surfactant ion; γ is the surface tension of the solution; A is the surface area of a surfactant molecule; e is a unit charge, and ψ is the surface potential. The other notations have the ordinary meanings. According to Gouy's theory,

$$\psi = (2\boldsymbol{k}T/e)\sinh^{-1}\{(\sigma/C^{1/2})(500\pi/D\boldsymbol{R}T)^{1/2}\} \qquad (3)$$

In this equation, C is the total electrolyte concentration in mol./l.; D is the dielectric constant of the solvent, and $\sigma = e\Gamma$, where Γ is the surface excess of a surfactant in mol./cm^2.

1) R. Matuura, H. Kimizuka and K. Yatsunami, This Bulletin, **32**, 646 (1959); R. Matuura, H. Kimizuka and A. Matsubara, ibid., **34**, 1512 (1961); R. Matuura, H. Kimizuka, A. Matsubara, K. Matsunobu and T. Matsuda, ibid., **35**, 552 (1962).

2) K. Shirahama and M. Matuura, ibid., **38**, 373 (1965).

3) R. Matuura, H. Kimizuka, S. Miyamoto and R. Shimozawa, ibid., **31**, 532 (1958).

4) W. D. Harkins and F. E. Brown, *J. Am. Chem. Soc.*, **38**, 288 (1916); **41**, 499 (1919).

When $\psi \geqq 100$ mV., Eq. 3 reduces to:

$$\psi = (2\boldsymbol{k}T/e)\ln\{(2e\Gamma/C^{1/2})(500\pi/D\boldsymbol{R}T)^{1/2}\} \quad (4)$$

The activities a^s and a in Eqs. 1 and 2 can be replaced by concentrations when the solutions are sufficiently dilute. Using Eq. 4 and the relation $C^s = 1000\Gamma/d$, where C^s is the surface concentration expressed in mol./l., and d, the surface thickness,[5] we obtain from equating Eqs. 1 and 2, after rearrangment:

$$3\boldsymbol{k}T \ln \Gamma = \mu^o - \mu^{os} + \gamma A + \boldsymbol{k}T \ln D + K \quad (5)$$

where $K = 2\boldsymbol{k}T \ln C - \boldsymbol{k}T \ln(10^6 e^2\pi/2d\boldsymbol{R}T)$. Here, we are primarily interested in the relative adsorption, Γ_x/Γ_0, where the subscripts 0 and x refer to the water and dioxane-water mixtures, respectively. Hence at a constant surfactant concentration in the bulk phase, we have:

$$\log(\Gamma_x/\Gamma_0) = \frac{1}{3}\{(\mu_x^o - \mu_0^o)/2.3\boldsymbol{R}T + (\gamma_x - \gamma_0)A/2.3\boldsymbol{R}T + \log(D_x/D_0)\} \quad (6)$$

The first term of the right hand side of Eq. 6 can be estimated from the solubility data shown in the previous paper,[2] while the other terms can easily be calculated from the data of the surface tension and the dielectric constant of the solution and the solvent (Table I). The calculated values are shown by the solid lines in Fig. 1. The rather good agreement with experimental values may show the validity of Eq. 6. In order to see what term of the three in the R.H.S. of Eq. 6 is the most effective in effecting the decrease in the surface adsorption with the dioxane concentration, the magnitude of each term is shown in Table II.

TABLE I. VARIOUS PROPERTIES OF THE SOLUTION

Dioxane wt. fraction	Surface tension (dyne/cm)			Dielectric constant*
	SHS	STS	SDS	
0.0	66.0	71.6	70.8	78.5
0.1	54.5	54.1	56.5	70.0
0.2	52.0	49.0	49.0	61.6
0.4	48.9	43.0	48.0	42.8
Surfactant concn. (mol./l.)	10^{-5}	5×10^{-5}	10^{-4}	

* Dielectric constant was quoted from Ref. 6.

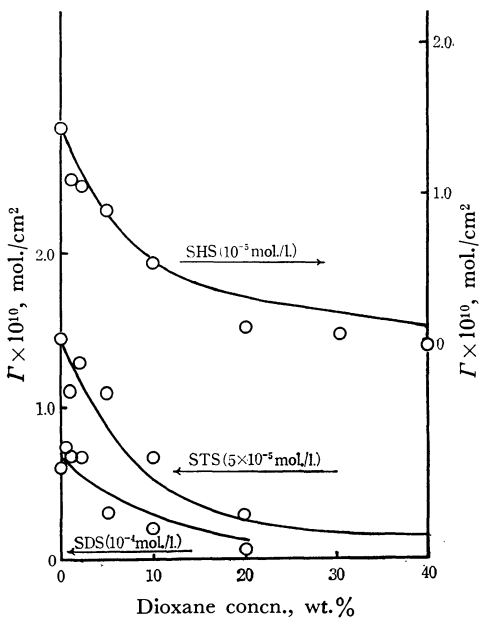

Fig. 1. Surface adsorption vs. dioxane concentration.
Circles are the measured points at 25°C.

TABLE II. THE CALCULATION OF EACH TERM OF Eq. 6

Dioxane wt. fr.	$-(\mu_x^o - \mu_0^o)/2.3\boldsymbol{R}T$*	$-(\gamma_x - \gamma_0)A/2.3\boldsymbol{R}T$**	$-\log(D_x/D_0)$
	SHS $C = 10^{-5}$ mol./l.		
0.1	0.974	0.238	0.0496
0.2	1.59	0.292	0.106
0.4	2.58	0.356	0.263
	STS $C = 5\times10^{-5}$ mol./l.		
0.1	0.898	0.364	
0.2	1.45	0.468	
0.4	2.01	0.594	
	SDS $C = 10^{-4}$ mol./l.		
0.1	0.800	0.300	
0.2	1.31	0.468	

* Calculated on the molar concentration basis, while in the previous paper the free energy of transfer was calculated on the mole fraction basis.

** γA was calculated in kcal. with A taken as 20Å^2.

It is evident that the free energy of transfer term, $(\mu_x^o - \mu_0^o)$, is the major factor. This means that the surfactant becomes more solvophilic as the dioxane concentration increases, and that it is pulled down from the surface to the bulk phase. As to the surface tension term, it also contributes, although not dominantly, to the decrease in the surface adsorption. Finally, the low dielectric constant of the mixed solvent affects the surface adsorption so as to strengthen the electric field due to the ions in the diffuse layer, and in turn, to increase the surface electrical energy. Thus, the bulk phase becomes more favorable for the surfactant to escape from the surface, and, in the region of dioxane concentration greater than 40 wt.%, the surfactant is no longer "surface-active."

5) J. T. Davies and E. K. Rideal, "Interfacial Phenomena," Academic Press, London (1961), p. 154.

6) J. B. Hasted. G. H. Haggis and P. Hutton, *Trans. Faraday Soc.*, **47**, 577 (1951).

This corresponds to the fact that no micelle formation was detected in this region.[2] In spite of the larger bulk concentration in the case of SDS and STS, the surface adsorptions disappear at a dioxane concentration smaller than that in the case of SHS. This, however, may easily be understood. The shorter hydrocarbon chain would become readily solvophilic upon the addition of a smaller amount of dioxane.

The approximation made in the derivation of Eq. 4 from Eq. 3 was checked; it was found to be satisfied at all points measured. The other assumption is the complete dissociation of the adsorbed surfactant. In an aqueous medium, an almost complete dissociation has been suggested by a comparison of the surface excess measured by the radiotracer method with the one calculated from the surface tension measurement.[3] In a dioxane-rich solvent, there should be an appreciable ionic association, but such a solvent is outside our present area of interest.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1019—1027 (1966)

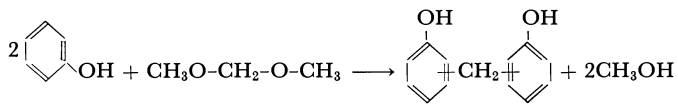
The Reaction between Phenol and Formaldehyde in Non-Aqueous Media. I. The Kinetics of the Reaction Catalyzed by Boron Trifluoride-Etherate

By Shin'ichi MURAYAMA

Central Research Laboratory, Sumitomo Bakelite Co., Ltd., Totsuka-ku, Yokohama

(Received October 16, 1965)

The papers of this series are kinetic studies of the reaction between phenol and formaldehyde in non-aqueous media; this reaction has, however, not been investigated as thoroughly as the reactions in aqueous media. During the course of the reaction, the reactants and products have been determined by gas chromatography. Within the range of low conversion, the overall reaction between phenol and methylal may be represented by:



Moreover, the kinetic equation and the apparent activation energy have been estimated as follows :

$$\frac{\mathrm{d[methyl\ alcohol]}}{\mathrm{d}t} = -\frac{\mathrm{d[phenol]}}{\mathrm{d}t} = \frac{k[\mathrm{phenol}]^2[\mathrm{methylal}]^0[\mathrm{catalyst}]^1}{[\mathrm{methyl\ alcohol}]^3}$$

$$E \fallingdotseq 18.6 \text{ kcal./mol.}$$

At the same time, methyl phenyl formal is detected as an intermediate in the reaction system. Judging from these experimental results, it seems that the acetal exchange reaction, and the substitution on aromatics proceed concurrently and consecutively in the complex system.

The reaction between phenol and aldehydes has been investigated intensively over the past fifty years, and the mechanisms of the reaction in aqueous media have been almost established.[1,2] However, very little is known concerning the reaction in non-aqueous media.

Since formaldehyde in aqueous media exists as a mixture of methylene glycol, polymethylene glycol, their hemiacetals and acetals (when an alcohol is present),[3] the reactions in aqueous media may be very complicated, especially when such a solvent as alcohol or dioxane is present in the system.[4]

(1)

Several years ago, Uenaka, Naokawa and Yoshino[5] developed a new technique of producing phenol resins; this was one of the earliest examples of the reaction in non-aqueous media. They used paraformaldehyde as the source of formaldehyde, butyl alcohol as the solvent, and calcium hydroxide as the catalyst; then the water produced was removed from the reaction system by azeotropic distillation during the course of the reaction. It was shown by their results that both the rates and the products of the reaction in the non-aqueous media differed remarkably from those of the reaction in the aqueous media. It was also found that the presence of butyl phenyl formal in the reaction system had a significant effect on the rate of reaction.[6]

Recently, Horiuchi[7] found, by means of gas chromatography, that a small amount of methyl phenyl formal was present only at the early stage of the reaction between phenol and the formaldehyde solution containing water and methyl alcohol. However, the alkyl phenyl formal produced at an earlier phase of the reaction was subsequently decomposed by hydrolysis and the rate of the overall reaction may not be appreciably influenced by this intermediate in aqueous media.

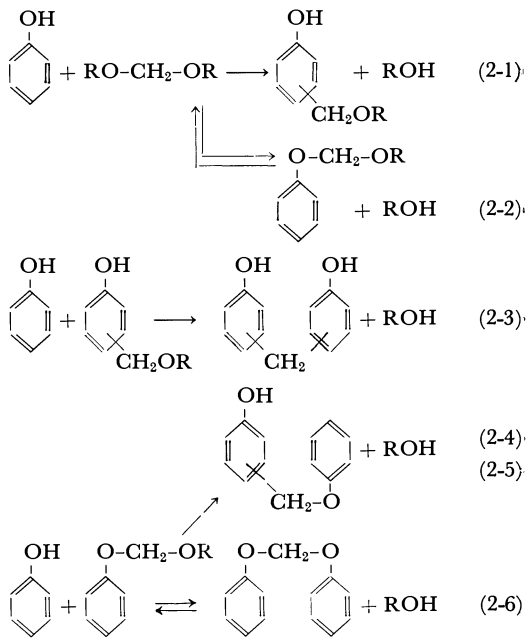
More recently, Heslinga and Schors[8] developed a new type of phenolic resin, one prepared by curing novolac with cyclic formals in the presence of an acid as the catalyst at room temperature and under atmospheric pressure. Although the preparation,[8] the processing and the physical properties[9] of the phenol formal resins were studied extensively, however, the mechanism of the reaction between phenol (or novolac) and cyclic formals was not fully investigated.

Meerwein[10] has reviewed recent research on the reactions of acetals including the syntheses, the decomposition, the acetal exchange, the hydrolyses, and the alcoholyses. In this review, some aspects of the behavior of alkyl aryl formals are described, especially those of methyl phenyl formal.

Since acetals are relatively stable in alkaline media, but not in acidic media, almost all the reactions of acetals can be catalyzed by a small amount of an acid, for example, hydrochloric acid, sulfuric acid, phosphoric acid, ferric chloride, calcium chloride, ammonium chloride, boron trifluoride, hydrogen sodium sulfate, monochloroacetic acid, *p*-touenesulfonic acid or the acidic forms of ion exchange resins.

It seems probable that the principal reactions between phenol and formals in non-aqueous media are the acetal exchange[10,11] and the substitution on the aromatic ring; the former is reversible, while the latter is irreversible.

If formaldehyde is added to the system as a formal, the acid-catalyzed phenol-formaldehyde reactions in non-aqueous media may be simpler than those in aqueous media.



If the reaction is fully represented by Eqs. 2-1—2-6, if that is, the products of the reaction are only the mono-substituted phenols and the unsubstituted binuclear compounds, the amount of phenol consumed must be equivalent to the amount of methyl alcohol produced. By actual measurements, the above condition was found to hold at conversions up to 30%; this experimental evidence simplifies the kinetic treatment.

Even though the phenol-formaldehyde reaction in non-aqueous media is one of the most important problems in the field of phenol resins, no kinetic studies have been done on this reaction, as has been mentioned earlier. From this point of view, this investigation has been undertaken, therefore, first to deduce the kinetic equation for the reaction between phenol and methylal in non-aqueous media; second, to elucidate the reaction mechanism,

and third, to point out several interesting problems incident to these results.

Investigations of the mechanism of the reaction in non-aqueous media should be based on exact and detailed experimental results with many kinds of reactants, catalysts and solvents over a wide range of reaction conditions; consequently, the present work should be considered as a mere attempt in this direction.

Experimental

Materials.—The reactants, solvents and catalysts used are purified by conventional methods and, their purity is checked by gas chromatography.[12] Methyl phenyl formal, an important intermediate, is prepared from monochloromethyl methyl ether and potassium phenolate in dioxane,[13] and checked by gas chromatography.[7] Diphenyl formal is prepared from diiodomethane and potassium phenolate in xylene,[14] and checked by gas chromatography.[15]

The Determination of the Concentration of Reactants by Gas Chromatography.—*Apparatus.*—A Kotaki Model GU-21 vapor fractiometer was used with a hot wire detector. The column used for methylal and methyl alcohol was 3 meters long, formed of 4.5 mm.ϕ copper tubing packed with 30% of polyethylene glycol 1500 on diabase A, and the gas chromatography was carried out at 100°C with a helium flow of 40 ml. per minute as measured at the column exit.[12] The column used for phenol and methyl phenyl formal was 1.5 m. long, formed of 4.5 mm.ϕ copper tubing packed with 20% of dilauryl phthalate on diabase A, and the gas chromatography was carried out at 155°C with a helium flow of 40 ml. per minute as measured at the column exit.[7] The correction for the differences in the amounts of samples injected was made by using carbon tetrachloride, toluene and *p*-chlorotoluene as internal markers for methylal, methyl alcohol and phenol (methyl phenyl formal) respectively.

Procedure.—The reactants, the catalyst ($BF_3 \cdot OEt_2$) and the solvent (nitromethane) were mixed, and then the mixture was placed, without stirring, in a water bath regulated at a constant temperature (usually

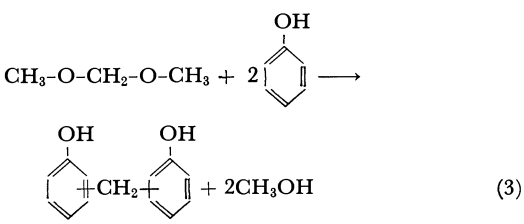
30±0.1°C). During the course of the reaction, two milliliters of the solution were withdrawn, and these samples were added to a dioxane solution (0.5 ml.) containing the internal markers (CCl_4, CH_3–C_6H_5, and p-CH_3–C_6H_4–Cl) and the reaction stopper (tribenzyl amine). Then they were subjected to gas chromatographic analysis in order to determine the amounts of methylal, methyl alcohol and sometimes phenol.

The Detection of the Intermediates by Paper Chromatography.—The following intermediates in the reaction system are examples of the intermediates detected by the two-dimensional paper chromatography developed by Seto and Ozaki:[16] mononuclear compounds (*o*-, or *p*-methoxymethyl phenol), dinuclear compounds (*o*-*o*' *o*-*p*' and *p*-*p*' dioxydiphenyl methane, and their derivatives containing methoxymethyl group), and trinuclear compounds. On the other band, intermediates such as methyl phenyl formal are detected by gas chromatography.[7,15]

Results and Discussion

Before a detailed discussion of the experimental results is undertaken, it is advantageous to consider the overall processes of the reaction in non-aqueous media, as determined by gas chromatography. The overall reaction between phenol and methylal may be represented as follows:



$$CH_3\text{-}O\text{-}CH_2\text{-}O\text{-}CH_3 + 2\,C_6H_5OH \longrightarrow HO\text{-}C_6H_4\text{-}CH_2\text{-}C_6H_4\text{-}OH + 2CH_3OH \quad (3)$$

This equation shows a stoichiometric relationship in which the rate of consumption of phenol is equal to the rate of the production of methyl alcohol, or twice the rate of the consumption of methylal. In the actual reactions these relationships were examined as is shown in Fig. 1. When the conversion is low (up to 30%), these quantitative relationships hold among the reactants and the products. This equation does not, however, show the details of the kinetics; they will be discussed later.

The characteristic features of the reaction are as follows: 1) The reaction rate is very fast at earlier stages, becomes considerably slower later, but does not reach an equilibrium even after 24 hr. or more (cf. Figs. 2 and 5).

2) As the initial concentration of phenol is increased, the rate of conversion is decreased. Accordingly, it seems clear that the overall reaction order is a minus value (cf. Figs. 10 and 15).

3) Because of the facts described in 1) and 2), the reaction order may not be determined by the use of only conventional methods, such as the half-lives, the initial rates or the integration.

4) The reaction products, such as methyl alcohol or methyl phenyl formal, have significant effects on the reaction order.

5) The above experimental results suggest that the reaction rate is very much contributed to by rapid reactions, such as acetal exchange, which are more probable in non-aqueous media than in aqueous media.

On the basis of these considerations, the experimental determination of kinetic equation of the reaction can be carried out. To start with, the following expression will represent the kinetic equation:

$$\frac{dx}{dt} = \frac{d[\text{methyl alcohol}]}{dt} = -\frac{d[\text{phenol}]}{dt} = k[\text{phenol}]^{\alpha}[\text{methylal}]^{\beta}\cdot[\text{methyl alcohol}]^{\gamma}[\text{catalyst}]^{\delta} \quad (4)$$

The Effect of Methylal.—As is shown in Fig. 2, the reaction rates do not depend upon the initial concentration of methylal over the range of 0.5—3.0 mol./l., when the initial concentrations of phenol and the catalyst are kept constant. Accordingly, the order with respect to methylal, β, can be estimated to be about zero; this implies the presence of a very fast opposing reaction involving methylal. Because of this experimental fact, the further kinetic examination was considerably simplified.

The Effect of Phenol.—In this experiment, a small amount of methyl alcohol is added into each reaction system in order to retard the initial reaction

rate. The effect of the initial concentrations of phenol is shown in Fig. 3, at constant initial concentrations of methyl alcohol, methylal and catalyst. As is shown in Fig. 3, the higher the initial concentration of phenol, the lower the rate of conversion becomes. The reaction rates at various phenol concentrations were compared after negating the influence of methyl alcohol. When $\beta=0$, and the concentrations of methyl alcohol and the catalyst are kept constant, Eq. 4 will be simplified to:

$$\Delta x/\Delta t = K_1[\text{phenol}]^{\alpha} \quad (4')$$

$$\log \Delta t = (\log \Delta x - \log K_1) - \alpha \log[\text{phenol}] \quad (5)$$

The values of Δx are kept constant as 0.0125 mol./l. and the values of Δt are calculated from the curves of Fig. 3. Then, $\log \Delta t$ is plotted against log-[phenol] to be as is shown in Fig. 4.

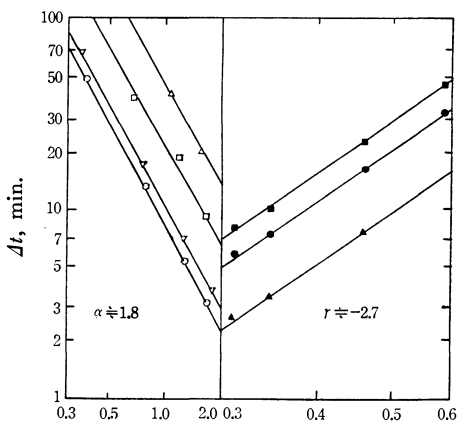

Fig. 4 Fig. 5

Fig. 4. Reaction order of phenol.
$\Delta x/\Delta t=k_1[\text{phenol}]^{\alpha}$

▽ : 0.231 mol./l. ○ : 0.206 mol./l.
Phenol
■ : 1.0 mol./l. ● : 1.2 mol./l.
▲ : 1.8 mol./.l

If Eq. 5 is applicable to this system, the relationship between $\log \Delta t$ and log[phenol] should be linear, and the slope of the straight line must correspond to the reaction order of phenol. From the slopes of straight lines in Fig. 4, the order of phenol, α, is estimated to be about two for the period of low conversion (up to about 30%).

The Effect of Methyl Alcohol.—The effect of methyl alcohol can be deduced by negating the influence of the phenol remaining according to a method similar to the one used in the earlier section. The time intervals, Δt, which elapsed for the production of methyl alcohol, Δx, at the same concentrations of phenol are calculated from the results of Fig. 4. As is shown in Fig. 5, parallel straight lines are obtained. From the slopes of these lines, the order of methyl alcohol is estimated by the relation of Eq. 5' to be about minus three;

$$\log \Delta t \fallingdotseq (\log \Delta x - \log K_2) - \gamma[\text{methyl alcohol}] \quad (5')$$

Thus, the reaction order with respect to methyl alcohol, γ, can be determined experimentally by considering the effect of methyl alcohol on the reaction rates.

Thus, the kinetic equation obtained over the range of low conversion is as follows:

$$\frac{\mathrm{d}[\text{methyl alcohol}]}{\mathrm{d}t} = k\frac{[\text{methylal}]^0[\text{phenol}]^2}{[\text{methyl alcohol}]^3} \quad (6)$$

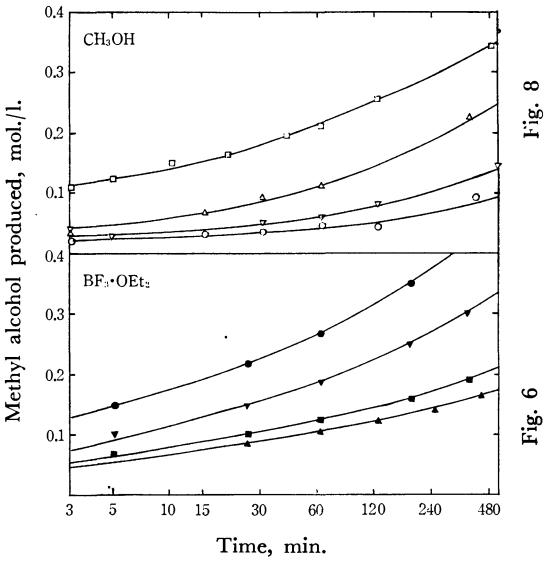

Fig. 8

■ : 0.001 mol./l. ▲ : 0.005 mol./l.

The Effect of the Methyl Alcohol Added.—In order to confirm the appropriateness of the kinetic equation obtained in the earlier section, the following supplementary experiments were undertaken. Figure 6 shows the relationship between the reaction rates and the initial concentrations of methyl alcohol over the range of 0.15—0.5 mol./l., when the initial concentrations of phenol, methylal and catalyst are kept constant.

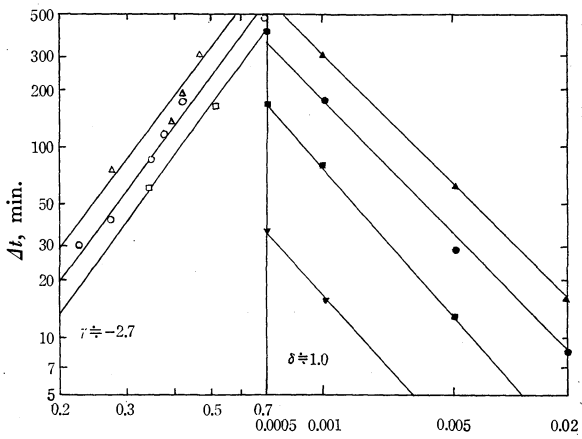

Fig. 7 Fig. 9

Fig. 7. Reaction order of methyl alcohol.
$\Delta x/\Delta t = k_3[\text{methyl alcohol}]^{\gamma}$
Methyl alcohol
△ : 0.175 mol./l. □ : 0.05 mol./l.
○ : 0.125 mol./l.

Fig. 9. Reaction order of catalyst
$\Delta x/\Delta t = k_4[\text{catalyst}]^{\delta}$
Methyl alcohol
▲ : 0.250 mol./l. ■ : 0.150 mol./l.
● : 0.200 mol./l. ▼ : 0.100 mol./l.

As was expected, the order of methyl alcohol is about minus three (Fig. 7). This confirms the reaction order of methyl alcohol determined in the earlier section.

The Effect of the Catalyst.—The effect of the concentration of the catalyst on the reaction rate is shown in Fig. 8. In a similar way, the concentration of the catalyst is plotted against the time intervals in Fig. 9. From the slopes of the straight lines in Fig. 9, the order of the catalyst is estimated to be about one. The catalyst used is $BF_3 \cdot OEt_2$, which easily reacts with one or two moles of water or alcohol to produce complex compounds. If a large amount of methyl alcohol is present in the reaction system, the activity of the catalyst is considerably decreased as a result of the formation of a relatively inactive complex compound, such as $BF_3 \cdot [CH_2OH]_2$.[17] The interaction between the catalyst and methyl alcohol may be one of the reasons why the reaction order of methyl alcohol has a minus value in this reaction system:

$$[BF_3 \cdot \text{solvent}] + 2CH_3OH \rightleftarrows [BF_3 \cdot CH_3OH] + CH_3OH + \text{solvent} \rightleftarrows [BF_3 \cdot 2CH_3OH] + \text{solvent} \quad (7)$$

The Integral Form of Kinetic Equation.—In general, kinetic studies should be conducted in two or more ways, for example, differential or integration methods. After a number of attempts, the following integral form of the kinetic equation, with certain initial conditions, has been found to be most satisfactory for the reaction between phenol and methylal in nitromethane. The differential form;

$$\frac{dx}{dt} = \frac{k(a-x)^2}{(b+x)^3}$$

The integral form:

$$kt = \frac{(a+b)^2}{2}[(1-p)^2 - 6(1-p) + 6\ln(1-p) + 6\ln(a+b) + 2/(1-p)] - C_0 \quad (9)$$

where

x : the concentration of CH_3OH produced
b : the initial concentration of CH_3OH
a : the initial concentration of HO-ϕ
p : a variable depending upon the conversion

that is:

$$p = (b+x)/(a+b) \quad (10)$$

C_0: integral constant
x/a: the conversion of phenol
$(b+x)$: the concentration of CH_3OH present
$(a-x)$: the concentration of HO- remaining

The initial conditions:

at $t = 0$,

$$x = 0.035a,\ p = (b + 0.035a)/(a + b) \quad (11)$$

Therefore,

$$C_0 = \frac{(a+b)^2}{2}\left[\left(\frac{0.965a}{a+b}\right)^2 - 6\left(\frac{0.965a}{a+b}\right) + 6\ln(0.965a) + 2\frac{(a+b)}{0.965a}\right] \quad (12)$$

In Figs. 10 and 11, the solid lines are the calculated values, while the points plotted are the measured values. There is a good agreement between them within the range of low conversion up to 30%. If x is assumed to be zero at $t=0$ as the initial condition of Eq. 9, the calculated values differ significantly from the measured values, especially in Fig. 11, which corresponds to a system containing a relatively high concentration of methyl alcohol. Careful examination shows that the kinetic equation obtained above is good enough to explain any experimental results over a wide range of conditions.

The Reaction Rate over the Range of High Conversion.—When no methyl alcohol is added to the system, the overall reaction rate is remarkably fast at an early stage of the reaction, and the conversion often reaches 30% or more within a few minutes, especially in the case of a low initial concentration of phenol, as is shown in Fig. 12. Over the range of high conversion, the estimated

values of the reaction orders of phenol and methyl alcohol are about 1 and −2.5 respectively; these values differ significantly from the values in a low conversion, as Figs. 13—15 show.

The differential form:

$$\frac{dx}{dt} = \frac{k(a-x)^1}{(b+x)^{2.5}}$$

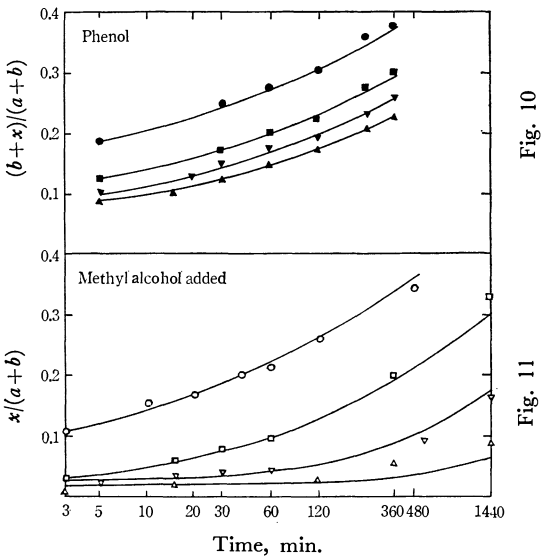

Fig. 10

Fig. 11

Fig. 10, 11 Comparison of calculated values and experimental values.

$kt=((a+b)^2/2)\{(1-p)^2-6(5p)+6\ln(1-p)+2/(1-p)+6\ln(a+b)\}+C_0$

at $t=0$, $x=0.035a$, $p=(b+x/a+b)$

where

x: the concentration of CH_3OH produced

a: the initial concentration of phenol

b: the initial concentration of CH_3OH added

p: a variable depending upon the conversion, that is,

$$p = (b+x-0.035a)/(a+b) \quad (15)$$

The initial conditions:

$$x = 0$$

$$x = 0.035a,\ p = \frac{b}{a+b}$$

C_0: integral constant

As is shown in Fig. 15, although there is a fair agreement between the experimental and the calculated values over the range of high conversion, still the stoichiometric relation in Eq. 3 does not hold in this system. Consequently, it seems probable that the reaction mechanism changes gradually, depending upon the degree of conversion, particularly in the range of conversion beyond 30%.

The Temperature Dependence of the Reaction Rate.—A comparison of reaction rates at various temperature (30, 25, 20, 10°C) is shown in Fig. 16. The time intervals, Δt, which elapse for the production of a certain amount of methanol at each temperature are measured from Fig. 16. The relation between a logarithm of the time interval and a reciprocal temperature is a straight line, as Fig. 17 shows. From the slope of Fig. 17, the apparent activation energy in this non-aqueous medium can be said to be about 18.6 kcal./mol., which is comparable to that in aqueous media.[1] Nevertheless, the overall rate of the reaction in non-aqueous media is faster than that in aqueous media. The kinetic system is too complicated for the entropy of activation to be discussed. However, the difference in overall reaction rate between non-aqueous and aqueous media may be ascribed to the entropy of activation rather than to the energy of activation.

The Estimation of the Reaction Scheme.—

The reaction in non-aqueous media is very complex; it involves substitution on aromatics, acetal exchange by methyl alcohol or phenol, and interaction between methyl alcohol and $BF_3 \cdot OEt_2$, etc.. A probable reaction scheme is shown in Fig. 18.

Phenol and methyl phenyl formal can be identified by gas chromatography, while *p*-methoxymethylphenol and dioxydiphenylmethane (*pp'* and *op'*) can be identified by paper chromatography; however, the other intermediate can not be detected so definitely. Therefore, it seems probable that the process passing through methyl phenyl formal is important in non-aqueous media. A detailed discussion of the reaction mechanism will be given in the following reports.

The author is indebted to Professor Hiromu Murata of the Faculty of Science of Hiroshima University for his helpful discussions and encouragement throughout this work. He also wishes to express his gratitude to Dr. Keiji Oshima, Managing Director of Sumitomo Bakelite Co., Ltd. and Director of the Central Research Laboratory of the same company for permission to publish this paper, and to Dr. Ryuzo Nakatsuka and Mr. Mitsuo Niwa of this Laboratory for valuable assistance.

The Reaction between Phenol and Formaldehyde in Non-Aqueous Media. II. The Behavior of Methyl Phenyl Formal in the Reaction Catalyzed by Boron Trifluoride - Etherate

By Shin'ichi MURAYAMA

Central Research Laboratory, Sumitomo Bakelite Co., Ltd., Totsuka-ku, Yokohama

(Received October 16, 1965)

Methyl phenyl formal (MPF) is one of the most important intermediates in the acid-catalyzed reaction between phenol and methylal in non-aqueous media. On the acidic decomposition of MPF itself, phenol and methylal are mainly produced, along with a small amount of methyl alcohol at the first step; at the same time, there exists an equilibrium state between the reactants and the products. At the second step, the phenol produced is gradually consumed, and the reaction eventually yields methyl alcohol and such condensation products of phenol as methoxymethylphenol and dioxydiphenylmethane. Thus, the acetal exchange proceeds faster than the substitution on aromatics. On the other hand, the acidic decomposition of MPF is retarded remarkably by methyl alcohol, considerably by methylal, and fairly much by phenol. This behavior of MPF can be explained by its interaction with the catalyst and the opposing reactions with it. As a result, the reaction of MPF can better be understood.

The previous paper reported on the kinetics of the phenol-formaldehyde reaction in non-aqueous media, but it was confined to the experimental characterization of the complex system.[1] This paper will deal with several intermediates of the reaction, such as methyl phenyl formal, methoxymethylphenols and dioxydiphenylmethanes, which were detected in the reaction system. It seems probable that methyl phenyl formal is one of the most important intermediates in the reaction of non-aqueous media; an understanding of its behavior is the key to an elucidation of the reaction mechanism.

Therefore, the objects of this investigation are: (1) to examine the reaction of methyl phenyl formal with and without other reactants, and then (2) to establish a reaction scheme for these reactions.

There have been only a few reports on the reaction of alkyl aryl formal, especially in non-aqueous media. In the presence of a trace of an acid, alkyl aryl formal may change at once partly to symmetric formals, and probably also to nuclear-substituted compounds.[2] Though a small amount of methyl phenyl formal has been obtained in the acid-catalyzed phenol-formaldehyde reaction in aqueous media by Horiuchi,[3] the role of the formal as an active intermediate has been not thorouglhy studied in aqueous media, because

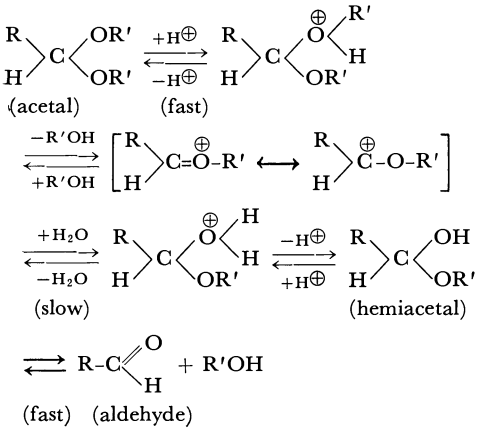
3) H. Horiuchi, *J. Chem. Soc. Japan, Ind. Chem. Sect.* (*Kogyo Kagaku Zasshi*), **66**, 150 (1963).

the formal is easily hydrolyzed in acidic aqueous media. The extensive studies of the kinetics and the mechanisms of the reactions of acetals have been performed with regard only to the hydrolysis[4] or the alcoholysis.[5]



According to this mechanism, the rate of the acid-catalyzed hydrolysis of an acetal depends mainly on either the stability of the carbonium ion produced or on the electron density on the oxygen atom, while the rate of the hydrolysis of a hemiacetal is very rapid, even in the absence of an acid catalyst.[4]

On the other hand, the acetal-exchange reaction with an alcohol or an aldehyde also proceeds in the presence of an acid catalyst, such as HCl, H_2SO_4, $FeCl_3$ or BF_3.[5,6]

$$RCH(OR')_2 + R''(OH) \rightleftarrows RCH(OR')(OR'') + R'(OH)$$

$$RCH(OR')(OR'') + R''(OH) \rightleftarrows RCH(OR'')_2 + R'(OH)$$

$$RCH(OR')_2 + R'''CHO \rightleftarrows R'''CH(OR')_2 + RCHO$$

The rates and the equilibrium constants of the hydrolyses of acetals have been studied systematically. Dimethyl formal is one of the most stable acetals, while alkyl aryl formals are unstable; diaryl formals are stable.[6]

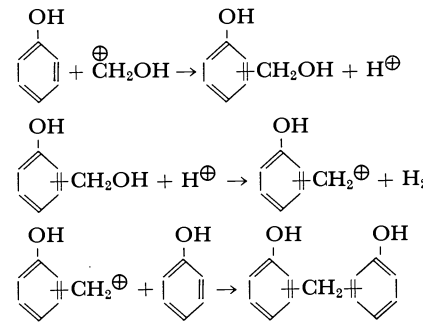
The catalytic action of boron trifluoride-etherate is very complex, but it may be regarded as the action of hydrogen ions produced by the reaction between the catalyst and a trace of water present in the reaction system. It is known that boron trifluoride - etherate easily forms complex compounds with alcohols, ether, nitromethane or phenol.[7]

$$[BF_3 \cdot OEt_2] + H_2O \rightleftarrows [BF_3 \cdot H_2O] + OEt_2 \overset{+H_2O}{\rightleftarrows}$$

$$[BE_3 \cdot 2H_2O] \rightleftarrows [BF_3 \cdot OH]^{\ominus} + H_3O^{\oplus}$$

$$[BF_3 \cdot H_2O] \rightleftarrows [BF_3 \cdot OH]^{\ominus} + H^{\oplus}$$

As for the acid-catalyzed phenol-formaldehyde reaction in aqueous media, the reaction mechanism has been established by Imoto et al.[8] to be:

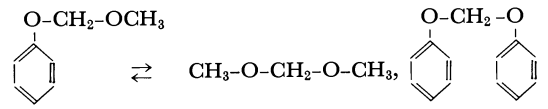


etc.

The ratio of the amounts of *o*- and *p*-derivatives produced mainly depends upon the reaction temperature and upon the catalyst (or pH) in an aqueous media.[9]

Therefore, it seems that the main reactions of methyl phenyl formal in the presence of boron trifluoride - etherate include the following two types of reactions:

(A) Acetal exchange



(B) Substitution on aromatics

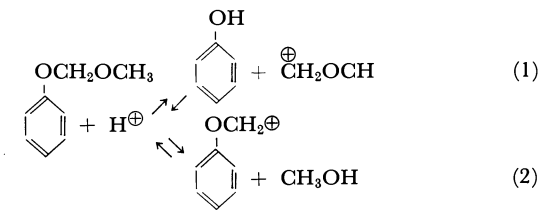
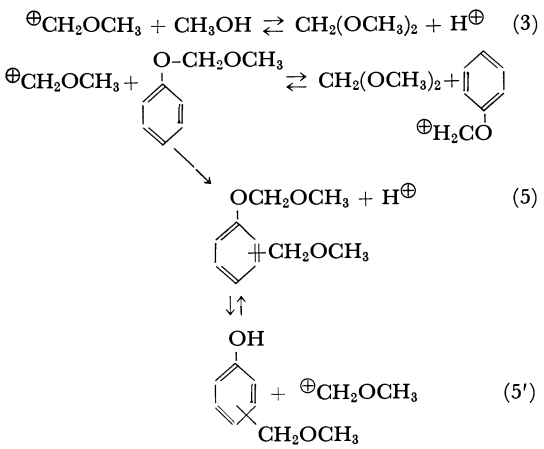
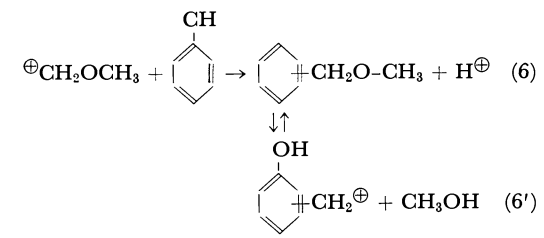
By analogy with the reaction in aqueous media, the following reaction scheme may be postulated. (1) The Activation of MPF by $H^{\oplus}$ (MPF= methyl phenyl formal):

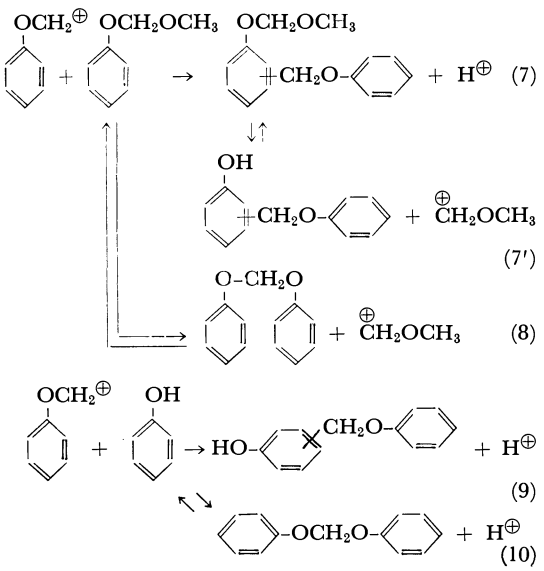


(2) The Reactions of the methoxymethyl cation:

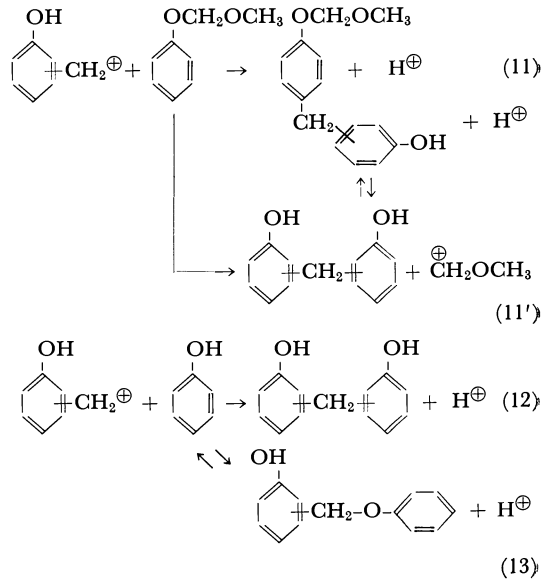




(3) The Reactions of the phenoxymethyl cation:



(4) The Reactions of the oxybenzyl cation:



The scheme postulated above will now be examined through experiments on the reactions of the intermediates. It is expected that the effects of the other reactants, catalysts and solvents can be understood better through these experiments.

Experimental

Materials.—The reagents, the solvent and the catalyst used were purified by the conventional methods and were checked by gas chromatography.[1)]

Analytical Method.—The amounts of methyl phenyl formal, phenol, methyl alcohol and methylal were measured quantitatively by gas chromatography.[1)]

Procedure.—Conventional techniques were used throughout this study. In every experiment, nitromethane was used as the solvent and boron trifluoride - etherate was used as the catalyst.

Results and Discussion

The Decomposition of Methyl Phenyl Formal (MPF).—In order to investigate the decomposition of MPF (1 mol./l.) in the presence of the boron trifluoride - etherate catalyst (0.001—0.00025 mol./l.), the amounts of MPF, phenol, methylal and methyl alcohol were determined during the course of the reaction, as is shown in Fig. 1.

At the first step of the acidic decomposition of MPF, the amount of phenol produced is almost equal to that of the methylal produced, while only a small amount of methyl alcohol is produced.

It follows from this fact that the two reactions activating MPF by proton (Eqs. 1 and 2) are very fast and of almost equal rates. This means that the methoxy-methyl cation, methyl alcohol, phenol and the phenoxymethyl cation are produced

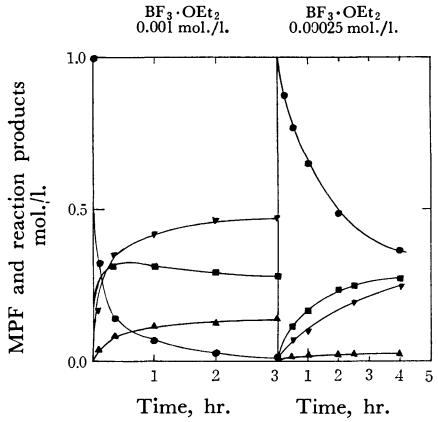


Fig. 1. The effect of the catalyst on the reaction of M.P.F.

M.P.F. 1 mol./l. in nitromethane at 30°C
●: MPF; ■: Phenol; ▼: Methylal;
▲: Methyl alcohol

in amounts almost equivalent to one another. Then, the methoxymethyl cation reacts with methyl alcohol at once to produce methylal, while the phenoxymethyl cation reacts with MPF to form various condensation products by Eqs. 7, 7', 8, etc.

After the reaction has proceeded to some extent, the amount of phenol in the system becomes so great that the reactions of phenol, such as Eqs. 6 and 6', take place significantly. Then the amounts of methyl alcohol and methylal remarkably increase, while the amount of phenol decreases gradually after passing through a maximum; at the same time, the amount of MPF decreases rapidly toward zero.

The reactions of the earlier stage (such as Eqs. 1, 2 and 3) proceed rapidly in the presence of a very low concentration of the catalyst, but the rates of the reactions of the later stage (such as 6 and 6') depend markedly upon the concentration of the catalyst, as is shown in Fig. 1.

It seems probable that the unstable assymmetric acetal (MPF) is changed to the stable symmetric acetal (methylal) by the acetal exchange in the presence of a trace of an acidic catalyst, until an equilibrium is established between them.

Diphenyl formal was not detected in the reaction mixture under these conditions, contrary to our expectation; this fact may have something to do with the stability or the rate of formation of the diaryl formal.

The substitution reactions on aromatics may easily accompany the acetal exchange reactions at relatively high concentrations of the catalyst, and the amounts of methyl alcohol produced may indicate the amounts of the di- or polynuclear compounds produced.

The Reaction of MPF with Phenol.—The reaction between MPF (1 mol./l.) and phenol (1 mol./l.) in the presence of $BF_3 \cdot OEt_2$ (0.00025 mol./l.) was also investigated. Figure 2 shows the amounts of the reactants and the products produced during the course of the reaction.

The reaction of MPF with phenol is very similar to the decomposition of MPF alone, but it has the following distinctive characteristics : 1) The amount of phenol produced is certainly smaller than that of methylal.

2) The overall reaction rate is slightly decreased by the addition of phenol to the reaction system.

The condensation reactions of phenol, such as Eqs. 6, 9, 10, 12, and 13, will proceed markedly to consume phenol in the presence of a considerable amount of phenol, and thus, the overall reaction rate might be increased by these reactions. On the other hand, phenol may form relatively stable complexes with catalysts such as $[BF_3 \cdot$ $-OH]$

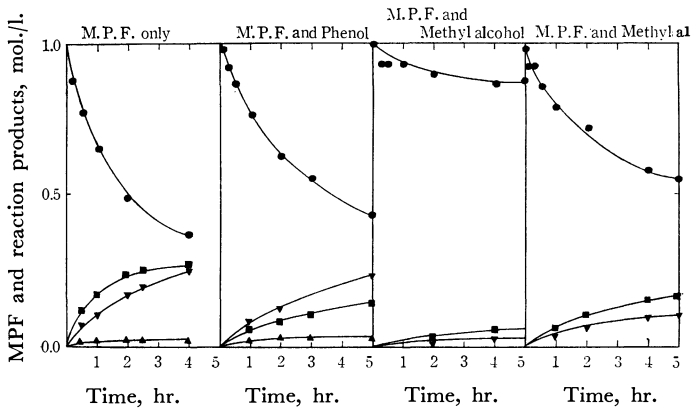

Fig. 2. The effect of reactants on the reaction of MPF
MPF 1 mol./l., $BF_3 \cdot OEt_2$ 0.00025 mol./l. in nitro methane at 30°C other reactant 1 mol./l. (if present)
●: MPF., ■: Phenol; ▼: Methylal; ▲: Methylalcohol

or $[BF_3 \cdot 2C_6H_5OH]$; the formation of these complexes should result in the decrease of the overall reaction rate. These two effects of phenol on the reaction rate compensate each other, and the net effect of the addition of phenol was a slight decrease in the overall reaction rate, while a relatively large amount of the nuclear-substituted compounds are produced.

The Reaction of MPF with Methylal.—The reaction between MPF (1 mol./l.) and methylal (1 mol./l.) in the presence of $BF_3 \cdot OEt_2$ (0.00025 mol./l.) was investigated by measuring the amounts of the reactants and products during the course of the reaction; the results are shown in Fig. 2. In this case, the overall reaction rate is considerably lower than that of MPF by itself, and methyl alcohol is not produced at all, while phenol and methylal are produced as in the case of MPF alone. These results indicate that, in the presence of a considerable amount of methylal, the reaction of methylal with the phenoxymethyl cation (the back reaction of Eq. 4) is very fast and produces the methoxymethyl cation, which then consumes methyl alcohol (by Eq. 3) and probably phenol (by the back reaction of Eq. 1). Thus, the presence of methylal inhibits the overall rate of the reaction by promoting various opposing reactions, though the interaction of methylal with the catalyst may be negligibly small.

The Reaction of MPF with Methyl Alcohol.—In the presence of methyl alcohol (1 mol./l.), the reaction of MPF (1 mol./l.) with $BF_3 \cdot OEt_2$ (0.00025 mol./l.) as a catalyst is significantly inhibited, and both MPF and methyl alcohol are consumed very gradually; this fact shows that methyl alcohol may promote the opposing reaction. The catalyst readily changes to a stable complex by reacting with methyl alcohol. Since the two types of effects in the presence of methyl alcohol are additional, methyl alcohol decreases the overall reaction rate remarkably.

Summary

The acidic decomposition of MPF in nitromethane has been studied, and the reaction mechanism has been investigated. 1) There must exist an equilibrium between MPF, methylal, phenol and methyl alcohol through acetal exchange reactions, but the actual equilibrium state is changed successively by substitution reactions on aromatics.

2) The acetal exchange reactions proceed very fast, even in the presence of a very low concentration of the catalyst, while the substitution reactions on aromatics proceed more slowly under the same conditions.

3) The formation of complex compounds between the catalyst and such reactants as phenol, methylal and methyl alcohol results in various decreases in the overall reaction rate according to the stabilities of the various complexes.

4) The acidic decomposition of MPF may be significantly inhibited by methylal and methyl alcohol as a result of the opposing reactions, but not inhibited by phenol, if the effects of complex formations on reaction rates are eliminated. The reaction using sulfuric acid as the catalyst may prove this fact more clearly.[10]

5) The behavior of MPF can be explained by supposing that the reaction proceeds through some reactive intermediates, such as the methoxymethyl cation, the phenoxymethyl cation and the oxybenzyl cation.

6) Diphenyl formal is not formed during the disproportionation reactions of MPF, contrary to our expectation. This experimental evidence suggests a difference in reactivity between the methoxymethyl cation and the phenoxymethyl cation.

7) From the results of this experiments, the mechanism of the reaction between phenol and methylal in non-aqueous media can be better understood.

The author is indebted to Professor Hiromu Murata of the Faculty of Science of Hiroshima University for his helpful discussions and encouragement throughout the work. He also wishs to express his gratitude to Dr. Keiji Oshima, Managing Director of the Sumitomo Bakelite Co., Ltd., and Director of the Central Research Laboratory of the same company for permission to publish this paper, and to Dr. Ryuzo Nakatsuka and Mr. Mitsuo Niwa of this Laboratory for their valuable assistance.

The Reaction between Phenol and Formaldehyde in Non-Aqueous Media. III. The Mechanism of the Reaction Catalyzed by Boron Trifluoride-Etherate

By Shin'ichi MURAYAMA

Central Research Laboratory, Sumitomo Bakelite Co., Ltd., Totsuka-ku, Yokohama

(Received October 16, 1965)

In the previous papers of this series, the reaction between phenol and methylal in non-aqueous media has been investigated by means of the experimental characterization of the kinetic system; a plausible reaction scheme has thus been presented. The object of the present paper is to make a mathematical characterization of the kinetic system, a kinetic equation has been obtained by calculation based on the probable reaction scheme; it has been found to be in good agreement with the kinetic equation obtained experimentally.

There are only few reactions which lend themselves to a simple kinetic description in terms of the reaction order in the field of the resin-forming condensation reactions. Since there are many processes by which the reaction proceeds, the author has expected to find a concomitant difficulty in expressing the rates of phenol-formaldehyde reactions in simple terms. Since the phenol-formaldehyde reactions involve the opposing, concurrent and consecutive reactions, their kinetic studies have been established only in aqueous media.[1] Unfortunately, the mechanism of the reactions in aqueous media is not suitable for explaining the behavior of the reactions in non-aqueous media. The series of works conducted at this laboratory have aimed at clarifying the differences between the reactions in non-aqueous media and those in aqueous media.

The previous papers of this series have dealt with the kinetics of the reaction between phenol and formaldehyde in nitromethane catalyzed by boron trifluorideetherate. The course of the reaction was followed by the quantitative gas chromatographic analysis of the reactants and products.

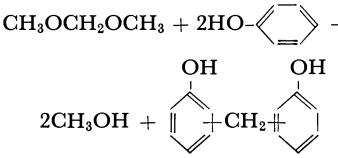
After the experimental characterization of this reaction system, the following kinetic equation was obtained:[2]

$$\frac{\mathrm{d[methyl\ alcohol]}}{\mathrm{d}t} = \frac{k[\mathrm{catalyst}][\mathrm{phenol}]^2[\mathrm{methylal}]^0}{[\mathrm{methyl\ alcohol}]^3}$$

Methyl phenyl formal was detected as one of the reactive intermediates in this reaction system; the behavior of methyl phenyl formal was therefore studied as a means of estimating the reaction scheme.[3] The objects of the present paper are: (1) to perform a mathematical characterization of the kinetic system, and (2) to gain detailed information about the mechanism of the phenol-formaldehyde reaction in non-aqueous media.

Results and Discussion

Reaction Scheme.—The reaction between phenol and methylal in nitromethane catalyzed by boron trifluoride-etherate may be represented in the following simplified form:



(1)

The stoichiometric relations of Eq. 1 are in accordance with the experimental findings[2] that the rate of phenol consumed is almost equal to the rate of methyl alcohol produced, and that the ratio of the rates of the consumption of methylal and phenol is 1 : 2, when the conversion is low (up to 30%).

On the other hand, the acidic decomposition of methyl phenyl formal can be explained by using an ionic mechanism, which involves the formation of such active intermediates as the methoxymethyl cation, the phenoxymethyl cation and the oxybenzyl cation.

From the experimental evidence, it seems that the reaction between phenol and methylal in non-aqueous media should be regarded as a complex kinetic system consisting of two series of consecutive reactions passing through methoxymethylphenols or methyl phenyl formal, and that each of the two series involves such concurrent

1) M. Imoto et al., *Kobunshi Tenbo*, **4**, 60 (1951); ibid., **8**, 29, 33 (1952).

2) Part I of this Series: S. Murayama, This Bulletin, **39**, 1019 (1966).

3) Part II of This Series: S. Murayama, ibid., **39**, 1027 (1966).

reactions as the acetal exchange and the substitution on aromatics. Nevertheless, from the analogy of acidic reactions in aqueous media, the formation of di- or tri-methoxymethylphenols may also be neglected in non-aqueous media so as to simplify the mathematical calculation. The differences in the reactivities of the ortho- and para-positions of phenol is not taken into consideration.

The following reaction scheme may, then, be presented for the phenol-formaldehyde reaction in non-aqueous media:

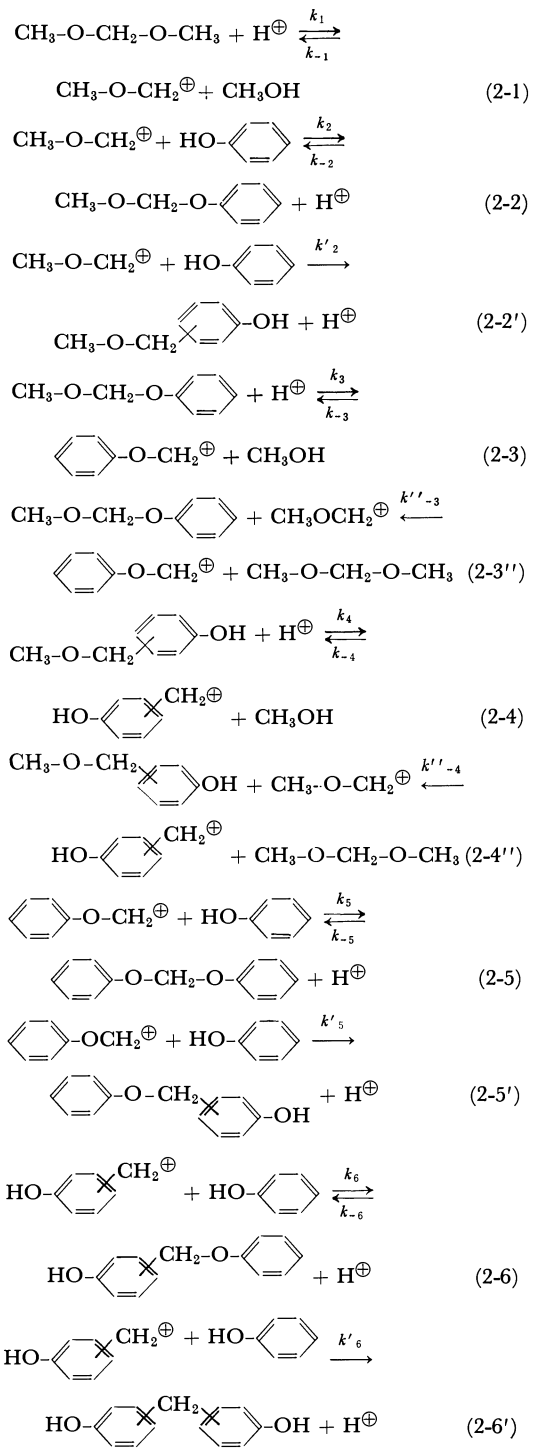


Fig. 1. Reaction scheme.

The Mathematical Calculation of the Reaction Rate.—On the basis of the reaction scheme shown in Fig. 1, the rate of the methyl alcohol produced is calculated by using the stoichiometric relations and the stationary-state hypothesis.

First, the terms and the rate of production (or consumption) of reactants and intermediates are represented as follows:

m: methylal
p: phenol
a: methyl alcohol
c^*: the effective concentration of catalyst
α: the methoxymethyl cation
β: methylphenyl formal
γ: methoxymethylphenol
δ: the phenoxymethyl cation
ε: the oxybenzyl cation
ρ: phenoxymethylphenol
φ: diphenyl formal

$$\frac{d\alpha}{dt} = -(k_{-1}a+k_2p+k'_2p)\alpha + k_{-2}c^*\beta + k''_{-3}m\delta + k''_{-4}m\varepsilon + k_1mc^* \quad (3\text{-}1)$$

$$\frac{d\beta}{dt} = k_2p\alpha + (k_{-3}a + k''_{-3}m)\delta - (k_3c^* + k_{-2}c^*)\beta \quad (3\text{-}2)$$

$$\frac{d\gamma}{dt} = k'_2p\alpha + (k_{-4}a + k''_{-4}m)\delta - k_4c^*\gamma \quad (3\text{-}3)$$

$$\frac{d\delta}{dt} = k_3c^*\beta + k_{-5}c^*\varphi - (k_{-3}a + k''_{-3}m + k_5p + k'_5p)\delta \quad (3\text{-}4)$$

$$\frac{d\varepsilon}{dt} = k_4c^*\gamma + k_{-6}c^*\rho - (k_{-4}a + k''_{-4}m + k_6p + k'_6p)\varepsilon \quad (3\text{-}5)$$

$$\frac{d\varphi}{dt} = k_5p\delta - k_{-5}c^*\varphi \quad (3\text{-}6)$$

$$\frac{d\rho}{dt} = k'_5p\delta + k_6p\varepsilon - k_{-6}c^*\rho \quad (3\text{-}7)$$

$$-\frac{dp}{dt} = (k_2 + k'_2)p\alpha - k_{-2}c^*\beta + (k_5 + k'_5)p\delta + (k_6 + k'_6)p\varepsilon - k_{-5}c^*\varphi - k_{-6}c^*\rho \quad (3\text{-}8)$$

$$\frac{da}{dt} = k_1c^*m - k_{-1}a\alpha + k_3c^*\beta - k_{-3}a\delta + k_4c^*\gamma - k_{-4}a\varepsilon \quad (3\text{-}9)$$

$$\frac{dm}{dt} = -k_1a\alpha + k''_{-3}m\delta + k''_{-4}m\varepsilon + k_1mc^* \quad (3\text{-}10)$$

Second, we have two conditions:

Conditions (A):

(i) Stoichiometric relations:

$$-\frac{dp}{dt} = \frac{da}{dt} = -2\frac{dm}{dt} \tag{4}$$

(ii) Stationary-state hypothesis:

$$\frac{d\alpha}{dt}=\frac{d\beta}{dt}=\frac{d\gamma}{dt}=\frac{d\delta}{dt}=\frac{d\varepsilon}{dt}=\frac{d\varphi}{dt}=\frac{d\rho}{dt}=0 \tag{5}$$

From these conditions, we can obtain the solution of each variable as follows:

$$\alpha = k_1k'_6Fmc^*/\Delta_0 \tag{6-1}$$

$$\beta = k_1k_2k'_6m[k''_{-3}m + k_{-3}a + k'_5p]/\Delta_0 \tag{6-2}$$

$$\gamma = k_1[k_2k_3k'_5D + k'_2(D+k'_6)F]mp/k_4\Delta_0 \tag{6-3}$$

$$\delta = k_1k_2k_3k'_6mc^*/\Delta_0 \tag{6-4}$$

$$\varepsilon = k_1(k_2k_3k'_5+k'_2F)mc^*/\Delta_0 \tag{6-5}$$

$$\rho = k_1k_2k_3k_5k'_6mp/k_{-5}\Delta_0 \tag{6-6}$$

$$\varphi = k_1\{k_2k_3k'_5(k_6+k'_6) + k'_2k_6F\}mp/k_{-6}\Delta_0 \tag{6-7}$$

where:

$$\Delta_0 = k_{-1}k'_6Fa + \{k_2k_3k''_{-3}k'_6-k''_{-4}(k_2k_3k'_5 + k'_2F)\}m+(k_2k_3k'_5+k'_2F)k'_6p \tag{6'-1}$$

$$F = k_3k'_5 + k_{-2}k'_5 + k_{-2}(k_{-3}a/p + k''_{-3}m/p) \tag{6'-2}$$

$$D = k_{-4}a/o + k''_{-4}m/p \tag{6'-3}$$

Lastly, the general equation for the rate of the production of methyl alcohol is obtained as follows:

$$\frac{da}{dt} = 2[k_2k_3k'_5 + k'_2F]k_1k'_6mpc^*[k_{-1}k'_6Fa + (k''_{-3}k_2k_3k'_6 - k_2k_3k''_{-4}k'_5 - k'_2k''_{-4}F)m + (k_2k_3k'_5 + k'_2F)k_6'p]^{-1} \tag{7}$$

When further plausible assumptions are added to Eq. 7, a simple form of the kinetic equation is deduced.

Assumptions (B):

$$k''_{-3} \gg k_{-3}$$

$$k''_{-3} \gg k'_5$$

$$k_{-2}k''_{-3} \gg k_3k'_5$$

$$k_2k_3k'_5 \gg k_2'k_{-2}k''_{-3} \quad (\text{or } k_2 \rangle\rangle\rangle k_2') \tag{8'}$$

$$k_{-1}k_{-2} \gg k_2k_3$$

$$k_{-1}k_{-2}k''_{-3}k'_6 \gg k_2k_3k''_{-4}k'_5 \quad (\text{or } k''_{-3}k'_6 \geq k''_{-4}k'_5)$$

$$\frac{da}{dt} = \frac{2k_1k_2k_3k'_5}{k_{-1}k_{-2}k''_{-3}}\frac{p^2c^*}{a} \tag{8}$$

On the other hand, we assume that the effective concentration of the catalyst, c^*, can be estimated from the consideration of the equilibrium of the reaction forming the complex with methyl alcohol:

$$[BF_3\cdot\text{solvent}] + 2CH_3OH \overset{K}{\rightleftarrows} [BF_3\cdot 2CH_3OH] + \text{solvent} \tag{9}$$

where the equilibrium constant, K, is very large,

$$[BF_3\cdot\text{solvent}] = \frac{[BF_3\cdot 2CH_3OH][\text{solvent}]}{K[CH_3OH]^2} \tag{10}$$

$$\therefore \quad c^* = \frac{k_0\cdot c}{a^2} \tag{11}$$

From Eqs. 8 and 11, the kinetic equation 12 is deduced.

The calculated equation:

$$\frac{da}{dt} = \frac{2k_0k_1k_2k_3k'_5}{k_{-1}k_{-2}k''_{-3}}\frac{m^0p^2c^1}{a^3} \tag{12}$$

The experimental equation:

$$\frac{d[\text{methyl alcohol}]}{dt} = \frac{k[\text{methylal}]^0[\text{phenol}]^2[\text{catalyst}]^1}{[\text{methyl alcohol}]^3} \tag{12'}$$

Thus, the kinetic equation obtained by calculations based on the reaction scheme of Fig. 1 is in good agreement with the kinetic equation obtained experimentally. This fact indicates that the reaction scheme of Fig. 1 represents the reactions actually taking place. Therefore, our attempt to elucidate the mechanism of the reaction may be regarded as satisfactory.

The Probable Reaction Paths.—The probable paths of the reaction between phenol and methylal in non-aqueous media are shown in Fig. 2. In Fig. 2, the assumptions used for the deduction of Eq. 8 from Eq. 7 are presented in relation to the behavior of intermediates.[3]

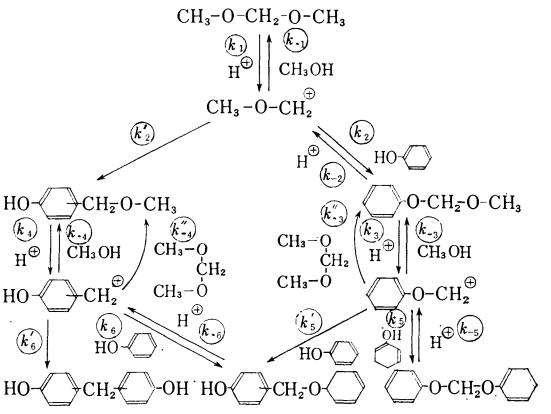

Fig. 2. Reaction scheme.

The assumption, that $k_2 \gg k'_2$ means that the reaction passes mainly through methyl phenyl formal instead of methoxymethylphenol, that is, that the methoxymethyl cation reacts more easily with the phenolic OH group than with the aromatic nuclei of phenol. The assumption that $k''_{-3} \gg k_{-3}$ or that $k_3'' \gg k'_5$ means that the phenoxymethyl cation reacts more easily with methylal than with methyl alcohol or phenol

The assumptions that $k_{-1}/k_2 \gg k_3/k_{-2}$, that $k''_{-3}/k'_5 \geq k''_{-4}/k'_6$ and that $k''_{-3}/k'_5 \gg k_3/k_{-2}$ are connected with the reactivities of the methoxymethyl cation, the phenoxymethyl cation, the oxybenzyl cation and methyl phenyl formal.

The assumptions used in the calculation are plausible and are not contradictory to the actual behavior of the reactants and the intermediates.[3)]

The probable reaction path from methylal to dioxydiphenylmethane in this system is estimated to be as follows:

The Activation of Methylal.—In the first step of the reaction, methylal is activated by the proton to produce methyl alcohol and the methoxymethyl cation in a reversible manner.

The proton is produced by the reaction of the BF_3· solvent with a trace of water in the reaction system; therefore, the affinities of BF_3 toward the solvent, the reactants, and the products have a remarkable effect on the activity of the catalyst. Particularly, the activity of the catalyst depends upon the concentration of methyl alcohol because of the formation of stable complexes from the catalyst and methyl alcohol.

The Reaction of the Methoxymethyl Cation with Phenol.—The methoxymethyl cation readily attacks the oxygen atom of phenol, instead of the benzene ring, to produce methyl phenyl formal in a reversible manner. Consequently, the main path passes through methyl phenyl formal, instead of methoxymethylphenols. The reaction of the methoxymethyl cation with phenol is considerably inhibited by the competing reactions with methyl alcohol.

The Activation of Methyl Phenyl Formal by Proton.—The acidic decomposition of methyl phenyl formal yields the methoxymethyl cation and the phenoxymethyl cation in a reversible manner.

The Reaction of the Phenoxymethyl Cation with Phenol.—Phenoxymethylphenols are produced slowly in the irreversible reaction of phenoxymethyl cations with the nuclei of phenol; this reaction may be the rate-determining step of this reaction system.

At the same time, the phenoxymethyl cation easily attacks the oxygen atom of methylal to reproduce the methoxymethyl cation and methyl phenyl formal; accordingly, methylal inhibits the reaction rate in this reaction step. Though it was expected that the phenoxymethyl cation would rapidly attack the oxygen atom of phenol, not even a trace of diphenyl formal was detected in the reaction system.

Phenoxymethylphenols change in the presence of proton to dioxydiphenylmethane, passing through the oxybenzyl cation in a similar manner; at the same time, methoxymethylphenols are formed as by-products.

The Reaction Rate at Higher Conversions.—As has been mentioned above, the reaction mechanism can be explained when the conversion is low (up to 30%). If the B asumptions and Eq. 8′ are changed slightly, then the calculated equation, Eq. 8, is modified as follows:

Modified assumptions C:

$$k''_{-3} \gg k_{-3}$$
$$k_3'' \gg k_6'$$
$$k_{-2}k''_{-3} \gg k_3k'_5$$
$$k_2k_3k'_5 \gg k'_2k_{-2}k''_{-3} \quad (\text{or } k_2 \rangle\rangle\rangle k'_2) \qquad (13')$$
$$k''_{-3}k'_6 \gg k''_{-4}k'_5$$
$$k_{-1}k_{-2} \geq k_2k_3$$

Modified calculated equation:

$$\frac{da}{dt} = \frac{2k_1k_2k_3k'_5 \cdot pc}{(k_{-1}k_{-2}k''_{-3} \cdot a/p + k_2k_3k''_{-3})a^2} \qquad (13)$$

Experimental equation at higher conversions[2)]:

$$\frac{d[\text{methyl alcohol}]}{dt} = \frac{k[\text{phenol}]^1[\text{methylal}]^0[\text{catalyst}]^1}{[\text{methyl alcohol}]^{2.5}} \qquad (14)$$

The calculated equation, Eq. 13, may be almost equal to the experimental equation, Eq. 14. Equations 13 and 14 are applicable only for the systems of a high conversion.

It seems probable that there are few differences between Eqs. 12 and 13 with respect to the mathematical characterization of the kinetic system, while the stoichiometric relations, Eq. 4, and the stationary state hypothesis, Eq. 5, may not be used so exactly in systems of a higher conversion.

Summary

By the mathematical calculation of the reaction system, a kinetic equation has been deduced, and it has been found to represent satisfactorily the experimental findings of the phenol-formaldehyde reaction in non-aqueous media.

The reaction mechanism has then been elucidated from both the experimental and the mathematical points of view.

The most important difference between the aqueous and non-aqueous media is the contribution of formals as reactive intermediates.

Moreover, several interesting information regarding the effects of the solvent or the catalyst on the reaction mechanism have been obtained.

The author is indebted to Professor Hiromu Murata of the Faculty of Science of Hiroshima University for his helpful discussions and encouragement throughout the work. He also wishes to express his gratitude to Dr. Keiji Oshima, Managing Director of the Sumitomo Bakelite Co., Ltd., and Director of the Central Research Laboratory of the same company, for permission to publish this paper, and to Dr. Ryuzo Nakatsuka and Mr. Mitsuo Niwa of this Laboratory for their valuable assistance.

The Conversion of Cellulose into Soluble Glucose Polymers in a Sulfur Dioxide Solution of Sulfur Trioxide

By Yoshio SAKAI

Faculty of Agriculture, Tokyo University of Education, Komaba, Meguro-ku, Tokyo

(Received October 18, 1965)

The conversion of cellulose into soluble glucose polymers was shown to be composed of a set of irreversible reactions in series: $A \xrightarrow{k_1} B \xrightarrow{k_2} C$, where A is cellulose; B, a soluble glucose polymer, and C, the decomposition product, which does not give reducing sugar under further hydrolysis by dilute acid. The first-order rate constants, k_1 (hr^{-1}) and k_2 (hr^{-1}), were given in 0.32 to 3.3% sulfur dioxide solutions of sulfur trioxide:

$$k_1 = 2.64 \times 10^{11} C^{1.63} \exp[-16700/(RT)] \quad \text{(for 0—50°C)},$$

and

$$k_2 = 8.99 \times 10^{15} C^{1.63} \exp[-24500/(RT)] \quad \text{(for 25—50°C)}.$$

From k_1 and k_2, the sulfur trioxide concentration, C, and temperature, T, the maximum yields of the soluble glucose polymer and the time required to attain a maximum yield were obtained. It was shown that the application of the technique to wood saccharification is possible.

In a sulfur dioxide solution of sulfur trioxide, cellulose reacts with sulfur trioxide to form water-soluble cellulose sulfate.[1] The product and the cellulose residue are insoluble in the solution. This is interesting from the viewpoint of wood saccharification. After the treatment of wood in a liquid sulfur dioxide solution of sulfur trioxide, the insoluble product can be easily separated from the solution. The product is water-soluble and ready for hydrolysis in a dilute acid. The recovered sulfur dioxide solution, fortified by sulfur trioxide, is readily adaptable for repeated use. If this reaction takes the place of the mainhydrolysis in wood saccharification, it is possible to regard it as a new process which can be carried out with a minimum consumption of sulfuric acid.

Materials and Methods

Materials.—*Cellulose.*—Filter paper (Tôyô Roshi, No. 2) ground to small flakes with a grater was used.

Wood.—Sawdust of Yachidamo wood (*Fraxinus mandshurica*, Rupr.) passed through a 20-mesh sieve was used. Before use the sawdust was prehydrolyzed in 10% sulfuric acid at 100°C for 3 hr., washed with water, and dried at 105°C. The prehydrolyzed wood contained 69.9% potential reducing sugar, 1.7% potential pentose, and 32.4% lignin.

Sulfur Trioxide.—An asbestos-like sulfur trioxide was redistilled before use.

Sulfur Dioxide.—Liquid sulfur dioxide distilled from the gas cylinder was used.

Procedure.—The pressure glass vessels[2] were used. The bottle containing a cellulose and sulfur dioxide solution of sulfur trioxide was shaken in a water-bath at different temperatures for various periods. After the reaction, the product was filtered off and the residue was washed five times with sulfur dioxide. The sulfur dioxide adsorbed on the washed product was stripped off overnight by suction. The water-insoluble part was then centrifuged and washed with water. The reducing sugar and the potential reducing sugar in the soluble and the insoluble parts were determined. The soluble part was easy to hydrolyze in dilute acid. The insoluble part was, however, as difficult to as cellulose.

Analytical Methods.—The reducing sugar was determined by Somogyi's new reagent.[3]

The potential reducing sugar in the insoluble part was determined by the method of Saeman, Bubl and Harris.[4] From the result, the amount of unreacted cellulose was obtained.

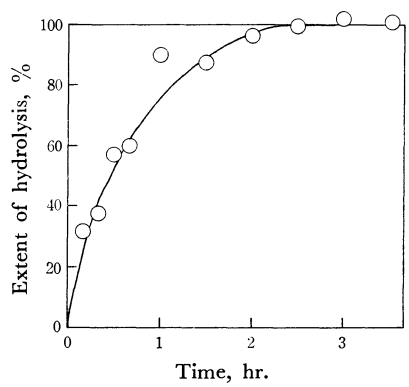

Fig. 1. Hydrolysis of soluble glucose polymer obtained in SO_2 solution of SO_3, in 2.5% HCl at 100°C.

The determination of the potential reducing sugar in the soluble part was carried out by Somogyi's method after hydrolysis in 2.5% hydrochloric acid at 100°C for 3 hr. (Fig. 1). From the result, the amount of the soluble glucose polymer was obtained.

In this paper, the soluble glucose polymer and the unreacted and initial celluloses are expressed in terms of the potential reducing sugar.

Results and Discussion

Reaction Mechanism.—After treating cellulose in a liquid sulfur dioxide solution of sulfur trioxide for different times at 0, 25 and 50°C, the unreacted cellulose was determined. The extent of cellulose degradation was indicated by the ratio of the residual cellulose to the initial cellulose (Fig. 2). Figure 2 shows the progress of the reaction according to the equation of the first-order reaction, with reference to cellulose degradation. At the same time, the produced soluble glucose polymer was also determined as is shown in Fig. 3. The soluble glucose polymer rose to a maximum and then fell. The amount of decomposition product (the difference between the initial cellulose and the sum of the soluble and insoluble glucose polymers) rose continuously (Fig. 3). These findings suggest that the reaction belongs to a set of irreversible reactions in series:

$$A \xrightarrow{k_1} B \xrightarrow{k_2} C \qquad (1)$$

where A is cellulose; B, the soluble glucose polymer; C, the decomposition product which does not give reducing sugar under further hydrolysis by dilute acid; k_1, the first-order rate constant which governs the A→B reaction, and k_2, the constant for B→C. The amounts of A and B at any time, t, are given for such a system by:

$$c_A = a \exp(-k_1 t) \qquad (2)$$

$$c_B = a k_1 [\exp(-k_1 t) - \exp(-k_2 t)]/(k_2 - k_1) \qquad (3)$$

where a is the initial amount of cellulose and c_A and c_B are the amounts of A and B at time t. Equation 2 fits in with the present data, as has been described above (Fig. 2). The values of k_1 found at 30°C in a 2.2% sulfur trioxide concentration and at 50°C in a 1.1% concentration were 0.375 and 1.88 hr^{-1}. Using these k_1 values, the reaction times, t, and the corresponding amounts of the soluble glucose polymer produced, c_B, k_2 can be calculated according to Eq. 3 to be 0.0327 hr^{-1} at 30°C in 1.1% sulfur trioxide and 0.335 hr^{-1} at 50°C in 2.2% sulfur trioxide. The c_B-time curves calculated from k_1 and k_2 agreed with the observed data, as is shown in Fig. 3. These facts prove that, with reference to cellulose, the present reaction progresses according to the mechanism described by the successive first-order reactions 1.

The Rate Constant of Cellulose Degradation.—Because it was previously found that the degradation of cellulose took place as a first-order reaction, the rate constants, k_1, were determined, using Eq. 2 and the c_A/a values observed in sulfur trioxide concentrations ranging from 0.32 to 3.3% at 0, 25, and 50°C for various times. The k_1's (hr^{-1}) are shown in Table I. When the logarithm of the reaction rate constant was plotted against the logarithm of the percentage concentration of sulfur trioxide in a liquid sulfur dioxide solution, the parallel straight lines were obtained at intervals depending on the temperature (Fig. 4). The slope of the lines is 1.63. The plotting of the logarithm of k_1 at a 1% sulfur trioxide concentration (Fig. 4) against the reciprocal of the absolute temperature

gives the straight line shown in Fig. 5. The slope of the line is −3650°K. Using these two values, the following experimental equation, which fits the observed k_1 (hr^{-1}) values (Table I), was obtained:

$$\log k_1 = 11.4215 + 1.63 \log C - 3650(1/T)$$

or $$k_1 = 2.64 \times 10^{11} C^{1.63} \exp[-16700/(\mathbf{R}T)] \quad (4)$$

where C is the sulfur trioxide concentration in liquid sulfur dioxide; T, the absolute temperature (273—323°K), and $\boldsymbol{R}$, the gas constant (cal./deg.).

The Rate Constant of the Decomposition of the Soluble Glucose Polymer to Substances Other than Reducing Sugar.—The soluble glucose polymer yield, c_B, at the time t and the corresponding k_1 (hr^{-1}) value gave the k_2 (hr^{-1})

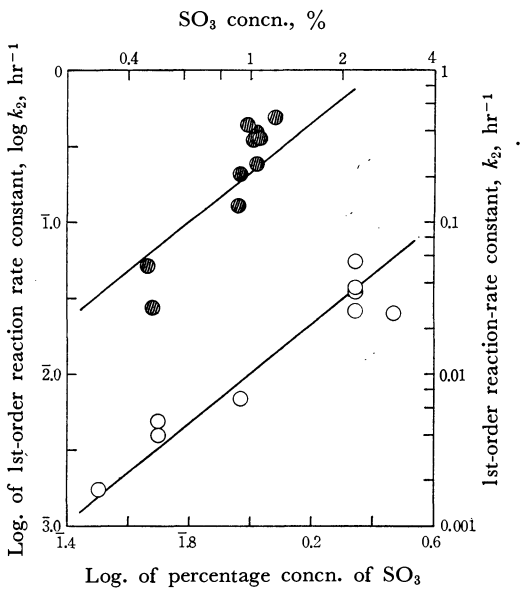

Fig. 6. First-order reaction-rate constants of soluble glucose polymer decomposition in various concentrations of SO_2 solution of SO_3 at 25 and 50°C.
▨ 50°C, ○ 25°C

value according to Eq. 3. The values are shown in Table I. The values at 0°C were so small that they could be taken as zero. The equation describing k_2 (hr^{-1}) as a function of the temperature and of the sulfur trioxide concentration was obtained in the same manner as the equation describing k_1 (Figs. 5 and 6):

$$\log k_2 = 15.953 + 1.63 \log C - 5380(1/T)$$

or $$k_2 = 8.99 \times 10^{15} C^{1.63} \exp[-24600/(\mathbf{R}T)] \quad (5)$$

Maximum Yield.—The yield of the soluble glucose polymer at the maximum is given by:

$$c_B = K^{1/(1-K)}$$

where $K = k_1/k_2 = 2.94 \times 10^{-5} \exp(3990/T)$ (6)

For example, the maximum yields are 84 and 72% at 25 and 50°C. At a lower temperature, such as 0°C, the yield must be higher than that given by the equation, because scarcely any sugar decomposition occured.

The yield of the soluble glucose polymer reaches a maximum at the time, t_m (hr.), given by Eq. 7.

$$t_m = 2.303(\log k_1 - \log k_2)/(k_1 - k_2) \quad (7)$$

where k_1 and k_2 are given by Eqs. 4 and 5. For example, a reaction time of 1.7 hr. is necessary to obtain the maximum yield at 50°C, and 6.6 hr, at 25°C.

Application to Wood Saccharification.—The prehydrolyzed sawdust of hardwood was treated by a sulfur dioxide solution of sulfur trioxide. The results are shown in Fig. 7. Although a portion of lignin was dissolved in the solution, it precipitated again after the dilute acid hydrolysis.

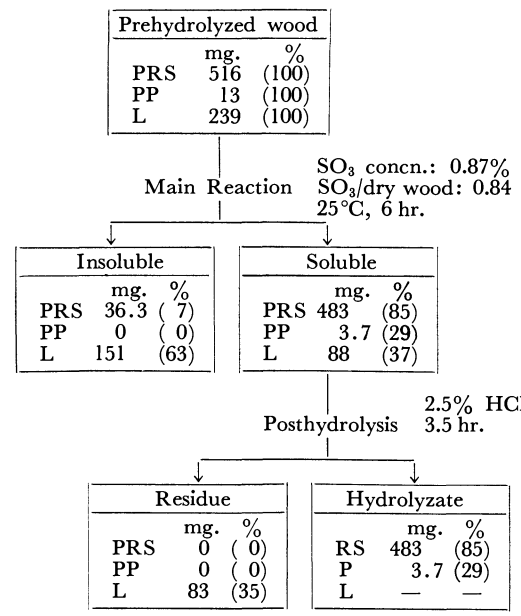

Fig. 7. Saccharification of prehydrolyzed hardwood using sulfur dioxide solution of sulfur trioxide.

The Phosphorylation of Alcohols by the Reaction of Monobromocyanoacetamide with Monobenzyl Phosphite or Inorganic Phosphorous Acid

By Teisuke OBATA, Masaaki UEKI and Teruaki MUKAIYAMA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received October 19, 1965)

This paper describes a successful method of preparing monoalkyl phosphates by the reaction of monobromocyanoacetamide with monobenzyl phosphite or inorganic phosphorous acid in the presence of alcohols. When equimolar amounts of monobromocyanoacetamide and either of the above-mentioned phosphorus compounds in alcohols were heated at about 100°C, the corresponding monoalkyl dihydrogen phosphates were obtained as anilinium salts in fairly good yields, together with cyanoacetamide and benzyl bromide or hydrogen bromide. The reaction can be interpreted in terms of a mechanism in which the initially-formed enol-phosphonium salts of cyanoacetamide are easily transformed to the second phosphonium salts by the action of the alcohols present from the salts, alkyl dihydrogen phosphates are produced.

A previous paper[1] presented a successful method of oxidizing various triesters of phosphorous acid or phosphines to triesters of phosphoric acid or phosphine oxides by means of monobromocyanoacetamide, along with either benzyl or allyl alcohol. In a similar way, dialkyl phosphates were prepared from the corresponding dialkyl phosphites.[2] The reaction was then further extended to the synthesis of monoalkyl dihydrogen phosphates (IV) by the oxidation of dibenzyl phosphite (I) with monobromocyanoacetamide (II) in alcohols and by subsequent catalytic debenzylation.[2]

$$\underset{\text{(I)}}{(C_6H_5CH_2O)_2\overset{O}{\overset{\|}{P}}H} + \underset{\text{(II)}}{NCCHBrCONH_2} \xrightarrow{ROH} \underset{\text{(III)}}{C_6H_5CH_2O-\overset{O}{\overset{\|}{P}}\begin{matrix}OR\\OH\end{matrix}}$$

$$\text{III} \xrightarrow{H_2/PdO} \underset{\text{(IV)}}{RO-\overset{O}{\overset{\|}{P}}\begin{matrix}OH\\OH\end{matrix}} + C_6H_5CH_3 \qquad (1)$$

In the present paper, a similar type of the phosphorylation of alcohols was attempted, employing monobenzyl phosphite or inorganic phosphorous acid and monobromocyanoacetamide.

First the reaction of monobenzyl phosphite with monobromocyanoacetamide in the presence of an equimolar amount of benzyl alcohol was attempted; a 27% yield of monobenzyl dihydrogen phosphate was thus obtained.

The result can be explained in terms of the following mechanism involving a quaternary phosphonium salt (VI), which is similar to that shown in the preceding paper[2]:

$$C_6H_5CH_2O-\overset{O}{\overset{\|}{P}}\begin{matrix}H\\OH\end{matrix} \rightleftarrows C_6H_5CH_2O-P\begin{matrix}OH\\OH\end{matrix}$$

$$\xrightarrow{NCCHBrCONH_2} \underset{\text{(V)}}{\left[\begin{matrix}NCCH{=}C{-}NH_2\\ \vdots\\ C_6H_5CH_2O\end{matrix}\!\!>\!\overset{+}{P}\!<\!\begin{matrix}OH\\OH\end{matrix}\right)Br^-\Big]}$$

$$V + ROH \longrightarrow \underset{\text{(VI)}}{\left[\left(\begin{matrix}C_6H_5CH_2O\\HO\end{matrix}\!\!>\!\overset{+}{P}\!<\!\begin{matrix}OH\\OR\end{matrix}\right)Br^-\right]}$$

$$\longrightarrow RO-\overset{O}{\overset{\|}{P}}\begin{matrix}OH\\OH\end{matrix} + C_6H_5CH_2Br \qquad (2)$$

In order to elucidate the proposed mechanism and examine the possibility of its application to the phosphorylation of alcohols, the reaction of ethanol with monobenzyl phosphite and monobromocyanoacetamide was attempted. In this case, it was expected that monoethyl dihydrogen phosphate would primarily be formed, since benzyl bromide, rather than the other alkyl or hydrogen bromide, is preferentially eliminated from the proposed quaternary phosphonium salt (VI, R= C_2H_5); thus, the phosphorylation of alcohols would be successful, and alkyl dihydrogen phosphates could be synthesized by a one-step procedure.

Indeed, when a mixture of monobenzyl phosphite and monobromocyanoacetamide in dry ethanol was refluxed for two hours, monoethyl phosphate and benzyl bromide were obtained in 46% and 63% yields respectively.

Similarly, *n*-propyl, isopropyl and *n*-butyl dihydrogen phosphates were obtained as anilinium salts when the phosphite and monobromocyanoacetamide were treated in the corresponding alcohols.

However, this procedure is not applicable to the phosphorylation of long-chain solid alcohols or those available in only small amounts, because the

1) T. Mukaiyama, O. Mitsunobu and T. Obata, *J. Org. Chem.*, **30**, 101 (1965).
2) O. Mitsunobu, T. Obata and T. Mukaiyama, ibid., **30**, 1071 (1965).

reaction should be carried out in a large excess of alcohol (usually in alcohol solvents); probably, the initially-formed quaternary phosphonium salt (V) is very unstable and the spontaneous decomposition takes place before it reacts with alcohols, giving several kinds of phosphorus compounds, some of which are not well characterized by paper chromatography.

Next, this type of reaction was further extended to a selective phosphorylation of alcohols, starting from inorganic phosphorous acid.

The reaction proceeds through the formation of quaternary phosphonium salt (VII), which is similar in structure to V. Therefore, the subsequent elimination of hydrogen bromide from VIII will result in the formation of alkyl dihydrogen phosphates.

When an equimolar amount of phosphorous acid and monobromocyanoacetamide in ethanol were refluxed for two hours, monoethyl dihydrogen phosphate was obtained in a 78% yield as chromatographically-pure anilinium salt.

Similarly, methyl, *n*-propyl, and *n*-butyl dihydrogen phosphates were obtained from the corresponding alcohols as the anilinium salts in 87, 82 and 64% yields respectively (see Table II).

As is the case with dialkyl or monoalkyl phosphite, inorganic phosphorous acid is expected to react with monobromocyanoacetamide in its tautomeric trivalent structure, giving enol-phos phonium salt of cyanoacetamide (VII), which is in turn transformed to the second quaternary phosphonium salt (VIII) by the action of the alcohols present.

This assumption was confirmed by the following experiments. Phosphoric acid was exclusively produced when water or benzyl alcohol was treated with monobromocyanoacetamide and phosphorous acid; in either case, hydrogen bromide or benzyl bromide was also detected.

$$(HO)_2\overset{\overset{O}{\|}}{P}H \rightleftarrows (HO)_3P + NCCHBrCONH_2$$

$$\longrightarrow \left[\begin{pmatrix} NCCH{=}C{-}NH_2 \\ | \\ HO\diagdown \\ HO\diagup P\diagdown O \\ \quad\quad\diagup OH \\ + \end{pmatrix} Br^- \right]$$

(VII)

$$VIII + ROH \longrightarrow \left[\begin{pmatrix} HO\diagdown \\ RO\diagup P\diagdown OH \\ \quad\quad\diagup OH \\ + \end{pmatrix} Br^- \right]$$

(VIII)

$$\longrightarrow RO{-}\overset{\overset{O}{\|}}{P}\begin{matrix} OH \\ \diagup \\ OH \end{matrix} + HBr \qquad (3)$$

(R=H or alkyl)

Monoalkyl phosphates could not be isolated as pure anilinium salts when an equimolar amount of alcohol was to be phosphorylated by this method; at the same time, several uncharacterized phosphorus compounds were also produced, thus making the purification much more difficult.

Experimental

Materials.—Monobromocyanoacetamide[3] and monobenzyl phosphite[4] were prepared by the method given in the literature. Inorganic phosphorous acid was obtained from a commercial source and dried over phosphorus pentoxide under a high vacuum. The alcohols and solvents used were purified by ordinary procedures. Phosphorus compounds were identified by paper chromatography; solvent system: *n*-propyl alcohol : conc. NH_4OH : H_2O=6 : 3 : 1.

The Oxidation of Monobenzyl Phosphite by Means of Monobromocyanoacetamide and Benzyl Alcohol.—A solution of equimolar amounts of monobenzyl phosphite (1.54 g., 0.01 mol.), monobromocyanoacetamide (1.63 g., 0.01 mol.) and benzyl alcohol (1.08 g., 0.01 mol.) in 20 ml. of dry peroxide-free tetrahydrofuran was refluxed for 2 hr. under a nitrogen atmosphere. After the solvent had then been removed under reduced pressure, 10 ml. of dry ether was added to separate the cyanoacetamide (0.57 g., 68%). The filtrate was concentrated and distilled to give benzyl bromide (b. p. 32—36°C/0.15 mmHg; 0.93 g., 54%). The oily residue was dissolved in 99% ethanol (10 ml.), and aniline (4 g., 0.04 mol.) was added. Precipitated anilinium salt of monobenzyl phosphate was filtered, washed twice with 99% ethanol (2 ml.) and dried over phosphorus pentoxide in a desiccator (0.89 g., 24%). Paper chromatography showed one spot (R_f: 0.57); this was identical with that of an authentic specimen. One recrystallization from 95% ethanol gave an analytical sample, m. p. 149—152°C.

Found: N, 7.56, Calcd. for $C_{19}H_{18}N_2O_4P$: N, 7.48%.

The Phosphorylation of Ethanol by the Reaction of Monobenzyl Phosphite and Monobromocyanoacetamide.—A solution of equimolar amounts of monobenzyl phosphite (1.54 g., 0.01 mol.) and monobromocyanoacetamide (1.63 g., 0.01 mol.) in absolute ethanol (10 ml.) was refluxed for an hour under a nitrogen atmosphere. The reaction mixture was concentrated and 10 ml. of chloroform was added to separate the cyanoacetamide (0.78 g., 92%). From the filtrate, benzyl bromide (b. p. 46—47°C/2 mmHg, 1.08 g., 63%) was obtained by fractionation. The residue was dissolved in 99% ethanol (10 ml.), and aniline (1.7 g.) was added. After the mixture had been cooled to −20°C, anilinium salt of monoethyl phosphate (m. p. 132—149°C, 1.02 g., 46%) was filtered. One recrystallization from acetonitrile-water gave an analytically-pure sample (m. p. 160—164°C; lit.[2] 164—165°C).

Found: N, 6.30, Calcd. for $C_8H_{14}NO_4P$: N, 6.39%.

The R_f-value shown by paper chromatography was identical with that of an authentic specimen.[2]

Similarly, the other alkyl phosphates were prepared and characterized by comparison with authentic samples[2] (see Table I).

The Phosphorylation of Ethanol by the Reaction of Phosphorous Acid and Monobromocyanoacetamide.—Equimolar amounts of phosphorous acid (0.82 g., 0.01 mol.) and monobromocyanoacetamide (1.63 g., 0.01 mol.) were dissolved in absolute ethanol

* A trace of phosphorous acid is contaminated in the product.

ml.), and then the mixture was refluxed for 2 hr. under a nitrogen atmosphere. After the excess ethanol had been evaporated, cyanoacetamide (0.79 g., 92%) was filtered out. The filtrate was dissolved in 99% ethanol (5 ml.) and then aniline (2 ml.) was added. After the mixture had stood for 30 min., monoethyl dihydrogen phosphate (1.67 g., 82%) was filtered out. Recrystallization from 15 ml. of 95% ethanol gave an analytical sample (m. p. 162—164°C; 1.15 g.; lit.[2] 164—165°C).

Found: N, 6.37. Calcd. for $C_8H_{14}NO_4P$: N, 6.39%. Paper chromatography showed one spot, R_f: 0.37 (lit.[2] 0.36—0.37).

The other alkyl dihydrogen phosphates were prepared by a similar method. The yields and the physical constants are summarized in Table II.

The Reaction of Phosphorous Acid with Monobromocyanoacetamide in the Presence of Water or Benzyl Alcohol.—A solution of equimolar amounts of phosphorous acid (0.41 g.) and monobromocyanoacetamide (0.82 g.) in acetonitrile (15 ml.) and water (2 ml.) was refluxed for an hour. The paper chromatography of the reaction mixture showed only one yellow spot of inorganic phosphoric acid (R_f: 0.17—0.18); the strong blue spot of inorganic phosphorous acid (R_f: 0.28) had completely disappeared. This shows that the phosphorylation of water or the oxidation of phosphorous acid has taken place. The same result was also observed when benzyl alcohol was employed in place of water in the above reaction. In this case, a good deal of benzyl bromide was formed; it was characterized by distillation and by its lachrymatory odor.

The authors wish to express their hearty thanks to Dr. Oyo Mitsunobu for his helpful suggestions and to Miss Keiko Nakamura for her microanalysis.

The Polarographic Investigation on the Reaction between Chromium(II)-ethylenediaminetetraacetate and Nitrate Ions

By Nobuyuki TANAKA and Tasuku ITO

Department of Chemistry, Faculty of Science, Tohoku University, Sendai

(Received October 19, 1965)

The effect of nitrate ions on the polarographic waves of ethylenediaminetetraacetatoaquochromate(III) ions has been studied in acetate buffer solutions and acid potassium chloride solutions. Nitrate ions are chemically reduced in the vicinity of the mercury drop of the electrode by chromium(II)-EDTA complexes which are formed by the electroreduction of chromium(III)-EDTA complexes. The chromium(III)-EDTA complexes thus formed are reduced again at the DME and the intermediate products of nitrate ions are reduced further chemically with chromium(II)-EDTA complexes or electrochemically, resulting in the enhancement of the current. The nature of the limiting current is investigated and compared with that predicted from the theoretical treatment. The reaction between chromium(II)-EDTA and nitrate ions has also been investigated in acetate buffer solutions and its rate constant, 35 l. mol^{-1} sec^{-1} at nearly 0°C, $\mu=0.1$, has been compared with 30 l. mol^{-1} sec^{-1}, the value obtained from the polarographic catalytic current under almost the same condition.

Catalytic poloargraphic currents due to the presence of nitrate have been observed in several electrolytic reductions. The effect of nitrate ions on the reduction waves of uranyl ions,[1-5] molybdate ions[6-8] and chromium complexes[9-11] has been reported. In the last case, it has been known that the reduction of chromium complexes with glycine,[9] alanine[10] thiourea[11] and oxalate give peculiar maximum waves in the presence of nitrate ions. This was attributed to the induced reaction of nitrate ions.

In addition, another kind of polarographic catalytic wave due to nitrate ions was found in the course of a systematic investigation of the chromium complexes in this laboratory. It was considered as due to the reaction between nitrate ions and chromium(II)-EDTA complexes taking place at the electrode surface, the latter being formed by the electroreduction of ethylenediaminetetraacetatoaquochromate(III) ions at the electrode.

In this communication the polarographic investigation on this reaction taking place in the solution and at the electrode surface is presented; the stoichiometry and the rate constant of the reaction are determined and the reaction mechanisms are discussed.

Experimental

Hydrogen ethylenediaminetetraacetatoaquochromate(III), H[Cr(H_2O)edta], was prepared according to the procedure of Hamm.[12] It was identified by the measurement of the absorption spectra and by the determination of hydrogen, nitrogen and carbon contents.

Found: C, 33.05; N, 7.82; H, 4.26. Calcd. for H[Cr(H_2O)edta]: C, 33.40; N, 7.80; H, 4.21%.

All the chemicals used were of a guaranteed reagent grade.

Current-potential curves were obtained with a pen-recording polarograph, Yanagimoto Galvarecorder Model GR-103, with an automatic potential scanner. The same polarograph but without an automatic potential scanner was used for the automatic recording of limiting current-time curves of the reactions in the solution. The dropping mercury electrode (DME) used had a rate of mercury flow, m, of 1.65_7 mg./sec. and a drop time, t_d, of 5.22 sec., when measured in an air-free solution containing 0.1 M acetate buffer (pH 4.9) at −0.5 V. vs. SCE and at 50 cm. of height of a mercury reservoir. The potential of the DME was referred to the saturated calomel electrode (SCE). The temperature of the electrolytic solution was maintained by means of a water thermostat at 25°C, unless otherwise stated. The dissolved oxygen in the electrolytic solution was removed by bubbling pure nitrogen gas through the solution. No maximum suppressor was used.

The measurements were made in 0.1 M acetate buffer

solutions (pH 4.9), unless otherwise stated. The experimental conditions were in most cases such as those postulated in the theoretical treatment so that it was possible to compare the experimental results with the theoretical ones.

The controlled potential electrolysis was carried out with a Yanagimoto automatic potentiostat, Model VE-3. The working electrode was a mercury pool and the auxiliary electrode was platinum wire which was connected to the electrolytic solution through a potassium chloride agar bridge. The potential of the working electrode was controlled against the saturated calomel electrode (SCE). The solution was stirred by means of a magnetic stirrer. Nitrogen gas was bubbled through the solution continuously to provide stirring and to remove atmospheric oxygen.

Results

Polarographic Characteristics of Ethylenediaminetetraacetatoaquochromate(III) Ions in the Presence of Nitrate.—Ethylenediaminetetraacetatoaquochromate(III) ions, $[Cr(H_2O)edta]^-$, gave a well-defined polarographic reduction wave in a 0.1 M acetate buffer solution. This wave was found to correspond to the one-electron reduction of chromium(III) to chromium(II). The half-wave potential, $E_{1/2}$, was -1.24 V. vs. SCE and the diffusion current constant, I, was 1.48 μamp. $sec^{1/2}$ mM^{-1} $mg^{-2/3}$, both of which were in accord with the values obtained by Pecsok, Shields and Schaeffer.[13]

The addition of nitrate caused the exaltation of the limiting current, although the solutions with or without nitrate ion gave the identical current-potential curves in the absence of $[Cr(H_2O)edta]^-$ (Fig. 1). The exaltation phenomenon was so sensitive that the effect of nitrate ion on the d. c. polarograms could be observed at the concentration as low as 10^{-6} M of $[Cr(H_2O)edta]^-$.

The effect of nitrate ions on the polarograms of $[Cr(H_2O)edta]^-$ was found to be of the catalytic nature, as will be proved later. The polarographic characteristics of the solution containing $[Cr(H_2O)edta]^-$ and nitrate ions were examined and compared with those predicted from the theoretical studies on the catalytic polarographic current.[14,15]

The polarograms obtained at various concentrations of $[Cr(H_2O)edta]^-$ and at the given concentration of nitrate are shown in Fig. 2. The limiting current at -1.34 V. was found to be almost proportional to the concentration of $[Cr(H_2O)edta]^-$.

Figure 3 indicates a relation between the limiting current and the concentration of nitrate, which was obtained at the given concentration of $[Cr(H_2O)edta]^-$. When the concentration of nitrate was relatively small, in other words, when the experimental condition was not that postulated in the theoretical study on the catalytic current, the catalytic current, $\bar{i}_c$, (the additional portion on the limiting current caused by the presence of nitrate, cf. Fig. 1) was almost proportional to the concentration of nitrate (Fig. 4). The presence of nitrate did not bring about the plateau but the rather inclined limiting current, even after the residual current was corrected. The inclination of the limiting current became larger with increasing concentrations of nitrate.

The catalytic currents obtained at various heights of the mercury reservoir are given in Table I. The total limiting currents are almost proportional to the square root of the height of the mercury reservoir under the conditions where $\bar{i}_c$ is proportional to the concentration of nitrate.

Table I. Limiting currents of $[Cr(H_2O)edta]^-$ obtained in the presence of nitrate ions at various heights of the mercury reservoir (h) in acetate buffer solutions

h cm.	Solution 1*		Solution 2**	
	$\bar{i}_t$, μamp.	$\bar{i}_c$, μamp.	$\bar{i}_t$, μamp.	$\bar{i}_t/h$
65	3.1	2.4	5.1	1.6
60	3.0	2.3	4.9	1.6
55	2.9	2.3	4.8	1.5
50	2.8	2.2	4.6	1.5
45	2.7	2.1	4.5	1.5
40	2.6	2.1	4.3	1.5

* Solution 1 contains 0.2 mM $[Cr(H_2O)edta]^-$ and 19.6 mM KNO_3.

** Solution 2 contains 1.0_3 mM $[Cr(H_2O)edta]^-$ and 0.8_3 mM KNO_3.

The measurements were also made at various pH's of the solution (Fig. 5). The lower the pH value was, the larger the catalytic waves were obtained in acetate buffer solutions. However, the further increase in hydrogen ion concentration with hydrochloric acid decreased the height of the catalytic waves. At lower pH of the solution, chromium(II) ion is no longer Cr(II)-EDTA, but some other aquated species which are considered less or least effective in the catalytic process.*

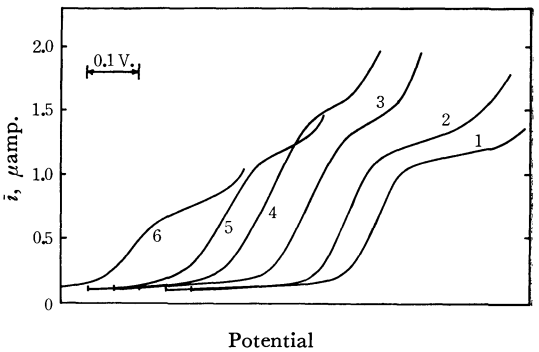

Fig. 5. Polarograms of 0.2 mM $[Cr(H_2O)edta]^-$, obtained in the presence of 2.0 mM KNO_3 in 0.1 M acetate buffer solutions of pH 5.5_0 (1), 4.8_8 (2) and 3.4_0 (3) and in 0.1 M potassium chloride solutions of pH 2.9_5 (4), 2.6_8 (5) and 2.0_2 (6). Each curve starts at -0.90 V. vs. SCE. Residual currents are not corrected.

The Reaction between Cr(II)-EDTA and Nitrate Ions in Solutions.—The presence of nitrate has no effect unless the potential is negative enough so that the reduction of $[Cr(H_2O)edta]^-$ occurs (Fig. 1). The fact strongly suggests that Cr(II)-EDTA formed at the electrode surface reacts with nitrate ion. In order to find the mechanism of the reaction taking place at the electrode surface, the characteristics of the reaction between Cr(II)-EDTA and nitrate ions in solutions were studied.

Cr(II)-EDTA was prepared by reducing the corresponding chromium(III) complex, $[Cr(H_2O)edta]^-$, at a mercury pool cathode, whose potential was controlled at -1.3 V. vs. SCE using an automatic potentiostat. The electrolysis cell used was shown in Fig. 6. Polarograms obtained after the electrolysis are of the typical reversible oxidation-reduction wave of chromium(II)- and chromium-

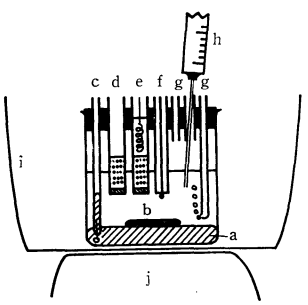

Fig. 6. Electrolysis cell: a, Hg-pool served as working electrode; b, stirrer; c, contact of working electrode; d, KCl-agar bridge connected to SCE; e, Pt-wire electrode; f, DME; g, N_2 gas disperser; h, syringe used for adding reagent after electrolysis; i, water thermostat; j, magnetic stirrer.

* According to Pecsok et al., the Cr(II)-EDTA complex has 13.61 of logarithmic stability constant and -3.00 of logarithmic acidity constant.[13] From these values, the percentage of the species Cr(II)edta, Cr(II)edtaH and Cr^{2+} which are in equilibrium in the solution are calculated to be 0, 0, ~100% at pH 2, 19, 19, 62% at pH 3, 82, 8, 10% at pH 4 and 98, 1, 1% at pH 5, respectively.

2	0.69_6	0.049_5	0.39_4	7.9_6	27.0
3	0.57_6	0.049_5	0.39_8	8.0_4	26.5
4	0.70_9	0.049_5	0.39_2	7.9_4	26.5
5	0.74_5	0.049_5	0.39_9	8.0_4	25.5
6	0.64_4	0.049_5	0.39_4	7.9_6	25.5

(III)-EDTA complexes.* The concentration of Cr(II)-EDTA formed was determined by the measurement of the decrease in the reduction wave of $[Cr(H_2O)edta]^-$ at −1.4 V. vs. SCE or by the measurement of the height of the oxidation wave of Cr(II)-EDTA at −0.55 V. vs. SCE. In all experiments at pH 4.9 the sum of the height of the reduction wave at −1.4 V. and that of the oxidation wave at −0.55 V. after the electrolysis was approximately equal to the height of the reduction wave at −1.4 V. before the electrolysis. However this did not hold at lower pH, because the dissociation of Cr(II)-EDTA complex takes place. The anodic current observed at −0.55 V. results from the oxidation of Cr(II)-EDTA, but not from the oxidation of the aquated species.

When nitrate ions were added to this solution, the oxidation wave was decreased or sometimes completely obliterated according to the quantities of nitrate added. The formation of $[Cr(H_2O)edta]^-$ was at first confirmed spectrophotometrically. The stoichiometry was then ascertained at room temperature (ca. 25—27°C). The consumption of Cr(II)-EDTA by the addition of a known quantity of nitrate ions showed that one mole of nitrate reacted with eight moles of Cr(II)-EDTA (Table II).

This stoichiometry seems to show that the reaction proceeds as,

$$8\,Cr(II)\text{-}EDTA + NO_3^- + 10H^+ + 5H_2O = 8[Cr(H_2O)edta]^- + NH_4^+ \quad (1)$$

and that the final product in the reduction of a nitrate ion is an ammonium ion. The fact well accords with the results which were obtained by Lingane and Pecsok[16,17] on the reaction between chromium(II) and nitrate ions in sulfuric acid solutions.

In order to clarify the kinetics of the reaction, the decrease in the concentration of Cr(II)-EDTA by the addition of nitrate was pursued at approximately 0°C; the change in height of the oxidation wave of Cr(II)-EDTA at −0.55 V. was followed with time. Figure 7 shows an example of the wave height-time relationship. The rate constant was calculated with the assumption that the reaction is of second order. This assumption was not proved strictly but seemed to be most probable. Let a and b represent the initial concentrations of Cr(II)-EDTA and nitrate, respectively. At a given time t, x moles of nitrate react with $8x$ moles of Cr(II)-EDTA, and then we have

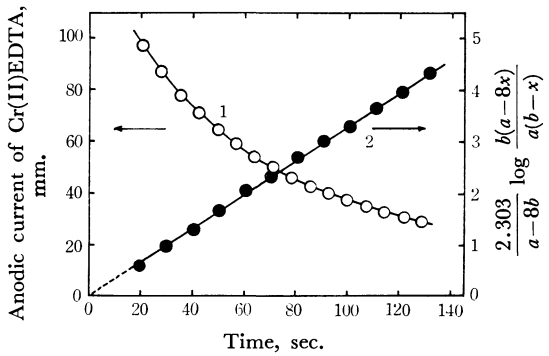

Fig. 7. The relation of the anodic limiting current with time (1) and that of the right-hand side of Eq. 4 with time (2), of the Cr(II)EDTA-nitrate reaction, obtained in a 0.1 M acetate buffer solution at nearly 0°C. The current was measured at −0.55 V. vs. SCE. The initial concentrations of Cr(II)-EDTA and KNO_3 were 0.24_6 and 0.06_1 mM, respectively.

$$-\frac{1}{8}\frac{d(a-8x)}{dt} = -\frac{d(b-x)}{dt} = k(a-8x)(b-x) \quad (2)$$

$$\frac{dx}{dt} = k(a-8x)(b-x) \quad (3)$$

Integrating and using the boundary values, the following relation is obtained:

$$kt = \frac{1}{a-8b}\ln\frac{b(a-8x)}{a(b-x)} \quad (4)$$

The rate constant can be determined from the slope of the straight line which is obtained from the plot of t against the right-hand side of Eq. 4. The value of $(a-8x)$ can be found by the measurement of the polarogram. As an example, the

* It was impossible to reduce completely, even though the dissolved and the atmospheric oxygen was sufficiently removed. Therefore, the sample solution of Cr(II)-EDTA always contained Cr(III) species, $[Cr(H_2O)edta]^-$.

17) H. A. Laitinen, "Chemical Analysis," McGraw-Hill Book Company, New York (1960), p. 449.

Table III. The rate constant of the reaction between Cr(II)-EDTA and nitrate ions, obtained in 0.1M acetate buffer solutions of various pH's at nearly 0°C

pH	Initial concentration Cr(II)-EDTA mM	Initial concentration KNO_3 mM	Rate constant l.mol^{-1}sec^{-1}
5.0_4	0.27_0	0.060_5	35
4.9_0	0.33_3	0.024_8	37
4.8_8	0.28_1	0.024_8	35
4.7_7	0.37_0	0.060_5	34
4.0_2	0.26_9	0.060_5	38
3.4_1	0.21_6	0.060_5	35

relation mentioned above is also given in Fig. 7. The rate constants thus obtained at various pH's are given in Table III.

According to the stability constant obtained by Pecsok et al., the acid complex Cr(II)edtaH is formed at lower pH.[13] Nevertheless, the kinetic studies at various pH's yielded approximately the same rate constant. This seems to indicate that Cr(II)edtaH reacts with nitrate ion as fast as Cr(II)edta dose.

Discussion

The experimental results clearly show that the effect of nitrate ions on the polarographic reduction waves of $[Cr(H_2O)edta]^-$ is of a catalytic nature and that the initiation of the catalytic process is the reaction of Cr(II)-EDTA with nitrate ions. The reoxidized $[Cr(H_2O)edta]^-$ is reduced again at the DME, resulting in an exaltation of the current. The reaction product of nitrate is again reduced by Cr(II)-EDTA or it may be reduced electrochemically, until it is reduced to the final product.

The reaction between Cr(II)-EDTA and nitrate ions at the vicinity of the electrode surface proceeds regardless of the electrode potential. The presence of EDTA causes the decrease of the limiting current of $[Cr(NCS)_6]^{3-}$ over some potential range to split a one-electron reduction wave into two steps. This is caused by the electro-oxidation of Cr(II)-EDTA wich is formed at the electrode surface through the chemical reaction following the electron transfer.[18-20] When nitrate is added to this solution, the decrease of the limiting current of $[Cr(NCS)_6]^{3-}$ becomes smaller, because some of the Cr(II)-EDTA formed were not oxidized electrochemically but chemically by the reaction with nitrate ions (Fig. 8). This indicates that the exaltation phenomena described in this paper are entirely different from those obtained in the reduction of nitrate ions in the presence of multi-

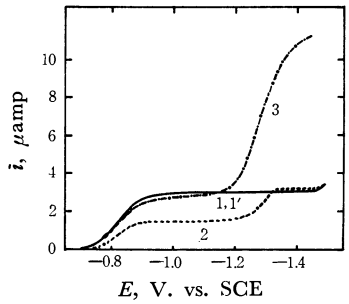

Fig. 8. Polarograms of 1.0 mM $K_3[Cr(NCS)_6]$, obtained in the solutions containing 0.9 M KSCN, 0.1 M acetate buffer and 0.005% gelatin without (1) and with (1') 5.0 mM KNO_3 and also after the addition of 0.5 mM EDTA without (2) and with (3) 5.0 mM KNO_3.

valent cations.[21]

In the case of catalytic currents, substance O is reduced to substance R, and the latter is oxidized again to substance O by the reaction with substance Z:

$$O + ne \rightarrow R \quad (5)$$

$$R + Z \xrightarrow{k} O \quad (6)$$

In the following discussion, the currents denoted by $\bar{i}_d$, $\bar{i}_c$ and $\bar{i}_t$ represent the diffusion current of substance O, the catalytic current due to the presence of substance Z and the total limiting current, respectively (Fig. 1.). The symbol k means the rate constant of the reaction 6.

The polarographic characteristics of the catalytic currents and the relation between k and $\bar{i}_c$ were reported by Delahay and Stiehl[14] and Koutecký[15]. The experimental results concerned with the dependency of the current on the concentration of $[Cr(H_2O)edta]^-$ (Fig. 2) and nitrate ion (Fig. 3) and the height of the mercury reservoir (Table I) are consistent, although not satisfactorily, with the theoretical prediction.

The results given in Fig. 4 and the last two columns of Table I were obtained under the condition where the concentration of nitrate is relatively small. Under this condition, it seems that the rate of the catalytic process is determined by the rate of the diffusion of nitrate ions, as was observed by Kolthoff et al. in the study of the catalytic current of the uranyl ions.[1]

The effect of pH on the catalytic waves was observed as given in Fig. 5. The decrease of the limiting current at pH 2 is explained, as mentioned before, by considering the dissociation of Cr(II)-EDTA complexes.

Collat and Lingane[5] studied by means of the controlled potential coulometric analysis the

reduction product of nitrate which was formed in the electrode reaction of uranyl ions taking place in the presence of nitrate. From the consumption of electricity and that of hydrogen ion and the chemical analysis, they concluded that nitrate ions were primarily reduced to hydroxylamine. They also reported that the reduction of nitrate ion was accompanied by the reduction of hydrogen ion and that a considerable fraction of the electricity was evidently consumed for the reduction of hydrogen ions.

In the present case, similar reactions may take place. The phenomenon that the limiting current increased with decreasing pH in acetate buffer solutions may be attributed to the change in the quantity of the reduction of hydrogen ions. The formation of acid complex, $[CredtaH]^-$, does not seem to bring about the larger limiting current, because the $[CredtaH]^-$ was found to react with nitrate ion at almost the same rate as $[Credta]^{2-}$.

From the above discussions, the catalytic reduction of nitrate ion in the electrode reaction of $[Cr(H_2O)edta]^-$ is considered as follows. The reduction of nitrate ion is initiated by the reaction with Cr(II)-EDTA, which is followed by a series of rapid consecutive reactions, presumably both electrochemical and chemical. That the electrochemical and the chemical reactions are both involved might be the cause for the inconsistency of the polarographic characteristics with the prediction of the theoretical study on the catalytic polarographic current. There may be some possibilities that a nitrate ion is reduced to a product different from that in the homogeneous reaction. Hydroxylamine, which is formed by the six-electron reduction of nitrate ion, can react with Cr(II)-EDTA in solution, but the rate is not so large as that of the reaction of nitrate. Hydroxylamine can be reduced also at the DME and gives the polarographic wave as shown in Fig. 9.

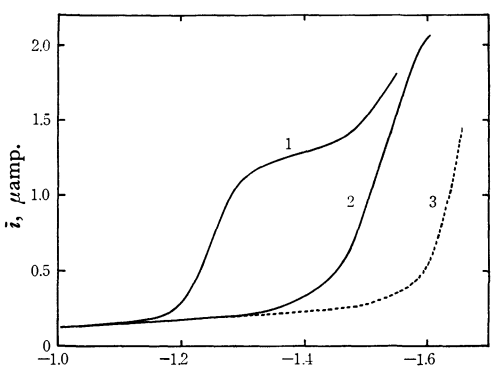

Fig. 9. Polarograms of (1) 0.2 mM $[Cr(H_2O)edta]^-$ with 2.0 mM KNO_3 and (2) 0.2 mM $NH_2OH \cdot HCl$, obtained in 0.1 M acetate buffer solutions of pH 4.8_8. Curve 3 represents the residual current.

The rate constant of the reaction between Cr(II)-EDTA and nitrate ion given by Eq. 1 or 6 was calculated from the catalytic polarographic current, using the Koutecký's equation with the assumption that the reaction occurring in the vicinity of the electrode surface proceeds in the same way as the homogeneous reaction does. In other words, nitrate ions were assumed to be reduced chemically, but not electrochemically. With a further assumption that the backward reaction is negligible, the ratio $\bar{i}_t/\bar{i}_d$ is written in the form,

$$\frac{\bar{i}_t}{\bar{i}_d} = 0.812\chi^{-1/2} + 1.92\chi^{-7/6} \quad (7)$$

with

$$\chi = \alpha k C_Z t_d \quad (8)$$

where t_d represents the drop time and α is the stoichiometry of the reaction 6($\alpha=8$ in the present case).[15,22] Using the numerical relation between χ and $\bar{i}_t/\bar{i}_d$ calculated by Koutecký,[15,23] the rate constant in the present case was determined, from the current at −1.34 V. vs. SCE to be approximately 30 $l.mol^{-1}sec^{-1}$ at 0°C and 70 $l.mol^{-1}sec^{-1}$ at 25°C, $\mu=0.1$, pH 4.9 (Table IV). It should be noted that only a small portion, if any, of the measured catalytic current is considered to be due to the reduction of hydrogen ions.

TABLE IV. THE RATE CONSTANT OBTAINED FROM THE CATALYTIC CURRENT AT −1.34 V. VS. SCE IN 0.1 mM $[Cr(H_2O)edta]^-$ SOLUTIONS CONTAINING 0.1M ACETATE BUFFER AND VARIOUS AMOUNTS OF KNO_3 AT NEARLY 0°C

Temp. °C	Concn. of KNO_3 mM	$\bar{i}_d$ μamp.	$\bar{i}_t$ μamp.	Rate constant $l.mol^{-1}sec^{-1}$
0	11.7_3	0.1_7	0.4_6	28
0	15.0	0.1_7	0.5_2	28
0	23.2_6	0.1_7	0.6_6	28
0	31.4	0.1_7	0.7_9	30
25	15.0	0.2_5	1.2_7	72
25	19.1_5	0.2_5	1.5_5	64
25	23.2_6	0.2_5	1.5_9	73
25	27.3_8	0.2_5	1.7_2	73

The rate constant obtained from the catalytic current is in good agreement with the one obtained in the homogeneous reaction. However this agreement seems to be rather fortuitous, if the complication of the reaction at the electrode surface is considered. A more precise comparison between the result from the homogeneous reaction and that from the electrode reaction seems less feasible, unless the reaction mechanisms are clarified on both kinds of the reactions.

The authors wish to thank the Ministry of Education for the financial support granted for this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1049—1054 (1966)

The Chemistry of Polyazanes. II. 1, 8-Di-*p*-tolyl-3, 6-diphenyl-1, 4, 7-octaaztriene

By Hiroshi MINATO, Masayoshi OKU* and Samuel Hung-Pui CHAN

Department of Chemistry, International Christian University, Mitaka, Tokyo

(Received October 19, 1965)

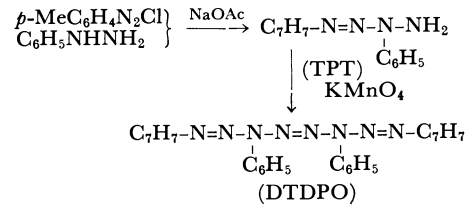
1, 8-Di-*p*-tolyl-3, 6-diphenyl-1, 4, 7-octaaztriene (DTDPO) was prepared by the potassium permanganate oxidation of 1-*p*-tolyl-3-phenyl-1-tetraazene (TPT), and the kinetics and the products of the decomposition of DTDPO were investigated. The experimental results can best be explained by assuming a mechanism in which DTDPO decomposes homolytically to yield a nitrogen molecule and two triazenyl radicals, which then combine to form 1, 3, 4, 6-tetraaryl-1, 5-hexaazdiene; the latter is very unstable and decomposes quickly to yield substituted azobenzenes and phenyl and *p*-tolyl radicals. The rather slow rate of decomposition of DTDPO was also discussed.

Except for carbon, very few elements are capable of forming compounds with chains of the same atoms linked linearly. Nitrogen is one of these few exceptions, and the polyazanes appear to be very interesting compounds. Our laboratories have been investigating the chemistry of various polyazanes; in this paper the chemistry of 1, 8-di-*p*-tolyl-3, 6-diphenyl-1, 4, 7-octaaztriene (DTDPO) will be described.

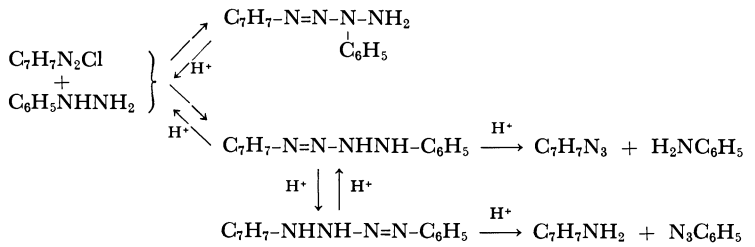
Wohl and Schiff[1] reported on the synthesis of DTDPO by the oxidation of 1-*p*-tolyl-3-phenyl-1-tetraazene (TPT) with an aqueous potassium permanganate solution at 0°C. Although they reported that DTDPO was very unstable, no precise kinetic measurements were made, nor were the products of the decomposition studied. Therefore, this investigation was undertaken in order to determine the rates of decomposition, the activation parameters, and the products of the decomposition of DTDPO.

Results and Discussion

1, 8-Di-*p*-tolyl-3, 6-diphenyl-1, 4, 7-octaaztriene (DTDPO) was synthesized by the potassium permanganate oxidation of 1-*p*-tolyl-3-phenyl-1-tetraazene (TPT), which had been prepared from the coupling of *p*-toluenediazonium chloride with phenylhydrazine.



In the reaction between *p*-toluenediazonium chloride and phenylhydrazine, the fact that the α-nitrogen, not the β-nitrogen, receives the electrophilic attack of the diazonium ion is worthy of attention. However, this fact should not be interpreted to mean that α-nitrogen is more basic than β-nitrogen. The analysis of the side products of this coupling reaction indicated the presence of aniline, *p*-toluidine, phenyl azide and *p*-tolyl azide, which are the decomposition products of 1, 4-diaryl-1-tetraazenes, the latter being formed by the attack of the diazonium ion on the β-nitrogen atom of the phenylhydrazine. Undoubtedly both the α- and β-nitrogens are attacked by electrophilic diazonium ions. The TPT formed is susceptible to the attack of a proton and goes back to the diazonium ion and phenylhydrazine when the medium is acid. 1, 4-Diaryl-1-tetraazenes are also susceptible to the attack of a proton, but for these compounds three reactions are possible; one is the back reaction, the



* American Chemical Society-Petroleum Research Fund Scholar.

1) A. Wohl and H. Schiff, *Ber.*, **33**, 2741 (1900).

second is the isomerization by the transfer of the double bond on the nitrogen chain, and the third is decomposition to yield an azide and an amine. The only irreversible products formed from the various reactions described above are the azides and the amines. When the medium was sufficiently acid, the only products isolated were azides and amines, and no TPT was obtained. Even when a quantity of sodium acetate sufficient for the neutralization of the diazonium chloride was present, the formation of some azides and amines was unavoidable.

The crude TPT containing some moisture changed into azides and amines in three days, even at −17°C, whereas the recrystallized TPT remained unchanged for at least two weeks at −17°C. The pure TPT decomposed into only azides and amines when it was allowed to stand in the open air at room temperature for 50 hr. The crude TPT smoked and then exploded when allowed to stand at 30°C for ten minutes.

TPT is very soluble in benzene or toluene, and slightly soluble in methanol or ethanol. In all of these solvents, however, TPT gradually decomposed at room temperature, and the color of the solution changed into brownish red and then into dark brown. Apparently the backward reaction yielded some diazonium compounds which reacted further to produce the coloration. TPT is very soluble in methylene chloride and slightly soluble in carbon tetrachloride, but TPT decomposed very fast in these chlorinated hydrocarbons and the solutions became dark brown within five minutes.

DTDPO was prepared by oxidizing TPT with potassium permanganate below 0°C. The crude DTDPO could be purified by the recrystallization in ether at −73°C. The pure yellow crystals of DTDPO were rather stable at room temperature when no mechanical shock was applied. However, they violently exploded when scratched or rubbed. DTDPO crystals must be handled with extreme caution.

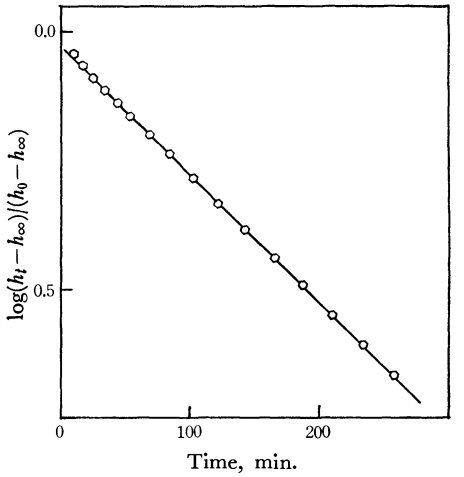


Fig. 1. Rate of decomposition of DTDPO in cumene at 30.0°C.
h_0, h_t and h_∞ are the difference of the mercury heights at $t=0$, $t=t$ and $t=\infty$, repectively.

TABLE I. RATES OF DECOMPOSITION OF DTDPO IN CUMENE

Temp. °C	$10^5 k_1$ sec^{-1}	Half life min.
10.0	0.417	2760
20.0	1.90	605
30.0	9.35	123

The spontaneous decomposition of DTDPO was investigated by dissolving about one gram of DTDPO in about 40 ml. of cumene at lower temperatures and by warming up the solution to 10.0°C, 20.0°C and 30.0°C and keeping it there. The decomposition followed good first-order kinetics, as is seen in Fig. 1. The first-order rate constants at these three temperatures are shown in Table I, together with the half-lives. When $\ln(k/T)$ was plotted against $1/T$, a straight line was obtained, as is seen in Fig. 2. The values of the activation parameters obtained from the slope of Fig. 2 were $\Delta H^{\ddagger}=25.1$ kcal./mol. and $\Delta S^{\ddagger}=5.8$ e.u. Table II lists the products obtained

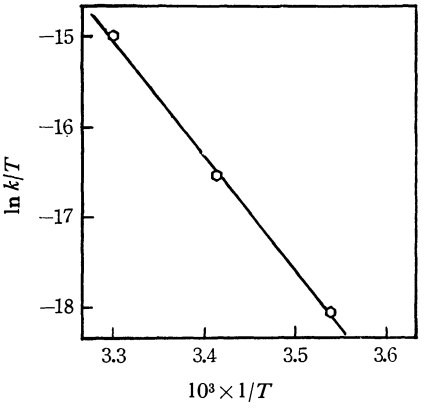

Fig. 2. $\ln k/T$ vs. $1/T$ for the decomposition of DTDPO.

TABLE II. PRODUCTS OF DECOMPOSITION OF DTDPO IN CUMENE AT 30.0°C*

Product	mmol.	mol./mol. DTDPO

C_6H_6	1.45	0.66
C_6H_5Me	3.10	1.41
$(C_6H_5CMe_2)_2$	1.12	0.51

* 0.9878 g. of DTDPO (2.20 mmol.) was dissolved in 39.0 ml. of degassed cumene, and decomposed at 30.0°C for 24 hr.

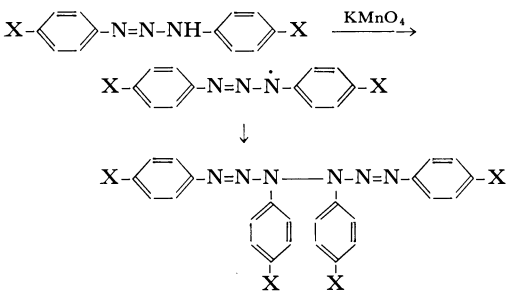
from the decomposition of DTDPO at 30°C.

It is plausible that the initial step of the decomposition of DTDPO in inert solvents may be represented as follows:

$$MeC_6H_4\text{-}N{=}N\text{-}\underset{\displaystyle C_6H_5}{N}\text{-}N{=}N\text{-}\underset{\displaystyle C_6H_5}{N}\text{-}N{=}N\text{-}C_6H_4Me \xrightarrow{(1)} MeC_6H_4\text{-}N{=}N\text{-}\dot{\underset{\displaystyle C_6H_5}{N}} + N_2 + \dot{\underset{\displaystyle C_6H_5}{N}}\text{-}N{=}N\text{-}C_6H_4Me$$

The production of toluene, bezene, azobenzenes, and about three moles of nitrogen from a mole of DTDPO cannot be explained by the reaction 1. Obviously further consideration and refinement of the mechanism is necessary.

Theilacker and Fintelmann[2] oxidized 1, 3-diaryl-triazenes with potassium permanganate, thus obtaining unstable crystals of 1, 3, 4, 6-tetraaryl-1, 5-hexaazdienes from the triazenes substituted with electron-withdrawing groups on the arene rings.



When there are no substituents or when there are electron-releasing substituents on the arene rings, no hexaazdienes were obtained, only such decomposition products as azobenzenes. Even the hexaazdienes substituted with electron-withdrawing groups were rather unstable; they were found to decompose gradually, even in cold, yielding substituted azobenzenes.

$$Ar\text{-}N{=}N\text{-}\underset{\displaystyle Ar'}{N}\text{-}\underset{\displaystyle Ar'}{N}\text{-}N{=}N\text{-}Ar \rightarrow 2Ar\text{-}N{=}N\bullet + Ar'\text{-}N{=}N\text{-}Ar' \rightarrow 2Ar\bullet + 2N_2$$

These facts appear to be quite relevant to the decomposition of DTDPO in cumene. It is likely that the diaryltriazenyl radicals formed by the reaction 1 combine to form 1, 3, 4, 6-tetraaryl-1, 5-hexaazdienes, which then rapidly decompose to yield substituted azobenzenes, toluene, benzene, and bicumyl. Since these arene rings are either nonsubstituted or substituted with electron-releasing groups, it is understandable that no hexaazdienes were found as the intermediates in the decomposition of DTDPO.

Table II shows that only a small amount of 1-*p*-tolyl-3-phenyltriazene was formed; one has therefore to assume that the majority of the triazenyl radicals combine with each other. This assumption is supported by the formation of almost three moles of nitrogen and considerable amounts of azobenzenes, benzene, toluene, and bicumyl. It is reasonable that the triazenyl radicals do not react with the solvent molecules and do not survive long enough to recombine with each other, since the triazenyl radical is more stable than the 1-methyl-1-phenylethyl radical, which is formed by hydrogen-abstraction from cumene by the triazenyl radical.

Since the triazenyl radical formed by the abstraction of a hydrogen atom from 1-*p*-tolyl-3-phenyltriazene is stabilized by the resonance:

$$MeC_6H_4\text{-}N{=}N\text{-}\dot{N}\text{-}C_6H_5 \leftrightarrow MeC_6H_4\text{-}\dot{N}\text{-}N{=}N\text{-}C_6H_5$$
(A) (B)

there are three possible combinations of these radicals: A and A, A and B, and B and B. Upon decomposition, A-A would yield azobenzene, the *p*-tolyl radical and nitrogen; A-B would yield 4-methylazobenzene, *p*-tolyl and phenyl radicals and nitrogen; B-B would yield 4, 4-dimethylazobenzene, the phenyl radical and nitrogen. Since no 4, 4-dimethylazobenzene was found in the decomposition products of DTDPO, the

$$2MeC_6H_4\cdot + 2N_2 + C_6H_5\text{-}N{=}N\text{-}C_6H_5 \xleftarrow{(3)} MeC_6H_4\text{-}N{=}N\text{-}\underset{\displaystyle C_6H_5}{N}\text{-}N{=}N\text{-}C_6H_4Me \text{ (A)-(A)}$$

$$\xleftarrow{(2)} \boxed{MeC_6H_4\text{-}N{=}N\text{-}\dot{\underset{\displaystyle C_6H_5}{N}} + \dot{\underset{\displaystyle C_6H_5}{N}}\text{-}N{=}N\text{-}C_6H_4Me} \xrightarrow{(4)} MeC_6H_4\text{-}N{=}N\text{-}\underset{\displaystyle C_6H_5}{\overset{\displaystyle C_6H_4Me}{N}}\text{-}N{=}N\text{-}C_6H_5 \text{ (A)-(B)}$$

$$\xrightarrow{(5)} MeC_6H_4\cdot + 2N_2 + C_6H_5\text{-}N{=}N\text{-}C_6H_4Me' + \cdot C_6H_5$$

$$MeC_6H_4\cdot + C_6H_5CHMe_2 \xrightarrow{(6)} MeC_6H_5 + C_6H_5\dot{C}Me_2$$

$$C_6H_5\cdot + C_6H_5CHMe_2 \xrightarrow{(7)} C_6H_6 + C_6H_5\dot{C}Me_2$$

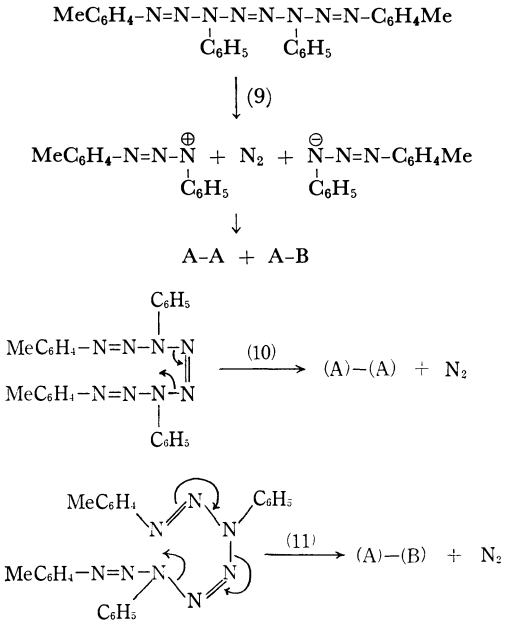
$$2C_6H_5\dot{C}Me_2 \xrightarrow{(8)} (C_6H_5CMe_2)_2$$

2) W. Theilacker and E-C. Fintelmann, *Chem. Ber.*, **91**, 1597 (1958).

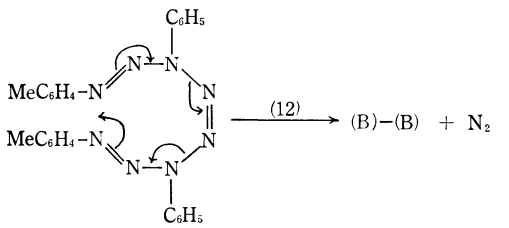
combination between B and B did not occur to any measurable extent. Both phenyl and *p*-tolyl radicals would abstract hydrogen atoms from cumene molecules, and the cumyl radicals thus produced would combine to form bicumyl molecules.

The reactions 1—8 are consistent with the experimental results and can account for all the products shown in Table II.

However, the formation of the 1, 3, 4, 6-tetraarylhexaazdienes, A-A and A-B, is possible by another route, namely, the heterolytic decomposition of DTDPO:



Although B-B was not found in the decomposition products, the formation of B-B is also possible by a similar cyclic route:



The heterolytic decomposition of DTDPO and the subsequent decomposition of hexaazdienes (i. e., the reactions 9, 10, 11, 3, 5, 6, 7, and 8) can account for all the products shown in Table II.

The choice between the homolytic mechanism and the heterolytic mechanism for the decomposition of DTDPO cannot be made easily. However, the homolytic mechanism (Reactions 1—8) seems more plausible than the heterolytic mechanism (Reactions 9, 10, 11, 3, 5, 6, 7 and 8), in view of the facts that: (a) the activation parameters

TABLE III. RATES OF DECOMPOSITION OF VARIOUS AZO COMPOUNDS

Azo compound	Solvent	Temp. °C	$10^4 k_1$ sec^{-1}	Ref.
Me–N=N–Me	(Gas)	300	5.6	5

Ph–N=N–CPh_3	Toluene	53	2.25	8
	Benzene	25	0.042	9
DTDPO	Cumene	20	0.190	
C_7H_7–N=N–$N(C_7H_7)$–N=N–C_7H_7	Cumene	25.8	12.9	4

($\Delta H^{\ddagger}$=25.1 kcal./mol., $\Delta S^{\ddagger}$=5.8 e. u.) are consistent with a homolytic decomposition rather than a heterolytic decomposition, and (b) the symmetric azo compounds or peroxides rarely undergo heterolytic decomposition.

In Table III, the rate of the decomposition of DTDPO is compared with the rates of the decomposition of several azohydrocarbons. The fact that DTDPO is more stable than 1, 3, 5-tri-*p*-tolyl-1, 4-pentaazdiene is rather surprising. This fact should be discussed further.

The lone-pair electrons of 3- and 6-nitrogen atoms of DTDPO are in resonance with the *p*-orbitals of azo linkages; hence, these orbitals

are probably parallel with one another, as is shown in Fig. 3(a). When the molecule of DTDPO with the structure shown in Fig. 3(a) is to decompose, the $MeC_6H_4N{=}N{-}\dot{N}{-}C_6H_5$ radical to be formed in the transition state does not have the resonance energy which is available to the molecules with the 3(b) structure. The rotation of the groups in 3(a) to obtain 3(b) is possible in solution. However, the molecule of DTDPO possesses four bulky arene rings on the chain of eight nitrogen atoms; it is very rare for the molecule of DTDPO with so much freedom to have the orientation represented in Fig. 3(b). Thus, the extremely small possibility of attaining a transition state stabilized with the resonance represented in Fig. 3(b) may be the reason for the rather slow rate of decomposition of DTDPO.

Experimental

Materials.—Tokyo Kasei Co. G. R. cumene was shaken with portions of concentrated sulfuric acid until the acid layer no longer became colored on long shaking. After washing with water, a sodium bicarbonate solution, and water again, the cumene was dried with calcium chloride and distilled from sodium through a 90-cm. column packed with glass helices. The center fraction, boiling at 152—153.2°C, was stored under nitrogen atmosphere and used.

All the other chemicals were those of the best grade commercially available, and were used without further purification.

The Synthesis of 1-*p*-Tolyl-3-phenyl-1-tetraazene (TPT).—The method of Wohl and Schiff[3] was modified a little. Into a mixture of 22 g. of *p*-toluidine (0.2 mol.) and 30 ml. of water, 52 ml. of concentrated hydrochloric acid (0.6 mol.) was added. The mixture was heated to dissolve its elements, and then the solution was cooled thoroughly by adding cracked ice to it and by placing it in an ice bath. The diazotization was carried out at 0°C by adding a solution of 14 g. of sodium nitrite (0.2 mol.) in 40 ml. of water the toluidine hydrochloride solution drop by drop.

Into a mixture of 22 g. of phenylhydrazine (0.2 mol.), 50 ml. of water, and 12 g. of acetic acid (0.2 mol.), a solution of 82 g. of sodium acetate (1 mol.) in 20 ml. of acetic acid and 120 ml. of water was added all at once; the mixture was then cooled to 0°C. Into this phenylhydrazine mixture the *p*-toluenediazonium chloride solution was stirred in portions at temperatures between 0 and 2°C. A light yellow substance was formed at once and floated on the surface of the water layer. It changed to a yellowish brown after one hour of stirring in an ice bath. The crude brown product was then collected by filtration; 22 g. (50%). The melting point of the crude product was 63—67°C, but when 22 g. of the crude product was recrystallized in ether at −73°C, 9.8 g. of fine yellow crystals was obtained, melting at 74.5°C with gas evolution (reported by Wohl and Schiff, 66—67°C).[1]

The Synthesis of 1,8-Di-*p*-tolyl-3,6-diphenyl-1,4,7-octaaztriene (DTDPO).—The method of Wohl and Schiff[1] was modified a little. After two grams of TPT had been dissolved in 25 ml. of ether cooled at 0°C, the solution was cooled to −12°C. Into this cold TPT solution, 50 ml. of a 1% potassium permanganate solution was added slowly over a 20-min. period A pale yellow substance gradually appeared and floated at the top of the upper ethereal layer, and the violet color of potassium permanganate changed to dark brown. The mixture was stirred for 30 min. at −4—1°C after the potassium permanganate solution had been added.

The two layers were then separated with a separatory funnel, and the pale yellow product, contaminated with some black manganese dioxide, was filtered from the ethereal layer. Fifteen milliliters of a 3% sulfurous acid solution cooled to 0°C was added to the residue in the funnel in order to wash away the black manganese dioxide. The crude DTDPO was then washed well with cold water. The yield of the crude DTDPO was 0.6 g.; m. p. 61.5—64°C (with an evolution of gas).

The slightly wet DTDPO (0.6 g.) was dissolved in 5 ml. of ether at room temperature, and the solution was cooled to −73°C. The ice formed was removed by decantation. After 10 min. at −73°C, light yellow needles were formed and collected by filtration. The yield was 0.3 g.; m. p. 65.5—66.0°C (reported by Wohl and Schiff[1], 64—67°C).

The crystals of DTDPO are extremely sensitive to mechanical shock. After the crystals had been dried by an aspirator for about four minutes at room temperature, and the rubber tubing had then been taken off, the stream of air suddenly flowing into the vessel was a shock sufficient to cause an explosion of DTDPO crystals. DTDPO also exploded when it was rubbed in a mortar, or when it was dropped into concentrated hydrochloric or sulfuric acid.

When crystals of DTDPO were dissolved in carbon tetrachloride, dichloromethane, ether or toluene at room temperature, they quickly decomposed, with an evolution of gas. However, the solid DTDPO was rather stable when there was no mechanical shock. The crystals of DTDPO did not decompose at all when kept at −17°C in darkness for at least three weeks; the melting point of crystals decreased by only 1—2°C when they were placed in the open air for two days. The fact that it is rather stable as a solid but unstable in a solution is reminiscent of the behavior of 1, 3, 5-tri-*p*-tolyl-1, 4-pentaazdiene.[4]

Kinetic Procedure.—About 1 g. of DTDPO was placed in a glass vessel attached to an end of a U-shaped tube, and then about 40 ml. of cumene was

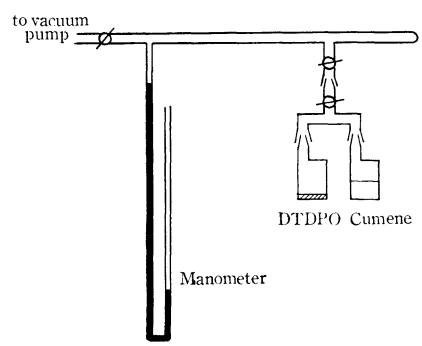

Fig. 4

placed in a glass vessel attached to the other end of the U-shaped tube, as is shown in Fig. 4. These two were degassed and then mixed at −78°C. Then this U-tube was attached to a vacuum system of a known volume with the mercury manometer. The U-tube was immersed in a small bath of a constant temperature by elevating the bath with a lab-jack. By turning a stopcock, the U-tube was opened to the evacuated system, and the increase in the pressure of the system was measured versus the time. After the U-tube had been warmed to the temperature of the bath, the plots of the increase in the pressure showed good first-order behavior. The infinity point was taken after about ten half-lives.

Procedure for Product Studies.—The DTDPO solution used for kinetic studies was analyzed for the products of decomposition. The amount of nitrogen was determined from the data on the pressure, the volume and the temperature of the system. The cumene solution was distilled to yield brownish solids and a distillate. When the distillate was investigated by a Shimadzu Gas Chromatograph GC-2B, the peaks corresponding to benzene and toluene were observed, in addition to the peak of cumene. The amounts of benzene and toluene were determined by using ethanol as the internal standard.

The infrared spectrum of the brownish residue showed the absorptions of bicumyl (2, 3-dimethyl-2, 3-diphenylbutane), azobenzene, 4-methylazobenzene, and 3-phenyl-1-*p*-tolyltriazene. The elution chromatography of these brownish solids on alumina yielded bicumyl as the first fraction, a mixture of azobenzene and 4-methylazobenzene as the second fraction, and 3-phenyl-1-*p*-tolyltriazene as the last fraction. The identity of bicumyl and 3-phenyl-1-*p*-tolyltriazene was established by comparing their melting points and infrared spectra with those of authentic samples. The amounts of azobenzene and 4-methylazobenzene were determined by comparing the infrared spectrum of the mixture with those of authentic samples, and finally by preparing a synthetic mixture of azobenzene and 4-methylazobenzene; the infrared spectrum of this synthetic mixture was identical with that of the mixture derived from the reaction products.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1054—1058 (1966)

The Chemistry of Polyazanes. III. The Reaction of Nitrosobenzene with Hydrazine and Phenylhydrazine

By Hiroshi MINATO and Takiko FUJISAWA

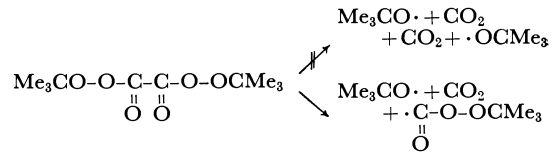
Department of Chemistry, International Christian University, Mitaka, Tokyo

(Received October 19, 1965)

The reaction between nitrosobenzene and hydrazine was studied. Aniline and nitrogen were found to be the products, but it was not certain whether or not phenyltriazene existed as an intermediate. Then the reaction between nitrosobenzene and phenylhydrazine was studied. The products were azoxybenzene, diphenylamine, benzene and nitrogen. The reaction between *p*-nitrosotoluene and phenylhydrazine yielded 4, 4′-azoxytoluene, 4-methyldiphenylamine, benzene and nitrogen. The mechanisms of these reactions were discussed on the basis of these findings.

It has been of interest to seek for the initiators which form free radicals at low temperatures. *t*-Butyl triphenylperacetate is an unstable perester, decompositing at lower temperatures to yield free radicals, but this compound cannot be used as an initiator, since one of the free radicals produced, the triphenylmethyl radical, is so stable that it does not initiate polymerization.

The possibility of producing two carbon dioxide molecules to further hasten decomposition while still producing highly-reactive radicals has been explored in the study of di-*t*-butyl peroxalate,[1,2] but later work[3,4] has suggested that in decomposing these peroxalates form only one molecule of carbon dioxide in the transition state.



In view of the fact that the attempt to produce two carbon dioxide molecules at the transition state failed, it seemed of great interest to attempt to prepare the 1, 4-disubstituted tetraazdienes, which might decompose with a concerted breakage

* Reactants were mixed below −30°C, and then the mixture was gradually warmed up to room temperature.

of three bonds, with the expulsion of two molecules of nitrogen. It is known that nitrosobenzene reacts with aniline to yield azobenzene, and it seemed plausible that the reaction between nitrosobenzene and hydrazine might yield a tetraazdiene. Therefore, the reaction between nitrosobenzene and hydrazine has been investigated:

$$C_6H_5NO + H_2NC_6H_5 \rightarrow C_6H_5\text{-}N{=}N\text{-}C_6H_5$$

$$2C_6H_5NO + N_2H_4 \overset{?}{\rightarrow} C_6H_5\text{-}N{=}N\text{-}N{=}N\text{-}C_6H_5$$

During the investigation of various polyazanes, we have come across a paper, written by Mills, reporting that the reaction between nitrosobenzene and phenylhydrazine yields nitrogen and azobenzene.[5]

$$C_6H_5NO + H_2NNHC_6H_5 \rightarrow N_2 + C_6H_5\text{-}N{=}N\text{-}C_6H_5$$

Since the reaction between nitrosobenzene and aniline yields azobenzene, one would expect that the reaction between nitrosobenzene and phenylhydrazine would yield 1, 3-diphenyltriazene, which is a well-characterized, stable compound:

$$C_6H_5NO + H_2NNHC_6H_5 \overset{?}{\rightarrow} C_6H_5\text{-}N{=}N\text{-}NH\text{-}C_6H_5$$

Obviously the reaction of nitrosobenzene and phenylhydrazine yielding azobenzene is not straightforward; it therefore calls for further investigation. Therefore, the reaction between nitrosobenzene and phenylhydrazine and the reaction between *p*-nitrosotoluene and phenylhydrazine have been investigated and will be described in this paper.

Results and Discussion

The Reaction between Nitrosobenzene and Hydrazine.—When nitrosobenzene was mixed with hydrazine in dichloromethane at −50——78°C most of the nitrosobenzene remained as a solid due to its low solubility at low temperatures, unless a great amount of the solvent was used. However, when the solution was warmed up to about −30°C, a homogeneous solution with a light green color was obtained; the color did not appear to change when the solution was kept at this temperature. Apparently, nitrosobenzene and hydrazine do not react at this temperature. When however, the solution was further warmed up to about −8°C, the green color of nitrosobenzene began to change to a yellowish brown, with an evolution of nitrogen. The evolution of nitrogen was complete after the solution had been kept at room temperature for three hours. Besides the nitrogen evolved, the products of the reaction were aniline, azobenzene and unreacted nitrosobenzene, as is shown in Table I. In any case, the gas chromatographic analysis showed the absence of benzene, which is a product likely to be formed if 1, 4-diphenyl-1, 3-tetraazdiene was formed. Apparently, one mole of hydrazine reacted with only one mole of nitrosobenzene, and aniline and nitrogen were produced. It is not certain whether or not phenyltriazene was present as the intermediate.

$$C_6H_5NO + N_2H_4 \rightarrow (C_6H_5\text{-}N{=}N\text{-}NH_2\ ?) \rightarrow C_6H_5NH_2 + N_2$$

Dimroth prepared phenyltriazene by reducing phenyl azide with stannous chloride and dry hydrogen chloride in absolute ether at −20°,C and then by purifying the phenyltriazene through its copper derivative, which was then decomposed with aqueous potassium cyanide at a low temperature:[6]

$$C_6H_5\text{-}N{=}N^+{=}N^- \xrightarrow{SnCl_2} C_6H_5\text{-}N{=}N\text{-}NH_2$$

Phenyltriazene was found to be in the form of colorless leaflets melting at 50°C, and it was very unstable. It rapidly decomposed into aniline anp nitrogen n all solvents at room temperature:

5) C. Mills, *J. Chem. Soc.*, **67**, 925 (1895).

6) O. Dimroth, *Ber.*, **40**, 2378 (1907).

$$C_6H_5\text{-}N{=}N\text{-}NH_2 \rightarrow C_6H_5NH_2 + N_2$$

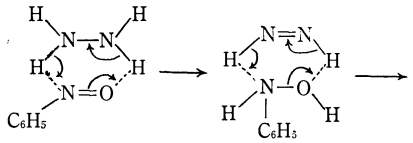
It seemed of interest to determine whether or not the phenyltriazene was the intermediate at the reaction between hydrazine and nitrosobenzene. Attempts have been made to find experimental conditions where nitrosobenzene and hydrazine react and yet the product (presumably phenyltriazene) does not decompose to yield nitrogen. Whether nitrosobenzene has reacted or not can be determined from the loss of the light green color. However, it was found that the loss of the green color was always accompanied by the evolution of nitrogen, even though the solution was warmed up very slowly. In an attempt to facilitate the reaction between the hypothetical phenyltriazene and another mole of nitrosobenzene, sodium methoxide was added to the reaction mixture, but there was no essential difference in the products.

These experimental findings can be explained by either of the following two assumptions:

(A) Nitrosobenzene reacts with hydrazine to form phenyltriazene, which is so unstable that it immediately decomposes before reacting with another mole of nitrosobenzene.

(B) Nitrosobenzene reacts with hydrazine to yield aniline and nitrogen, without going through phenyltriazene as the intermediate.

The mechanism B may best be described in the following scheme:



$$C_6H_5NH_2 + N_2 + H_2O$$

The experimental findings described so far are not sufficient for us to make a choice between these two mechanisms, but the experimental evidence to be described below for the reaction between nitrosobenzene and phenylhydrazine seems to indicate that the reaction between nitrosobenzene and hydrazine is best described by the mechanism B.

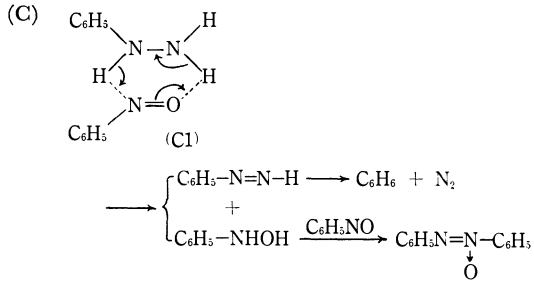
The Reaction between Nitrosobenzene and Phenylhydrazine.—Phenylhydrazine was added drop by drop to a stirred solution of nitrosobenzene in dichloromethane at room temperature until no more evolution of nitrogen occurred. The products of the reaction were then identified by the use of elution chromatography and by a study of the infrared spectra; the results are summarized in Table II.

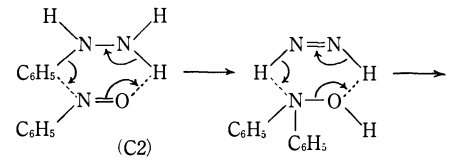
TABLE II. PRODUCTS OF THE REACTION BETWEEN NITROSOBENZENE AND PHENYLHYDRAZINE

Reactant	Nitrosobenzene	10.0 mmol.
	Phenylhydrazine	3.95
Product	Benzene	1.90 mmol.
	Azoxybenzene	3.59
	Diphenylamine	1.38
$\%C_6H_5$ of C_6H_5NO	accounted for	81.7%
$\%C_6H_5$ of $C_6H_5N_2H_3$	accounted for	83.0%

The formation of benzene, azoxybenzene and diphenylamine can be explained by either of the following two mechanisms, C and D:

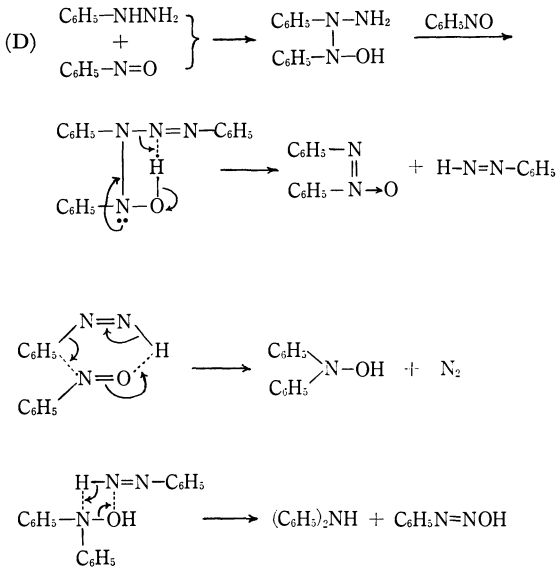
(C)





$$(C_6H_5)_2NH + N_2 + H_2O$$

(D)



Although the mechanism C looks more attractive than the mechanism D, the products of the reaction are consistent with the mechanism D as well. Therefore, the reaction between *p*-nitrosotoluene and phenylhydrazine was investigated in order to find out which of these two mechanisms is better applicable to these reactions.

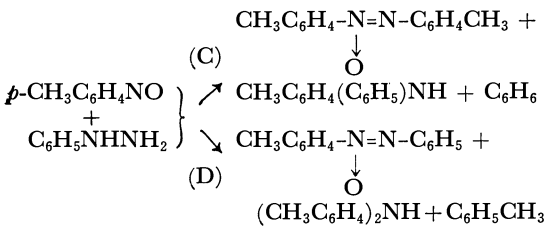
The Reaction between *p*-Nitrosotoluene and Phenylhydrazine.—*p*-Nitrosotoluene and phenylhydrazine were allowed to react in the same manner

as in the case of nitrosobenzene and phenylhydrazine. The rate of the evolution of nitrogen was less vigorous than in the case of nitrosobenzene. The products of the reaction are summarized in Table III.

Table III. Products of the reaction between *p*-nitrosotoluene and phenylhydrazine

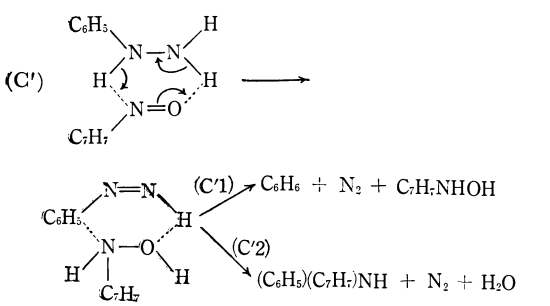
Reactant	*p*-Nitrosotoluene	10.0 mmol.
	Phenylhydrazine	4.37
Product	Benzene	1.63 mmol.
	4, 4'-Azoxytoluene	3.37
	4-Methyldiphenylamine	0.79
	Phenylhydrazine	0.63
$\%CH_3C_6H_4$ of $CH_3C_6H_4NO$ accounted for		75.3%
$\%C_6H_5$ of $C_6H_5N_2H_3$ accounted for		69.8

If the mechanism C is right, the products should be 4, 4'-azoxytoluene, 4-methyldiphenylamine and benzene. On the other hand, if the mechanism D is right, the products should be 4-methylazoxybenzene, 4, 4'-dimethyldiphenylamine and toluene:



The products of the reaction shown in Table III contradict the mechanism D, but they are consistent with the mechanism C.

The mechanism C assumes both phenylhydroxylamine and diphenylhydroxylamine as intermediates. However, a modified mechanism, C', is possible, which assumes only phenylhydroxylamine as an intermediate:



According to the mechanism C', combined phenyldiimide and *p*-tolylhydroxylamine either depart from each other to yield benzene and nitrogen according to the step C'1, or react further in a solvent cage to yield 4-methyldiphenylamine according to the step C'2. The ratio of C'1 to C'2 can be calculated from the yields of benzene and 4-methyldiphenylamine to be 2.06; in other words, 67% of the reaction proceeds by C'1, while 33% proceeds by C'2. In th ecase of nitrosobenzene, the ratio of C'1 to C'2 is 1.38; in other words, 58% of the reaction proceeds by C'1, while 42% proceeds by C'2.

In the case of the reaction between nitrosobenzene and hydrazine, we assumed a combination of intermediates, diimide and phenylhydroxylamine similar to that in the mechanism B. In this case, however, all the phenylhydroxylamine must have been reduced with diimide in a solvent cage, because if some phenylhydroxylamine departs from diimide without being reduced further, it should react with nitrosobenzene to yield azoxybenzene; the latter was not, however, found in any products studies of the reaction. These findings show the stronger reducing power of diimide compared with that of phenyldiimide.

As for the choice between the mechanisms C and C', no experimental evidence is available which favors one over the other, although C' appears a little more attractive than C.

Experimental

Materials.—Nitrosobenzene and *p*-nitrosotoluene were prepared by the reduction of nitrobenzene and *p*-nitrotoluene respectively.[7] Commercial hydrazine hydrate was dehydrated by refluxing it with sodium hydroxide.

4, 4'-Azoxytoluene was prepared by heating 500 mg. of 4, 4'-azotoluene in 2.5 ml. of acetic acid containing 0.1 ml. of 30% hydrogen peroxide in a water bath.[8] The yellow crystals obtained were recrystallized from ethanol, m. p. 70°C.

All the other chemicals were of the best grade commercially available and were used without further purification.

The Reaction between Nitrosobenzene and Hydrazine.—*Run. 1.*—To a solution of hydrazine (0.0512 g., 1.60 mmol.) in dichloromethane (2.587 g.), nitrosobenzene (0.1069 g., 1.00 mmol.) was added at −30°C. The transparent, light green solution thus obtained did not change when kept at −30°C. When it was gradually warmed up, the color changed to a yellowish green at −10°C, and nitrogen gas started to evolve at −8°C. The evolution of nitrogen ceased when the solution was kept for three hours at room temperature, and the color of the solution changed to a yellowish brown. The infrared specturm of the solution was completely accounted for by the absorption of aniline and azobenzene. 0.855 mmol. of aniline and 0.0697 mmol. of azobenzene were found to be present by the use of the absorptions at 1620 cm^{-1} (for aniline) and 1073 cm^{-1} (for azobenzene.).

Run 2.—The procedure was essentially the same as in Run 1, except that about equimolar amounts of

7) E. C. Horning, "Organic Syntheses," Coll. Vol. I, 668 (1955).

8) T. Parsons, Jr., and J. C. Bailar, Jr., *J. Am. Chem. Soc.*, **58**, 269 (1936).

nitrosobenzene and hydrazine were used and the reactants solutions were degassed before mixing. The infrared specturm of the dichloromethane solution of the products was completely accounted for by the absorption of aniline and undecomposed nitrosobenzene. The amount of nitrosobenzene was determined by the use of an absorption at 1120 cm^{-1}.

Run 3.—A solution of hydrazine (0.286 g., 8.92 mmol.) in 20 ml. of methanol was placed in a container attached to one end of a U-shaped tube; solid nitrosobenzene (2.388 g., 22.3 mmol.) was placed in a container attached to the other end of the U-shaped tube. After these two had been degassed by the usual technique on a vacuum system, they were mixed at −78°C and then gradually warmed up. The evolution of gas started at −10°C, it became vigorous when the mixture was further warmed up to room temperature. The reaction had been completed in about three hours at room temperature. After the mixture had been kept at room temperature for one day, it was distilled in a vacuum; a greenish distillate and a brownish residue were thus obtained. The greenish distillate was found to be a methanol solution, with small amounts of nitrosobenzene and water, by a study of its infrared spectrum and by vapor-phase chromatography. No benzene was found in the distillate. The infrared spectrum of the brownish residue was completely accounted for by the absorption of aniline, nitrosobenzene and azobenzene.

Run 4.—The procedure was essentially the same as the one used for Run 3, except that sodium methoxide (2.0 mmol.) was added to the mixture.

The Reaction between Nitrosobenzene and Phenylhydrazine.—Phenylhydrazine was stirred, drop by drop, into a solution of nitrosobenzene (1.072 g., 10.0 mmol.) in dichloromethane (3.0 ml.) at room temperature. Reaction occurred with a vigorous evolution of nitrogen upon the addition of each drop of phenylhydrazine. When 0.4273 g. (3.95 mmol.) of phenylhydrazine was added, no more reaction occurred upon the addition of another drop of phenylhydrazine. When the dark red solution obtained was distilled, a colorless distillate and a dark red oil were obtained.

The colorless distillate was viewed against pure dichloromethane in the infrared region, and the spectrum was superimposable upon that of pure benzene. 1.90 mmol. of the benzene was found to be present by a comparison of the specturm with that of a solution containing a known amount of benzene.

1.1548 g. of dark red oil was chromatographed on about 25 g. of alumina. Fractions 1—6, eluted with petroleum ether - benzene, were in the form of light yellow crystals (0.6377 g.), melting at 34.5—35.5°C. Its infrared spectrum was identical with that of azoxybenzene. When recrystallized from ethanol, the crystals melted at 36°C; the melting point was not depressed when authentic azoxybenzene (m. p. 36°C) was mixed with these yellow crystals.

Fractions 8—11, eluted with benzene-ether, were in the form of colorless crystals (0.1770 g.), melting at 52—53°C. The infrared spectrum was identical with that of diphenylamine. When recrystallized, the crystals melted at 54°C, and the melting point was not depressed when authentic diphenylamine (m. p. 54°C) was mixed with these crystals. Fraction 7, eluted with benzene, was a mixture of azoxybenzene and diphenylamine; the amounts of the compounds were determined by a comparison of the infrared spectrum of the mixture with the spectra of authentic samples.

The Reaction between *p*-Nitrosotoluene and Phenylhydrazine.—Phenylhydrazine was stirred drop by drop into a solution of *p*-nitrosotoluene (1.2109 g., 10.0 mmol.) in dichloromethane (5.0 ml.) at room temperature. The evolution of nitrogen occurred less vigorously than in the case of nitrosobenzene and phenylhydrazine. When 0.4720 g. (4.37 mmol.) of phenylhydrazine was added, no more reaction occurred upon the addition of another drop of phenylhydrazine. When the dark orange solution was distilled, a colorless distillate and a brown solid were obtained.

The colorless distillate was viewed against pure dichloromethane in the infrared region; the spectrum was identical with that of pure benzene. 1.63 mmol. of benzene was found to be present by comparison with the spectrum of a solution containing a known amount of benzene.

1.1924 g. of a brown solid was chromatographed on about 25 g. of alumina. Fractions 1—9, eluted with petroleum ether - benzene, were light yellow crystals (0.7135 g.), melting at 69—70°C. Its infrared spectrum was identical with that of 4, 4'-azoxytoluene. The melting point was not depressed when authentic 4, 4'-azoxytoluene (m. p. 69—70°C) was mixed with these light yellow crystals.

Fractions 11—13, eluted with benzene - ether, were colorless needles (0.0729 g.), melting at 79—86°C. Its infrared spectrum was very similar to that of diphenylamine. When recrystallized from ligroin, the colorless needles melted sharply at 88—89°C, the melting point of authentic 4-methyldiphenylamine. Since diphenylamine melts at 54°C and 4,4'-dimethyldiphenylamine, at 79°C, this colorless crystalline amine can be identified with 4-methyldiphenylamine.

Fraction 10, eluted with benzene, weighed 0.0493 g. and was a mixture of 4, 4'-azoxytoluene and 4-methyldiphenylamine. The amounts of each compound were determined by a comparison of the infrared spectrum of the fraction 10 with the spectra of pure compounds.

Fractions 14 and 15, eluted with ether and methanol, were a black oil, weighing 0.1286 g., which was found to contain 0.0678 g. of unreacted phenylhydrazine.

The Pyrolysis and Thermochromism of the Crystalline Powder of Dianthraquinone

By Haruo KURODA and Ryoichi SUDO*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received November 15, 1965)

The crystalline powder of dianthraquinone changes its color from yellow to green when it is heated above 250°C. A heat-treated powder of a green color exhibits an ESR absorption, the line width of which is about 7 gauss, and the *g*-value, 2.0032. The intensity of the ESR absorption was studied as a function of the temperature of heat-treatment and the heating time. The activation energy for the formation of the paramagnetic species is estimated to be 74 kcal./mol. The X-ray diffraction patterns of heat-treated specimens indicate that a marked disorder is produced in the crystal structure by the heat treatment and that, finally, the dianthraquinone crystal becomes an amorphous solid. A close correlation can be found between the intensity of ESR absorption and the structural change. Polymerization occurs at higher temperatures and results in the formation of a dark green solid insoluble in organic solvents. It is suggested that the initial process of these thermal changes is associated with the thermochromism of dianthraquinone.

It is well known that a solution of dianthraquinone shows a thermochromism, namely, a reversible change of color from yellow to green, as its temperature is raised.[1-3] Nielsen and Fraenkel found that the solution shows an electron-spin-resonance (ESR) absorption when it is in the green-colored state at an elevated temperature.[4] Thus, it is suggested that the thermochromism of dianthraquinone is due to the thermal equilibrium between two isomeric forms of the molecule, in which the high energy form is in a biradical state or a triplet state. The molecular structure of this high energy form has been a matter of discussion for a long time, different models have been proposed by several investigators.[5-8]

A crystalline powder of dianthraquinone shows a similar color change at elevated temperatures.[1] The color changes from yellow to green when it is heated to about 250°C. In this case, however, the change is not reversible, and the powder remains in the green colored state as the temperature is lowered. According to Mayer,[1] the original color can be completely recovered by recrystallization. Matsunaga[9] showed that the diamagnetic susceptibility of the dianthraquinone powder appreciably decreases when it is treated for about 1 hr. at temperatures above 240°C. This suggests the formation of paramagnetic species, which is in agreement with the observation of ESR absorption by Nielsen and Fraenkel.[4] According to Matsunaga,[9] however, the change caused by the heat treatment is by no means reversible, and some kind of polymerization seems to occur during the heat treatment, which makes it hard to dissolve the heat-treated solid in organic solvents. He concluded, therefore, that the color change of the dianthraquinone powder is not due to the thermochromism, but to a chemical reaction or a pyrolysis.

Extensive investigations have been made into the evolution of paramagnetism in the process of the pyrolysis of various organic materials.[10-13] When we compare the behavior of dianthraquinone with the pyrolysis of a usual organic compound, the initial variation in ESR absorption with the heat-treatment at temperatures below 300°C is considerably different. It seems of interest to see, therefore, whether this peculiarity in the thermal change of dianthraquinone powder is associated with the thermochromism or not. In the present study we have investigated the ESR absorption and the X-ray diffraction on the heat-treated powder of dianthraquinone in order to elucidate the nature of the thermal change.

Experimental

Dianthraquinone was synthesized from the commercial anthraquinone,[9] and purified by recrystallization repeated three times.* The dianthraquinone powder was heat-treated in an atmosphere of ambient nitrogen by means of a small electric furnace. The heat-treatment temperature (HTT) was varied in the 200—300°C range. The powder was heat-treated while sealed in a glass capillary to facilitate ESR measurement. The X-ray diffraction was examined by using a X-ray diffractometer, Geigerflex (Rigaku Denki Co.), with Cu$K\alpha$ radiation, and the ESR spectrum, by means of a Hitachi MPS-1 ESR Spectrometer. All measurements were made at room temperature.

Results and Discussion

At a low HTT, below 200°C, the dianthraquinone powder changes little in color, even if it is heated for several hours. No ESR absorption can be detected with a heat-treated powder in this case. The color change becomes appreciable, however, as the HTT exceeds 240°C. After a 25 min. treatment, the color becomes pale green at 250°C and green at 270°C. The ESR absorption can be observed with a green-colored powder, as has been reported by Nielsen and Fraenkel. Its intensity increases parallel with the color change, the absorption being weak for a pale green powder and strong for a green one. The spectrum consists of one broad line without a structure, the line width being about 7 gauss and the g-value, 2.0032. The spin concentration estimated from the intensity of the ESR absorption is given in Table I for the powders treated for 25 min. at several temperatures. In the 200—300°C, range, the spin concentration increases as the temperature is raised, but it decreases in the 300—400°C range. If the HTT is raised above 400°C, a carbonaceous solid of a black color is formed, and the intensity of ESR absorption increases again. The change which occurs above 500°C is not different from the one found for the pyrolysis of usual organic solids.

Table I. The spin concentrations of the heat-treated powder of dianthraquinone

HTT °C	Spin concn., spins/g. Heated for 15 min. in nitrogen	Heated for 15 min. in air
230	0.84×10^{17}	1.06×10^{17}
240	1.73×10^{17}	1.85×10^{17}
252	1.11×10^{18}	1.72×10^{18}
270	7.6×10^{18}	1.36×10^{19}

The spin concentration is dependent not only on the HTT but also on the length of heat treatment. Its variation with time is shown in Fig. 1. The spin concentration increases at first linearly with time, but reaches a maximum and decreases afterward. The results shown in Fig. 1 evidently suggest that two different processes are involved in the thermal change observed here. The one is the formation of paramagnetic species, while the other is a reaction that results in the disappearance of the paramagnetism.

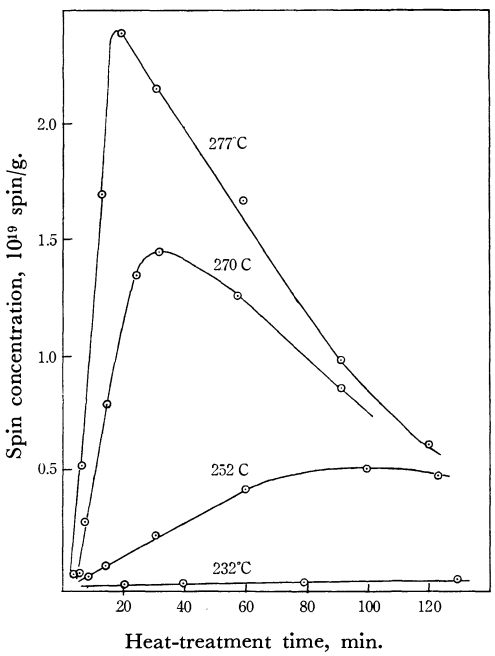

Fig. 1. The variation of spin concentration on heat-treatment of the dianthraquinone powder.

The pyrolysis of an aromatic compound usually begins at a temperature about 400°C. The paramagnetism appears at the same time, and increases with the progress of the carbonization. When the starting material contains some free radicals, however, the pyrolysis begins at lower temperatures because of the instability of the free radicals. This causes an initial decrease in the spin concentration at temperatures about 300°C.[12] In the region of much higher HTT values, however, the dependence of the spin concentration on the HTT is similar to that for the pyrolysis of usual organic compounds. The behavior of dianthraquinone powder seems similar to the case described above except that the free radicals are not present from the beginning, but are formed in the first step of the thermal change.

It should be mentioned here that the ESR absorption of the heat-treated dianthraquinone is little affected by the oxygen. No appreciable change can be found in the intensity as well as in the line width of the ESR spectrum when a specimen prepared in vacuo or in nitrogen is exposed to air. The difference in the spin concentration

* Solvesso-100 (Standard Vacuum Oil Co.) was used as the solvent.

is quite small even if dianthraquinone is heat-treated in air instead of in nitrogen, as is shown in Table I.

The X-ray diffraction patterns of several heat-treated specimens are shown in Fig. 2. The diffraction peaks due to the dianthraquinone crystal are reduced in their intensity by the heat-treatment, and a diffuse scattering appears in the background. The intensity of the diffuse scattering increases with the progress of the thermal change. A dark green solid formed by the one-hour treatment at 270°C shows a diffraction pattern consisting only of diffuse scattering, like amorphous carbons. No diffraction peak associated with a new crystalline phase appears in the HTT range studied here. We can conclude that the heat treatment causes a marked disorder in the crystal lattice of dianthraquinone, finally resulting in the formation of an amorphous solid.

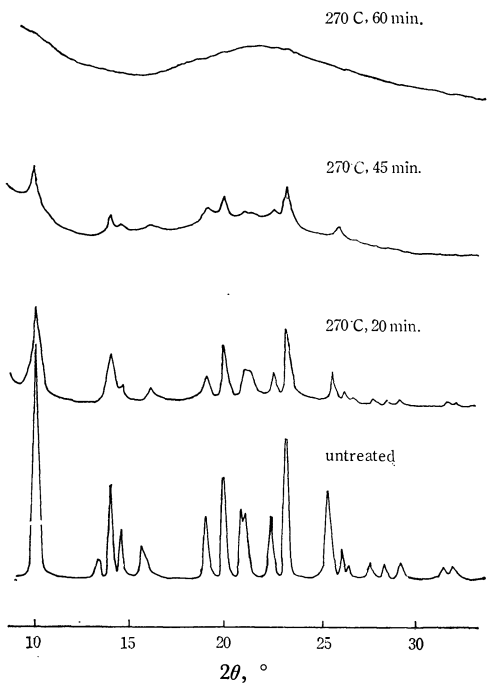

Fig. 2. The X-ray diffraction patterns of the heat-treated powders of dianthraquinone.

The ratio of the intensity of the crystalline diffraction to that of the diffuse scattering can be a measure of the crystallinity. For the value to represent the crystallinity of a heat-treated powder of dianthraquinone, we shall define here a quantity, K, by the following equation;

$$K = \int_{15°}^{30°} I_C \mathrm{d}(2\theta) \Big/ \int_{15°}^{30°} I_D \mathrm{d}(2\theta) \qquad (1)$$

where I_C is the intensity of the crystalline diffraction; I_D, that of the diffuse scattering, and 2θ, the diffraction angle. The variation of K with the heat-treatment time is shown in Fig. 3.

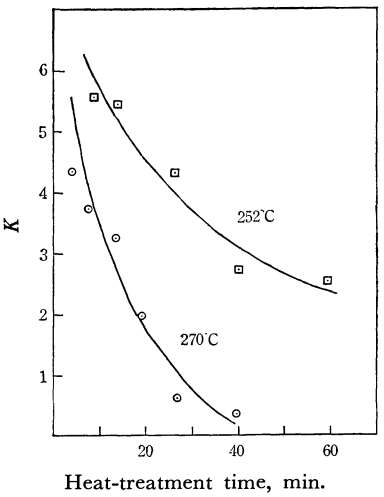

Fig. 3. The change in the crystallinity of dianthraquinone powder on heat-treatment.

In Fig. 4, the spin concentration, as determined from the ESR absorption, is plotted against the value of K. Interestingly, the points fall on a single curve in spite of the difference in the HTT. This means that the formation of the paramagnetic species and the change in the crystal structure are directly related to each other.

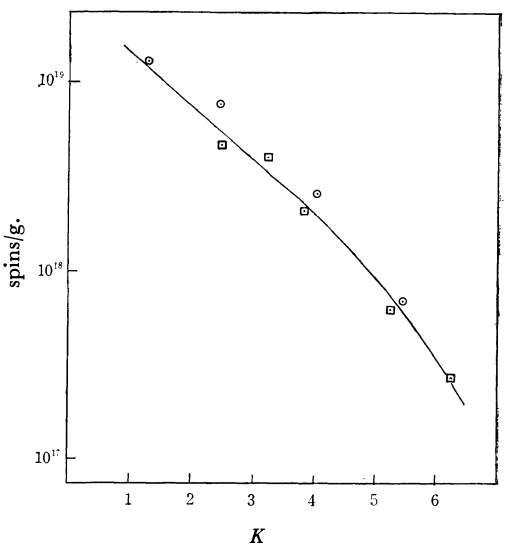

Fig. 4. The relation between the spin concentration and the crystallinity.
⊡ 252°C ⊙ 270°C

The pale green powder obtained by a short heat treatment at a low HTT can be dissolved in several organic solvents, and the original yellow color can be recovered by the recrystallization. However, a dark green powder prepared by a long treatment at 270° is insoluble in organic solvents; this is in agreement with the observation

reported by Matsunaga. Between these two extremes, there is an intermediate state where the heat-treated powder is partialy soluble. We can extract unreacted dianthraquinone from a green specimen by treating it with a solvent. In this stage of thermal change, the dianthraquinone powder gives a diffraction pattern consisting of the diffraction peaks due to dianthraquinone and a diffuse scattering, but if dianthraquinone is extracted from it, the residue shows only a diffuse scattering similar to that of the dark green solid. Therefore, the main part of the insoluble component seems to be the product of polymerization. Suppose that the evolution of the paramagnetism is entirely due to the polymerization of dianthraquinone; the residue of the extraction may then be expected to have a higher spin concentration. However, the spin concentration after the extraction of dianthraquinone is a little smaller than that before the extraction. For example, the powder treated for 25 min. at 270°C originally has 13×10^{18} spins/g., but it has 4×10^{18} spins/g. after the extraction of the unreacted dianthraquinone. It seems that the paramagnetism is associated not only with the products of polymerization, but also with dianthraquinone molecules. Presumably the initial evolution of the paramagnetism is due to the formation of dianthraquinone molecules in a metastable triplet state, as it is in the case of thermochromism in the solution.

We can estimate the activation energy required for the formation of the paramagnetic species in the dianthraquinone crystal by using the experimental data obtained on the ESR absorption. As is shown in Fig. 1, the spin concentration of the heat-treated dianthraquinone at first increases linearly with the heat-treatment time. This can be fitted to a kinetic equation of the first-order reaction. We estimated the apparent rate constant, k, at several HTT value by assuming Eq. 2:

$$dn/dt = kN \qquad (2)$$

where n is the spin concentration, and N, the number of molecules per gram. If the logarithm of k is plotted against the reciprocal of HTT, a straight line can be obtained, as is shown in Fig. 5; the activation energy can thus be estimated to be 74 kcal./mol. On the other hand, the energy difference between the two isomeric forms has been experimentally determined to be 3.4 kcal./mol. for the thermochromism in the solution. Therefore, the observed activation energy for the formation of paramagnetic species in the solid state is too large to be simply attributed to the energy difference between the two isomeric forms of the thermochromism.

According to the model given by Hirschberg and Fischer or that by Wassermann, the shape of a dianthraquinone molecule is not greatly different between the two isomeric forms. If this is the case, a molecule can be transformed from the one form to the other in the crystal without a drastic change in the crystal structure; accordingly, the energy required for this ought to be of the same order as that for a free molecule. On the other hand, Gruff and Kistiakowsky[2] supposed that anthrone halves are perpendicular to each other in the high-energy form of the thermochromism, Matlow[8] also showed later, by the molecular orbital treatment, that a triplet state is lower than the lowest singlet state for the conformation of the molecule mentioned above, and that the energy difference between this state and the ground state, in which anthrone halves are parallel to each other, is 3.3 kcal./mol., in good agreement with the observed energy difference between the two isomeric forms of the thermochromism. For the high-energy form, Kortüm and his collaborators also proposed a model in which anthrone halves are considerably twisted.[3,6] If we assume models of this type, we must consider that the transformation of a dianthraquinone molecule to the high-energy form can not occur without producing quite a large distortion in the crystal lattice; consequently, the energy necessary for this transformation must be very large compared with that for a free molecule. This seems compatible with our experimental results, since we have actually observed that the formation of paramagnetic species is accompanied by the introduction of a marked disorder into the crystal lattice, and since the activation energy for the

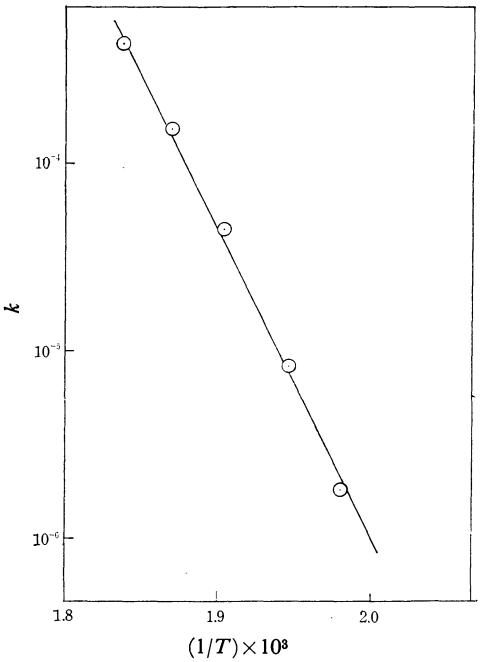

Fig. 5. The plot of $\log k$ against $(1/T)$.

formation of the paramagnetic species in the crystal is large enough to assume such a process. In conclusion, we may suppose that the initial changes in the color and in the ESR absorption are due to the excitation of molecules to the state corresponding to the high-energy form of the thermochromism. In the solid state, however, once a molecule is transformed to such a state at an elevated temperature, it remains in that state even after the temperature is lowered, since a large activation energy is also required in the reverse process because of the necessary rearrangements of the neighboring molecules.

Naturally a molecule in the metastable triplet state is rather unstable, and can be expected to take part in the second process of the thermal change, a polymerization. The X-ray diffraction pattern of the heat-treated powder gives, however, little information on the structure of the polymerization product. The infrared absorption spectrum of the dark green solid of an amorphous structure prepared by 60 min. treatment at 270°C is shown in Fig. 6, together with the spectrum of the dianthraquinone powder. A sharp and strong absorption at 1650 cm^{-1} in the spectrum of dianthraquinone can be attributed to the C=O stretching vibration. Since this band changes little between the two spectra shown in Fig. 6, we can consider that the C=O group of dianthraquinone remains in the pyrolysis product. The absorption bands in the 1400—1600 cm^{-1} region, which are associated with the skeletal vibrations of the aromatic nucleus, are broadened a little. A remarkable change is found in the 650—950 cm^{-1} region, associated with the C–H bending vibrations.

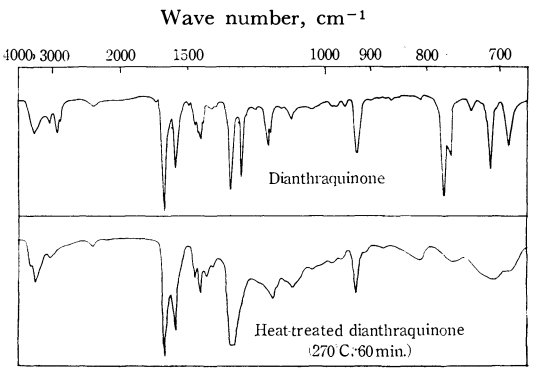

Fig. 6. The change in the infrared absorption spectrum of the dianthraquinone powder on heat-treatment.

These results seem to suggest that, in the polymerization product, the neighboring dianthraquinone molecules are connected by a bridge formed at the periphery of the anthrone halves, presumably at the expense of hydrogen atoms. Interestingly, the char obtained from the pyrolysis of dianthraquinone in the solid state is a non-graphitizing carbon. If the pyrolysis of dianthraquinone in the solid state proceeds in the manner suggested in the present paper, the orientations of aromatic nuclei may be expected to be quite random in the dianthraquinone-char. This might be what makes the char hard to be graphitized in heat treatment at high temperatures.

The authors wish to thank Professor Hideo Akamatu for his valuable discussions, and Dr. Minoru Kinoshita for his advise given on the ESR absorption experiment.

NOTES

A High Frequency Titrimetric Study of the Reaction between Thorium and Alkali Molybdate

By M. L. MITTAL* and S. S. DUBE*

Department of Chemistry, Government College, Kota (Rajasthan), India

(Received March 19, 1965)

The reaction between Th^{4+} and MoO_4^{2-} ions has been investigated by means of high frequency titrations of thorium nitrate with sodium molybdate, by both the direct and reverse methods, in 30% ethanolic media. The end-points obtained from the well-defined breaks in titration curves provide cogent evidence for the formation of normal thorium molybdate, $ThO_2 \cdot 2MoO_3$, in the pH range from 4.2 to 5.8. The precipitation of the compound has been found to be quantitative. The reaction offers a simple, rapid, and accurate method for the determination of thorium as molybdate.

One of the present authors, Mittal,[1-3] has made a detailed study of this reaction by several electrometric methods. The present investigation has been undertaken with a view of substantiating the previous results and studying the possibility of developing a reaction for the analytical determination of thorium. There is, however, no reference in the literature to any high-frequency titrimetric study of this reaction.

Anal. R. (BDH) reagents, thorium nitrate, and sodium molybdate were used; their solutions were prepared in air-free conductivity water. A high-frequency titrimeter of the HFT 30 C type (WTW Germany) with a working frequency of 10 Mc./s. ±1% and a capacity range of 0.25 pF was used; all the high-frequency titrations were carried out by adopting the deflection method. One hundred milliliters of a 30% ethanolic solution of titre was taken into the cell each time. After each addition of a titrant, the cell solution was stirred by an electrically-driven stirrer and the corresponding scale reading was noted and plotted against the volume of titrant added. Only one figure has been given for the sake of brevity (Fig. 1).

Using different concentrations of reactants, thorium nitrate and sodium molybdate a series of high-frequency titrations were carried out by both the direct and inverse methods. Table I illustrates the concentrations employed and the results of study.

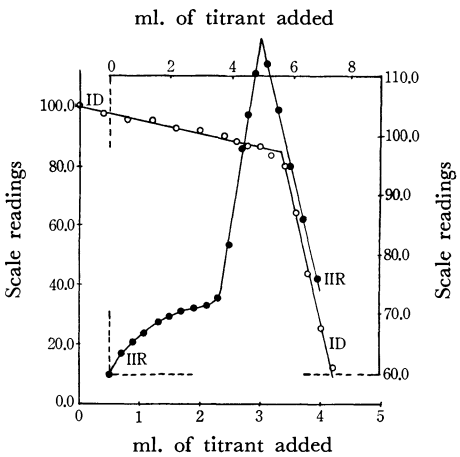

Fig. 1. Direct (curve ID; M/10 $Th(NO_3)_4$ vs. M/150 Na_2MoO_4) and reverse (curve IIR; M/10 Na_2MoO_4 vs. M/400 $Th(NO_3)_4$) high frequency titrations between thorium nitrate and sodium molybdate.

In direct titrations, when sodium molybdate is used as the titre (Fig. 1, curve ID), it may be noted that, on the addition of the titrant (thorium

nitrate), the scale reading decreases slightly until the stoichiometric end-point is reached; then, when all the MoO_4^{2-} ions have been removed by precipitation as thorium molybdate, there is a sudden decrease in the scale reading. In the case of reverse titrations when thorium nitrate solutions were used as titre, upon the addition of sodim molybdate the scale reading first increases slightly and then, in the vicinity of the end-point, appreciably until the point corresponding to the $ThO_2 : MoO_3$ ratio of 1:2 is reached, after which there is a rapid decrease. Both direct and reverse titrations yield well-defined breaks and suggest the formation of normal thorium molybdate, $ThO_2 \cdot 2MoO_3$. The accuracy and reproducibility of these titrations have been found to be excellent, even at considerably low dilutions of thorium salt (0.5 mM). In view of the accuracy of the method and its applicability to dilute solutions, this reaction can be recommended for the quantitative determination of thorium as molybdate.

The results of high-frequency titrations fully support those obtained with other electrometric methods (loc. cit.).

The authors are indebted to Professor Dr. R. S. Saxena, Malaviya Regional Engineering College, Jaipur, India, for his invaluable help.

The Synthesis of Several Gold Chelates[1)]

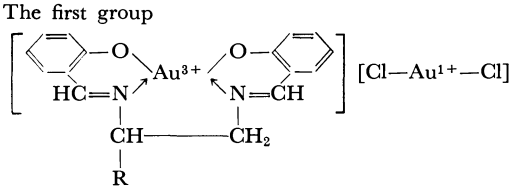
By Takahiko INAZU

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received May 24, 1965)

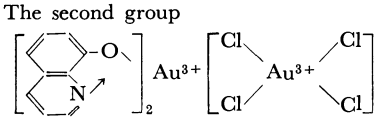
Very few papers have, until recently, been published reporting on the synthesis of gold chelates.[2,3)] In this paper, the synthesis of several gold chelates will be reported. In each case, the gold chelate was obtained by the addition of an ethanolic or an aqueous solutions of chloroauric acid to an ethanolic solution of a ligand. Seven chelates were obtained in a crystalline state, and two as powder.

The first group



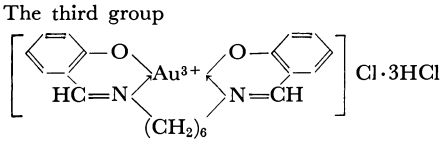
A R=H, CH_3

The second group



B cis and trans.

The third group



C

They may be classed roughly into three groups (see Fig. 1). It is well known that aurous gold always appears to be two-covalent, while auric gold is always four-convalent and the four valencies are coplanar with the gold atom.[4,5)] Considering the above facts, and the results of paper ionophoresis and the analytical data, it seems most reasonable to assume that one of two gold atoms in the chelate

molecule of the first group is in a reduced univalent state.[6] In the case of 8-hydroxyquinoline chelates, which belong to the second group, two kinds of crystals, of different colors, were obtained. They may be cis and trans isomers each other. In these chelates, the oxidation states of both golds in the cationic and the anionic parts might be considered to be tervalent[7] on the basis of the analytical data and the paper ionophoresis (Fig. 2, No. 2). The chelates of the third group contain one tervalent gold atom and three molecules of hydrogen chloride in each chelate molecule. All the chelates decomposed spontaneously within a year.

No. 2

Fig. 2. Paper ionophoresis of gold chelates.

Experimental

The following examples represent the methods of preparing the chelates obtained.

Bis(8-quinolinolato)gold (III) - tetrachloroaurate-(III) (B).—A solution of 210 mg. of 8-hydroxyquinoline in 25 ml. of ethanol was mixed with a solution of 300 mg. of chloroauric acid tetrahydrate in 15 ml. of ethanol. After this mixture had stood overnight, a mixture of green crystals and amber needles was obtained. Each of the separated crystals was then collected and washed with a little ethanol. They were slightly soluble in acetone and insoluble in water.

Bis[10-benzo-(h)-quinolinolato]gold(III) - chloride Trihydrogen Chloride (E).—A solution of 85 mg. of chloroauric acid tetrahydrate in 10 ml. of ethanol was mixed with a solution of 127 mg. of a chelating agent[8] in 10 ml. of ethanol. Dark violet needles were immediately formed; these were collected and washed with a little ethanol. They were slightly soluble in acetone and chloroform and insoluble in water.

Paper Ionophoresis.—Tôyô Roshi No. 51 filter paper was used, with a solvent system of acetone - acetic acid - water (1 : 1 : 1 by vol.) (500 V., 2 hr.). The papers were dried in an oven at 120°C, and then left standing overnight. Without further treatment, gray spots of reduced gold were obtained.

N, N' -Disalicylidene-ethylenediaminato-gold(III) - dichloroaurate(I).—(Fig. 2, No. 1).—Two spots were obtained; one spot in the plus region due to $Au(I)Cl_2^-$, and one spot in the minus region due to $Au(III)Ln^+$. (Ln =ligand).

Bis (8 - quinolinolato) gold (III) - tetrachloroaurate(III).—(Amber needles, Fig. 2, No. 2).—Two spots with long tailings were obtained; one spot in the plus region due to $Au(III)Cl_4^-$, and one spot in the minus region due to $Au(III)Ln_2^+$.

The author withes to thank Professor Tokuichi Tsumaki, Professor Tamotsu Yoshino and Dr. Masaru Yamaguchi for their kind direction of this work.

6) As an example of this type, there is the dimethylglyoxime gold complex, confirmed by X-ray diffraction analysis; cf. Ref. 2.
7) The $\alpha, \beta, \gamma, \delta$-tetraphenyl porphine gold complex also belongs to this type; cf., Ref. 3.

Infrared Absorption Spectral Studies of the Complexes with Substituted 2-Thioureas. I. Bis(1-phenyl-2-thiourea)copper(I) Chloride

By M. A. NABAR

Department of Chemical Technology, University of Bombay, Bombay 19, India

(Received May 31, 1965)

Several co-ordinated complexes in which the ligands are urea and 2-thiourea have been reported. Quagliano and his co-workers[1] have established that, among the urea complexes, some are co-ordinated through one of the nitrogen atoms, and the others, through the oxygen atom of the urea molecule. They have then extended these studies to 2-thiourea and 1-methyl-2-thiourea complexes,[2,3] and have concluded that although the co-ordination takes place either through the sulphur atom or one of the nitrogen atoms when 1-methyl-2-thiourea is a ligand, the sulphur atom is exclusively involved in the co-ordination in the 2-thiourea complexes. Rivest[4] came to a similar conclusion from his studies of the co-ordinate complexes of titanium(IV) chloride with alkyl and aryl substituted 2-thioureas. More recently Berni and others[5] have studied the properties of the metal ion complexes of ethylene urea (2-imidazolidinone).

The present investigations were undertaken in order to examine the influence of substituents such as alkyl, aryl and acyl[6] groups on the relative donor abilities towards co-ordination of either the sulphur or the nitrogen atom of the 2-thiourea.

Cuprous salts form many complexes with ligands such as 1-phenyl- and 1-acetyl-2-thioureas in different mole-ratios.[7] This note will present the results of the infrared absorption studies of $CuCl \cdot 2C_6H_5NHCSNH_2$.

Experimental

Preparation of the Compound—Eastman-Kodak white-label 1-phenyl-2-thiourea was used without further purification. The $CuCl_2 \cdot 2H_2O$ used was of the reagent grade. Bis(1-phenyl-2-thiourea)copper(I) chloride was prepared according to the method of Banerjee and Sukthankar[7]; it was recrystallised from acetone and dried in a vacuum desiccator for a constant analysis.

Absorption Measurements—The spectra were obtained with a Perkin-Elmer recording infrared spectrophotometer, model 21. A sodium chloride prism was used over the complete infrared region to be reported on. As a routine, polystyrene film was used for the wave number calibration. The spectra were taken using the KBr disc technique and were checked using Nujol and fluorolube mulls. The spectra obtained are illustrated in Fig. 1, while the experimental results, along with the corresponding assignments of the frequencies, are given in Table I.

Results and Discussion

As a necessary prerequisite, the assignments required for this analysis were made on a comparative basis, mainly with 2-thiourea and 1-methyl-2-thiourea,[2,3] since there are no adequate published assignment data on 1-phenyl-2-thiourea.[8] For phenyl-ring and ring-hydrogen vibrations, the assignments of Randle and Whiffen[9] were used.

The absence in the 2500—2600 cm^{-1} region of the absorption band characteristic of the SH group in the spectra of the complex and the ligand (1-phenyl-2-thiourea) indicates that the ligand is in its thiocarbonyl resonance form.

The formation of S→M bonds is expected to result in an increased double-bond character for the carbon-to-nitrogen bond and a lowering of it for the carbon-to-sulphur bond.

A comparison of the spectrum of 1-phenyl-2-thiourea with that of the copper(I) complex shows that the general spectral profile of the complex in the 3 μ region is almost unchanged. These bands, which can be assigned to N–H absorptions, are neither shifted to significantly lower frequencies not split into groups with a decrease in intensity, on the formation of the complex. This indicates the absence of nitrogen-to-metal bonds; therefore, the bonding must be between sulphur and the metal atoms. The broadening of these bands can be attributed to a considerable amount of hydrogen bonding, perhaps a Cl···H–N type of hydrogen bonding, in the complex.[10]

811 mw	795 mw	CS stretching + CN sym. stretching and X sensitive*
750 ms	747 ms	CH out-of-plane deformation and NH out-of-plane bending
~ 707 sh		Ring out-of-plane deformation
693 ms	692 ms	Ring out-of-plane deformation

* In monosubstituted benzenes (C_6H_5X) there are six fundamental frequencies, out of the possible thirty, sensitive to the mass and the nature of X, the substituent (-$NHCSNH_2$ in the present case). These are classified as X sensitive. The two bands observed here are mainly CX stretching vibrations with some contribution from one of the ring breathing vibrations and CX in-plane deformation vibration.[9]

Abbreviations : s=strong ; m=medium ; w=weak ; sh=shoulder ; b=broad ; v=very.

The strong broad band at 1522—1527 cm^{-1} can be explained as an "hydrid" band due to N–H deformation and C–N antisymmetric stretching vibrations. On co-ordination, this band is shifted to a higher frequency, indicating the increased double-bond character of the C–N bond and, hence, co-ordination through the sulphur atom. Similar behaviour was observed in complexing in the case of 2-thiourea and 1-methyl-2-thiourea.[2,3]

The N–C–N stretching band at 1465 cm^{-1} in the 1-phenyl-2-thiourea corresponds to the 1470 cm^{-1} band of 2-thiourea. The frequency of this band is increased by about 33 cm^{-1} on complexing, again indicating an increased double-bond character of the carbon-to-nitrogen bond.* A similar shift has been observed by Kutzelnigg and Mecke[10] in the $CuCl{\cdot}4CH_3CSNH_2$ complex.

A marked difference in the spectrum of the free ligand and its metal complex appears in at about 1100 cm^{-1}. A sharp absorption band at 1062 cm^{-1} of 1-phenyl-2-thiourea, corresponding to the 1083 cm^{-1} and 972 cm^{-1} bands of 2-thiourea and 1-methyl-2-thiourea[2,3] respectively, is very much broadened and weakened. The contribution of the C=S vibration and, hence, the intensity of this band is decreased on co-ordination through the sulphur atom. The symmetric N–C–N stretching

* It seems likely that this band corresponds to the "thioureide" band assigned by Randall and others[11] between 1613—1471 cm^{-1}, by Ettlinger,[12] at 1508 cm^{-1} and by Mann,[13] at 1495 cm^{-1}.

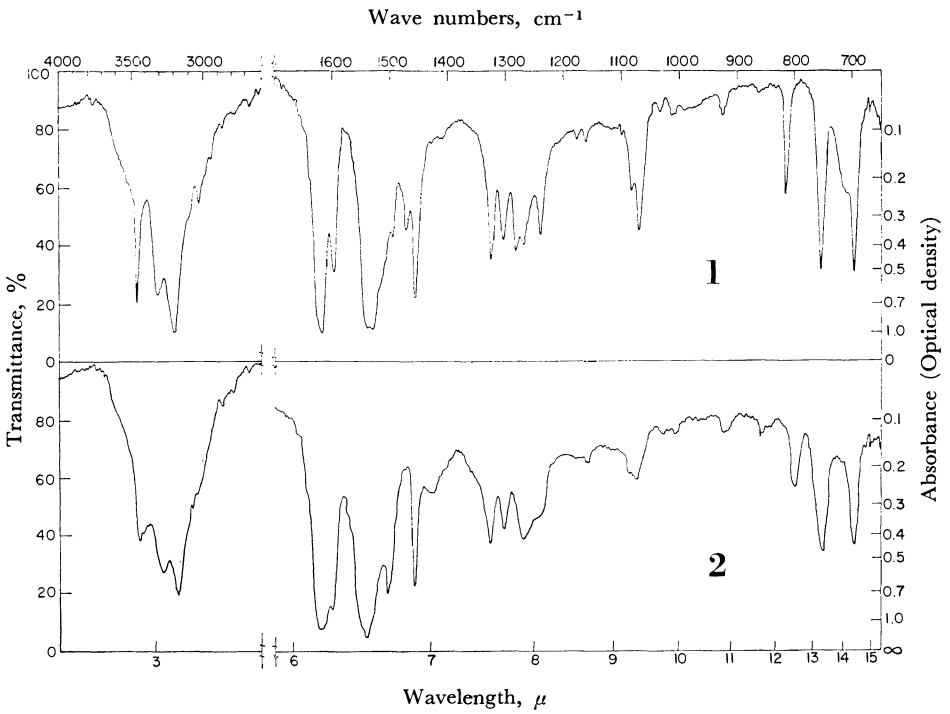

Fig. 1. Infrared spectra in KBr disk.
1. 1-phenyl-2-thiourea 2. Bis(1-phenyl-2-thiourea)copper(I) chloride

vibration can not contribute much to this band, as has been shown for the spectra of urea and 2-thiourea; this explains the overall decrease in intensity. A similar weakening or complete disappearance of a band was observed in co-ordination through sulphur in the case of 2-thiourea and 1-methyl-2-thiourea.[2,3]

The band at 811 cm^{-1} of 1-phenyl-2-thiourea is considered to correspond to the 731 cm^{-1} and 774 cm^{-1} bands in 2-thiourea and 1-methyl-2-thiourea respectively,[2,3] bands arising mainly from the C=S stretching vibration, though with a little contribution from the symmetric C–N stretching vibration. The lowering of this frequency by about 16 cm^{-1} can be attributed to the reduced double-bond character of the carbon-to-sulphur bond.

The above-mentioned three bands could also be identified as "–N–C=S" I, III and IV bands respectively, according to Rao.[14] However in the region to which he assigned the "–N–C=S"–II band, no definite conclusions could be drawn, mainly because of the other overlapping regions.

No significant changes have been observed in the remaining bands of the spectra of the ligand on complexing; this is not unexpected, as these could be identified as arising from the presence of the phenyl ring and from the ring hydrogen vibrations.[9]

The co-ordination of 1-phenyl-2-thiourea to copper(I) shifts certain infrared absorption frequencies, notably at about 1450, 1100 and 800 cm^{-1}; these shifts can be correlated with the changes in the double-bond character of the C–S and C–N bonds. Such a situation suggests a considerable covalent character of the sulphur-copper bonds, indicating a ligation through the sulphur atom in a complex.

The author wishes to thank Mr. R. Ironside of the Analytical Section, Applied Chemistry Division, National Research Council, Canada, for repeating some spectral work, and also the National Research Council, Canada, for a post-doctoral Fellowship, during the tenure of which this paper was written.

The Formation Constants of 1 : 1 and 1 : 2 Complexes of Ethyl Acetate and Phenyl Acetate with Phenol

By S. Sriraman and V. Shanmugasundaram

Department of Physics, Annamalai University, Annamalainagar, South India

(Received July 19, 1965)

The detection of complex formation is convincingly accomplished by the study of infrared spectra. A complete survey of the literature wherein infrared spectroscopy is used as an analytical tool for the detection of such complexes has been made by Pimentel and McClellan.[1] Several recent studies[2-4] of the hydrogen bonding of phenols to different proton-acceptor groups have indicated the existence of at least two different types complexes in most of the systems over a wide range of concentration. A large number of values of the equiliarium constants for the formation of 1 : 1 complexes is available for many systems, but no quantitative values are available for the 1 : 2 complexes. The main purpose of this work is to obtain the formation constants for such complexes, along with the formation constants for 1 : 1 complexes; these values will make possible the determination of the concentrations of different molecular species in the system under consideration.

The formation constants, K_{11} and K_{12}, of 1 : 1 and 1 : 2 complexes of ethyl acetate and phenyl acetate with phenol in carbon tetrachloride were determined by studying the infrared absorption in the hydroxyl and carbonyl regions. The measurements were made with a Hilger H 800 double-beam spectrophotometer equipped with sodium chloride optics; approximately 0.04 M solutions of phenyl acetate and ethyl acetate 0.25 mm. thick were placed in a variable-path-length micrometer cell supplied by the Hilger. The temperature of the cell was maintained at 22°C.

The modified method of Brown and Kubota[5] developed by Whetsel and Kagarise[4] was used for the calculation of the equilibrium constants for the formation of the complexes of the $A+B \rightleftarrows AB$ and $AB+B \rightleftarrows AB_2$ types, where A represents the ester and B, the monomeric phenol. This method, given in detail by those authors, involves the calculation of a set of K_{11} values for different assumed values of K_{12}. A plot of the values of K_{11} against the concentration of the phenol results in a series of lines with different slopes and intercepts (Fig. 1). The value of K_{12} which gave a line of zero slope was taken as the best value, and the intercept of this line was taken as K_{11}. The formation constants of 5.9±1 l./mol. and 13.5±2 l./mol. were obtained for the 1 : 1 and 1 : 2 phenyl acetate and phenol complexes respectively. For the ethyl acetate - phenol system, values of 8.6±1 l./mol. and 25±2 l./mol. were obtained for K_{11} and K_{12} respectively.

The formation constants for the 1 : 1 complexes were also obtained by the method suggested by Nash.[6] This method, derived by Nash, utilises the $Y=X(K-\alpha)-K$ relation, where Y is the reciprocal of the concentration of monomeric phenol at equilibrium and

$$X = \frac{1}{1-A/A_0}$$

where A_0 and A are the absorbances of the ester at a given frequency in the absence and in the presence of the donor respectively. The equilibrium concentrations of phenol required were determined from the hydroxyl absorption, and A and A_0 were taken in the carbonyl region near the characteristic frequency of the 1 : 1 complex. The intercept of the plot of Y against X is the negative value of the formation constant for the 1 : 1 complex.

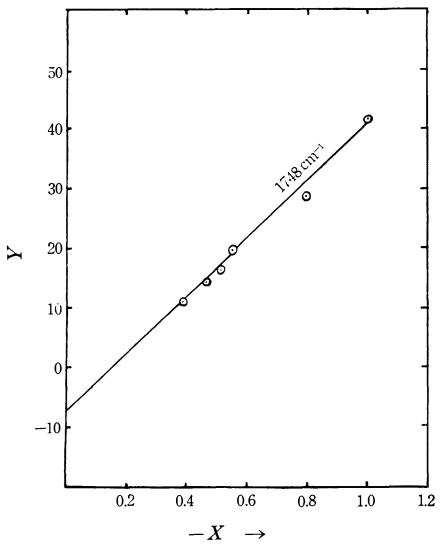

Fig. 2. Formation constant for 1:1 complex phenyl acetate with phenol determined by Nash method.

Figure 2 shows such a plot for the phenyl actate - phenol system. A value of 6.5 l./mol. was obtained for the formation constant K_{11} for the phenyl acetate - phenol system. In a similar manner, a value of 8 l./mol. was obtained for K_{11} for ethyl acetate - phenol system. The values of the formation constants of 1 : 1 complexes obtained by the two methods agree well.

The values of K_{11} obtained in the present investigation compare favourably with the value of 8.68 l./mol. at 27.85°C obtained by Powell and West[7] for the phenol - ethyl acetate system. Also, the value of 7.1 l./mol. at 30°C for the same system reported by Nagakura[8] from his ultraviolet studies agrees closely with the results of our present investigation.

7) D. L. Powell and R. West, *Spectrochim. Acta*, **20**, 983 (1964).
8) S. Nagakura, *J. Am. Chem. Soc.*, **76**, 3070 (1954).

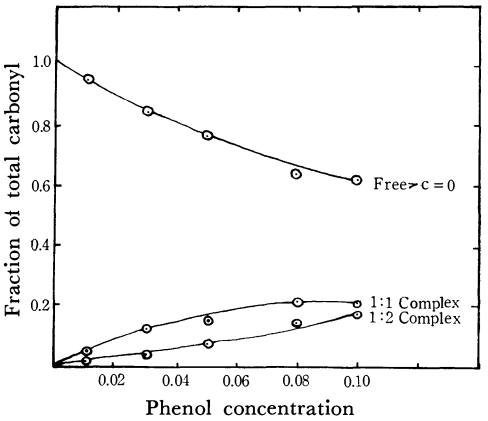

Fig. 3. Relative abundance of free and complexed phenyl acetate in mixtures of phenol and CCl_4.

It should be noted that the K_{11} and K_{12} values obtained in the present investigation for the phenyl acetate - phenol system are relatively lower than those for the ethyl acetate - phenol system. This may be due to the molecular complexity of phenyl acetate, which may hinder the possibility of the formation of specific complexes.

From the knowledge of the formation constants K_{11} and K_{12} the relative abundance of 1 : 1 and 1 : 2 complexes can be easily determined. Figure 3 shows that a high fraction of the complexed ester is present as 1 : 2 species and that at higher concentrations of phenol the 1 : 2 complex may predominate.

The authors wish to express their thanks to Dr. M. G. Krishna Pillai, Reader in Spectroscopy, Annamalai University, and to Dr. K. Ramaswamy, Infrared Division, National Physical Laboratory, New Delhi, for their kind and valuable suggestions throughout the progress of this work.

The NMR of Benzene/Water Emulsion

By Toshiro OKAMURA, Iwao SATAKE and Ryohei MATUURA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received August 7, 1965)

To date, no paper has reported the application of the high-resolution NMR technique to the investigation of emulsion except that of Cratin and Robertson.[1] Since the emulsion state is heterogeneous and thermodynamically-metastable, its complete analysis is very difficult. In this communication, some information obtained with the NMR technique concerning the benzene/water emulsion will be reported.

1) P. D. Cratin and B. K. Robertson, *J. Phys. Chys. Chem.*, **69**, 1087 (1965).

Experimental

The emulsions were prepared by shaking portions of benzene with equal amounts of water containing an emulsifier in various concentrations. As the emulsifier sodium dodecyl sulfate (SDS) was used. The emulsions thus obtained were of the o/w type. The freshly-prepared emulsion was left to stand for about 24 hr. before the NMR investigation was started in order to secure the state of the emulsion which was stable enough during the NMR measurement.

The chemical shifts of the proton in water, benzene and SDS were measured at constant temperatures, but the shifts of the latter two were so small as to fall within the range of experimental error; therefore, the final measurements were made solely with the water proton peaks. The shifts were measured by using a Japan Electron Optics JNM-3 high-resolution NMR spectrometer, with dioxane as the external reference. The experimental error was less than 0.5 c. p. s.

Results and Discussion

Figure 1 shows the water proton chemical shifts in SDS solutions of various concentrations and temperatures. The water proton gave a single but somewhat broad resonance line; this line shifted towards the higher applied field with an increase in the SDS concentration and temperature. The single line in this case represents the rapid proton exchange between different species, and the higher field shift is assumed to show that the structure of water is increasingly destroyed by the increase in the concentration of SDS, as well as by the rise in temperature, the shift per mole of SDS nearly corresponding to that per ten degrees of temperature. There should be a kink at the critical micelle concentration (CMC) on the curve of the shift vs. SDS concentration, as was shown by Pethica,[2] but in this experiment the range of the SDS concentration is so high that the kink at the CMC is not clear. However, it may be said from Fig. 1 that the slope of the curve below the CMC decreases with the temperature, while that above the CMC is independent of the temperature.

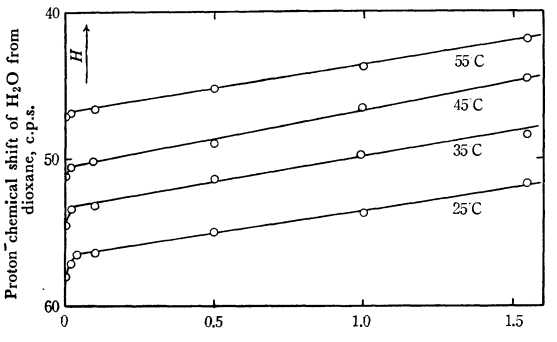

Fig. 1. Proton chemical shift of H_2O vs. SDS concentration at various temperatures.

The concentration of the SDS solution used for preparing the emulsion in this experiment was far above the CMC, and the amount of benzene added was large enough so that the bulk solution should have been saturated with benzene (solubilization). The chemical shift of the water proton in the SDS solution saturated with benzene was, therefore, measured. The results are shown in Fig. 2. In the presence of solubilized benzene, the water proton shifts to a higher field than in the absence of benzene; this shift increases with the amount of benzene solubilized. When Wiedmann's theory is applied, the chemical shift due to the change in bulk susceptibility is less than 0.4 c. p. s. at the SDS concentration of 1.0 mol./l. The observed value is much larger than this. Therefore, the higher field shift due to solubilized benzene may be attributed to the magnetic anisotropy of benzene. If the solubilized benzene is only in the central part of micelles, this effect can not be expected. It is, therefore, reasonable to consider that the solubilized benzene is, as Eriksson[3] proposed, near the micelle surface, or that, as Nakagawa et al.[4] showed, benzene molecules in the micelle exchange with those in the bulk solution.

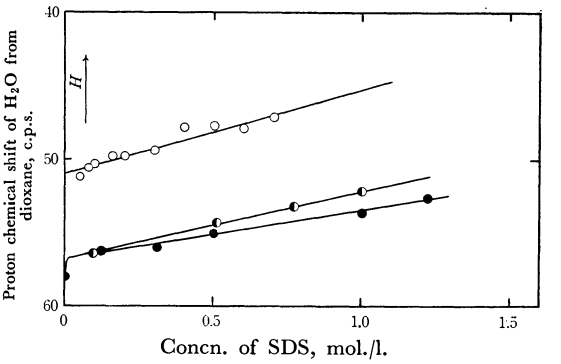

Fig. 2. Proton chemical shift of H_2O vs. SDS concentration at 25°C.
○ In emulsion ● In SDS solution
◐ In SDS solution saturated with benzene

Also in Fig. 2, the chemical shift of the water proton in the benzene/water emulsion is plotted against the SDS concentration, the latter being determined after the destruction of the emulsion. It may be seen that the shift of the water proton in the emulsion state containing SDS as an emulsifier is further towards the higher magnetic field than in the case of the SDS solution containing solubilized benzene. This higher field shift can not be due to the magnetic anisotropy of benzene, since we found a similar shift in the case of the cyclohexane/water

emulsion. The observed difference between the chemical shift of the water proton in the SDS solution, which has solubilized benzene, and that in the benzene/water emulsion state is to be attributed to the surface effect of the emulsion particles.

At the oil/water interface the SDS molecules are considered to form an adsorbed layer. Accordingly, the water molecules near the interface are different in structure from those of the bulk water due to the charge as well as to the dipole effect of the adsorbed SDS molecules. It is difficult to distinguish the true interface effect (without an adsorbed emulsifier) from the effect of the adsorbed layer of the emulsifier, but it would be natural to consider that the higher field shift of the water proton in the emulsion state over the shift of that in the bulk solution containing benzene is caused chiefly by the breaking of the hydrogen bond structure of water at the interface. Again, it is assumed that the exchange of water between the surface and the bulk is rapid. When the chemical shifts of water protons in the emulsion state, at the interface, and in the bulk solution, are denoted by δ_e, δ_s, and δ_b respectively, then:

$$\delta_e = X_s\delta_s + (1 - X_s)\delta_b \quad (1)$$

where X_s is the mole fraction of water near the interface causing δ_s. From Eq. 1 we have:

$$\Delta\delta/X_s = \delta_s - \delta_b \quad (2)$$

where $\Delta\delta = \delta_e - \delta_b$. We have attempted to determine the particle-size distribution of the benzene droplets in the emulsion by microscopic observations as a function of the SDS concentration. From this we can estimate the value corresponding to X_s at each SDS concentration, assuming that X_s is proportional to the interfacial area between benzene droplets and water. For δ_b the chemical shift of the water proton in the SDS solution saturated with benzene can be used. From these data the $\Delta\delta/X_s$ vs. δ_b plot can be obtained. Unfortunately, due to errors accompanying the particle-size distribution of the emulsion, we could only roughly confirm the linear relationship between $\Delta\delta/X_s$ vs. δ_b. We are expecting to reach a more precise conclusion after the particle-size distribution has been improved.

An Anomalous Electric Property Found in Grain and at the Grain Boundary of the Barium Titanate Ceramic Doped with Bismuth

By Masato YANASE and Katsuhiro OHNO

The Central Research Laboratories, Mitsubishi Electric Corporation, 80 Nakano, Minamishimizu, Amagasaki, Hyogo

(Received August 26, 1965)

It has been reported[1-3] that the resistivity of the polycrystalline barium titanate ceramic doped with bismuth increased anomalously above its Curie point. It is generally considered that this increase is due to the existence of a particular barrier at the grain boundary of the ceramic. However, the experimental results obtained with a single crystal do not seem to support this view. For example, Brown and Taylar[4] recently indicated that the single crystal of barium titanate doped with niobium prepared by the zone-melting process showed the same anomaly. Also, Kawabe and Inuishi[5] reported that a similar increase in resistivity could be found in the semiconductor obtained by reducing the barium titanate single crystal with hydrogen.

These results may suggest that the polycrystalline and single crystals of this ceramic have different electric properties.

A large-grained ceramic with an anomalous increase in resistivity was prepared, and the potential changes in the grain and at the grain boundary were studied (see Fig. 1).

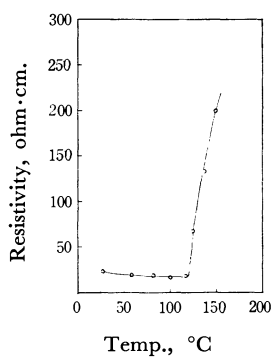

Fig. 1. Resistivity-temperature dependence of specimens used this experiment.

5) K. Kawabe and Y. Inuishi, *Japanese J. Appl. Phys.*, **2**, 590 (1963).

Experimental

Specimens of barium titanate ceramic doped with bismuth were prepared from barium titanyl oxalate[6] as the starting substance. This powder was mixed with 0.1 mol.% bismuth sesquioxide using a ball mill and was calcined at 1000°C in air. It was then pressed into disks 50 mm. in diameter and 3 mm. thick and was sintered at 1400°C in air. The mean grain diameter was found under a mecroscope to be about 500 μ. This was cut into plates 1 mm. thick, 20 mm. long and 5 mm. wide, pasted into glass plates, lapped to a thickness below 300 μ in order to obtain a single grain layer, and etched in order to make it possible to see the grain boundary. The electrodes were made at both sides of the specimen by utilizing the special nickel plating shown in Fig. 2.

The potential change produced in the specimen was measured by the two-points method using a sharp-headed probe made of tungsten wire 0.3 mm. in diameter. The head was wet with liquid indium-mercury alloy[7] in order to obtain an ohmic contact.

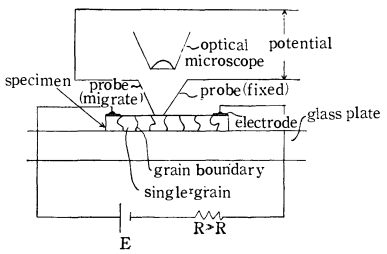

Fig. 2. Scheme of specimen and measure method.

Results and Discussion

Figure 3 shows the variation in the electrical potential between two probes. The one was fixed at the side of the specimen, while the other was moved on the surface on the grain. A large potential difference was always observed across the grain boundary. This shows that a barrier exists at the grain boundary, but its magnitude is different according to the specimen. This may indicate that the amount of barrier existing at the grain boundary varies and that the property of this barrier may be affected by the grain.

It is clear that the grain boundaries of the barium titanate ceramic doped with bismuth have a particular potential barrier. However, it is not clear whether the height of this potential barrier depends on the temperature above the Curie point. Therefore, the temperature-dependence of the potential drop should be measured. For this purpose, the resistivity of the grain was measured at various temperatures. The specimen was heated and its temperature was measured by a 0.1 mm.-in-diameter copper-constantan thermocouple pasted on the glass plate attached to the specimen.

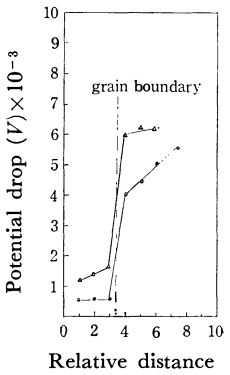

Fig. 3. Potential drop variation in case that crossed a grain boundary.

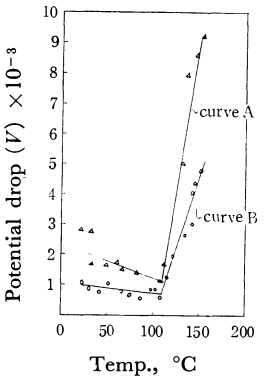

Fig. 4. Potential drop-temperatures dependence of the inside of grain.

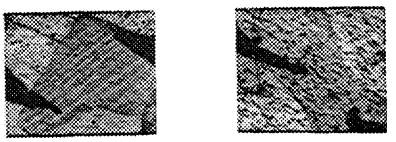

Fig. 5. Measured grains correspond with Curves A and B.

The potential change was found to be at about 110°C (see Figs. 4 and 5). In Fig. 4, the anomalous increase in resistivity in the grain is shown. This suggests that the anomalous increase of resistivity can not be attributed only to the barrier at the grain boundary. However, it was not possible to determine separately the temperature-dependent resistivity in the grain and that due to the barrier existing at the grain boundary.

The results obtained from this experiment may be summarized as follows: (1) A particular barrier causing a large potential change would exist at the grain boundary of the barium titanate ceramic doped with bismuth. (2) An anomalous increase in resistivity was observed in the grain of the barium titanate ceramic doped with bismuth, but it is

not clear whether the mechanism of the increase of the resistivity of this material is to be attributed to the barrier at the grain boundary or to that in the grain.

The authors wish to acknowledge many valuable discussions with Dr. Sumiaki Ibuki of their laboratory.

The Absolute Configuration of *trans*-2-Methylcyclopropanecarboxylic Acid[1]

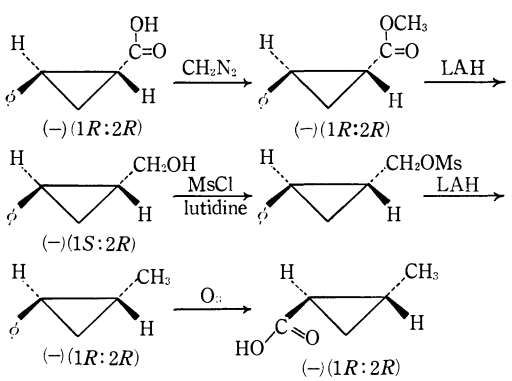
By Toshio SUGITA and Yuzo INOUYE

Institute for Chemical Research, Kyoto University, Takatsuki, Osaka

(Received August 30, 1965)

In the course of our studies of asymmetric syntheses in Simmons-Smith reactions, it was necessary to establish the absolute configuration of *trans*-2-methylcyclopropanecarboxylic acid.[2] We wish, at this time, to report the absolute assignment of the configuration of this acid by means of a direct chemical transformation. In a previous paper[3], the absolute configurations of (−)-*trans*-1, 2-cyclopropanedicarboxylic acid and (+)-*trans*-2-phenylcyclopropanecarboxylic acid were established as 1*R* : 2*R* and 1*S* : 2*S* respectively by an unequivocal correlation with *trans*-1, 2-dimethylcyclopropane of a known configuration. This provides us with the mean of correlating *trans*-2-methylcyclopropanecarboxylic acid with *trans*-2-phenylcyclopropanecarboxylic acid.

Methyl *trans*-2-phenylcyclopropanecarboxylate, $[\alpha]_D^{12}$ −171.9°, of a 51.3% optical purity, which had resulted from the quantitative esterification with diazomethane of the corresponding (−)-acid, was reduced with lithium aluminum hydride to the carbinol, $[\alpha]_D^{12}$ −46.6°. The carbinol was then converted with methanesulfonyl chloride in lutidine into the mesylate; then due to the instability of the mesylate, it was immediately reduced with lithium aluminum hydride to 1-methyl-2-phenylcyclopropane, $[\alpha]_D^{16}$ −57.7°. The ozonolysis of the laevorotatory hydrocarbon produced (−)-*trans*-2-methylcyclopropanecarboxylic acid, $[\alpha]_D^{19}$ −42.9° (chloroform), $[\alpha]_D^{19}$ −39.7° (ethanol). On the basis of this chemical conversion, (−)-*trans*-2-methylcyclopropanecarboxylic acid can be assigned the 1*R* : 2*R* absolute configuration.



The predictions of the direction and the magnitude of rotation by the Brewster calculation of conformational asymmetry[4] show a good agreement with the observed values of (−)-(1*R* : 2*R*)-1-methyl-2-phenylcyclopropane, $[M]_D$ −148.7° (Found; chloroform), $[M]_D$ −140° (Calcd.) and (−)-(1*R* : 2*R*) - 2 - methylcyclopropanecarboxylic acid, $[M]_D$ −83.7° (Found; chloroform), $[M]_D$ −90° (Calcd.).

Experimental

Methyl (—)-*trans*-2-Phenylcyclopropanecarboxylate.—(−)-*trans*-2-Phenylcyclopropanecarboxylic acid ($[\alpha]_D^{22}$ −200.8° (*c* = 3.168, 1 dm., ethanol); optical purity 64.4% based on $[\alpha]_D$ 311.7°[3]; 6.8 g.) was esterified by the standard method with diazomethane to give the methyl ester, b. p. 128—131°C/10 mmHg; n_D^{20} 1.5292; $[\alpha]_D^{12}$ −215.7° (*c* 3.786, 1 dm., ethanol). Yield, 7.1 g. (95%).

(—) - *trans* - 1-Hydroxymethyl-2-phenylcyclopropane.—Methyl (—)-*trans*-2-phenylcyclopropanecarboxylate, $[\alpha]_D^{12}$ −171.9°; of a 51.3% optical purity, 12.4 g.; 0.07 mol., was stirred drop by drop into a slurry of lithium aluminum hydride (1.9 g.; 0.05 mol.) in 200 ml. of dry ether at room temperature. After the addition had been completed, the reaction mixture was gently refluxed by stirring it for 30 min. To the reaction mixture chilled in ice water, there was then added enough dilute hydrochloric acid (*ca.* 30 ml. of concentrated hydrochloric acid in 200 ml. of ice water) to effect a clear solution. The acidic solution was extracted with ether, and the ethereal extract was washed with aqueous sodium bicarbonate and sodium chloride solutions and dried over sodium sulfate. After ether had been removed, the residue was distilled under reduced pressure to give the carbinol, b. p. 133—135°C/10 mmHg; n_D^{21} 1.5502;

1) This work was supported by Grant 1240-A4 from the Petroleum Research Fund, administered by the American Chemical Society.

2) Asymmetric syntheses of this acid have been achieved by Simmons-Smith reactions in our laboratory and will be described in detail later elsewhere.

3) Y. Inouye, T. Sugita and H. M. Walborskv, *Tetrahedron*, **20**, 1695 (1964).

4) J. H. Brewster, *J. Am. Chem. Soc.*, **81**, 5483 (1959).

$[\alpha]_D^{13}$ −46.6° (c=2.640, 1 dm., ethanol). Yield, 10.4 g. (quantitative).

***trans*-1-Mesyloxymethyl-2-phenylcyclopropane.**—Into a solution of the (−)-carbinol (10.4 g.; 0.07 mol.) in 40 g. of dry lutidine (freshly distilled over barium oxide) methanesulfonyl chloride (10 g.; 0.096 mol.) was effectively stirred under a nitrogen atmosphere so as to maintain the reaction temperature at −10—0°C. After the addition had been completed, stirring was continued for an additional 3 hr. under cooling. The pasty product was then poured onto a mixture of concentrated hydrochloric acid (35 ml.) and crushed ice. The oily product which separated was collected with ether and dried over anhydrous magnesium sulfate. The ether was removed in vacuo and an oily product was obtained which solidified on dry-ice cooling. Because of the instability, no further purification of the crude mesylate (16.8 g.; 106%) was attempted. The infrared spectrum of the crude mesylate indicated SO_3-bands at 1172 and 1350 cm^{-1}, while the OH-band originally present in the carbinol had disappeared.

(—)-*trans*-1-Methyl-2-phenylcyclopropane.—The mesylate (16.8 g.) in 100 ml. of dry ether was stirred into a slurry of lithium aluminum hydride (7.6 g.; 0.2 mol.) in dry ether (500 ml.) at room temperature. The reaction mixture was then gently refluxed for an additional 3 hr. After ice water containing 70 ml. of concentrated hydrochloric acid had been added to the chilled reaction mixture, the ethereal solution was separated and the aqueous layer was extracted with ether. The combined extract was washed with an aqueous sodium bicarbonate solution and dried over sodium sulfate. Upon distillation, a crude hydrocarbon was obtained, b. p. 184—192°C; (6.7 g.) Since this product was colored a dark wine-red, it was percolated through an alumina column using petroleum ether as the eluent. The colorless effluent was redistilled under reduced pressure to give the (−)-hydrocarbon, b. p. 77—78°C/18 mmHg; n_D^{20} 1.5181; $[\alpha]_D^{13}$ −49.2° (c 3.432, 1 dm., ethanol); $[\alpha]_D^{13}$ −52.8° (c 1.60, 1 dm., chloroform). Yield, 6.69 g. (72% based on the carbinol). Since the v. p. c. analysis of the product indicated contamination by a by-product, the product was fractionated by means of preparative v. p. c. to give pure (−)-*trans*-1-methyl-2-phenylcyclopropane, b. p. 74—76°C/18 mmHg; n_D^{21} 1.5185; $[\alpha]_D^{16}$ −57.7° (c 3.676, 1 dm., chloroform) (lit.[5] b. p. 78—79°C/20 mmHg; n_D^{25} 1.5204 for a racemic sample). Yield, 3.2 g. The infrared spectrum of the contaminant fraction showed a nonconjugated C=C band at 1641 cm^{-1} and CH_2=CH– bands at 911, 995 and 1414 cm^{-1}; these bands suggested 3-phenylbutene-1 and/or 4-phenylbutene-1, but no further investigation was attempted.

(—)-*trans*-2-Methylcyclopropanecarboxylic Acid.—A stream of crude ozone was passed through a solution of the (−)-hydrocarbon (2.8 g.; 0.021 mol.) in carbon tetrachloride (70 ml.) at 40°C for 29 hr. After the reaction mixture had been allowed to stand still overnight at room temperature with 30 ml. of 10% hydrogen peroxide, another 10 ml. of 30% hydrogen peroxide was added and the mixture was gently refluxed for 1 hr. The acid was taken up a dilute sodium hydroxide solution and the alkaline solution, free from neutral substances, was acidified with dilute hydrochloric acid and distilled in steam. The distillate was thoroughly extracted with ether and dried over sodium sulfate. The distillation of the extract under reduced pressure gives (−)-*trans*-2-methylcyclopropanecarboxylic acid, b. p. 97—100°C/18 mmHg; n_D^{20} 1.4331; $[\alpha]_D^{19}$ −42.9° (c 3.625, 2 dm., chloroform); $[\alpha]_D^{19}$ −39.4° (c 3.060, 2 dm., ethanol); (lit.[6] b. p. 96.0—97.0°C/16 mmHg; n_D^{25} 1.4348 for a racemic sample). Yield, 1.0 g. (47%). The infrared spectrum was identical in every respect with that of an authentic specimen.[6] *p*-Phenylphenacylester, m. p. 105—106°C, laths (from methanol) $[\alpha]_D^{14}$ −33.4° (c 1.065, 2 dm., chloroform).

Found: C, 77.25; H, 6.22, Calcd. for $C_{19}H_{18}O_3$: C, 77.53; H, 6.16%.

(±)-*trans*-2-Methylcyclopropanecarboxylic acid prepared from (±)-*trans*-2-phenylcyclopropanecarboxylic acid by the same route as above had a b. p. of 96—102°C/18 mmHg, n_D^{21} 1.4350, and was identified by means of its infrared spectrum as well as by its amide, m. p. 108—108.5°C, needles (from chloroform and petroleum ether) (lit.[6] m. p. 111.3—112.0°C).

Found: C, 60.35; H, 9.26. Calcd. for C_5H_9ON: C, 60.59; H, 9.15%.

Since the starting material used in the correlation work was of a 51.3% optical purity, the maximum rotations of (−)-*trans*-2-methylcyclopropanecarboxylic acid and (−)-*trans*-1-methyl-2-phenylcyclopropane should be $[\alpha]_D$ −83.6° and $[\alpha]_D$ −112.5° respectively in chloroform.

The Interaction of Thorium(IV) with Pyrocatechol-3, 5-disulfonate at a 1 : 1.5 Molar Ratio

By Yukito MURAKAMI and Arthur E. MARTELL

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka and Department of Chemistry, Illinois Institute of Technology, Chicago 16, Illinois, U.S.A.

(Received September 3, 1965)

In a previous paper[1] potentiometric measurements were reported on the chelating behavior of pyrocatechol-3, 5-disulfonate toward thorium(IV) ion at various molar ratios of ligand to metal ion. For ligand to metal ratios of 1.5 : 1 or higher the formation of a unique chelate of 1.5 : 1 ratio was observed, regardless of the amount of excess ligand present. The nature of this chelate was established by spectrophotometric measurements as well as by extraction[2] and ultracentrifugation[3] studies. The present work consists of a detailed study of the 1 : 1.5 thorium(IV) - pyrocatechol-3, 5-disulfonate system by means of potentiometric measurements to clarify the nature of the dinuclear thorium chelate.

Experimental

Materials.—Disodium pyrocatechol-3, 5-disulfonate (Tiron) was purchased from LaMotte Chemical Products Co., Baltimore, Md., U. S. A. and used without further purification. An aqueous stock solution of this ligand was standardized by potentiometric titration with standard base. Reagent grade thorium nitrate tetrahydrate, $Th(NO_3)\cdot 4H_2O$, purchased from Allied Chemical and Dye Corp., N. Y., was standardized gravimetrically and used to make up a stock solution for use in potentiometric titration.

Potentiometric Measurements. — A Beckman Model GS pH meter equipped with extension glass and calomel electrodes was used to measure hydrogen ion concentration directly. Calibration of the pH meter was performed by the aid of acetic acid buffer as well as standard hydrochloric aicd and sodium hydroxide. Measurements were carried out at 25.0± 0.05°C in a jacketed titration cell fitted with a magnetic stirrer, nitrogen inlet and outlet tubes, microburet delivery tube and electrodes. In all titrations the ionic strength was maintained at approximately 0.10 M with potassium nitrate, and a nitrogen atmosphere was maintained.

Results and Discussion

Potentiometric titration curves obtained at three different concentrations for the thorium(IV) - pyrocatechol-3, 5-disulfonate chelate system of a 1.5 : 1 molar ratio of ligand to metal ion are shown in Fig. 1. A sharp inflection region was observed at $m=3.0$ as has been previously observed for chelate systems of higher ligand to metal ratio.[1] On the basis of the rapid equilibria observed in the first buffer region, a simple reaction process is proposed for this range. Since the value of $([H^+]+T_{OH})/T_M$, the number of protons liberated per mole of total thorium species, already exceeds 2.0 at the start of titration, it may be concluded that the 1 : 1 metal chelate is nearly completely formed at this point. Thus, the predominant reaction, which proceeds in the buffer region lying below $m=3.0$, may be represented as:

$$2ThL + H_2L \rightleftarrows Th_2L_3 + 2H^+$$

$$K_D = \frac{[Th_2L_3][H^+]^2}{[ThL]^2[H_2L]} \quad (1)$$

The stoichiometric relations involved in this system*1 are:

$$T_M = [ThL] + 2[Th_2L_3] \quad (2)$$

$$T_L = [ThL] + 3[Th_2L_3] + [H_2L] \quad (3)$$

$$T_{OH} + [H^+] = 2[ThL] + 6[Th_2L_3] \quad (4)$$

where T_M and T_L represent the total analytical concentration of the metal species and of the ligand species present in a solution, while T_{OH} is the analytical concentration of the hydroxide ions added to a solution during the titrations. Combination and rearrangement of Eqs. 2 through 4 gives expressions for $[Th_2L_3]$, $[ThL]$ and $[H_2L]$ in terms of the measurable or known quantities m, $[H^+]$ and T_M. When these relations are introduced into Eq. 1, the equilibrium constant K_D may be expressed as:

$$K_D = \frac{\{(m-2)T_M+[H^+]\}[H^+]^2}{\{(3-m)T_M-[H^+]\}^3} \quad (5)$$

The logarithm of this equilibrium constant (log K_D) was calculated as 0.89.

In contrast to the first buffer region, the rate of attaining equilibrium was found to be extremely slow in the second buffer region ranging from 3.0 to 4.0. In addition, from the appearance of a second inflection at around $m=4.0$, it is assumed that a simple intramolecular olation reaction takes place

I ○, H_2O; Ⓜ, Th

Table I. Equilibrium relationships for Th(IV) chelates at 25°C, μ=0.10 (KNO_3)

Ligand	Type formula	Equilibrium constant: Quotient	Log K
EDTA[4]	H_4L	$[ThL]/[ThL(OH)][H^+]$	7.04±0.05
		$[ThL]^2/[Th_2L_2(OH)_2][H^+]^2$	9.82±0.05
		$[Th_2L_2(OH)_2]/[ThL(OH)]^2$	4.3±0.1
CDTA[4]	H_4L	$[ThL]/[ThL(OH)][H^+]$	7.58±0.05
		$[ThL]^2/[Th_2L_2(OH)_2][H^+]^2$	10.84±0.05
		$[Th_2L_2(OH)_2]/[ThL(OH)]^2$	4.3±0.1
Tiron	H_2L	$[Th_2L_3]/[Th_2L_3(OH)_2][H^+]^2$	12.8±0.1
		$[ThL]^2[H_2L]/[Th_2L_3(OH)_2][H^+]^4$	11.9±0.1

EDTA: ethylenediaminetetraacetic acid
CDTA: 1, 2-diaminocyclohexanetetraacetic acid

in the second buffer region.*2 Thus, the simple dissociation type reaction assumed for this region is:

$$Th_2L_3 \rightleftarrows Th_2L_3(OH)_2 + 2H^+$$

$$K_{D(OH)_2} = \frac{[Th_2L_3(OH)_2][H^+]^2}{[Th_2L_3]} \quad (6)$$

Stoichiometric relations consistent with Eq. 6 are:

$$T_M = 2[Th_2L_3(OH)_2] + 2[Th_2L_3] \quad (7)$$

$$T_{OH} + [H^+] - [OH^-] = 2[Th_2L_3(OH)_2] \quad (8)$$

Since $[H^+]-[OH^-]$ may be neglected in this pH region, the expression for the equilibrium constant $K_{D(OH)_2}$ simplifies to:

$$K_{D(OH)_2} = m'[H^+]^2/(1 - m') \quad (9)$$

where $m' = m - 3$.

At the half-neutralization point ($m' = 1/2$), the equilibrium constant becomes equal to the square of the hydrogen ion concentration. Although the present titration data do not provide an equilibrium constant of high accuracy for the above-assumed reaction, an approximate value has been obtained by use of Eq. 9. The estimated constant is given in Table I together with values for the EDTA and the CDTA chelate systems.[4] The dimeric thorium-(IV) - pyrocatechol-3, 5-disulfonate chelate may be considered at least qualitatively to show an olation tendency similar in magnitude to the other thorium chelates listed in Table I. A probable structure for the reaction product (I) is quite similar to that proposed for the ethylenediaminetetraacetate and the 1, 2-diaminocyclohexanetetraacetate chelates of thorium.[4]

In the second inflection region lying beyond $m = 4.0$, reaction equilibrium was reached extremely slowly. Therefore, further rearrangement and disproportionation reactions of the chelate formed in the second buffer region presumably take place with the participation of hydroxide ions.

*2 These experimental data do not eliminate the possibility of olation-polymerization through which the 2 : 3 Th(IV) - pyrocatechol-3, 5-disulfonate chelate further polymerize with hydroxide ions as bridging components. Further detailed studies on the 1 : 1.5 titration curve in much wider concentration range would help to clarify such an interaction.

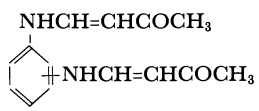
The Condensation of Methyl β-Chlorovinyl Ketone with Aromatic Diamines

By Yoshimori OMOTE, Katsumi KURIHARA, Yumiko KURABAYASHI and Noboru SUGIYAMA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received September 11, 1965)

The condensation of methyl β-chlorovinyl ketone (I) with amines such as aniline and *p*-aminophenol has previously been reported from this laboratory,[1] while the reaction of monoamines with I has been reported by Yakubovich.[2] While the reaction of α, β-unsaturated ketone with aromatic diamine is well known,[3] no example involving the condensation of I, an α, β-unsaturated ketone with chlorine on the β-position, with a diamine is found in the literature. During the course of a synthetic investigation of cyclic-conjugated compounds containing nitrogen it, however, became desirable to prepare new condensation products of I with aromatic diamines. This paper is concerned with the reaction of I with aromatic diamines, e. g., *o*-, *m*-, and *p*-phenylenediamines.



II: *o*-
III: *m*-
IV: *p*-

The reaction of two moles of I with one mole of *o*-phenylenediamine in the presence of potassium carbonate afforded a resinous substance which was sparingly soluble in ether. By the chromatographical fractionation of the resinous substance, a small quantity of crystals was obtained and identified with V on the basis of its elementary analysis and its ultraviolet and infrared absorption spectra. V showed an ultraviolet absorption spectrum

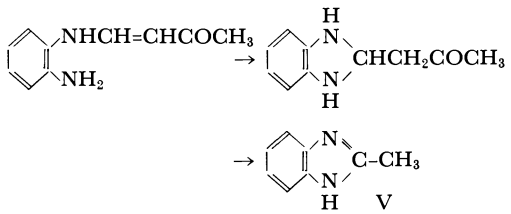
analogous to that of 2-methylbenzimidazol[4] and, as its infrared absorption maxima, 3400 (ν_{N-H}) and 2950 (ν_{C-H}) cm^{-1}. The formation of V might be explained as follows.



The reaction of two moles of I with one mole of *m*-phenylenediamine or *p*-phenylenediamine in the presence of potassium carbonate gave the expected condensation products, III and IV respectively. The ultraviolet absorption maximum of III appeared at 352 mμ in a neutral solution and at 351 mμ in an acid solution. If the nitrogen atom in the conjugated system of III had been protonated in an acid solution, the maximum of the absorption should move to the shorter wavelength. The preceeding observation that the absorption did not show the hypsochromic shift means that the protonation on the oxygen atom of the acetyl group in III is preferable to that on the nitrogen atom. The similar discussion will be supported by the fact that the ultraviolet absorption maximum of IV was 386 mμ in neutral and 395 mμ in acid solution. The infrared absorption maxima were found at 3400 (ν_{N-H}) and 1640 ($\nu_{C=O}$) cm^{-1} for III and at 3400 (ν_{N-H}) and 1630 ($\nu_{C=O}$) cm^{-1} for IV. These spectral data are consistent with structures III and IV.

The reactivity of III or IV with formaldehyde or benzaldehyde in the presence of piperidine acetate was so small that the aldol condensation products could not be formed. Both III and IV were found to be reasonably stable to sunlight, ultraviolet ray or γ-ray irradiation.

Experimental

All the melting points are uncorrected.

The Reaction of *o*-Phenylenediamine with Methyl β-Chlorovinyl Ketone.—Freshly-distilled methyl β-chlorovinyl ketone (10 g., 0.1 mol.) and *o*-phenylenediamine (5 g., 0.05 mol.) were dissolved in water (50 ml.); to this mixture potassium carbonate (27 g., 0.2 mol.) was then gradually added. The reaction product was resinous and insoluble in ether. The ethanol solution of the product was chromatographed on alumina. From the elution a trace of colorless crystals (V) was obtained; m. p. 176°C.

Found: C, 71.29; H, 5.37; N, 21.07. Calcd. for $C_8H_8N_2$: C, 72.70; H, 6.10; N, 21.20%.

UV: λ_{max}^{EtOH} (ε) 245 (6100), 273 (5900), 279 (6800) mμ, λ_{max}^{acid} 240, 268, 274 mμ, IR: ν_{N-H} 3400, ν_{C-H} 2950, 2850, ν_{C-H} 1360 cm^{-1}.

It was difficult to crystallize most of the resinous substance whose ultraviolet absorption maximum was near 390 mμ. This suggested the formation of II, but the resinous substance could not be sublimed in vacuo (10^{-3}—10^{-4} torr.) with a molecular still. Consequently, this substance must not be II but must be composed of polymers containing a conjugation similar to that of II.

***N, N'*-Di-(2-acetylvinyl)-*m*-phenylenediamine (III).**—To the mixture of methyl β-chlorovinyl ketone (10 g., 0.1 mol.) and *m*-phenylenediamine (5 g., 0.05 mol.) in water (50 ml.), potassium carbonate (27 g., 0.2 mol.) was gradually added. The reaction product was extracted with ether, and the ether layer was concentrated and kept in a refrigerator; brown fine cyrstals, 1.35 g., m. p. 195°C, were thus afforded.

Found: C, 68.89; H, 6.46; N, 11.52. Calcd. for $C_{14}H_{16}O_2N_2$: C, 68.83; H, 6.60; N, 11.47%.

UV: λ_{max}^{EtOH} (ε) 352 (41000) mμ, λ_{max}^{acid} 351 mμ.

IR: ν_{N-H} 3400, $\nu_{C=O}$ 1640, ν_{C-H} 1350 cm^{-1}.

***N, N'*-Di-(2-acetylvinyl)-*p*-phenylenediamine (IV).**—The reaction mixture of methyl β-chlorovinyl ketone (10 g., 0.1 mol.) and *p*-phenylene diamine (5 g., 0.05 mol.) in the presence of potassium carbonate (27 g., 0.2 mol.) was extracted with ether, dissolved in hot ethanol, and kept at room temperature. After recrystallization, fine orange-yellow needle crystals were obtained, m. p. 193°C.

Found: C, 68.72; H, 6.56; N, 11.48. Calcd. for $C_{14}H_{16}O_2N_2$: C, 68.83; H, 6.60; N, 11.47%.

UV: λ_{max}^{EtOH} (ε) 386 (47000) mμ, λ_{max}^{acid} 395 mμ.

IR: ν_{N-H} 3400, $\nu_{C=O}$ 1630, ν_{C-H} 1360 cm^{-1}.

The Attempted Condensation of III or IV with Aldehydes.—Equimolecular mixtures of III or IV and formaldehyde or benzaldehyde were kept at room temperature or heated under reflux in the presence of piperidine acetate or piperidine. From each reaction mixture III or IV and aldehyde were recovered.

The Change of III or IV with Sunlight, Ultraviolet Ray or γ-Ray Irradiation.—III and IV were stable to sunlight for a week, and to the ultraviolet rays of a high-pressure mercury lamp for two days. The γ-ray irradiation of III and IV, with a total dose of 5×10^7 r./hr. and a dose rate of 1.5×10^7 r./hr. showed little change in the ultraviolet absorption spectrum. The precise results will be reported elsewhere.[5]

The Determination of Dissolved Oxygen by the Use of Its Stoichiometric Reaction with Metallic Lead

By Yūsuke UJIHIRA, Hideo WATANABE* and Eiji NIKI

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received September 15, 1965)

The study of the quantitative determination of minute amounts of dissolved oxygen is receiving particular attention, with special regard being paid to the control of the oxygen content of feeding water to a high-pressure boiler plant, or to the biochemical processes.

Among the many techniques proposed for the estimation of oxygen dissolved in water,[1] the method based on the oxidation and dissolution of metal is thought to be most promising.

The oxidation of metallic thallium to a thallous ion and subsequent determination by means of the electric conductivity,[2] the radioactive ^{204}Tl tracer technique,[3,4] or by polarography[4] have been investigated recently; also a several p. p. m. concentration of oxygen has been measured by the oxidation of zinc amalgam[5] or copper metal[6,7].

The authors, in the course of a study of the reaction of metal and dissolved oxygen, noticed a stoichiometry in lead-aqueous oxygen system.

The resultant of the reaction was lead hydroxide, which can be dissolved with an acetic acid and sodium acetate solution, whereas lead metal is not bitten by the acetate mixture. The reaction is conjectured to be:

$$Pb + 1/2O_2 + H_2O \rightarrow Pb(OH)_2$$

$$Pb(OH)_2 + 2CH_3COOH \rightarrow Pb(CH_3COO)_2 + 2H_2O$$

or

$$Pb + 1/2O_2 + 2CH_3COOH \rightarrow Pb(CH_3COO)_2 + H_2O$$

The eluted plumbous ion was determined directly by a. c. polarography. Useful information was obtained thus for designing a method of determining the oxygen dissolved in water.

Experimental, Results and Discussion

The sample solution was prepared by boiling pure water in an atmosphere of nitrogen, and the dissolved oxygen content was calibrated by the amperometric titration with two polarized electrodes, as reported by Potter and White.[8] The standardized sample solution was fed to the reaction column (diam. 1.2 cm., height 7.0 cm.), which had been filled with metallic lead grain (diam. 2—3 mm.), together with a 50% acetic acid solution, saturated with sodium acetate. The schematic diagram of the experimental system is shown in Fig. 1.

a electrolytic cell, the quantity of lead was determined by measuring the wave height of the a. c. polarogram.

The results of this experiment are shown in Table I.

TABLE I. THE STOICHIOMETRY OF $Pb+1/2O_2+2CH_3COOH \rightarrow Pb(CH_3COO)_2+H_2O$ REACTION

Oxygen content in sample sol. (p.p.m.)	Quantities of lead dissolved per ml. calcd. (μg.)	Dissolved quantities of lead. obsd. (μg.)	Obsd./Calcd.
7.50	97.5	96.0	0.98
4.86	63.2	65.7	1.04
3.14	40.8	37.5	0.92
2.80	36.4	38.0	1.04
1.51	19.6	22.5	1.15
0.34	4.4	7.2	1.64

The stoichiometry of the $Pb+1/2O_2+2CH_3COOH \rightarrow Pb(CH_3COO)_2+H_2O$ reaction above the p.p.m. region could be confirmed because the ratio of the observed to the calculated quantity of dissolved lead was approximately one.

Accordingly, the linearity of the aqueous oxygen content vs. the dissolved lead is perfect in the 1—10 p.p.m. range.

The completeness of the reaction of a metallic lead and aqueous oxygen was confirmed by the fact that no oxygen reduction wave was detected in the polarogram. Though a marked departure from the stoichiometrical linearity was observed for the extremely low oxygen content solution, this seems to result from the leakage of air into the sample and the acetate buffer solution, through polyvinyl tubings or through the interstice between polyvinyl and glass tubings in the course of the experiments. The advantages of the lead column method over the other methods (especially the thallium column method) will be outlined below:

(1) A lead column can be used effectively for a weak acidic sample, whereas the thallium method results in a serious positive error due to the dissolution of metallic thallium by a sample solution.

(2) A lead column can be readily prepared by filling the commercially-available lead grain in a glass tubing.

(3) The lead is more immune to oxidation by air than is the thallium.

(4) The dissolved quantities of lead can be determined by the use of the radioactivity, as ^{210}Pb is readily available.

(5) The lead-column method is readily applicable to the continuous measurement of the aqueous oxygen content.

A Semiempirical Unrestricted SCF Calculation of the *trans*-Stilbene Anion Radical

By Keiji MOROKUMA, Takashi KAWAMURA, Shoichi MATSUNAMI and Teijiro YONEZAWA

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received September 27, 1965)

In recent electron spin resonance studies of the anion radicals of *trans*-stilbene,[1] azobenzene,[2] benzaldehyde and acetophenone,[3] it has been found that the isotropic coupling constants of the protons of two *ortho*-positions, and also that of two *meta*-positions in the phenyl ring, differ from each other. These differences can not be interpreted by either the Hückel molecular orbital (HMO) method or the McLachlan procedure,[4] because in these methods the resonance integrals between non-bonded atoms are not taken into account.

Hence, we will make an semiempirical unrestricted SCF calculation, as proposed by Pople and Nesbet[5] and developed by Brickstock and Pople,[6] for the *trans*-stilbene anion radical. It will be shown in the present treatment that the difference between spin densities at two *ortho*-positions and also that at two *meta*-positions appear in accordance with the experimental results.

The Method of Calculation

In the semiempirical unrestricted SCF method, two sets of LCAO coefficients, $\chi_{i\mu}{}^{\alpha}$ and $\chi_{i\mu}{}^{\beta}$, are calculated as follows:

$$\sum_{\nu} F^{\alpha}_{\mu\nu}\chi^{\alpha}_{i\nu} = E^{\alpha}_{i}\chi^{\alpha}_{i\mu}; \quad \sum_{\nu} F^{\beta}_{\mu\nu}\chi^{\beta}_{i\nu} = E^{\beta}_{i}\chi^{\beta}_{i\mu} \qquad (1)$$

where:

Table I. Calculated and experimentally found[1] spin distributions in the *trans*-stilbene anion radical

Position	a_H[a]	$\mid \rho_{exp} \mid$[9]	ρ_{SCF}	$\rho_{McL.}$	ρ_{HMO}
1	2.90	0.132	+0.1230	+0.1232	+0.0750
2	0.81	0.036	−0.0672	−0.0804	+0.0063
3	3.89	0.173	+0.1747	+0.1436	+0.0984
4	0.30	0.013	−0.0651	−0.0804	+0.0063
5	1.90	0.0844	+0.1168	+0.1232	+0.0750
6	—	—	+0.0205	−0.0031	+0.0472
7	4.37	0.194	+0.1974	+0.2739	+0.1919

a) From Ref. 1), in units of gauss. The assignment of the coupling constants of two sets of *ortho*-protons and of *meta*-protons is made based on our calculation.

$$\left.\begin{aligned} F^{\alpha}_{\mu\mu} &= U_{\mu\mu} + P^{\beta}_{\mu\mu}\gamma_{\mu\mu} + \sum_{\sigma(\neq\mu)}(P_{\sigma\sigma} - 1)\gamma_{\mu\sigma} \\ F^{\beta}_{\mu\mu} &= U_{\mu\mu} + P^{\alpha}_{\mu\mu}\gamma_{\mu\mu} + \sum_{\sigma(\neq\mu)}(P_{\sigma\sigma} - 1)\gamma_{\mu\sigma} \\ F^{\alpha}_{\mu\nu} &= \beta_{\mu\nu} - P^{\alpha}_{\nu\nu}\gamma_{\mu\nu} \quad (\mu \neq \nu) \\ F^{\beta}_{\mu\nu} &= \beta_{\mu\nu} - P^{\beta}_{\mu\nu}\gamma_{\mu\nu} \quad (\mu \neq \nu) \end{aligned}\right\} \quad (2)$$

$$\left.\begin{aligned} P^{\alpha}_{\mu\nu} &= \sum_{i}^{occ} \chi^{\alpha}_{i\mu}\chi^{\alpha}_{i\nu}; \quad P^{\beta}_{\mu\nu} = \sum_{i}^{occ} \chi^{\beta}_{i\mu}\chi^{\beta}_{i\nu} \\ P_{\mu\nu} &= P^{\alpha}_{\mu\nu} + P^{\beta}_{\mu\nu} \end{aligned}\right\} \quad (3)$$

In Eq. 1, 2 and 3, all the notations are the same as Brickstock and Pople's.[6] The spin density at the carbon atom μ, ρ_μ, is obtained from Eq. 4:

$$\rho_\mu = P^{\alpha}_{\mu\mu} - P^{\beta}_{\mu\mu} \quad (4)$$

As the penetration integral is neglected, $U_{\mu\mu}$ becomes a constant over all the carbon atoms. $\gamma_{\mu\nu}$ is calculated by means of the approximation of Pariser and Parr.[7] The resonance integral, $\beta_{\mu\nu}$, is calculated by means of Eq. 5:

$$\beta_{\mu\nu} = \begin{cases} -10.44\, S_{\mu\nu}\ \text{eV.} & (R_{\mu\nu} < 3.0\text{Å}) \\ 0 & (R_{\mu\nu} \geq 3.0\text{Å}) \end{cases} \quad (5)$$

where $R_{\mu\nu}$ is the distance between the μth and νth atoms, and $S_{\mu\nu}$ is the overlap between two $2P_Z$ Slater-type atomic orbitals with $Z^* = 3.25$.

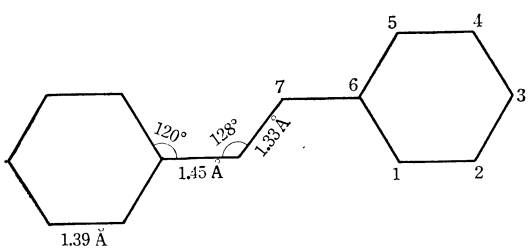

Fig. 1. Structure and numbering of positions of *trans*-stilbene.

The structure[8] and the numbering of the positions in *trans*-stilbene are shown in Fig. 1.

Results and Discussion

The spin distribution calculated with the semiempirical unrestricted SCF method and the observed coupling constants[1] and the spin densities[9] are tabulated in Table I.

Chang and Johnson[1] assigned coupling constants of 2.96 gauss and 1.90 gauss, which correspond to the spin densities of 0.132 and 0.0844 respectively,[9] to the *ortho*-protons, but they did not make clear which of these coupling constants is due to the proton in the C–H bond at the carbon atom 1 (1-proton) and which to that at the carbon atom 5 (5-proton). We obtained $\rho_1 = +0.1230$ and $\rho_5 = +0.1168$ as the spin densities at the *ortho*-carbons by means of our SCF calculation. Through a comparison of these coupling constants and calculated spin densities, we could assign the coupling constant of 2.96 gauss to the 1-proton and that of 1.90 gauss to the 5-proton. By then comparing the coupling constants of the *meta*-protons and the calculated spin densities at the *meta*-carbons, we could assign the coupling constant of 0.81 gauss to the 2-proton and that of 0.30 gauss to the 4-proton. The values in the second and in the third columns in Table I are written according to the above-mentioned assignment. The agreement between the observed spin distribution and the spin distribution calculated by means of the SCF method seems fairly good.

Spin distributions calculated by means of the HMO method and by means of the McLachlan procedure with $\lambda = 1.00$ are also listed in Table I for the sake of comparison.

The SCF and HMO calculations were carried out on the KDC-I digital computer of Kyoto University.

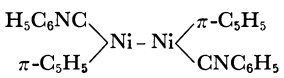
Bis[cyclopentadienyl(cyclohexyl isocyanide)nickel]

By Yasuhiro YAMAMOTO and Nobue HAGIHARA

The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received October 4, 1965)

It has already been well established that isocyanides, analogous to carbon monoxide, produce various isocyanide complexes of transition metals. Pauson and Stubbs[1] have prepared bis[cyclopentadienyl(phenyl isocyanide)nickel] by means of the reaction of nickelocene with tetrakis(phenyl isocyanide)nickel; they have suggested the sturucture I on the basis of the peak of the infrared spectrum at 2175 cm^{-1}.



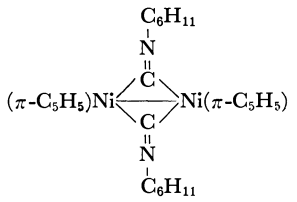
(I)

Recently, Pauson and his co-workers[2] have reported an iron complex with a bridging isocyanide group and have also established that bis[cyclopentadienyl(phenyl isocyanide)nickel] has a bridged structure in a solid state, but these points have not been discussed in detail.

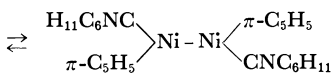
We wish to report the direct preparation of a similar compound from nickelocene by means of cyclohexyl isocyanide. During the studies of the polymerization of cyclohexyl isocyanide using various metallocenes as catalysts, we found that the use of nickelocene as a catalyst was very favorable to the polymerization; in this case bis[cyclopentadienyl(cyclohexyl isocyanide)nickel] (II) was isolated as an intermediate of the polymerization reaction.

When nickelocene was treated with cyclohexyl isocyanide at room temperature, the reaction took place instantaneously, as was shown by the rapid color change from green to red brown, and gave a 38% yield of bis[cyclopentadienyl(cyclohexyl isocyanide)nickel] as red brown needles. The infrared spectrum of this compound in Nujol mull showed two peaks, at 1870 and 1830 cm^{-1}; these peaks were analogous to those of bis[cyclopentadienyl(carbonyl-nickel] with bridging carbonyl groups. The spectrum in benzene showed a strong peak at 2140 cm^{-1} and two weak peaks, at 1880 and 1840 cm^{-1}, while in *n*-hexane it showed only a strong peak at 2140 cm^{-1}.

It was concluded from the infrared spectrum that bis[cyclopentadienyl(cyclohexyl isocyanide)nickel] had a bridged isocyanide structure II-a in a solid state and that it existed in an equilibrium between a bridged isocyanide structure II-a and a terminal isocyanide structure II-b in solutions, in which the former should make a greater contribution than the latter.



(II-a)



(II-b)

The reaction of cyclohexyl isocyanide with bis[cyclopentadienyl(carbonyl)nickel] took place readily at room temperature, and it also gave a 15% yield of bis[cyclopentadienyl(cyclohexyl isocyanide)nickel]. Analogously, dicyclopentadienyl(acetylene)dinickel gave a 12% yield of the same compound.

Experimental

Materials.—Cyclohexyl isocyanide,[3] nickelocene,[4] bis[cyclopentadienyl(carbonyl)nickel],[5] and dicyclopentadienyl(acetylene)dinickel[6] were prepared by methods described in the literature.

The Reaction of Cyclohexyl Isocyanide with Nickelocene. — A solution of 1.0 g. (5.3 mmol.) of nickelocene in 40 ml. of a benzene - *n*-hexane mixture (1 : 1) was treated with 0.6 g. (5.5 mmol.) of cyclohexyl isocyanide at room temperature and then kept for 3 hr. The reaction mixture was evaporated to about 10 ml. under reduced pressure and chromatographed on alumina. Eluting with a benzene - *n*-hexane mixture gave raw products, from which bis[cyclopentadienyl(cyclohexyl isocyanide)nickel] was obtained as red brown needles by recrystallization from the benzene - *n*-hexane mixture (1 : 5). (Yield. 38%; m. p. 155—156°C (decomp.)) This compound was sensitive to air, so all the procedures mentioned above were performed under a nitrogen atmosphere.

* By the cryoscopic benzene method.

Found: C, 61.59; H, 7.01. Calcd. for $[Ni(C_5H_5)(CNC_6H_{11})]_2$ C, 61.85; H, 6.87%. M. w. 451* (466).

The Reaction of Cyclohexyl Isocyanide with Bis[cyclopentadienyl(carbonyl)nickel] (III) or Dicyclopentadienyl(acetylene)dinickel (IV) $(C_5H_5)Ni(HC{\equiv}CH)Ni(C_5H_5)$.—The procedure was similar to the reaction described above except that dry benzene was used as the solvent. The working-up of the reaction mixture gave bis[cyclopentadienyl(cyclohexyl isocyanide)nickel]. The yields of II from III and IV were 12% and 15% respectively.

The Reduction of Styrene Derivatives with the Commercial Sodium-Lead Alloy

By Katsumi TABEI, Hidetoshi HIRANUMA and Norio AMEMIYA

Tokyo College of Pharmacy, Kashiwagi, Shinjuku-ku, Tokyo

(Received October 26, 1965)

Recently a sodium-lead alloy was marketed as a drying agent of organic solvents.[1] A sodium-lead alloy had previously been used in the reduction of multivalent metal ions, such as titanium(IV), vanadium(V), and chromium(III),[2] but the alloy has not yet been used in organic reduction.

The present authors have tried the commercial sodium-lead alloy, "Drynap," as a reducing agent in place of sodium amalgam for the reduction of cinnamic acid in an aqueous sodium hydroxide solution according to the method of Erlenmeyer[3]; hydrocinnamic acid was thus obtained in a 87% yield. From this successful result, the Drynap reduction of several styrene derivatives was also attempted; a little of the information so obtained will be reported here.

The reduction was carried out in an ethanol solution by using the commercial sodium-lead alloy and acetic acid as in the method of amalgam reduction.[4,5] Under these conditions, benzylideneacetone, dibenzylideneacetone, benzylideneacetophenone, piperonylideneacetone, and methyl-cinnamate were not reduced to the corresponding di- or tetra-hydrogenated compound, but were dimerized to 4, 5-diphenyl-2, 7-octanedione, 1, 5, 6, 10-tetraphenyl-1, 9-decadiene-3, 8-dione, 1, 3, 4, 6-tetraphenyl-1, 6-hexanedione, 4, 5-di-(3, 4-methylenedioxyphenyl)-2, 7-octanedione, and dimethyl 2, 4-diphenyladipate respectively. ω-Nitrostyrene was also reduced with Drynap and acetic acid in an ethanol solution to phenylacetaldoxime in about a 60% yield.

In the above reactions, the yield generally increased at higher temperatures, but decreased above 60°C because of the increase in polymerization. The yield also decreased in the reaction on a larger scale.

On the other hand, styrene, isosafrol, and cinnamyl alcohol were not affected by the sodium-lead alloy under the above conditions; the reaction then resulted in the recovery of the starting material. Cinnamaldehyde was also not reduced with sodium-lead alloy and acetic acid, and was easily polymerized, even at low temperatures.

On the basis of the above results, the authors recommend the use of sodium-lead alloy as the mild reducing agent; however, it has the disadvantage of being expensive.

Experimental

The Reduction of Cinnamic Acid with the Sodium-Lead Alloy.—Ten grams of cinnamic acid

TABLE I. THE PRODUCTS OF DRYNAP REDUCTION

Material	Product	M. p., °C	Yield, %
Ph-CH=CH-$COCH_3$	[Ph-CH-CH_2-$COCH_3$]$_2$	116	10—35
Ph-CH=CH-CO-CH=CH-Ph	[Ph-CH-CH_2-CO-CH=CH-Ph]$_2$	210	58
Ph-CH=CH-CO-Ph	[Ph-CH-CH_2-CO-Ph]$_2$	193	45
$(H_2C\langle^{O}_{O}\rangle C_6H_3)$-CH=CH-$COCH_3$*	[$(H_2C\langle^{O}_{O}\rangle C_6H_3)$-CH-$CH_2$-$COCH_3$]$_2$	228	25—30
Ph-CH=CH-$COOCH_3$	[Ph-CH-CH_2-$COOCH_3$]$_2$	178	~5
Ph-CH=CH-NO_2	Ph-CH_2-CH=N-OH	103	~60

was dissolved in 70 ml. of a 5% sodium hydroxide solution. Into the solution, 50 g. of the commercial sodium-lead alloy "Drynap" (contains more than 9.5% of active sodium metal) was vigorously stirred in small portions at 55—60°C. After one hour, the alkaline mixture was acidified with hydrochloric acid; 9.0 g. of hydrocinnamic acid, m. p. 49°C, was thus obtained in a 87% yield.

The General Procedure of the Reduction with Drynap and Acetic Acid.—Into an ethanol solution of 0.02 mol. of material described in Table I, 20 g. of Drynap (corresponding to 0.08 atom of sodium metal) and 5 ml. of gracial acetic acid were vigorously stirred in small portions. The reaction temperature was maintained below 60°C.

After 1 or 1.5 hr., the reaction mixture was separated from the residual spongy lead, and the filtrate was evaporated in order to remove the solvent. The residue was extracted with benzene.

The extract was washed with 5% sodium hydrogen carbonate solution and water, and dried over sodium sulfate. The crude product was dissolved in benzene, passed through an alumina column, and recrystallized with benzene or ligroin.

The materials and reduced products are listed in Table I.

The authors wish to thank Dr. Akio Nara for his microanalyses, and the Wako Pure Chemical Co., Ltd., for its gift of Drynap.

SHORT COMMUNICATIONS

Asymmetric Hydrogen with Modified Raney Nickel. VII

By Yoshiharu IZUMI, Susumu TATSUMI and Masami IMAIDA

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received December 24, 1965)

It has been reported from our laboratory[1] that Raney nickel catalyst, modified with aqueous solutions of optically active 2-amino and 2-hydroxycarboxylic acids, shows an asymmetric hydrogenation activity in the hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate, and that optically-active dihydroxy dicarboxylic acids, such as D- or L-tartaric acid, and their *C*-alkyl-substituted derivatives are very effective in the asymmetric modification.

The present paper will describe the asymmetric activity of Raney nickel modified with (+)-1, 2-dihydroxycyclohexane-1, 2-dicarboxylic acid,* which is a sort of *C, C'*-disubstituted tartaric acid. The asymmetric activity of the catalyst in the hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate was measured as described in a previous paper.[1]

When Raney nickel was modified at 0°C with an aqueous solution of the acid, its asymmetric activity was greatly influenced by the pH of the modifying solution, as is shown in Fig. 1, this influence being quite different from those of catalysts obtained on modifications with tartaric acid, *C*-methyl- and *C, C'*-dimethyltartaric acid.[1] Optimum asymmetric activities were observed at pH 5—7; this pH range approximately corresponds to the pH-jumping region of the neutralization curve of the acid, as is shown in Fig. 2. However, there was a very great diminution in activity at pH values below pH 5. It is likely that both carboxyl groups of the modifying reagent are adsorbed upon the nickel metal under acidic conditions, while at pH 5—7, one of them is desorbed completely from the metal and forms a massive steric hindrance, which then regulates the approach of methyl acetoacetate to the catalyst. Further details will be reported in the near future.

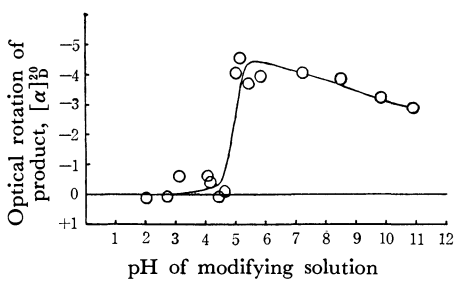

Fig. 1. Modification with (+)-1,2-dihydroxycyclohexane-1,2-dicarboxylic acid.

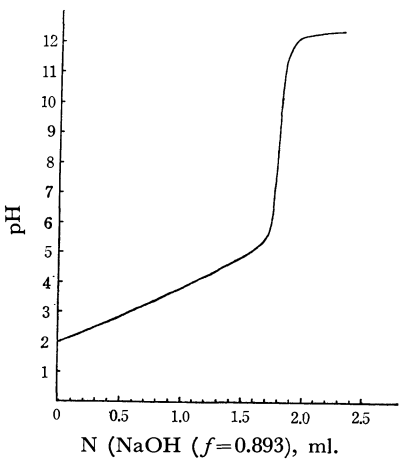

Fig. 2. Neutralization curve of 1% acid solution with N NaOH.

* The preparation of this hydroxy acid will be reported in this Bulletin in the near future.

The Preparation of Polymeric Fine Powder with Crosslinkage and Its Application as a Mordant

By Yukio MIZUTANI

Tokuyama Soda Co., Ltd., Tokuyama, Yamaguchi

(Received November 29, 1965)

It has been well known that a polymeric fine powder can be prepared by emulsion polymerization; no other method of preparation has yet been reported. A new method of preparing a polymeric fine powder with crosslinkage (PFPC) and its application as a mordant for poorly dyeable fibers will be reported in this paper. Vinyl monomers and divinyl benzene (DVB) were polymerized in some specified solvents (for example, an aliphatic hydrocarbon or an aliphatic alcohol) with stirring using benzoyl peroxide (BPO) as a polymerization initiator; PFPC was thus obtained. Table I shows examples of the polymerization at 80 ±5°C. The usefulness of these solvents may be attributed to the behavior of these solvents, in which the monomers are soluble but the polymer is insoluble. Furthermore, DVB should be effective in promoting the separation of the polymer from the solvent and in making the polymer very fine powdery. The PFPC prepared by this new method was a spherical powder with a diameter of about 0.1 μ or less; accordingly, its application as a mordant for poorly dyeable fibers could be expected.

Also, it has been known that the blend of some dyeable polymers, such as polymethyl methacrylate[1] or polyvinylpyridine[2], is effective in improving the polypropylene dyeability; the dyeable polymer is thus finely dispersed[1] because of its immiscibility to the fiber substrate.[3] The dyeable polymers thus blended can easily be extracted by acetone, but the newly-developed PFPC was inextractable because of its crosslinked structure. A common disadvantage of these blend systems, however, is that the dye in the substrate is not fixed perfectly by the chemical bond, and so can easily be extracted by acetone. Following the general idea mentioned above to improve the dyeability of a polymer-blended system, the author finally decided to apply the glycidyl group to PFPC as a reactive functional group; this proved to be very useful not only in dyeability but also in resistance to the the solvent extraction of the dyeings. Some of the results are shown in Table II.

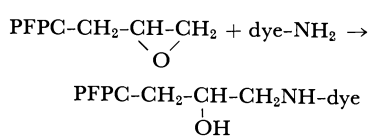
Table II. The dyeing result with celliton blue extra type*3

Sample blended*1	Color after dyeing	Color after acetone-extraction*2
A	medium colored	none
B	medium colored	none
C	medium colored	medium colored

*1 The quantity of PFPC added: 3.8% by weight.

*2 The extraction was carried out for 8 hr. by the use of a Soxhlet extractor.

*3 



In conclusion, we recommend using PFPC with a reactive functional group which may behave as a mordant in the dyeing of polypropylene fiber. The details will be reported soon.

The Relationship between Allylic or Homoallylic-coupling Constants and Electron Localization on C=N Double Bonds in Some Schiff Bases and Their *N*-Oxides

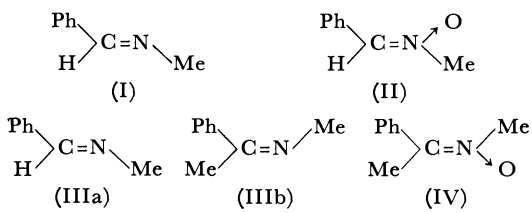
By Kazuo TORI, Masako OHTSURU and Tanekazu KUBOTA

Shionogi Research Laboratory, Shionogi & Co. Ltd., Fukushima-ku, Osaka

(Received February 17, 1966)

It is well known that the magnitude of an allylic or a homoallylic coupling constant[1] depends upon the degree of σ-π overlaps[1,2] and the amount of electron localization on the intervening double bond.[1,3,4] A similar situation is also seen when the central double bond is C=N.[1,3,5,6]

We have recently observed the PMR spectra of benzal-*N*-methylamine (I),[7] its *N*-oxide (II),[7] methylbenzal-*N*-methylamine (III),[8] and its *N*-oxide (IV).[9] The spectral data obtained by the first-order approximation are listed in Table I.



The introduction of the N→O bond into I extends the conjugation and causes an electron delocalization on the C=N double bond, as our previous study by ultraviolet absorption spectroscopy proved.[7] Therefore, it may readily be expected that the allylic or the homoallylic coupling constants vary from compound to compound and with the protonation occurring in such an acid solvent as trifluoroacetic acid. The fairly large $|J_{H,CH_3}|$ value in I becomes smaller in a deuterotrifluoroacetic acid solution and much smaller in II, in spite of the increase in the electronegativity of the nitrogen atom by the protonation to I and also by introducing an N→O group into I. These decreases in the $|J_{H,CH_3}|$ value should, accordingly, be attributed to the decreasing double-bond character of the C=N bond. In fact, π-bond orders calculated by Hückel MO method[10] are consistent with these results (Table I). However, the J_{CH_3,CH_3} value in IV, which is considerably larger than the $|J_{H,CH_3}|$ value in II, does not decrease appreciably in comparison with the J_{CH_3,CH_3} value in IIIb. These facts can be ascribed to the steric hindrance of the phenyl group with the methyl groups, which interrupts the conjugation of the benzene ring with the C=N bond. These conclusions are consistent with the results obtained by the earlier ultraviolet absorption spectroscopic study.[7] A study of the solvent effects and a theoretical study of the chemical shifts of these and other related compounds in connection with electron densities and other factors are now in progress.

TABLE I. PMR SPECTRAL DATA*1 AND RESULUS OF HÜCKEL MO CALCULATION*2

Compound	Chemical shift (τ)		Coupling constant*3, (c.p.s.)		π-Bond order of C=N
	=CH or =C-CH_3	=N-CH_3	J_{H,CH_3}	J_{CH_3,CH_3}	
I	1.81 (1.18)*4	6.53 (6.03)*4	−1.6 (−1.1)*4	—	0.873 (0.529)*5
II	2.76	6.21	−0.5	—	0.732
IIIa	7.82 (7.06)*4	6.69 (6.33)*4	—	+0.8 (+0.6)*4	
IIIb	7.82 (~7.05)*4	7.03 (6.42)*4	—	+1.4 (+0.9)*4	
IV	7.69	6.45	—	+1.2	

*1 The spectra were recorded on a Varian A-60 spectrometer by using solutions in CCl_4 containing Me_4Si as an internal reference, unless otherwise noted.

The Configuration of Verarine[1]

By Tadashi MASAMUNE, Iwao YAMAZAKI and Mitsuo TAKASUGI

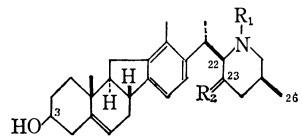
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received March 7, 1966)

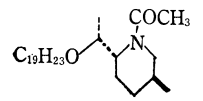
Tomko and Bauer have recently isolated a steroid alkaloid named verarine from *Veratrum album subsp. lobelianum*. From a chemical and spectroscopic investigation of this substance, they have concluded that the alkaloid is 23-desoxy-veratramine,[2] but until now no details have been available of its steric configuration. Our present study confirms their structural formula and, in addition, provides the stereochemistry of the compound.

The treatment of veratramine (I) with acetic anhydride (6 mol.) in pyridine at −10°C, followed by chromatography, afforded, in a 44% yield, 3, *N*-diacetylveratramine[3] (II), m. p. 161—163°C; IR,[3] ν_{max} 1027 cm^{-1}. On oxidation with Jones' reagent, II was converted to 23-dehydro-3, *N*-diacetylveratramine (III) in a 73% yield, m. p. 196—198°C; UV,[3] λ_{max} 302 mμ (ε 250); ORD,[3] a strong negative Cotton effect. The treatment of III with sodium methoxide in refluxing methanol and subsequent acetylation led to an isomeric ketone (IV), m. p. 246—248°C; UV, λ_{max} 303 mμ (ε 290); ORD, a weak negative Cotton effect. III and IV were isolated in the ratio of 1 : 10 from an equilibrium mixture in an alkaline solution. As the benzyl part at C-22 and the 26-methyl group in the piperidine ring are *cis*-oriented in III,[4] those groups in IV must have a *trans*-configuration.

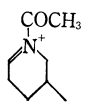
III was treated with ethane-1, 2-dithiol in methanol saturated with hydrogen chloride at 0°C. The product showed two main spots on a thin-layer chromatogram on silica gel. The fraction with the large R_f value yielded 23-ethylene thioketal (V), m. p. 155—156°C, while the product



I R_1=H, R_2=-H, ···OH
VI R_1=Ac, R_2=H_2



VII



VIII

obtained from the fraction with the small R_f value again showed the same two spots. Having available the facile isomerization of the latter, V was isolated in a 73% yield. The treatment of V with Raney nickel in refluxing ethanol resulted in desulfurization, giving *N*-acetyl-23-desoxy-veratramine (VI) in a 60% yield, m. p. 195—197 °C; $[\alpha]_D$[3] −21°; UV, λ_{max} 267 mμ (ε 930) and 275 (900); IR, ν_{max} 3410, 1610, 1068 and 808 cm^{-1}. On the other hand, the Huang-Minlon reduction of III led to the removal of the 23-oxygen, with a concomitant epimerization at C-22, and gave an isomeric 23-desoxy compound (VII) in a good yield, m. p. 240—242°C; $[\alpha]_D$ −28°; UV, λ_{max} 269 mμ (ε 870) and 278 (810); IR, ν_{max} 3419, 1622, 1060 and 810 cm^{-1}. Both VI and VII showed strong peaks at *m/e* 140 due to a fragment, VIII, in the mass spectra.[5] In view of the process of the Huang-Minlon reaction, it is apparent that VI has the same configuration as III. Through the kindness of Dr. J. Tomko, VI was proved to be identical with *N*-acetylverarine in all respects. Since the configurations of all the asymmetric carbon atoms in I have already been established,[6] the present transformation completes the stereochemistry of verarine.

An X-Ray Analysis of Blasticidin S Monohydrobromide

By Shigeki ONUMA, Yoshiharu NAWATA and Yoshihiko SAITO

The Institute for Solid State Physics, The University of Tokyo, Azabu, Tokyo

(Received March 16, 1966)

Blasticidin S is an antibiotic isolated[1] from *Streptomyces griseochromogenes*. In cooperation with the organic chemical investigation of Yonehara et al.,[2] blasticidin S monohydrobromide has now been subjected to X-ray analysis in order to elucidate its molecular structure.

Small plate-like crystals were kindly supplied by Professor H. Yonehara and Professor N. Otake. They are orthorhombic, of the space group $P2_12_12_1$, with four molecules of $C_{17}H_{26}O_5N_8 \cdot HBr$ in a unit cell with dimensions of $a=20.39$, $b=21.34$ and $c=4.81$Å.

The intensities were estimated visually from equi-inclination Weissenberg photographs of the $hk0$–$hk3$ layers; the multiple-film technique was employed. The relative values of the observed structure amplitudes of 1653 reflections were collected by means of Cu $K\alpha$ radiation. The exposures were such that the various layers were approximately on the same relative scale; the absolute scale of each layer was obtained at a later stage by correlation with the calculated structure amplitudes. No absorption correction was applied.

At first the analysis proceeded directly on the basis of the usual two-dimensional sign-determining heavy-atom method, because the c-axis is fairly short. The initial coordinates of the bromide ion were determined by calculating the Patterson projection. With the signs determined by only the bromide ion and with the observed 354 $hk0$ amplitudes, the first two-dimensional electron-density distribution was calculated; however, it was hard to interpret. The heavy atom did not seem to be powerful enough for the signs to be determined correctly. Many cycles of iterative Fourier syntheses had to be carried out until a structure was found plausible enough for further refinement. At later stages of the analysis, the structure was refined by the difference syntheses and by the isotropic least-squares method. The final R index for $hk0$ reflections was about 0.15.

The final two-dimensional electron-density distribution and the corresponding molecular framework are shown in Fig. 1. The topography of the final difference synthesis is flat, even in the neighborhood of the bromide ion, within the range of ± 1 e/Å^2. The individual isotropic temperature factors, B, refined by the least-squares method are reasonable values of 4.3 for the bromide ion and 2.5—3.9 for the carbon, nitrogen and oxygen atoms; the light atoms were assigned correctly. The resulted molecular structure is consistent with the modified structure reported by the chemical group.

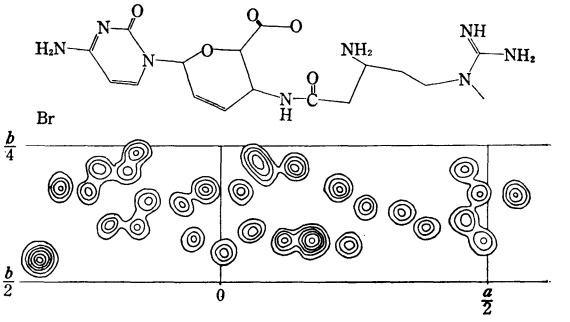

Fig. 1

A three-dimensional analysis is now in progress; the results will be published elsewhere.

The Photo-Ionization of Molecules in Solutions. II. Electron Transfer from Aromatic Diamine to Pyrene

By Hiroshi TSUBOMURA, Naoto YAMAMOTO and Yoshihiro NAKATO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received March 23, 1966)

We have found that the process of the photo-ionization of *N*, *N*, *N'*, *N'*-tetramethyl-*p*-phenylenediamine (TMPD) in solutions shows interesting differences depending on the nature of the solvent and on the temperature.[1]

The deoxygenated rigid matrix at 77°K composed of 1 part methylcyclohexane and 1 part isopentane (hereafter called MP), which contained 10^{-4} mol./l. TMPD and various concentrations of pyrene (Pyr) (10^{-2}—10^{-4}mol./l.), was illuminated by a Hg lamp at wavelengths between 3000—4000 Å. It showed not only the absorption spectrum of $TMPD^+$, but also that of Pyr^-. The latter is identical with the spectrum obtained by Hoijtink and others by the reduction of Pyr with sodium.[2] The spectrum persists for a long time at 77°K. As there is no sign of complex formation between TMPD and Pyr at either 77°K or 20°C, as may be seen from the absorption spectra, it may reasonably be assumed that they are distributed randomly. Then, we can estimate the mean distances between TMPD and Pyr, which should be proportional to $[Pyr]^{-1/3}$ under conditions where $[Pyr^-] \gg [TMPD^+]$. (Here [ ] means the concentration.) The ratio ω defined by $[Pyr^-]/[TMPD^+]$ can be determined experimentally by the use of the molecular extinction coefficients of both species. The ω values thus obtained are plotted against [Pyr] in curve b, Fig. 1. Here, for instance, $\omega=0.5$ means that one half the electrons ejected from TMPD are trapped in the matrix, while the rest of them reach Pyr. From a simple statistical treatment, we can conclude that, in MP, some of the electrons can travel at least 80 Å away from TMPD. This result may be the first definite proof that the photo-ejected electrons can migrate a considerable distance away from the molecule.

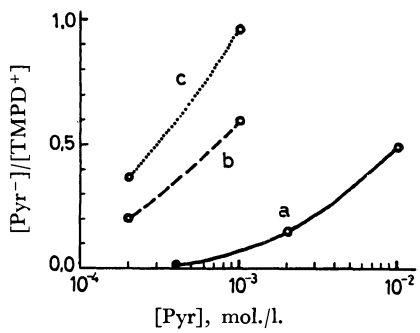

Fig. 1. Formation of ions by ultraviolet excitation of TMPD: a) in EPA matrix, b) in MP matrix, c) the same, illuminated with infrared light. (With prolonged ultraviolet excitation the ratio ω decreases in all three cases.)

By the illumination in the infrared (0.7—5 μ) region, the MP matrix containing $TMPD^+$ and Pyr^- emits light. At the same time, $[TMPD^+]$ slightly decreases and $[Pyr^-]$ largely increases (curve c, Fig. 1). This shows that the electrons trapped in the matrix are excited by the infrared light and migrate randomly in the matrix. The emission is probably due to the fluorescence and phosphorescence of TMPD.[3] By pulling the sample cell in which the ionized species are contained out of the Dewar, a thermoluminescence was observed; when this was measured photographically, it was seen that there is only one band, with a maximum at 476 mμ. We may assume that this emission is due to the transition from the charge transfer state formed by the encounter of $TMPD^+$ and Pyr^- in the half-melting matrix to the ground state.[4]

In degassed EPA matrices at 77°K containing TMPD and Pyr, $TMPD^+$ and Pyr^- are also formed by the ultraviolet excitation. This time, however, the ratio ω is much smaller than that for the MP matrix, showing that more electrons are trapped in the solvent (curve a, Fig. 1). The illumination in the infrared region and down to 6000 Å does not change $[TMPD^+]$ and $[Pyr^-]$, nor does it stimulate the emission. Illumination in the range of the absorption spectrum of Pyr^-, ($\lambda<5000$ Å), lowers the $[Pyr^-]$ value. The color of the solution fades instantaneously as the matrix is warmed, although a small amount of the cation remains for some time. However, no thermoluminescence is observed.

Potentiometric Studies of the Reaction between Mercury(I) Nitrate and Sodium Arsenate

By C. S. BHATNAGER

Department of Chemistry, Government College, Kota (Rajasthan), India

(Received May 1, 1965)

The reaction between mercury(I) nitrate and sodium arsenate has been studied potentiometrically at various concentrations, by both the direct and reverse methods, employing bright platinum foil as an indicator electrode in conjunction with a saturated calomel electrode. The end-points obtained from the sharp inflections in titration curves and pronounced maxima in dE/dV provide cogent evidence for the formation and precipitation of mercury(I) arsenate, Hg_3AsO_4, in the 8.2—9.4 pH range. The precipitation of the compound is almost quantitative. The reaction can be successfully used for the determination of Hg_2^{2+} or AsO_4^{3-} ions in solutions at suitable concentrations and pH ranges.

The formation of mercury(I) arsenate has been studied earlier analytically. Coloriano[1] and Gognet[2] obtained mercury(I) arsenate (Hg_3AsO_4) by heating arsenic(V) oxide and mercury in a sealed tube at 230°C for 60 hr., and Haack,[3] by treating meraury(I) nitrate with an excess of sodium arsenate, while Simon[4] prepared it by adding a solution of mercury(I) nitrate into a concentrated solution of arsenic acid and redissolving the white precipitate so formed in an excess of acid, which had the composition of $HgHAsO_4 \cdot 1/2H_2O$. Recently Guerin and Boulitrop[5] studied the arsenic(III) oxide - mercury(I) oxide - water system at 60°C and reported the formation of Hg_3AsO_4. There is, however, no reference in the literature concerning its study by electrometric techniques. The H^+ ion concentration plays an important role in the formation of such compounds.

Because of the complexity of reaction equilibria between alkali metal arsenates as a result of the appreciable tendency for hydrated forms to be concerted into higher aggregated products, which causes the precipitation of heavy metal salts of varying compositions, belonging some times to one type and some times to another,[6] the conclusions of the reports on analytical investigations on this reaction seem to be overstrained and require a further approach using recent electrometric methods, which provide more conclusive evidence.[7] The present investigation has, therefore, been undertaken with a view to study the reaction between mercury(I) nitrate and alkali arsenate more precisely.

Experimental

Merck's guaranteed extra-pure reagents, mercury(I) nitrate and Na_3AsO_4 were used; their solutions were prepared in air-free conductivity water. The sodium arsenate solution was standardised by the method given by Williams.[8] The mercury(I) nitrate solution was prepared in the minimum quantity of nitric acid and was then estimated by titrating it against a standard sodium chloride solution potentiometrically.

The E. M. F. measurements of the cells, which consisted of a bright platinum electrode, acting as an indicator electrode, in conjuction with a saturated calomel electrode dipped into a titre solution, were carried out with a Backmann pH meter. Twenty milliliters of the titre solution was taken in the cell each time, the cell was kept immersed in an electrically-maintained thermostat, and the solution was stirred by an electrical stirrer. The observed values of E. M. F. were plotted against the volume of the titrant added, and the end-points were located graphically; the locations were then checked further by determining the maximum value of dE/dV.

Using different concentrations of the reactants, mercury(I) nitrate and $NaAsO_4$, a series of potentiometric titrations were carried out with each of the reagents, using them alternately as titrants. The reaction was also followed in the presence of 15% and 30% ethanolic media. The results of this study have been tabulated below (Table I); only one figure (Fig. 1) illustrating direct and reverse titrations has been given, in the interests of brevity.

Discussion

Figure 1 illustrates the direct and reverse potentiometric titrations between mercury(I) nitrate and Na_3AsO_4. In the case of inverse titrations, when the mercury(I) nitrate solution is added to the Na_3AsO_4 solution, the arsenate ions are removed from the solution by precipitation and the E. M. F. gradually rises up to the addition of about 2.5 mol. of mercury(I) nitrate per mole of Na_3AsO_4, but at the stoichiometric end-point which corresponds to the formation of Hg_3AsO_4 a sharp upward jump in potential is noted, after which the E.M.F. becomes practically constant. In direct titration (curve I), i. e., when Na_3AsO_4 solution was added to the mercury(I) nitrate solution taken into a cell, the E. M. F. of the cell gradually decreases up to the vicinity of the end-point which is indicated by a sharp fall in E. M. F.; after this the E. M. F. assumes a practically constant value. Both the direct and reverse potentiometric titrations yield a sharp inflection at the point where the molecular ratio of mercury(I) and AsO_4^{3-} is 3 : 1, corresponding to the formation of mercurous arsenate, Hg_3AsO_4, in the 8.2—9.4 pH range. The accuracy and reproducibility of these titrations have been found to be excellent, and the precipitation of the compound is almost quantitative.

It has been noted that each titration takes about half an hour for completion, and that a thorough stirring in the vicinity of the end-point has a favourable effect. The presence of ethanol increases the sharpness of the end-point and, consequently, the magnitude of the dE/dV, as it reduces the solubility of the precipitates formed and decreases the hydrolysis and adsorption of AsO_4^{3-}.

It is apparent from the above study that, when mercury(I) nitrate reacts with Na_3AsO_4, the formation of mercury(I) arsenate, Hg_3AsO_4, takes place in the 8.2—9.4 pH range. As the precipitation of the compound is quantitative, the reaction can be successfully utilised for the determination of Hg_2^{2+} or AsO_4^{3-} ions in solutions at suitable concentrations and pH range.

The author is thankful to Professor Dr. R. S. Saxena, D. Sc., Professor of Chemistry, Malaviya Regional Engineering College, Jaipur, India, for his kind help.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1095—1101 (1966)

The Autoxidation of α-Methylstyrene in the Presence of Metal Salt[1)]

By Etsuo NIKI and Yoshio KAMIYA

Department of Fuel Engineering, The University of Tokyo, Hongo, Tokyo

(Received May 14, 1965)

The azobisisobutyronitrile-initiated autoxidation of α-methylstyrene in the presence of metal salt was studied from the viewpoints of rate and products. The over-all activation energy was found to be 19.7 kcal./mol. In most cases, metal salts had a retarding effect on the rate of oxidation. With manganese and copper salts, an increase in the concentration of the metal decreased the rate of oxidation monotonously. However, cobalt naphthenate had an accelerating effect within a limited range of concentration, although it also had an inhibiting effect at higher concentrations. The products were acetophenone, formaldehyde, α-methylstyrene oxide and α-methylstyrene polyperoxide. Metal salt had little effect on the products of oxidation, with the exception of cobalt salt, which gave α-methylstyrene oxide in considerable yield even at 760 mmHg of oxygen pressure, where little α-methylstyrene oxide was formed in the presence of other metal salts or in the absence of catalysts.

The initiated and metal-catalyzed oxidation of hydrocarbons has received considerable attention in recent years.[2)] The functions of the metal salts in the autoxidizing systems are not yet, however, fully understood in detail. Most of the previous work on the metal-catalyzed autoxidation of unsaturated hydrocarbons has been concerned with compounds that have relatively unreactive double bonds. The metal-catalyzed oxidation of unsaturated compounds with reactive and polymerizable double bonds has received little attention. In view of these circumstances, it is a matter of theoretical as well as technological interest to study the autoxidation of olefins with reactive double bonds in the presence of the metal salts.

The purpose of this work is to study the azobisisobutyronitrile-initiated autoxidation of α-methylstyrene in the presence of metal naphthenate from the viewpoints of rate and products.

Mayo, Miller and Russell[3)] studied the oxidation of unsaturated compounds with reactive double bonds in the presence of azobisisobutyronitrile as a free radical initiator, although in the absence of metal catalysts. They showed that the autoxidation of α-methylstyrene by a free radical mechanism gives two simultaneous reactions, a copolymerization of α-methylstyrene with oxygen and a cleavage reaction to form acetophenone, formaldehyde and α-methylstyrene oxide.

Experimental

Materials.—α-Methylstyrene was obtained from Allied Chemical; it was more than 99.8 mol.% pure. Prior to the experiment it was washed with alkali to remove the inhibitor, passed through activated alumina, and stored under nitrogen. Guaranteed reagent-grade azobisisobutyronitrile (hereafter designated as ABN) was stored in an ice box. Metal salt catalysts were obtained from the Dainippon Printing Ink Mfg. Co. and the Nihon Kagaku Sangyo Co. The metals used were cobalt, manganese, copper, lead, zinc, iron, and nickel (10.0, 8.2, 10.2, 30.3, 10.6, 10.0, and 8.0% respectively). The catalysts were used as metal naphthenates. The purity of the oxygen and the nitrogen was more than 99% (as determined by gas chromatography).

Procedures.—Two procedures were employed, one for measuring the oxidation rate of the monomer (R_M) and the rate of formation of the products, and the other for measuring the rate of oxygen absorption ($-dO_2/dt$). In the former procedure, a catalyst was dissolved in 65 ml. of α-methylstyrene in advance; then this solution and ABN were added to a 300-ml., 4-necked flask equipped with ground glass joints. The mixture was stirred vigorously by a Teflon paddle using a magnetic stirrer. All of the reaction was performed under one atmosphere. The reaction gas was sometimes diluted with nitrogen to make a fixed-oxygen partial pressure and was fed in at the rate of 4 cc./sec. The exhaust gas was taken out through a reflux condenser and then a trap cooled by methanol and dry ice to −50°C. The reaction mixture was sampled periodically and analyzed. The rate of oxygen absorption was measured by a manometer in a constant-pressure closed system.

Analyses.—The oxidation rate of the monomer was measured by following the disappearance of the monomer by gas chromatography A (Apiezon-L column;

column temperature, 180°C; nitrogen carrier gas, 30 cc./min.). The oxidation products were analyzed by gas chromatography A, a study of the infrared spectra and by chemical analysis. The internal standard method was employed for the gas chromatographic analyses of the reaction mixture, using styrene as an internal standard. Infrared spectra analyses were made as well, because there was some possibility that peroxide decomposed in the gas chromatography to form the decomposition products. It was found, however, that the decomposition of peroxides in the gas chromatographic column was negligible. Acetophenone was sometimes determined gravimetrically with 2, 4-dinitrophenylhydrazine. In a few experiments, formaldehyde was measured as a dimethone derivative. However, its quantitative analysis was extremely difficult since most of the formaldehyde formed in the oxidation became attached to the wall as paraformaldehyde. Several iodometric methods were employed in an attempt to determine the peroxide, but no satisfactory procedure could be found. Carbon monoxide and carbon dioxide were measured by gas chromatography with a column of Molecular Sieve-13X and Acetonyl Acetone-S respectively. The formation of both gases was found to be negligible. The water content was measured by Karl Fisher titration; its formation was very small, below 0.1% of the products. Moreover, no other products could be detected either by gas chromatography or by a study of the infrared spectra. It was assumed, therefore, that formaldehyde was formed in an amount equivalent to acetophenone and that the only product other than acetophenone, formaldehyde and α-methylstyrene oxide was α-methylstyrene polyperoxide.

The Preparation of α-Methylstyrene Oxide.—α-Methylstyrene oxide was prepared as follows for use as the standard of the gas chromatographic analyses. A mixture of 102 g. of acetic anhydride and 2.4 g. of sulfuric acid was vigorously stirred into 57 g. of 30% hydrogen peroxide at room temperature and then reacted for an hour. Fifty grams of α-methylstyrene was then dropped into the solution, with the temperature kept at 0°C, and stirred for two hours. After the reaction, *t*-butylcathecol, an inhibitor, was added, the reaction mixture was extracted with benzene, and acetic acid was removed by 5% sodium bicarbonate, washed with water and dehydrated. The products thus obtained were distilled in vacuo.

The Preparation of α-Methylstyrene Polyperoxide.—The reaction was carried out like the other experiments. The final reaction mixture was poured into twice as much cold methanol to precipitate the methanol-insoluble polyperoxide. The polymer was then washed with methanol until it became stiff. It was dissolved in benzene, precipitated, and washed with methanol. This operation was repeated twice. Finally it was dried in vacuo to remove the methanol.

Results and Discussion

The products of the oxidation of α-methylstyrene are acetophenone, formaldehyde, α-methylstyrene oxide and α-methylstyrene polyperoxide. A typical example of the reaction of α-methylstyrene with oxygen is shown in Fig. 1.

The Effect of ABN on the Rate and Products of Oxidation.—The rates of oxygen absorption at 0.003, 0.005 and 0.010 mol./l. of ABN were 0.29, 0.36 and 0.51 mol./l./hr. respectively, when α-methylstyrene was oxidized at 70°C in the absence of the metal salt. These results show that the rate of oxidation is proportional to the square root of the ABN concentration. This suggests that, at a sufficiently high oxygen pressure, termination is a bimolecular reaction of two radicals. The reaction sequence must be as follows[2a,b]:

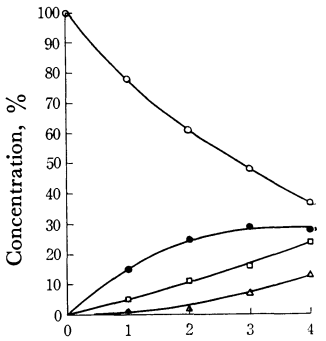

Fig. 1. Oxidation of α-Methylstyrene at 70°C, ABN 0.030 mol./l., Co-N 3.4×10^{-3} mol./mol. and oxygen pressure 760 mmHg.

$$\mathrm{ABN} \xrightarrow{k_i} 2\mathrm{R'}\cdot \rightarrow 2e\mathrm{M}\cdot \quad (1)$$

$$\mathrm{M}\cdot + \mathrm{O_2} \rightarrow \mathrm{MOO}\cdot \quad (2)$$

$$\mathrm{MOO}\cdot + \mathrm{M} \rightarrow \mathrm{M}\cdot \quad (3)$$

$$2\mathrm{MOO}\cdot \rightarrow \text{non-radical products} \quad (4)$$

where R'· is the dimethylcyanomethyl radical, e is the efficiency of ABN, and M is the α-methylstyrene monomer. M· and MOO· represent free radicals of an unspecified length and ending in monomer and peroxide units respectively. In this paper, M· and MOO· correspond to $\sim CH_2C(CH_3)(C_6H_5)\cdot$ and $\sim CH_2C(CH_3)(C_6H_5)OO\cdot$. In fact, this mechanism is simplified; for example, the alkoxy radical MO·, i. e., $\sim CH_2C(CH_3)(C_6H_5)O\cdot$, which may arise from the depolymerization of the polyperoxy radical, is left out of consideration, and also consumption of oxygen in reaction 1 is disregarded. Under steady state conditions, the rate of oxidation is given by Eq. 5;

$$-\mathrm{d}[\mathrm{O_2}]/\mathrm{d}t = \frac{k_3}{(2k_4)^{1/2}}[\mathrm{M}](R_i)^{1/2} \quad (5)$$

where $R_i=2ek_i[\mathrm{ABN}]$. The experimental data coincide with this rate equation provided e is constant independent of the concentration of the initiator. It was also confirmed that the rate was first-order with respect to α-methylstyrene

Table I. Oxidation of α-methylstyrene at 70°C, ABN 0.030 mol./l. and oxygen pressure 760 mmHg

Catalyst		Conv.[a]	Rate (R_M)[b]	Products Yields in mol. %[c]

b) Observed rate of oxidation of monomer.
c) Based on α-methylstyrene reacted.
d) N represents naphthenate.

(shown in Fig. 5).

Nitrogen evolution by the decomposition of the initiator must be taken into consideration in some cases. The fragments from ABN are assumed to either take up oxygen to produce the dimethylcyanomethyl peroxy radical or recombine in the "cage." The resulting peroxy radicals can initiate the chains. This situation is indicated by the following eqautions;

$$\mathrm{ABN} \xrightarrow{k_t} 2\mathrm{R'}\cdot + \mathrm{N_2} \qquad (1')$$

$$2\mathrm{R'}\cdot \xrightarrow{\mathrm{O_2}} 2e\mathrm{R'OO}\cdot + (1-e)(\mathrm{R'-R'}) \qquad (1'')$$

$$2e\mathrm{R'OO}\cdot \xrightarrow{\mathrm{M}} 2e\mathrm{M}\cdot \qquad (1''')$$

Hence, the net oxygen absorption by the monomer is given by the observed value plus $(1-e)k_i$[ABN]. However, the kinetic chains in this reaction are long enough so that the consumption of oxygen and the monomer, and the nitrogen evolution in reaction 1 may be disregarded. As a matter of fact, $(1-e)k_i$[ABN] is equal to 1.5×10^{-3} mol./l./hr. at 70°C and with 0.030 mol./l. of ABN, assuming e to be 0.7. This value is less than 1% of the observed value.

As for the products, an increase in the concentration of ABN increases the cleavage products, acetophenone, formaldehyde and α-methylstyrene oxide. These results may probably be attributed to the increase in the rate of termination.

The Effect of Metal Salt on the Rate and Products of Oxidation.—The rates and the products of the oxidation of α-methylstyrene in the presence and in the absence of various metal salts are shown in Table I.

As Table I shows, manganese and copper salts retard the oxidation significantly. However, the activity of the catalyst cannot be compared directly in Table I, since it depends on the concentration of the catalyst. The effect of the concentration of the metal salts on the rate of oxidation is shown in Fig. 2. Manganese and copper naphthenates act as retarders independent of their concentrations, and an increase in the concentration of these salts decreases the rate of oxidation monotonously. The inhibiting effect of metal salt catalysts is observed in some cases at a high concentration of catalysts,[4] but it is seldom observed that manganese and copper salts show an inhibiting effect independent of their concentrations. The effect of the cobalt naphthenate catalyst differs from that of manganese and copper catalysts.

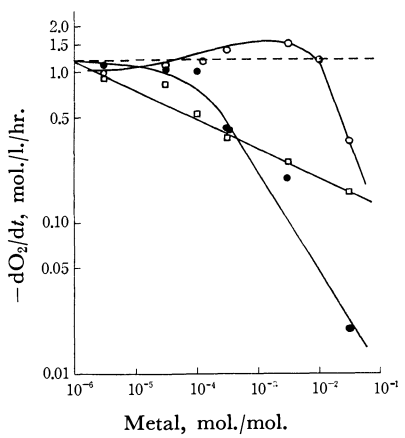

Fig. 2. Effect of the metal concentration on the rate of oxidation at 70°C, ABN 0.030 mol./l. and oxygen pressure 760 mmHg.
○: Co, ●: Mn, □: Cu
The broken line illustrates the rate of oxidation in the absence of metal catalysts.

The rate of oxidation increases gradually with an increase in the concentration of the cobalt salt catalyst, reaches a maximum at 3.4×10^{-3} mol./mol. of cobalt naphthenate, and then falls rapidly with a further, small increase in the catalyst.

It is assumed that these inhibiting effects of

1) Rate of initiation. Calculated from Ref. 5. $R_i=2ek_i[ABN]$ e was assumed to be 0.7.
2) Chain length$=R_M/R_i$

the catalyst may be attributed to the direct termination and/or the deactivation of active radicals, for example, the transfer reaction between radicals and metal ions or the formation of an inactive complex, by the metal salt catalyst.

One of the authors previously proposed the following chain termination in the oxidation of tetralin[2d];

$$ROO\cdot + Me \rightarrow \text{inactive products} \quad (6)$$

or, alternatively:

$$ROO\cdot + Me^{2+} \rightarrow (ROO^-Me^{3+}) \quad (7)$$

$$(ROO^-Me^{3+}) + ROO\cdot \rightarrow \text{inactive products} \quad (8)$$

If the chain termination is assumed to be reaction 6, or reactions 7 and 8 instead of reaction 4, they give the following rate equations:

$$-d[O_2]/dt = \frac{k_3[M](R_i)}{k_8[Me]} \quad (9)$$

or

$$-d[O_2]/dt = \frac{k_3[M](R_i)^{1/2}}{(2K_8k_9[Me])^{1/2}} \quad (10)$$

respectively. Indeed, these chain terminations by the catalyst are competitive with the reaction 4, but at a sufficiently high concentration of the metal salt the former reactions may well be predominant, while at the utmost limit Eq. 5 must be replaced by Eq. 9 or 10.

In Fig. 2 it may be seen that the rate of oxidation is approximately inversely proportional to $[Cu\text{–}N]^{0.2}$. In the presence of manganese naphthenate, the rate decreases slowly as the metal concentration is increased, but when it exceeds 10^{-4} mol./mol., the rate decreases sharply and is inversely proportional to $[Mn\text{-}N]^{0.7}$. These results may well be attributed to the chain termination reaction by metal salt in addition to reaction 4; probably in the case of copper salt, reactions 7 and 8, and in the case of manganese salt, reaction 6.

Cobalt showed quite a different effect, as has been stated above, which must now be discussed in connection with the products. The yields of the products are shown in Table I. A distinctive feature is that a considerable amount of α-methylstyrene oxide is formed in the presence of the cobalt naphthenate catalyst, although in the presence of other salts, as well as in the absence of the metal salt, little epoxide was formed under these reaction conditions. The effect of the concentration of cobalt salt on the yield of α-methylstyrene oxide was found to be analogous to that on the rate of oxidation. The results, shown in Fig. 3, indicate that the increase in the

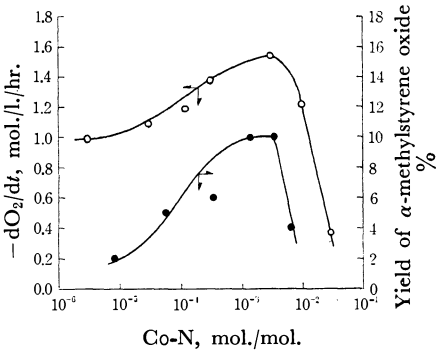

Fig. 3. Effect of Co-N concentration on the rate of oxidation and the yield of α-methylstyrene oxide (at conv.=50%) at 70°C, ABN 0.030 mol./l. and oxygen pressure 760 mmHg.

rate of oxidation and the formation of epoxide are closely related. Cobalt naphthenate, unlike manganese and copper salts, is assumed to be able to increase the rate of oxidation and to form α-methylstyrene oxide as well. However, it also terminates chains as it is increased above a critical concentration, i. e., 3.4×10^{-3} mol./mol. The decrease in the rate of oxidation is very sharp, and, in Fig. 2, it may also be seen that the rate is inversely proportional to $[Co\text{-}N]^{1.0}$, suggesting that the reaction 4 is replaced by the reaction 6.

The apparent order of the oxidation on the metal, however, is complex. Moreover, the proportions of the two valence states of the metal and the nature of the ligands probably change during the oxidation, further complicating the apparent order.

Other metal naphthenate catalysts had little effect on the products of the oxidation.

The Effect of the Temperature on the Rate and Products of Oxidation.—Reactions were carried out over the temperature range from 50 to 90°C. The results are summarized

in Table II. From Table II the over-all activation energy of the oxidation of α-methylstyrene in the presence of ABN and cobalt naphthenate may be found to be 19.7 kcal./mol. The effect of the temperature on the formation of acetophenone is shown in Fig. 4. Polyperoxide was supposed

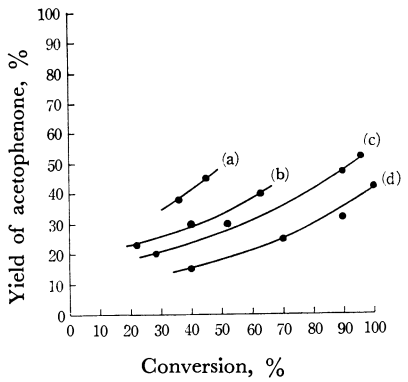

Fig. 4. Effect of temperature on the yield of acetophenone in the oxidation of α-methylstyrene with ABN 0.030 mol./mol., Co-N 3.4×10^{-3} mol./mol. and oxygen pressure 760 mmHg. (a) 60°C, (b) 70°C, (c) 80°C, (d) 90°C

to decompose more rapidly at higher temperatures, causing an increase in the yields of the cleavage products. On the contrary, the yield of acetophenone became lower as the reaction temperature rose. The new broad band near 3500 cm^{-1}, probably due to the polymeric hydroxy group, appeared in the infrared spectrum of the products more significantly at higher temperatures.

The Effect of the Oxygen Pressure on the Rate and Products of Oxidation.—This effect had been studied in detail by Mayo and Miller[3d] in the absence of the metal catalysts. We obtained similar results in the presence of catalysts. At low oxygen pressures, the rate of oxidation increased with the oxygen pressure, becoming independent of it above 365 mmHg. These results indicate that, at low oxygen pressures, chain termination reactions involve the monomer radicals in addition to the peroxy radicals. The yield of α-methylstyrene oxide varied considerably with the oxygen pressure, although the formation of acetophenone was not influenced so much. The yields of α-methylstyrene oxide under 175, 365, and 760 mmHg of oxygen pressure were 20, 13, and 9%, while those of acetophenone were 30, 33, and 33%, respectively, when 50% of the initial α-methylstryene was oxidized at 70°C with 0.030 mol./l. of ABN and 3.4×10^{-3} mol./mol. of cobalt naphthenate. An increase in the oxygen partial pressure decreases the yield of α-methylstyrene oxide.

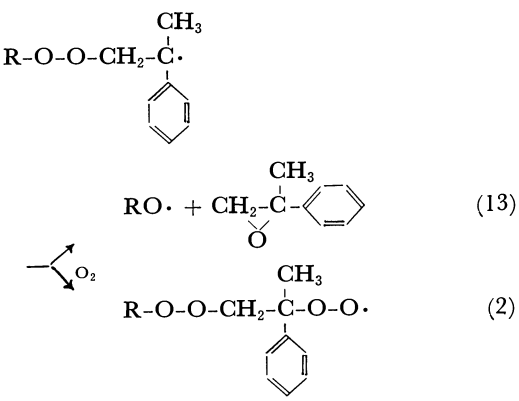
Three mechanisms have been proposed for the formation of epoxides[6]; (a) the direct addition of oxygen to a double bond via a cyclic peroxide; (b) the addition of hydroperoxide to a double bond, and (c) the addition of peroxy radicals to a double bond.

(a) $\rangle C{=}C\langle + O_2 \rightarrow \rangle C(-O-O-)C\langle \rightarrow \rangle C(-O-)C\langle$ (11)

(b) $\rangle C{=}C\langle + ROOH \rightarrow \rangle C(-\overset{+}{C}-)\langle \rightarrow \rangle C(-O-)C\langle + ROH$ (12)

(c) $\rangle C{=}C\langle + ROO\cdot \rightarrow \rangle C(-\dot{C}-)\langle \rightarrow \rangle C(-O-)C\langle + RO\cdot$ (13)

The effect of oxygen pressure on the yield of α-methylstyrene oxide supports the reaction 13. The decomposition of the intermediate radical, in this case a free radical of an unspecified length ending in the monomer unit $ROOCH_2C(CH_3)(C_6H_5)\cdot$, into epoxide and alkoxy radical is competitive with reaction 2, the addition of oxygen to the monomer radical. Therefore, the more



slowly the intermediate β-peroxy alkyl radical reacts with oxygen, the more chance the radical has to decompose unimolecularly.[3d,7] The formation of epoxide is thereby increased by lowering the oxygen partial pressure.

The Effect of the Reaction Time on Rate and Products of Oxidation.—As is shown in Fig. 5, the rate of oxidation is first-order with respect to α-methylstyrene, confirming Rate Eq. 5. The yield of the products depends on the time; the yield of polyperoxide decreases, and that of the cleavage products increases, with time. As will be discussed later, α-methylstyrene polyperoxide is quite stable under the reaction conditions employed; hence, these results do not arise from the

○: α-methylstyrene
●: α-methylstyrene polyperoxide
□: acetophenone
△: α-methylstyrene oxide

decomposition of polyperoxide. The reason for this is not definitely known. One possibility is the decrease in the concentration of α-methylstyrene, a strong radical scavenger itself. The peroxy radical reacts competitively in two ways; one is the addition to the double bond of α-methylstyrene (reaction 3), while the other is the cleavage reaction to form the cleavage products (reaction 14):

$$RO_2CH_2C(CH_3)(C_6H_5)O_2\cdot \rightarrow RO_2\cdot + CH_2O + C_6H_5C(O)CH_3 \qquad (14)$$

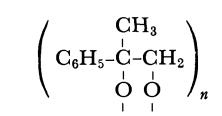
This must be also applied to the alkoxy radical. The decrease in the concentration of α-methylstyrene, as a result, presumably increases the life time of peroxy and alkoxy radicals and gives these radicals more chance to decompose into the cleavage products.

α-Methylstyrene Polyperoxide.—The polymer prepared by the method described in the experimental part was colorless, transparent and a little gummy. The composition of methanol-insoluble α-methylstyrene polyperoxide was determined by elementary analyses. The results are illustrated in Table III.

The effects of the end groups are not taken into consideration in the values calculated from $(C_9H_{10}O_2)_n$. The difference between the data obtained and the calculated value is evidently due to the end groups. Mayo and Miller[3d] reported that $HO_2CH_2C(CH_3)(C_6H_5)-$, $O=CHC(CH_3)(C_6H_5)-$ and H- were good possibilities. However, the data indicate that the end groups do not contain oxygen. Here two end groups, H- and $(C_6H_5)(CH_3)C=CH-$, are presumed; the values calculated from these end groups are also listed in Table III.

From these data $H-(C_9H_{10}O_2)_{10}-CH=C(CH_3)-(C_6H_5)$ may be expected to be most plausible. The infrared spectra show the disappearance of the double bond and the formation of peroxide (at 1030 cm^{-1}). α-Methylstyrene polyperoxide is believed to be rather clear compared with styrene polyperoxide. In the absence of oxygen, no reaction at all was observed. This absence of the homopolymerization of α-methylstyrene practically eliminates the excess monomers from the polymer and reduces irregularities in the polymer. It may be presumed, however, that the composition of α-methylstyrene polyperoxide is not always uniform but has some irregularities, and that the molecular weight has a wide distribution.

Mayo and Miller[3d] reported that the structure of α-methylstyrene polyperoxide was substantially $(-OOCH_2C(CH_3)(C_6H_5))_n-$; they based their conclusion on the experimental findings that the pyrolysis of it gave acetophenone and formaldehyde in yields up to 93% and its reduction to α-methylstyrene glycol in a 60% yield. On the other hand, Hock and Siebert[8] proposed the following structure:



They also proposed the reaction mechanism shown in Fig. 6. However, the effect of oxygen pressure on the yield of α-methylstyrene oxide cannot be illustrated in this sequence.

The decomposition of α-methylstyrene polyperoxide in the presence of a metal salt catalyst

8) H. Hock and M. Siebert, *Chem. Ber.*, **87**, 546 (1954).

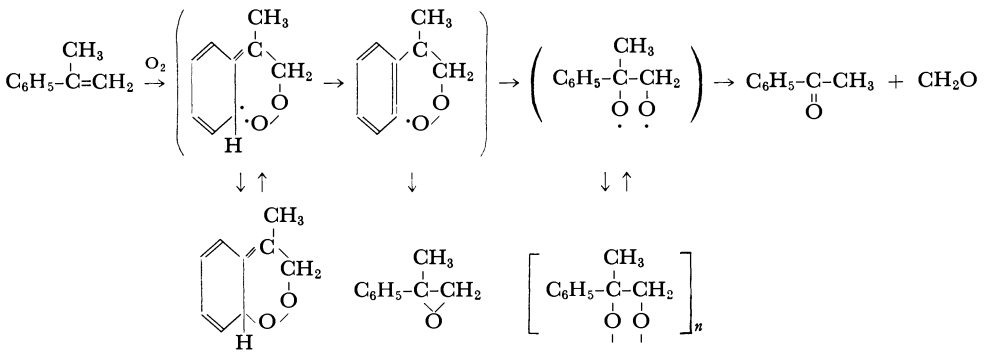


Fig. 6. Reaction mechanism by Hock and Siebert.[8]

was also studied. Some examples of the experiments are given blow.

Expt. A.—The product of oxidation at 70°C, ABN 0.030 mol./l. and oxygen pressure 760 mmHg was distilled in vacuo in order to remove both unreacted α-methylstyrene and cleavage products. The residue was dissolved in chlorobenzene (a guaranteed reagent was shaken with sulfuric acid, washed with water, and distilled). Cobalt naphthenate was added to the solution, and the reaction was carried out for 2 hr.

Expt. B—The oxidation of α-methylstyrene was carried out for 2 hr. at 70°C, ABN 0.030 mol./l., and oxygen pressure 760 mmHg, and in the absence of a metal salt catalyst. Then the stream was converted from oxygen to nitrogen, cobalt naphthenate was added to the reaction mixture, and the reaction was continued for another 3 hr.

These experiments demonstrated that α-methyl styrene polyperoxide is surprisingly stable under these reaction conditions, and no depolymerization was observed. After all, the cleavage products are expected to be formed not by the depolymerization of polyperoxide, but by the decomposition of the peroxy radicals and/or alkoxy radicals which are produced from peroxy radicals or by reaction 13, the splitting off of epoxide from a polyperoxy radical ending in a monomer unit.

The authors take this opportunity to express their thanks to Professor Shingo Ando and Dr. Nobuto Ohta for their continuing encouragement and discussions.

The Amperometric Determination of Thallium(III) and Silver(I) with Ascorbic Acid Using Two Polarized Indicator Electrodes

By D. SINGH and Uma BHATNAGAR

Department of Chemistry, Banaras Hindu University, Varanasi, India

(Received May 15, 1965)

Amperometric determinations of thallium(III) and silver(I) with ascorbic acid have been carried out with two polarized electrodes at 100 mV. and 50 mV. respectively. A simple method for the successive determination of thallium(III) and silver(I) has been developed. At an acidity of 0.1 to 1.0 N with respect to sulphuric acid, only thallium(III) is reduced; silver (I) remains unaffected. After the completion of the reaction with thallium(III), the pH of the solution is adjusted to 6.5 to 7.0 and the silver(I) is titrated with ascorbic acid.

In recent studies in this laboratory, it has been shown that the amperometric method using two polarized electrodes (biamperometric titration) can be applied with success to the successive determination of cerium and iron,[1] iron and vanadium[2] and a number of other elements.[3,4]

This paper will report the results of the biamperometric titration of thallium(III) and silver(I)

separately and also together in a mixture, with a standard ascorbic acid solution used as the titrant.

Of the various methods employed to determine thallium(III), a few gravimetric and volumetric methods are important. The most useful titrimetric method was developed by Hollens and Spencer,[5] who reduced thallium(III) ion with iodide and titrated the liberated iodine with thiosulphate or arsenite. Smith[6] determined thallium(III) gravimetrically by precipitating it with tetraphenyl arsonium chloride in the presence of a considerable amount of hydrochloric acid. Busev et al.[7] estimated thallium(III) by complexometric titration, and Berka and Busev[8] determined it potentiometrically. Majumdar and Bhatnagar[9] used the same method to determine thallium(III) with chromium(II).

Experimental and Results

A thallium(III) sulphate solution was prepared by dissolving thallium(III) oxide in 20.0 N sulphuric acid, and then making up the volume in a 100-ml. standard flask with distilled water; the solution was standardized iodimetrically. A stock solution of silver nitrate (A. R.) was prepared and standardized as usual. A weighed quantity of ascorbic acid, sold for medical purposes, was dissolved in water, and then a few milliliters of 25% formic acid was added as a stabilizer. The ascorbic acid solutions to be used were obtained by the accurate dilution of a more concentrated stock solution, which was standardized every day before use against a standard potassium iodate solution. All the other chemicals used were of C. P. grade.

Amperometric titrations at a constant voltage with two platinum electrodes were carried out with a circuit similar to those described by Foulk and Bawden[10] and Stone and Scholten.[11] The titration vessel was a 100 ml. beaker, covered with a tight-fitting rubber stopper provided with holes for the platinum electrodes, an inlet and an outlet for nitrogen, and a burette; a constant voltage of 50 mV. or 100 mV. was applied between the platinum electrodes, and the variations in the current were measured by a sensitive-mirror galvanometer with a lamp and scale arrangement. The galvanometer was shunted by a variable resistance so as to obtain the desired deflexions on the scale. The solution was uniformly stirred during the titration by a magnetic stirrer. The titration mixture, usually 20 ml. in the desired medium, was taken into the titration cell, and then the titrant was added from a 2.0-ml. semi-microburette with 0.01-ml. divisions. Equivalence points were obtained graphically by the plot of the galvanometer deflexion against the volume of the titrant added. A few typical titration curves are shown in Figs. 1 and 2. A large number of experiments were carried out, and each determination was repeated several times in order to obtain good and satisfactory results. The results of the determinations of thallium(III) and silver(I) are summarized in Tables I and II respectively.

6	1.259	1.266	+0.09	+0.4
9	1.079	1.085	+0.55	+3.1
5	0.5395	0.5340	−1.00	−2.1
4	0.2158	0.2114	−2.00	−4.2

The successive determinations of thallium(III) and silver(I) present together in test solutions were carried out, taking special care to maintain the acidity of the solution. Into a 0.1 N to 1.0 N medium with respect to sulphuric acid, ascorbic acid is an excellent reducing agent for thallium(III); silver(I) is, however, not reduced in this medium. Tervalent thallium has thus been successfully titrated with two polarized electrodes at an applied voltage of 100 mV. After the completion of the reduction of thallium(III), as established by a fall in the galvanometer deflexion to a constant value, a 6.0 N ammonia solution was added drop by drop until the pH of the solution became 6.5 to 7.0. The mixture was then titrated again at 100 mV. against

The graphical method was employed to determine the equivalence point of these estimations, as is shown in Fig. 2; the results of the successive determinations of thallium(III) and silver(I) in various mixtures are presented in Table III.

Discussion

The normal oxidation-reduction potential of the Tl^{3+}/Tl^{+} system is $E_0=1.21$ V., while that of Ag^{+}/Ag^{0} couple is $E_0=0.7991$ V. As the normal redox potential of ascorbic acid is 0.40 V. at $[H^{+}]=1$, it can be used for the quantitative determination of thallium(III) in 0.1 N to 1.0 N sulphuric acid in the presence of univalent silver, since the latter is reduced only at pH 6.5 to 7.0.

In the present investigation reversible Tl^{3+}/Tl^{+}, Ag^{+}/Ag^{0} couples are titrated by an irreversible system, with an appreciable current flowing through the cell before the end point. In the determination of thallium(III), the current is the greatest at the very beginning of the titration, since there is a considerable quantity of thallium(III) ions in the the sample taken for estimation. The concentration of the thallium(III) ions diminishes with the addition of the titrant, and thus there is a rapid decrease in the galvanometer deflexion; on the other hand, as the concentration of Ag^{+} diminishes, the galvanometer deflexion reaches a maximum when the titration has proceeded by 50%, and then falls on the further addition of ascorbic acid; this is in essential agreement with the earlier findings.[1-3,11] At the equivalence point and thereafter in both cases, no thallium(III) or silver(I) ions are left in the solution, and the limiting current for the couples, Tl^{3+}/Tl^{+} or Ag^{+}/Ag^{0}, is virtually zero. Although both components of the ascorbic acid/dehydroascorbic acid system are present in the solution, practically no current flows through the titration cell since the couple is irreversible. The current will, therefore, attain a constant value depending upon the resistance of the circuit, and the curves have the shape shown in Figs. 1 and 2.

The authors' thanks are due to the authorities of Banaras Hindu University for providing the facilities for the work. The financial assistance of the Government of India in the form of a Research Training Scholarship to one of the authors, Miss Uma Bhatnagar, is also gratefully acknowledged.

The Decomposition of Formic Acid on the Intermetallic Compounds of 3d-Transition Metals

By Chiyoko SUZUKI and Ikuya MATSUURA

Department of Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka

(Received July 3, 1965)

The catalytic behavior of the intermetallic compounds of Cr-Co, Fe-Cr, Fe-Mo, Ni-V and Fe-V systems on the decomposition reaction of formic acid was studied by the usual static method and compared with that of some alloys and manganese. A zeroth-order decomposition reaction was observed throughout the catalysts employed and the adsorption of formic acid on the catalysts during the decomposition reaction approched to the saturation value under the experimental condition, i. e., under the pressure range of 10—20 mmHg, and at the temperature of 200—300°C. The activation energy of the reaction varied from 13.5 to 20.7 kcal./mol. for various catalysts. It has been also found that the activation energy of the reaction catalyzed by the intermetallic compounds increased with the ratio of the electrons in d- and s-bands to atom of the catalyst.

The low catalytic activity of an intermetallic compounds as compared with the corresponding alloy is generally attributed to the presence of some linkage of covalent nature in the compound.

The catalytic behavior of alloys of silver, gold, and copper with other metals has been studied by Schwab,[1] and it has been revealed that the activation energy of the catalytic decomposition of formic acid on copper-tin alloy catalyst became higher with increasing content of tin in the alloy from about 24 kcal./mol., making a very distinct maximum (33 kcal./mol.) at the phase (20 atomic % of tin) which has a deformed body-centered cubic lattice. Then, the energy falls again with the increasing content of tin in the alloy.

On the other hand, the binary alloys of the 3d-transition metals, chromium-cobalt, iron-chromium, iron-molybdenum, nickel-vanadium and iron-vanadium, have sigma phases, and the sigma phase of the crystals of these alloys are intermetallic compounds having the deformed body-centered cubic lattice. The 3d-transition metals have partially filled *d* electron levels, and the ratio of electron to atom in these compounds is around seven.

The present work deals with the catalytic behavior of some intermetallic compounds of 3d-transition metals on the decomposition reaction of formic acid, was compared with some alloys and with metallic manganese having seven electrons in the d- and s-bands of the atom.

Experimental

Apparatus.—The experiment was carried out by a usual static method. The volume of the system corresponded to 702.3 ml. at 30°C, with the reaction vessel held at 250°C.

Material.—A certified reagent grade formic acid (98—100%) obtained from Merck was dried over anhydrous cupric sulfate, and distilled under a reduced pressure at room temperature. The purified acid was stored in a cold and dark place.

Catalysts.—The metallic manganese used was prepared from manganese oxide. The oxide was reduced at 250°C for 300 hr. by circulating hydrogen. The alloy catalysts, chromium-cobalt, iron-chromium, iron-molybdenum, nickel-vanadium and iron-vanadium were prepared by the fusion of the components having the suitable composition for the formation of the sigma phases, as is shown in Table I, followed by a heat-treatment at about 1000°C for a week in a reaction vessel in an atmosphere of argon. All the catalysts were used as 100 mesh powder. The phase composition and the lattice constant in the sigma phase of each alloy are summarized in Table I, together with the temperatures of the heat-treatment used in the preparation of the intermetallic compound. The specimens of the catalysts prepared were subjected to the X-ray diffraction measurements to confirm the formation of intermetallic compounds, and the lattice constants of these catalysts were found to be in agreement with the reported values for the corresponding intermetallic compounds. The surface areas of these catalysts

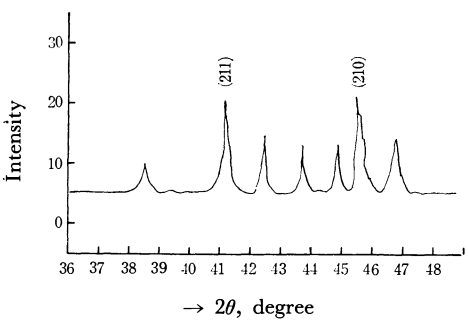

Fig. 2. X-Ray diagram of Ni-V powder with Cu-$K\alpha$ radiation and Ni filter.

were determined by the B. E. T. method by using nitrogen gas at the temperature of liquid nitrogen (cf. Table II).

Procedure.—The alloy or the intermetallic compound (approximately 10 g.) placed in the reaction vessel was maintained at 350°C for 20 hr. under a pressure of less than 10^{-6} mmHg, and reduced with hydrogen (1 atm.) at 350°C for 48 hr. Then the reaction vessel was kept at the same temperature under a vacuum overnight. After this treatment, a known amount of the purified formic acid was introduced into the reaction system and the decomposition reaction was followed by measuring the pressure of the reaction system at suitable time intervals. The composition of the reaction products was determined by mass spectrometry. In most cases, the products were found to be carbon dioxide and hydrogen. The decomposition reaction was carried out over the range of temperatures from 200 to 300°C and the range of the pressures from 10 to 20 mmHg.

Results

The catalytic decomposition of formic acid was carried out in the presence of carbon dioxide or hydrogen to find out the influence of the reaction products on the decomposition reaction. No

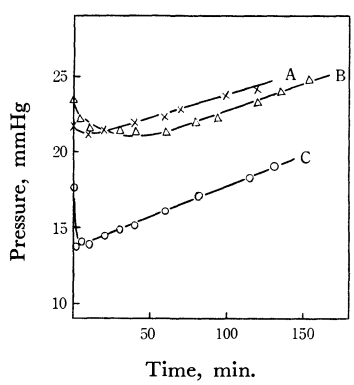

Fig. 3. The decomposition of formic acid on Mn at 225°C in the presence of H_2 and CO_2.

appreciable effect on the reaction rate is observed, as is shown in Fig. 3.

The pressure-time curve of the reaction on a manganese catalyst at 250°C gave a characteristic S shape, as is shown in Fig. 4. The rapid decrease of the pressure of the reaction system in the first few minutes can be reasonably attributed to the adsorption of the acid on the catalyst surface. After about 100 min., the slight decreace in activity due to the influence of poisoning of the catalyst caused by a negligible amount of water which was produced by a side decomposition reaction became appreciable. However, the S curve has a good linear part at reaction times between 20 and 100 min.

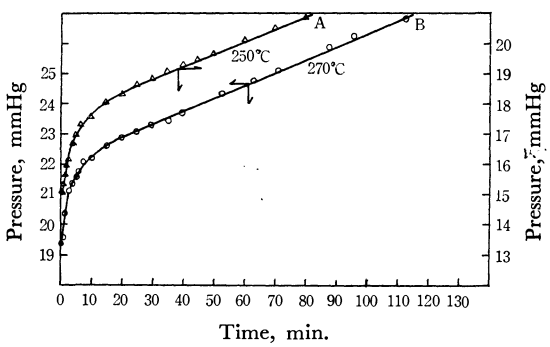

Fig. 5. The pressure-time curves for the decomposition of formic acid.
A. Fe-V intermetallic compound, B. Fe-Mo alloy

The change in pressure in the decomposition of formic acid on the iron-vanadium intermetallic compound and the iron-molybdenum alloy are indicated in Fig. 5. In both experiments, the time-pressure curve clearly indicates the presence of an inflection point, the first part with a steeper slope, ending at the reaction time of about 5 min., and the second part with a flatter slope. This fact suggests that the reaction first occurs at the most active points of the surface of the catalyst, after which the activity remained almost constant.

The rate constants of the zeroth-order decomposition reactions at different temperatures were obtained, their logarithms are plotted against $1/T$, i. e., the reciprocal of the absolute temperature (Fig. 6). The curve in Fig. 7 indicates how the values of the activation energies on the intermetallic compounds are correlated with the ratios of the electrons in the d- and s-bands to the atom of the catalysts.

Discussion

In the present work every effort has been made to prepare intermetallic compound catalysts which are homogeneous both in bulk and on surface. The homogeneity of the catalysts was confirmed by the X-ray diffraction measurements.

Although the decomposition of formic acid has

been much studied,[2-4] it has often proved difficult to elucidate its mechanism. Recently, it has been confirmed that the formic acid is adsorbed on the surface of metal as formate ions which are observed by means of infrared spectra.[5,6]

In the case of the present work, the following scheme was presented as the mechanism of the decomposition of formic acid on a 3d-transition metal catalyst.

$$M + HCOOH \rightleftarrows M/H^+ + HCOO^- \quad (1)$$

$$M + HCOO^- \rightleftarrows M/HCOO^- \quad (2)$$

$$M/HCOO^- \rightarrow M^-/H + CO_2 \quad (3)$$

$$M/H^+ \rightleftarrows M^+/H \rightleftarrows M^+ + H \quad (4)$$

$$M^-/H + M^+ + H \rightarrow 2M + H_2 \quad (5)$$

In the initial step, the formic acid molecule is dissociated by chemisorption, yielding formate ions, $HCOO^-$, and adsorbed hydrogen, M/H^+; the measurement of the heat of the adsorption of formic acid on a catalyst made it clear that the catalyst was covered completely by the formic acid at a pressure of about 10 mmHg at 150°C. It can, therefore, be assumed that the decomposition of adsorbed ions is the rate-determining step; in this stage the adsorbed formate ions donate electrons to the catalyst, resulting in the decomposition of the formate ions into carbon dioxide and chemisorbed hydrogen. According to the above-stated mechanism, the reaction should be of the zeroth-order. In fact, the present results indicate that the reaction is of the zeroth-order in all the cases under the experimental conditions (see Figs. 3 and 4).

The activation energy was found to increase with the ratio of electrons in the d- and s-bands to the atom of the intermetallic compounds excepting the case of the iron-molybdenum catalyst. The relatively high activation energy in the case of iron-molybdenum catalyst might be due to a larger d character of molybdenum, though it was expected to be the same or lower than that of the case of iron-chromium from the ratio of the electrons in d- and s-bands to the atom.

The decrease of the heat of adsorption of hydrogen on metals or intermetallic compounds with the increase in the ratio of electrons in d- and s-bands to the atom of the catalyst was reported by one of the present authors (I. M.)* (see Fig. 8).

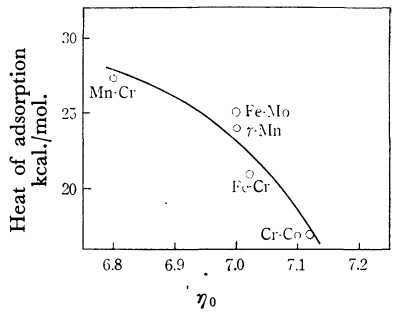

Fig. 8. The drop of the heat of adsorption of hydrogen with the degree of coverage of 0.3 is plotted against the ratio of electron in s- and d-bands to atom of catalyst.

Accordingly, an intermetallic compound having low electron concentration should be effective as the catalyst in an electron-donating reaction as in the case of the decomposition of formic acid via formate ion, on the other hand, an intermetallic compound having high electron concentration should be a good catalyst in an electron-accepting reaction as in the case of the above-mentiond adsorption of hydrogen.

It is also evident from Table II that the catalytic activity of an intermetallic compound is poorer than that of an alloy, though they have the same reaction order in the decomposition of formic acid. The detailed discussion about this point will be published in a following paper.

The authers are grateful to Professor Kiyoshi Kamei for his helpful advice.

Normal Coordinate Analysis of Trigonal Bipyramidal XY_5 Type Molecules*

By Robert A. CONDRATE** and Kazuo NAKAMOTO

Department of Chemistry, Illinois Institute of Technology, Technology Center, Illinois 60616, U. S. A.

(Received July 12, 1965)

Normal coordinate analysis has been carried out for trigonal bipyramidal XY_5 molecules such as PF_5, SbF_5, PCl_5 and $SbCl_5$. It has been found that the simple Urey-Bradley force field does not provide satisfactory results for the bending modes of these molecules. The results have been improved considerably by introducing an interaction constant between equatorial and axial angle coordinates. In carrying out normal coordinate analysis, the repulsive force constants were first estimated from a Lennard-Jones type potential. Then the stretching and bending force constants were adjusted to fit the observed frequencies. Finally, the new interaction constant was introduced to minimize the errors in the bending frequencies. The force constants thus obtained are consistent through the four molecules studied. Some conflicting band assignments made by previous investigators have been discussed on the basis of the present calculations.

The vibrational spectra of trigonal bipyramidal XY_5 type molecules have already been studied extensively. Although the band assignments for antimony pentachloride and phosphorous pentafluoride are consistent among several investigators, no difinite band assignments are yet available for antimony pentafluoride and phosphorus pentachloride. In the present investigation, we have carried out a systematic normal coordinate analysis of the four molecules mentioned above. The present work differs from the previous normal coordinate analyses in the following respects: (1) The most recent spectral data which were not available in previous investigations have been used. (2) A modified Urey-Bradley force field has been developed to express the potential energy. (3) All the force constants have been selected so that their values are consistent for the four molecules studied and are reasonable in view of their electronic structure.

Experimental

Most of the spectral data used for the normal coordinate analyses were taken from the literature. The Raman spectrum of phosphorus pentachloride was obtained, however, to confirm some of the calculated frequencies. A saturated benzene solution of phosphorus pentachloride (Baker Analyzed Reagent) was analyzed in a Hilger E-612 two-prism Raman spectrograph. Mercury light of wavelength 4358 Å was used for exciting the Raman transitions. A solution of Dupont rhodamine 5 GDN-Extra dye mixed with an ethanol solution of *p*-nitrotoluene was used to filter out the other mercury lines. Eastman 103a-J plates were employed to record the spectra. In addition to a number of Raman lines due to benzene, the following lines were observed for phosphorus pentachloride 585cm^{-1}(medium strong), 394 cm^{-1} (very strong), 282 cm^{-1} (strong), 273 cm^{-1} (strong), 264 cm^{-1} (medium strong). The transitions below 200 cm^{-1} could not be observed because of strong background scattering. Figure 1 shows the microdensitometer reading plotted against the frequency in the range between 430 and 200 cm^{-1}.

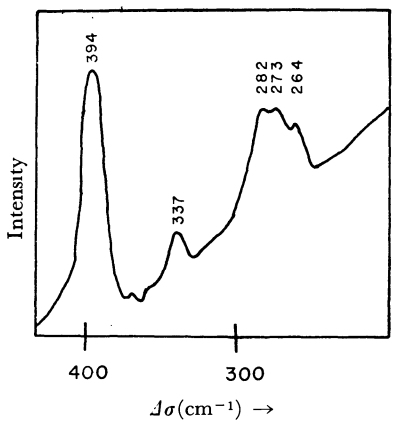

Fig. 1. Microdensitometer tracing vs. frequency for PCl_5.

Procedure of Calculation

The trigonal bipyramidal XY_5-type molecule shown in Fig. 2 belongs to the point group D_{3h}, and its twelve normal modes of vibration are grouped into the four species A_1', A_2'', E', and E''. The appropriate symmetry coordinates used are given in Table I, and the elements of the $\boldsymbol{G}$ and $\boldsymbol{F}$ matrices are listed in Tables II and III. The $\boldsymbol{G}$ matrix elements were calculated using the bond distances reported in the literature.† The matrix secular

nonbonded atoms. The symbols K, H, and F represent stretching, bending, and repulsive force constants, respectively. The primed letters donote first derivatives; r, d, r_α, r_β, q_{rr}, and q_{dr} are the values of the distances at equilibrium; they are inserted to make the dimensions of the force constants the same. The quantities K' and H' vanish in the final result, since they can be expressed in terms of F' using the equilibrium condition. F' was taken as $-0.1F$ by assuming that the repulsive energy between the nonbonded atoms is proportional to r^{-9}.

In adjusting the force constants, we first estimated the reasonable values for the repulsive force constants from a Lennard-Jones type potential. Figures III and IV illustrate the repulsive force constants which are derived from the 6-12 Lennard-Jones potentials for Ne···Ne and Ar···Ar repulsions, respectively. Then, we have adjusted these values to obtain the best fit to the observed frequencies. The final repulsive force constants thus obtained are plotted in the same figures together with those used

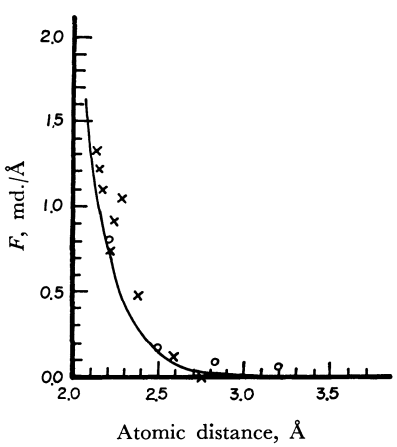

Fig. 3. Repulsive force constants derived from 6-12 Lennard-Jones potential for Ne···Ne repulsion and F···F repulsive force constants (×, Shimanouchi et al.; ○, present work)

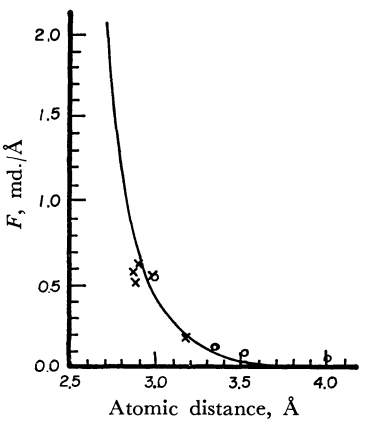

Fig. 4, Repulsive force constants derived from 6-12 Lennard-Jones potential for Ar···Ar repulsion and Cl···Cl repulsive force constants (×, Shimanouchi et al.; ○, present work)

by Shimanouchi and his coworkers[3] for other molecules. It is seen that our values are quite close to those predicted from the Lennard-Jones potentials. Table IV lists the final sets of force constants thus obtained. Tables V to VIII compare the observed frequencies with those calculated for each molecule. It is seen immediately that the two bending modes (σ_6 and σ_7) belonging to the E' species show marked deviation from the observed frequencies. Evidently, the SUBF field is not satisfactory for trigonal bipyramidal XY_5 type molecules.

In order to improve these results, we have introduced an additional force constant to the SUBF field. After several trials, we have found that the addition of a term, $\sum_{k\neq i<j} [H_{\alpha\beta}(r_\alpha \Delta\alpha_{ij})(r_\beta \Delta\beta_{ik})]$ to the potential energy improves the results considerably. Here, $H_{\alpha\beta}$ denotes an angle-angle interaction constant between α and β which lie in planes perpendicular to each other and share

3) J. Hiraishi, I. Nakagawa and T. Shimanouchi, *Spectrochim. Acta*, **20**, 819 (1964).

a common bond. The last columns in Tables V to VIII indicate the calculated frequencies obtained by using this modified Urey-Bradley force (MUBF) field. It is seen that the agreement between calculated and observed frequencies becomes quite satisfactory; the average deviation for 32 frequencies is 1.1%, and the maximum deviation is 34 cm^{-1}.

Results and Discussion

Antimony Pentachloride.—Table V compares the calculated frequencies with those observed by Siebert (Raman),[4] Wilmshurst (gaseous-phase IR),[5] and Carlson (Raman and matrix-phase IR).[6] All the band assignments made by these investigators are consistent with each other, and the calculated frequencies are in perfect agreement with those observed.

Phosphorus Pentachloride.—As is seen in Table VI, the previous band assignments differ seriously among the investigators. Siebert[4] assigned a Raman line at 271 cm^{-1} to σ_2, whereas Carlson assigned it to σ_6 (E' species) because an infrared band was observed at 273 cm^{-1}. Wilmshurst and Bernstein[7] assigned a Raman line at 394 cm^{-1} to both σ_2 and σ_1 on the assumption of accidental degeneracy. However, this assignment seems highl unlikely because, with this assumption, the stretching force constants for both the axial and the equatorial bonds would have to be of the same magnitude. On the contrary, an electron diffraction[1] and a tracer study[8] show that the axial and the equatorial bonds are not equivalent. Although Taylor and Woodward[9] assigned a Raman line at 370 cm^{-1} to σ_2, it is rather weak as is seen in Fig. 2. The corresponding line for antimony pentachloride is relatively strong. We, therefore, assigned it to a combination band ($\sigma_6+\sigma_7$ or $\sigma_2+\sigma_7$).

According to our normal coordinate analysis, σ_2 should be around 260 cm^{-1}. As is shown in Fig. 2, we have observed three Raman lines in the region 290—260 cm^{-1} using the photographic method. Therefore, the line at 264 cm^{-1} which is closest to our calculated frequency, is assigned to the σ_2 mode. It should be mentioned that Wilmshurst and Bernstein[7] also observed a Raman line at 264 cm^{-1} which they attributed to a combination band. However, one of the fundamentals (176 cm^{-1}), which was assumed to be a component of this combination band, was not observed by Carlson[6] in his infrared spectrum. Therefore, the Raman line at 264 cm^{-1} cannot be a combination band.

The calculated frequency for σ_4 (303 cm^{-1}) is in good agreement with that observed by Carlson (299 cm^{-1})[6] in the infrared spectrum. The frequencies predicted by Wilmshurst and Bernstein (176 cm^{-1})[7] and by Siebert (124 cm^{-1})[4] are too low for this mode. Furthermore, Carlson did not observe any infrared band arount 176 or 124 cm^{-1}. The calculated frequency for σ_5 (588 cm^{-1}) is in good agreement with that observed by Wilmshurst and Bernstein (592 cm^{-1}), and is fairly close to that observed by Carlson (580 cm^{-1}). Although Siebert assigned it to a Raman line at 495 cm^{-1}, it was found that this line is due to phosphorus oxychloride contaminated in a solution of phosphorus pentachloride.

The calculated frequency for σ_6 (278 cm^{-1}) is in good agreement with that observed by Carlson (273 cm^{-1})[6] and by the present investigators (273 cm^{-1}). Carlson observed this mode both in the infrared and Raman spectra. Therefore, it must belong to the E' or A'' species. Although Taylor and Woodward[9] assigned σ_6 to a Raman line at 281 cm^{-1}, no infrared band was observed at this frequency. On the other hand, Wilmshurst and Bernstein[7] assigned it at 335 cm^{-1}. However, Taylor and Woodward did not observe any Raman line near 335 cm^{-1}.

The calculated frequency for σ_8 (277 cm^{-1}) is close to the Raman line observed at 282 cm^{-1} in the present work. This line was also observed by Wilmshurst and Bernstein and by Calrson, and was assigned by both to the σ_8 mode.

Recently, Radhakrishnan[10] and Krynauw et al.[11] have carried out normal coordinate analysis of phosphorus pentachloride using the band assignments made by Wilsmshurst and Bernstein[7] and by Carlson[6], respectively. Our results are different from those of previous workers since our band assignments and force field are different from theirs.

Antimony Pentafluoride. — The infrared and Raman spectra of antimony pentafluoride were observed by Akers[12] and by Gaunt and Ainscough,[13] but their band assignments are in complete disagreement, as is seen in Table VII. Furthermore, Akers presented two different sets of band assignments both of which differ from that of Gaunt and Ainscough. Nagarajan,[14] and Haarhoff and Pistorius[15] have carried out normal coordinate analysis using the band assignments by

Gaunt and Ainscough, and have obtained a large negative interaction force constant between two axial bond stretching coordinates in the general valence force field. They suggested that this might be due to incorrect assignments for σ_2 and σ_3 made by Gaunt and Ainscough.

In order to solve these conflicting band assignments, it is useful to consider the frequency order observed in antimony pentachloride and phosphorus pentachloride. From Table V and VI, it is seen that the stretching frequencies (σ_1, σ_2, σ_3, and σ_5) are much higher than the bending frequencies (σ_4, σ_6, σ_7, and σ_8), and the order of the stretching frequencies is always σ_5(asym. in-plane) > σ_3(asym. out-of-plane) > σ_1(sym. in-plane) > σ_2-(sym. out-of-plane) the six fundamental observed by Akers[12] and the two fundamentals observed by Gaunt and Ainscough[13] were rearranged with this trend in mind. The four bending frequencies were also rearranged so as to obtain the frequency order $\sigma_6 > \sigma_8 > \sigma_4 > \sigma_7$, which was found to hold for antimony pentachloride. As is seen in Table VII, the agreement between the calculated and observed frequencies is quite satisfactory. It should be mentioned that the set of the fundamentals selected by the present investigators can account for all the other observed frequencies on the assumption that they are overtones and combination bands.

Phosphorus Pentafluoride.—Table VIII compares the calculated frequencies with those observed by Gutowski and Liehr (infrared),[16] by Pemsler and Planet (infrared),[17] and by Griffith et al. (infrared and Raman).[18,19] All the band assignments made by these investigators are consistent with one another and agree quite well with the calculated frequencies.

Trends in Force Constants.—The force constants listed in Table IV have several interesting implications. First of all, the stretching force constants involving the fluorine atoms are much larger than those involving the chlorine atoms. This is consistent with the fact that the heat of formation of phosphorus pentafluoride (−290 kcal./mol.) is much larger than that of phosphorus pentachloride (−95.35 kcal./mol.). Secondly, the stretching force constants for the equatorial bonds (K_r) are larger than those for the axial bonds (K_d) in all the four molecules studied. This trend is consistent with the results of X-ray[20] and electron diffraction[1] studies which indicate that the equatorial bonds are shorter than the axial bonds.

Table IV also indicates that the bending force constants of the fluorides are always larger than those of the corresponding chlorides, and that the bending force constants of the phosphorus compounds are always larger than those of the corresponding antimony compounds. All these changes which occur upon the replacement of either the central or the halogen atom can be explained satisfactorily in terms of the electron pair repulsion theory developed by Gillespie.[21] His theory also predicts that the bending force constants for the axial bond angle (H_β) should be larger than that for the equatorial bond angle (H_α). As is seen in Table IV, this was found to be the case.

As stated previously, the repulsive force constants follow the trends predicted from the 6—12 Lennard-Jones potential. Therefore, their values increase progressively as the bond distances decrease. Thus, we have the following orders:

$$F_{rr}(SbF_5) < F_{dr}(SbF_5) < F_{rr}(PF_5) < F_{dr}(PF_5)$$

$$F_{rr}(SbCl_5) < F_{rr}(PCl_5) < F_{dr}(SbCl_5) < F_{dr}(PCl_5)$$

It has already been shown that the introduction of an angle-angle interaction constant, $H_{\alpha\beta}$, improves the calculated frequencies for the σ_6 and σ_7 modes considerably. It is interesting to note that these two vibrations are responsible for "pseudorotation" which was proposed by Berry[22] for trigonal bipyramidal XY_5 type molecules. Since the angles α and β must be interchanged during pseudorotation, it is reasonable to introduce such an interaction term in the potential energy.

The Coprecipitation Behavior of Rare Earth Elements with Calcium Oxalate upon Precipitation from a Homogeneous System

By Masakazu MATSUI

Institute for Chemical Research, Kyoto University, Sakyo-ku, Kyoto

(Received July 19, 1965)

The effects of the pH value, the concentration of organic acid and several other variables upon the distribution coefficient were studied for the coprecipitation process of the calcium-lanthanide oxalate system. The logarithmic distribution law was followed in all cases of the coprecipitation of rare earth elements. Of the several variables studied which affected the logarithmic distribution coefficient, the most important were the pH value and the concentration of an organic acid. The coefficient decreased as the acid anion content increased. This can be attributed to the fact that the acid anion formed complex compounds with lanthanide and calcium. The distribution coefficients of several rare earth elements in producing the precipitate from a similar solution were closely related to their basicity or to the solubility of their oxalate salts. The order of the magnitude of the distribution coefficient was as follows: Lu>Y>Eu>Ce; this was in the reverse order of the basicity of rare earth elements or of the solubility of their oxalate salts.

Coprecipitation has often been used for the chemical concentration or enrichment of trace elements from dilute solutions and for the chemical separation of radioisotopes. Furthermore, coprecipitation phenomena are observed in the precipitation method of gravimetric analysis and in geochemical processes.

When a macro component is precipitated, micro components in the solution are distributed between the solid and liquid phases. The initial distribution may be quite random, but structural transformation must occur in the recrystallization process of the precipitate. As equilibrium conditions are reached, an orderly rearrangement is achieved. For such a system, macro and micro components distribute themselves to obey the following equation, which was introduced by Chlopin[1] and by Henderson and Kracek[2]:

$$\left(\frac{\text{tracer}}{\text{carrier}}\right)_{\text{crystal}} = D\left(\frac{\text{tracer}}{\text{carrier}}\right)_{\text{solution}} \qquad (1)$$

where D is the homogeneous distribution coefficient and is constant for a given system. This homogeneous distribution law represents a true thermodynamic equilibrium.

Beside the homogeneous distribution in crystals, there are many possible heterogeneous arrangements. Only one of these was given by Doerner and Hoskins' distribution equation.[3] It is called the logarithmic distribution law and is expressed as follows:

$$\log\left(\frac{\text{initial quantity}}{\text{quantity left in soln.}}\right)_{\text{tracer}} = \lambda \log\left(\frac{\text{initial quantity}}{\text{quantity left in soln.}}\right)_{\text{carrier}} \qquad (2)$$

where λ is the logarithmic distribution coefficient and is also constant for a given system. It is postulated in the logarithmic law that a distribution equilibrium is attained between the ions in the solution and the ions on the solid surface as each new crystal layer is formed. A crystal formed under such circumstances retains a radial gradient of the concentration of the tracer component distributed in a logarithmic manner. If λ is larger than unity, the tracer component is enriched in the crystal and the concentration of the tracer component is the highest at the center of each crystal, decreasing gradually toward the outer part of the crystal. When λ is smaller than unity, the tracer component is enriched in the solution, and the radial concentration gradient in the crystal becomes the reverse of that of the case of values of λ greater than unity.

The coprecipitation method using calcium oxalate as a carrier is often used for the enrichment of strontium, scandium and rare earth elements from dilute solutions for the separation of those radioisotopes from the other elements.

Some attempts have been made to reveal the distribution behavior of macro and micro components. In general, due to the low solubility of oxalates, coprecipitation from a homogeneous system was used. This also gave rise to the more reproducible results.

Feibuch, Rowly and Gordon[4] reported that the coprecipitation of pairs of rare earth oxalates obeyed the logarithmic distribution law. Purkayastha and Bhattacharyya[5] showed that the coprecipitation of yttrium and europium with calcium oxalate also followed the logarithmic distribution law. Previously, Shigematsu et al. had studied the coprecipitation behavior of scandium[6] and yttrium ions[7] with calcium oxalate from a homogeneous system and found that there were distinct differences between the two cases. In the calcium-yttrium system, the logarithmic distribution law was followed, regardless of the composition of the solutions, while the distribution of scandium deviated gradually from the logarithmic law with an increase in the pH value, and under similar conditions yttrium gave larger distribution coefficients than did scandium. On the basis of the above results, it was deduced that yttrium was more stable than scandium in the calcium oxalate crystal, because the ionic radius of bivalent calcium is closer to that of tervalent yttrium than to that of tervalent scandium.

In this research, the coprecipitation of rare earth elements with calcium oxalate was investigated. The effects of the pH values, the concentration of acetate used as the buffer solution and several other variables on the distribution coefficient were studied, using cerium-144, yttrium-91, europium-152, 154 and lutetium-177 as the radiotracers. The distribution coefficients of rare earth elements coprecipitated under the same conditions were compared.

Experimental

Apparatus and Reagents.—Radioactivity countings were made with a Phillips halogen-quenched G-M tube connected to a dekatron scaler (Metro Model D-5), and with a NaI (Tl) ($1^3/_4' \times 2'$) well-type scintillation counter (Kobe Kogyo Model PS-300) connected to a scaler (Model SA-230). A Hitachi-Horiba pH meter, Model M-3, was used for the pH measurements.

Radioisotopes were supplied as chloride in hydrochloric acid from The Radio Chemical Centre, Amersham, England. Reagent-grade dimethyl oxalate was purified by recrystallization from anhydrous methanol and was stored in a dry atmosphere to prevent it from hydrolysis by moisture. Stock solutions of rare earth elements were prepared by dissolving their reagent-grade oxides in hydrochloric acid. The calcium solution was prepared by dissolving reagent-grade calcium carbonate in hydrochloric acid. The EDTA solution (0.01 M) containing a Mg-EDTA complex was standardized with a standard calcium solution.

The other chemicals were chemically pure or were reagent-grade materials.

Procedure.—A representative procedure adopted in the homogeneous coprecipitation is as follows.

Twenty milliliters of a calcium chloride stock solution (2.0 M) and a suitable volume of a rare earth solution, with an appropriate amount of radioactive isotopes, are placed in a 250-ml. Erlenmeyer flask. Twenty milliliters of 10 M acetic acid or formic acid (as a buffer solution), a suitable volume of a sodium hydroxide solution, and 2.36 g. of dimethyl oxalate dissolved in water are added, the resulting solution is diluted to 200 ml., and the pH of the solution is measured. Then the flask, equipped with a reflux condenser, is placed in a thermostat, and the solution is stirred continuously with a mechanical stirrer to prevent it from supersaturation.

When the temperature of the solution rises to 60°C, 2 ml. of the solution is pipetted out into a glass counting dish 25 mm. in diameter for beta counting or into a polyethylene counting tube 12 mm. in diameter for gamma counting. After calcium ions begin to be precipitated by the oxalate ions released from dimethyl oxalate, 2.0 ml. of the solution is pipetted out from the reacting solution through a sintered glass filter into a counting vessel at appropriate intervals of time, and 0.2 ml. of concentrated hydrochloric acid is added immediately to stop any precipitation which may occur in cooling. The radioactivities of the liquid samples in the dish or tube are measured to determine the amount of rare earth elements in the solution phase. This solution is then washed out into a beaker with 5 N hydrochloric acid, dried slowly, and ashed by fuming it repeatedly with perchloric acid on a hot plate. After dilution with water and the addition of a buffer solution, the calcium ion is titrated with a 0.01 M EDTA standard solution containing its magnesium chelate, using Eriochrome Black T as an indicator. The homogeneous and logarithmic distribution coefficients, D and λ, are calculated from Eqs. 1 and 2.

Results and Discussion

The effect of the pH value on the coprecipitation was studied. The results in the calcium-cerium(III) system are shown in Fig. 1, in which the percentages of coprecipitated cerium at several pH values are plotted against the fractions of calcium precipitated. The diagram shows that the cerium ion is enriched in the precipitate in the pH range investigated, with the extent of enrichment increasing as the pH decreases. This is a similar case to that of yttrium.

The logarithmic and homogeneous distribution coefficients, λ and D, were calculated from these data, and λ was plotted against the percentage of the precipitation of a macro component (cf. Figs. 2 and 3). As Fig. 2 shows cerous ion coprecipitates obey the logarithmic law regardless of pH, and the value of λ increases with the decrease in pH, when the precipitation occurs in a 1 M formate solution. The value of λ which was obtained in a 1 M acetate solution is affected by the pH value in a similar manner, as is shown in Fig. 3. In the experiment made at a lower pH, λ does not seem to be constant; instead, it increases as the precipitation proceeds. The fact that deviation is more influenced in the more weakly-buffered pH range can be explained from the fact that the pH value is lowered and the value of λ increases as the oxalates are formed. Considering the shift of pH during the reaction progress, there is no doubt that the distribution in a 1 M acetate solution also follows the logarithmic distribution law.

Europium and lutetium ions behave in the same way as a cerous ion does. In Fig. 4, the logarithmic distribution coefficients are plotted against the pH in calcium-cerium and calcium-lutetium systems. Although λ increases as the pH decreases, in the pH range studied these systems obey the logarithmic law. It should be pointed out that a difference was found between the distribution curves obtained in acetate and formate buffer solutions. The coefficients change monotonously with the change in pH and gradually approach a constant value in each buffer solution, though as different curves, depending upon the species of organic acid used as the buffer substance. This can be interpreted in terms of the complex formation of metal ions with those acids. The coefficients of lutetium are somewhat higher than cerium throughout the pH range investigated in Fig. 4.

The effect of the organic acid concentration on the coefficient was examined in the calcium-cerium system. The precipitations were carried out on solutions containing 2.0, 1.0 and 0.5 M of acetate at pH 4.50, a value which was suitable

for the estimation of λ. Although the coefficient increases slightly in the process of the precipitation, much as in Fig. 3, the distribution must obey the logarithmic law, taking account of shift in pH mentioned above.

The values extrapolated to zero percent of calcium on the coefficient-precipitated calcium curve are taken as the exact coefficient at pH 4.50. The results are represented in Fig. 5, where it is evident that the coefficient is remarkably increased by the decrease in the acetate concentration.

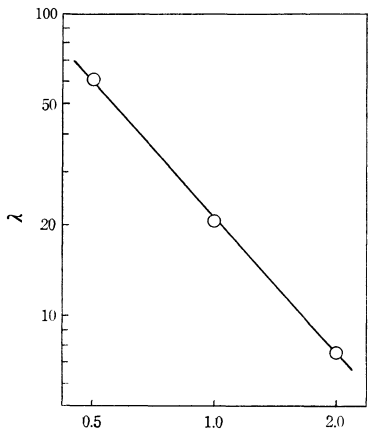

Fig. 5. Effect of acetate concentration on distribution coefficient for calcium-cerium system.
pH: 4.50, Others are the same as in Fig. 1.

The effects of other such variables as the concentration of coexisting ions and the concentration of micro component will be discussed below, although they are not so evident. To examine the effect of the ionic concentration, sodium chloride was added to make the final concentration nil, 1.0 and 2.0 M at pH 4.50 in the calcium-lutetium system. The experiment was performed in a 0.5 M acetate solution, which was selected as being suitable in respect to ionic concentration and buffer action. The results shown in Fig. 6 indicate that the coefficient is scarcely influenced by the ionic concentration. The influence of the concentration of a micro component was also hardly recognized in the calcium-lutetium system. The value of λ at pH 4.50 in 1 M acetate was 19.3 at 10^{-7} M and 19.5 at 10^{-5} M of lutetium ions respectively. As has been mentioned above, it is obvious that the factors influencing the coefficient are the pH of the solution and the concentration of a coexisting organic acid.

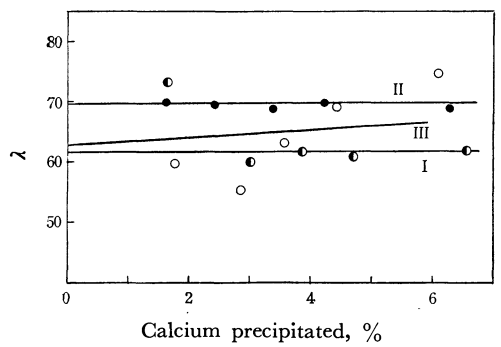

Fig. 6. Effect of ion concentration on distribution coefficient for calcium-lutetium system.
NaCl added: I, none, II, 1 M, III, 2 M,
Acetate: 0.5 M, pH: 4.50,
Others are the same as in Fig. 1.

Chlopin[8] offered the following explanation for the relation between the composition of a solution and the homogeneous distribution coefficient, D: if the ratio of the ionic concentration of a micro component to that of a macro component does not vary, even when the composition of the solution varies, the value of D will practically not change. When a complex or an insoluble compound is formed with a change in the composition of the solution, or when the ionic concentration of a macro or micro component undergoes a change separately, the value of D will increase if the ionic concentration of a macro component decreases more rapidly than that of a micro component, and vice versa.

This explanation can be applied to the system studied, which obeyed the logarithmic distribution law. When the pH becomes higher or when the concentration of organic acid used as a buffering agent becomes higher, the ionic concentration of the organic acid increases. The acid anion forms complex compounds with rare earth and calcium, the former complex being more stable than the latter. Then, as the ionic concentration of the acid anion increases, the decrease in the concentration of calcium ions will be less than that of rare earth ions, although the situation is complicated by the formation of a hydroxo complex or by other factors which should also be taken into consideration. Therefore, the logarithmic coefficient will gradually decrease.

The coprecipitation of several rare earth elements was examined by conducting the precipitation under identical conditions; the distribution coefficient of these elements were then compared. The results are summarized in Figs. 7 and 8. Figure 7 shows the relationship between the ionic radii of several rare earth ions and their distribution coefficients obtained at pH 3.50 in a 1 M formate solution. The coefficients of several elements in Fig. 8 are obtained in the same way at pH 4.50 in 1 M acetate. The ionic radii of tervalent rare earth ions are quoted from the numerical values obtained by Goldschmidt. A

divalent calcium ion is equal in ionic radius to a tervalent yttrium ion. The limiting distribution coefficient of the calcium-scandium system in these figures was cited from the previous paper[6] for the sake of comparison. As is shown in the figures, the distribution coefficients of rare earth ions, the ionic radii of which come closer to that of divalent calcium, are closely related to their basicity or to the solubility of their oxalate salts. The order of the basicity of rare earth elements or of the solubility of their oxalate salts is as follows: Ce>Eu>Y>Lu, which is the reverse of the order of the distribution coefficients found in the present work.

Scandium ion constitutes an exception. Although it has a weaker basicity than rare earth elements, scandium is rather unstable in a calcium oxalate crystal and shows a smaller coefficient. This may be caused by the fact that the difference between the ionic radius of tervalent scandium and that of divalent calcium is quite large. This fact is a typical example showing that the ionic radius plays an important role in the coprecipitation process.

Gordon has questioned whether the logarithmic distribution equation (Eq. 2) can be justifiably applied to coprecipitation systems in which the charges of the ions are different; he has thus proposed an equation in which the charges of ions were taken into account.[9,10]

The present system is an example of the coprecipitation of the tervalent cation with divalent calcium salt. The equilibrium is represented by the following equation:

$$3Ca^{2+}_{cryst.} + 2M^{3+}_{aq.} = 3Ca^{2+}_{aq.} + 2M^{3+}_{cryst.}$$

The equilibrium constant, D^1, is defined as follows:

$$D' = \frac{[Ca^{2+}]^3_{aq.}[M^{3+}]^2_{cryst.}}{[M^{3+}]^2_{aq.}[Ca^{2+}]^3_{cryst.}}$$

When the equation proposed by Gordon[9] is applied to the above system, the following equation is obtained:

$$\log \frac{M_{initial}}{M_{final}} = 0.8686\ \lambda_g (Ca_{final}^{-1/2} - Ca_{initial}^{-1/2}) \quad (3)$$

where $M_{initial}$ and $Ca_{initial}$ represent the initial concentrations in a solution; M_{final} and Ca_{final} represent the final concentrations in a solution, and λ_g is the distribution coefficient of this system.

Equation 3 suggests that when the ions have different charges the distribution coefficient is dependent upon the initial calcium concentration. Therefore, the effect of the initial calcium concentration on λ and λ_g was examined. It is represented in Table I. The results show that λ and λ_g are about equally constant throughout the reaction process, and λ is more extensively affected than λ_g by the initial calcium concentration. However, it is doubtful from these data whether Eq. 3 is valid for the present system. Further research is needed to justify the applicability of Eq. 3 to systems involving differently-charged ions.

In this paper, λ was calculated by means of the logarithmic distribution equation of Doerner and Hoskins (Eq. 2), because the coprecipitation behavior shows the same tendency, whichever coefficient is used, and also because the applicability of λ_g still remains to be studied.

The author wishes to thank Professor Tsunenobu Shigematsu and Dr. Masayuki Tabushi for their kind and valuable advice throughout this study.

Reactions of 2-Chlorocycloalkanone Oximes. I. Their Preparations and Conversion to 2-Alkoxy-, 2-Acyloxy- and 2-Alkylthiocycloalkanone Oximes[1]

By Masaji OHNO, Norio NARUSE, Seiichi TORIMITSU and Masaru OKAMOTO

Basic Research Laboratories, Toyo Rayon Co., Ltd., Tebiro, Kamakura

(Received July 22, 1965)

The preparation of 2-chlorocycloalkanone oximes has been investigated in detail. 2-Chlorocyclooctanone oxime is prepared in an excellent yield by the reaction of cyclooctene with nitrosyl chloride under the irradiation of light from a high-pressure mercury lamp. 2-Chlorocyclododecadienone oxime, 2-chlorocyclohexanone oxime and 3-chloronorcamphor oxime are prepared in good yields by the addition of nitrosyl chloride to *cis*, *trans*, *trans*-1, 5, 9-cyclododecatriene, cyclohexene and norbornene respectively in the presence of hydrochloric acid. Their displacement reactions with such nucleophilic reagents as sodium alkoxides, sodium ethanethiolate and sodium salts of carboxylic acids have been studied, and the syntheses of 2-alkoxy-, 2-ethylthio- and 2-acyloxycycloalkanone oximes have been successfully achieved.

The addition of nitrosyl chloride to olefins has been of considerable importance in the developement of cyclic terpene chemistry.[2,3] It has mainly played an important role in unsaturation tests of natural products by affording dimers of nitrosochlorides, which are very easily obtained in crystalline forms if the formation of bimolecular compounds is not prevented from steric hindrance (Eq. 1):

$$>C=C< + NOCl \rightarrow ON-\underset{|}{\overset{|}{C}}-\underset{|}{\overset{|}{C}}-Cl \rightleftarrows (ON-C-C-Cl)_2 \qquad (1)$$

The first synthetic application of the reaction was studied by Wallach[4] and Deussen[5] on exo double bonds of cyclohexane derivatives and on a sesquiterpene, caryophyllene, as is expressed in Eqs. 2 and 3 respectively:

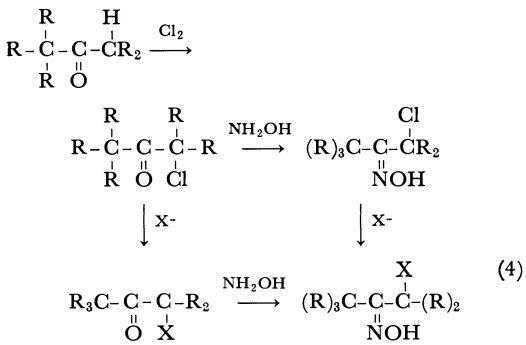
(3)

However, these reactions were limited to trisubstituted olefins, and later investigations have shown that stable adducts nitrosochlorides can be formed only from tetra and trisubstituted olefins,[3] while disubstituted olefins have been considered to afford unstable or tarry materials.

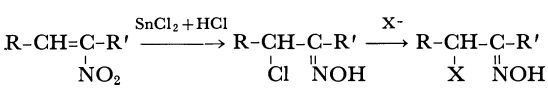
Another way[6,7] of preparing α-chlorooximes is based on ketones, as is expressed in Eq. 4:



(4)

This method has been chiefly applied to steroidal ketones; it obviously requires many steps and affords by-products.

Recently, Dornow[8] reported the new method of preparing α-chlorooxime from nitroolefins expressed in Eq. 5:



(5)

The method is limited to acyclic olefins.

In this report, we have first investigated the reactions of cyclohexene, cyclooctene, cyclododecatriene and norbornene with nitrosyl chloride, since these disubstituted olefins are now easily available as a result of the recent progress in petroleum chemistry but have not been treated with nitrosyl chloride in detail. Secondly, the successful preparation of their α-chlorooximes has enabled us to investigated their displacement reactions with nucleophilic reagents.

Results

When cyclohexene was treated with nitrosyl chloride in liquid sulfur dioxide, an isomer of bis(1-chloro-2-nitrosocyclohexane) was isolated in a 60—90% yield.[9] Another isomer of bis(1-chloro-2-nitrosocycolhexane) was obtained from the reaction in trichloroethylene.[10] These adducts were, however, found to be unsatisfactory as starting materials for displacement reactions. Therefore, the hydrochloride of 2-chlorocyclohexanone oxime, prepared from a reaction of cyclohexene and nitrosyl chloride in the presence of hydrochloric acid,[11] has been used in this research.

2-Chlorocyclooctanone oxime was obtained in an excellent yield when cyclooctene was treated with nitrosyl chloride under the irradiation of light from a high-pressure mercury lamp. The usual addition method affords 2-chlorocyclooctanone oxime in a poor yield,[12,13] and the product of the addition in the presence of hydrochloric acid is accompanied by a considerable amount of 2-chlorocyclooctanone when it is converted into the free oxime with a base.

2-Chlorocyclooctanone oxime is very stable at room temperature, while 2-chlorocyclohexanone oxime is very unstable to air and heat; the extreme instability of the latter might be the main reason why synthetic reactions for such a simple system have not yet been investigated.

The reaction of *cis, trans, trans*-1, 5, 9-cyclododecatriene with nitrosyl chloride in the presence of hydrochloric acid afforded 2-chlorocyclododecadienone oxime in nearly quantitative yields.[14] It should be mentioned that the product is obtained in a free oxime state simply by recrystallization from such organic solvents as ligroin and ethanol. Furthermore, the double bond preferentially attacked by nitrosyl chloride was found to be one of the *trans* double bonds of *cis, trans, trans*-1, 5, 9-cyclododecatriene. This method provides the most convenient way to prepare α-chlorooxime of a 12-membered ring system, since the starting material is now easily available from the trimerization of butadiene.[15]

The addition of nitrosyl chloride to norbornene in the presence of hydrochloric acid afforded 3-chloronorcamphor oxime hydrochloride in a good yield and did not involve molecular rearrangement. Previously, Miller[16] showed that the dimeric

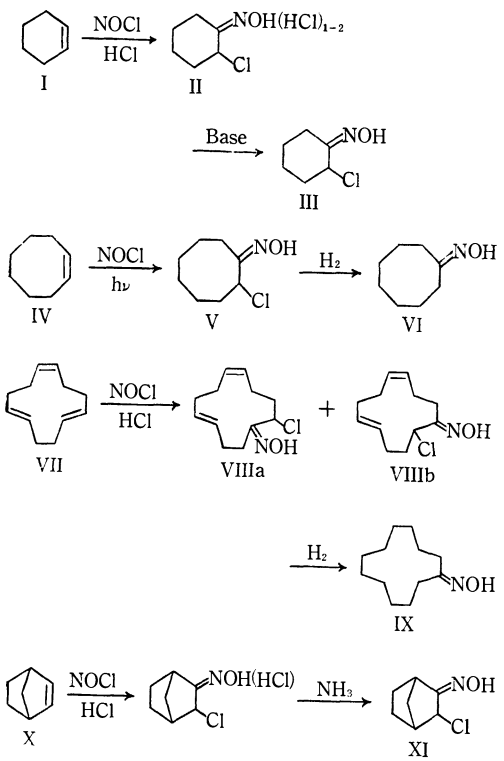
nitrosochloride of norbornene can be converted into α-chlorooxime with neither hydrochloric acid nor heat, but with urea; therefore, our method presents a simple method for the preparation of 3-chloronorcamphor oxime.

The methods of preparing 2-chlorocycloalkanone oximes are shown in the following schemes:



Displacement reactions of 2-chlorocyclooctanone and 2-chlorocyclododecadienone oximes with sodium alkoxides, sodium ethanethiolate, and sodium salts of carboxylic acids were investigated first, and then the investigation was extended to unstable 2-chlorocyclohexanone oxime.

α-Chlorooximes were treated with sodium alkoxides in the corresponding alcohol or in tetrahydrofuran at 40—60°C. Methanol, ethanol, 2-propanol, *t*-butyl alcohol and phenol were used for the displacement reactions. The best yields were generally obtained when more than two mole equivalents of sodium alkoxide were used. In each reaction, a blue color was always observed at the beginning, but it always disappeared soon, strongly suggesting the formation of nitroso compounds during the reaction. The reaction with 2-propanol and *t*-butyl alcohol afforded products only in the case of the 8-membered ring.

It has been shown that the yields of α-alkoxyoximes of the 8- and 12-membered rings are better than those of the 6-membered ring and that no appreciable amount of an unsaturated oxime was detected in these reactions, contrary to the cases of trisubstituted olefins.[4]

Treatments of α-chlorooximes with sodium ethanethiolate were carried out in tetrahydrofuran with vigorous stirring. The expected α-ethylthiooximes were obtained in good yields from the 8- and 12-membered rings, but not from the 6-membered ring. In these cases, too, a blue color was observed during the reactions.

α-Chlorooximes were treated with sodium salts of various carboxylic acids in tetrahydrofuran or acetone, affording α-acyloxyoximes in good yields.

The yields of these reactions are summarized in Table I.

Table I. Displacement reactions with RONa, EtSNa, and RCOONa

Reagent	2-Substituted-cyclohexanone oxime %	2-Substituted-cyclooctanone oxime %	2-Substituted-cyclododecadienone oxime %
MeONa	77	97.5	90
EtONa	55	90	88
i-PrONa	*	40—58	*
t-BuONa	*	60—80	*
PhONa	*	80	*
EtSNa	*	72	84.6
HCOONa	*	80	*
CH_3COONa	86	80	81
PhCOONa	65	72	65

* Only a tarry material was obtained; the isolation of the expected products was unsuccessful.

The mechanism of these reactions seems not to be a simple S_N2-type, but a Michael-type, addition of nucleophiles to the α, β-unsaturated nitroso compound formed during the reaction, since a freshly-prepared solution of 2-chlorocyclooctanone oxime and *n*-butyllithium in tetrahydrofuran possessed a deep blue color with maximum absorptions at 258 mμ (ε, 3300) and 645 mμ (ε, 10).

Experimental

2-Chlorocyclohexanone Oxime (III).[11]—Cyclohexene (100 g.) was placed in a 300-ml. three-necked round-bottom flask equipped with a stirrer, a gas inlet and gas outlet tubes; then at the bottom of the flask a two-way stop cock was fitted in order to remove the products. A mixed gas of nitrosyl chloride (1.3 mole equivalent) and hydrogen chloride was passed through cyclohexene, and the reaction temperature was kept at about −10°C. The oily product which was gradually formed at the bottom of the flask was removed through the stopcock. The oily product (62 g.) solidified on standing at room temperature and was confirmed to be the hydrochloride of 2-chlorocyclohexane oxime from its infrared spectrum and from its conversion into cyclohexanone oxime by catalytic reduction. Free 2-chlorocyclohexanone oxime was obtained by neutralizing the hydrochloride with aqueous ammonia, followed by extraction with ether and the removal of the solvent.

It was immediately used for displacement reactions.

2-Chlorocyclooctanone Oxime (V).—Nitrosyl chloride (13 g.) was passed through a solution of cyclooctene (10 g.) in a mixed solvent of methylene chloride (100 ml.) and methanol (15 ml.) under the irradiation of light from a high-pressure mercury lamp (200 W.) for 70 min. After the reaction, and after the solvent had been removed under reduced pressure, a colorless solid (17 g.) was obtained, along with a very small amount of an oily material. The solid material was washed with ligroin and recrystallized from methanol. It melted at 98—99°C and showed infrared absorptions at 3200 cm^{-1} for the hydroxy group and 1650 cm^{-1} for the C=N group. The NMR spectrum showed a triplet signal at τ 5.48; thus the structure proved to be 2-chlorocyclooctanone oxime.

Found: C, 54.70; H, 8.06; N, 8.07; Cl, 20.24. Calcd. for $C_8H_{14}NOCl$: C, 54.71; H, 8.05; N, 8.01; Cl, 20.21.

2-Chlorocyclododecadienone Oxime (VIIIa and VIIIb). — *cis, trans, trans*-1, 5, 9-Cyclododecatriene (200 g.) dissolved in 1 l. of trichloroethylene was placed in a 2-l. three-necked flask equipped with a stirrer and an inlet tube for nitrosyl chloride. A mixed gas of nitrosyl chloride (81 g.) and hydrogen chloride was bubbled into the solution over 3 hr, while the reaction temperature was kept below 12°C. After the addition of nitrosyl chloride, hydrogen chloride was passed through the solution for another hour. After the reaction, the solvent was removed under aspirator pressure; a pale-yellow crude product (287 g.) was thus obtained. It was crystallized from ligroin, showing a m. p. of 127—129°C.

Found: C, 63.15; H, 7.85; N, 5.85; Cl, 15.99. Calcd. for $C_{12}H_{18}NOCl$: C, 63.29; H, 7.92; N, 6.16; Cl, 15.60.

Its infrared spectrum showed absorptions at 980 cm^{-1} characteristic of a *trans* double bond and at 707 cm^{-1} characteristic of a *cis* double bond, thus showing that one of the *trans* double bonds was preferentially attacked by nitrosyl chloride. Besides the above absorptions, an absorption for the hydroxyl group was observed at 3210 $cm.^{-1}$ No skeletal change or transannular reaction was observed, since its hydrogenation with palladium charcoal afforded cyclododecanone oxime in a quantitative yield. Therefore, the product must be a mixture of 2-chloro-*cis*-5, *trans*-9-cyclododecadienone oxime (VIIIa) and 2-chloro-*trans*-5, *cis*-9-cyclododecadienone oxime (VIIIb), which were used for displacement reactions without separation.

Similar reactions using methylene chloride, chloroform, and carbon tetrachloride showed that there was no essential change in the product, which always afforded 2-chlorocyclododecadienone oxime in yields of 60—90%.

3-Chloronorcamphor Oxime (XI).—A mixed gas of nitrosyl chloride (17.5 g.) and hydrogen chloride was introduced into a solution of norbornene (25 g.) in 120 ml. of trichloroethylene over a 2-hr. period, During the reaction, the temperature was kept at 0—5°C. The reaction mixture became green at the beginning, and then colorless precipitates were formed. After the reaction, a solid fraction (60 g.) was separated by filtration. It was treated with a 2 N ammonia solution to neutralize it and extracted with ether. The ethereal solution afforded colorless needle crystals (38 g.), m. p. 117—119°C, which were recrystallized from ethanol.

Found: C, 52.95; H, 6.21; N, 8.41; Cl, 22.36; M. W.=161.3. Calcd. for $C_7H_{10}NOCl$: C, 52.68; H, 6.32; N, 8.74; Cl, 22.22%; M. W.=159.6.

The NMR spectrum showed a signal (singlet, 1H) at 0.38τ for the hydroxyl proton and a signal (doublet J=3 c. p. s., 1H) at 5.60τ for the endo hydrogen on C-3.

2-Methoxycyclooctanone Oxime.—Sodium metal (3 g.) was dissolved in 100 ml. of methanol. 2-Chlorocyclooctanone oxime (10 g.) dissolved in 50 ml. of methanol was then added to the solution over a 1 hr. period. The reaction temperature was kept at 50—60°C. A blue color was observed immediately after chlorooxime was added, but it soon disappeared. After another hour, the solvent was removed under reduced pressure. When the residue was treated with water and then ether, the ethereal solution afforded a pale-yellow solid (9.5 g.). It was recrystallized from *n*-hexane and melted at 65—67°C. The infrared spectrum showed absorptions at 3,300 cm^{-1}(-OH), 1640 cm^{-1}(-C-N-), and 1085 cm^{-1}(-C-O-C).

Found: C, 60.14; H, 10.06; N, 7.60. Calcd. for $C_9H_{17}NO_2 \cdot 1/2H_2O$: C, 59.97; H, 10.07; N, 7.77%.

2-Methoxycyclododecadienone Oxime. — 2-Chlorocyclododecadienone oxime (10 g.) dissolved in 100 ml. of methanol was treated with a sodium methoxide solution, prepared from 2 g. of sodium and 100 ml. of methanol, at 40—50°C for 3 hr. After the reaction, the methanol was removed under reduced pressure, and the residue was treated with water and then ether. The ethereal solution afforded a colorless, oily product. The infrared spectrum showed absorptions at 3300 cm^{-1}(-OH), 1650 cm^{-1}(>C=N-), and 1080—1090 cm^{-1}(-C-O-C). The 2, 4-dinitrophenylhydrazone showed a m. p. of 191—193°C.

Found: C, 57.97; H, 7.20; N, 14.23. Calcd. for $C_{19}H_{28}O_5N_4$: C, 58.14; H, 7.19; N, 14.28%.

2-Methoxycyclohexanone Oxime. — Crude 2-chlorocyclohexanone oxime (10 g.), freshly prepared from its hydrochloride by treatment with ammonium hydroxide, was dissolved in a methanol solution (100 ml.) of sodium methoxide prepared from 4 g. of sodium. It was then heated to 40—50°C for 2 hr. After usual treatments, a brown oily material was obtained. The chromatography on alumina using ether as an eluent afforded a pale-yellow oil (6.2 g.). An attempt to distill the oil was unsuccessful, since it decomposed readily at 80°C. Therefore, it was hydrolyzed to 2-methoxycyclohexanone, b. p. 70—72°C/12 mmHg (reported b. p. 72—73°C/14 mmHg[17]), according to the procedure of DePuy and Ponder.[18] The phenylhydrozone showed a m. p. of 92—94°C (reported m. p. 94—96°C[17]).

Found: C, 71.42; H, 8.21; N, 12.52. Calcd. for $C_{13}H_{18}ON_2$: C, 71.51; H, 8.32; N, 12.84%.

2-Ethoxycyclooctanone Oxime.—Sodium (2.6 g.) was dissolved in ethanol (50 ml.), and then 2-chlorocyclooctanone oxime (10 g.) dissolved in ethanol (50 ml.) was added to the solution. After one hour at 40—50°C, the reaction mixture was treated as usual. The

18) C. H. DePuy and B. W. Ponder, *J. Am. Chem. Soc.*, **81**, 4629 (1959).

ethereal extract was washed with water, dried, and evaporated to dryness to give 9.5 g. of a yellow solid. It was recrystallized from aqueous ethanol, giving an analytical sample, m. p. 84.5—85.5°C.

Found: C, 65.11; H, 10.34; N, 7.78; O, 17.14. Calcd. for $C_{10}H_{19}O_2N$: C, 64.83; H, 10.34; N, 7.56; O, 17.27%.

2-Ethoxycyclododecadienone Oxime.—2-Chlorocyclododecadienone oxime (20 g.) was treated with a sodium ethoxide solution prepared from sodium (4.5 g.) and ethanol (100 ml.). A pale yellow oily product (18.5 g.) was obtained after the usual work-up, described above. The 2, 4-dinitrophenylhydrazone showed a m. p. of 143—145°C.

Found: C, 59.22; H, 7.60; N, 13.80. Calcd. for $C_{20}H_{30}O_5N_4$: C, 59.09; H, 7.44; N, 13.79%.

2-Ethoxycyclohexanone Oxime. — According to procedures similar to those described above, 2-ethoxycyclohexanone oxime (8.2 g.), an oily product, was obtained from the reaction of 2-chlorocyclohexanone oxime (10 g.) with sodium ethoxide (14.1 g.). The infrared spectrum showed abosrptions at 3300 cm^{-1} (–OH), 1660 cm^{-1}(–C=N–), and 1100 cm^{-1}(–C–O–C). It was distilled under reduced pressure to give an oily material, b. p. 87—88°C/1.3 mmHg.

Found: C, 61.02; H, 9.41; N, 9.00. Calcd. for $C_8H_{15}O_2N$: C, 61.12; H, 9.62; N, 8.91%.

2-*t*-Butoxycyclooctanone Oxime.—According to procedures similar to those described above, 2-*t*-butoxycyclooctanone oxime (9.8 g.), an oily product, was obtained from the reaction of 2-chlorocyclooctanone oxime (20 g.) with sodium *t*-butoxide (7.1 g.). IR: 3300, 1645, 1100 cm^{-1} (KBr). NMR: 6.14 τ (1H, triplet). The dinitrophenylosazone showed a m. p. of 205—207°C.

Found: C, 48.24; H, 4.22; N, 22.01. Calcd. for $C_{20}H_{20}N_8O_8$: C, 48.64; H, 4.02; N, 22.39%.

2-Isopropoxycyclooctanone Oxime.—According to procedures similar to those described above, 2-isopropoxycyclooctanone oxime (6.7 g.), an oily product, was obtained from the reaction of 2-chlorocyclooctanone oxime (10 g.) with sodium isopropoxide (5.2 g.). IR: 3300, 1650, 1110 cm^{-1} (KBr). NMR: 6.18 (1H, triplet), 6.32 (1H, multiplet), 8.66 τ (6H, doublet). It formed the same osazone as has been described above.

2-Phenoxycyclooctanone Oxime.—Sodium phenoxide was prepared from sodium (4 g.) and phenol (25 g.) in tetrahydrofuran (100 ml.). To the solution was added a solution of 2-chlorocyclooctanone oxime (10 g.) in tetrahydrofuran (50 ml.) over a 30 min. period. The reaction mixture was kept at 50°C while being stirred for 2 hr. The solvent was then removed under reduced pressure. The ethereal extract was washed with water, dried, and evaporated to dryness to give 21.2 g. of a pale-yellow solid. It was recrystallized from ligroin, giving an analytical sample with a m. p. of 76—78°C.

Found: C, 72.31; H, 8.26; N, 5.88. Calcd. for $C_{14}H_{19}NO_2$: C, 72.07; H, 8.21; N, 6.00%. IR: 3250(–OH), 1650(–C=N–), 1600(–C_6H_5), 1030 (–C–O–C), 750(–O–C_6H_5)cm^{-1} (KBr).

2-Ethylthiocyclooctanone Oxime.—Sodium ethanethiolate was prepared in tetrahydrofuran from ethanethiol (30 ml.) and sodium (3.5 g.). 2-Chlorocyclooctanone oxime (20 g.) dissolved in tetrahydrofuran (50 ml.) was added to the solution over a 1 hr. period. A blue color was observed immediately after the addition, but it soon disappeared. The reaction was continued for 3 hr. with stirring. Sodium chloride was removed by filtration, and the solvent of the filtrate was removed under reduced pressure. The ethereal extract of the residue was washed with water, dried, and evaporated to dryness to give 16.5 g. of pale yellow needle crystals. They were recrystallized from ligroin, giving an analytical sample with a m. p. of 95—96.5°C.

Found: C, 59.75; H, 9.56; N, 6.67; S, 15.90. Calcd. for $C_{10}H_{19}NOS$: C, 59.66; H, 9.51; N, 6.96; S, 15.93%.

IR: 3200(–OH), 1640(–C=N–) cm^{-1} (KBr).

2-Ethylthiocyclododecadienone Oxime.—According to procedures similar to those described above, an oily product (31 g.) was obtained from the reaction of 2-chlorocyclododecadienone oxime (35 g.) and sodium ethanethoilate (20 g.) in tetrahydrofuran. This product was chromatographed on silica gel and eluted with chloroform. A homogeneous oily product (27 g.) was thus obtained, showing the presence of an ethyl group in the NMR spectrum; this was consistent with 2-ethylthiocyclododecadienone oxime.

Found: C, 66.69; H, 9.44; N, 5.93. Calcd. for $C_{14}H_{23}NOS$: C, 66.37; H, 9.15; N, 5.53%.

The Reaction of 2-Chlorocyclohexanone Oxime with Sodium Ethanethiolate. — 2-Chlorocyclohexanone oxime (6 g.) was treated with sodium ethanethiolate (a 2.13 mole equivalent) at 40—50°C for 2 hr. The reaction product was chromatographed on silica gel and eluted with chloroform, but an attempt to isolate a homogeneous fraction was unsuccessful.

2-Formyloxycyclooctanone Oxime.—Acetone (100 ml.) and sodium formate (6.8 g.) were placed in a 300 ml. three-necked round-bottom flask equipped with a stirrer, a condenser, and a separatory funnel. 2-Chlorocyclooctanone oxime (8.8 g.) dissolved in acetone (50 ml.) was added to the sodium formate solution over a 15 min. period. The reaction mixture was refluxed for 3 hr. and the precipitates were removed by filtration. The filtrate was evaporated under reduced pressure; the residue afforded a solid product (8.2 g.) when triturated with cyclohexane. It was recrystallized from cyclohexane, giving an analytical sample with a m. p. of 82—83°C.

Found: C, 58.48; H, 8.25; N, 7.54. Calcd. for $C_9H_{15}O_3N$: C, 58.36; H, 8.16; N, 7.56%.

2-Acetoxycyclooctanone Oxime.—2-Chlorocyclooctanone oxime (8.8 g.) dissolved in tetrahydrofuran (50 ml.) was added to a solution of sodium acetate (8.2 g.) in tetrahydrofuran, over a 15 min. period, using the reaction vessel which has been described in the case of the formyloxylation. It was refluxed for 2 hr. A blue color was observed during the reaction and disappeared in 30 min. After the reaction, sodium chloride was removed, and the filtrate was evaporated under reduced pressure. The residue was triturated with a small amount of cyclohexane, affording 8.0 g. of a solid. It was recrystallized from cyclohexane, giving an analytical sample with a m. p. of 92—93°C. The infrared spectrum showed the absorptions at 1740 cm^{-1} and 1210—35 cm^{-1} characteristic of the acetoxyl group.

Found: C, 60.14; H, 8.54; N, 6.95. Calcd. for $C_{10}H_{17}O_3N$: C, 60.28; H, 8.60; N, 7.03%.

2-Benzoyloxycyclooctanone Oxime. — 2-Chlorocyclooctanone oxime (8.8 g.) dissolved in acetone (70 ml.) was added to a solution of sodium benzoate (14.5 g.) in acetone (100 ml.) over a 15 min. period and heated to 50°C for 2 hr. with stirring, using the reaction vessel described in the case of the formyloxylation. After a similar treatment, a solid (9.5 g.) was obtained. It was recrystallized from cyclohexane, giving an analytical sample with a m. p. of 93—94°C. The infrared spectrum showed the absorptions at 1725 cm^{-1} and 1210 cm^{-1} characteristic of the benzoyloxy group.

Found: C, 68.97; H, 7.24; N, 5.35. Calcd. for $C_{15}H_{19}O_3N$: C, 68.94; H, 7.33; N, 5.36%.

2-Acetoxycyclododecadienone Oxime.—2-Chlorocyclododecadienone oxime (10 g.) dissolved in acetic acid (50 ml.) was added to a solution of sodium acetate (25 g.) in acetic acid (100 ml.) over a 15 min. period and then heated to 70°C for 2 hr. After the reaction, water (300 ml.) was added to the reaction mixture, and a solid (9 g.) was deposited. This solid was recrystallized from cyclohexane and shown to have a m. p. of 117—119°C. The infrared spectrum showed the absorptions at 1740 and 1230 cm^{-1} characteristic of the acetoxyl group.

Found: C, 67.07; H, 8.49; N, 5.73. Calcd. for $C_{14}H_{21}O_3N$: C, 66.90; H, 8.42; N, 5.57%.

A part of the 2-acetoxycyclododecadienone oxime (2.5 g.) was hydrogenated with 10% palladium charcoal in acetic acid, absorbing two mole equivalents of hydrogen and affording 2.3 g. of a colorless product. This product, when recrystallized from cyclohexane, showed a m. p. of 111—112°C.

The infrared spectrum showed no absorption of a double bond; thus, the structure of the hydrogenated product was consistent with that of 2-acetoxycyclododecanone oxime.

Found: C, 65.77; H, 9.77; N, 5.44. Calcd. for $C_{14}H_{25}O_3N$: C, 65.85; H, 9.87; N, 5.49%.

2-Benzoyloxylcyclododecadienone Oxime.—2-Chlorocyclododecadienone oxime (10 g.) dissolved in acetone (100 ml.) was stirred into a solution of sodium benzoate (23 g.) in acetone (100 ml.) over a 15 min. period and then refluxed for 3 hr.

The sodium chloride formed was removed by filtration immediately after the reaction, and the filtrate was evaporated to dryness to give a solid material (9.1 g.).

When this solid material was recrystallized from ethanol, it showed a m. p. of 163—164°C. The infrared spectrum showed the absorptions at 1725 and 1210 cm^{-1} of the benzoyloxy group, besides those at 980 cm^{-1} and 707 cm^{-1} for *trans* and *cis* double bonds respectively.

Found: C, 72.69; H, 7.40; N, 4.44. Calcd. for $C_{19}H_{23}O_3N$: C, 72.82; H, 7.40; N, 4.47%.

The unsaturated product (3.2 g.) was further hydrogenated in methanol with 10% palladium charcoal. Two mole equivalents of hydrogen were absorbed, and a colorless material was quantitatively obtained, with a m. p. of 125—126°C after recrystallization from ethanol.

The infrared spectrum showed no double-bond absorption.

Found: C, 71.81; H, 8.51; N, 4.34. Calcd. for $C_{19}H_{27}O_3N$: C, 71.89; H, 8.57; N, 4.41%.

2-Acetoxycyclohexanone Oxime.—2-Chlorocyclohexanone oxime hydrochloride (9.5 g.) suspended in acetone (100 ml.) was stirred into a solution of sodium acetate (24.6 g.) in acetone (100 ml.) and heated at 50°C for 2 hr. A colorless solid (7.2 g.) was obtained after treatment similar to that described above. It was recrystallized from cyclohexane, giving an analytical sample with a m. p. of 103—104°C. IR: 3200(-OH), 1725(-$OCCH_3$), 1660(-C=N-), 1230—1260(-$OCCH_3$), cm^{-1} (KBr).

Found: C, 55.99; H, 7.45; N, 8.06. Calcd. for $C_8H_{13}O_2N$: C, 56.12; H, 7.65; N, 8.15%.

2-Benzoyloxycyclohexanone Oxime.—2-Chlorocyclohexanone oxime hydrochloride (19 g.) dissolved in acetone (100 ml.) was added to a suspension of sodium benzoate (57.6 g.) and sodium carbonate (20 g.) in acetone (200 ml.) over 30 min. and then heated at 50°C for 2 hr. while being stirred. After a usual work-up, a solid (16 g.) was obtained. It showed a m. p. of 118—119°C after recrystallization from cyclohexane.

Found: C, 67.10; H, 6.50; N, 5.96. Calcd. for $C_{13}H_{15}O_3N$: C, 66.93; H, 6.48; N, 6.01%. IR: 3450 (-OH), 1705 (-OCC_6H_5), 1660(-C=N-), 1280 (-OCC_6H_5), 720(-C_6H_6) cm^{-1} (KBr).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1125—1128 (1966)

Reactions of 2-Chlorocycloalkanone Oximes. II.[1] Syntheses of 3-Aminocycloalka[C]isoxazoles[2]

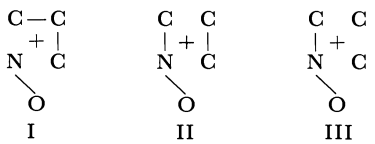
By Masaji OHNO and Norio NARUSE

Basic Research Laboratories, Toyo Rayon Co., Ltd., Tebiro, Kamakura

(Received July 22, 1965)

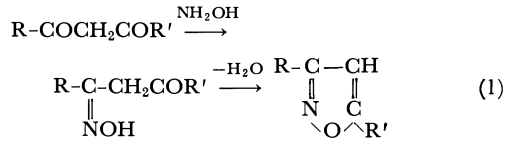
The displacement reactions of α-chlorocycloalkanone oximes with sodium cyanide in dimethyl sulfoxide or ethanol have been studied. It has been shown that 3-aminocycloalka[C]-isoxazoles can be obtained in excellent yields. α-Chlorooximes of cyclohexanone, cyclooctanone, cycloocten-5-one, cyclododecanone, and cyclododecadien-5, 9-one have been subjected to the reaction, affording the corresponding isoxazole derivatives in 48, 96, 89, 95, and 90% yields respectively. The application of the method to 3-chloronorcamphor oxime and α-chlorooximes from acyclic olefins afforded cyanooximes; it failed to give isoxazole derivatives. The hydrogenation of 3-aminocycloocta[C]isoxazole gave 2-amino-1-cyclooctanecarbonamide by the hydrogenolysis of the nitrogen-oxygen bond of the isoxazole ring system. The amino-carbonamide was treated with either the base or acid to give 2-oxycyclooctanecarboxylic acid.

Various methods of synthesizing isoxazole derivatives have been extensively investigated, and excellent reviews have been published by Quilico[3] and by Kochetkov and Sokolov.[4] The known synthetic plans of an isoxazole ring can be expressed by the following three general schemes, indicated by I, II, and III:



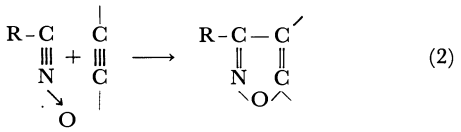
I II III

The reaction of 1, 3-dicarbonyl compounds with hydroxylamine is the method which has been used most widely for the synthesis of isoxazoles; it belongs to type I (Eq. 1);



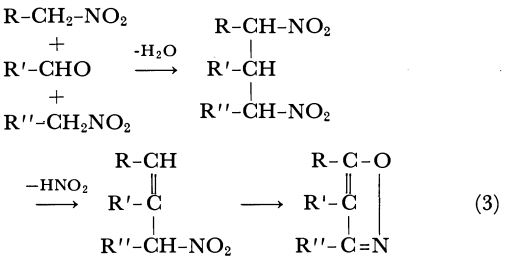
(1)

The isoxazole synthesis from nitrile oxides is another interesting method; it belongs to type II (Eq. 2):



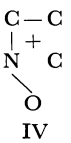
(2)

A special method for the formation of trisubstituted isoxazoles, one which starts from primary nitro derivatives, belongs to type III (Eq. 3):



(3)

During the investigation of the displacement reaction of 2-chlorocycloalkanone oximes with various nucleophilic reagents,[1] we have found a new method of synthesizing cycloalka[C]isoxazoles, one which is different from any of the methods mentioned above; it belongs to a new type, IV:



IV

In this report, the scope and limitations of the new synthesis and some reactions of 3-aminocycloalka[C]isoxazoles will be described.

2-Chlorocycloalkanone oximes were prepared readily by the reaction of cycloalkenes with nitrosyl chloride.[1] The reaction of 2-chlorocyclohexanone oxime with potassium or sodium cyanide in dimethyl sulfoxide or ethanol afforded a colorless crystalline material in a 48% yield. The infrared spectrum showed no absorption due to a nitrile group, but it did show absorptions at 3310 and 3160 cm^{-1} due to a primary amino group, and

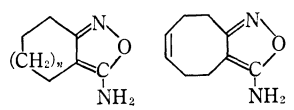
Table I. Yields and physical properties of 3-aminocycloalka[C]isoxazoles

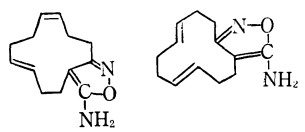
Cycloalkene	Formula	Yield, %	M. p., °C	3-Aminocycloalka[C]isoxazoles UV, mμ	IR, cm^{-1}
Cyclohexene	V	48	117—118	243 (ε, 7400)	3310 3160 1655 1640 1500
Cyclooctene	VI	96	77— 78	252 (ε, 9700)	3380 3210 1650 1610 1500
Cyclooctadiene	VII	89	81.5—82.5	251 (ε, 8230)	3310 3180 1645 1610 1500
Cyclododecene	VIII	95	119—121	253 (ε, 7960)	3430 3280 3120 1650 1610 1495
cis, trans, trans-1,5,9-Cyclododecatriene	IX	95	148—150	244 (ε, 8000)	3420 3310 3180 1645 1615 1500
trans, trans, trans-1,5,9-Cyclododecatriene	X	90	131—134	256 (ε, 7900)	3420 3310 3180 1645 1915 1500

absorptions at 1655, 1640, and 1500 cm^{-1} due to a conjugated double bond system. The ultraviolet spectrum showed an absorption at 243 mμ (ε, 7400).

These spectral data, together with those of the elementary analysis, show that the structure of this compound can be identified as 3-amino-4, 5, 6, 7-tetrahydrocyclohexa[C]isoxazole (V). This has been confirmed further by a comparison of the melting point and spectra with those of an authentic sample.[5]



V $n=1$ VII
VI $n=3$
VIII $n=7$



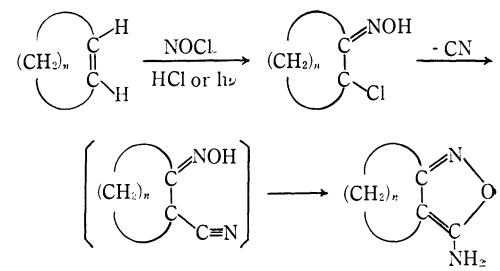
IX X

The formation of an isoxazole ring can be easily explained in terms of the displacement of an active chlorine atom with a cyanide anion, followed by an instantaneous ring closure between the oxime and the cyano groups.

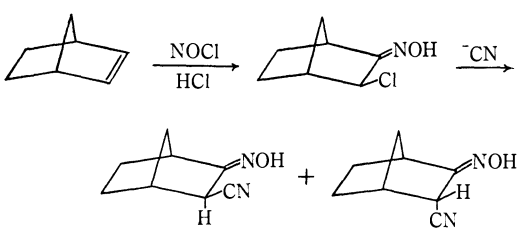
This method has now been extended to α-chlorooximes of cyclooctanone, 5-cyclooctenone, and cyclododecanone, and to those[1] from *cis, trans, trans*-1, 5, 9-cyclododecatriene, and *trans, trans, trans*-1, 5, 9-cyclododecatriene. The corresponding 3-aminocycloalka[C]isoxazoles, VI, VII, VIII, IX, and X, have been obtained in excellent yields.

5) K. v. Auwers, Th. Bahr and E. Frese, *Ann.*, **441**, 68 (1925).

The results are summarized in Table I, and the synthetic method is expressed in the following successive formulae:



In order to clarify the scope and limitations of the reaction, the method was applied to norbornene, which is an example of the more strained olefins. The treatment of 3-chloronorcamphor oxime[1] with sodium cyanide in dimethyl sulfoxide afforded a mixture of two stereoisomers (XI and XII) of 3-cyanonorcamphor oxime, which did not form isoxazole.

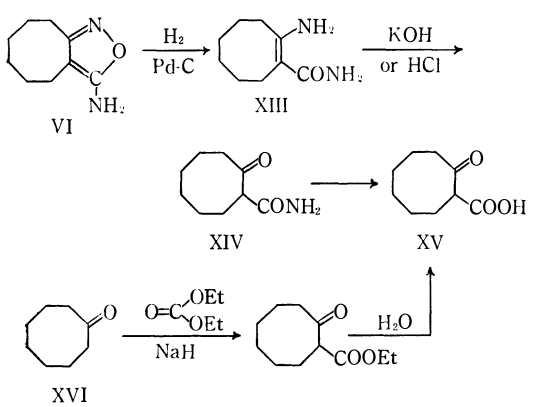


XI XII

This result suggests that the increase in ring strain is unfavorable for the formation of an isoxazole ring, but that the formation from 8- and 12-membered rings can be achieved easily because of no substantial ring strain. The application of this reaction to acyclic α-chlorooximes, which can be formed from isobutylene and butene-2,

also failed to give the isoxazole compounds, but did give the corresponding cyano-compounds.

The hydrogenation of 3-aminocycloocta[C]-isoxazole and the chemical degradation of the hydrogenated product were investigated with a view to ascertaining some properties of the system. Just one-mole equivalent of hydrogen was absorbed by the catalytic hydrogenation of 3-aminocycloocta[C]isoxazole, using 5% palladium charcoal under atmospheric pressure; a crystalline product was thus obtained in a 98% yield. The infrared spectrum showed absorptions at 3400, 3300, and 3150 cm^{-1} due to a primary amino group, and absorptions at 1642 and 1610 cm^{-1} due to an amide group. The ultraviolet spectrum showed a maximum absorption at 242 mμ (ε, 8000), suggesting the presence of a conjugated amide. The spectral evidence is very consistent with 2-amino-1-cyclooctenecarbonamide (XIII). The hydrogenated product (XIII) was treated with either hydrochloric acid or potassium hydroxide to form 2-oxo-cyclooctylcarbonamide (XV). The prolonged treatment of the compound XIV with alkali gave 2-oxo-cyclooctylcarboxylic acid (XV), together with a small amount of cyclooctanone (XVI). The β-ketocarboxylic acid, XV, has been proved to be identical with an authentic sample prepared by the reaction of cyclooctanone with sodium hydride - ethyl carbonate and by subsequent hydrolysis. Therefore, the structure of the hydrogenated product (XIII) has been proved to be correct.



Experimental

3 - Amino - 4, 5, 6, 7-tetrahydrocyclohexa [C] iso - xazole (V).—Freshly-prepared 2-chlorocyclohexanone oxime[1] (10 g., 0.068 mol.) was treated with sodium cyanide (5 g., 0.10 mol.) in 50 ml. of ethanol under reflux for 2.5 hr. After the reaction, the sodium chloride formed and the unreacted sodium cyanide were removed by filtration and ether was added to the filtrate to remove the insoluble fraction. After the etherael solution had been evaporated, a brown solid was obtained. It was recrystallized from a mixed solvent of ether and petroleum ether to give a colorless crystalline material (4.5 g., 48%), m. p. 117—118°C. The infrared and ultraviolet spectra are shown in Table I.

Found: C, 61.19; H, 7.42; N, 20.23. Calcd. for $C_7H_{10}N_2O$: C, 60.85; H, 7.30; N, 20.28%.

This substance was shown to be completely identical with an authentic sample[5,6] by a mixed melting point determination and by a study of the spectral evidence. The authentic sample was prepared in the following way. Chlorocyan (7 g.) dissolved in 20 ml. of dioxane was added drop by drop to a solution of morpholine enamine (16 g.) of cyclohexanone in 130 ml. of dioxane at 0—5°C over a 2 hr. period. The reaction mixture was then allowed to stand overnight at room temperature. The reaction mixture was poured into ice-water and extracted with ether. After it had been dried and the ether had been evaporated, a yellow oil was obtained. It was distilled under reduced pressure to give a colorless oil, b. p. 120—130°C/1 mmHg, which was confirmed to be 2-cyanocyclohexanone. The cyano-ketone was treated with hydroxylamine, generated from hydroxylamine hydrochloride and sodium carbonate, for 1 hr. After it had then been extracted with ether, the ethereal solution afforded colorless crystalline 3 - aminocyclohexa[C]isoxazole, m. p. 115—116°C, after recrystallization from ether - petroleum ether.

Found: C, 60.75; H, 7.30; N, 20.27. Calcd. for $C_7H_{10}N_2O$: C, 60.85; H, 7.30; N, 20.28%.

3 - Amino - 4, 5, 6, 7, 8, 9 - hexahydrocycloocta[C]-isoxazole (VI).—2-Chlorocyclooctanone oxime (10 g., 0.056 mol.) dissolved in 30 ml. of dimethyl sulfoxide was vigorously stirred, over a 20 min. period, into a suspended solution of sodium cyanide (4 g., 0.081 mol.) in 40 ml. of dimethyl sulfoxide at 80—95°C. The reaction was continued for further 1.5 hr. at the same temperature. The reaction mixture was then treated with water and ether. The ethereal solution was dried and evaporated to give a pale yellow product (8.2 g., 96%). It was recrystallized from ether - petroleum ether to give a colorless analytical sample, m. p. 77—78°C.

Found: C, 65.26; H, 8.46; N, 16.70; O, 10.01. Calcd. for $C_9H_{14}N_2O$: C, 65.03; H, 8.49; N, 16.85; O, 9.63%.

The infrared and ultraviolet spectra are shown in Table I.

3 - Amino - 4, 5, 8, 9 - tetrahydrocycloocta [C] iso-xazole (VII).—2-Chlorocyclooctenone oxime (2 g., 0.01 mol.) was treated with sodium cyanide (1 g., 0.02 mol.), in a manner similar to that described above, and a crystalline material, m. p. 81.5—82.5°C, was obtained in a 89% yield.

Found: C, 65.63; H, 7.41; N, 17.10. Calcd. for $C_9H_{12}N_2O$: C, 65.83; H, 7.37; N, 17.06%.

3 - Amino - 4, 5, 6, 7, 8, 9, 10, 11, 12, 13 - decahydro-cyclododeca[C]isoxazole (VIII).—2-Chlorocyclododecanone oxime (3.0 g.) was treated with sodium cyanide (2 g.) in dimethyl sulfoxide in a manner similar to that described above; after the usual work-up, a crystalline product, m. p. 119—121°C, was obtained in a 95% yield.

Found: C, 70.14; H, 9.96; N, 12.56. Calcd. for $C_{13}H_{22}N_2O$: C, 70.23; H, 9.97; N, 12.60%.

6) M. E. Kuehine, *J. Am. Chem. Soc.*, **81**, 5400 (1959).

3-Amino-4, 5, 8, 9, 12, 13-hexahydrododeca[C]-isoxazole (IX).—2-Chlorocyclododecadienone oxime (3.5 g., 0.015 mol.), prepared by the reaction of *cis, trans, trans*-1, 5, 9-cyclododecatriene with nitrosyl chloride, was treated with sodium cyanide (2 g., 0.04 mol.) suspended in dimethyl sulfoxide at 80—90°C for 3 hr. After the usual treatment of the reaction mixture, a pale-yellow solid (3.2 g., 95%) was obtained; it was recrystallized from ether-petroleum ether to give an analytical sample, m. p. 148—150°C.

Found: C, 71.32; H, 8.31; N, 12.83. Calcd. for $C_{13}H_{18}N_2O$: C, 71.52; H, 8.31; N, 12.83%.

3-Amino-4, 5, 8, 9, 12, 13-hexahydro-*trans*-6, *trans*-10-cyclododeca[C]isoxazole (X).—2-Chlorocyclododecadienone oxime (5 g., 0.022 mol.), prepared by the reaction of *trans, trans, trans*-1, 5, 9-cyclododecatriene with nitrosyl chloride, was treated with sodium cyanide (3 g., 0.06 mol.) under the conditions described above. After usual treatment, a solid (4.2 g., 90%) was obtained; an analytical sample showed a m. p. of 131—134°C.

Found: C, 71.90; H, 8.31; N, 12.84. Calcd. for $C_{13}H_{18}N_2O$: C, 71.52; H, 8.31; N, 12.83%.

The Reaction of 3-Chloronorcamphor Oxime with Sodium Cyanide.—3-Chloronorcamphor oxime (10 g.) was treated with two mole equivalents of sodium cyanide in dimethyl sulfoxide under the conditions described above. A solid product was obtained in a 90% yield, one showing a m. p. of 107—130°C after recrystallization from ether-petroleum ether. The infrared spectrum showed an absorption at 2245 cm^{-1} characteristic of a saturated nitrile group, besides those characteristic of the oxime group, and no absorption characteristic of an isoxazole ring system.

The NMR spectrum showed signals for the hydrogen next to the oxime group at τ 6.76 and τ 6.56, with coupling constants of 2.7 c. p. s. and 4.7 c. p. s. respectively. Therefore, the product must be a mixture of two stereoisomers (XI and XII) of 3-cyanonorcamphor oxime.

Found: C, 63.71; H, 6.71; N, 18.51. Calcd. for $C_8H_{10}N_2O$: C, 63.98; H, 6.71; N, 18.65%.

The Hydrogenation of VI with Palladium Charcoal.—3-Aminocycloocta[C]isoxazole (VI, 1.0 g.) was hydrogenated in ethanol with 5% palladium charcoal (0.25 g.) under atmospheric pressure while being stirred. Hydrogen (131 ml.) was absorbed during a 3 hr. period; this is in accord with the calculated amount (129 ml. for one mole equivalent of hydrogen). After filtration the alcoholic solution was evaporated to dryness to give a colorless solid (1.0 g.). This was recrystallized from ethanol to give an analytical sample, m. p. 111—113°C.

Found: C, 64.01; H, 9.46; N, 16.16. Calcd. for $C_9H_{16}N_2O$: C, 64.25; H, 9.59; N, 16.35%.

The infrared spectrum showed absorptions at 3400 (s), 3300 (w), 3150, 1642 (s), 1610 (s), and 1535 (m) cm^{-1}.

The ultraviolet spectrum showed a maximum at 242 mμ (ε, 8000). Therefore, the structure was identified as 2-amino-1-cyclooctene carbonamide (XIII).

The Hydrolysis of XIII with Potassium Hydroxide.—Compound XIII (3 g.) was added to a solution of potassium hydroxide (0.3 g.) dissolved in a mixture of water (25 ml.) and ethanol (25 ml.), the reaction mixture was then refluxed for 8 hr. After the ehanol had been evaporated, the residue was treated with hydrochloric acid and then extracted with ether-chloroform. The organic layer was dried and evaporated to dryness to give a pale-yellow solid (1.24 g., 42%). It was chromatographed on silica gel, using chloroform as an eluent; a crystalline substance, m. p. 106—108°C, was thus obtained. The infrared spectrum showed absorptions at 1710 cm^{-1} of carbonyl group, and 1670 and 1630 cm^{-1} of an amide group. The NMR spectrum showed signals at τ 6.48 for tertiary hydrogen. Therefore, the product was identified as 2-oxocyclooctanecarbonamide (XIV); it proved to be identical with an authentic sample prepared by the reaction of cyclooctanone and diethylcarbonate in the presence of sodium hydride and by subsequent hydrolysis.

Found: C, 64.07; H, 8.83; N, 8.34. Calcd. for $C_9H_{15}NO_2$: C, 63.88; H, 8.94; N, 8.28%.

The prolonged treatment of XIII with potassium hydroxide afforded cyclooctanone as a by-product.

The Hydrolysis of XIII with Hydrochloric Acid.—Compound XIII (1.0 g.) was added to a mixture of ethanol (30 ml.) and 1 N hydrochloric acid (20 ml.); then the reaction mixture was refluxed for 2 hr. The oil obtained by the extraction with ether-methylene chloride was chromatographed on silica gel using chloroform. The solid (0.78 g., 80%) obtained was identical with that obtained from treatment with potassium hydroxide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1129—1134 (1966)

Reactions of 2-Chlorocycloalkanone Oximes. III.[1] Displacement Reactions with Various Nucleophilic Reagents[2]

By Masaji OHNO, Seiichi TORIMITSU, Norio NARUSE, Masaru OKAMOTO and Ikuo SAKAI

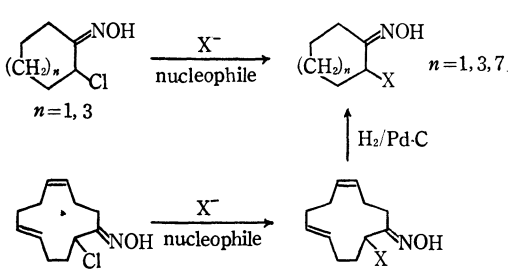
Basic Research Laboratories, Toyo Rayon Co., Ltd., Tebiro, Kamakura

(Received July 22, 1965)

The displacement reactions of 2-chlorocycloalkanone oximes with various nucleophilic reagents, such as ammonia, primary and secondary amines, silver and sodium nitrite, sodium azide, Grignard reagents, and carbanions derived from acetylacetone and ethyl malonate, have been investigated. α-Alkylamino, α-nitro, α-azido, and α-alkyloximes of the 8- and 12-membered rings have been prepared in excellent yields, and those of the 6-membered ring, in moderate yields. It has been shown that 2-chlorocyclohexanone oxime hydrochloride can be treated directly with a large excess of the nucleophilic reagents. 2-Chlorocyclooctanone oxime was used in the free state, and 2-chloro-5, 9-cyclododecadienone oxime was first treated with nucleophilic reagents; the resulting α-substituted oximes of the 12-membered ring were hydrogenated to the corresponding saturated oximes with palladium charcoal. These reactions have shown that α-chlorocycloalkanone oximes have a potential synthetic utility.

In previous papers[1,3] of this series, we have described the preparation of 2-chlorocycloalkanone oximes by the reaction of disubstituted olefins or cycloolefins with nitrosyl chloride, i. e., the syntheses of 2-alkoxy-, 2-acyloxy-, and 2-alkylthio-cycloalkanone oximes. We have also described a simple way of preparing 3-aminocycloalka[C]isoxazoles. These results have clearly shown that α-chlorooximes obtained by the addition of nitrosyl chloride to cycloolefins have a potential synthetic utility besides the potential testing reagent for the unsaturation of natural products.[4]

In this report, we will investigate the displacement reactions of 2-chlorocycloalkanone oximes with various nucleophilic reagents, such as ammonia, primary amines, secondary amines, metal nitrite, sodium azide, Grignard reagents, and carbanions derived from acetylacetone and diethyl malonate, in an effort to establish the scope and limitations of the synthetic application of the α-chlorooximes. The general scheme of the reactions is shown by the following equations:



As usual in our procedure, the displacement reactions of 2-chlorocyclooctanone oxime with various amines were first investigated in detail, since this starting material is the most stable to handle and can be prepared easily in a state of free oxime.[3]

The treatment of 2-chlorocyclooctanone oxime with ammonia did not form 2-aminocyclooctanone oxime, but it did give 2, 2'-iminodicyclooctanone oxime in a 30% yield. Reactions with morpholine, piperidine, *n*-butylamine, and hydrazine gave the corresponding α-aminooximes in excellent yields, as had been expected. The same reaction was then applied successfully to 2-chlorocyclohexanone oxime and 2-chlorocyclododecadienone oxime to give the corresponding α-aminooximes. 2-Aminocyclododecadienone oximes obtained were selectively hydrogenated to 2-aminocyclododecanone oximes by catalytic reduction with palladium charcoal.

Since cyclododecene is not easily available[3] and since only *trans*-cyclododecene reacts with nitrosyl chloride, 2-aminocyclododecanone oxime has been prepared conveniently by the reaction of *cis*, *trans*, *trans*-1, 5, 9-cyclododecatriene with nitrosyl chloride. In the case of 2-chlorocyclohexanone oxime, the hydrochloride[3] was treated directly with a large excess of amines. Since the hydrochloride is unstable and is considered to be a mixture of mono- and dihydrochloride,[5] the yields could not be estimated exactly.

As in the case of displacement reactions with sodium salts of alcohols, carboxylic acids and ethanethiol, maximum yields in the present investigation were also obtained when amounts greater than two mole equivalents of amines were used.[6] These results are shown in Table I.

In order to introduce a strong electron-withdrawing substituent to the α-position of the oxime group, 2-chlorocycloalkanone oximes were treated with silver and sodium nitrite. α-Chlorooximes of 8- and 12-membered rings gave the corresponding α-nitrooximes in excellent yields when treated with silver nitrite in dimethylsulfoxide. Since the same reaction with 2-chlorocyclooctanone oxime in ether did not form 2-nitrocyclooctanone oxime at all and since the starting material was then recovered, dimethylsulfoxide is the most effective solvent for this reaction in these cases. This method is thus a new way of preparing α-nitrocycloalkanone oximes, which were formerly prepared by the reaction of cycloolefins with nitric oxide in the presence of oxygen.[7]

6) A. Cornow and H. D. Jordan, *Chem. Ber.*, **94**, 1960 (1961).

7) D. Klamann and W. Koser, *Angew. Chem.*, **76**, 591 (1964).

These results are summarized in Table II.

Next, the displacement reaction with azide ion has been investigated, since the negative charge of the ion is distributed over more than one polarizable atom and the ion is well known as a strong nucleophilic reagent.[8] The treatment of 2-chlorocyclooctanone oxime and of 2-chloro-5, 9-cyclododecadienone oxime with sodium azide in dimethylsulfoxide, ethanol or acetonitrile gave the corresponding α-azidooxime in 75 and 80% yields respectively. The structure is supported by the fact that the infrared spectrum showed a characteristic strong absorption, at 2140 cm^{-1}, of an asymmetric stretching vibration of azide.[9] Both of the α-azidooximes were hydrogenated with palladium charcoal in the presence of moist hydrochloric acid to give hydrochlorides of the corresponding α-aminoketones.

The reactions of α-chlorooximes of the acyclic system with Grignard reagents and carbanions to give higher oximes have been investigated by Dornow.[10] In the case of α-chlorooximes of cyclic systems, however, no investigation has been reported. To check this point, 2-chlorocycloalkanone oximes were treated with various Grignard reagents, such as phenylmagnesium bromide, ethylmagnesium bromide, and phenylethynylmagnesium bromide. The products from the reaction of the oximes of 2-chlorocyclohexanone and 2-chlorocyclooctanone with Grignard reagents were unstable oily materials, and all attempts to isolate pure substances were unsuccessful. However, the reaction of 2-chloro-5, 9-cyclododecadienone oxime with phenylmagnesium bromide and with phenylethynylmagnesium bromide gave the corresponding α-substituted oximes (Table II) successfully. It is of interest to note that 2-(phenylethyl)cyclododecadienone oxime has been converted into an allene derivative with sodium ethoxide.

Finally, displacement reactions with carbanions derived from various active hydrogen compounds were investigated. The treatments of the oximes of 2-chlorocyclohexanone, 2-chlorocyclooctanone, and 2-chloro-5, 9-cyclododecadienone with sodium salts of ethyl malonate and acetylacetone gave the corresponding α-substituted oximes (Table II). The yields of the products of the 8- and 12-membered rings were excellent, but those of the 6-membered ring were rather poor. The reactions of α-chlorocycloalkanone oximes with nitromethane, acetone, and ethyl acetate in the presence of a base did not afford the corresponding α-substituted oximes at all, but rather resinous matters, which might be formed by the polymerization of an α, β-unsaturated nitroso compound.

10) A. Donow and H. D. Jordan, *Chem. Ber.*, **94**, 76 (1961).

The accumulated evidence of the displacement reactions of 2-chlorocycloalkanone oximes described above have established the following points: (1) Most of the nucleophilic reagents replace the chlorine atoms of 2-chlorocyclolakanone oximes smoothly. (2) No appreciable amounts of unsaturated compounds were formed in the displacement reactions of α-chlorooximes of cycloolefins. (3) α-Chlorooximes of the 8- and 12-membered rings can be transformed into α-substituted oximes in excellent yields, but that of the 6-membered ring affords the product in a moderate yield. These results suggest that the stability of the α, β-unsaturated nitroso compounds formed as intermediates during the reactions is dependent upon the ring size. (4) The α-chlorooximes obtained by the addition of nitrosyl chloride to cycloolefins have a potential synthetic utility.

Experimental[11]

The Reaction of 2-Chlorocyclooctanone Oxime with Ammonia.—2-Chlorocyclooctanone oxime was treated with ammonia in the presence of sodium amide in tetrahydrofuran. A colorless solid was obtained in a 30% yield, m. p. 182—183°C. The infrared spectrum showed an absorption at 1650 cm^{-1} due to an oxime group.

Found: C, 64.81; H, 9.87; N, 14.06. M. W. 298. Calcd. for $C_{16}H_{29}N_3O_2$: C, 65.05; H, 9.90; N, 14.23%. M. W., 295.42.

2-Morpholinocyclooctanone Oxime (II).—Morpholine (19 g.) and ethanol (10 ml.) were placed in a 300-ml. three-necked round bottom flask equipped with a stirrer, a reflux condenser, and a dropping funnel. 2-Chlorocyclooctanone oxime (17.5 g.) dissolved in 70 ml. of ethanol was then added to the solution over a 30-min. period. The reaction mixture was then stirred at room temperature for 3 hr. After the solvent had been removed under reduced pressure, a solid product (19.7 g.) was obtained after washing the residue with water. It was recrystallized from ethanol to give an analytical sample, m. p. 133—134°C.

Found: C, 63.50; H, 9.73; N, 12.32. Calcd. for $C_{12}H_{22}N_2O_2$: C, 63.68; H, 9.80; N, 12.39%. IR: 3300—3000, 1640, 1500, 1115 cm^{-1} (KBr).

2-Pyrrolidinocyclooctanone Oxime (III).—2-Chlorocyclooctanone oxime (17.5 g.) dissolved in 70 ml. of ethanol was treated with pyrolidine (20 g.) in ethanol (100 ml.) for 3 hr. After the solvent had been removed and the residue washed with water, a solid product (17.5 g.) was obtained; this was recrystallized from ethanol to give an analytical sample, m. p. 161—162°C.

Found: C, 68.26; H, 10.46; N, 13.15. Calcd. for $C_{12}H_{22}ON_2$: C, 68.53; H, 10.54; N, 13.32%. IR: 3300—3000, 1650, 1512, 1120, 1095 cm^{-1} (KBr).

2-Piperidinocyclooctanone Oxime (IV).—2-Chlorocyclooctanone oxime (26.3 g.) was treated with piperidine (25 g.) in ethanol. After a work-up similar to that described above, a solid product (28.5 g.) was obtained; it was recrystallized from ethanol to give analytical sample, m. p. 162—163°C.

Found: C, 69.48; H, 10.76; N, 12.51. Calcd. for

11) All melting points are uncorrected.

$C_{13}H_{24}ON_2$: C, 69.60; H, 10.78; N, 12.49%. IR: 3300—3000, 1643, 1500, 1100 cm^{-1} (KBr).

2-Anilinocyclooctanone Oxime (V).—2-Chlorocyclooctanone oxime (17.5 g.) was treated with aniline (37 g.) in ethanol and, after a similar work-up, a solid product (21.2 g.) was obtained; it was then recrystallized from ethanol to give an analytical sample, m. p. 135—136°C.

Found: C, 72.27; H, 8.73; N, 11.86. Calcd. for $C_{14}H_{20}ON_2$: C, 72.38; H, 8.68; N, 12.06%. IR: 3370, 3200—3100, 1610, 1520, 1500, 750 cm^{-1} (KBr).

2-(*n*-Butylamino)cyclooctanone Oxime (VI).—2-Chlorocyclooctanone oxime (17.5 g.) was treated wtih *n*-butylamine (30 g.) in ethanol; after the usual work-up, a solid product (19 g.), m. p. 134—135°C, was obtained.

Found: C, 67.82; H, 11.34; N, 13.27. Calcd. for $C_{12}H_{24}ON_2$: C, 67.88; H, 11.39; N, 13.19%. IR: 3250, 1642, 1500, 1100 cm^{-1} (KBr).

2-(Oxyamino)cyclooctanone Oxime (VII).—In a 500-ml. three necked round bottom flask equipped with a stirrer, a dropping funnel, and a reflux condenser there were placed 200 ml. of ethanol containing hydroxylamine (about 7 g.) and water containing sodium carbonate (10 g.). 2-Chlorocyclooctanone oxime (17.5 g.) dissolved in 70 ml. of ethanol was stirred into the solution over a period of 30 min. The reaction mixture was then refluxed for 2 hr. After the usual work-up, as described in the case of 2-morpholinocyclooctanone oxime (II), a solid product (13.1 g.), m. p. 144—145°C, was obtained

Found: C, 55.64; H, 9.18; N, 16.11. Calcd. for $C_8H_{16}O_2N_2$: C, 55.79; H, 9.36; N, 16.27%. IR: 3250, 1645, 1510, 1110 cm^{-1} (KBr).

2 - Morpholino-5, 9-cyclododecadienone Oxime (VIII).—2-Chlorocyclododecadienone oxime (23 g.) was treated with morpholine (18 g.) in ethanol for 3 hr. After the solvent had been removed under reduced pressure, an oily product was obtained. By adding an excess of water to the product, a solid material (19.7 g.) was obtained and recrystallized from methanol to give an analytical sample, m. p. 106—109°C. The infrared spectrum showed absorptions at 1650, 980, and 707 cm^{-1} characteristic of an oxime group, and of *traus* and *cis* double bonds respectively, and absorptions at 1000—1100 cm^{-1} characteristic of an morpholino group.

Found: C, 68.81; H, 9.36; N, 10.09. Calcd. for $C_{16}H_{26}O_2N_2$: C, 69.03; H, 9.41; N, 10.06%.

The Hydrogenation of VIII.—2-Morpholinocyclododecadienone oxime (VIII, 2.8 g.) dissolved in 100 ml. of acetic acid was hydrogenated with 10% palladium charcoal (1 g.) under atmospheric pressure and at room temperature. Two mole equivalents of hydrogen was absorbed in 3 hr. After the solvent had been removed, the reaction product was treated with a 4 N sodium hydroxide solution to afford a colorless solid. This was recrystallized from methanol to give an analytical sample, m. p. 104—106°C. The infrared spectrum showed no absorption for carbon-carbon double bonds, and it was consistent with 2-morpholinocyclododecanone oxime.

Found: C, 67.89; H, 10.63; N, 9.90. Calcd. for $C_{16}H_{30}O_2N_2$: C, 68.04; H, 10.71; N, 9.92%.

2 - Pyrrolidino-5, 9-cyclododecadienone Oxime (IX).—2-Chlorocyclododecadienone oxime (23 g.) was treated with pyrrolidine (28 g.) in ethanol at 60—70°C for 2 hr. After the usual work-up, a solid product (21 g.) was obtained and recrystallized from methanol, m. p. 112—113°C.

Found: C, 73.13; H, 9.89; N, 10.61. Calcd. for $C_{16}H_{26}ON_2$: C, 73.24; H, 9.99; N, 10.68%. IR 3200, 1660, 1510, 970, 720 cm^{-1} (KBr).

This product (2.6 g.) was then hydrogenated in acetic acid (100 ml.) with 10% palladium charcoal (1 g.). After the absorption of two mole equivalents of hydrogen, the solvent was removed under reduced pressure; the residue was neutralized with a 4 N sodium hydroxide solution to afford a colorless solid in a nearly quantitative yield. It melted at 146—148°C after recrystallization from methanol. The infrared spectrum was consistent with the structure of 2-pyrrolidinocyclododecanone oxime.

Found: C, 72.18; H, 11.35; N, 10.53. Calcd. for $C_{16}H_{30}ON_2$: C, 72.13; H, 11.35; N, 10.52%. IR: 3200, 1650, 1510 cm^{-1} (KBr).

2-Piperidino-5, 9-cyclododecadienone Oxime (X).—2-Chlorocyclododecadineone oxime (24 g.) was treated with piperidine (35 g.) in ethanol at 60—70°C for 3 hr. After the usual work-up, a solid product (22.3 g.) was obtained and recrystallized from methanol to give an analytical sample, m. p. 100—103°C.

Found: C, 73.80; H, 10.20; N, 10.06. Calcd. for $C_{17}H_{28}ON_2$: C, 73.86; H, 10.21; N, 10.14%. IR: 3300, 1660, 1120, 960, 705 cm^{-1} (KBr).

A part of the product (2.8 g.) was hydrogenated in acetic acid (100 ml.) with 10% palladium charcoal (1 g.). Two mole equivalents of hydrogen were absorbed during a 3-hr. period. After a work-up similar to that described in the case of 2-morpholinocyclododecanone oxime, a solid product was obtained in a nearly quantitative yield; this was recrystallized from methanol to give an analytical sample, m. p. 96—97°C.

Found: C, 72.58; H, 11.45; N, 9.95. Calcd. for $C_{17}H_{32}ON_2$: C, 72.80; H, 11.50; N, 9.99%. IR: 3300—3000, 1640, 1110 cm^{-1} (KBr).

2-Morpholinocyclohexanone Oxime (XI).—Hydrochloride of 2-chlorocyclohexanone oxime (25 g.) dissolved in ethanol (100 ml.) was stirred, over a 30-min. period, into a solution of morpholine (50 g.) in ethanol (15 ml.) at 40°C; the reaction was then continued at 70°C for another hour. After the solvent had been removed, the residue solidified and was washed with water. When recrystallized from ether, it showed a m. p. of 117—118°C.

Found: C, 60.39; H, 9.06; N, 14.07. Calcd. for $C_{10}H_{18}O_2N_2$: C, 60.58; H, 9.15; N, 14.13%.

2-Pyrrolidinocyclohexanone Oxime (XII).—The hydrochloride of 2-chlorocyclohexanone oxime (12 g.) was treated with pyrrolidine (23 g.) in ethanol. After the usual work-up, described above, a solid product (10.7 g.) was obtained and recrystallized from ether, m. p. 120—121°C.

Found: C, 65.78; H, 9.92; N, 15.35. Calcd. for $C_{10}H_{18}ON_2$: C, 65.89; H, 9.96; N, 15.37%.

2-Piperidinocyclohexanone Oxime (XIII).—The hydrochloride of 2-chlorocyclohexanone oxime (9.5 g.) was treated with piperidine (25 g.) in ethanol. After the usual work-up, a solid product (8.5 g.) was obtained and recrystallized from ether, m. p. 117—118°C.

Found: C, 67.24; H, 10.23; N, 14.26. Calcd. for $C_{11}H_{20}ON_2$: C, 67.30; H, 10.27; N, 14.27%.

2-(*n*-Butylamino)cyclohexanone Oxime (XIV).—The hydrochloride of 2-chlorocyclohexanone oxime (18.4 g.) was treated with *n*-butylamine (36 g.) in ethanol.

After the usual work-up, a solid product (16 g.) was obtained and recrystallized from ether, m. p. 79—80°C.

Found: C, 65.39; H, 10.88; N, 15.15. Calcd. for $C_{10}H_{20}ON_2$: C, 65.17; H, 10.94; N, 15.20%.

2-Nitrocyclooctanone Oxime (XV).—Silver nitrite (13.2 g.) and ether (100 ml.) were placed in a 500-ml. three-necked round-bottom flask equipped with a stirrer, a condenser, and a dropping funnel. A solution of 2-chlorocyclooctanone oxime (15 g.) dissolved in 150 ml. of ether was then vigorously stirred into the above suspended solution over a 1-hr. period, after which the reaction was continued for 4 hr. at room temperature. The precipitate of silver chloride was removed by filtration, and the filtrate was washed with water. The ethereal solution was dried over sodium sulfate and evaporated to dryness to give a yellow solid (14.2 g., 89.3%). It was dissolved in hot ligroin and treated with activated carbon to give a pale-yellow solid, which was then further recrystallized from ligroin to afford colorless needles, m. p. 95—96°C. The infrared spectrum showed absorptions at 3310 and 1640 cm^{-1} for the oximino group, and at 1550 cm^{-1} (strong) for the nitro group.

Found: C, 51.71; H, 7.66; N, 14.85. Calcd. for $C_8H_{14}O_3N_2$: C, 51.60; H, 7.58; N, 15.04%.

In a separate run, 2-chlorocyclooctanone oxime (5 g.) was treated with silver nitrite (4.5 g.) in dimethylsulfoxide at room temperature for 1 hr. The ether extract of the reaction mixture was dried and evaporated to dryness to give 4.5 g. of a yellow solid, which was confirmed to be identical with the product obtained from the above reaction using ether as the solvent. When sodium nitrite was used in dimethylsulfoxide, 2-nitrocyclooctanone oxime was obtained in about a 66% yield, but in ether no detectable amount of 2-nitrocyclooctanone oxime was obtained.

2-Nitro-5, 9-cyclododecadienone Oxime (XVI).—2-Chlorocyclododecadienone oxime (10 g.) was treated with silver nitrite (7 g.) in dimethylsulfoxide at room temperature for 1 hr. After treatment similar to that described above, a yellow solid (8.4 g.) was obtained; it was recrystallized from ligroin to give a colorless solid, m. p. 115—117°C. The infrared spectrum showed absorptions at 980 and 707 cm^{-1} characteristic of *trans* and *cis* double bonds respectively, at 3320 and 1640 cm^{-1} characteristic of an oximino group, and at 1560 cm^{-1} characteristic of nitro group.

Found: C, 60.54; H, 7.68; N, 11.47. Calcd. for $C_{12}H_{18}O_3N_2$: C, 60.48; H, 7.61; N, 11.76%.

2-Azidocyclooctanone Oxime (XVII).—2-Chlorocyclooctanone oxime (36 g.) was treated with sodium azide (14g.) in acetonitrile while being stirred and heated on a steam bath for 5 hr. To the reaction mixture, water (500 ml.) was added, and the ethereal extract was dried and evaporated to dryness to give a solid product. It was recrystallized from a mixed solvent of ether and petroleum ether to give an analytical sample, m. p. 52—53°C.

Found: C, 52.45 : H, 7.69; N, 30.66. Calcd. for $C_8H_{14}ON_4$: C, 52.73; H, 7.74; N, 30.65%.

The product was hydrogenated in moist ethanol containing hydrochloric acid with 5% palladium charcoal under atmospheric pressure. The infrared spectrum of the hydrogenated product, m. p. 186—188°C (decomp.) showed a strong absorption at 1705 cm^{-1} characteristic of 8-membered ring ketone and one at 3300 cm^{-1} characteristic of an amino group. Thus the structure may be though to be that of the hydrochloride of 2-aminocyclooctanone.

2-Azido-5, 9-cyclododecadienone Oxime (XVIII).—2-Chlorocyclododecadienone oxime (68.25 g.) was treated with sodium azide (23.4 g.) in dimethyl sulfoxide (600 ml.) while being vigorously stirred and heated on a steam bath for 12 hr. After treatment similar to that described above, a solid product (56 g.) was obtained and recrystallized from a mixed solvent of ether and petroleum ether to give a colorless material, m. p. 63—65°C.

Found: C, 61.77; H, 7.85; N, 24.11. Calcd. for $C_{12}H_{18}ON_4$: C, 61.51; H, 7.74; N, 23.91%.

In order to confirm the structure, the product was hydrogenated with 5% palladium charcoal in moist ethanol containing hydrochloric acid. The infrared spectrum of the hydrogenated procuct, m. p. 223°C (decomp.), showed a strong absorption at 1704 cm^{-1} characteristic of 12-membered ring ketone, and one at 3320 cm^{-1} characteristic of an amino group, with neither the absorption at 980 nor that at 707 cm^{-1} characteristic of *trans* and *cis* double bonds respectively.

Found: C, 61.30; H, 10.28; N, 6.06; Cl, 15.30. Calcd. for $C_{12}H_{24}NOCl$: C, 61.20; H, 10.35; N, 5.96; Cl, 15.05%.

2-Phenyl-5, 9-cyclododecadienone Oxime (XIX).—In a 2-l. three necked round-bottom flask equipped with a stirrer, a condenser, and a dropping funnel, magnesium (7.3 g.) was placed. A solution of bromobenzene (47.1 g.) dissolved in tetrahydrofuran (400 ml.) was then vigorously stirred into the reaction vessel. After phenyl magnesium bromide had been made, 2-chlorocyclododecadienone oxime (22.75 g.) dissolved in tetrahydrofuran (100 ml.) was added slowly at 20—25°C and the reaction was continued for 15 hr. at room temperature. The reaction mixture was treated with ice, diluted hydrochloric acid, and extracted with ether. The ethereal extract was treated with a sodium carbonate solution and then with a saturated solution of sodium chloride, dried, and evaporated to dryness to give a crude product (20 g.). This was recrystallized from methanol, m. p. 133—135°C.

Found: C, 80.13; H, 8.54; N, 5.12. Calcd. for $C_{18}H_{23}ON$: C, 80.25; H, 8.61; N, 5.20%. IR: 3300, 1660, 960, 760, 710 cm^{-1} (KBr).

2-(Phenylethynyl)cyclododecadienone Oxime (XX).—2-Chlorocyclododecadienone oxime was treated with phenylethynyl magnesium bromide under conditions similar to those described above. 2-(Phenylethynyl)-5, 9-cyclododecadienone oxime was thus obtained in a 60% yield, m. p. 120—121°C.

Found: C, 81.63; H, 7.90; N, 4.67. M. W., 306. Calcd. for $C_{20}H_{23}ON$: C, 81.87; H, 7.90; N, 4.77%. M. W., 293.

The compound XX was treated with sodium ethoxide to afford an isomer, m. p. 136—139°C. The infrared spectrum showed an absorption at 1930 cm^{-1} characteristic of allene and not the absorption at 2240 cm^{-1} characteristic of the acetylene group observed in the compound XX.

Found: C, 81.92; N, 8.01; N, 4.77%.

Ethyl α-Oximinocyclooctylmalonate (XXI).—Sodium salt of ethyl malonate was prepared by a reaction of sodium (5.3 g.) with ethyl malonate (35 ml.) in ether (200 ml.). To the solution there was added, drop by drop, 2-chlorocyclooctanone oxime (17.5 g.)

dissolved in ether (100 ml.) over a 1-hr. period; the reaction was then continued for an additional 2 hr. The excess of the sodium salts was decomposed with ice water, and the reaction mixture was extracted with ether. The ethereal extract was dried and cooled at 0°C to deposit a colorless solid. After the solid had been separated by filtration, the filtrate was evaporated to remove the ether and the ethyl malonate, thus giving a solid product. The combined solid materials (28.5 g.) were recrystallized from ethanol to give a pure substance, m. p. 89—90°C. The infrared spectrum was consistent with that of ethyl α-oximinocyclooctylmalonate (XXI).

Found: C, 60.35; H, 8.37; N, 4.66. M. W., 300. Calcd. for $C_{15}H_{25}O_5N$: C, 60.18; H, 8.42; N, 4.68%. M. W., 299.

Ethyl α-Oximinocyclododecadienylmalonate (XXII).—According to a procedure similar to that described above, compound XXII (33.8 g.) was prepared by the reaction of 2-chlorocyclododecadienone oxime (22.8 g.) with sodium salt of ethyl malonate. It was recrystallized from ethanol to give an analytical sample, m. p. 91—92°C.

Found: C, 64.93; H, 8.32; N, 3.99. M. W., 359. Calcd. for $C_{19}H_{29}O_5N$: C, 64.95; H, 8.35; N, 3.94%. M. W., 351.

Ethyl α-Oximinocyclohexylmalonate (XXIII).—According to a procedure similar to that described above, compound XXIII (18.8 g.) was prepared by the reaction of hydrochloride of 2-chlorocyclohexanone oxime with sodium salt of ethylmalonate. It was recrystallized from ethanol to give an analytical sample, m. p. 71—72°C.

Found: C, 57.41; H, 7.78; N, 5.07. M. W., 274. Calcd. for $C_{13}H_{21}O_5N$: C, 57.55; H, 7.80; N, 5.16. M. W., 271.

2-(Diacetylmethyl)cyclooctanone Oxime (XXIV).—Sodium salt of acetylacetone was prepared from sodium (5.3 g.) and acetylacetone (50 ml.) in ether (200 ml.). 2-Chlorocyclooctanone oxime (17.5 g.) was then stirred into the above solution at 0—5°C over a 1-hr. period. After 2 hr., the reaction mixture was treated with ice water in ordor to decompose the excess of the sodium salt. A colorless solid (17.2 g.) was thus obtained; it was recrystallized from ethanol, m. p. 155—156°C. IR (cm^{-1}): 3010, 2925, 2850, 2560, 1708, 1605, 1255, 1205, 1160, 1150. UV: λ_{max}^{EtOH} 240 mμ (ε, 10700); NMR(τ), 6.30 (1 H, doublet), 6.77 (1 H, multiplet), 7.65 (6 H, singlet). This spectroscopic evidence shows that the structure is 2-(diacetylmethyl)cyclooctanone oxime (XXIV).

Found: C, 65.31; H, 8.85; N, 5.82. M. W., 249. Calcd. for $C_{13}H_{21}O_3N$: C, 65.24; H, 8.85; N, 5.85%. M. W., 239.

2-(Diacetylmethyl)cyclododecadienone Oxime (XXV).—According to a procedure similar to that described above, compound XXV (29 g.) was obtained by the reaction of 2-chlorocyclododecadienone oxime (22.8 g.) with sodium salt of acetylacetone. It was recrystallized from ethanol to give an analytical sample, m. p. 159—160°C. IR (cm^{-1}): 3000—3100, 1705, 1595; UV: λ_{max}^{EtOH} 241 mμ (ε, 13000). NMR (τ), 4.5 (4H, m), 6.30 (1H, d), 6.9 (1H, m), 7.67 (6H, singlet).

Found: C, 69.90; H, 8.54; N, 4.68. M. W., 308. Calcd. for $C_{17}H_{25}O_3N$: C, 70.07; H, 8.65; N, 4.81%. M. W., 301.

2-(Diacetylmethyl)cyclohexanone Oxime (XXVI).—According to a procedure similar to that described above, compound XXVI (2.8 g.) was prepared by the reaction of hydrochloride of 2-chlorocyclohexanone oxime (18.4 g.) with sodium salt of acetylacetone. It was recrystallized from ethanol, m. p. 154—155°C.

IR (cm^{-1}), 3050, 1710, 1630. UV: λ_{max}^{EtOH} 239.5 mμ (ε, 10000).

Found: C, 62.45; H, 8.19; N, 6.59. M. W., 210. Calcd. for $C_{11}H_{17}O_3N$: C, 62.54; H, 8.11; N, 6.63%. M. W., 211.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1134—1146 (1966)

The Molecular Structure and Force Constants of Boron Trifluoride and Boron Trichloride

By Shigehiro KONAKA*, Yoshitada MURATA, Kozo KUCHITSU and Yonezo MORINO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received August 4, 1965)

The interatomic distances and the mean amplitudes of BF_3 and BCl_3 have been determined, by the sector-microphotometer method of gas electron diffraction, to be: $r_g(B-F)=1.3156\pm 0.0044$ Å, $r_g(F\cdots F)=2.2733\pm 0.0041$ Å, $l(B-F)=0.0398\pm 0.0029$ Å, and $l(F\cdots F)=0.0541\pm 0.0020$ Å for BF_3 and $r_g(B-Cl)=1.7421\pm 0.0044$ Å, $r_g(Cl\cdots Cl)=3.0134\pm 0.0060$ Å, $l(B-Cl)=0.0505\pm 0.0023$ Å, and $l(Cl\cdots Cl)=0.0700\pm 0.0023$ Å for BCl_3. The force constants have also been determined from the mean amplitudes. Their values are in good agreement with those obtained by the isotopic shifts and by the Urey-Bradley force field. The complex scattering factors for B, F, and Cl have been calculated from the Hartree-Fock potential, and it has been shown that the background intensity and the mean amplitudes of BF_3 and BCl_3 are much better accounted for by these scattering factors than by those calculated from the Thomas-Fermi potential.

The force constants of molecules are usually determined from their vibrational frequencies. In most cases, however, the number of observable frequencies is not sufficient for all the force constants in a general quadratic form of the potential function to be determined. In order to overcome this difficulty, it is a common procedure to assume a simple model such as the Urey-Bradley force field, or to use the isotopic shifts of the vibrational frequencies. A more desirable way for determining the force field directly from experiment is to make use of the phenomena closely connected with the force field of the molecule. The mean amplitudes obtained by electron diffraction have thus been used to measure the force constants of several molecules with the aid of vibrational frequencies.[1-3]

The principal purpose of the present report is to determine the structure of boron trifluoride and boron trichloride as accurately as possible, and also to determine the force constants of these molecules from the experimental mean amplitudes. The resulting force constants will be compared with those obtained by other methods. The theoretical scattering factors will also be critically examined on the basis of the experimental mean amplitudes and backgrounds.

The atomic distances in boron trifluoride and trichloride were formerly determined by the visual method. The results obtained by Lévy and Brockway[4] were: $r(B-F)=1.30\pm0.02$ Å, $r(F-F)=2.25\pm0.03$ Å, $r(B-Cl)=1.73\pm0.02$ Å and $r(Cl-Cl)=2.99\pm0.03$ Å, while the results obtained by Braune and Pinnow[5] and those obtained by Sutton et al.[6] were $r(B-F)=1.31$ Å and $r(B-Cl)=1.76\pm0.02$ Å respectively.

During the course of the analysis of the mean amplitudes, it has been made clear that some property of the *l-l* curve is closely related to an empirical law known in spectroscopy regarding the off-diagonal elements of the $\boldsymbol{L}$ matrix. The results will be discussed in the Appendix.

Experimental

The diffraction photographs were taken with an apparatus equipped with an r^3-sector[7] at the camera length of 11.8 cm. The accelerating voltage (43—49 kV.) was automatically stabilized within 0.1%.

The sample of boron trifluoride was kindly provided by Dr. Ryohei Nakane of the Institute of Physical and Chemical Research, and that of boron trichloride, by the Central Research Institute of the Tokyo Shibaura Electric Co. The gas sample was led into the diffraction chamber through a drum-type nozzle at the temperature of 16°C for BF_3 and at 31°C for BCl_3. KEL-F stopcock grease was used to avoid the erosion of the lubricant. The vacuum of the chamber, initially 1—2 $\times10^{-5}$ mmHg, was kept under 1×10^{-4} mmHg even when the gas was introduced into the chamber. The beam current was about 0.006 μ amp., and the exposure time was about 3 minutes.

The patterns were recorded on Fuji Process Hard plates and were developed at 20°C for 5 min. with an FD-131 developer. The wavelengths of the primary electron beam were measured by using the transmission patterns of gold foil.

In order to make sure that the reference gold foil was placed exactly at the position of the diffraction center, gas patterns were also taken with the nozzle rotated around the nozzle axis by 180° by using the sample of boron trifluoride[8] (Fig. 1).

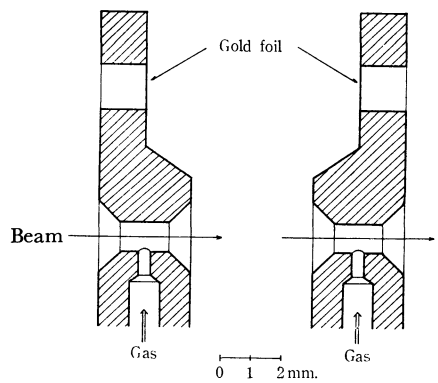

Fig. 1. Cross section of the nozzle used in the present study: normal orientation (left) and reversed orientation (right).

Photographic densities were measured using a Rigaku-Denki MP-3 microphotometer. In order to eliminate undesirable effects of the time lag of this recorder, the plates were scanned along the diameter; the charts thus obtained were measured and averaged on both sides of the center.[8] Four plates at the normal position of the nozzle and three plates at the reversed position were used for the structure analysis of boron trifluoride. Six plates at the normal position were used for the analysis of boron trichloride.

The optical densities of these plates were all between 0.6 and 0.1, where the linear relation between the density and the electron intensity has been confirmed.[9]

Analysis

The molecular intensity curve was obtained by drawing a smooth background line through the intensity curve, which had been corrected for the deviation of the sector shape from an ideal r^3 curve. In order to investigate the effects of atomic scattering factors on the molecular parameters, three

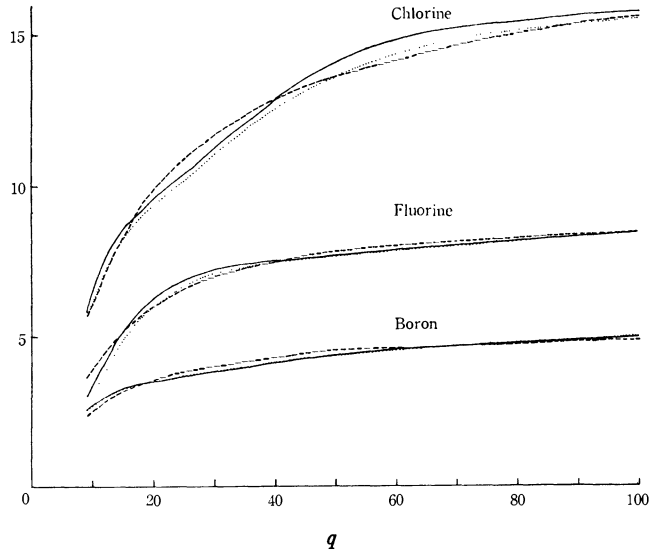

Fig. 2. The atomic scattering factors for electron diffraction.

—— $\frac{h^2s^2}{8\pi^2me^2}f^{B}=Z-f_X$, where f^{B} is the Born scattering factor and f_X is the atomic form factor for X-rays.

---- $\frac{h^2s^2}{8\pi^2me^2}|f|_{T.F.}$, where $|f|_{T.F.}$ is the absolute value of the complex scattering factor calculated from the Thomas-Fermi potential.

..... $\frac{h^2s^2}{8\pi^2me^2}|f|_{H.F.}$, where $|f|_{H.F.}$ is the absolute value of the complex scattering factor calculated from the Hartree-Fock potential.

kinds of atomic scattering factors were used for each atom (Fig. 2). The first, the Born scattering factor, f^{B}, was obtained by taking an appropriate average of the atomic form factors, f_x, calculated by several authors.[10-13] In the first Born approximation, the scattering factor, f^{B}, is equal to $8\pi^2me^2(Z-f_x)/h^2s^2$.[14] The second was the complex atomic scattering factor, $|f|_{T.F.}e^{i\eta_{T.F.}}$, calculated by Ibers and Hoerni using the partial-waves method based on the Thomas-Fermi potential.[15] The phase shift, $\eta_{T.F.}$, was also used, together with the f^{B} of the first set as $f^{B}e^{i\eta_{T.F.}}$. The third was the scattering factor, $|f|_{H.F.}e^{i\eta_{H.F.}}$, calculated by the present authors by using the partial-waves method based on the Hartree-Fock potential[16] (Table I). The inelastic scattering factors were taken from the table given by Bewilogua.[17]

By using the intensity curve from each plate, the molecular structure was analyzed by the method of least squares.[18] The theoretical expression of the molecular intensity is:

$$qM(q) = k\sum_i\sum_j{}' A_{ij}\mu_{ij}\cos\Delta\eta_{ij}\sin\frac{\pi}{10}q\left[r_{aij} - \left(\frac{\pi}{10}q\right)^2\kappa_{ij}\right]\exp\left[-\frac{1}{2}\left(\frac{\pi}{10}q\right)^2 l_{ij}^2\right] \quad (1)$$

$$A_{ij} = \frac{10}{\pi}\frac{1}{r_{aij}}\frac{Z_iZ_j}{\sum_k Z_k(Z_k+1)} \quad (2)$$

$$\mu_{ij} = \frac{|F_i||F_j|}{\sum_k|F_k|^2+\sum_k S_k}\frac{\sum_k Z_k(Z_k+1)}{Z_iZ_j},$$

$$|F| = h^2s^2|f|/8\pi^2me^2 \quad (3)$$

The parameters to be determined by the least-squares analysis were the atomic distances, r_a(B–X) and r_a(X–X), the mean amplitudes, l(B–X) and l(X–X), and the index of resolution, k.

The anharmonicity parameters, κ, were estimated by assuming potential functions of the Morse type for both the bonded B–X and the non-bonded X–X pairs; they were not varied as parameters. The following rough approximation was used:[3,19]

Fig. 3. Weight functions for the least-squares analysis.
(a) Weight functions used for BF_3. (b) Weight functions used for BCl_3.
(A) A conventional weight function. (B) Weights assumed to be inversely proportional to the square of the standard deviation $\sigma(q)$ of the molecular intensities $qM(q)$. (C) Weights estimated from the residuals of the least-squares fitting by the procedure described in Ref. 21. (D) Modification of (C) by the use of σ_m estimated from the standard deviation $\sigma(q)$ of the observed intensity curves. (E) Molecular intensity curves, $qM(q)$.

$$\kappa(\text{B-X}) \simeq \frac{1}{9} l^2(\text{B-X}) \langle \Delta z(\text{B-X}) \rangle \simeq \frac{a}{6} l^4(\text{B-X})$$

$$\kappa(\text{X-X}) \simeq \frac{\sqrt{3}}{9} l^2(\text{X-X}) \langle \Delta z(\text{B-X}) \rangle$$

$$\simeq \frac{\sqrt{3}}{6} a l^2(\text{B-X}) l^2(\text{X-X}) \qquad (4)$$

The anharmonicity constant, a, was estimated to be about 2 $Å^{-1}$.[20]

The initial least-squares analysis was based on a conventional weight function, A, which is shown in Fig. 3. In order to examine the effect of the choice of weight functions on the parameter values, however, three additional weight functions were estimated (Fig. 3). The weight function B was assumed to be inversely proportional to the square of the standard deviation, $\sigma(q)$, of the molecular intensities, $qM(q)$.[9] The other functions, C and D, were calculated by estimating the standard deviation of the population of $qM(q)$, σ_m, which is related to the errors of the measurement of the abscissa and the ordinate of the photometer chart as follows:[21]

$$\sigma_m^2 = G_x^2 \cdot \sigma_x^2 + G_y^2 \cdot \sigma_y^2 \qquad (5)$$

The weight C was obtained in a way similar to that reported previously;[3] that is, σ_m^2 was first estimated from the residuals of the least-squares fitting and was then improved by eliminating the non-essential irregularities of σ_y.

The estimation of σ_m^2 by this procedure is not always reliable, since it tends to put too much weight on the points where the residuals are accidentally very small, while the weights for other points may be severely underestimated. Such effects may be partly compensated for, because the residuals are averaged over several plates and because the weight function is modified by the smoothing of σ_y. It seems to be preferable, however, to estimate σ_m^2 by the variance of the observed intensity curves, $\sigma^2(q)$, and not by the least-squares residuals alone. The weight function D was, accordingly, obtained from $\sigma^2(q)$, with modification by means of Eq. 5. The weight functions were normalized in such a way that about 15% of the observations had the full weight. Figure 4 shows a typical illustration of the observed and smoothed σ_y values which is similar to Fig. 2a of Ref. 21. The σ_y curve was

standard deviation for the average value where n is the number of intensity curves. The symbol σ_2 is the standard deviation evaluated by the fluctuation among several sets of the observed values,[3,21] $\sigma_2=\sqrt{\sum(X_i-X)^2/n(n-1)}$. While there are no appreciable differences among the results based on different weights for boron trichloride, the values of the index and the amplitudes differ slightly among one another for boron trifluoride.

The differences between the bond lengths obtained from the plates taken with the normal and the reversed directions of the nozzle were 0.11% for r(B–F) and 0.14% for r(F–F). The average, 0.12%, may be regarded as the difference in the scale factors between the two nozzle directions; the interval between the position of the gold foil and the center of diffraction is, therefore, about 0.06% of the camera length, i. e., about 0.07 mm. This is shorter than the interval of about 0.12 mm. which was determined in a similar way for the asymmetric nozzle used in the study of silicon tetrachloride.[3] The scale factor for boron trichloride must, then, be corrected by 0.06%, since the photographs were taken only for the normal nozzle direction. The results corrected for the difference in the camera lengths due to the different nozzle directions are shown in Table III. The σ_1 and σ_2 values of BF_3 in this table were calculated by the following relation:

$$\sigma=\sqrt{\frac{7}{40}}\,[2\sigma^2_{\text{normal}}+\sigma^2_{\text{reversed}}]^{1/2} \qquad (6)$$

The apparent increases in the mean amplitudes

were determined by measuring the distribution of gas molecules on the basis of the discrepancies in the observed and theoretical backgrounds[22] (Fig. 5) (Table IV). The estimates of these corrections depend on the kind of scattering factors used.

The Estimation of Experimental Errors

The reliability of the observed parameters may be represented by the 99% confidence interval. This interval is equal to 2.5 σ if we assume the normal distribution of errors with a standard deviation, σ.[21] The greater of the σ_1 and σ_2 values of each parameter may safely be taken as the standard deviation, σ, corresponding to random errors. The random errors, 2.5 σ, and various systematic errors (which are considered to correspond to the above confidence interval) are listed in Tables V and VI.

For atomic distances the systematic errors were estimated as follows.[22] The error of the wavelength of the primary electron beam is less than 0.05% because the accelerating voltage was stabilized within 0.1%. When the wavelengths are determined from the reference gold foil, the uncertainty in the lattice constant of the gold foil and the personal errors in the measurement committed by the observer constitute systematic errors which influence the bond distances. The errors associated with the corrections for the inclination of photographic plates were estimated previously.[9]

As the photographs for BCl_3 were taken with only the normal orientation of the nozzle, the errors associated with the correction due to the deviation of the center of diffraction from the position of the gold foil should be taken into consideration. One half of the correction is, therefore, assigned to this source of error in Table V. The errors of the anharmonicity constants, κ, were estimated from the difference in the outputs of the least-squares analyses where the κ constants were either taken as variable parameters or as constants based on the various estimation.

For mean amplitudes, the errors associated with the correction for the distribution of gas molecules around the nozzle were assumed to be 50% of the correction. Errors coming from the arbitrariness of the weights were taken into consideration for both molecules.

The confidence intervals were estimated from the square root of the squared sum of errors, by assuming that these errors occur independently.

Results and Discussion

Atomic Distances and Mean Amplitudes.— The final results of the molecular constants obtained by using the Born scattering factors, $f^{B}e^{i\eta_{T.F.}}$, are given in Table VII. The average interatomic

a) The parameters listed in this table should be regarded as the final results of this study.

distances, r_g, were calculated from r_a by the relation: $r_g = r_a + l^2/r_a$, and the mean amplitudes were corrected for the finite sample size. The results obtained by the use of the complex scattering factors, $|f|_{T.F.}e^{i\eta_{T.F.}}$ and $|f|_{H.F.}e^{i\eta_{H.F.}}$, are also listed in Tables VIII and IX respectively. For the reason given in the next subsection, the values listed in Table IX should be regarded as the final results of this study.

If the BX_3 molecules were exactly in a rigid planar triangular form, the X–X distance should be equal to $\sqrt{3}$ times the B–X distance. However, when we calculate $\delta_g = \sqrt{3}r_g(\text{B–X}) - r_g(\text{X–X})$, it is not equal to zero, because of the perpendicular amplitudes caused by thermal vibrations.[23] It was found in this experiment that $\delta_g = 0.0054 \pm 0.0057$ Å for BF_3 and $\delta_g = 0.0040 \pm 0.0041$ Å for BCl_3.

The shrinkage mentioned above was calculated by the following relation:

$$\delta_g(\text{calcd.}) = \sqrt{3}\left(\frac{\langle \Delta x^2\rangle + \langle \Delta y^2\rangle}{2r_e}\right)_{B-X} - \left(\frac{\langle \Delta x^2\rangle + \langle \Delta y^2\rangle}{2r_e}\right)_{X-X} \quad (7)$$

where the perpendicular amplitudes, $\langle \Delta x^2\rangle$ and $\langle \Delta y^2\rangle$, can be calculated by using the $\boldsymbol{L}$ and $\boldsymbol{G}$ matrix elements. For the B–X pair,

$$\langle \Delta x^2\rangle = \frac{2}{9}\left(L_{43}^2\langle Q_3^2\rangle + L^2{}_{44}\langle Q_4^2\rangle\right)$$

$$\langle \Delta y^2\rangle = \frac{1}{9}L_{22}^2\langle L_2^2\rangle$$

and for the X–X pair.

$$\langle \Delta x^2\rangle = \frac{1}{6}\{(\sqrt{3}L_{33} - L_{43})^2\langle Q_3^2\rangle + (\sqrt{3}L_{34} - L_{44})^2\langle Q_4^2\rangle\}$$

$$\langle \Delta y^2\rangle = 0$$

The thermal-average distance, r_α, is defined as[24] the sum of the equilibrium distance, r_e, and an anharmonic term, $\langle \Delta z\rangle$; that is, $r_\alpha = r_g - (\langle \Delta x^2\rangle + \langle \Delta y^2\rangle)/2r_e - \delta r$. The centrifugal stretching terms, δr, were calculated to be 0.0003 Å, 0.0006 Å, 0.0005 Å and 0.0009 Å for the B–F, F–F, B–Cl and Cl–Cl pairs respectively.[25] The observed r_α distances are listed in Tables VII, VIII and IX. In this average structure, the nonlinear shrinkage effect should disappear if the molecule is exactly in a planar triangular form. The ratio of the B–X distance to the X–X distance in this structure, $r_\alpha(\text{F–F})/r_\alpha(\text{B–F}) = 1.7306 \pm 0.0045$, $r_\alpha(\text{Cl–Cl})/r_\alpha(\text{B–Cl}) = 1.7323 \pm 0.0023$, is equal to $\sqrt{3}$ within the range of experimental error. It is therefore proved, to within an order of 0.001 Å, that the BF_3 and BCl_3 molecules take a planar triangular form in the average structure, and also in the equilibrium structure.

Although the above results are consistent with those given in previous papers[4-6] within their ranges of experimental error, the present study has provided more direct and confirmative support for the planarity of these molecules.

The thermal average B–F distance, $r_g = 1.3156 \pm 0.0044$ Å, is significantly larger than the effective distance, $r_0 = 1.295_1$ Å, obtained by Nielsen[26] from the rotational constant, B_0, in the analysis of the infrared ν_2 band of BF_3. While a part of this discrepancy stems from the difference in the definition of the internuclear distance, their assignment seems to be questionable. This problem will be studied in more detail in a forthcoming paper.

A Comparison of the Atomic Scattering Factors.—A similar electron diffraction analysis for boron tribromide[27] has revealed that the complex atomic scattering factors, $|f|_{H.F.}e^{i\eta_{H.F.}}$, calculated from the Hartree-Fock potentials provide a value of the mean amplitude, l(B–Br), more reasonable than the other scattering factors, $f^{Be^{i\eta_{T.F.}}}$ and $|f|_{T.F.}e^{i\eta_{T.F.}}$, and that the theoretical background line calculated from $|f|_{H.F.}$ is in better agreement with the observations than those calculated from the scattering factors, f^B and $|f|_{T.F.}$. Accordingly, it seemed desirable to compare the background lines calculated from these atomic scattering factors for the other halides.

The effects of the difference in the scattering factors appear on the mean amplitudes and on the backgrounds, but not appreciably on the atomic distances. The observed mean amplitudes obtained from the three scattering factors are shown in Fig. 6, where the closed areas show the limits of error of the mean amplitudes obtained by using the Hartree-Fock scattering factors, $|f|_{H.F.}e^{i\eta_{H.F.}}$.

As may be seen in Fig. 5, the theoretical backgrounds of boron trifluoride based on the three scatter-ing factors are in good agreement with the observed curve. Slight differences, each within the limits of error, are observed in the mean amplitudes listed in Tables VII—IX however. The results based on $f^{Be^{i\eta_{T.F.}}}$ and $|f|_{H.F.}e^{i\eta_{H.F.}}$ are compatible with the spectroscopic value within the limits of error, while that based on $|f|_{T.F.}e^{i\eta_{T.F.}}$ is in poorer agreement. For the mean amplitudes of boron trichloride, the result based on each scattering factor is in good agreement with the spectroscopic value, with the exception that the $|f|_{T.F.}$ factor gives a poor result for the background. It thus seems that the results based on the $|f|_{T.F.}$ factor are not quite satisfactory. This may be ascribed to the inadequacy of the Thomas-Fermi potential

for such light elements as boron, fluorine and chlorine.

Force Constants.—The BX_3 molecules belong to the point group D_{3h} and have four fundamental frequencies. ν_1 is a totally symmetric stretching vibration (A_1' species), ν_2 is an out-of-plane vibration (A_2'' species), and ν_3 and ν_4 are doubly-degenerate vibrations (E' species). Although the force constants of A_1' and A_2'' species can easily be determined from the vibrational frequencies alone, those of E' species cannot be determined uniquely because the number of the force constants (three) exceeds that of the frequencies (two).

So far, several sets of force constants have been calculated by using the frequencies of the boron isotopes as additional observables. Since, however, the mass ratio of ^{10}B to ^{11}B is nearly unity, small experimental errors in the frequencies may lead to large errors in the force constants. The Urey-Bradley force constants of boron trihalides have also been reported.[28,29] The force constants can also be determined more precisely if the Coriolis coupling constants are observed. Thus far, one of the Coriolis constants of boron trifluoride has been determined from the band shape of the ν_4 frequency and used to calculate the force constants.[30] Nevertheless, this finding does not seem to be well-grounded experimentally, since the Coriolis constant was determined only indirectly. For this reason, it seems profitable to calculate the force constants from the mean amplitudes observed by electron diffraction.

The general quadratic potential function, in terms of the internal coordinates for BX_3 molecules, is:

$$2V = \sum f_r(\Delta r_i)^2 + 2\sum f_{rr}(\Delta r_i)(\Delta r_j) + f_\tau(r_0\Delta\tau)^2 + \sum f_\alpha(r_0\Delta\alpha_i)^2 + 2\sum f_{\alpha\alpha}(r_0\Delta\alpha_i)(r_0\Delta\alpha_j) \sum f_{r\alpha}(\Delta r_i)(r_0\Delta\alpha_i) + 2\sum f'_{r\alpha}(\Delta r_i)(r_0\Delta\alpha_j) \quad (8)$$

The internal coordinates are Δr_1, Δr_2, Δr_3, $r_0\Delta\alpha_1$, $r_0\Delta\alpha_2$, $r_0\Delta\alpha_3$ and $r_0\Delta\tau$, where Δr_i is the change in the length of the ith bond, $\Delta\alpha_i$ is the change in the bond angle opposite to r_i, and r_0 is the bond distance. $\Delta\tau$ is the change in the angle between any one of the bonds and the molecular plane.*

The following symmetry coordinates are used:

$$\begin{aligned}
&A_1' \text{ species}, && S_1 = \frac{1}{\sqrt{3}}(\Delta r_1 + \Delta r_2 + \Delta r_3)\\
&A_2'' \text{ species}, && S_2 = r_0\Delta\tau\\
&E' \text{ species}, && S_3 = \frac{1}{\sqrt{6}}(2\Delta r_3 - \Delta r_1 - \Delta r_2)\\
& && S_4 = \frac{1}{\sqrt{6}} r_0(2\Delta\alpha_3 - \Delta\alpha_1 - \Delta\alpha_2)\\
& && S_3' = \frac{1}{\sqrt{2}}(\Delta r_1 - \Delta r_2)\\
& && S_4' = \frac{1}{\sqrt{2}} r_0(\Delta\alpha_1 - \Delta\alpha_2) \quad (9)
\end{aligned}$$

The elements of the $\boldsymbol{F}$ matrix in the symmetry coordinates have the following relations to the constants in Eq. 8:

$$\begin{aligned}
&A_1' \text{ species}, && F_{11} = f_r + 2f_{rr}\\
&A_2'' \text{ species}, && F_{22} = f_\tau\\
&E' \text{ species}, && F_{33} = f_r - f_{rr}\\
& && F_{34} = f_{r\alpha} - f'_{r\alpha}\\
& && F_{44} = f_\alpha - f_{\alpha\alpha} \quad (10)
\end{aligned}$$

When the above transformation (9) is expressed in

* If the displacements of the Cartesian coordinates perpendicular to the molecular plane are denoted as y, they are related to $\Delta\tau$ as $r_0\Delta\tau = y_1 + y_2 + y_3 - 3y_0$, while the $\boldsymbol{G}$ matrix for A_2'' species is given by $G_{22} = 3/m_X + 9/m_B$.

a matrix form:

$$\boldsymbol{S}=\boldsymbol{UR}, \tag{11}$$

the mean amplitudes of vibration are given by[31]:

$$\langle \boldsymbol{R}\tilde{\boldsymbol{R}} \rangle = \tilde{\boldsymbol{U}}\boldsymbol{L}\langle \boldsymbol{Q}\tilde{\boldsymbol{Q}} \rangle \tilde{\boldsymbol{L}}\boldsymbol{U} \tag{12}$$

where $\langle \boldsymbol{Q}\tilde{\boldsymbol{Q}} \rangle$ is a diagonal matrix having the elements of:

$$\langle Q_i^2 \rangle = \frac{h}{8\pi^2\nu_i} \coth\left(\frac{h\nu_i}{2kT}\right) \tag{13}$$

From Eq. 12 the mean square amplitudes for the BX_3 molecules are found to be:

$$\begin{aligned} l^2(\text{B-X}) &= \frac{1}{3} L_{11}^2\langle Q_1^2 \rangle + \frac{2}{3}\{L_{33}^2\langle Q_3^2 \rangle \\ &\quad + L_{34}^2\langle Q_4^2 \rangle\} \\ l^2(\text{X-X}) &= L_{11}^2\langle Q_1^2 \rangle + \frac{1}{6}\{(\sqrt{3}L_{33} \\ &\quad - L_{43})^2\langle Q_3^2 \rangle + (\sqrt{3}L_{34} - L_{44})^2\langle Q_4^2 \rangle\} \end{aligned} \tag{14}$$

In a rigorous sense, the normal frequencies, ν_e, should be used in the calculation of the force field, but at present we do not have enough knowledge of vibrational anharmonicities to convert the fundamental frequencies, ν, to ν_e for boron trihalide.[32] Table X shows the fundamental frequencies used for the calculation[26,33,34] and the uncertainties of the frequencies which are estimated by analogy with other simple polyatomic molecules. When these observed ν values are used, the force constants have only one degree of freedom, and the two mean amplitudes, l(B–X) and l(X–X), cannot be independent. The curve of l(X–X) versus l(B–X) is illustrated in Fig. 6. The spread of the curves corresponds to the errors in the frequencies estimated above. Any one point on the curve corresponds to a set of the force constants. The ranges of the observed mean amplitudes based on the scattering factors, $|f|_{\text{H.F.}}e^{i\eta_{\text{H.F.}}}$, are within the ellipses drawn in solid lines in Fig. 6, while the overlapping regions of the curves indicate reasonable sets of the force constants. The observed value of l(B–F) is smaller than that to be expected from vibrational frequencies by about 0.003 Å, possibly because of some unknown systematic error. The uncertainties in the force constants of boron trifluoride were estimated from the overlapping region of the l-l curve and an ellipse displaced by 0.003 Å parallel to the l(B–F) axis. The displaced ellipse is shown by a dashed line in Fig. 6. The force constant, F_{34}, was determined from the corresponding region in the curve of F_{34} versus (B–X) in Fig. 7, while the other constants, F_{33} and F_{44}, were obtained from the value of F_{34}. The force constants obtained in this way are shown in Table XI.

It is found that the force constants determined from the mean amplitudes are in good agreement with those obtained by the isotopic shifts and the Urey-Bradley force fields (Table XI). The errors

in the force constants derived from the mean amplitudes are similar in magnitude to those of the force constants obtained by the isotopic shifts. Nevertheless, the force constants are now considered to have been confirmed, since the two different experimental methods have given coincident results.

As is shown in Fig. 6, the positions of the observed mean amplitudes of BF_3 and BCl_3 are at the left-hand edge of the l-l curve. Similar phenomena have also been observed in the CCl_4, $GeCl_4$[1], $SiCl_4$[3], $TiCl_4$[8] and BBr_3[27] molecules which have previously been studied in our laboratory. It, therefore, seems unlikely that this is merely a coincidence. An analysis to be shown in the Appendix will prove that the physical meaning of this effect is related to a well-known empirical rule that the normal modes of stretching vibrations have essentially no dependence on the bending coordinates.[35]

Summary

The atomic distances and the mean amplitudes of boron trifluoride and boron trichloride have been determined by the sector-microphotometer method of gas electron diffraction (Table IX). The force constants determined from the mean amplitudes and the vibrational frequencies are in good agreement with those obtained by the isotopic shifts and by the Urey-Bradley force field.

It has been found that the Born scattering factors and the complex scattering factors for boron trifluoride and boron trichloride calculated from the Hartree-Fock potential give more reasonable mean amplitudes and theoretical backgrounds than the complex scattering factors calculated from the Thomas-Fermi potential.

The authors wish to express their gratitude to Dr. Ryohei Nakane for providing the boron trifluoride, and to the Central Research Institute of the Tokyo Shibaura Electric Co. for supplying the boron trichloride. They are also grateful to of the Ministry Education for a research grant.

Appendix

A simple relation has been observed empirically between the observed mean amplitudes of the X-Y and Y-Y distances for the tetrahedral XY_4 molecules (CCl_4, $GeCl_4$[1], $SiCl_4$[3] and $TiCl_4$[8]) and for the planar trigonal XY_3 molecules (BF_3, BCl_3 and BBr_3[27]). Without exception, the observed values of l(X-Y) and l(Y-Y) fall close to the left-hand edge of the l-l ellipse, as is shown in Fig. 6.

We will here show that this phenomenon can be explained quite simply with relation to the characteristic modes of molecular vibrations, that is, by the empirical rule $L_{ij}(i<j) \fallingdotseq 0$, where the normal coordinates and the symmetry coordinates are numbered from the higher to the lower frequencies. According to the following argument, the mean amplitudes of a bonded pair, X-Y, takes a minimum value when $L_{34}=0$.

The l(X-Y) amplitude is related to the $\boldsymbol{L}$ matrix elements as follows:

$$l^2(\text{X-Y}) = \frac{1}{3}\Sigma_1 + \frac{2}{3}\Sigma_3 \qquad \text{for } XY_3 \qquad \text{(A1)}$$

$$= \frac{1}{4}\Sigma_1 + \frac{3}{4}\Sigma_3 \qquad \text{for } XY_4 \qquad \text{(A2)}$$

$$\Sigma_1 = L_{11}^2\langle Q_1^2\rangle \qquad \text{(A3)}$$

$$\Sigma_3 = L_{33}^2\langle Q_3^2\rangle + L_{34}^2\langle Q_4^2\rangle \qquad \text{(A4)}$$

where Σ is the mean amplitude matrix defined by Cyvin.[36] The first terms of Eqs. A1 and A2 have definite values, because $L_{11}^2=G_{11}=1/m_Y$, while the second terms depend on the choice of the force constants, because L_{33} and L_{34} change with the force constants. Therefore, it is sufficient to prove that Σ_3 takes a minimum value in order to prove that the l(X-Y) takes a minimum. Using the relation $\boldsymbol{G}=\boldsymbol{L}\tilde{\boldsymbol{L}}$, we obtain the following formulas:

$$G_{33} = L_{33}^2 + L_{34}^2$$

$$G_{34} = L_{33}L_{43} + L_{34}L_{44}$$

$$G_{44} = L_{43}^2 + L_{44}^2$$

$$\therefore\ (G_{33} - L_{34}^2)(G_{44} - L_{44}^2) = L_{33}^2L_{43}^2 = (G_{34} - L_{34}L_{44})^2 \qquad \text{(A5)}$$

From these equations, we can express L_{34} in terms of the $\boldsymbol{G}$ matrix elements and a parameter, β, where $\beta=L_{34}/L_{44}$:

$$L_{34}^2 = \frac{\beta^2 G_{44}|\boldsymbol{G}|}{(\beta G_{44}-G_{34})^2 + |\boldsymbol{G}|}, \quad |\boldsymbol{G}| = G_{33}G_{44} - G_{34}^2 \qquad \text{(A6)}$$

Then Σ_3 can also be expressed in terms of the parameter β:

$$\Sigma_3 = L_{33}^2\langle Q_3^2\rangle + L_{34}^2\langle Q_4^2\rangle = G_{33}\langle Q_3^2\rangle + L_{34}^2(\langle Q_4^2\rangle - \langle Q_3^2\rangle) = G_{33}\langle Q_3^2\rangle + \frac{\beta^2 G_{44}|\boldsymbol{G}|}{(\beta G_{44}-G_{34})^2 + |\boldsymbol{G}|} \times (\langle Q_4^2\rangle - \langle Q_3^2\rangle) \qquad \text{(A7)}$$

Since $|\boldsymbol{G}|$ and $(\langle Q_4^2\rangle - \langle Q_3^2\rangle)$ are both positive, it is clear that Σ_3 takes a minimum when $\beta=0$, that is, when $L_{34}=0$, and takes a maximum when $\beta=G_{33}/G_{34}$, that is, when $L_{33}=0$. The curve of Σ_3 is shown in Fig. 8.

For molecules of the bent XY_2 type, l(X-Y) takes the minimum value when $L_{12}=0$, since the following relation is the same as those for the planar XY_3 and tetrahedral XY_4 molecules.

$$l^2(\text{X-Y}) = \frac{1}{2}(\Sigma_1 + \Sigma_3) \qquad \text{(A8)}$$

$$\Sigma_1 = L_{11}^2\langle Q_1^2\rangle + L_{12}^2\langle Q_2^2\rangle \qquad \text{(A9)}$$

$$\Sigma_3 = L_{33}^2\langle Q_3^2\rangle \qquad \text{(A10)}$$

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1146—1154 (1966)

The Mean Amplitudes and Atomic Scattering Factors of Boron Tribromide

By Shigehiro KONAKA*, Tetsuzo ITO* and Yonezo MORINO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received August 4, 1965)

The mean amplitudes and the interatomic distances of BBr_3 have been determined by the sector-microphotometer method of gas electron diffraction. The B–Br and Br–Br distances (r_g) have been found to be 1.8932 ± 0.0054 Å and 3.2830 ± 0.0053 Å respectively. The values of the mean amplitudes are dependent on the atomic scattering factors used in the analysis. The complex scattering factors for B and Br, as calculated on the basis of the Hartree-Fock potential, have given mean amplitudes which are consistent with the vibrational frequencies observed by spectroscopy, while the mean amplitudes derived from the use of other scattering factors are less reasonable. It has been shown that the Hartree-Fock function for the Br atom is a better representation of the atomic potential function than the Thomas-Fermi function. The utility of the method of gas electron diffraction for the study of atomic scattering factors and atomic potential functions in some favorable cases has been pointed out.

Although the difference between the absolute values $|f|$ of the complex atomic scattering factor and the Born scattering factor, f^B, is large for atoms of large atomic numbers, it does not necessarily cause serious trouble in the analysis of usual molecules by gas electron diffraction, since in the calculation of the molecular intensity the difference which appears in the numerator (the total intensity) compensates for that in the denominator (the background).

For boron tribromide, however, the difference in the scattering factors has a serious effect on the observed value of the mean amplitude, l(B–Br). This suggests that information about the atomic scattering factors may be obtained from gas electron diffraction; it is possible to make a critical examination of the theoretical scattering factors by comparing the value of l(B–Br) estimated from the observed vibrational frequencies with the observed values of l(B–Br), which depend on the scattering factors used in the analysis. The experimental backgrounds should provide additional information about the theoretical scattering factors.

It also seems important to determine the molecular structure of boron tribromide as accurately as possible by taking into consideration the effect of the scattering factors. One electron diffraction study of boron tribromide has been carried out, by the visual method, by Lévy and Brockway.[1] Their results were: r(B–Br)$=1.87\pm0.02$ Å and r(Br–Br)$=3.25\pm0.03$ Å.

Experimental

The diffraction apparatus used in this study was the same as that reported on in a previous paper.[2] The diffraction patterns were taken on Fuji Process Hard plates by using an r^3 sector. The camera distances were either 11.8 cm. (short camera distance), which covered the region from $q=17$ to $q=98$, or 27.9 cm. (long camera distance), which covered the region from $q=6$ to $q=36$. The accelerating voltage (43 kV.) was automatically stabilized within 0.1% during the experiment. The sample of a commercial grade was purified by distillation. KEL-F stopcock grease was used to avoid the erosion of the lubricant by the sample. The gas sample was led into the diffraction chamber through a drum-type nozzle (the same as that reported on in a preceding paper)[3] at the temperature of 17°C. The beam current was about 0.005 and 0.002 μamp., and the exposure times were about 3 and 5 min. for the short and long camera distances respectively. The wavelengths of the primary electron beam were measured by making use of the transimission patterns of gold foil.

The densities of the photographs developed at 20°C for 5 minutes with an FD-131 developer were measured using a Rigaku-Denki MP-3 microphotometer. The undesirable effects of the time lag of the recorder were eliminated by the method described in a preceding paper.[3] Seven plates for each camera distance were used for analysis. The optical densities (0.1—0.6) of these plates were all within the range where the linearity between density and intensity has been established by experiment.[4]

Analysis

A molecular intensity curve was obtained by drawing a smooth background line through the undulation of the intensity curve corrected for imperfections in the sector shape. The background line was corrected according to the criterion of minimum ghosts in the radial distribution curve.[5]

Two sets of atomic scattering factors were used to calculate the radial distribution curves: the Born scattering factors, f^B, as calculated by several authors[6-8], and the absolute value, $|f|$, of the complex scattering factors as calculated by Ibers and Hoerni[9] (Fig. 1). The phase shifts, $\Delta\eta_{BBr}=\eta_{Br}-\eta_B$, taken from their table were used for both sets. The inelastic scattering factors were taken from the table of Bewilogua.[10]

The expression of molecular intensity is given by[11]:

$$qM(q)=k\sum A_{ij}\mu_{ij}\cos\Delta\eta_{ij} \times \sin\left(\frac{\pi}{10}qr_{ij}\right)\exp\left(-\alpha_{ij}q^2\right) \quad (1)$$

where:

$$\alpha_{ij}=\frac{1}{2}\left(\frac{\pi}{10}\right)^2 l_{ij}^2 \quad (2)$$

$$\mu_{ij}=\frac{\sum_k Z_k(Z_k+1)}{Z_iZ_j}\frac{|F_i||F_j|}{\sum_k|F_k|^2+\sum_k S_k}$$

$$|F|=\boldsymbol{h}^2s^2|f|/8\pi^2\boldsymbol{m}\boldsymbol{e}^2 \quad (3)$$

The curves of the μ-factors $\mu_{BBr}\cos\Delta\eta_{BBr}$ and μ_{BrBr} are shown in Fig. 2. Since the values of $1-\mu_{BBr}\cos\Delta\eta_{BBr}$ are not small for a small q region ($q<17$) or for a large q region ($q>50$), the usual corrections[12] for non-nuclear scattering, $1-\mu_{ij}\cos\Delta\eta_{ij}$, are not suitable. The molecular intensity for the short camera distance was, therefore, modified into the following $qM(q)_c$ by adding the correction term of $\Delta qM(q)$ to Eq. 1, taking into account the apparent splitting of the B–Br distance because of the failure of the Born approximation:[11]

* The minimum l(B-Br) value allowed by spectroscopic data is 0.0502 Å

which takes into account the apparent increase in the B-Br mean amplitude because of the slight deviation from the Born formula:[13]

$$qM(q)_c = k\gamma A_{BBr}\sin\left(\frac{\pi}{10}qr_{BBr}\right)e^{-\alpha'_{BBr}q^2} + kA_{BrBr}\sin\left(\frac{\pi}{10}qr_{BrBr}\right)e^{-\alpha_{BrBr}q^2} \quad (6)$$

$$\Delta qM(q) = k\gamma A_{BBr}\left\{1-\frac{\mu_{BBr}\cos\Delta\eta_{BBr}}{\gamma\exp(-\beta q^2)}\right\}\times\sin\left(\frac{\pi}{10}qr_{BBr}\right)e^{-\alpha'_{BBr}q^2} + kA_{BrBr}(1-\mu_{BrBr})\times\sin\left(\frac{\pi}{10}qr_{BrBr}\right)e^{-\alpha_{BrBr}q^2} \quad (7)$$

where:

$$\alpha'_{BBr} = \alpha_{BBr} + \beta \quad (8)$$

and where γ is a constant.

As a result of the above modifications, the $\Delta qM(q)$ values, shown in Fig. 3, were made much smaller than the conventional correction terms, $1-\mu_{ij}\cos\Delta\eta_{ij}$.

When the backgrounds were revised by the non-negativity criterion of the radial distribution curve,[5] the molecular intensity for the long camera distance (q=6—36) agreed with that for the short distance (q=17—98), especially over the region q=18—25 (Fig. 4).

Seven molecular intensity curves were obtained by combining each one of the molecular intensity curves for the short camera distance with any one of those for the long distance in the above q region (18—25). The molecular parameters were determined by the least-squares fitting of the observed molecular intensity to the following theoretical expression,[14] including the anharmonicity parameters κ, which were neglected in the above treatment of the radial distribution curves:

$$qM(q) = k\sum A_{ij}\mu_{ij}\cos\Delta\eta_{ij}\times\sin\frac{\pi}{10}q\left[r_{aij}-\left(\frac{\pi}{10}q\right)^2\kappa_{ij}\right]\times\exp\left[-\frac{1}{2}\left(\frac{\pi}{10}q\right)^2 l_{ij}^2\right] \quad (9)$$

The anharmonicity parameters, κ, were estimated in the way reported on in a preceding paper[3]; they were not varied as parameters. The results of the least-squares analysis are listed in Table I.

Results and Discussion

Mean Amplitudes and Atomic Scattering Factors.—According to the scattering theory of partial waves, the atomic scattering factors, $f(\theta)$, which are required in the analysis of gas electron diffraction are given by:

$$f(\theta) \equiv |f(\theta)|e^{i\eta(\theta)} = (2ik)^{-1}\sum_{l=0}^{\infty}(2l+1)(\exp[2i\delta_l]-1)P_l(\cos\theta) \quad (10)$$

for the elastic scattering of electrons by a central potential, $V(r)$. Here k is the wave number of the electron, and δ_l is the phase shift of the lth partial wave. The complex scattering factors, $|f|e^{i\eta}$, were calculated by Ibers and Hoerni by this formula.[9]

The atomic scattering factors given by the first Born approximation is:

$$f(\theta) \simeq f^B(\theta) = -\frac{8\pi^2 m}{h^2}\int_0^\infty V(r)\frac{\sin sr}{sr}r^2dr \quad (11)$$

which is related to the X-ray form factor, $f_x(\theta)$, by:

$$f^{B}(\theta)=\frac{8\pi^2 me^2}{h^2 s^2}(Z-f_x(\theta)) \qquad (12)$$

where m is the relativistic mass of the incident electron.

While the phase shift, η, calculated by the method of partial waves has been used in most of the recent analysis, the Born scattering factor, f^{B}, has sometimes been used in place of the absolute value, $|f|$. This is possibly due to the fact that f^{B} has been regarded as more reliable than the $|f|$ value as calculated by Ibers and Hoerni, since their partial-waves calculations for most atoms were based on the Thomas-Fermi potential.

The difference between $|f|$ and f^{B} is large for heavy atoms, but its effect is negligible for most molecules in the calculation of the molecular scattering intensity, $qM(q)$, since the scattering factors appear in the numerator and in the denominator of the μ-factor, so the effect is essentially cancelled. Consequently, the difference between the scattering factors, $|f|$ and f^{B}, is large for the bromine atom (Fig. 1), but it has only a negligible effect on the μ-factor of the Br–Br pair (Fig. 2). For the B–Br pair, however, the difference in the scattering factors has a great influence on the μ-factor, as is shown in Fig. 2. This can be easily understood from the following approximate expression of μ_{BBr},

which is obtained by neglecting the $|F|$ of the boron atom and the inelastic scattering factors, S_k, relative to the $|F|$ of the bromine atom in the denominator of f_{BBr}:

$$\mu_{BBr} \propto |F|_B/|F|_{Br} \qquad (13)$$

If the scattering factor $|f|$ is replaced by f^B in this fraction, the denominator changes considerably, while the numerator remains almost unchanged. The value of $\mu_{BBr} \cos \Delta\eta_{BBr}$ then changes the least-squares result of the mean amplitude, l(B–Br), seriously.

In a preceding paper,[3] it was shown that the value of l(B–Br) takes a minimum value when one of the off-diagonal elements of the $\boldsymbol{L}$ matrix, L_{34}, equals zero. The minum value of l(B–Br) allowed by the observed vibrational frequencies is 0.0502 Å at 17°C. Since it is expected, on the basis of the well-known empirical rule stated in the preceding paper,[3] that the value of L_{34} is very nearly zero, the true value of l(B–Br) is expected to be very close to the minimum value, 0.0502 Å. The $l-l$ curve of BBr_3 is shown in Fig. 5, while the vibrational frequencies used in the calculation are listed in Table II.[15]

Table II. Fundamental frequencies used in the calculation[a] (in cm^{-1} units)

ν_3	819.8	856.1	±2
ν_4	148	148	±3

a) Ref. 15.
b) Limits of error assumed in the present study.

The least-squares result of l(B–Br) obtained by using f^B is much smaller than the above minimum value and the values of the mean amplitudes observed for ordinary molecules. The l(B–Br) value obtained by using the $|f|$ value calculated by Ibers and Hoerni is about twice the value given by f^B, but it is still inconsistent with the spectroscopic value. This is possibly to be ascribed to the errors associated with the use of the Thomas-Fermi potential function for the bromine atom in the partial-waves calculation of Ibers and Hoerni.[9]

The complex scattering factors of the bromine atom have recently been calculated by using the Hartree-Fock potential by Bonham and Peacher,[16] but those of the boron atom had never been calculated from the Hartree-Fock potential. The boron-scattering factors were, therefore, calculated in the present study by the method of partial waves by using the Hartree-Fock potential. The results of the calculations are shown in the Appendix.

The values of $|f(\theta)|$ are found to be nearly equal to those obtained from the Thomas-Fermi potential (Fig. 1), whereas the phase shifts $\Delta\eta(\theta)$ are appreciably smaller (Fig. 6); this makes the factor $\mu_{BBr} \cos \Delta\eta_{BBr}$ increase (Fig. 2). The least-squares results obtained by using the new μ-factors are shown in Table I (C). It is noticeable that the standard error of the least-squares analysis for l(B–Br) was made smaller by the use of the revised μ-factors.

The apparent increase in the mean amplitudes due to the sample delocalization was estimated by comparing the observed background line with the theoretical one obtained from the absolute values of the complex atomic scattering factors. The corrections were −0.0012 Å and −0.0019 Å for l(B–Br) and l(Br–Br) respectively.

The estimation of the experimental errors in the mean amplitudes is shown in Table III, while the final results obtained by using the scattering factors calculated from the Hartree-Fock potential

Table III. Limits of error of the mean amplitudes and index (l in Å units)

····· $|f|_{H.F.}$

by the method of partial waves are listed in Table V.

As is shown in Fig. 5, both the l(B–Br) and l(Br–Br) values are now compatible with those calculated from the observed vibrational frequencies. From the present gas electron diffraction study of boron tribromide, the Hartree-Fock function is, hence, found to be a better representation of the atomic potential function than the Thomas-Fermi function for the bromine atom, which has an intermediate atomic number.

Atomic Distances.—The corrections for the nozzle asymmetry stated in the preceding paper[3] are −0.0011Å and −0.0020 Å for r(B–Br) and r(Br–Br) respectively.

The limits of error of the atomic distances are estimated to be as shown in Table IV. Table V shows the final results obtained by using the scattering factor calculated from the Hartree-Fock potential by the method of partial waves. The results of the atomic distances are consistent with those given in a previous paper.[1]

A Comparison of the Theoretical and Observed Backgrounds.—In Fig. 7, the theoretical backgrounds calculated from the three atomic scattering factors are compared with the observed backgrounds. It is found that the $|f|_{T.F.}$ scattering factors gave a poorer background than the Born scattering factors. This tendency was also encountered in the analysis of boron trichloride.

For boron trifluoride and boron trichloride, the Born scattering factors gave results similar to those obtained from the Hartree-Fock complex scattering factors in the calculations of the mean amplitudes and the backgrounds.[3] For boron tri-

bromide, however, the Born scattering factors were found to give less reasonable backgrounds than the $|f|_{H.F.}$ factors. This gives additional support for the conclusion of the previous subsection that the $|f|_{H.F.}$ scattering factor is superior to f^B for bromine.

Summary

Boron tribromide has been studied by the sector-microphotometer method of electron diffraction in order to make a critical examination of the atomic scattering factors. The complex atomic scattering factors, $|f|_{H.F.}e^{i\eta_{H.F.}}$, calculated from the Hartree-Fock potentials have provided a more reasonable value of the mean amplitude, l(B–Br), than the Born and Thomas-Fermi scattering factors, $f^Be^{i\eta_{T.F.}}$ and $|f|_{T.F.}e^{i\eta_{T.F.}}$. The theoretical background curve calculated from $|f|_{H.F.}$ is also in better agreement with the observed one than are those calculated from the other scattering factors. This indicates that the Hartree-Fock potential function is a better representation of the atomic potential function than the Thomas-Fermi function for the bromine atom. The present study suggests the usefulness of the method of gas electron diffraction for the study of atomic scattering factors and atomic potential functions in some favorable cases.

The authors wish to express their thanks to Professor R. A. Bonham for his advice in the calculation of the complex atomic scattering factors.

Appendix

Partial-waves Calculations of the Scattering Factors of the Boron and Bromine Atoms by the Use of the Hartree-Fock Potential.—The Hartree-Fock potential has been expressed by Bonham[17] in the following analytical expression:

$$V(r)=-\frac{Ze^2}{r}\left(\sum_{i=1}^{2}\gamma_i e^{-\lambda_i r}+r\sum_j \gamma_j e^{-\lambda_j r}\right) \quad \text{(A1)}$$

a) Interpolated values according to the table of Ibers and Hoerni (Ref. 9).
b) Ref. 16. Present calculations have given almost identical results.

18) J. Karle and R. A. Bonham, ibid. **40**, 1396 (1964).

of the second kind, and Q_l' is the first derivative of Q_l. When l is large, this formula can be approximated by:

$$\delta_l=\alpha\left\{\sum_i \gamma_i K_0\left[\left(l+\frac{1}{2}\right)\lambda_i/k\right]+\frac{l+(1/2)}{k}\sum_j \gamma_j K_1\left[\left(l+\frac{1}{2}\right)\lambda_j/k\right]\right\} \quad \text{(A3)}$$

where K_0 and K_1 are the modified Bessel functions of the second kind. The phases can also be evaluated by the asymptotic WKBJ formula:

$$\delta_l=\frac{k\alpha}{Ze^2}\int_{(l+\frac{1}{2})/k}^{\infty} V(r)\left[k^2-\left(l+\frac{1}{2}\right)^2/r^2\right]^{-1/2}\mathrm{d}r \quad \text{(A4)}$$

which is reduced to Eq. A3 by using Eq. A1 for the potential $V(r)$.[19,20] Selected values of the δ_l of the boron atom are listed in Table VI.

The sum in Eq. 10 in the text has been taken in the range of $0\leq l\leq 250$ by using the phases of the partial waves given by Eq. A3, which may be good approximations for both the Born phases and the WKBJ phases. The results of the partial-waves calculations are shown in Tables VII and VIII.

Studies of Calcichrome as a Spectrophotometric Reagent. I. A New Spectrophotometric Method for the Determination of Copper with Calcichrome and Its Basic Study

By Hajime Ishii and Hisahiko Einaga

Central Research Laboratory, Onoda Cement Co., Ltd., Koto-ku, Tokyo

(Received August 9, 1965)

It was found that Calcichrome, which has been recently established as a reagent for the determination of calcium, forms a stable 1-to-1 complex with copper. Basic studies were carried out, in which the acid dissociation constants of Calcichrome and the apparent formation constant of the complex were determined to be $pK_{a_7}=7.2$, $pK_{a_8}=11.5$, and $K=4.1\times10^8$ respectively. A new method for the determination of copper was also established.

Calcichrome, the self-coupling product of H-acid, was recently suggested by Close and West[1] as a selective metallochromic indicator for the complexometric titration of calcium. As the reagent has several points of excellence, for instance, an easy solubility in water and a stability for storage, it has been used for the determination of calcium in various materials by several investigators.[2-5] It has also been found that the reagent can be used as a spectrophotometric reagent for the determination of calcium.[2-4] The applicability of the reagent to the determination of elements other than calcium as a metallochromic or spectrophotometric reagent has not, however, yet been reported. The authors have recently discovered that the reagent reacts to form complexes with many other metals, such as copper(I and II), iron(II and III), aluminum(III), and titanium(IV). The present paper will describe a direct spectrophotometric method for the determination of copper with Calcichrome and the results of a basic study of it, the outline of this work has already been reported in Short Communication.[6]

Experimental

Reagents.—*Calcichrome Solution.* — A Calcichrome solution (2×10^{-3} M) was prepared by dissolving 0.9909 g. of Calcichrome in distilled water and diluting it to 500 ml. Working solutions were prepared from this solution by dilution. The Calcichrome used in this study was synthesized and purified by the method proposed by Close et al.[1] However, as it contains a small amount of chloride and sodium, furhter purification was carried out as follows for use in potentiometric titrations: Calcichrome was dissolved in distilled water, and the resulting solution was passed through a column packed with cation exchange resin, Amberlite IR-120 (H-form), and then evaporated to dryness on a steam bath, followed by drying at 105°C in an air oven. The Calcichrome thus obtained was free from chloride and sodium.

Standard Cupric Solution.—A standard cupric solution corresponding to 1×10^{-2} mol./l. of copper(II) was prepared by dissolving 2.4969 g. of cupric sulfate penta-hydrate in distilled water, by then adding small amounts of sulfuric acid to prevent any possible hydrolysis, and by diluting the mixture to 1 l. Working solutions of copper(II) were prepared from this solution by dilution.

Standard Cuprous Solution.—A standard cuprous solution corresponding to about 1×10^{-2} mol./l. of copper(I) was prepared by dissolving about 1 g. of cuprous chloride

in distilled water containing small amounts of hydrochloric acid, by then adding about 1 g. of hydroxylamine hydrochloride to prevent any possible oxidation, and by diluting the mixture to 1 l. This solution was standardized by the EDTA titration method, using xylenol orange as an indicator. Working solutions of copper(I) were prepared by diluting the standard solution with distilled water.

Buffer Solutions.—Buffer solutions were prepared by mixing 1 M acetic acid and 1 M sodium acetate in the ratios required.

Apparatus. — A Hitachi automatic recording spectrophotometer, model EPS-2, and a Hitachi spectrophotometer, model 139, were used, together with 1 cm. matched cells, for obtaining absorption curves and for all the other absorbance measurements respectively. A Toa Dempa glass-electrode pH meter, model HM-5A, was used for all the pH measurements.

The Proposed Procedure for the Determination.—To a sample solution containing copper in a 50 ml. volumetric flask, 5 ml. of the Calcichrome solution (4×10^{-4} M) and 10 ml. of the buffer solution (pH 5.2) were added. After the solution had then been diluted with distilled water to the mark, the absorbance of the solution was measured at 535 or 310 mμ against a reagent blank treated in a similar manner.

Results and Discussion

Absorption Curves.—The absorption curves of the copper-Calcichrome complex are shown in

Figs. 1-a, 1-b, and 1-c. By comparing Fig. 1-a with Fig. 1-b, it will be found that these two figures are exactly the same. The copper(I)-Calcichrome complex, therefore, can not be distinguished from the copper(II)-Calcichrome complex, and the

species of the complex formed under the conditions studied are one and the same because the maximum absorption wavelengths of the curves obtained against reagent blanks are identical at 535 mμ. (Although curve V in Fig. 1-a or 1-b differs from the others, this is due to the fact that the absorption curve of Calcichrome itself shifts to the long wavelength side). The ultraviolet and visible absorption curves of the copper(II)-Calcichrome complex at pH 5.0 at various ratios of copper and Calcichrome are shown in Fig. 1-c, from which it may be seen that the complex consisting of a 1-to-1 mixture has two absorption maxima in the ultraviolet (λ_{max} 307 mμ) and visible (λ_{max} 565 mμ) regions, one shoulder at about 700 mμ, and two isosbestic points at 415 and 595 mμ respectively. The curves obtained against a reagent blank have three absorption maxima (λ_{max} 310, 535, and 650 mμ). Although these three wavelengths may be used for the determination of copper(II), the sensitivities at the first two wavelengths are higher than that at the last, and approximately the same sensitivity was obtained at the former.

The ultraviolet and visible absorption curves of the copper(I)-Calcichrome complex under the same conditions were exactly the same as those of the copper(II)-Calcichrome complex; they are therefore omitted here. Judging from the results obtained above, the same considerations can be made of the complex between copper(I) and Calcichrome.

The Effect of pH on the Color Development.—The effect of pH on the color development of the copper(II)-Calcichrome complex was examined by measuring the absorbance of the complex at two wavelengths, 310 and 535 mμ, in which cases the concentrations of copper(II) and Calcichrome were made to 4×10^{-5} mol./l. The results are shown in Fig. 2, from which it can be seen that the maximum color development can be obtained in the pH ranges from 5.0 to 6.5 when measured at 310 mμ and from 5.0 to 5.5 at 535 mμ, and that approximately the same color intensity is obtained in these pH regions.

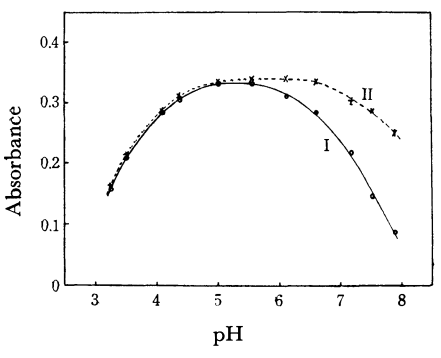

Fig. 2. Effect of pH on absorbance of the Cu(II)-Calcichrome complex.
Concn. of Cu(II): 4×10^{-5} mol./l.
Concn. of Calcichrome: 4×10^{-5} mol./l.
I: at 535 mμ II: at 310 mμ

The effect of pH on the color development of the copper(I)-Calcichrome complex was the same as on that of the copper(II)-Calcichrome complex.

The Effect of the Amount of Calcichrome.—The effect of the reagent concentration on the color development was studied with two series of colored solutions, one of which contained 31.8 μg. of copper(II) (corresponding to 1×10^{-5} mol./l.) and the other, 63.5 μg. of copper(II) (corresponding to 2×10^{-5} mol./l.). The pH values of the solutions were kept constant at 5.2, and the absorbance measurements were carried out at 535 mμ. The results are shown in Fig. 3. For both series, about a 2-fold excess of the reagent over the copper(II) concentration is necessary to obtain the maximum color intensity.

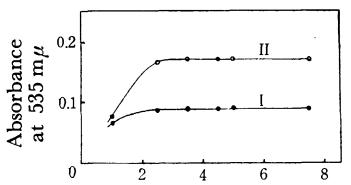

Fig. 3. Effect of amount of Calcichrome.
pH: 5.2, Reference: reagent blank
I: Cu(II), 31.8 μg. II: Cu(II), 63.5 μg.

The same results were obtained when copper(I) was used instead of copper(II). As a compromise between sensitivity and absorbance by the blank solution, 5.0 ml. of a 4×10^{-4} M reagent solution should be used with these copper concentrations.

The Stability of the Color.—The color of the copper(I or II)-Calcichrome complex develops instantaneously at room temperature and is very stable, and there was no change in absorbance over a period of 24 hr.

Adherence to Beer's Law.—The linear relationship between the absorbance and the concentration of copper at 535 mμ was found to be dependent upon the concentration of Calcichrome; Beer's law was obeyed when the molar ratio of copper(II) to Calcichrome was less than about 0.8. The molar extinction coefficient (ε) was about 8×10^3, and the sensitivity was 0.008 μg. Cu(II)/cm^2, which corresponds to log $(I_0/I)=0.001$. Similar results were obtained at 310 mμ.

With the copper(I)-Calcichrome complex, similar results (ε: 8×10^3, sensitivity: 0.008 μg. Cu(I)/cm^2) were obtained.

The Effect of Diverse Ions.—The effect of diverse ions on the determination of copper was examined at pH 5.0. The results are summarised in Table I, from which it can be concluded that aluminum(III), iron(II and III), titanium(IV),

vanadium(V), and zirconium(IV) interfere markedly, even in the smallest amounts, and that nickel(II), oxalate and thiosulfate, also interfere. Among these, the interference by cations seems to be due to the complex formation with Calcichrome under the conditions examined.

The Composition of the Complex.—Attempts to obtain the composition of the complex were made by two methods, the continuous variation method and the mole ratio method. These attempts were performed at pH 5.2, and the absorbance measurements were made at three wavelengths between 510 and 545 mμ. Both methods revealed that copper(I or II) forms a 1-to-1 complex with Calcichrome. These findings were further confirmed by the experiments described below. As an example, the results obtained by the application of the continuous variation method to the copper(II)-Calcichrome complex are shown in Fig. 4-a, and those obtained by the application of the mole ratio method to the copper(I)-Calcichrome complex, in Fig. 4-b.

The Potentiometric Titration of Calcichrome and Its Copper Complex. — The potentiometric titration of Calcichrome and its copper(II) complex were carried out in order to establish the mechanism of the reaction between Calcichrome and copper, in which case the concentrations of Calcichrome and copper(II) were made to 5×10^{-4} mol./l. the ionic strength was kept constant at 0.1 using a sodium chloride solution and the titration was carried out at 25°C with a 0.3 N potassium hydroxide solution. The results are shown in Fig. 5, in which the curves I and II show the titration curves of Calcichrome and

II: Copper(II)-Calcichrome complex

its 1-to-1 copper(II) complex respectively. From Fig. 5 it may be noticed that Calcichrome dissociates to liberate five protons up to about pH 5 (point a) that a) sixth proton is liberated up to about pH 8.5 (point b), and that the sixth proton is also liberated in the complexation. According to the constitutional formula of Calcichrome proposed by Close et al.[1] or Lukin et al.[2], six sulfonic radicals are contained in one molecule of Calcichrome. Taking into consideration of the facts described above, it is considered that sulfonic radical may participate in the complexation. However, the dissociation of sulfonic radicals are generally considered to occur in the lower pH region due to their strongly acidic properties as are seen in the cases of the dissociations of Chromotropic acid and its derivatives. Therefore, there remain some doubts to be concluded directly from the results of the potentiometric titration alone that sulfonic radical may participate in the complexation and further studies should be carried out to solve the problem.

Aside from the experimental results obtained above, the authors considered here on the basis of the general consideration that the group which participate in the complexation is hydroxyl radical rather than sulfonic. Therefore, it may be considered that the dissociation of Calcichrome is shown by Eq. 1, and that copper(II) and/or copper(I) is combined with a hydroxyl radical in the Calcichrome molecule, the reaction in this case being shown by Eq. 2 or 3:

$$H_9Cch^0 \rightleftarrows H_{9-m}Cch^{m-} + mH^+ \quad (1)$$

$$H_3Cch^{6-} + Cu^{2+} \rightleftarrows CuH_2Cch^{5-} + H^+ \quad (2)$$

$$H_3Cch^{6-} + Cu^{+} \rightleftarrows CuH_2Cch^{6-} + H^+ \quad (3)$$

The Effect of pH on the Absorbance of Calcichrome.—The effect of pH on the absorbance of Calcichrome was examined. Here the concentration of Calcichrome was 4×10^{-5} mol./l., the ionic strength was kept constant at 0.25 using a sodium chloride solution, and the absorbance measurements were carried out at 630 mμ. The results are shown in Fig. 6, from which it will be found that three

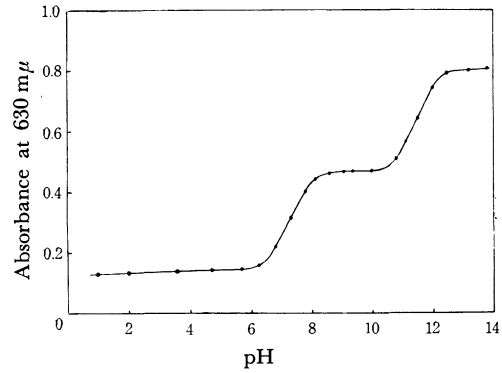

Fig. 6. Effect of pH on absorbance of Calcichrome.

Concn. of Calcichrome: 4×10^{-5} mol./l.
Ionic strength: 0.25

ionic species are present under the conditions examined. Taking account of the discussions described above, these three species are considered to correspond to H_3Cch^{6-}, H_2Cch^{7-}, and $HCch^{8-}$ respectively.

The Acid Dissociation Constant of Calcichrome.—As has been described already, Calcichrome is dissociated as shown by Eq. 1. The seventh and eighth acid dissociation constant, K_{a_7} and K_{a_8}, are:

$$K_{a_7} = [H_2Cch]\,[H]/[H_3Cch] \quad (4)^*$$

$$K_{a_8} = [HCch]\,[H]/[H_2Cch] \quad (5)^*$$

Therefore,

$$pK_{a_7} = pH - \log[H_2Cch]/[H_3Cch] \quad (6)^*$$

$$pK_{a_8} = pH - \log[HCch]/[H_2Cch] \quad (7)^*$$

As the concentrations are proportional to the absorbances, pK_{a_7} and pK_{a_8} are given by the following equations:

$$pK_{a_7} = pH - \log(E_1 - E)/(E - E_2) \quad (8)$$

$$pK_{a_8} = pH - \log(E_2 - E')/(E' - E_3) \quad (9)$$

in which E_1, E_2, and E_3 are the absorbances of H_3Cch^{6-}, H_2Cch^{7-}, and $HCch^{8-}$ respectively at a constant wavelength, and E and E' are the absorbances of the solutions, consisting of H_3Cch^{6-} and H_2Cch^{7-}, and H_2Cch^{7-} and $HCch^{8-}$ respectively, at arbitrary pH values.

The actual examinations were carried out as follows: The concentration of Calcichrome was

* Electronic charges were omitted for the sake of simplicity.

maintained at a constant value, 4×10^{-5} mol./l., and suitable amounts of a disodium hydrogen phosphate - potassium dihydrogen phosphate buffer solution (for the determination of pK_{a_7}) or a 0.1 N sodium hydroxide solution (for the determination of pK_{a_8}) were added to give seven arbitrary pH values between 6.60 and 8.00, or between 10.80 and 11.90, respectively. In both cases, suitable amounts of a sodium chloride solution were added to keep the ionic strength (μ) constant at 0.1. The absorbance measurements were then carried out at 630 mμ. The pK_{a_7} and pK_{a_8} values were calculated from Eqs. 8 and 9 respectively, and the average values of the seven runs are shown in Table II.

TABLE II. pK_{a_7} AND pK_{a_8} OF CALCICHROME

pK_{a_7}	7.2	(μ=0.1, 27°C)
pK_{a_8}**	11.5	(μ=0.1, 23°C)

The Equilibrium Constant.—From the results described above, it seems obvious that copper reacts with Calcichrome to form a 1-to-1 complex and that one proton is liberated as the result of deprotonation during the complex formation. Independent of these facts, on the other hand, the following assumptions and the related examinations were made in order to obtain the equilibrium constant, and also to confirm the facts described above. If the reaction between Calcichrome and copper is obeyed to Eq. 10,

$$Cu^{2+} + H_{9-n}Cch^{n-} \rightleftarrows CuH_{9-(n+m)}Cch^{(n+m)-} + mH^+ \quad (10)$$

the total absorbance at equilibrium, D, is:

$$D = \varepsilon_1(a-x) + \varepsilon_2(b-x) + \varepsilon x \quad (11)$$

where ε_1, ε_2, and ε are the molar extinction coefficients of copper, Calcichrome, and the complex respectively, a and b are the initial concentrations of copper and Calcichrome respectively, and x is the concentration of the complex at equilibrium. As ε_1 is equal to 0, and so may be neglected under these conditions, Eq. 11 can be rearranged to:

$$D = \varepsilon_2(b-x) + \varepsilon x \quad (12)$$

The equilibrium constant, K', may be defined as Eq. 13:

$$K' = [CuH_{9-(n+m)}Cch][H]^m/[Cu][H_{9-n}Cch] = x[H]^m/(a-x)(b-x) \quad (13)^*$$

If the initial concentration of copper, a, is chosen to be equal to that of Calcichrome, Eq. 13 can be rearranged to:

$$K' = x[H]^m/(b-x)^2 \quad (14)$$

By introducing Eq. 12 into Eq. 14, Eq. 15 is obtained:

$$a/(D-D') = 1/(\varepsilon-\varepsilon_2) + \{1/K'(\varepsilon-\varepsilon_2)\}^{1/2}\{[H]^m/(D-D')\}^{1/2} \quad (15)$$

where D' is the absorbance of the reagent blank. When experiments are carried out under suitable conditions and the experimental values of $a/(D-D')$ are plotted against the values of $\{[H]^m/(D-D')\}^{1/2}$, and if the assumption of the value of m is correct, the plots give straight lines with a slope of $\{1/K'(\varepsilon-\varepsilon_2)\}^{1/2}$ and an intercept of $1/(\varepsilon-\varepsilon_2)$.

The actual experiments were carried out under the following conditions. The concentrations of Calcichrome and copper were kept at the same concentration (2×10^{-5} M), the ionic strengths of the solutions were kept at 0.1 with an acetic acid - sodium acetate buffer solution which was added to each solution in order to control the pH value, and the absorbance measurements were carried out at 525, 535, and 545 mμ on six solutions of different pH values between 3.91 and 4.63. The results obtained by plotting the experimental values of

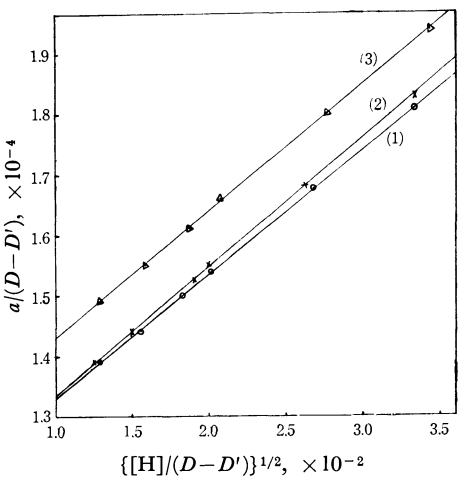

Fig. 7-a. Plots of $a/(D-D')$ vs. $\{[H]/(D-D')\}^{1/2}$ at various wavelengths (in the case of $m=1$). (1): at 535 mμ, (2): at 525 mμ, (3): at 545 mμ

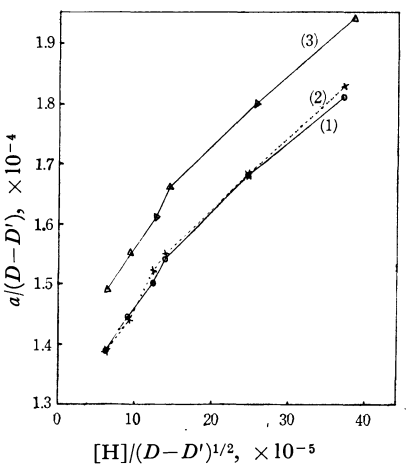

Fig. 7-b. Plots of $a/(D-D')$ vs. $[H]/(D-D')^{1/2}$ at various wavelengths (in the case of $m=2$). (1): at 535 mμ, (2): at 525 mμ, (3): at 545 mμ

Table III. Slope and intercept of lines and equilibrium constant (in the case of $m=1$)

Wavelength	at 535 mμ	at 525 mμ	at 545 mμ	Average
Slope	2.07×10^{-3}	2.12×10^{-3}	2.11×10^{-3}	2.10×10^{-3}
Intercept	1.12×10^{-4}	1.12×10^{-4}	1.22×10^{-4}	1.15×10^{-4}
K'	26.1	24.9	27.4	26.1

$a/(D-D')$ against the values of $\{[H]^m/(D-D')\}^{1/2}$ are shown in Figs. 7-a and 7-b. As may be seen from Fig. 7-a, when the value of m was assumed to be unity, the plots gave straight lines with a slope of 2.10 (on the average). When another value, e. g., two, was assumed for m, however, no straight lines were obtained (shown in Fig. 7-b). Therefore, it may be concluded that one proton is liberated during the complex formation and that the copper-Calcichrome complex formed at the investigated pH value has a molar ratio of 1 to 1. The slopes and the intercepts of lines indicated in Fig. 7-a, which were calculated by the method of least squares, are shown in Table III. The equilibrium constant, K', calculated from these values is also shown in Table III.

The Apparent Formation Constant.—The apparent formation constant, K, was then calculated by Eq. 16 using the values of the acid dissociation constant, pK_{a_7}, and the equilibrium constant, K', already obtained. The value of 4.1×10^8 was obtained as the value of K:

$$K = [CuH_2Cch]/[Cu][H_2Cch] = K'/K_{a_7} \qquad (16)^*$$

which shows a fair stability of the complex.

Summary

The reaction between copper(I or II) and Calcichrome has been studied spectrophotometrically in order to establish the optimum conditions for the determination of copper. In the pH range approximately from 3 to 8, copper(I or II) reacts with Calcichrome to form a stable bluish-violet 1-to-1 complex. The complex has three absorption maxima, at 310, 535, and approximately at 650 mμ, when measured against a reagent blank. Beer's law is obeyed when the molar ratio of copper to Calcichrome is less than about 0.8. The molar extinction coefficient of the complex has been calculated to be 8000. The acid dissociation constants of Calcichrome (pK_{a_7} and pK_{a_8}) and the apparent formation constant (K) were 7.2 and 11.5 ($\mu=0.1$), and 4.1×10^8 respectively. Many other metals, such as aluminum(III), iron(II and III), titanium (IV), vanadium(V) and zirconium(IV), interfere with the determination.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1160—1163 (1966)

The Behavior of Polonium Evaporated from Fused Salt

By Yuichiro KAMEMOTO and Shigeru YAMAGISHI

Division of Fuel Research and Development, Japan Atomic Energy Research Institute, Tokai, Ibarki, Japan

(Received August 16, 1965)

Studies were made of the evaporation of polonium from a fused potassium chloride - lithium chloride mixture and of the deposition of the evaporated polonium on several metal plates under different temperatures. Approximately 100% of the polonium evaporates, probably as polonium tetrachloride, from the fused salt at the fused salt temperature higher than 500°C when heated for 3 hr. in an argon atmosphere. The evaporated polonium deposited on copper, platinum, palladium and silver plates which were held over the fused salts. The relationship between the percentage of polonium evaporated from these metal plates and the temperature shows that the polonium deposits on these metal plates as elementary polonium or polonide.

Polonium-210 can easily be obtained by separating it from the neutron-irradiated bismuth, the reaction involved being $^{209}Bi\ (n, \gamma)^{210}Bi \xrightarrow{\beta^-\text{-decay}} {}^{210}Po$. The present authors previously studied the extraction of polonium from the irradiated bismuth, using a fused salt, and reported the distribution of polonium between the fused potassium chloride - lithium chloride (eutectic) mixture and the fused bismuth metal.[1] It was found that the polonium in the fused salt was easily evaporated

1) Y. Kamemoto and S. Yamagishi, *J. At. Energy Soc. Japan*, **6**, 500 (1964).

and was removed more rapidly from the fused bismuth metal in contact with fused salt than from that not in contact with fused salt. If the polonium evaporated from the fused salt - fused bismuth system could be collected, this system would be a useful method of separating polonium from the irradiated bismuth.

The evaporation of polonium from the fused potassium chloride - lithium chloride mixture and the deposition of the evaporated polonium on several metal plates were examined under different temperatures, using polonium-210 as the tracer.

Experimental

Reagents.—*Potassium Chloride - Lithium Chloride Eutectic Mixture.*[2]—Potassium chloride and lithium chloride were separately dried by slow heating at 120°C, cooled in a vacuum desiccator, and mixed in the eutectic ratio. The product was fused in an anhydrous hydrogen chloride atmosphere, and the hydrogen chloride was removed from the melt by passing through it purified argon gas. The melt was solidified by pouring it into carbon tetrachloride.

Polonium Tracer.—Polonium-210 was separated by the ion exchange method[3] from a solution of Ra-D, -E and -F extracted from a radon tube. This method involves the adsorption of Ra-D, -E and -F on the anion exchange resin, the elution of Ra-D with a 2 M hydrochloric acid solution, the elution of Ra-E with a 10 M hydrochloric acid solution, and the elution of Ra-F(Po) with a nitric acid solution. The final eluate was evaporated several times with hydrochloric acid, and the residue was dissolved in dilute hydrochloric acid.

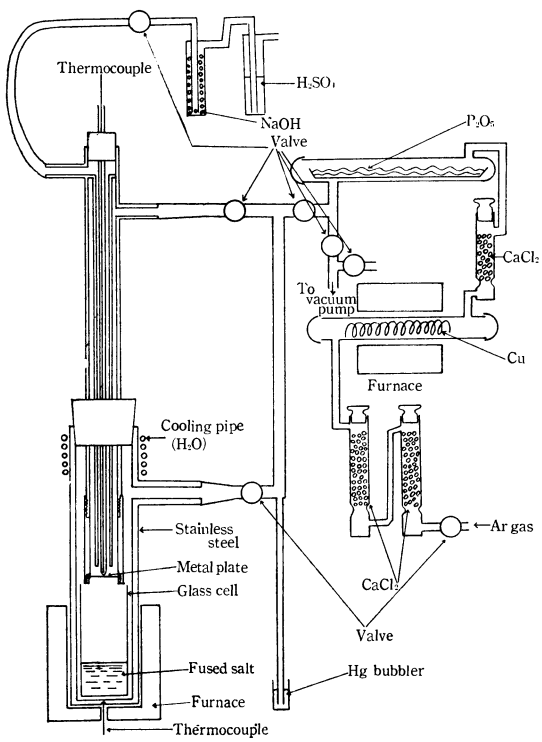

Fig. 1. Experimental apparatus.

Experimental Apparatus.—The apparatus is shown in Fig. 1. The evaporation vessel consists of two cells, an outer, stainless steel cell and an inner, glass cell. The metal plate (24 mm. in diameter) is held over the inner cell with a stainless stell holder. The temperatures of the plate and the fused salt are measured by thermocouples and kept constant by a temperature controller.

Experimental Procedure.—A tenth of a ml. of a polonium tracer solution was added to 10 g. of the potassium chloride - lithium chloride mixture in the inner cell, which was dried by slow heating under reduced pressure. After this inner cell had been placed in the outer cell, as is shown in Fig. 1, the air in the outer and the inner cell was replaced with argon gas, which had been purified by calcium chloride, phosphorus pentoxide, and copper net heated at 350°C. The fused salt, containing polonium-210, was then heated at a certain temperature for 3 hr. under a pressure slightly higher than 1 atm. After cooling, the polonium remaining in the salt was determined and the percentage of polonium evaporated was calculated.

The amount of polonium deposited on the metal plate was also determined, and the percentage of polonium deposited was calculated. The metal plates were disks (24 mm. in diameter) of copper, platinum, palladium and silver.

The metal plate on which polonium had deposited upon the evaporation was held at the middle point in the outer cell with a quartz holder and heated at certain temperatures for 1 hr. in an argon atmosphere; the amount of polonium evaporated was then measured.

Procedure for the Determination of the Polonium.—The amount of polonium deposited on the disk was determined by α-ray counting with a proportional 2π counter.

The polonium remaining in the salt was determined by dissolving the salt in dilute nitric acid, pouring a 10-ml. portion into the cell shown in Fig. 2, depositing spontaneously the polonium on a silver plate by stirring the solution for 1 hr., and counting the alpha activity.

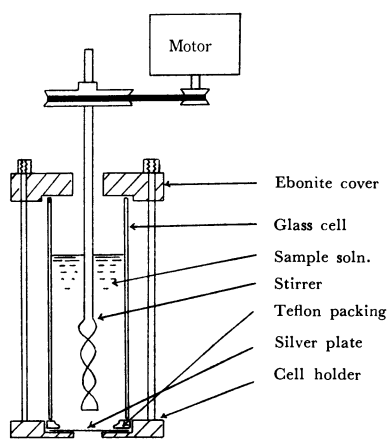

Fig. 2. Apparatus for spontaneous deposition of polonium.

3) T. Ishimori, This Bulletin, **28**, 432 (1955).

Results

The Evaporation of Polonium from the Fused Potassium Chloride-Lithium Chloride.—The relationship between the temperature of fused salt and the percentage of polonium evaporated is shown in Fig. 3. Approximately 100% of the polonium evaporated from the fused salt at a temperature higher than 500°C within 3 hr. in an argon atmospher.

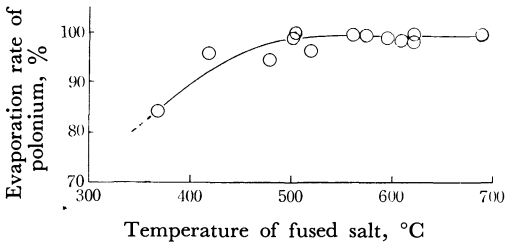

Fig. 3. Evaporation of ^{210}Po from fused salt in argon atmosphere.

The Deposition of Evaporated Polonium on Metal Plates.—The deposition of the polonium evaporated from the fused salt on copper, platinum, palladium and silver plates was determined at various temperatures. The results are shown in Figs. 4—7.

The deposition of polonium on the copper plate decreases with an increase in the temperature of the plate. However, polonium was not deposited on the platinum, palladium and silver plates at temperatures lower than about 290, 300 and 250°C respectively. The amounts of polonium deposited on platinum, palladium and silver plates are constant in the regions between 290—480, 300—400 and 250—425°C respectively, but decrease sharply at higher temperatures.

The Evaporation of the Polonium Deposited on the metal Plates.—The relationship between the amounts of polonium evaporated from metal plates and their temperatures is given in Fig. 8. The evaporation originates at the critical deposition temperatures of polonium (Figs. 4—7). This appears to indicate that the decrease in the percentage of polonium deposited is due to the partial evaporation of polonium from the metal plates.

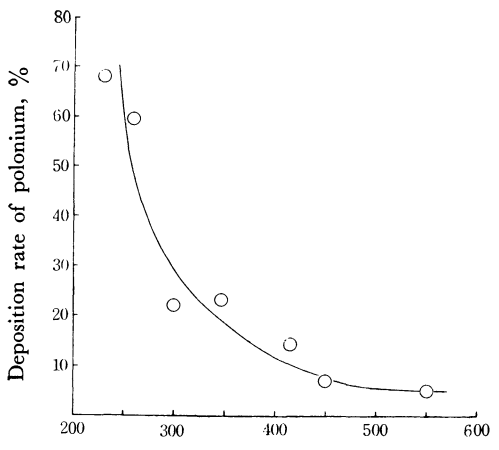

Fig. 4. Deposition of ^{210}Po on copper metal.

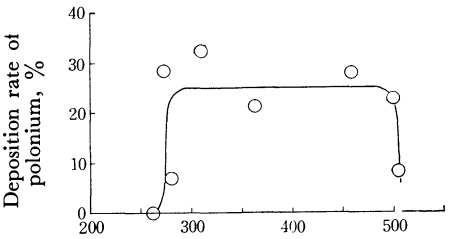

Fig. 5 Deposition of ^{210}Po on platinum metal.

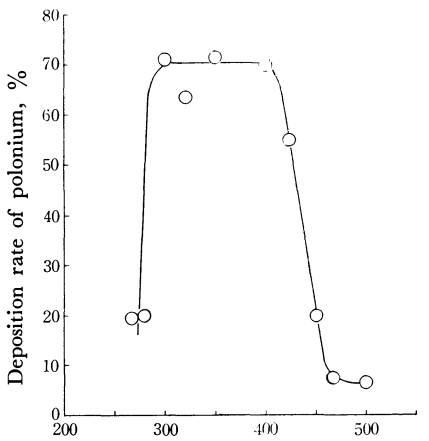

Fig. 6. Deposition of ^{210}Po on palladium metal.

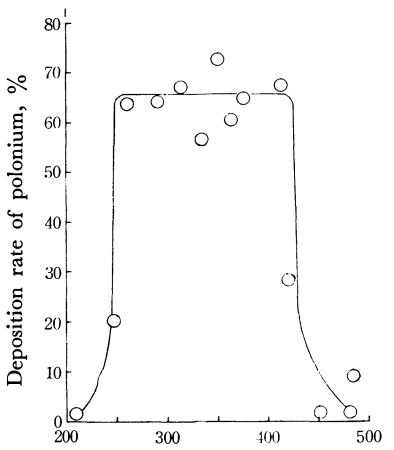

Fig. 7. Deposition of ^{210}Po on silver metal.

Discussion

In the polonium solution extracted from a radon tube, polonium probably exists as tetrachloride,

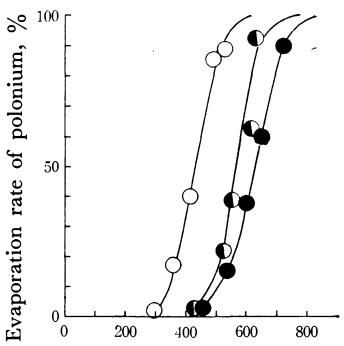

Fig. 8. Evaporation of ^{210}Po from metal plate in argon atmosphere.
○ Cu ● Ag ◐ Pt

because polonium tetrachloride[4-6] is produced by evaporating a solution obtained by dissolving metallic polonium in hydrochloric acid. Thus the fused potassium chloride - lithium chloride mixture, to which this tracer solution has been added, seems to contain polonium in the same form at a low temperature. From this fused salt, polonium is completely evaporated at 500°C in an argon atmosphere under our experimental conditions. The evaporated polonium can not be in the form of polonium dioxide or polonium metal, because neither compound seems to evaporate at this temperature (polonium dioxide sublimes at 885°C and the polonium metal boils at 962°C). The vaporized polonium may be polonium tetrachloride, as its boiling point is 390°C, near to the vaporization temperature experimented with.

Paneth and Hevesy[7-8] reported that almost all the polonium was condensed on a palladium or platinum foil when trace amounts of polonium were distilled in a quartz tube in the flow of a gas and the foil was placed in the cold region of the tube. However, in our experiment, the polonium evaporated from the fused salt was not deposited at a low temperature, but it was deposited at higher temperatures. These results suggest that the polonium evaporated from fused potassium chloride - lithium chloride is not metallic polonium but some polonium compound (probably polonium tetrachloride). This compound seems to be deposited on the metal plate by some reaction and not by adsorption.

Platinum polonide and silver polonide decompose at 450—600°C and approximately 559°C respectively.[7,9] These decomposition temperatures agree with the respective evaporation temperatures of the polonium deposited on platinum and silver metal by our technique using the fused salt. On the other hand, Abe et al. studied the evaporation of polonium-210, at several temperatures and in an argon atmosphere, from certain metal plates on which polonium had spontaneously deposited from a dilute nitric acid solution.[10] Their findings on the relationship between the percentage of polonium evaporated and the temperature of the metal plate are shown in Fig. 9. The evaporation curves of polonium from copper and silver plates, in Figs. 8 and 9, are similar to each other. This shows that the polonium evaporated from the fused salt deposits on the copper and the silver plates in the same form as that spontaneously deposited from a dilute nitric acid solution. It has been thought that the chemical form of the spontaneously-deposited polonium is elementary. From these observations, it seems that the polonium evaporated from the fused potassium chloride - lithium chloride mixture deposits on the metals as elementary polonium or polonide.

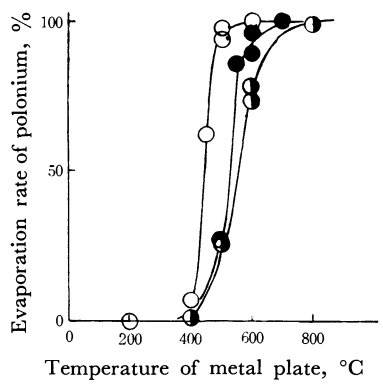

Fig. 9. Evaporation of ^{210}Po deposited spontaneously on metal plate.
○ Cu ● Ag ◑ Ni

On the basis of the arguments presented above, the following explanation can reasonably be made of our results. Polonium is evaporated from the fused potassium chloride - lithium chloride mixture as polonium tetrachloride and deposits on several metals as elementary polonium or polonide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1164—1167 (1966)

Studies on the Chemical Decomposition of Simple Sugars. XVII. Pyruvic Acid Formation from D-Glucose-6-^{14}C*

By Sinichi OTANI**

Chemistry Institute, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received November 29, 1965)

The formation of pyruvic acid from D-glucose-6-^{14}C in a concentrated potassium acid phosphate buffer solution (40%, pH 6.6), was studied. It was found that the C-6 of the glucose was converted into the methyl carbon of pyruvic acid. In view of the formation of pyruvic acid from D-glucose-1-^{14}C, the C-1 and C-6 of the glucose were converted into the methyl carbon of pyruvic acid. This reaction mechanism was similar to that of the formation of acetol (J. Hayami, This Bulletin, **34,** 927 (1961)). The mechanism presented may be summarized as follows: 1) The formation of α-diketose by β-hydroxy-carbonyl elimination after isomerization to 3-ketose or 4-ketose. 2) The formation of acetylformoin by a second β-hydroxy-carbonyl elimination after isomerization to the β-diketose. 3) The hydrolytic cleavage of the acetylformoin.

The formation of pyruvic acid from carbohydrate has never been well studied because of its instability, the low yield, and the difficulty of isolation. Nodzu et al.[1] found pyruvic acid as the 2, 4-dinitrophenylhydrazone in the decomposition of D-glucose, and proposed[2] a mechanism of pyruvic acid formation in which acetylformoin was included as a direct precursor of pyruvic acid. Recently, Hayami et al.[3] effectively used ^{14}C-labeled sugars and methylated sugars for an investigation of the formation of acetol which was formed along with pyruvic acid, and presented a mechanism of the formation of pyruvic acid. In the preceding report,[4] the formation of pyruvic acid from D-glucose-1-^{14}C was examined. The degradation of the alanine which had been derived from pyruvic acid 2, 4-dinitrophenylhydrazine revealed that the C-1 of the D-glucose was converted into the methyl carbon of pyruvic acid.

In the present study, D-glucose-6-^{14}C was decomposed and the relative distribution of a label in the pyruvic acid was determined in order to obtain further evidence of the mechanism of pyruvic acid formation.

Experimental

The Assay Method of Radioactivity.—A sample was converted into barium carbonate by Van Slyke-Folch wet combustion. The barium carbonate was collected on filter paper and counted in an infinite thickness with a 2π-gas flow counter.

The Decomposition of D-Glucose-6-^{14}C.—D-Glucose-6-^{14}C (20 g.) in 200 ml. of a concentrated potassium acid phosphate buffer solution (40%, pH 6.6) was heated and distilled in a way described earlier.[4]

The Isolation of Crude Pyruvic Acid 2, 4-Dinitrophenylhydrazone, and the Reduction of Pyruvic Acid 2, 4-Dinitrophenylhydrazone to Alanine.—These procedures were also carried out in ways described earlier.[4]

The Purification of Alanine.—The crude alanine (16 mg.) was recrystallized from ethanol.

The Degradation of Alanine.—The experiment was carried out in a way described earlier,[4] using 80 mg. of active alanine.

Results and Discussion

In the case of D-glucose-6-^{14}C, radioactivity was mostly found in the methyl carbon of the alanine. This means that the C-6 of D-glucose was converted into the methyl carbon of pyruvic acid. Considering the findings regarding D-glucose-1-^{14}C in the preceding report,[4] it may be concluded

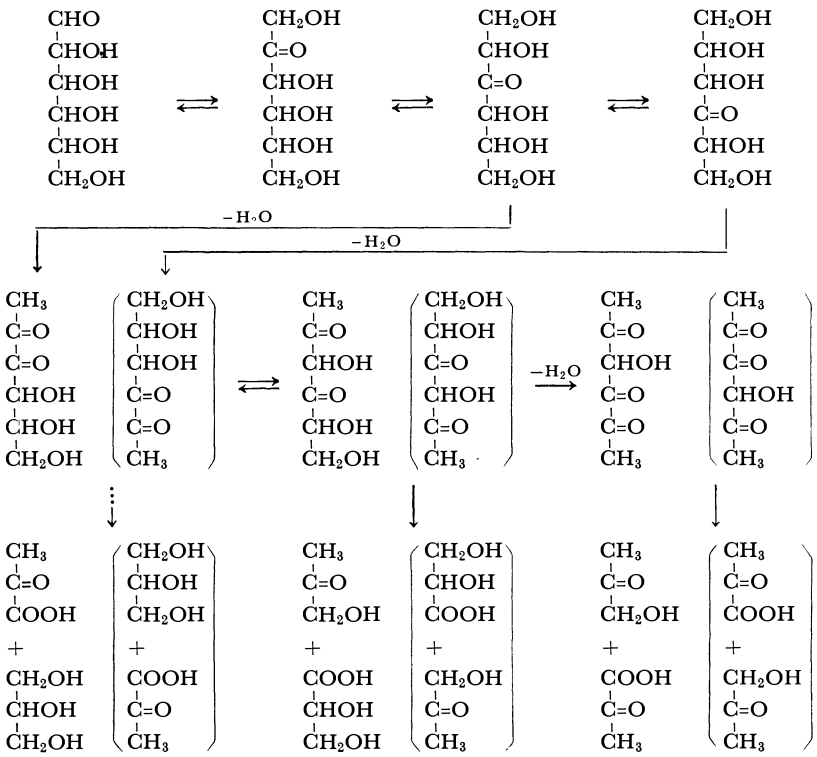

Scheme 1

that the C-1 and C-6 of the glucose were converted into the methyl carbon of pyruvic acid.

In the case of acetol,[3] along with the formation of pyruvic acid, the C-1 and C-6 of the original glucose were converted into the methyl carbon of the acetol, and the C-3 and C-4 of the original glucose were converted into the hydroxymethyl carbon of the acetol. In addition, the acetol-1-^{14}C, which was formed from D-glucose-3, 4-$^{14}C_2$, was found to preserve the molar radioactivity of the original glucose. Therefore, in the formation of acetol, the C-1, 2, 3 and the C-4, 5, 6 portions of the original glucose behaved as units; no skeletal rearrangement in these C_3 units was involved.

Considering the simultaneous formation of acetol and of pyruvic acid from glucose,[1] it seems quite possible that pyruvic acid is formed by a mechanism similar to that of acetol. The mechanism of the pyruvic acid formation can be expressed as shown in Scheme 1.

3-Ketose or 4-ketose, formed by the enolization-ketonization route, is subjected to dehydration by β-hydroxycarbonyl elimination. This conclusion is based on the facts that the methyl carbon of pyruvic acid[4] and of the acetol[3] was found to be converted from the terminal carbon atoms, and that the acetol formation[3] was depressed in the case of 3-*O*-methyl-D-glucose, whereas it was accelerated in the cases of 1-*O*-methyl-D-fructose and 6-*O*-methyl-D-glucose.

The first three steps are known as the Lobry de Bruyn - Alberda van Ekenstein transformation.[5] Since Lobry de Bruyn et al.[6] found the transformation between glucose, mannose and fructose in aqueous alkaline solutions in 1895, the transformation reactions of most reducing sugars have been studied, and the transformation has been recognized to proceed through 1, 2-enediol. Later, transformations by C-3- and C-4-epimerization were observed. For instance, Hough et al.[7] observed the formation of D-psicose from D-glucose by the action of ammonia. Sowden et al.[8] isolated (DL+D)-sorbose from the transformation products of D-glucose in the presence of a strong basic ion-exchange resin.* This means that enolization-ketonization proceeds

* It was thought that (DL+D)-sorbose could be formed by the aldol condensation of the glyceraldehyde and dihydroxyacetone formed by the fragmentation. In fact, glyceraldehyde gave DL-sorbose and DL-fructose in the presence of alkali.[9] Sowden et al.[10] isolated (DL+D)-sorbose-1-^{14}C from the reaction mixture of D-glucose-1-^{14}C, and from the relative distribution of a label of the enantiomorphs they obtained data showing that the racemic ketose was formed almost exclusively by the enolization-ketonization mechanism, while the fragment-recombination played only a minor role in the isomerization.

through all of the secondary carbon atoms of the chain. Therefore, 1, 2-, 2, 3-, 3, 4-, 4, 5-enediols are possible intermediates in the alkaline isomerization of hexose.

The transformation reaction is usually studied in the presence of bases and placed in the category of alkaline isomerizations, and a sugar is considered to proceed in the form of an anion. However, some instances were found in the presence of acid. This is understandable in view of the facts that the enolization is subjected to a general acid and base catalysis and that the transformation proceeds via enolization.[5] For instance, Ost[11] and Ohno et al.[12] reported the isomerization of D-glucose into D-fructose in dilute sulfuric acid at room temperature. Petuely,[13] observing the isomerization between D-glucose and D-fructose in an acid-catalyzed reaction, considered the protonated sugars to be reaction intermediates. In the formation of the furfural derivatives in the presence of acids, 1, 2-enediol is generally thought to be formed in the first step[14]; in this case, protonation has to be thought of as an important reaction process. Spoehr et al.[15] observed the transformation between D-glucose, D-mannose and D-fructose in a disodium hydrogen phosphate buffer solution (pH 6.69). Ashmarin et al.,[16] using acetate, succinate and formate buffers at pH 4.2, found D-glucose to be transformed to D-fructose. Englis et al.[17] heated D-glucose in a potassium dihydrogen phosphate solution (pH 6.4—6.6) in an autoclave and observed the formation of ketoses the main part of which was D-fructose. Wolfrom et al.[18] obtained (DL+D)-sorbose and (DL+D)-allose from D-fructose in an aconitic acid - potassium hydroxide system (initial pH 8.00; after 24 hr., pH 6.15). In addition to these results, the author observed that D-fructose was formed from D-glucose by heating it in the same medium for one or two hours under the same conditions as those in which pyruvic acid and acetol were formed.[19] From these results, enolization-ketonization can be considered to occur in the present experimental conditions. The mechanism of enolization-ketonization in these nearly neutral solutions has been little discussed. However, Ashmarin et al.[16] proposed that anions of the weak acids were acting as bases, according to Brønsted's conception.

Lobry de Bruyn et al.[6] obtained an unfermentable reducing substance, which they called glutose, as a 3-ketose in an alkali-isomerization mixture of glucose or fructose. Sattler et al.,[20] however, observed that the glutose from D-fructose was a mixture of fructose anhydride and difructose dianhydride. Recently, Sera[21] reported that the so-called "glutosazone" was an impure glucosazone. Thus, 3-ketose has never been proved directly to be formed in an isomerization reaction. When Schaffer synthesized[22] D-manno-3-heptulose and isomerized[23] it in a diluted calcium hydroxide solution at room temperature for a week, he could not detect it in the reaction solution. Stoodley[24] and Sera[25] synthesized a 3-ketopentulose, 3-xylulose. They observed that 3-xylulose was very unstable and that it was easily converted into *erythro*-2-pentulose and *threo*-2-pentulose, even without alkali.* These facts showed that 3-ketose was reactive under the conditions of the Lobry de Bruyn-Alberda van Ekenstein transformation and that the direct detection of 3-ketose in the transformation reaction was impossible.

The next reaction, dehydration by β-hydroxycarbonyl elimination, is generally observed in carbohydrate chemistry. The formation of saccharinic acids[27] in the presence of bases is explained by a benzylic acid-type rearrangement after the dehydration. The formation of furfural derivatives in the presence of acid is also explained by the dehydration.[14,28] Under the present experimental conditions, methylglyoxal was formed from glyceraldehyde by the same type of dehydration.[1]

The α-diketose thus formed isomerizes to the β-diketose without being subjected to the benzylic acid-type rearrangement, and acetylformoin is formed by the second dehydration by β-hydroxycarbonyl elimination. About the isomerization of α-diketone to β-diketone, Hesse et al.[29] recognized that pentane-2-ol-3, 4-dione isomerized

to pentane-3-ol-2, 4-dione in the presence of proton or hydroxide ion, and reported the isomerization between butane-1-ol-2, 3-dione, butane-2-ol-1, 3-dione, and butane-3-ol-1, 2-dione. Simon,[30] using ^{14}C-labeled sugars, proposed a mechanism including α-diketose $\rightarrow$ β-diketose $\rightarrow$ acetylformoin processes in the formation of 2, 4-dihydroxy-3-piperidino-5-methyl-2-cyclopentanone from 1-deoxy-1-piperidino-D-fructose.

The last step is the hydrolytic cleavage of acetylformoin to form pyruvic acid and acetol. Acetylformoin was synthesized by Nodzu et al.,[31] and found to give pyruvic acid and acetol in a good yield.[32] Compounds with a structure similar to acetylformoin were found to be cleft. For instance, Combes[33] observed the formation of acetol from pentane-3-ol-2, 4-dione by alkali. Blatt et al.[34] and Karrer et al.[35] reported that dibenzoylcarbinol gave benzoylcarbinol and benzoic acid by the use of sodium hydroxide or sodium carbonate. Juni et al.[36] also observed that 3-methylpentane-3-ol-2, 4-dione gave butane-2-ol-3-one and acetic acid by sodium hydroxide. House et al.[37] confirmed the formation of propionic acid and pentane-2-ol-3-one by the sodium hydroxide cleavage of 4-methylheptane-4-ol-3, 5-dione. The hydrolytic cleavage of the carbon-carbon bond between the C-3 and C-4 in the β-diketose stage was the acetol formation process proposed by Hayami et al.[3] The cleavage in the stage of the α-diketose may be conjectured to take place and to give pyruvic acid and glycerin, but there is no experimental data for it. In the case of D-glucose-1-^{14}C,[4] compared with the molar radioactivity of the original labeled glucose and that of the alanine, the lower half of the D-glucose contributed to the formation of the pyruvic acid more than the upper half. The result is compatible with the mechanism in which the acetylformoin is a precursor of pyruvic acid and the acetol, because 3-ketose is thought to be more favorable than 4-ketose in the isomerization reaction.

Thus, the formation of the pyruvic acid can be summarized as follows:

1) The formation of α-diketose by β-hydroxy-carbonyl elimination after isomerization to 3-ketose or 4-ketose.

2) The formation of acetylformoin by a second β-hydroxy-carbonyl elimination after isomerization to the β-diketose.

3) The hydrolytic cleavage of the acetylformoin.

Compared with other carbohydrate reactions in solution, the furfural formation requires neither the transformation nor the benzylic acid - type rearrangement; the saccharinic and the isosaccharinic acid formations need both the *trans*-formation and the rearrangement, and the metasaccharinic acid formation needs the rearrangement, but no transformation. In the present case, it seems probable that the transformation is required without the rearrangement.

The author wishes to express his thanks to Professor Ryozo Goto for his helpful guidance and encouragement, and to Dr. Jun'ichi Hayami for his kind suggestions throughout the course of this work.

The Thermal Treatment of Dibenzanthronyls

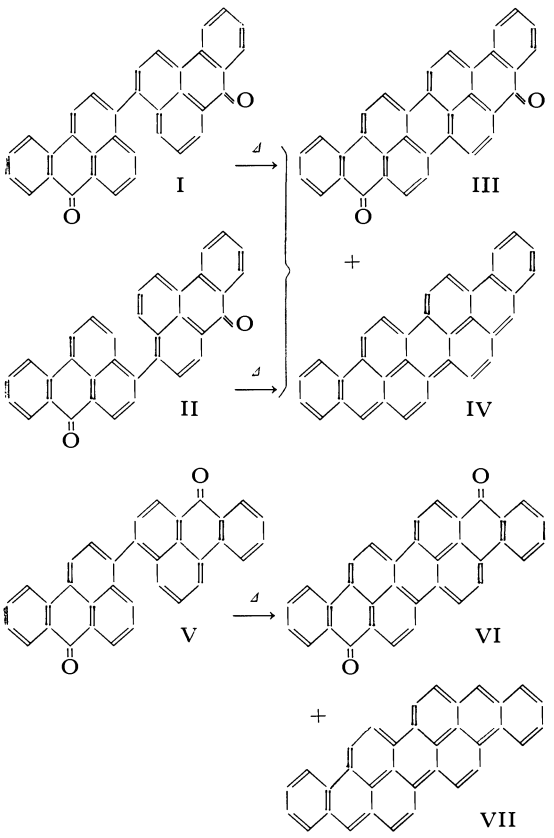
By Yoshio NAGAI and Kotaro NAGASAWA

The Institute of Industrial Science, The University of Tokyo, Azabu, Tokyo

(Received August 27, 1965)

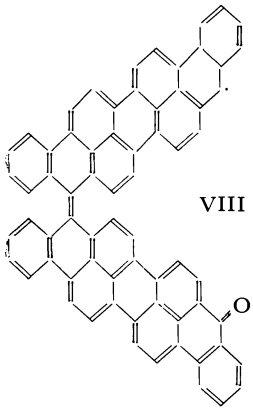
The ring closure of 3, 3'-dibenzanthronyl to form dibenzanthrone was previously effected by means of homogeneous melting at 430°C in an open vessel or in vacuo (Y. Nagai et al., *J. Chem. Soc. Japan, Ind. Chem. Sect. (Kogyo Kagaku Zasshi)*, **67**, 1977 (1964)). In this report, the thermal treatment of 3, 3'-dibenzanthronyl and its isomers, 3, 4'- and 4, 4'-dibenzanthronyls, in a closed vessel is described. The reaction was carried out in the following way: a glass tube was filled with finely-powdered dibenzanthronyl. The tube was then placed in a stainless-steel bomb and heated to 425—435°C for 25 min. Thus, 3, 3'- or 4, 4'-dibenzanthronyl yielded dibenzanthrone and dibenzanthrene, along with a putative secondary thermal reaction product in the form of a black powder; the nature of this briefly discussed. Similarly, 3, 4'-dibenzanthronyl was converted to isodibenzanthrone and isodibenzanthrene, together with a black powder.

Upon being heated in a closed vessel at 425—435°C, 3, 3'-dibenzanthronyl (I) or 4, 4'-dibenzanthronyl (II) was converted into dibenzanthrone (violanthrone) (III) and dibenzanthrene (IV). Similarly, 3, 4'-dibenzanthronyl (V) was turned into isodibenzanthrone (isoviolanthrone) (IV) and isodibenzanthrene (VII) by the same thermal treatment.

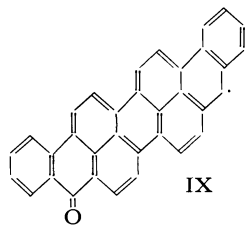


Previously 3, 3'-dibenzanthronyl (m. p. 430°C, uncorr.) was found to suffer from ring closure and to give dibenzanthrone when melted at 430°C in an open vessel under ordinary atmospheric pressure or in vacuo.[1] Its isomers, 3, 4'-dibenzanthronyl (m. p. 330—331°C, uncorr.) and 4, 4'-dibenzanthronyl (m. p. 338—339°C, uncorr.), were, however, not changed by the same treatment, for sublimation prevailed under these conditions. On the other hand, the interference values between hydrogen atoms at the 3- and 4-positions of the benzanthrone residues of these dibenzanthronyls were supposed to be of approximately the same magnitude, and no considerable topochemically-significant differences were found among them. Therefore, further investigations have been made as to whether these dibenzanthronyls give the quinones upon thermal treatment in a vessel closed so as to prevent sublimation. It was thus found, that on separating the pyrolyzed product, the threne was formed unexpectedly, along with the quinone, as has been mentioned above. In addition, when the dibenzanthronyl was heated above 425°C in a closed vessel, a "secondary" thermal reaction product was also obtained as a black powder which dissolved in concentrated sulfuric acid, giving a dark blue color at 50°C. It showed a single, sharp absorption of electron spin resonance, with a spin concentration of the order of 10^{20} spin/g. in the case of 3, 3'-dibenzanthronyl. The shape of the absorption curve indicated that the by-product was not a mere amorphous, graphite-like matter resulting from carbonization. Although further studies of its nature have yet to be carried out, a tentative structure is give in VIII, taking into consideration the fact that the partial reduction product of the quinone, such as that shown in IX, was not separated.

1) Y. Nagai and K. Nagasawa, *J. Chem. Soc. Japan, Ind. Chem. Sect. (Kogyo Kagaku Zasshi)*, **67**, 1977 (1964).



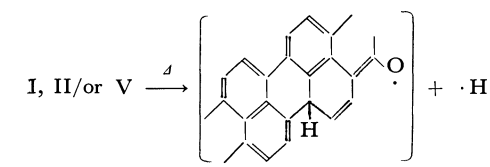
VIII



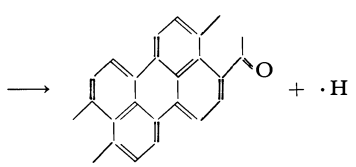
IX

In this connection, dibenzanthrone itself has been reported to be thermally stable up to 475°C,[2] and a dark-red dibenzanthrene was found not to yield any appreciable amount of black matter upon being heated at 450°C. Therefore, it can safely be said that dibenzanthrone and dibenzanthrene are independently unaffected thermally, at least up to 450°C.

Upon being heated above 425°C, with the hydrogen evolved confined in a reaction vessel, 2 mol. of the quinone and 1 mol. of the threne, along with 2 mol. of water, would be produced from 3 mol. of the dibenzanthronyl, if the hydrogen atoms eliminated from the dibenzanthronyl were completely used up in the reduction of carbonyl; this does not take the secondary thermal reaction product into consideration. When the reduction efficiency is taken as unity for this case, the actual efficiencies range from 0.55 to 0.39. The relatively high reduction efficiencies make it probable that the dehydrogenation of the dibenzanthronyl does not proceed by way of molecular hydrogen, but by the step-by-step elimination of the hydrogen radical:



X



This assumption makes it necessary to consider a radical, such as that shown in **X**, as a presumed transient intermediate for the threne and the secondary thermal reaction product.

The analogous ring closure by means of the thermal treatment of a polynuclear aromatic compound which possesses sterically-hindered C-H bonds is rather sporadic, according to the literature. To cite an example, Clar et al.[3] reported that tetrabenzoperopyrene melts at 482°C, with the evolution of hydrogen, and that it resolidifies with the formation of hexabenzocoronene; the latter can also be obtained from less densely-fused hexaphenylbenzene.[4]

Experimental

The Preparation of Dibenzanthronyls.—*3, 3'-Dibenzanthronyl.*—3, 3'-Dibenzanthronyl was prepared by the condensation of benzanthrone with manganese dioxide in a concentrated sulfuric acid - polyphosphoric acid medium.[5] Purified 3, 3'-dibenzanthronyl, which was negative in its ESR spectum, had a m. p. of 430°C (uncorr.) and was in the form of microscopic yellow needle crystals.

3, 4'-Dibenzanthronyl (II).—3, 4'-Dibenzanthronyl was prepared by cross condensation between 3-chlorobenzanthrone and benzanthrone in sodium anilide at 0°C, following the method of Luttringhaus et al.[6] Purification was carried out with chromatography*1 and recrystallization (m. p. 330—331°C, uncorr.) (331—332°C in the literature), resulting in yellow needle crystals. For the sake of identification, these crystals were then melted with potassium hydroxide; the infrared spectrum of the resultant black violet powder coincided with that of an authentic specimen of isodibenzanthrone.

4, 4'-Dibenzanthronyl.—4, 4'-Dibenzanthronyl was prepared by the alcoholic potash-fusion of benzanthrone at 105°C.[7] With recrystallizations, followed by chromatographic purification, 4, 4'-dibenzanthronyl was obtained as pale yellow plate et crystals (m. p. 338—339°C, uncorr.) (326°C, corr., in the literature). After being subjected to kali-fusion, the resultant black violtet powder was identified from its infrared spectrum as dibenzanthrone.

The Thermal Treatment of Dibenzanthronyls.—*3, 3'-Dibenzanthronyl.* — Finely-powdered 500 mg. of 3, 3'-dibenzanthronyl were charged into a semi-hard glass tube, the open side of which was pulled to a capillary and bent downward. When the tip of the capillary was closed, the glass tube exploded at an elevated temperature in a reaction tube, necessitating the troublesome separation of the glass pieces scattered in the organic matter. The tube was then placed in a stainless-steel reaction tube with a needle bulb mounted on it, and the whole was installed in an electric furnace which had previously been heated to 300°C. Then the temperature was rapidly raised

*1 Commercial alumina for chromatography was deactivated hygroscopically, so that the R_f value (the ratio of development in the radial direction) of the benzanthrone dissolved and developed with benzene lay between 0.6 and 0.7 in disk chromatography. The deactivated alumina is used throughout this report whenever the utilization of alumina or chromatography is described.

7) T. Maki, *J. Chem. Soc. Japan, Ind. Chem. Sect.* (*Kogyo Kagaku Zasshi*), **46**, 1256 (1943).

to 450°C (inner temperature; 430±5°C) (the pressure gauge indicated 2.5 kg./cm² at the maximum). After being kept for 25 min. at that temperature, the reaction tube was immediately taken out of the furnace and cooled to room temperature. By cutting the glass-tube, a dull black-violet mass was obtained. This was pulverized and extracted by refluxing it with 100 g. of *o*-dichlorobenzene. Extraction was repeated as long as a green fluorescence remained in the filtrate. The extracts were then condensed and passed through 5 g. of an alumina layer on a glassfilter (1.5 cm. in diameter). The alumina layer was successively washed with hot *o*-dichlorobenzene until no green fluorescence could be observed in the eluate. *o*-Dichlorobenzene solutions were collected and condensed, then subjected to steam distillation to yield 110 mg. of a dull brownish-red powder, which dissolved in concentrated sulfuric acid with a bluish-green color. After this powder had been sublimed in vacuo, 75 mg. of a dark red crystalline powder were obtained. It did not melt at 450°C, and its infrared spectrum was identical with that of an authentic specimen*2 at the following absorption maxima in the fingerprint region; 735, 742, 784, 818, 840, 870, 938, 1015, and 1198 cm^{-1} (NaCl prism, KBr tablet).

The alumina layer, now free from the reduction product, was impregnated with black violet quinone and the secondary thermal reaction product. It was treated with concentrated sulfuric acid at 50°C, and then the acid was filtered off. The violet filtrate was poured into ice water, and a dark-colored precipitate was collected and washed with water. Then in the form of a dull black slurry, the material was treated with an alkaline sodium dithionite solution at 50—60°C. A red-violet vat was filtered and washed with a warm alkaline sodium dithionite solution to which a small quantity of ethyl alcohol had been added. The vat was then triturated by aeration at room temperature. A black violte precipitate was collected by filtration and dried at 110°C to give 215 mg. of dibenzanthrone (43.4% of the theoretical yield, based on 3, 3'-dibenzanthronyl). This gave a red-fluorescent blue solution with hot *o*-dichlorobenzene and dissolved in concentrated sulfuric acid with a reddish-violet color. Coincidences between its infrared spectrum and that of an authentic specimen were observed at the following absorption maxima; 694, 753, 807, 951, 1034, 1195, 1281, 1298, 1336, 1381, 1450, 1572, and 1642 cm^{-1}.

Unvattable black powder was thoroughly washed with water and dried at 110°C, and then refluxed with 30 g. of nitrobenzene for 1 hr. and filtered while hot. The refluxing was repeated as long as a red fluorescence persisted in the filtrate. Thus, 85 mg. of black powder which was practically insoluble in nitrobenzene were obtained. It became dark blue in warm concentrated sulfuric acid, and when boiled with *asym*-trichlorobenzene, a small quantity of it dissolved and became dark blue. It gave rise to a very sharp ESR signal, corresponding to about 10^{20} spin/g., and showed absorption maxima at $\lambda_{max}^{conc.H_2SO_4}=720$ and 580 mμ. Its infrared spectrum showed an ill-defined absorption at about 1640 cm^{-1}.

When the thermal treatment of 3, 3'-dibenzanthronyl was carried out in a sealed tube at 470°C, no dibenzanthrone was separated, but 70 mg. of dibenzanthrene and 305 mg. of the secondary thermal reaction product were obtained from 500 mg. of the sample.

4, 4'-Dibenzanthronyl.—Under the same conditions as in the case of 3, 3'-dibenzanthronyl, a 100 mg. portion of finely-powdered 4, 4'-dibenzanthronyl was submitted to heating in a sealed tube at 425—435°C for 25 min., yielding 94 mg. of a black powder with a greenish hue. The black powder was then dissolved in 40 cc. of concentrated sulfuric acid at 50°C and poured into ice water. The precipitates were collected and washed until they were neutral. The greenish-black slurry was treated with 50 cc. of a warm alkaline sodium dithionite solution to which 3—4 cc. of pyridine had been added. By filtering and air-oxidizing the red-violet vat, 21 mg. of dibenzanthrone were obtained (21.2% of the theoretical yield). After the unvattable portion had been washed thoroughly with water and then dried, it was refluxed with 50 cc. of nitrobenzene for a few hours. The solution was then passed through 1 g. of alumina on a glass-filter. The eluate was condensed and steam-distilled to give 19 mg. of crude dibenzanthrene, which were recrystallized from *asym*-trichlorobenzene to yield 13 mg. of dibenzanthrene. From the alumina layer, 30 mg. of the secondary thermal reaction product were obtained as a black powder. The infrared spectra of dibenzanthrone and dibenzanthrene were identical with those of the authentic specimens.

3, 4'-Dibenzanthronyl. — Finely-powdered 100 mg. of 3, 4'-dibenzanthronyl were treated at 425—435°C for 25 min. in a sealed tube. The resultant 93 mg. black mass was treated much as in the case of 4, 4'-dibenzanthronyl. From a clear bluish-violet vat, 38 mg. of isodibenzanthrone (38.4% of the theoretical yield) were obtained. This dissolved in concentrated sulfuric acid with a green color, and its infrared spectrum coincided at the following absorption maxima with that of an authentic specimen; 702, 750, 805, 977, 1077, 1281, 1310, 1380, 1474, 1501, 1563, 1588, and 1638 cm^{-1}.

Out of the unvattable portion, 30 mg. of crude isodibenzanthrene were separated; after this had been sublimed in vacuo, 12 mg. of isodibenzanthrene were obtained as a dark red crystalline powder which did not melt at 450°C. Coincidences of the infrared spectrum with that of an authentic specimen at the following maxima in the fingerprint region were observed; 737, 745, 790, 826, 876, 934, 1020, and 1186 cm^{-1}.

Besides the above reaction products, 13 mg. of a black powder were yielded; this powder dissolved in concentrated sulfuric acid at 70°C with a dark color.

The authors are indebted to Professor Shizuo Fujiwara of the Faculty of Science, the University of Tokyo, for providing facilities for measuring the ESR spectra and to Associate Professor Nobuyuki Goto of the Institute of Industrial Science, the University of Tokyo, for his valuable suggestion. They also wish to thank Mr. Osamu Iwayama for his assistance in carrying out the experiments.

*2 The authentic specimens of dibenzanthrene and isodibenzanthrene were prepared by means of the Clar reduction of pure dibenzanthrone and isodibenzanthrone respectively, followed by purification with sublimation in vacuo (E. Clar. *Ber.*, **72**, 1645 (1939); J. Aoki, dissertation, The University of Tokyo, 1964).

Syntheses of Peptides Related to the *N*-Terminal Structure of Corticotropin. VI. The Synthesis of Ser^1- and Gly^1-Decapeptides Corresponding to the First Ten-amino-acid Sequence of Corticotropin

By Hideo OTSUKA, Ken INOUYE, Fusako SHINOZAKI and Makoto KANAYAMA

Biochemistry Division, Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received August 27, 1965)

t-Butyloxycarbonyl-seryl-(and-glycyl-)tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine have been synthesized as the first step of the synthesis of adrenocorticotropically active peptides. The trifluoroacetic acid treatment of these two compounds afforded the free decapeptides, seryl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine, which corresponded to the amino-acid sequence of positions 1 to 10 in the corticotropin molecule, and its glycine^1-analog. Concerning the synthesis of serine peptides, a tetrapeptide derivative, corresponding to the first four amino acid residues of corticotropin, was obtained by using *O*-benzyl-serine.

In 1961 Hofmann and Yajima reported that a synthetic tridecapeptide amide, corresponding to the first thirteen amino acid residues of corticotropin (ACTH), exhibited a very low but reproducible ACTH activity.[1] Later Li and his collaborators synthesized a pentadecapeptide which had a sequence corresponding to positions 1—10 plus positions 15—19 of the corticotropin molecule, and the product was found to be active at a low level of potency.[2] From these facts it seemed that the amino terminal decapeptide portion might have a structure functionally essential for the hormonal activity, even if the decapeptide itself did not elicit any appreciable potency.

We have recently completed the synthesis of some biologically-active peptides related to the corticotropin molecule.[3-5] Each of them was obtained by connecting the amino terminal decapeptide fragment with the carboxyl terminal moiety of the molecule. During the course of these syntheses, we prepared the free decapeptide, corresponding to the first ten amino acid residues of corticotropin, and its analog, which had a glycine in place of the amino terminal serine; we prepared, that is, seryl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine (α-$^{1-10}$-ACTH) (I) and glycyl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine (α^{1-10}-Gly^1-ACTH) (II).*1 As has been stated above, peptide I may provide a functional core for the ACTH activity, while its protected derivative is a key fragment for the synthesis of adrenocorticotropically-active peptides. In this respect, peptide II may be considered to be the same as peptide I, since the hydroxyl group of the terminal serine has been recognized as being nonessential for the activity.[6] We wish to describe here the synthesis of peptides I and II in detail. Concerning the synthesis of serine peptides, the use of *O*-benzylserine will also be described.

The Synthesis of α^{1-10}-Gly^1-ACTH (II).— Serine was acylated by using 1.1—1.2 equivalent moles of *t*-butyl azidoformate[7,8] to obtain *t*-butyloxycarbonyl-serine (III), which was first isolated in the form of a dicyclohexylamine salt[9] in a 60 per cent yield. The dicyclohexylamine salt was then treated with Dowex-50 (H^+-form) in order to recover compound III, which crystallized as the monohydrate. The crystalline monohydrate became sirupy in a desiccator as a result of the immediate loss of water. When a 100 per cent excess of the azide was used for the above acylation, we could not obtain the crystalline III after all; it appeared most likely that the *O*-acylation of serine had occurred to some extent as a side reaction. The *N*, *N'*-dicyclohexylcarbodiimide (DCCl)-induced coupling[10] of III with the methionine

* In 0.05 M "Tris" buffer (pH 7.85, 0.005 M Mg^{2+}) - dioxane (4 : 1) at 37°C for 24 hr.

** A solution of the substrate (ca. 1 μmol.) in 0.1 ml. of 0.1 N hydrochloric acid was neutralized with 0.1 N sodium hydroxide and to this were quickly added 0.5 ml. of 0.05 M "Tris" buffer (pH 7.85, 0.005 M Mg^{2+}) and the enzyme solution (1 mg./ml. in the same "Tris" buffer as above).*2 The mixture was then incubated at 37°C for 36 hr.

† Recovery 98%. †† Recovery 97%.

methyl ester yielded the *t*-butyloxycarbonyl-seryl-methionine methyl ester (IV) in a good yield (84%). Compound IV was treated with dry hydrogen chloride in ethyl acetate to give seryl-methionine methyl ester hydrochloride as an oil. In this case, it was found that the protective group was not split appreciably, even after 30 min. at room temperature, when anhydrous methanol was used as the solvent in place of ethyl acetate. We previously used a formyl group[11] for the protection of an amino function of the peptide containing a methionine residue.[12] The *t*-butyloxycarbonyl group,[7] which has recently become available, seems to be more advantageous than the formyl group, since the former unlike the latter,[11] usually offers no opportunity for the coupling procedures to be employed. The oily hydrochloride of the seryl-methionine methyl ester was converted into the free base (V), which then crystallized readily from ethyl acetate in a 80 per cent yield based on the IV used. The *t*-butyloxycarbonyl-glycyl-tyrosine methyl ester was easily obtained by the DCCl-mediated condensation of *t*-butyloxycarbonyl-glycine with the tyrosine methyl ester. The amorphous protected dipeptide ester, which was found to be homogeneous in thin-layer chromatography, was converted into the crystalline hydrazide (VI) in a 85 per cent yield based on the *t*-butyloxycarbonyl-glycine used. *t*-Butyloxycarbonyl-glycyl-tyrosine azide, which was derived from compound VI, was made to react with V in acetonitrile to give, in a moderate yield (62%), a crystalline-protected tetrapeptide *t*-butyloxycarbonyl - glycyl - tyrosyl - seryl - methionine methyl ester (VII). Compound VII was then converted into the corresponding hydrazide (VIII).

For the synthesis of a protected decapeptide, *t*-butyloxycarbonyl-glycyl - tyrosyl - seryl - methionyl-γ-*t*-butyl - glutamyl - histidyl - phenylalanyl - arginyl - tryptophyl-glycine (IX), compound VIII was treated with nitrous acid and the resultant azide was allowed to react with the hexapeptide, γ-*t*-butyl - glutamyl - histidyl - phenylalanyl - arginyl - tryptophyl-glycine, the synthesis of which has already been described.[13] The decapeptide (IX) was purified by reprecipitation from dimethylformamide-methanol in a yield of 63 per cent. The purified IX was found to be entirely homogeneous in thin-layer chromatography. The protective group of IX were removed by treatment with trifluoroacetic acid to liberate the decapeptide II (α^{1-10}-Gly^1-ACTH). The synthetic peptide II gave a single spot (R_f=0.36) reactive to ninhydrin, Pauly, Ehrlich, Sakaguchi and methionine (P_tI_6'') reagents on paper in the *n*-butanol - acetic acid - pyridine - water (30 : 6 : 20 : 24 by volume) system.[14] Acid hydrolysis afforded a mixture of the constituent amino acids in the ratios expected by theory, with the exception of the tryptophan, which had partially decomposed with acid.[15] The intact peptide was determined spectrophotometrically to contain tyrosine and tryptophan in a molar ratio of 1 : 1.[16] The peptide II was also submitted to leucine aminopeptidase (LAP) digestion at various enzyme/substrate ratios. The results are presented in Table I, together with those obtained for peptide I. The table shows that the first half of the mol-

ecules could be digested completely, whereas their carboxyl terminal moieties seemed to be somewhat resistant to the action of the enzyme under the conditions used. The difficulty may have arisen from some inhibition by the accumulated products, since the hexapeptide, which was derived from γ-*t*-butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine, an intermediate for the synthesis of peptides I and II, has been found to be completely digestible by the enzyme.[13] Schwyzer and Kappeler[20] described that their preparation of the decapeptide (I) was completely digested by LAP. However, the rate of the hydrolysis by LAP depends partly on the contamination of some endopeptidases, which may promote the digestion. It is, therefore, difficult to compare our results with their directly. The present data may, then, be considered to provide a proof of the optical homogeneity of our decapeptide preparations.

The Synthesis of α^{1-10}-ACTH (I).—*t*-Butyloxycarbonyl-serine (III) was treated with diazomethane in order to obtain the corresponding methyl ester; the resultant oily ester was then converted into *t*-butyloxycarbonyl-serine hydrazide (X) in a yield of 88 per cent based on the III used. Iselin and Schwyzer reported the synthesis of X by another route, starting with the serine methyl ester.[17] The *t*-butyloxycarbonyl-seryl-tyrosine methyl ester (XI) was synthesized by the azide-coupling procedure from compound X and the tyrosine methyl ester in a moderate yield (66%). The melting point of our preparation agrees fairly well with the value reported for XI by Hofmann et al., but the optical rotation differs significantly from theirs.[18] The hydrazide (XII), which was derived from XI, had the same optical rotation as that given by them. Concerning the synthesis of XI, attempts were also made to achieve the DCCl-induced condensation of *t*-butyloxycarbonyl-serine (III) with the tyrosine methyl ester, but the reaction appeared so complicated that it was very difficult to isolate the pure XI from the medium. Concerning this point, it should be noted that Li et al. obtained the carbobenzoxy analog of XI in an excellent yield by the DCCl procedure.[19] *t*-Butyloxycarbonyl-seryl-tyrosine azide, which was derived from XII, was allowed to react with the seryl-methionine methyl ester (V) to yield a tetrapeptide derivative, the *t*-butyloxycarbonyl-seryl-tyrosyl-seryl-methionine methyl ester (XIII). Compound XIII failed to crystallize, but it was found to be homogeneous in thin-laryer chromatography. The optical rotation of our material agrees satisfactorily with the value described for XIII by Iselin and Schwyzer.[17] Compound XIII was then converted almost quantitatively into the crystalline hydrazide (XIV), the melting point and the optical rotation of which coincided fairly well with those reported in the literature.[17]

The protected tetrapeptide hydrazide (XIV) was transformed into the azide, and this was then coupled with γ-*t*-butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine[13] to give a protected decapeptide *t*-butyloxycarbonyl-seryl-tyrosyl-seryl-methionyl-γ-*t*-butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine (XV), which was found to be homogeneous in thin-layer chromatography after reprecipitation from dimethylformamide-methanol. The yield of the purified XV amounted to 80 per cent when the hydrazide XIV was used in a 50 per cent excess relative to the hexapeptide. Our preparation of XV showed a good agreement in the optical rotation with the substance as prepared by other investigators.[20,21] The free decapeptide I (α^{1-10}-ACTH) was obtained by the trifluoroacetic acid treatment of compound XV. The peptide I was found to be homogeneous to ninhydrin, Pauly, Ehrlich, Sakaguchi and methionine (P_tI_6'') reagents in paper chromatography. Acid hydrolysis gave a mixture consisting of the constituent amino acids in the ratios expected by theory, with the exception of the tryptophan. The intact peptide contained tyrosine and tryptophan in a molar ratio of 1 : 1.[16]

Previously we described the use of *O*-benzyl-serine[22,23] in the synthesis of the *N*-terminal sequence of corticotropin, where the amino function of the *N*-terminal serine was protected by a carbobenzoxy group.[12] An attempt to determine if the *N*-acyl and the *O*-benzyl groups could be removed safely by reduction with sodium in liquid ammonia was made for the protected nonapeptide *N*-carbobenzoxy-*O*-benzyl-seryl-tyrosyl-*O*-benzyl-seryl-methionyl-γ-*t*-butyl-glutamyl-histidyl-phenylalanyl-N^G-tosyl-arginyl-tryptophan methyl ester (m. p. 220—221°C, $[\alpha]_D^{22.5}$ −10.5° (*c* 1.05, dimethylformamide)); it was proved that one of the serine residues, which might be the amino end, was transformed into glycine to an extent of 60—70 per cent upon the treatment.[24] We next synthesized the first tetrapeptide sequence of corticotropin in the form of the *t*-butyloxycarbonyl-*O*-benzyl-seryl-tyrosyl-*O*-benzyl-seryl-methionine methyl ester (XVIII) as an intermediate in the synthesis of corticotropin peptides, in order to test the role of the hydroxyl function of serine in the activity as well as to examine the behavior of the protective groups and the serine residues

in the treatment with sodium in liquid ammonia. We wish to describe here, however, only the synthesis of compound XVIII as an example of serine peptide. The synthetic procedure for XVIII is quite similar to that employed for compound VII. *t*-Butyloxycarbonyl-*O*-benzyl-serine (XVI), which failed to crystallize, was isolated as the dicyclohexylamine salt.[9] The coupling of compound XVI with the tyrosine methyl ester by the DDCI method involved no difficulty other than those encountered with compound XI.

We also tried to obtain *O*-benzyl-D-serine from the *N*-acetyl-*O*-benzyl-D-serine, which could be isolated from the optical resolution medium[23] after *O*-benzyl-L-serine ($[\alpha]_D^{24}$ +7.3° (*c* 2.0, N hydrochloric acid)) had been separated. The treatment of *N*-acetyl-*O*-benzyl-D-serine (m. p. 110—111°C, $[\alpha]_D^{23}$ −46.7° (*c* 2.0, acetic acid)) with 80% hydrazine hydrate at 100°C gave the desired *O*-protected D-serine in a 70 per cent yield, no fission of the *O*-benzyl group was detected. The resultant material had an optical rotation of $[\alpha]_D^{24.5}$ −7.2° (*c* 2.0, N hydrochloric acid); its *N*-*t*-butyloxycarbonyl derivative was also found to be fairly coincident with the L-antipode in optical rotation with an opposite sign.

Experimental

The amino acids used are of the L-configuration, unless otherwise indicated.

All melting points are uncorrected.

***t*-Butyloxycarbonyl-serine Dicyclohexylamine Salt.**—To a solution of 10.51 g. (0.1 mol.) of serine and 22.0 g. (0.24 mol.) of sodium bicarbonate in 200 ml. of water and 200 ml. of dioxane, 17.20 g. (0.12 mol.) of *t*-butyl azidoformate[7,8] was added drop by drop at a bath temperature of 45°C; the mixture was then stirred for 20 hr. at the above temperautre. The reaction mixture was chilled in an ice-bath, neutralized by the addition of 57.5 ml. of ice-cold 4 N hydrochloric acid (pH 4.6—4.8), and concentrated to about 80 ml. at 40°C in vacuo. The concentrated solution was then acidified to below pH 2 with ice-cold 4 N hydrochloric acid in the presence of 200 ml. of ethyl acetate at 0°C. The aqueous phase was extracted three times with 100 ml.-portions of cold ethyl acetate. The organic extracts were then pooled, dried over anhydrous sodium sulfate, and evaporated at 35—40°C in vacuo, thus affording the product as a sirup (13.83 g., 67.5%). The product was dissolved in 100 ml. of ether, and to this was added an ethereal solution of 12.20 g. (0.0675 mol.) of dicyclohexylamine. After the mixture had been stored in a refrigerator overnight, the crystals which separated were filtered off, washed with ether and dried; 23.56 g. (61.0%), m. p. 143—148°C. A 21.8 g.-sample was recrystallized from 220 ml. of hot ethyl acetate to give 19.6 g. of needles; m. p. 142—144°C, $[\alpha]_D^{25.5}$ +13.3±0.5° (*c* 3.044, methanol).

Found: C, 62.17; H, 9.80; N, 7.36. Calcd. for $C_8H_{15}O_5N \cdot C_{12}H_{23}N$: C, 62.15; H, 9.91; N, 7.25%.

***t*-Butyloxycarbonyl-serine Monohydrate (III).**—A solution of 17.40 g. (0.045 mol.) of the dicyclohexylamine salt which was obtained above in 200 ml. of 50% ethanol was shaken in the presence of 45 ml. (wet volume) of Dowex-50WX8 (H^+-form) at room temperature for 30 min. After the resin had been removed by filtration, the filtrate was concentrated to a small volume at 40—45°C in vacuo. The crystalline monohydrate, which separated soon when the mixture was chilled in an ice-bath, was collected and air-dried; 9.81 g. (97.7%), m. p. 45—47°C (sintering at 42°C), $[\alpha]_D^{26}$ −3.0±1° (*c* 2.330, acetic acid), $[\alpha]_D^{25}$ −7.6±0.5° (*c* 2.590, water).

Found: C, 43.25; H, 7.88; N, 6.52; H_2O, 7.19. Calcd. for $C_8H_{15}NO_5 \cdot H_2O$: C, 43.04; H, 7.68; N, 6.28; H_2O, 8.07%.

***t*-Butyloxycarbonyl-serine Hydrazide (X).**—To a solution of 5.58 g. (0.025 mol.) of III in 20 ml. of dioxane there was added, at 0°C, an ethereal solution of diazomethane until the yellow color persisted. After 10 more min. the solvent was removed in vacuo at 30°C. The resultant sirup was dissolved in 25 ml. of anhydrous ethanol; to this was added 3.0 ml. (0.06 mol.) of hydrazine hydrate, and the mixture was kept at room temperature for 24 hr. After the solvent had been removed in vacuo, the sirupy residue was treated with ethyl acetate to afford a crystalline solid. Recrystallization from hot ethyl acetate gave fine needles; 4.82 g. (88.0%), m. p. 109—110°C, $[\alpha]_D^{25.5}$ −9.0±0.5° (*c* 4.127, methanol). Lit.[17] m. p. 112—114°C, $[\alpha]_D^{27}$ −9.4±1° (*c* 4.1, methanol).

Found: C, 43.80; H, 7.91; N, 19.19;. Calcd. for $C_8H_{17}N_3O_4$: C, 43.83; H, 7.82; N, 19.17%.

***t*-Butyloxycarbonyl-seryl-methionine Methyl Ester (IV).** — A mixture of 5.99 g. (0.03 mol.) of methionine methyl ester hydrochloride, 6 ml. of water and 30 ml. of methylene chloride was chilled in an ice-bath and shaken with 15 ml. of ice-cold 50% potassium carbonate. The aqueous phase was then extracted again with cold methylene chloride. The organic extracts were combined, dried over anhydrous sodium sulfate, and evaporated at a bath temperature of 20°C in vacuo, affording the free base as an oil, which was then redissolved in methylene chloride. To this solution there were added 6.13 g. (0.0275 mol.) of compound III and a methylene chloride solution of 5.68 g. (0.0275 mol.) of *N*, *N'*-dicyclohexylcarbodiimide (DCCl); the reaction mixture was then kept in a refrigerator overnight. The *N*, *N'*-dicyclohexylurea (DCU) which formed was removed (5.81 g., 94.1%), and the filtrate was evaporated in vacuo. The residue was dissovled in ethyl acetate, and the solution was washed with ice-cold N hydrochloric acid, M sodium bicarbonate and saturated sodium chloride, dried over anhydrous sodium sulfate, and evaporated in vacuo. The resultant oily residue was dissolved in a small volume of acetonitrile, and the slight amount of the urea which separated upon chilling was removed. The evaporation of the solvent afforded an oily residue which crystallized during storage in a refrigerator. The crystals were washed with ether - petroleum ether and dried; 8.78 g. (91.1%), m. p. 64—66°C. Recrystallization from ethyl acetate - petroleum ether gave a yield of 8.21 g. (83.8%); m. p. 66—67.5°C, $[\alpha]_D^{25.5}$ −29.5±1° (*c* 2.220, methanol).

Found: C, 48.06; H, 7.61; N, 8.20; S, 9.34. Calcd. for $C_{14}H_{26}N_2O_6S$: C, 47.98; H, 7.48; N, 7.99; S,

9.15%.

Seryl-methionine Methyl Ester (V).—To a solution of 1.402 g. (4 mmol.) of IV in 2ml. of ethyl acetate there was added 2.5 ml. of 20% hydrogen chloride in ethyl acetate, the mixture was then allowed to stand at room temperature for 60 min. The solvent was evaporated in vacuo and the resultant oily ester hydrochloride was dissolved in methylene chloride. The solution was then treated with 50% potassium carbonate at 0°C, and the organic phase was dried over anhydrous sodium sulfate and evaporated at a bath temperature of 20°C in vacuo to give a sirupy residue, which crystallized upon the addition of ethyl acetate; 0.825 g. (82.5%), m. p. 84—85°C, $[\alpha]_D^{24.5}$ $-16.3\pm1°$ (*c* 1.791, methanol). Lit.[19] m. p. 86—88°C, $[\alpha]_D^{24}$ $-21°$ (*c* 1, N hydrochloric acid).

Found: C, 43.29; H, 7.29; N, 11.06; S, 12.66. Calcd. for $C_9H_{18}N_2O_4S$: C, 43.18; H, 7.25; N, 11.19; S, 12.81%.

***t*-Butyloxycarbonyl-glycyl-tyrosine Hydrazide (VI).**—To a solution of 2.32 g. of tyrosine methyl ester hydrochloride in 2 ml. of water, 10 ml. of ice-cold 50% potassium carbonate was added at 0°C. The crystalline precipitates which separated were filtered off, washed with cold water, and dried to give the free base of the tyrosine methyl ester; 1.81 g. (93.0%) the free base of the tyrosine methyl ester; 1.81 g. (93.0%), m. p. 134—135°C, $[\alpha]_D^{23.5}$ $+26.9\pm0.8°$ (*c* 2.411, methanol). Lit.[25] m. p. 135°C.

t-Butyloxycarbonyl-glycine (4.85 g., 0.0276 mol.) and 5.40 g. (0.0276 mol.) of the tyrosine methyl ester were dissolved in acetonitrile, and to this solution was added 5.72 g. (0.0276 mol.) of DCCl; the mixture was then kept in a refrigerator overnight. After the DCU which separated had been filtered off, the filtrate was evaporated in vacuo. The residue was dissolved in ethyl acetate, and the solution was washed successively with ice-cold N hydrochloric acid, water, M sodium bicarbonate and water, dried over anhydrous sodium sulfate, and evaporated in vacuo. The resultant amorphous dipeptide, which gave a single spot in thin-layer chromatography (R_f=0.50, Silica-gel G in ethyl acetate), was dissolved in 85 ml. of methanol, and 3.35 ml. of hydrazine hydrate was added. The mixture was then allowed to stand at room temperature for 48 hr. The crystalline precipitates which separated were collected, washed with a mixture of methanol and ether, and then ether, and dried in vacuo to give compound VI; 8.21 g. (84.5%), m. p. 187—188°C. A sample was recrystallized from methanol for analyses; m. p. 189.5—190°C, $[\alpha]_D^{26.5}$ $+0.5\pm1°$ (*c* 2.002, dimethylformamide).

Found: C, 54.56; H, 6.97; N, 15.93. Calcd. for $C_{16}H_{24}N_4O_5$: C, 54.53; H, 6.87; N, 15.93%.

***t*-Butyloxycarbonyl-seryl-tyrosine Methyl Ester (XI).**—Compound X (2.19 g., 0.01 mol.) was dissolved in 20 ml. of ice-cold N hydrochloric acid, and to this was added 6 ml. of ice-cold 2 M sodium nitrite at an ice-salt-bath temperature. After 4 min. the separated azide was taken into ethyl acetate. The organic solution was then washed with ice-cold M potassium carbonate and sodium chloride, and dried over anhydrous sodium sulfate. To this ethyl actate solution 1.95 g. (0.01 mol.) of the tyrosine methyl ester (free base) was added; the mixture was then concentrated to a small volume at a bath temperature of 5—10°C in vacuo, and about 25 ml. of tetrahydrofuran was introduced. The mixture was then left to stand at 0—4°C for 68 hr. The solvent was removed in vacuo, and the residue was redissolved in ethyl acetate. The solution was washed in an ordinary manner with ice-cold hydrochloric acid and sodium bicarbonate and dried. The evaporation of the solvent gave a foamy residue, which crystallized from ether; 2.50 g. (65.5%), m. p. 115—118°C, $[\alpha]_D^{25}$ $-5.0\pm2°$ (*c* 1.036, methanol). Lit.[18] m. p. 117—119°C, $[\alpha]_D^{28}$ $-13.3°$ (*c* 0.97, methanol).

Found: C, 55.94; H, 6.92; N, 7.56. Calcd. for $C_{18}H_{26}N_2O_7$: C, 56.53; H, 6.85; N, 7.33%.

***t*-Butyloxycarbonyl-seryl-tyrosine Hydrazide (XII).**—To a solution of 1.99 g. of compound XI in 20 ml. of anhydrous ethanol 1.3 ml. of hydrazine hydrate was added; the mixture was then allowed to stand at room temperature overnight. The crystalline precipitates which separated were collected, washed with ethanol and ether, and dried; 1.76 g. (88.5%), m. p. 188—190°C (decomp.). A sample was recrystallized from water for analyses; m. p. 193—195°C decomp., $[\alpha]_D^{24}$ $-19.8\pm1°$ (*c* 2.035, 50% acetic acid). Lit.[18] m. p. 199—200°C (decomp.), $[\alpha]_D^{28}$ $-18.6°$ (*c* 1.20, 50% acetic acid).

Found: C, 51.50; H, 7.15; N, 14.97. Calcd. for $C_{17}H_{26}N_4O_6\cdot{}^1/_2H_2O$: C, 52.16; H, 6.95; N, 14.31%.

***t*-Butyloxycarbonyl-glycyl-tyrosyl-seryl-methionine Methyl Ester (VII).**—To a solution of 1.76 g. (5.0 mmol.) of compound VI in 12.5 ml. of ice-cold N hydrochloric acid 3.0 ml. of ice-cold 2M sodium nitrite was added at an ice-salt bath temperature. After 4 min. 10 ml. of saturated sodium chloride was introduced, and the separated azide was placed in 20-ml. portions of ether. The organic extracts were combined, washed with ice-cold M sodium bicarbonate, dried over anhydrous sodium sulfate, and evaporated in vacuo to give a foamy residue, which was then redissolved in cold acetonitirle. To this solution 1.25 g. (5.0 mmol.) of compound V was added and the mixture was left to stand at 0—4°C for two days. The crystalline tetrapeptide VII which separated was filtered off, washed with cold ethyl acetate and ether, and dried; 1.40 g. (61.5%), m. p. 183—185°C (softening at 181°C). A suspension of this slightly-colored material in acetonitrile was boiled for a few minutes and then refrigerated. The treatment gave the colorless crystals with a recovery of 96.7 per cent; m. p. 183—185°C, $[\alpha]_D^{24}$ $-16.5\pm2°$ (*c* 1.15, methanol). A single spot was visible in thin-layer chromatography; R_f=0.48 (Silica-gel G, methanol-ethyl acetate (15:85)).

Found: C, 52.44; H, 7.01; N, 9.98; S, 5.70. Calcd. for $C_{25}H_{38}N_4O_9S$: C, 52.62; H, 6.71; N, 9.82; S, 5.62%.

***t*-Butyloxycarbonyl-glycyl-tyrosyl-seryl-methionine Hydrazide Hemihydrate (VIII).**—Hydrazine hydrate (0.6 mol.) was added to a solution of 1.20 g. of compound VII in 6 ml. of dimethylformamide; the mixture was allowed to stand at room temperature for 40 hr., after which time the hydrazide VIII was precipitated by the addition of 45 ml. of ethyl acetate in the form of a gelatinous mass. This amorphous solid was crystallized from hot water; 1.14 g. (93.9%), m. p. 202—204°C (decomp.), $[\alpha]_D^{23}$ $-17.8\pm1°$ (*c*

25) J. Ramachandran and C. H. Li, *J. Org. Chem.*, **28**, 173 (1963).

1.940, 50% acetic acid).

***t*-Butyloxycarbonyl-seryl-tyrosyl-seryl-methionine Methyl Ester (XIII).**—Compound XII (2.87 g., 7.5 mmol.) was dissolved in 19 ml. of ice-cold N hydrochloric acid containing 2 g. of sodium chloride, and to this was added 4.5 ml. of ice-cold 2M sodium nitrite at an ice-salt bath temperature. After 4 min. the azide was extracted three times with ethyl acetate. The organic extracts were combined, washed with ice-cold M sodium bicarbonate and saturated sodium chloride, and dried over anhydrous sodium sulfate. To this solution 1.33 g. (5.3 mmol.) of V was added, and the resultant suspension was concentrated to about 20—25 ml. at a bath temperature of 5—10°C in vacuo. During the concentration a greater part of the solid disappeared. The mixture was then kept at 0—4°C for 2 days. A little water was added to dissolve the gelatinous precipitates, which had separated, and the resultant clear solution was washed with ice-cold N hydrochloric acid, M sodium bicarbonate and water, dried over anhydrous sodium sulfate, and evaporated in vacuo to give a amorphous solid mass, which was then reprecipitated from hot ethyl acetate; 1.42 g. (44.8%), m. p. 125—130°C. A sample was reprecipitated from ethyl acetate for analyses; m. p. 129—134°C, $[\alpha]_D^{23}$ $-29.3\pm1°$ (*c* 2.053, methanol). Lit.[17] m. p. 115—125°C, $[\alpha]_D^{27}$ $-29.8\pm1°$ (*c* 2.1, methanol). A single spot was detected in thin-layer chromatography; $R_f=0.57$, methanol-ethyl acetate (15 : 85).

Found: C, 52.15; H, 6.88; N, 19.55; S, 5.38. Calcd. for $C_{26}H_{40}N_4O_{10}S$: C, 51.99; H, 6.71; N, 19.33; S, 5.34%.

***t*-Butyloxycarbonyl-seryl-tyrosyl-seryl-methionine Hydrazide (XIV).**—Compound XIII (0.78 g.) was dissolved in 5 ml. of dimethylformamide, and to this was added 0.3 ml. of hydrazine hydrate. The mixture was kept at 0—4°C for 40 hr. The tetrapeptide hydrazide XIV was then precipitated by the addition of ethyl acetate. The precipitates crystallized upon treatment with hot water; 0.76 g. (96.9%), m. p. 187—189°C (decomp.) (sintering at 175°C). A sample was recrystallized from water for analyses without any change in the melting point; $[\alpha]_D^{23.5}$ $-35.8°$ (*c* 1.966, 50% methanol). Lit.[17] m. p. 191—193°C, $[\alpha]_D^{25}$ $-36.7\pm1°$ (*c* 2.0, water-methanol 1 : 1).

Found: C, 49.09; H, 6.79; N, 13.99; S, 5.42. Calcd. for $C_{25}H_{40}N_6O_9S$: C, 49.99; H, 6.79; N, 13.99; S, 5.34%.

***t*-Butyloxycarbonyl-glycyl-tyrosyl-seryl-methionyl-γ-*t*-butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine Dihydrate (IX).**—To a solution of compound VIII (0.348 g.., 0.6 mmol.) in 3.5 ml. of dimethyl-formamide 1.8 ml. of ice-cold N hydrochloric acid and 0.66 ml. of M sodium nitrite were added at an ice-salt-bath temperature. After 4 min. saturated sodium chloride (20 ml.) was introduced, and the separated azide was taken into ethyl acetate. The organic extracts were combined, washed with ice-cold M sodium bicarbonate and water, and dried over anhydrous sodium sulfate. To this was added a solution of 0.496 g. (0.5 mmol.) of γ-*t*-butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine[13] and 0.21 ml. of triethylamine in 15 ml. of dimethylformamide, and the mixture was concentrated at 5—10°C in vacuo until it became clear. The reaction mixture was then allowed to stand at 0—4°C. The freshly prepared azide (derived from 0.232 g. (0.4 mmol.) of VIII as described above) was added after 20 hr. of reaction. After 40 hr. acetic acid (0.5 ml.) was added, and the mixture was poured into 200 ml. of cold ethyl acetate to separate the crude protected decapeptide, which were collected by filtration (0.607 g.). The crude product was twice reprecipitated from dimethylformamide-methanol (1 : 2); 0.461 g. (63.1%), m. p. 213—216°C (decomp.), $[\alpha]_D^{24}$ $-10.8\pm2°$ (*c* 1.077, dimethylformamide). A single spot was detected in thin-layer chromatography; $R_f=0.60$ (Silica-gel G, dimethylformamide - ethyl acetate - acetic acid (15 : 10 : 2).

Found: C, 55.04; H, 6.65; N, 15.30; S, 2.04. Calcd. for $C_{67}H_{92}N_{16}O_{17}S \cdot 2H_2O$: C, 55.05; H, 6.62; N, 15.33; S, 2.19%.

***t*-Butyloxycarbonyl-seryl-tyrosyl-seryl-methionyl-γ-*t*-butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine Dihydrate (XV).**—The azide, which was derived from 0.685 g. (1.14mmol.) of compound XIV, and 0.750 g. (0.76 mmol.) of γ-*t*-butyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl glycine[13] were made to react in an ethyl acetate-dimethylformamide solution at 0—4°C for 44 hr. in almost the same manner as in the case of the synthesis of IX. After the addition of 0.75 ml. of acetic acid, the reaction mixture was introduced into cold ethyl acetate; the resultant precipitates of crude XV were filtered off to give 1.041 g. The crude product was reprecipitated from dimethylformamide-methanol to afford 0.910 g. (80.2%) of the pure material, which was found to be homogeneous in thin-layer chromatography, $R_f=0.47$ (Silica-gel G, dimethylformamide - ethyl acetate - acetic acid (15 : 10 : 2)).; m. p. 202°C (decomp.), $[\alpha]_D^{24}$ $-13.2\pm2°$ (*c* 1.045, dimethylformamide). Lit. m. p. 203°C decomp., $[\alpha]_D$ $-12.4\pm0.8°$ (*c* 1.328, dimethylformamide);[20] m. p. 201—204°C (decomp.), $[\alpha]_D^{22}$ $-13.0\pm1°$ (*c* 1, dimethylformamide).[21]

Found: C, 55.24; H, 7.25; N, 14.99; S, 2.56. Calcd. for $C_{68}H_{94}N_{16}O_{18}S \cdot 2H_2O$: C, 54.75; H, 6.62; N, 15.02; S, 2.15%.

Seryl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine (I).—The protected decapeptide XV (50 mg.) was dissolved in 1 ml. of anhydrous trifluoroacetic acid, and the solution was ketp at room temperature for 60 min. The solvent was removed by evaporation at a bath temperature of 35—40°C in vacuo to give a sirupy residue, which was dried over sodium hydroxide in vacuo. The residue was then dissolved in water, and to this was added 2 ml. (wet volume) of Amberlite CG-4B (acetate form), and the mixture was stirred at room temperature for 40 min. After the resin had been removed by filtration, the filtrate was lyophilized to give quantitatively the decapeptide I as a colorless powder with a silky luster; it gave a single spot ($R_f=0.52$) reactive to ninhydrin, Pauly, Ehrlich, Sakaguchi and methionine (PtI_6'') reagents on paper in the solvent system of *n*-butanol - acetic acid - pyridine - water (30 : 6 : 20 : 24);[14] $\lambda_{max}^{N/10\ HCl}=280$ mμ (ε 6490), $\lambda_{shoulder}^{N/10\ HCl}=288.5$ mμ (ε 4870), $\lambda_{max}^{N/10\ NaOH}$ 281.5 mμ (ε 6810),

288.5 mμ (ε 6600), $[\alpha]_D^{24}$ −30.3±2° (*c* 0.551, N acetic acid). Amino acid ratios in acid hydrolysate:[15] Ser 1.83, Tyr 1.06, Met 1.03, Glu 1.00, His 0.99, Phe 1.02, Arg 0.94, Gly 0.92, Try 0.55,*3 NH_3 0.51.

Glycyl-tyrosyl-seryl-methionyl-glutamyl-histidyl-phenylalanyl-arginyl-tryptophyl-glycine (II).—The protected decapeptide IX (60 mg.) was treated with trifluoroacetic acid in exactly the same manner as has been described above for I, thus giving the free decapeptide II as a colorless fluffy powder, which gave a single spot (R_f=0.37) reactive to ninhydrin, Pauly, Ehrlich, Sakaguchi and methionine (PtI_6'') reagents in paper chromatography in *n*-butanol-acetic acid-pyridine-water (30 : 6 : 20 : 24);[14] $\lambda_{max}^{N/10\ HCl}$ =280 mμ (ε 6320), $\lambda_{shoulder}^{N/10\ HCl}$=288.5 mμ (ε 4820), $\lambda_{max}^{N/10\ NaOH}$=281.5 mμ (ε 7220), 288.5 mμ (ε 6950), $[\alpha]_D^{13.5}$ −32.2±2° (*c* 0.631, N acetic acid). Amino acid ratios in acid hydrolysate:[15] Gly 1.80, Tyr 1.04, Ser 0.87, Met 0.98, Glu 1.00, His 0.95, Phe 0.92, Arg >0.83, Try 0.57,*3 NH_3 0.37.

***N-t*-Butyloxycarbonyl-*O*-benzyl-serine Dicyclohexylamine Salt (XVI).**—*O*-Benzyl-serine[22,23] (4.88 g., 0.025 mol.) was acylated with 5.37 g. (0.0375 mol.) of *t*-butyl azidoformate and sodium bicarbonate in a water-dioxane (1 : 1) solution in almost the same manner as was used for compound III. The sirupy product (7.1 g.) was converted into the dicyclohexylamine salt as usual; 9.25 g. (77.6%), m. p. 135—136°C. Recrystallization from ethanol-ether gave a sample for analyses; m. p. 135.5—136°C, $[\alpha]_D^{24.5}$ +24.3±1° (*c* 2.494, methanol).

Found: C, 68.23; H, 9.34; N, 5.91. Calcd. for $C_{15}H_{21}NO_5 \cdot C_{12}H_{23}N$: C, 68.03; H, 9.03; N, 5.88%.

***N-t*-Butyloxycarbonyl-*O*-benzyl-seryl-tyrosine Hydrazide (XVII).**—A solution of 3.58 g. (7.5 mmol.) of compound XVI in 40 ml. of 50% ethanol was shaken in the presence of 10 ml. (wet volume) of Dowex-50W X8 (H^+ form) at room temperature for 30 min. After the resin had been removed by filtration, the filtrate was evaporated at 40—45°C in vacuo. The sirupy residue was dissolved in ether, and the solution was dried over sodium sulfate and evaporated in vacuo to give *N-t*-butyloxycarbonyl-*O*-benzyl-serine as a clear oil. To this were added a methylene chloride solution of 1.47 g. (7.5 mmol.) of the tyrosine methyl ester and then a methylene chloride solution of 1.55 g. (7.5 mmol.) of DCCI. The mixture was kept in a refrigerator overnight. Subsequent treatment was carried out in almost the same manner as for compound IV. The resulting dipeptide ester (3.60 g.) failed to crystallized, but it was found to be homogeneous in thin-layer chromatography; (R_f=0.53 (Silica-gel G, ethyl acetate)).

A 5.85 g.-sample of the dipeptide ester obtained as described above was dissolved in 40 ml. of anhydrous ethanol, and to this was added 1.45 ml. of hydrazine hydrate. The mixture was allowed to stand at room temperature for 40 hr. and then refrigerated. The crystalline product which separated was filtered off, washed with cold ethanol-ether and ether, and dried; 3.62 g., m. p. 178—181°C (decomp.) (sintering at 165°C). The concentration of the mother liquor afforded an additional 1.00 g. of the crystals with a m.p. of 168—170°C (decomp.). The total yield amounted to 4.62 g. (81.7%). Recrystallization from anhydrous ethanol gave, in a recovery of 93 per cent, crystals with a m. p. of 179—181°C decomp. (sintering at 168°C), $[\alpha]_D^{23.5}$ −12.2±1° (*c* 2.037, dimethylformamide).

Found: C, 61.02; H, 6.90; N, 11.88. Calcd. for $C_{24}H_{32}N_4O_6$: C, 61.00; H, 6.83; N, 11.86%.

***N-t*-Butyloxycarbonyl-*O*-benzyl-seryl-methionine Methyl Ester (XVIII).**—*N-t*-Butyloxy-carbonyl-*O*-benzyl-serine, which was derived from 4.76 g. (0.01 mol.) of the dicyclohexylamine salt (XVI) with the Dowex-50 treatment described above, and the methionine methyl ester (prepared from 2.40 g. (0.012 mol.) of the hydrochloride) were coupled in methylene chloride by the DCCI procedure, in almost the same manner as was used in the case of the synthesis of Compound IV, to give the protected dipeptide XVIII, which crystallized from ethyl acetate-petroleum ether; 4.11 g. (93.4%), m. p. 40—43°C. Recrystallization from the same solvent gave fine needles; m. p. 51—52°C, $[\alpha]_D^{25}$ −13.4±1° (*c* 2.169, methanol).

Found: C, 57.35; H, 7.51; N, 6.60; S, 7.52. Calcd. for $C_{21}H_{32}O_6N_2S$: C, 57.25; H, 7.32; N, 6.36; S, 7.28%.

***N-t*-Butyloxycarbonyl-*O*-benzyl-seryl-tyrosyl-*O*-benzyl-seryl-methionine Methyl Ester (XIX).**—Compound XVIII (2.20 g., 5.0 mmol.) was treated with hydrogen chloride in ethyl acetate to obtain *O*-benzyl-seryl-methionine methyl ester hydrochloride, which was then converted into the free base by treatment with 50% aqueous potassium carbonate in ether. Compound XVII (2.36 g., 5.0 mmol.) was dissolved in 8 ml. of dimethylformamide and chilled in an ice-salt bath. To this solution 20 ml. of ice-cold N hydrochloric acid and 2.75 ml. of ice-cold 2 M sodium nitrite were added. After 3 min. the azide which separated was taken into ether. The etheral solution was washed successively with ice-cold M potassium carbonate, water and saturated sodium chloride, and dried over sodium sulfate. This solution was then added to the oily dipeptide ester obtained above, and the reaction mixture was allowed to stand at 0—4°C for three days. The separated crystalline precipitates of the tetrapeptide XIX were filtered off, washed with cold ether, and dried; 1.41 g., m. p. 123.5—126°C. The mother liquor was washed with acid and bicarbonate as usual, and concentrated to a small volume to yield an additional quantity of XIX; 0.99 g., m. p. 124—127°C. The total yield amounted to 2.40 g. (61.3%). These crystals were recrystallized from ethyl acetate-petroleum ether in a recovery of 96.2 per cent; m. p. 127—129°C, $[\alpha]_D^{25.5}$ −11.1±0.7° (*c* 2.982, methanol).

Found: C, 61.67; H, 6.85; N, 7.26; S, 4.16. Calcd. for $C_{40}H_{52}N_4O_{10}S$: C, 61.52; H, 6.71; N, 7.17; S, 4.11%.

***O*-Benzyl-D-serine.**—*N*-Acetyl-*O*-benzyl-D-serine[23] (9.50 g., m. p. 110—111°C, $[\alpha]_D^{23}$ −46.7±1° (*c* 2.660, acetic acid); lit.[22] m. p. 103°C) was dissolved in 95 ml. of 80% hydrazine hydrate, and the mixture was heated under reflux at 100°C for 6 hr. Most of the hydrazine was removed by evaporation at 50—60°C in vacuo; the residue was dried over sulfuric acid in vacuo. The resultant crystalline solid was washed with cold water, ethanol and ether to give *O*-benzyl-D-serine; 5.69 g. (72.8%). A sample was recrystallized from water for analyses; $[\alpha]_D^{24.5}$ −7.2±0.3° (*c* 2.046, N hydrochloric acid).

*3 Tryptophan had been partially destroyed with acid.

Found: C, 61.55; H, 6.72; N, 7.18. Calcd. for $C_{10}H_{13}NO_3$: C, 61.45; H, 6.91; N, 6.81%.

***N*-*t*-Butyloxycarbonyl-*O*-benzyl-D-serine Dicyclohexylamine Salt.**—*O*-Benzyl-D-serine (0.98 g., 5.0 mmol.) and 1.375 g. (1.25 mmol.) of sodium carbonate were dissolved in 5 ml. of water, and to this was added 1.80 g. (7.5 mmol.) of *t*-butyl *p*-nitrophenyl carbonate[26] which had been dissolved in 7 ml. of *t*-butanol. The mixture was heated under reflux at 100°C for 30 min. and then evaporated to dryness in vacuo. The residue was extracted with cold water. The aqueous extract was neutralized to pH 5 by 4 N hydrochloric acid and washed with ether to remove the *p*-nitrophenol. The aqueous solution was then acidified to below pH 2 at 0°C and extracted with ether. The ether extract was dried over anhydrous sodium sulfate, and to this was added 1 ml. of dicyclohexylamine to afford the crystalline salt of *N*-*t*-butyloxycarbonyl-*O*-benzyl-D-serine; 1.22 g. (71.3%), m. p. 130—131°C, $[\alpha]_D^{24}$ $-23.6\pm1°$ (*c* 2.28, methanol).

Found: C, 68.54; H, 9.48; N, 5.96. Calcd. for $C_{15}H_{21}NO_5 \cdot C_{12}H_{23}N$: C, 68.03; H, 9.30; N, 5.88%.

The authors wish to express their deep thanks to Dr. Mitsuo Ebata and his staff for their amino acid analyses, to Dr. Kaoru Kuriyama and his staff for their optical rotation measurements, and to Dr. Satoshi Mizukami and his staff for their elemental microanalyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1178—1182 (1966)

The Homogeneous Hydrogenation of Acetylenes by Dicyclopentadienyltitaniumdicarbonyl[1)]

By Kenkichi SONOGASHIRA and Nobue HAGIHARA

The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received August 28, 1965)

The homogeneous hydrogenation of acetylenes and olefins in the presence of dicyclopentadienyltitaniumdicarbonyl (I) was studied. The results of the hydrogenation varied with the acetylene substituent. The relative activating effects of the substituents on the hydrogenation of such acetylenes as RC≡CH and R'C≡CR' are as follows: R: Ph>*t*-butyl>*n*-alkyl, R' : Ph>*n*-alkyl. The order is the reverse of that observed with the usual metal catalysts of the VIII group. In order to elucidate the mechanism of hydrogenation, the reaction of the dicarbonyl (I) with various acetylenes was studied, and the structures of the products were discussed.

Previous works in this laboratory have elucidated the catalytic behaviors of various metallocenes and their analogues, such as dibenzenechromium,[2)] nickelocene[3)] and vanadocene.[4)] During the course of an investigation of the catalytic actions of dicyclopentadienyltitaniumdicarbonyl (I) as a part of the above works, it was found that the compound I acts as a catalyst in a homogenous phase for the hydrogenation of 1-pentyne to 1-pentene under mild conditions.

The hydrogenations of other acetylenes and olefins by this catalyst have now been studied. The reductions were generally carried out in hydrocarbon solutions for 30 min. at 50—65°C under an initial hydrogen pressure of 50 atm. The results are summarized in Table I. The results of the catalytic reactions varied with the acetylene substituent. For example, 1-alkynes such as 1-pentyne and 1-hexyne were partially hydrogenated to 1-alkenes, while phenylacetylene was completely reduced to ethylbenzene and *t*-butylacetylene gave a mixture of partially and completely hydrogenated products. No hydrogenation was observed in the case of an alkyne without a terminal methylidyne group, 3-heptyne, although diphenylacetylene was completely hydrogenated to dibenzyl. On the basis of these results, the relative activating effects of the substituents of such acetylenes as RC≡CH and R'C≡CR' on the hydrogenation may be estimated as follows: R: Ph>*t*-butyl>*n*-alkyl, R': Ph>*n*-alkyl. It is interesting that the order is the reverse of that observed in the hydrogenations by the group VIII metal catalysts.

When the hydrogenation of phenylacetylene was carried out using a half quantity of hydrogen for complete reduction, 30% of ethylbenzene, 40% of styrene and 30% of recovered phenylacetylene were detected. The reduction must, therefore, involve a two-step process in which the phenylacetylene is first hydrogenated to styrene. In contrast with the complete hydrogenation of

Table I. Hydrogenation of olefins and acetylenes with dicyclopentadienyltitaniumdicarbonyl[a]

Substrate	Catalyst solution[b]	Reaction temp. °C	Reaction time min.	Product (yield, %)	Recovery %	Remarks
Styrene	A	50—60	30	Ethylbenzene (15)	85	c
Styrene	A	50—65	120	Ethylbenzene (70)	30	c
trans-Stilbene	A	50—60	30	—	100	d
Butadiene	B	50—65	30	—	—	d
1, 3-Cyclooctadiene	A	50—65	30	—	—	d
Acetylene	B	50—60	30	—	—	d
1-Pentyne	A or B	50—60	30	1-Pentene (95)	0	c, e
1-Hexyne	A	50—60	30	1-Hexene (90)	10	c
t-Butylacetylene	A	50—60	30	3, 3-Dimethyl-1-butene (40) 2, 2-Dimethylbutane (60)	0	c
3-Heptyne	A or C	50—65	30	—	100	c
Phenylacetylene	A or B	50—60	30	Ethylbenzene (95)	5	c, e
Diphenylacetylene	A	50—60	30	Dibenzyl (90)	0	e

a) Reactions were generally carried out with 20 mmol. of substrate, dissolved in 20 ml. of the catalyst solution, in a 100 ml. autoclave under an initial hydrogen pressure of 50 atm.
b) The catalyst solutions A, B and C were prepared as follows. Freshly sublimed dicyclopentadienyl titaniumdicarbonyl was dissolved in benzene (catalyst A), in *n*-heptane (B) or in xylene (C) (the concentration 25 mmol./l.) and stocked in a Schlenk tube under argon.
c) Yield was determined by gas chromatography.
d) No absorption of hydrogen was observed.
e) Yield was determined by isolation.

Table II. Nuclear magnetic resonance data

Compound	Position of peak (τ)[a]	Relative intensity[b]	Multiplicity	Assignment
$(\pi\text{-}C_5H_5)_2Ti(C_6H_5C{\equiv}CC_6H_5)_2$ in CCl_4	3.8	10	Singlet	C_5H_5
	3.3	20	Multiplet	C_6H_5
$(\pi\text{-}C_5H_5)_2Ti(C_6H_5C{\equiv}CH)_2$ in CCl_4	3.8	12	Singlet	C_5H_5 + ≡CH
	3.2	10	Multiplet	C_6H_5

b) Estimated to whole numbers by method of counting squares, relative to $C_5H_5=5$.

phenylacetylene, 1-alkynes were effectively subjected to partial hydrogenation to 1-alkenes. These facts also suggest that the kind of the substituent on acetylenes affects the type of hydrogenation.

In the hydrogenation of olefins and butadiene, only very slow absorption, or no absorption at all, of hydrogen was observed.

On the other hand, it was reported by Breslow and his collaborators[5] that the soluble Ziegler-type catalysts activated hydrogen for the homogeneous hydrogenation of olefins. It has been suggested that the study of the cited soluble catalysts should shed some light on the mechanism of the heterogeneous hydrogenat·on of olefins. However, in order to explain the mechanism of the hydrogenation in terms of organometallic chemistry, it is more useful to study the simple organometallic complex catalyst than to study a combined one, such as the Ziegler-type catalyst, because such a simple complex will make more convenient the isolation of an intermediate of the reaction.

Thus, in the present study the isolation of the intermediate was attempted. The dicarbonyl complex (I) was heated to 60°C for 20 min. with diphenylacetylene in a benzene solution under an inert atmosphere. From the reaction mixture, by chromatography on alumina and recrystallization from *n*-hexane, air-stable green crystals (II) were obtained in a 15% yield. On the other hand, Volpin and his collaborators[6] reported the synthesis of the same complex (II) by the reaction of diphenylacetylene, sodium cyclopentadienide and titanium tetrachloride. On the basis of the products of the reaction with hydrochloric acid or potassium hydroxide, they proposed the structures A and B. The present authors also investigated the structure of the complex II by means of studies of the NMR, infrared and electronic absorption spectra. The infrared spectrum of the complex II is in accord with either structure, A or B, because it shows π-bonded cyclopentadienyl

(B)

ligand absorptions and absorptions of sterically-hindered phenyl groups which are similar to that of π-cyclopentadienylcobalttetraphenylcyclobutadiene.[7] The data of NMR spectra are given in Table II, together with some assignments. The NMR spectrum of the complex II shows the aromatic multiplet at 3.2—3.65 τ and a sharp π-bonded cyclopentadienyl singlet at 3.8 τ. The phenyl/cyclopentadienyl proton ratio is 2.0 (calcd. 2.0).

The electronic absorption spectrum of the complex II is very similar to those of hexaphenylsilole, pentaphenylarsole and pentaphenylphosphole,[8] and it shows no characteristic absorption band of tetrasubstituted cyclobutadiene derivatives in the region of 320 mμ.[9,10] This fact supports the structure B, which has more sterrically-hindered phenyl groups than does the structure A.

The reaction of phenylacetylene with dicyclopentadienyltitaniumdicarbonyl was carried out under similar conditions. After the purification by chromatography on alumina, air-stable green needles (III) and a linear oligomer of phenylacetylene were obtained (yields, 7% and 25% respectively). The infrared spectrum of the complex III shows no acetylenic absorption bands, but it does show phenyl and π-bonded cyclopentadienyl absorptions. The NMR spectrum also shows phenyl and π-bonded cyclopentadienyl absorptions, where the ≡CH-proton band overlaps with the cyclopentadienyl band. The proton

····· II in tetrahydrofuran
—— III in tetrahydrofuran
–·–· hexaphenylsilole in cyclohexane

ratio of cyclopentadienyl (including methylidyne protons)/phenyl is 1.2 (calcd. 1.2). The electronic absorption spectrum of the complex III is given in Fig. 1. From the above consideration, it may be concluded that the complex III should have either the structure A or B. Of these structures, B seems more probable for the complex III as in the case of the complex II, since the complex III is even more stable than the complex II. However, we failed in an attempt to obtain structural proof by the direct synthesis of the complex III from the dicyclopentadienyltitanium dichloride and 1, 4-dilithiotetraphenylbutadiene by analogy with the synthesis of 1, 1-bis(π-cyclopentadienyl)-2, 3, 4, 5-tetraphenylzirconacyclopentadiene.[8]

When acetylene or pentyne is employed in a similar reaction with the dicarbonyl I, unstable green oils are obtained. Further investigation of these oils has been given up, however, because of their instability. Olefins and butadiene do not react with the dicarbonyl I. This finding agrees with the fact that the hydrogenation of olefins and butadiene is very slow.

Neither complex, II or III, catalyzes the hydrogenation of acetylenes. Therefore, the exact mechanism of the catalytic hydrogenation of acetylenes is not yet clear. However, it is possible at present to speculate that the active intermediate in the hydrogenation is a precursor of

the complex II or III, such as the complex IV, an analogue of the vanadium complex V which was reported on in a previous paper.[11]

Recently, the hydrogenation of olefins by dicyclopentadienyltitanium, which had been obtained by the decomposition of dicyclopentadienyldimethyltitanium with hydrogen,[12] was reported by Shikata and his collabolators.[13]

Experimental

The proton NMR data were obtained on a Varian A 60 spectrometer and a Japan Electron Optics Lab. JNM-4H-100 spectrometer, using tetramethylsilane as the internal standard. The infrared spectra were recorded on a Hitachi EPI-1 spectrometer. Gas chromatographic anaylses were carried out on Shimadzu GC-1 and GC-2B gas chromatographs. The melting and decomposition temperatures were observed by means of a hot-stage microscope and were not corrected.

The General Procedure of Hydrogenation.—The hydrogenation reactions were carried out in a 100-ml. autoclave. Since the catalyst was sensitive to air and moisture, all operations were carried out in an inert atmosphere. After the autoclave had been flushed with nitrogen, 20 ml. of the catalyst solution A, B or C (see below) was transferred from the stock tube by a syringe; then acetylene or olefin was charged in. The reduction was carried out under an initial hydrogen pressure of about 50 atm. and at 50—60°C for 30 min.. Although the hydrogenation of acetylenes did not proceed under 50°C, the rapid hydrogen uptake started at 50°C. In the case of olefins, no rapid reduction took place, even at 100°C. After the reaction, the hot solution was left standing in order to cool it. The products were analyzed and identified either by isolation or by gas chromatography. Several typical hydrogenation experiments are described below.

The Preparation of the Catalyst Solution.—Freshly-sublimed dicyclopentadienyltitaniumdicarbonyl was dissolved in benzene (catalyst A), in *n*-heptane (catalyst B) or in xylene (catalyst C), each concentration being 25 mmol./l., and stocked in a Schlenk tube under argon.

The Hydrogenation of 1-Pentyne.—A 100-ml. autoclave was charged with 2 ml. (20 mmol.) of 1-pentyne and 20 ml. of the catalyst solution A under nitrogen, and then with hydrogen up to a pressure of 50 atm. It was heated under shaking. A rapid hydrogen uptake started at 50°C, and the hydrogenation finished almost completely within 10 min. After it had been cooled with water, the reaction mixture was analyzed by gas chromatography. Found: 1-pentene 95%. Pentyne and pentane were not detected. (Dinonyl phthalate 3 m.; flow rate 32 ml./min. N_2; 55°C.) In a similar experiment, in which 5 g. of 1-pentyne, 0.5 g. of dicyclopentadienyltitaniumdicarbonyl and 20 ml. of benzene were used, 4.5 g. (90%) of 1-pentene was isolated by fractional distillation.

The Hydrogenation of Diphenylacetylene.—Into a 100-ml. autoclave, 3.4 g. of diphenylacetylene, 30 ml. of the catalyst solution A and 50 atm. of hydrogen were charged. The autoclave was shaken and heated. A rapid pressure drop took place at 50°C. After 30 min., the autocalve was cooled with water. The removal of the solvent yielded 3.6 g. of a pale yellow solid. It was purified by sublimation and recrystallization from methyl alcohol to give 3 g. of dibenzyl, m. p. 50—51°C (lit. 51.5—52.5°C). The infrared spectrum was identical with that of an authentic specimen.

The Partial Hydrogenation of Phenylacetylene. Into a 100-ml. autoclave, 2.7 g. (22 mmol.) of phenylacetylene, 20 ml. of the catalyst solution A and 6 atm. of hydrogen (22 mmol. of hydrogen) were charged. The autoclave was then shaken and heated. A rapid pressure drop took place at 50°C. After all the hydrogen had been absorbed, the autoclave was cooled with water. The reaction mixture was analyzed by gas chromatography, a study of its infrared spectrum, and the amount of the hydrogen absorption. Found: ethylbenzene 30%, styrene 40%, phenylacetylene 30%. (Thermol-2 3 m. and silicon-550 1.5 m.; flow rate 67 ml./min. N_2; 120°C; retention time: ethylbenzene 13 min.; styrene and phenylacetylene 16.5 min.) The styrene/phenylacetylene ratio was determined by the a amount of hydrogen absorption.

The Reaction of Diphenylacetylene with Dicyclopentadienyltitaniumdicarbonyl (I).—Dicylcopentadienyltitaniumdicarbonyl (I) (1.0 g., 4.3 mmol.) and diphenylacetylene (1.5 g., 8.6 mmol.) were heated in 20 ml. of benzene for 20 min. at 60°C. A violent evolution of gas took place, and the color of the reaction mixture changed to a greenish brown from red brown. After the mixture had cooled, the solvent was removed in vacuo and a green solid was obtained. Purification by chromatography on alumina and recrystallization from *n*-hexane yielded 0.3 g. of green crystals (II), m. p. 150°C in a sealed tube under nitrogen. A longer reaction time and a higher reaction temperature diminished the yield. Chromatographic purification must be carried out as quickly as possible because the green complex (II) slowly decomposes on alumina.

Found: C, 85.02; H, 5.59. Calcd. for $C_{38}H_{30}Ti$: C, 85.38; H, 5.66%.

An infrared spectrum in Nujol showed absorptions at 3080(w), 3040(w), 1590(m), 1495(sh), 1478(sh), 1442(m), 1362(w), 1257(s), 1175(w), 1152(w), 1145(w), 1095(sh), 1073(s), 1015(s), 940(vw), 905(vw), 835(w), 825(m), 803(vs), 796(vs), 772(m), 768(s), 750(m), 720(m), 697(vs), and 692(vs).

An electronic spectrum showed absorptions at 624 mμ (log ε, 1.90), 405 mμ (log ε, 3.16), 334 mμ (sh), 278 mμ(sh), and 240 mμ (logε, 4.24) in tetrahydrofuran.

The Reaction of Phenylacetylene with Dicyclopentadienyltitaniumdicarbonyl. — The dicarbonyl complex I (2.34 g., 10 mmol.) and phenylacetylene (2.0 g., 20 mmol.) were heated in 20 ml. of *n*-hexane for 20 min. at 60°C under nitrogen. A violent evolution of gas was observed, and the reaction mixture turned dark brown. The chromatography of the reaction mixture on alumina yielded 0.15 g. of an oxygenated product of the dicarbonyl complex I, 0.3 g. of a green solid (III), and 0.5 g. of a brown oligomer of phenylacetylene. After the recrystallization of the green solid (III) from *n*-hexane, 0.25 g. of green needles were obtained. M. p., 134—136°C in a sealed tube under nitrogen; yield, 7%.

Found: C, 81.95; H, 5.84. Calcd. for $C_{26}H_{22}Ti$, C, 81.67; H, 5.82%.

An infrared spectrum in Nujol showed absorptions at 3080(w), 3055(w), 1590(s), 1568(w), 1482(s), 1443(m), 1437(m), 1300(vw), 1277(w), 1262(vw), 1200(vw), 1175(vw), 1150(vw), 1125(vw), 1070(m), 1020(s), 1010(s), 992(vw), 920(vw), 895(vw), 840(s), 820(vs) 810(vs), 802(sh), 750(vs), 745(sh), and 690(s).

An electronic absorption spectrum showed λ_{max} at 608 mμ (log ε, 2.14), 410 mμ (log ε, 3.55), 340 mμ (log ε, 4.16), and 238mμ (log ε, 4.32) in tetrahydrofuran.

The Attempted Reaction of Dicyclopentadienyltitanium Dichloride with 1, 4-Dilithiotetraphenylbutadiene.—A suspension of 1, 4-dilithiotetraphenylbutatriene, prepared from 2 g. of diphenylacetylene in 5 ml. of ether as described by Braye and his collaborators,[8] was added to a suspension of 2 g. of dicyclopentadienyltitanium dichloride in 100 ml. of ether. After the mixture had been refluxed for 3 hr., the formation of no product could be observed and the dichloride was recovered. A similar reaction was also attempted in tetrahydrofuran, but no reaction took place.

The authors wish to thank Mr. Toshiki Shibano for the elemental analyses and Dr. Akira Nakamura for the measurement of the NMR spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1182—1185 (1966)

The Polymerization of Acetonitrile in the Presence of Acidic and Basic Substances

By Eizo OIKAWA, Kyoichi MORI and Goro SAITO

Faculty of Engineering, Niigata University, Nagaoka, Niigata

(Received September 3, 1965)

Complexes of saturated nitriles with metal chlorides polymerize readily. In this paper, the polymerization of acetonitrile was carried out with more nitrile, than was needed to form the complex with metal chlorides. The conversion of the polymer increased in comparison with the case of the polymerization of the complex, indicating that the complex would partly dissociated in the reaction. The trimer of acetonitrile, 4-amino-2, 6-dimethylpyrimidine, was isolated, and ammonia was detected in addition to the brown polymer. The mechanism of the trimer formation in the presence of metal chlorides was illustrated through the removal of a proton from acetonitrile with the help of the chlorides, and through dimer formation. Hydrochloric acid and metaphosphoric acid were less active than metal chlorides. Ammonia itself was found to be inactive for the trimerization, bringing only acetamide. Water was also inactive in response to acetonitrile in the absence of acidic or basic substances. The derivation of ammonia was attributed to the decomposition of the pyrimidine compound and/or to the degradation of the polymer, but not to the hydrolysis of acetamide. The reaction of the polymer with propionaldehyde, the hydrolysis of the product, the carbylamine test, and a treatment of the trimer similar to that used for the complex suggested that the pyrimidine rings are involved in the polymer structure.

In previous papers[1,2] the polymerization of complexes of saturated nitriles with metal chlorides and the structure of the polymers have been reported. The composition of complex of the nitrile (RCN) with metal chloride (MCl_n) is definite (generally $2RCN:MCl_n$). If however, the metal chlorides behave as catalysts in the polymerization, the chlorides need not necessarily be added in amounts large enough to convert the whole nitrile into the complex. In the present investigation the polymerization was carried out with the excess nitrile; in other words, more nitrile than was needed to form the complex was added to the polymerization system in order to investigate if it is valid to say that only the nitrile that forms the complex is able to polymerize, while the free nitrile in the system is not.

In the polymerization, the trimer, 4-amino-2, 6-dimethylpyrimidine, and ammonia were obtained in addition to the polymer. The formation of the trimer has briefly been reported by Kabanov et al.[3] The mechanism of these formations in the presence of acidic substances was investigated, and it was suggested that the polymers include pyrimidine rings.

Experimental

Materials and Procedure.—The materials and the procedure were the same as those described in a previous paper.[2] The nitrile was added to the metal chlorides under a nitrogen atmosphere.

The sealed tube was heated in an autoclave under

1) E. Oikawa and S. Kambara, *J. Polymer Sci.*, **B2**, 649 (1964).

2) E. Oikawa and S. Kambara, This Bulletin, **37**, 1849 (1964).

the pressure of isobutyl alcohol in order to prevent the tube from breaking. After they had been heated for the required time, the dark brown mass and liquid were transferred to a sublimation apparatus. The unconverted nitrile was distilled off, and sublimation followed. The white sublimate was submitted to elementary analyses. The ratio of acetamide and the pyrimidine in the sublimate was determined from the nitrogen concent by means of the Kjeldahl method using the following equation:

$$X = (N-23.7)/0.105$$

where X is the percentage of the pyrimidine compound (%) and N is the nitrogen content of the sublimate (%).

The Reaction of the Polymer with Propionaldehyde.—In a 100-ml. three-necked flask with a stirrer, a condenser and a thermometer, 25 ml. of propionaldehyde[4] and 0.3 g. of the pulverized polymer were placed. The reaction vessel was then heated in a water bath at 40°C, with stirring continued for 6 hr. After the propionaldehyde (b. p. 49°C) had been distilled off, the residue was washed with water and dried in a vacuum at 60°C. This specimen was subjected to infrared analysis. The hydrolysis of the reaction product was accomplished by refluxing it in a 0.1 N sodium hydroxide solution for 9 hr.

The Heat Treatment of 4-Amino-2, 6-dimethylpyrimidine with Metal Chlorides.—The pyrimidine compound was prepared by the trimerization of acetonitrile with sodium metal.[5] The procedure was the same as that described previously.[2] After the sublimation of the dark brown mass produced by heating, the residue was pulverized, washed with a diluted hydrochloric acid solution and water, and dried in a vacuum. For example, the heating of 1.03 g. of the pyrimidine compound with 2.38 g. of titanium tetrachloride ($[(CH_3CN)_3]/[TiCl_4]=2/3$) at 250°C for 4 hr. produced 0.50 g. of a brown solid (Found: N, 20.5%). The same treatment of 0.60 g. of the pyrimidine compound with 0.97 g. of zinc chloride for 8 hr. produced 0.24 g. of the product (Found: N, 16.6%). These products were insoluble or sparingly soluble in common organic solvents, but soluble in concentrated sulfuric acid.

Results and Discussion

The results of the polymerization with excess acetonitrile are shown in Table I.

In the same method as has been reported previously[1] the activation energy of the polymerization at a molar ratio of $r=13.8$ was found to be about 19 kcal./mol., which is equal to the value obtained from the polymerization of the acetonitrile complex with titanium tetrachloride. The conversions in Table I show that more nitrile than was needed to form the complex was converted to the polymer. These facts indicate that the following dissociation will occur at least partially under the polymerization conditions:

$$\begin{array}{l} 2RCN:MCl_n \rightleftharpoons 2RCN + MCl_n \\ \quad\downarrow \\ 2(RCN)_m:mMCl_n \rightleftharpoons 2(RCN)_m + mMCl_n \end{array}$$

The metal chlorides derived from dissociation can form a complex with free nitrile. Thus, the new complex and the undissociated complex will be converted to the polymer at the activation energy of 19 kcal./mol. The conversions in parentheses in Table I suggest that the chlorides do not have any remarkable catalytic effect.

The dark brown solutions of TA_32520 and ZA_22520 after polymerization were dried, and the residues were submitted to sublimation. A small amount of a white, crystalline substance was obtained; this was, for the most part, identified as 4-amino-2, 6-dimethylpyrimidine by a study of its melting point (179°C; 182°C[5]) and infrared spectrum and by elementary analyses (Found: C, 59.0; H, 7.4; N, 33.9. Calcd. for CH_3CN: C, 58.5; H, 7.3; N, 34.1%). This pyrimidine compound is usually prepared with basic catalysts, such as alkali metals and alkali metal alcoholates.[5]

In the polymerization of acetonitrile, there occurred the evolution of ammonia[2]; this might cause the trimerization of acetonitrile. The ammonia may be derived from the hydrolysis of acetamide with a trace of water included in the acetonitrile, or from the thermal degradation of the polymer.[2] The influence of ammonia on the trimerization, therefore, was investigated with and without water. The results are summarized in Table II. All the system changed dark brown and produced the polymer. Sublimation isolated a fine, opaque sublimate and transparent sublimate, which were identified by their melting points as 4-amino-2, 6-dimethylpyrimidine (179°C) and acetamide (81°C) respectively. The gradual decrease in the pyrimidine compound and the increase of acetamide with the increase in water content suggest that water was consumed only to form acetamide; the evolution of ammonia by the hydrolysis of acetamide was not confirmed.

In each experiment of Table II there was the odor of ammonia. Whether or not the ammonia exerts the catalytic action for trimerization was examined by adding concentrated ammonia (28%) to the nitrile. Table III shows the results. The sublimatoin of a white crystalline substance after distilling off the excess nitrile isolated almost only acetamide, which was also identified by a study of its infrared spectrum; there was no colored substance. Hence, ammonia does not behave as a catalyst for the formation of the pyrimidine.

It is considered that not only Lewis acid but also proton donating inorganic acids like hydrochloric acid will promote the polymerization of the nitrile if the reaction is initiated by the removal of a proton from the $H^+—{}^-CH_2{\equiv}C–N:{\rightarrow}MCl_n$ complex. The results of the experiments adding 35% hydrochloric acid and metaphosphoric acid

are given in Table IV. Ammonia was detected, and there was a very small yield of a brown polymer. The infrared spectrum of the white sublimate revealed the formation of a small amount of the pyrimidine compound. Therefore, hydrochloric acid and metaphosphoric acid are less active in the trimerization and polymerization than are zinc chloride and titanium tetrachloride.

The presence of water in the system in all the above results increased the yield of acetamide. The polymer formed during the reaction time has been found to cause autocatalysis.[3] Thus, an attempt was made to carry out the reaction under the same reaction conditions (250°C, 20 hr.), adding to the system separately a little water and the polymer prepared from the complex,[2] without any acidic and basic substances. In either case neither colored product nor sublimable substance was formed, and there was no odor of ammonia. Hence, the polymer does not behave as a catalyst for the trimerization, nor does it give the pyrimidine compound by the degradation of the polymer.

Since the evolution of ammonia was always accompanied with the formation of the trimer or the polymer, it may be concluded that ammonia would probably be given by the decomposition of the pyrimidine compound and/or the degradation of the polymer.

When the reaction conditions were changed from 250°C for 20 hr. to the refluxing condition for 20 hr. under an atmospheric pressure, the system of excess nitrile with zinc chloride did not give any colored product or sublimable substance. Therefore, the rise in pressure (about 30 atm. in the sealed tube at 250°C) and temperature seems always necessary. The application of high pressure (50000 atm.) and high temperature (200—400°C) to acetonitrile has brought about a similar formation of 4-amino-2, 6-dimethylpyrimidine.[6] However, the addition of metal chlorides does not need such drastic conditions, and it facilitates the trimerization and polymerization. The high conversion of the trimer with a strong basic catalyst is due to the easy removal of a proton from acetonitrile. The complex formation of the nitrile with metal chlorides may also help the removal of a proton from acetonitrile, which will in turn facilitate the following formation of a dimer and, finally, the trimer. The formation of the trimer through the dimer has been confirmed in a basic catalyst.[7]

1) Removal of a proton:

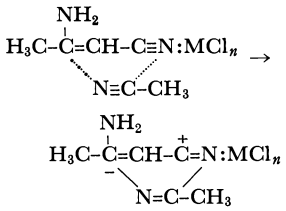
$$CH_3CN + MCl_n \rightarrow H^+ — {}^-CH_2\text{-}C{\equiv}N{:}{\rightarrow}MCl_n$$

$$H^+ + CH_3CN \rightarrow H_3C\text{-}C^+{=}NH$$

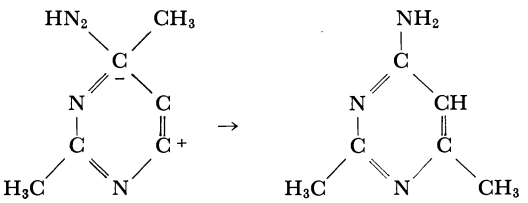
2) Formation of a dimer:

$$H_3C\text{-}C^+{=}NH + {}^-CH_2\text{-}C{\equiv}N{:}MCl_n \rightarrow H_3C\text{-}\underset{\underset{NH}{\|}}{C}\text{-}CH_2\text{-}C{\equiv}N{:}MCl_n \rightarrow H_3C\text{-}\underset{\underset{NH_2}{|}}{C}{=}CH\text{-}C{\equiv}N{:}MCl_n$$

3) Formation of a pyrimidine ring:



4) Rearrangement:



The polymer obtained in Tables I and II was similar in infrared spectra and nitrogen content to those obtained previously.[2] The polymer from the complex, when subjected to a carbylamine test, revealed positive results, while the sublimation of the polymer isolated nothing. Moreover, the infrared spectrum of a pulverized polymer suspended in propionaldehyde for 6 hr. at 40°C showed sharp new absorptions at 2850, 2920, and 2950 cm^{-1} which are probably due to C–H stretching vibrations, and a stronger absorption at 1620 cm^{-1} due to C=N. The former three absorptions disappeared upon alkaline hydrolysis. These facts support the idea that the polymer has an amino group.

The treatment of 4-amino-2, 6-dimethylpyrimidine with metal chlorides similar to that of the complex produced a dark brown solid whose infrared spectrum revealed absorptions similar to those of the polymer prepared from the complex (3400, 3000—2900 cm^{-1}: weak and broad; 1600 cm^{-1}: strong and broad). A strong odor of ammonia was found, and nothing was isolated by sublimation. The nitrogen contents of the products were comparable with those of the polymer obtained from the complex.[2]

Considering the formation of the pyrimidine compound in addition to the brown mass, it may be concluded that the pyrimidine compound takes part in the formation of the polymer as well as conjugated C–N groups.

The authors wish to acknowledge that these investigations have been undertaken with the aid of Yamaguchi funds. One of the authors (E. O.) is also indebted to Professor Shu Kambara of the Tokyo Institute of Technology for his generous help in carrying out a part of the experiments.

Osmotic Pressure Measurements for Poly-*p*-Chlorostyrene Solutions

By Kan'ichiro TAKAMIZAWA*

Department of Chemistry, Faculty of Science, Tokyo University of Education, Otsuka, Tokyo

(Received September 8, 1965)

Osmotic pressure measurements were made on poly-*p*-chlorostyrene fractions in toluene. Their intrinsic viscosities were measured in toluene, butanone, and chlorobenzene at 30°C. The intrinsic viscosity - molecular weight relationships of these systems were then evaluated for the monodisperse homologue by applying the proper correction for the heterogeneity in the sample. The unperturbed dimension of the polymer was estimated by the Kurata-Stockmayer method. A comparison of this estimate with that for polystyrene indicated that the chlorine atom at the para-position had no appreciable effect on the hindrance to the internal rotation of chain. The heat of the dilution of the polymer in toluene and chlorobenzene was also determined from measurements of the temperature coefficient of the osmotic pressure. It was endothermic in toluene and approximately zero in chlorobenzene. These results were then discussed in relation to the cohesive energy densities of the polymer and the solvents.

In the study of high polymers, the osmotic pressure is a primary source of information on the number average molecular weights of polymers and on the thermodynamic properties of polymer-solvent systems. In the measurement, however, we often encounter many technical difficulties which have not yet been completely solved. The main difficulty arises from solute permeation through semi-permeable membranes.[1,2] In practice, however, we may avoid this difficulty in the measurement of fractionated samples with molecular weights higher than 2×10^4 by making a suitable choice of the semi-permeable membrane.

A large number of experimental and theoretical work has been carried out in an effort to elucidate the solution properties of high polymers. It is interesting to examine how these properties are influenced by the structural units of the polymer molecule. In this connection, light-scattering measurements carried out in our laboratory have shown that, in comparison with a polystyrene chain, the chain extension of poly-*p*-chlorostyrene is modified in solution, possibly because of the polar character of its structural unit.[3]

The present investigation was undertaken in order to make a further study of the solution behavior of poly-*p*-chlorostyrene. As is well known, this behavior, for example, the relation between the intrinsic viscosity and the molecular weight, is affected by the heterogeneity in molecular weight. This difficulty can apparently be overcome by estimating the relation corresponding to a homogeneous homologue, using an appropriate molecular weight distribution function and the data for weight- and number-average molecular weights for each fraction of the fractionated sample. Furthermore, the temperature dependence of the osmotic pressure of the system was also measured in order to examine the way in which a polar group substituted in the polymer molecule affects the polymer-solvent interaction.

Experimental

Materials.—The poly-*p*-chlorostyrene fractions used were those described in a previous report.[3] The sample had been thermally polymerized at 100°C for 48 hr. and then fractionated by a successive precipitation procedure employing butanone as a solvent and methanol as a precipitant. The steps followed were to dissolve the fraction in butanone (about 2 per cent concentration) and then to pour the solution into excess methanol, which had previously been cooled by a dry ice - methanol mixture, before filtering and drying the sample in a vacuum (below 10^{-4} mmHg) for 10 hr. at 60°C.

Each solvent was purified in the usual manner.

Osmometry.—The osmotic pressure measurements were carried out with modified Zimm-Myerson osmometers. This type of osmometer was preferred because of its simple construction and operation.[4] Further, some investigators have developed refinements in the use of this instrument.[5-10] Our modification of the

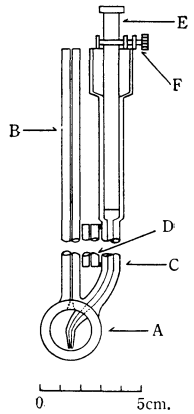

Fig. 1. Modified cell of Zimm-Myerson osmometer.
A, cell; B, measuring capillary; C, filling tube; D, reference capillary; E, positioning rod; F, screw cock

cell is presented in Fig. 1. The glass cell is 1.2 cm. deep and 2 cm. in inner diameter. The filling tube (in. diam. 2 mm.) extends from the side of the cell to within a few millimeters of the bottom, and the measuring capillary (int. diam. 0.8 mm.) extends to the top of the cell so that air bubbles in the cell may be easily eliminated. The filling tube is closed by a glass rod with a mercury seal, similar to that devised by Takenaka and Ikeda,[9] the rod being used to adjust the meniscus level of the solution. Membranes are clamped on by means of 18—8 stainless-steel plates with Teflon packings. The cell is filled and emptied with a hypodermic syringe fitted with a long needle. The osmometer cell is held in a large glass cylinder containing the solvent.

Gel-cellophane #300* was used as the semi-permeable membrane. After the membranes had been allowed to swell in water, they were clamped on the cell and then conditioned to a measuring solvent by a procedure similar to that proposed by Carter and Record.[11] Namely, they were transferred to toluene through 50/50 water-ethanol, absolute ethanol and 50/50 ethanol-toluene, being allowed to remain in each solvent for two days. Before measurements the membranes on the cell were immersed in toluene for at least two weeks.

The osmotic pressure measurements for the poly-*p*-chlorostyrene fractions were performed at 30.0 and 60.0°C by employing toluene and chlorobenzene as solvents. Though the osmometer was cotrolled in an thermostat within ±0.001°C at 30°C and ±0.005°C at 60°C, the results did not stabilize because of fluctrations of the room temperature; therefore, the thermostat was then placed in an air-bath, one controlled to within ±0.1°C of the measuring temperature.

In order to eliminate effects due to the absorption of the solute on the membranes,[2] new membranes were further conditioned with a solution at a higher concentration before use, and then the cell was rinsed three times with the solution to be measured. In the third rinsing it was immersed for a period of 0.5 to 1 hr. The osmotic pressure data were obtained by reading the height differences over 24 to 48 hr., since at least 5 hr. were required to attain equilibrium. No lowering of the height of the solution meniscus, which is possibly due to the permeation of the solute through the membranes, was observed during the measurement except in the case of the most concentrated solution (about 2.5 g./100 cc.). The dynamic osmotic procedure failed to give any reliable results because the relation between the rate of solvent permeation and the pressure difference was not linear. Membrane symmetries were assured within a range of ±0.01 cm. during each measurement.

Viscometry.—Viscosity was measured at 30±0.01°C with an Ubbelohde viscometer which had been modified to facilitate successive dilutions. Its flowing volume was about 2 cc., and the length of the capillary was 10 cm. The flow time of butanone was about 200 sec., permitting us to ignore the kinetic energy correction. The solvents used were toluene, butanone and chlorobenzene. The data obtained were treated according to Huggins' equation.

Results and Discussion

Extrapolation to Infinite Dilution.—Most of the fractions were osmotically measured in toluene at 30.0°C in a concentration range of 0.2 to 1×10^{-2} g./cm³. The values of the reduced osmotic pressure, π/c, are plotted against the concentration, c, in Fig. 2 (π in g./cm² and c in g./cm³). They are apparently represented by this equation:

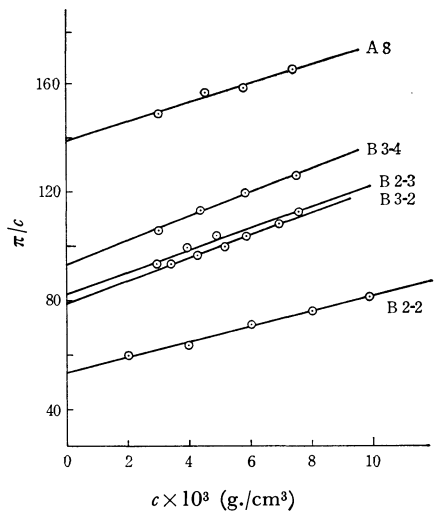

Fig. 2. Plots of π/c against c for fractions of poly-*p*-chlorostyrene in toluene at 30°C.

$$\pi/c = \boldsymbol{R}T[(1/M_n) + A_2c] \quad (1)$$

where $\boldsymbol{R}$ is the gas constant in g.cm./deg.mol.; M_n, the number-average molecular weight, and A_2, the second virial coefficient in cm³mol./g². The constants, M_n and A_2, were evaluated by the method of least squares, where Eq. 1 was rewritten

11) S. R. Carter and B. R. Record, *J. Chem. Soc.*, **1939**, 664.
* This was kindly supplied by the Tokyo Cellophane Co., Ltd.

in the form expressed as a c series, as recommended by Ducker et al.[12] Figure 2 apparently shows a good agreement between the experimental points and the rectilinear relation.

On the other hand, the osmotic pressures of toluene solutions of the fraction B 2-2 were measured over a larger concentration range, up to 2.5×10^{-2} g./cm^3, at two different temperatures, 30.0 and 60.0°C. Furthermore, the osmotic pressure of the fraction in chlorobenzene was measured at the same temperatures. A plot (Fig. 3) of the observed data, listed in Table I,

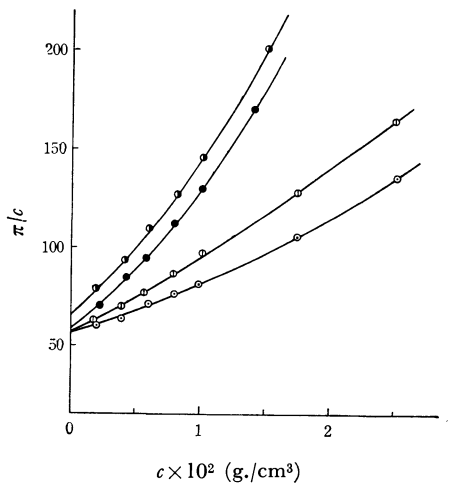

Fig. 3. Plots of π/c against c for fraction of B 2-2 in toluene (⊙ at 30°C, ⓘ at 60°C) and in chlorobenzene (● at 30°C, ◑ at 60°C).

shows that the values for both solvents fit curves with an upward curvature. Therefore, the relationship between π/c and c should be represented by an equation with larger virial coefficients:

$$\pi/c = \boldsymbol{R}T[(1/M_n) + A_2c + A_3c^2] \qquad (2)$$

where A_3 is the third virial coefficient in cm^{6}mol./g^3. In this case, there are two methods of analyzing the observed data; one is to determine the most possible curve for the experimental points by the least squares technique, as has been previously described, while the other is to fit the curve according to the equation derived from Flory's theory of dilute polymer solutions, i. e.,

$$\pi/c = (\boldsymbol{R}T/M_n)(1 + \Gamma_2c + g\Gamma_2^2c^2) \qquad (3)$$

where g is a factor whose value depends on the intermolecular potential energy.[13] As the theoretical work of Stockmayer and Casassa gave $g=1/4$, Eq. 3 may be written as:

$$(\pi/c)^{1/2} = (\boldsymbol{R}T/M_n)^{1/2}[1 + (\Gamma_2/2)c] \qquad (4)$$

This equation gives a linear relation between $(\pi/c)^{1/2}$ and c.[14]

The data observed for the fraction B 2-2 were treated by both methods; the results, i. e., M_n, A_2, and A_3, are summarized in Table II. The plots of $(\pi/c)^{1/2}$ against c, also shown in Fig. 4, indicate that they apparently obey a linear relationship. From Table II, however, it appears that the values of M_n and A_2 are nearly the same for both treatments, while the agreement between those of A_3 is far from satisfactory. The standard deviations of the observed values of π from those calculated by Eq. 3 with $g=1/4$ are larger than those obtained from Eq. 2. However, because the osmotic pressures of the fractions in toluene, except that of B 2-2, were measured for only a few concentrations and over a smaller concentration range, it may be better if the data for the fractions are treated by Flory's equation with $g=1/4$. The results are summarized in Table III, which contains the weight average molecular weight, M_w, as determined by Saito from light-scattering measurements.[3]

The Dependence of Solution Properties on the Molecular Weight.—The plot of the

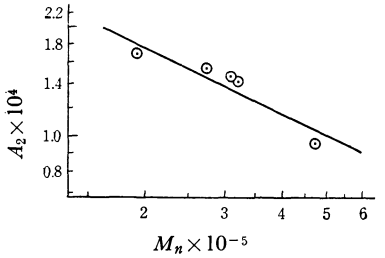

Fig. 5. Dependence of second virial coefficient on molecular weight for poly-*p*-chlorostyrene fractions in toluene at 30°C.

second virial coefficient against the molecular weight is shown in Fig. 5. It appears that A_2 decreases as M_n increases, as is generally recognized, and has a linear logarithmic relationship to M_n, corresponding to $A_2\propto M_n^{-0.6}$. The osmotic second virial coefficients have slightly higher values and a more marked dependence on the molecular weight than that determined by light-scattering measurements. This may be partly attributed to the molecular weight distribution of the fractions.

As a result of light-scattering measurements, it has been shown that the presence of a polar group in the molecule of poly-*p*-chlorostyrene has a marked influence on its solution behavior and increases its solubility in polar solvents. This tendency may be deduced from the fact that A_2 in a chlorobenzene solution is remarkably higher than that in toluene, as is shown in Table II, and also from the fact that the magnitude of the intrinsic viscosity of the fractions in toluene, butanone, and chlorobenzene increases as the polarity of the solvent is increased. The data for the intrinsic viscosity, $[\eta]$, are also summarized in Table III. The plot of $[\eta]$ against M_n for each solvent (Fig. 6) shows that the relation for each solution is apparently linear on a log-log scale. However, it is known that the degree of homogeneity with respect to the molecular weight has a much greater effect on the relation between $[\eta]$ and M_n than on that between $[\eta]$ and M_w. For comparison, the plot of $[\eta]$ against M_w is also shown in Fig. 6. These plots represents the effect of the heterogeneity on the Mark-Houwink equation:

$$[\eta] = KM^{\alpha} \tag{5}$$

It is desirable that the equation be established for a homogeneous homologue of the polymer

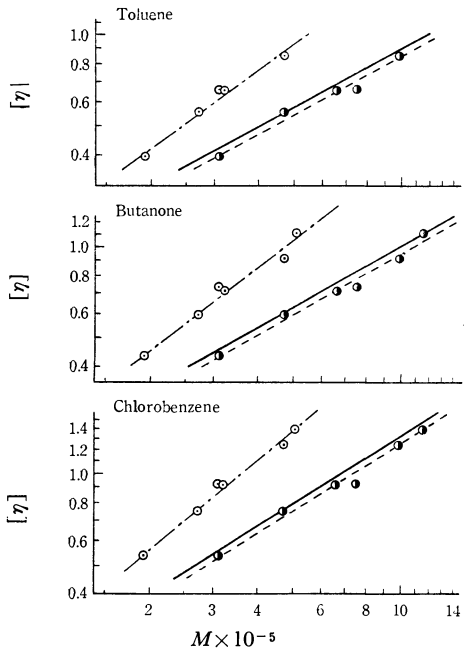

Fig. 6. Relation between intrinsic viscosity and molecular weights. Open circles, $[\eta]$-M_n; half-filled circles, $[\eta]$-M_w; full line, relation corresponding to homogeneous homologue.

before entering into a precise discussion. The K-value corresponding to homogeneous samples may be estimated from the experimental values, i. e., K_w in the $[\eta]$-M_w or K_n in the $[\eta]$-M_n relation, by assuming that the molecular weight distribution for each of the fractions is represented by the familiar Schulz-Zimm function:

$$w(M) = [y^{h+1}/\Gamma(h+1)]M^h \exp(-yM)$$

where

$$y = h/M_n = (h+1)/M_w$$

where Γ represents the gamma function, and where the value of the exponent, α, is approximately the same for the $[\eta]$-M_w relationship. The parameter, h, characterizing the heterogeneity of each fraction was experimentally determined. Therefore, the K value may be calculated by the equation:

$$K = K_w\Gamma(h+1)(h+1)^\alpha/\Gamma(\alpha+h+1)$$

or $$K = K_n\Gamma(h+1)h^\alpha/\Gamma(\alpha+h+1)$$

A detailed discussion will be given elsewhere. Thus, the relations were evaluated for the homogeneous homologue:

$$[\eta] = 1.29\times10^{-4}M^{0.64} \text{ (in toluene)}$$
$$[\eta] = 0.96\times10^{-4}M^{0.67} \text{ (in butanone)}$$
$$[\eta] = 0.48\times10^{-4}M^{0.74} \text{ (in chlorobenzene)}$$

They are shown by the full curves in Fig. 6. They show that the molecule of poly-*p*-chlorostyrene assumes the largest dimension in chlorobenzene and the smallest in toluene, and that the magnitude of the exponent increases with an increase in the polarity of the solvent.

Unperturbed Dimension.—According to the theory of the excluded volume effect, developed by Kurata, Stockmayer and Roig,[15] it may be possible to evaluate an unperturbed dimension of a polymer molecule from its $[\eta]$-M relationships. Recently a detailed review of the procedure has been presented.[16] Their theory results in the following equation:

$$[\eta]^{2/3}/M^{1/3} = K_\theta^{2/3} + Bg(\alpha_\eta)M^{2/3}/[\eta]^{1/3} \quad (6)$$

where K_θ is K in Eq. 5, corresponding to the theta condition; B, the constant which depends on the structure of the polymer molecule and the polymer-solvent interaction, and α_η, the hydrodynamic linear expansion factor, $([\eta]/[\eta]_\theta)^{1/3}$. The function of α_η, $g(\alpha_\eta)$, is given by the equation:

$$g(\alpha_\eta) = 8\alpha_\eta^3/(3\alpha_\eta^2+1)^{3/2} \quad (7)$$

From the first plot of $[\eta]^{2/3}/M^{1/3}$ against $M^{2/3}/[\eta]^{1/3}$, K_θ was approximately estimated by an extrapolation according to Eq. 6, and the α_η value for each fraction was evaluated. Then, $[\eta]^{2/3}/M^{1/3}$ was plotted against $g(\alpha_\eta)M^{2/3}/[\eta]^{1/3}$, using the estimated α_η value, thus affording an improved value for K_θ.

Our data were repeatedly analyzed with the least-square technique of Deming until K_θ converaged to a constant value. In this case the effect of the molecular weight distributions of each fraction was taken into account. That is, the observed value of $[\eta]$ for each fraction was corrected to that corresponding to a homogeneous sample by assuming the Schulz-Zimm distribution function. From the intercepts of the Kurata-Stockmayer plots for poly-*p*-chlorostyrene, which are shown in Fig. 7, the values of K_θ in toluene, butanone, and chlorobenzene are derived as

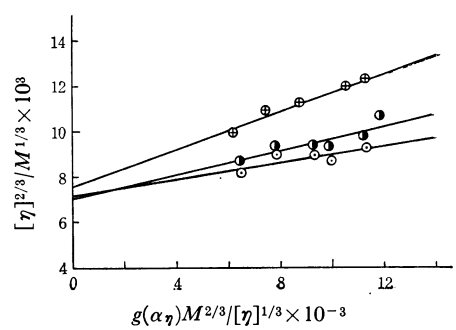

Fig. 7. Kurata-Stockmayer viscosity plots for poly-*p*-chlorostyrene fractions in toluene (open circles), butanone (half-filled circles), and chlorobenzene (crossed circles).

16) M. Kurata and W. H. Stockmayer, *Fortschr. Hochpolymere Forsch.*, **3**, 196 (1963).

6.1, 5.9, and 6.6×10^{-4} respectively. These values are considered to be in excellent agreement and give $K_\theta=(6.1\pm0.4)\times10^{-4}$. The unperturbed end-to-end distance of a polymer chain, $\langle r^2\rangle_0^{1/2}$, in cm., may be calculated by the equation:

$$\langle r^2\rangle_0^{1/2}=(K_\theta/\Phi)^{1/3}M^{1/2} \quad (8)$$

where Φ is a universal constant, given as 2.87×10^{21} for monodispersed systems. The σ factor may be generally used as a measure of the hindrance to internal rotations about the single bonds of the chain; it is defined as the ratio of $\langle r^2\rangle_0^{1/2}$ to the dimension, $\langle r^2\rangle_{0f}^{1/2}$, which corresponds to the model with fixed valence angles and a completely free internal rotation. In the case of poly-*p*-chlorostyrene, this gives a value for σ of 2.30 ± 0.06, which is slightly higher than that, 2.18 ± 0.07, cited in the literature.[16] On the other hand, the σ value for polystyrene is 2.22 ± 0.05.[16] It appears that the chlorine atom at the para-position has only a small effect on the hindrance to the internal rotations, whereas the presence of this polar group remarkably modifies the solubility of the polymer in comparison with that of polystyrene.

Thermodynamic Properties. — In examining polymer-solvent interactions, the results are usually expressed in terms of a purely empirical parameter, χ_1, which is expressed according to the Flory-Huggins lattice theory of polymer solutions by the equation:

$$A_2=[(1/2)-\chi_1]/V_1d_2^2 \quad (9)$$

where V_1 is the molar volume of the solvent and d_2, the density of the polymer. The density of the polymer was calculated from the relation between the solution density and the weight fraction of the polymer, the additivity of the partial volumes being assumed. The χ_1 values for the fraction B 2-2 at 30°C are 0.483 in toluene and 0.462 in chlorobenzene. Ogino reported that the values of the parameter for polystyrene and poly-*p*-chlorostyrene in benzene, as determined by the measurement of initial stress-strain relations for gels in the solvent, were 0.47 for the former system and 0.49_5 for the latter.[17] From the osmotic pressure measurements, Bawn et al. obtained χ_1 values of 0.443 to 0.447 for polystyrene solutions in toluene and of 0.484 to 0.487 for butanone solutions.[18] These figures show that toluene, as well as benzene, is a poor solvent for poly-*p*-chlorostyrene, and that the better solvent has a structure similar to that of the monomer unit of the polymer, i. e., chlorobenzene for poly-*p*-chlorostyrene and toluene for polystyrene.

Further information can also be obtained from the measurement of the temperature dependence of the osmotic pressure. According to thermodynamic relationships, the excess molar heat of dilution, Δh_1^E, and the excess entropy of dilution, Δs_1^E, are given by the temperature coefficients of the second and third virial coefficients, i. e.,

$$\Delta\mu_1^E/c^2V_1=-RT(A_2+A_3c)$$
$$\Delta h_1^E/c^2V_1=RT^2\{(\partial A_2/\partial T)+(\partial A_3/\partial T)c\}$$
$$T\Delta s_1^E/c^2V_1=RT\{A_2+T(\partial A_2/\partial T)+A_3c+T(\partial A_3/\partial T)c$$

where $\Delta\mu_1^E$ represents the excess free energy of dilution. The results are summarized in Table IV, in which the values of A_2 and A_3, evaluated by means of the method of the least squares, were used. The heat of dilution in chlorobenzene could be taken to be zero within the limits of experimental error over the concentration range from zero to 2×10^{-2} g./cm³. With a toluene solution the values show an endothermic heat of dilution. Bawn and Wajid reported that the heat of dilution in a polystyrene-toluene system was zero at all concentrations.[19] Polystyrene has a cohesive energy density (C. E. D.) of 82 cal./cm³, as elucidated by swelling experiments.[20] On the other hand, the value of the Hildebrand solubility parameter for toluene is reported to be 8.90 $(\text{cal./cm}^3)^{1/2}$ at 25°C; i. e., the C. E. D. of toluene is 79 cal./cm³. The solubility behavior of the polystyrene-toluene system may be interpreted in terms of their C. E. D.'s and in terms of the resemblance of the solvent molecule to the structural unit of the polymer. If this situation also holds in the case of a poly-*p*-chlorostyrene - chlorobenzene system, the C. E. D. of poly-*p*-chlorostyrene may lie near the value of that of chlorobenzene, i. e., 91 cal./cm³.

Table IV. Excess thermodynamic functions of dilution for poly-*p*-chlorostyrene in toluene and chlorobenzene at 30°C (cal.cm³/g.²)

$c\times10^2$ g./cm³	$\Delta\mu_1^E/c^2V_1$	$\Delta h_1^E/c^2V_1$	$T\Delta s_1^E/c^2V_1$

Summary

The osmotic pressure of poly-*p*-chlorostyrene fractions in toluene and the intrinsic viscosities at 30°C in toluene, in butanone, and in chlorobenzene have been measured. The relation

between the intrinsic viscosity and the molecular weight corresponding to a homogeneous homologue has been determined, taking into consideration the effect of the heterogeneity of each fraction on this relationship. The unperturbed dimension of the polymer, as evaluated by Kurata-Stockmayer's plots, showed that the polar group at the position of the benzene ring does not appreciably affect the hindrance to internal rotations about single bonds of its chain in comparison with the polystyrene chain. The heat of the dilution of poly-*p*-chlorostyrene in chlorobenzene and toluene has been determined from measurements of the temperature coefficients of the osmotic pressure. In the concentration range up to 2.5×10^{-2} g./cm^3, the $\Delta h_1^E/c^2V_1$ value, where V_1 is the molar volume of the solvent, was approximately zero in chlorobenzene and 0.3 cal. cm^3/g.^{2} in toluene. The results have been discussed in relation to the cohesive energy densities of the polymer and the solvents.

The author takes this opportunity to express his thanks to Professor Akira Kotera and Professor Keizo Suzuki for their continuing encouragement and helpful discussion. Thanks are also due to Dr. Takahide Saito for supplying the samples and permission to use his results and to Mr. Yasuo Hashino and Mr. Hiroshi Okamoto for their assistance in the experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1192—1196 (1966)

The Solution Behavior of Polystyrene Derivatives: Poly-*p*-methoxystyrene

By Akira KOTERA, Keizo SUZUKI, Takahide SAITO, Hideomi MATSUDA, Toshio KAMATA and Yoshiko HASHINO

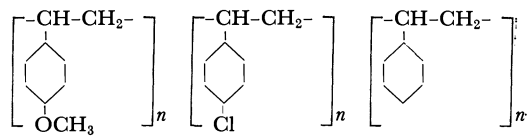
Department of Chemistry, Faculty of Science, Tokyo University of Education, Otsuka, Tokyo

(Received September 8, 1965)

The solution behavior of poly-*p*-methoxystyrene in toluene and butanone was measured by light-scattering and viscosity methods, and the results were compared with those of polystyrene and poly-*p*-chlorostyrene in order to discuss the mutual interactions between the solvent and the substituent on the phenyl group. The results show that toluene is a good solvent and butanone a poor one for poly-*p*-methoxystyrene; these relationships between poly-*p*-methoxystyrene and solvents are inverse to those for poly-*p*-chlorostyrene and similar to those for polystyrene, although the extensions of poly-*p*-chlorostyrene and poly-*p*-methoxystyrene are much larger than that of polystyrene at the same degree of polymerization because of the strong mutual interaction between the solvent and the substituent on the phenyl group. It is clear, from the application of Kurata-Stockmayer theory to the experimental results obtained for poly-*p*-methoxystyrene, that the unperturbed dimension of poly-*p*-methoxystyrene is larger than that of polystyrene; this result may be interpreted as being due to an increase in the volume of the chain element of the polymer molecule.

In a preceding paper,[1] the viscosity and light-scattering characteristics of poly-*p*-chlorostyrene in butanone and toluene were compared with those of polystyrene; it was concluded that the para substituent (chlorine atom) of the phenyl group affected the dependence of the viscosity, the extension, and the second virial coefficient on the molecular weight, and that the extension of poly-*p*-chlorostyrene, as compared with that of polystyrene, is markedly influenced by the polarity of the substituent.

In the present paper the viscosity and light-scattering characteristics of poly-*p*-methoxystyrene in butanone and toluene are compared with those of polystyrene and poly-*p*-chlorostyrene. This comparison provides information on the effect of the para methoxy substituent on the solution behavior of the polymer.



poly-*p*-methoxystyrene | poly-*p*-chlorostyrene | polystyrene

Experimental

Materials. — *p*-Methoxystyrene was polymerized without an initiator for 24 hr. at 100°C. The polymer was dissolved in benzene and was precipitated (from this solution) with methanol. Polymerization occurred to the extent of almost 100%.

Butanone and toluene were purified by the method used in the preceding paper.[1]

1) T. Saito, This Bulletin, **35**, 1580 (1962).

Fractionation.—About 14 g. of poly-*p*-methoxystyrene was dissolved in 500 ml. of butanone. Then fractions were obtained by the successive precipitation method with methanol as a precipitant at 37°C. Seven fractions were used for the measurements.

Viscosity and Light Scattering.—A conventional Ubbelohde viscometer was modified so that successive dilution could be performed. The intrinsic viscosity, $[\eta]$, and the Huggins constant, k', were obtained for the solution in toluene at 30°C and in butanone at 25°C.

An Aminco photometer was used for the measurement of the light scattering. The details of the measurement have been described in the preceding paper. The values of dn/dc, the increment of the refractive index of the solution with the concentration, were determined with a Zeiss interferometer; they were 0.219 ml./g. in butanone and 0.105 ml./g. in toluene at room temperature.

To remove dust, the solutions for light-scattering and viscosity studies were centrifuged for one hour at 20000 g. on a Phywe ultracentrifuge and were filtered into the light-scattering cell or the reservoir of the viscometer through a sintered glass filter (No. 6) just before the measurements.

Results and Discussions

Results.—Plots of the reduced viscosity, η_{sp}/C, vs. the concentration, C, for each fraction are shown in Figs. 1 and 2; the intrinsic viscosity, $[\eta]$, and the Huggins constant, k', were determined from these plots. The Zimm plot for Fraction 7, as an example of light-scattering measurements, is given in Fig. 3; the weight-average molecular weight, M_w, the second virial coefficient, A_2, and the z average root mean square end-to-end distance, $\langle D^2\rangle_z^{1/2}$,

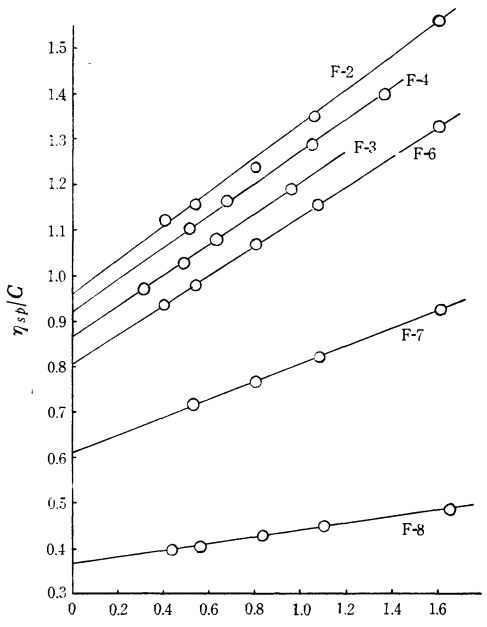


Fig. 1. Relation between reduced viscosity and concentration for poly-*p*-methoxystyrene in butanone at 25°C.

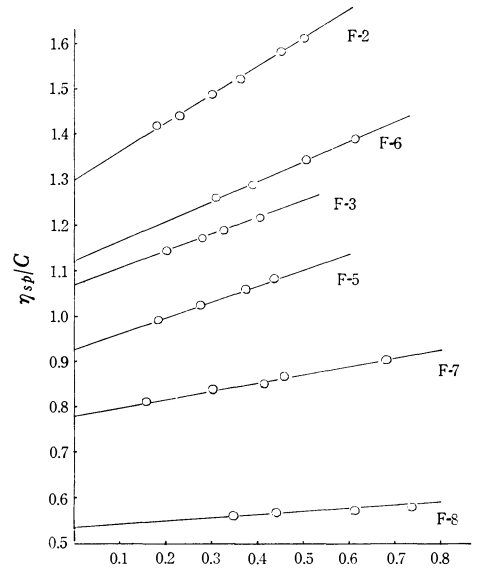

Fig. 2. Relation between reduced viscosity and concentration for poly-*p*-methoxystyrene in toluene at 30°C.

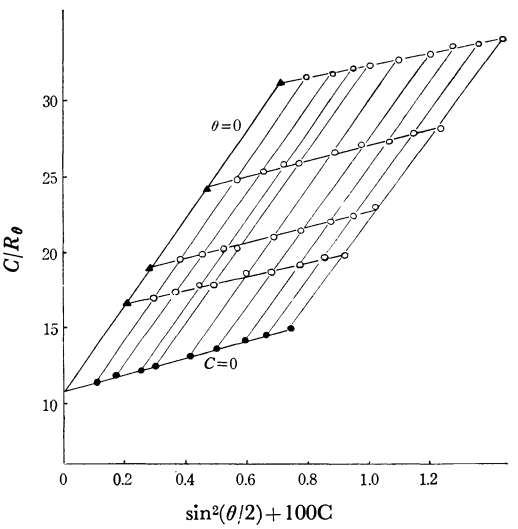

Fig. 3. Zimm plot of poly-*p*-methoxystyrene Fraction 7 in toluene for 436 mμ.

were determined for seven fractions from Zimm plots similar to those in Fig. 3.

The experimental results for seven fractions determined from the measurements of viscosity and light scattering are summarized in Tables I and II.

The log-log plot of the intrinsic viscosity vs. the weight-average molecular weight is shown in Fig. 4.

The relation between the intrinsic viscosity and the molecular weight is represented by the equation:

$$[\eta] = KM_w^{\alpha} \qquad (1)$$

8	0.364	0.54	22	1.7_8	37	1.6

Notation: M_w: weight average molecular weight, A_2: second virial coefficient, $\langle D^2\rangle_z^{1/2}$: z average root mean square end-to-end distance, $[\eta]$: intrinsic viscosity, k': Huggins constant, Φ: Flory parameter.

TABLE II. THE EXPERIMENTAL RESULTS FOR POLY-*p*-METHOXYSTYRENE IN TOLUENE

The light scattering measurements were made at 436 mμ and the viscosity measurements were carried out at 30°C.

Fraction	$[\eta]$	k'	$M_w\times 10^{-4}$	$A_2\times 10^4$	$\langle D^2\rangle_z^{1/2}$ mμ	$\Phi\times 10^{-21}$
2	1.300	0.36	85	2.1_3	92	1.4
3	1.080	0.23	70	1.8_9	83	1.3
5	0.935	0.40	56	2.1_8	71	1.5
6	1.120	0.36	78	2.0_4	87	1.3
7	0.783	0.29	43	3.1_0	66	0.9
8	0.532	0.30	22		41	1.7

The notations used in this table are the same as those in Table I.

where M_w is a weight-average molecular weight and K and α are constants determined from a plot of $\log[\eta]$ against $\log M_w$. Equation 1 for poly-*p*-methoxystyrene is as follows:

$$[\eta]=0.80\times 10^{-4} M_w^{0.69} \text{ in butanone at 25°C,}$$

$$[\eta]=2.41\times 10^{-4} M_w^{0.62} \text{ in toluene at 30°C.}$$

The dependence of the root mean square end-to-end distance on the molecular weight is expressed by:

$$\langle D^2\rangle_z^{1/2} \sim M_w^{\beta} \tag{2}$$

where β is a constant as determined from a plot of $\log(\langle D^2\rangle_z^{1/2})$ against $\log M_w$, and the relations for poly-*p*-methoxystyrene are:

$$\langle D^2\rangle_z^{1/2} \sim M_w^{0.57} \text{ in butanone}$$

$$\langle D^2\rangle_z^{1/2} \sim M_w^{0.58} \text{ in toluene}$$

The second virial coefficient of a polymer solution depends on the molecular weight:

$$A_2 \sim M_w^{\gamma} \tag{3}$$

and the dependences of poly-*p*-methoxystyrene are:

$$A_2 \sim M_w^{-0.20} \text{ in butanone}$$

$$A_2 \sim M_w^{-0.40} \text{ in toluene}$$

Discussion.—The constants, K, α, β and γ, in Eqs. 1, 2 and 3 are summarized in Table III, where the constants for polystyrene and poly-*p*-chlorostyrene are also included for the sake of comparison. The values of the constants for poly-*p*-methoxystyrene are similar to those given in the literature for various vinyl polymers, and it seems likely that there is no abnormal tendency in the solution behavior of poly-*p*-methoxystyrene. However, a detailed comparison of the data for poly-*p*-methoxystyrene with those for polystyrene and poly-*p*-chlorostyrene brings to light some interesting facts with regard to the effects of the solvent on the extension of the polymer chain. The dimensions of poly-*p*-methoxystyrene in toluene are larger than those in butanone; this relationship between the solvent and the dimension is the same as in the case of polystyrene, but it is reversed in the case of poly-*p*-chlorostyrene.

In order to clarify the effects of solvents on the dimensions of polymer chains, the $\langle D^2\rangle_z^{1/2}/D_f$ values for polystyrene derivatives in toluene and butanone are compared with one another at $P_w=10^4$; these values are shown in Table IV, where D_f is the end-to-end distance of the chain, assuming a free rotation model, and where $\langle D^2\rangle_z^{1/2}$ is obtained from a plot of $\log(\langle D^2\rangle_z^{1/2})$ vs. $\log P_w$.

Of course, a comparison of the effect of a solvent on the dimensions of the chain must be based on a value of $\langle D^2\rangle_z^{1/2}/\langle D_0^2\rangle_z^{1/2}$, where $\langle D_0^2\rangle_z^{1/2}$ is a z-average root mean square unperturbed end-to-end distance, but when the basic structures of the polymers are similar to each other, the $\langle D^2\rangle_z^{1/2}/D_f$ ratio can be considered to be a relative measure of the solvent effect.

As is shown in Table III or IV, toluene is a better solvent for poly-*p*-methoxystyrene than butanone;

TABLE III. CONSTANTS FOR THE SOLUTION BEHAVIOR OF POLYSTYRENE DERIVATIVES IN TOLUENE AND BUTANONE

Solvent	Polymer	$K\times10^4$	α	β	γ
Butanone (25°)	Poly-*p*-chlorostyrene	2.9_4	0.59	0.55	−0.17
	Poly-*p*-methoxystyrene	0.8_0	0.69	0.57	−0.20
	Polystyrene	3.9_0	0.58	0.58	−0.23
Toluene (30°C)	Poly-*p*-chlorostyrene	1.2_3	0.64	0.60	−0.40
	Poly-*p*-methoxystyrene	2.4_1	0.62	0.58	−0.40
	Polystyrene	1.3_0	0.70	0.68	−0.33

this relationship is the same as that for polystyrene.[2-4] However, the values of $\langle D^2\rangle_z^{1/2}/D_f$ obtained for poly-*p*-methoxystyrene show that the *p*-methoxy-phenyl groups are involved in greater mutual interactions than are the phenyl groups.

The finding that the extension of poly-*p*-methoxystyrene in toluene is nearly the same as, or slightly larger than, that of poly-*p*-chlorostyrene may be explained as follows: the increased stability of the extended form of the chain in the case of poly-*p*-methoxystyrene in comparison with the case of poly-*p*-chlorostyrene is to be attributed to the mutual interaction between the C_6H_5–OCH_3 group being greater than that between the C_6H_5–Cl groups.

Kotera et al.[5,6] measured the dipole moments of poly-*p*-chlorostyrene and poly-*p*-methoxystyrene at different temperatures and concluded from their experimental results that the chain of poly-*p*-methoxystyrene is more extensive than that of poly-*p*-chlorostyrene. Their measurements were carried out in a non-polar solvent; hence, their results are substantially in accord with our data.

Kurata and Stockmayer have recently proposed new equations for deriving the unperturbed dimension of polymer molecule from the intrinsic viscosity data of the polymer molecule in a good solvent; they have also shown the wide applicability of their method to the correct estimation of short-range interactions of a polymer molecule.[7] The new equations proposed by them are as follows:

TABLE IV. VALUES OF $\langle D^2\rangle_z^{1/2}/D_f$ FOR POLYSTYRENE DERIVATIVES IN TOLUENE AND BUTANONE AT $P_w=10^4$

The values for polystyrene were calculated from the data in Refs. 2 and 3.

Polymer	$\langle D^2\rangle_z^{1/2}/D_f$ Solvent	
	Butanone	Toluene
Poly-*p*-chlorostyrene	3.24	2.57
Poly-*p*-methoxystyrene	2.39	2.73
Polystyrene	1.86	2.14

TABLE V. THE RATIOS BETWEEN THE UNPERTURBED DIMENSIONS AND THE DIMENSION WHEN A FREE ROTATION MODEL IS ASSUMED FOR POLYSTYRENE, POLY-*p*-METHOXYSTYRENE AND POLY-*p*-CHLOROSTYRENE

Polymer	r
Poly-*p*-methoxystyrene	2.39
Poly-*p*-chlorostyrene	2.34
Polystyrene	2.30

$$([\eta]^2/M)^{1/3} = K^{2/3}+0.363B\Phi_0(g(\alpha_\eta)M^2/[\eta])^{1/3}$$
$$K^{1/3} = \Phi_0{}^{1/3}A$$
$$\alpha_\eta = [\eta]/[\eta]_\theta$$
$$g(\alpha_\eta) = 8\alpha_\eta{}^3/(3\alpha_\eta{}^2+1)^{2/3}$$

where α_η is an expansion parameter of the polymer molecule obtained from the intrinsic viscosity; M, the molecular weight; Φ_0, the Flory parameter (2.8×10^{21}); $g(\alpha_\eta)$, a function of the volume exclusion of the polymer, and a parameter, A, is related to the unperturbed dimension of the polymer. An approximate value of K, which permits us to obtain α_η or $g(\alpha_\eta)$, is obtained from plots of $([\eta]^2/M)^{1/3}$ against $(M^2/[\eta])^{1/3}$, ignoring $g(\alpha_\eta)$; then, using this result, an improved value of K is obtained from plots of $([\eta]^2/M)^{1/3}$ against $g(\alpha_\eta)(M^2/[\eta])^{1/3}$. The final value of K, K_θ, is obtained in the second trial.

The unperturbed dimension of the polymer molecule is calculated from the value of A and the ratio, r, between the unperturbed dimension of poly-*p*-methoxystyrene, or poly-*p*-chlorostyrene, obtained from this plot, and that obtained when a free rotation model for the polymer chain is assumed; these values of r, together with the one quoted for polystyrene in the literature, are shown in Table V. The values of r for both these para-substituted polymers (2.34 for poly-*p*-chlorostyrene and 2.39 for poly-*p*-methoxystyrene) are larger than that for polystyrene 2.30),* and the value of r for poly-*p*-methoxystyrene seems to be a little larger than that for poly-*p*-chlorostyrene; these results are in accord with that described above.

A detailed discussion of the values for the unperturbed dimension for the para-substituted polymer molecule obtained from the plots shown in Figs. 7 and 8, will be avoided here because some scatter exists in the plots of the dependences of $([\eta]^2/M)^{1/3}$ on $g(\alpha_\eta)(M^2/[\eta])^{1/3}$ and no experimental data for samples with small molecular weights are available.

Although there seems to be a little ambiguity in the values of K_θ obtained from our data for poly-*p*-methoxystyrene and poly-*p*-chlorostyrene, both r values for these polymers are larger than that for polystyrene; this result may be due to the larger molecular volumes of the monomer units for these polymers.**

The Flory parameter, Φ, is calculated by using the equation:

$$[\eta]=\Phi\langle D^2\rangle_z{}^{3/2}/M_w \qquad (4)$$

where $\langle D^2\rangle_z{}^{1/2}$ is the z-average root mean square end-to-end distance, M_w is the weight average molecular weight, and $[\eta]$ is the intrinsic viscosity. The values of Φ for poly-*p*-methoxystyrene are 1.5×10^{21} in toluene and 1.6×10^{21} in butanone; these results are similar to those for various vinyl polymers given in the literature.

Conclusion

The solution behavior of poly-*p*-methoxystyrene is similar to that of polystyrene; this may be ascribed to the comparatively similar basic structure of the two polymers. However, poly-*p*-methoxystyrene has the more extended chain, because the mutual interactions of *p*-methoxy-phenyl groups are larger than those of phenyl groups or *p*-chlorophenyl groups.

A part of the cost of this research has been defrayed from a Scientific Research Encouragement Grant from the Ministry of Education, to which the author's thanks are due.

* Obtained in our laboratory for polystyrene by measuring the light-scattering properties in cyclohexane at 35°C. The value of r for atactic polystyrene given by Kurata and Stockmayer is 2.20 ± 0.05.[7]

** The other approximation for the determination of the unperturbed dimension depending upon the same theoretical viewpoint as that by Kurata and Stockmayer was given by W. Stockmayer and M. Fixman (*J. Polymer Sci.*, **C1**, 137 (1963)). The results obtained from both approximations are the same.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1197—1201 (1966)

Syntheses of Organic Phosphates. I. Pyridylmethyl Phosphates*,**

By Yukito MURAKAMI, Makoto TAKAGI and Hiroshi NISHI

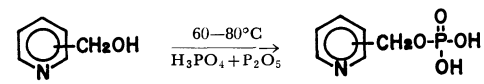
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received September 8, 1965)

The reaction of pyrophosphoric acid with 2-, 3- and 4-pyridylmethanols resulted in the formation of the corresponding pyridylmethyl phosphates. The separation of each ester from the corresponding phosphorylation mixture was performed by passing the mixture through a column of Dowex 50W-X8 [H^+] resin. The 2-, 3-, and 4-isomers were recrystallized from ethanol-water as white crystals with melting points of 182—182.5°C (part. decomp.), 194.5—195.5°C (part. decopm.), and 201.5—202.5°C (decomp.) respectively. An attempt to separate each of these esters from an artificial mixture of them consisting of an equal amount of each was performed by using an ion-exchange resin, Dowex 50W-X8 [H^+]. The acid dissociation constants were determined by a potentiometric method at 25.0°C and $\mu=0.10$ M (KNO_3); this gave three pK's for each phosphate, pK_{H_3A}, pK_{H_2A}, and pK_{HA}: 2-pyridylmethyl phosphate, 1.8, 4.42, 6.29; 3-pyridylmethyl phosphate, 1.9, 4.86, 6.23; 4-pyridylmethyl phosphate, 1.7, 5.14, 6.25. Of these pK's, pK_{HA} refers to the dissociation of a pyridinium proton, while the other pK's refer to those of phosphate protons.

In connection with the studies of nucleotides, various organic phosphates have been synthesized extensively, and many useful phosphorylating reagents have been developed as reviewed in the literature.[1-4] However, since the existing reagents have evident limitations, an appropriate phosphorylating reagent needs to be selected for a specified synthesis depending upon the structure and properties of the alcohol which is to undergo reaction.

In the present work, pyridylmethyl phosphates (I), the simplest analogs of vitamin B_6 phosphate, were prepared. The phosphorylation of 2-, 3-, and 4-pyridylmethanol by the use of pyrophosphoric acid, prepared from 85% orthophosphoric acid and phosphorus pentoxide, was performed with some modification, according to the procedures employed for the syntheses of the substituted 3-pyridylmethyl phosphates.[5] 3-Pyridylmethyl phosphate was also synthesized by the reaction of 3-chloromethylpyridine hydrochloride with trisilver phosphate in ether. The yield was not, however, satisfactory because of the heterogeneous nature of the reaction. Among the phosphates synthesized in this study, 3-pyridylmethyl phosphate had been prepared before and the vasodilating effect of its salts described.[6]



I

The Isolation of Phosphate Esters from Phosphorylation Mixtures.—The main problem in the present preparation was how to achieve the separation of the desired phosphates from phosphorylation mixtures which contain a large excess (about 6 to 12 times mol.) of inorganic phosphoric acid. A chromatographic method using cation-exchange resin, Dowex 50W-X8, was found most effective and simple for the separation of phosphate esters.

Some other methods of separation were also tried, however, for the sake of comparison. For 3- and 4-pyridylmethyl phosphates, the phosphates were separated as precipitates from coexisting inorganic phosphates when the reaction mixtures were treated with ethanol-ether. On the other hand, in the case of 2-pyridylmethyl phosphate, such a precipitation procedure failed to have any advantage. Only a small amount of the precipitate, which contains a fairly large amount of inorganic phosphate, was obtained from the reaction mixture. This precipitate was then dissolved in a small amount of water, and saturated aqueous barium hydroxide was added to adjust the final pH of the solution to about 11. Then the mixture was filtered to remove the white precipitate formed. The addition of two

volumes of ethanol to the filtrate brought down the white precipitate of barium salt. The barium salt was purified by re-precipitation with ethanol from its aqueous solution. Although the phosphorus analysis showed this white solid to be nearly pure as barium 2-pyridylmethyl phosphate, $C_6H_6NO_4PBa$, the yield was poor not exceeding a few per cent. Two major factors may be responsible for this low yield: first, the precipitation of phosphate ester from the reaction mixture was not effected by the combination of ethanol and ether at the initial step; and second, the inorganic phosphate precipitated upon the addition of saturated barium hydroxide contained a fairly large fraction of an organic substance. An attempt has been made to separate 3-pyridylmethyl phosphate as its barium salt through a procedure similar to that mentioned above, but it resulted in a poor yield. The barium salt of an ester was converted into the corresponding free form, either by precipitating barium sulfate with sulfuric acid or by passing its water suspension through a column of Dowex 50W-X8 [H^+] resin.

On the other hand, for the isolation of 3-pyridylmethyl phosphate from the phosphorylation mixture, repeated precipitation with ethanol was proved to be effective, though less so than the chromatographic method using cation-exchange resin.

The Separation of Phosphate Esters from an Artificial Mixture.—The experimental conditions which were required for the isolation of each isomeric phosphate ester from the coexisting orthophosphoric acid were somewhat different from each other. Therefore, the separation procedure used for 2-pyridylmethyl phosphate was not applicable to the other isomers. In order to obtain some additional information about these separation procedures, an artificial mixture which contained equal amounts of the three esters in an aqueous solution was run onto an ion exchange column of Dowex 50W-X8 resin, both in the acid and in the ammonium forms. The eluting behavior is illustrated in Fig. 1. It may be seen that a satisfactory separation of 2-pyridylmethyl phosphate was achieved with the acid-form resin, while 3- and 4-isomers were not separated from each other even though the initial fractions of the mixed effluent were largely composed of the 3-isomer and the final fractions were composed of the 4-isomer, judging from their ultraviolet absorption spectra (Fig. 1-A). With the ammonium-form resin used, 2-pyridylmethyl phosphate failed to be recovered from the ion exchange column in this experiment (Fig. 1-B). It should be noted that the eluting behavior of 3- and 4-pyridylmethyl phosphate were considerably different from those in the presence of inorganic phosphoric acid, where these phosphates exhibited a retention time as short as that of inorganic phosphate and failed to be separated from the latter as a result.

Acid Dissociation Constants.—The three

TABLE I. ACID DISSOCIATION CONSTANTS OF PYRIDYLMETHYL PHOSPHATES

25.0±0.1°C, μ=0.10 M (KNO_3)

Acid	pK_{H_3A}	pK_{H_2A}	pK_{HA}
2-Pyridylmethyl phosphate	1.8	4.42	6.29
3-Pyridylmethyl phosphate	1.9	4.86	6.23
4-Pyridylmethyl phosphate	1.7	5.14	6.25

isomeric pyridylmethyl phosphates prepared in this work were proved to be tribasic acids, as illustrated by the three kinds of acid dissociation constants in Table I. The value of $K_{H\ A}$ and that of K_{HA} do not vary significantly among the three isomers, while the K_{H_2A} value changes from one to the other. In addition, these pK_{H_3A} and pK_{HA} values are within a range of magnitude of the acid dissociation constants for ordinary dibasic phosphate monoesters.[7] Therefore, those protons dissociating in the first and third processes are most likely to be attributed to the phosphate-protons, while

the second dissociation step seems to involve a pyridinium proton, as is shown in Chart 1.* The

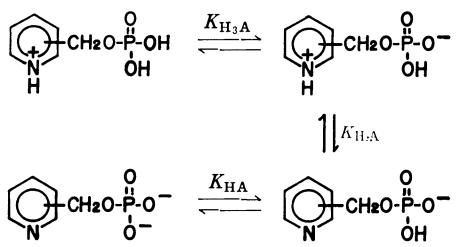

Chart. 1 Acid dissociation processes for pyridylmethyl phosphates.

pK_{H_2A} value is seen to be smallest with the methylphosphate group at the 2-position, and it increases as the substituent is placed further from the 1-position, the largest value being obtained with the 4-isomer. The electron-withdrawing effect of the substituent may provide a reasonable basis for the variation in the acidity of a pyridinium proton. An additional effect would be generated through the participation of the phosphate group in the formation of hydrogen bonding with pyridine-nitrogen in the case of 2-pyridylmethyl phosphate. In other words, such a tendency of hydrogen bond formation would facilitate the liberation of a pyridinium proton.

Experimental

2-Pyridylmethanol.—This material was synthesized from 2-picoline through the rearrangement of 2-picoline *N*-oxide to the acetate of 2-pyridylmethanol, which was subsequently hydrolyzed by acid to the methanol according to the method of Boekelheide and Linn;[8] b. p. 114—116°C/16—17 mmHg (reported[8] b. p. 110—112°C/15 mmHg); the picrate, m. p. 160.5—162.0°C (reported[8] m. p. 160.5—161.0°C).

3-Pyridylmethanol.—This alcohol was prepared by the reduction of ethylnicotinate (purchased from the Tokyo Kasei Kogyo Co. Ltd., Tokyo) with lithium aluminum hydride;[9-11] b. p. 117.5—118°C/3 mmHg (reported b. p. 144—145°C/20 mmHg,[9] 144°C/10 mmHg[10]); the picrate, m. p. 162.2—162.7°C (reported m. p. 159°C,[10] 158—160°C[11]).

4-Pyridylmethanol.—This methanol was synthesized from 4-picoline through a preparative route similar to that used for 2-pyridylmethanol, though the procedures were slightly modified from those mentioned in the literature.[8,12] 4-Picoline *N*-oxide was allowed to react with acetic anhydride at approximately 45°C for 2 hr., and then the reaction temperature was gradually raised to 90°C in 4 hr. After the mixture had been refluxed for a few minutes, the acetate of 4-pyridylmethanol containing an appreciable amount of acetic anhydride was distilled off. This acetate fraction with a boiling range of 99—107°C at 6 mmHg was hydrolyzed with 5 N hydrochloric acid, and then concentrated to dryness in vacuo. The residue was neutralized with aqueous potassium carbonate, made strongly alkaline with 20% sodium hydroxide, and then extracted with chloroform and ether. The combined extracts dried over anhydrous potassium carbonate were distilled to give the product; b. p. 124—128°C at 6 mmHg (reported b. p. 107—110°C/1 mmHg,[13] 152—154°C/15 mmHg[14]); m. p. 51—55°C (reported m. p. 57—60°C,[8] 57.8—58.8°C[12]); the picrate, m. p. 156.5—158°C in a sealed tube (reported m. p. 157—161°C[13]); yield 13 g. (14% from *N*-oxide).

2-Pyridylmethyl Phosphate.—A clear viscous liquid was obtained by the brief heating of 85% orthophosphoric acid and of phosphorus pentoxide at a 1 : 1 weight ratio.[15] A 20.2 g. sample of this mixture was mixed with 3.7 g. of 2-pyridylmethanol at room temperature in a 50-ml. flask protected from moisture. This reaction mixture, after having been heated on a water-bath at 77°C for 10 hr. with frequent shaking, was diluted with 10 ml. of water and then heated at 90°C for 30 min. in order to hydrolyze any polyphosphoric compounds. Approximately an equal volume of water was added to the hydrolysate, which was then divided into two portions, each applied to the top of a column (2×28 cm.) of Dowex 50W-X8 [H^+] resin (130 meq.) and eluted with water at 30 g. per hour. After the front effluent, which was strongly acidic (pH≈0.4), came off, the acidity of the effluent gradually lowered, reaching pH 4.0 at a total effluent of 100 ml. The collection of the fractions of the next 100-ml. portion resulted in the further pH elevation at the end to 4.8, which is nearly the same as that of the eluent (water). The ultraviolet measurements of the eluted fractions collected up to this stage showed the presence of no, or only trace amounts of, aromatic species. Then, an effluent turned acidic, accompanied by a strong increase in the optical density. After 450 ml. of the subsequent effluent had been collected, the pH came back to 4.8—5.0 and the ultraviolet absorption at 261 mμ disappeared. These latter fractions (450 ml.), which contained the phosphate ester, were concentrated to about 10 ml. under reduced pressure below 40°C. Tiny, white, pillar-like crystals were precipitated by adding 100 ml. of ethanol and by leaving the solution in a refrigerator overnight. After filtration, the precipitate was washed with ethanol; yield 5.5 g. (85%); m. p. 181—181.5°C (part. decomp.); upon recrystallization from ethanol-water (4 : 1), m. p. 182—182.5°C (part. decomp); extremely soluble in water and insoluble in ethanol; neutralization equivalence 94.8 (calcd.

A satisfactory separation was also attained by neutralizing the partially-hydrolyzed phosphorylation mixture with concentrated aqueous ammonia, followed by chromatographic separation with a column of Dowex 50W-X8 [H^+] resin. In this case, a larger amount of the ion exchanger was needed to convert the ammonium salt to the corresponding free acid, but the elution was carried out in the same manner, as is shown in Fig. 2.

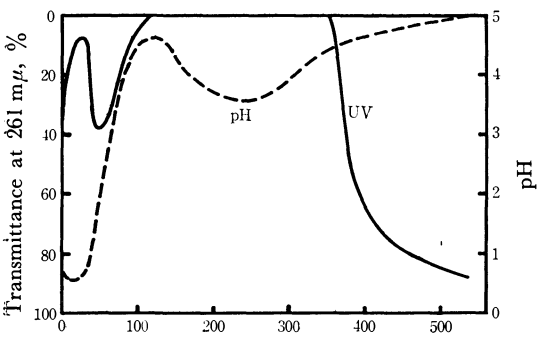

Fig. 2. Chromatographic separation of 2-pyridylmethyl phosphate from the phosphorylation mixture.

Mixture: partially-hydrolyzed phosphorylation mixture (with 0.4 g. of the alcohol as a starting material) neutralized to pH 8 with concentrated aqueous ammonia

Column: Dowex 50W-X8 [H^+] (130 meq.), 2×28 cm.

Eluent: mineral-free water

Elution rate: 30 g./hr.

3-Pyridylmethyl Phosphate.—The phosphorylation mixture, which was obtained by the reaction of 4 g. of 3-pyridylmethanol and 40 g. of pyrophosphoric acid in accordance with the method of Long and Morrison,[6] was poured into ethanol, and then ether was added. After the mixture had been kept in a refrigerator overnight, the clear supernatant liquid decanted. The residue dissolved in 70 ml. of 1 N hydrochloric acid and heated at 75°C for 30 min. To this acidic solution, after it had been concentrated to about 20 ml. on a water-bath (45°C) in vacuo, 100 ml. of hot acetone was added with vigorous shaking. After the mixture had then been cooled to room temperature, 100 ml. of ether was poured into it. The oily material which separated from the supernatant liquid was dissolved in a small volume of water and reprecipitated with ethanol. Three quarters* of the precipitate were neutralized to pH 8 with aqueous ammonia, then evaporated to dryness in vacuo. The residue, crystalline ammonium salt, was again dissolved in a minimum amount of water and charged to the top of a column (1.4×30 cm.) of Dowex 50W-X8 [H^+] resin (about 80 meq.). The elution was conducted with water at the rate of 20 g. per hour. As the pH of the effluent rose rather steadily throughout the elution, from strongly acidic to neutral without any distinctive features for separation, the effluent fractions were divided into two parts according to the optical density around 260 mμ. The second part consisted of fractions which came off beyond pH 2.0; its total volume (about 500 ml.) was concentrated to about 5 ml. in vacuo below 40°C. A white crystalline precipitate was recovered from the concentrated solution by adding 50 ml. of ethanol; it was recrystallized from ethanol-water (4 : 1) as tiny white pillars; yield 2.4 g. (50%); m. p. 194.5—195.5°C (part. decomp.) (reported m. p. 195—196°C[6]); extremely soluble in water and insoluble in ethanol; neutralization equivalence 94.3 (calcd. 94.6); λ_{max} 260 mμ (10^{-4} M aqueous solution), ε 5100.

Found: C, 38.17; H, 4.64; N, 7.34; P, 17.1. Calcd. for $C_6H_8NO_4P$: C, 38.11; H, 4.26; N, 7.41; P, 16.4%.

4-Pyridylmethyl Phosphate.—The phosphorylation of 4-pyridylmethanol (4 g.) with pyrophosphoric acid[15] (20 g.) was conducted at 80°C in a manner similar to that mentioned for 3-pyridylmethyl phosphate. After the addition of ethanol and ether to the reaction mixture, the oily material was separated from the clear supernatant liquid, dissolved in 15 ml. of water, and heated at 80°C for 45 min. Concentrated aqueous ammonia enough to convert the acid to the corresponding ammonium salt was added, and the salt was precipitated as white crystals by adding 200 ml. each of acetone and ether. The ammonium salt dissolved in a minimal volume of water was run onto a column of Dowex 50W-X8 [H^+] resin and eluted with water. The eluting behavior was found to be similar to that in 2-pyridylmethyl phosphate, as is shown in Fig. 2, and the product was recovered in a similar manner; recrystallization from ethanol-water (4 : 1); 3.8 g. of white rhombic prisms; extremely soluble in water and insoluble in ethanol; neutralization equivalence 94.6 (calcd. 94.6); λ_{max} 254 mμ (10^{-4} M aqueous solution), ε 4500.

Found: C, 38.06; H, 4.40; N, 7.28; P,* 15.2. Calcd. for $C_6H_8NO_4P$: C, 38.11; H, 4.26; N, 7.41; P, 16.4%.

The Separation of Phosphate Esters from an Artificial Mixture.—An aqueous solution containing 20 mg. each of the three isomeric esters in 4 ml. was applied to the top of a column (1.5×15 cm.) of Dowex 50W-X8 resin in the acid type (Fig. 1-A) and in the ammonium type (Fig. 1-B). The elution was conducted with water at the rate of 10 g. per hour. The effluents were classified according to their behavior in ultraviolet absorption, and each assembled portion was concentrated to dryness in vacuo. The measurements of the infrared and ultraviolet spectra as well as of the melting point were performed in order to identify such recovered material. With the ammonium-type resin, no 2-pyridylmethyl phosphate came off from the column, at least not while 400 g. of the effluent was being collected.

* One-quarter of the precipitate was purified by repeated precipitation with ethanol. The precipitate was dissolved in a small volume of water and reprecipitated with hot ethanol, the initial crop being removed. On repetition, the precipitate became somewhat crystalline; it was then suspended in boiling ethanol for an hour to remove the last traces of inorganic phosphoric acid, and finally recrystallized from ethanol-water.

* A sample for analysis was decomposed by heating it with concentrated nitric acid in a test tube. The amount of orthophosphoric acid thus formed was determined colorimetrically by the method of Allen (*Biochem. J.* (*London*), **34**, 858 (1940)). This method was applied to all the phosphates prepared in this work.

The Determination of Acid Dissociation Constants.—The acid dissociation constants of the three phosphate esters synthesized in this study were determined by potentiometric measurements. The apparatus and procedures have been described elsewhere.[16] The measurements were carried out at 25.0±0.1°C and at the ionic strength of 0.10 M in potassium nitrate for two different concentrations of the esters, i. e., 1.00×10^{-3} M and 2.00×10^{-3} M, by ensuring that no hydrolysis occurred during the measurements. In accordance with the tribasic nature of the esters, three acid dissociation constants were defined in the usual way:

$$K_{H_3A}=\frac{[H_2A][H^+]}{[H_3A^+]};\quad K_{H_3A}=\frac{[HA^-][H^+]}{[H_2A]};\quad K_{HA}=\frac{[A^{2-}][H^+]}{[HA^-]}$$

where H_2A stands for the neutral ester species, and the brackets indicate the concentration. For the first approximation, K_{H_2A} and K_{HA} were calculated from the data obtained in a moderate pH range, where K_{H_3A} did not play any important role, in accordance with a usual algebraic method described previously.[17] These calculated values then permitted to evaluate the K_{H_3A} value from the data in the more acidic region. The three kinds of acid dissociation constants obtained in the above manner were then re-investigated to give the more satisfactory values listed in Table I.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1201—1207 (1966)

The Vicinal Orientation. I. The Pivaloylation of Polymethylbenzenes[1)]

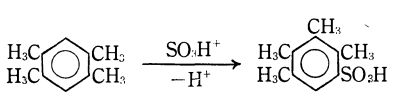
By Hitomi SUZUKI, Hisayuki WADA, Kazuhiro MARUYAMA and Ryozo GOTO

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received September 9, 1965)

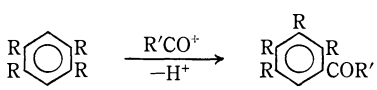
The direct introduction of a pivaloyl group by Friedel-Crafts acylation has been carried out with the following polymethylbenzenes: *o*-xylene, *m*-xylene, hemimellitene, pseudocumene, mesitylene, prehnitene and durene. The decarbonylation was not very significant, and seven new polymethylpivalophenones were prepared in fairly high yields. The hydrocarbon mixtures obtained simultaneously in these reactions usually consisted of at least four or five substances. In the pivaloylation of durene, the Jacobsen-type migration (vicinal orientation) of a methyl group was observed.

The introduction of a bulky group into the nucleus of polyalkylbenzenes often brings about the migration of alkyl groups, and results in the formation of unexpected products in which all the alkyl groups occupy the vicinal positions. The most typical of these anomalous reactions is the Jacobsen reaction.



This reaction has long been the object of many investigators' interest, but in spite of several recent proposals,[2)] its mechanism still remains uncertain. In order to get more precise knowledge about the puzzling features of this reaction, it seems pertinent to investigate some other reactions in which similar phenomena (vicinal orientation) are observed.

In the Friedel-Crafts acylation of polymethylbenzenes, one can sometimes observe unusual reactions in which the alkyl group migrates to the position meta to the entering acyl group, thus yielding the vicinal compounds[3,4)]:



This anomaly is generally attributed to steric stress and may be interpreted as follows: the migration of the alkyl group occurs in order to reduce the overcrowding caused by the introduction of the bulky acylium ion, while the entering acyl group, strongly electron-attracting in its nature, directs the migrating methyl group to the position meta to its original position.

1) The Reaction of Polysubstituted Aromatics. Part IX; Part VIII: This Bulletin, **39**, 128 (1966).

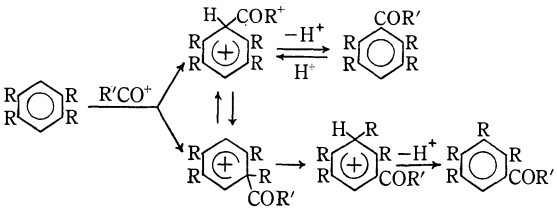
3) G. Baddeley and A. G. Pendleton, *J. Chem. Soc.*, **1952**, 807.

4) W. L. Mosby, *J. Am. Chem. Soc.*, **74**, 2564 (1952); *J. Org. Chem.*, **18**, 483 (1953); G. M. Badger, W. Carruthers and J. W. Cook, *J. Chem. Soc.*, **1949**, 2044; R. R. Aitken, G. M. Badger and J. W. Cook, ibid., **1950**, 331; B. J. Abadir, J. W. Cook and D. T. Gibson, ibid., **1953**, 8.



If the reaction occurs for such a sterical reason, the bulky tertiary acylium ion would be more effective in inducing these phenomena. In the literature, however, reactions are limited only to those with the primary acyl group; the direct introduction of the tertiary acyl group into the nucleus of polymethylbenzenes seems never to have been attempted. The use of a tertiary acyl halide as the acylating agent, however, creates some complications. Tertiary acyl halides, such as pivaloyl chloride, often decarbonylate in the presence of the Friedel-Crafts catalysts and act as an alkylating agent.[5] With such highly-reactive substrates as anisole or phenol, the acylation takes place almost exclusively. If the aromatic nucleus is more weakly activated, as in benzene and in toluene, both processes occur simultaneously, yielding the corresponding acylation and alkylation products. An increase in the number of the methyl groups attached to the ring would activate the nucleus and so favor the attack of the tertiary acylium ion upon it. This advantage would, however, be in part counterbalanced by the opposite effect — an increased resistance to the entrance of the bulky tertiary acyl group into the crowded nucleus. Furthermore, the tertiary alkyl cation formed by the decomposition of the tertiary acylium ion is also bulky, and in some cases brings about the alkyl migration.[6] Thus, in the Friedel-Crafts acylation of polyalkylbenzenes with tertiary acyl halides, one might expect the possibility of an alkyl migration analogous to the Jacobsen reaction, regardless of whether the reaction proceeds mainly through the acylation or through the alkylation.

Results

In the present work, we used pivaloyl chloride as the acylating agent; the non-vicinal polyalkylbenzenes used were pseudocumene, mesitylene and durene. *o*- and *m*-Xylene hemimellitene and prehnitene were also acylated for the sake of comparison. Aluminum chloride, titanium chloride and stannic chloride were employed as the catalysts, and carbon disulfide or nitromethane as the solvents. Preliminary experiments proved aluminum chloride to be the most effective catalyst; the other two brought about the decomposition of pivaloyl chloride to a great extent. Carbon disulfide was preferred to nitromethane, because the latter also favored the decarbonylation of the acid chloride.

On treatment with pivaloyl chloride in carbon disulfide at a low temperature, all the polymethylbenzenes used underwent acylation without any remarkable decarbonylation, although with less activated *o*- and *m*-xylene, or with mesitylene and durene, in which only the hindered positions were available, decarbonylation leading to the formation of a complex mixture of polymethylbenzenes was observed to a certain extent. The hydrocarbon mixtures simultaneously obtained in the reactions were found by gas chromatography to contain at least four or five, and in some cases even seven or eight, substances. Most of them, however, could not be identified. As the original hydrocarbons had little tendency toward disproportionation under the experimental conditions employed, the formation of various polyalkylbenzenes is probably to be attributed both to the alkyl migration caused by the introduction of the bulky pivaloyl group into the ring, and to the alkylation of polymethylbenzenes with isobutylene or its condensate products, formed by the decomposition of pivaloyl chloride.

Contrary to our expectations, most of the acylation, except in the case of durene, proceeded without any rearrangement. Only durene underwent an anomalous acylation to yield the vicinal product, 2, 3, 4, 5-tetramethylpivalophenone (VI).* A prolonged reaction time or an elevated temperatures resulted in an increased formation of the hydrocarbon parts and resinous matter, with a consequent decrease in the yield of the ketonic products.

The hindered ketones are generally known, in the presence of aluminum chloride, to isomerize

6) L. R. C. Barclay and E. E. Betts, *J. Am. Chem. Soc.*, **77**, 5735 (1955); L. R. C. Barclay and J. W. Hilchie, *J. Org. Chem.*, **22**, 633 (1957); P. C. Myhre and W. M. Schubert, ibid., **25**, 708 (1960). Also cf. R. M. Roberts and D. Schienthong, *J. Am. Chem. Soc.*, **86**, 2851 (1964).

gradually to the isomers of the less hindered structures. Thus acetodurene isomerizes to acetoprehnitene,[3,7] and acetomesitylene or acetopseudocumene, to acetohemimellitene.[8]

In expectation of such isomerization to the vicinal structure, 2, 3, 5, 6-tetramethylpivalophenone (VII) and 2, 4, 6-trimethylpivalophenone (V) were subjected to the action of an excess of aluminum chloride at room temperature. VII readily underwent a Jacobsen-type isomerization to give the vicinal isomer (VI). Such an easy transformation of VII into VI in comparison with that of the corresponding acetyl derivative[3,7] is no doubt due to the greater steric repulsion between the pivaloyl group and the adjacent ortho methyl group. In contrast to the tetramethyl compound, V was comparatively stable towards the action of aluminum chloride, and no alkyl migration was observed under ordinary condition even with a prolonged reaction time. The only reaction that took place was deacylation, followed by complicated side reactions involving alkylation by isobutylene or its condensates. This difference of ease between V and VII towards the vicinal orientation may be attributed to the buttressing effect of the methyl groups at the meta positions to the pivaloyl group.

In the hydrocarbon mixtures obtained by the rearrangement of VII, no noticeable amount of isodurene was found. This suggests that the Jaccobsen-type isomerization occurs via a direct rearrangement of the hindered ketone VII. If the vicinal product VI were formed through the step-by-step 1, 2-alkyl migration, as has been explained by Dewar,[9] with the intermediary formation of 2, 3, 4, 6-tetramethylpivalophenone, much isodurene would be detected in the hydrocarbon fraction, because the pivaloyl group in the highly-hindered position would readily be removed from the ring in the presence of a large excess of aluminum chloride. This however, did not happen. Durene was the only main tetramethylbenzene isolated.

Experimental

Materials. — Pivalic acid, prepared from *t*-butyl chloride by the Grignard reaction,[10] was carefully fractionated twice; the product had a b. p. of 159.5—161.5°C and an m. p. of 31—33°C. Freshly-distilled thionyl chloride was used for preparing the pivaloyl chloride, which, after careful distillation, had a b. p. of 104—106°C. Durene (m. p. 79—80°C) and prehnitene (b. p. 80—82°C/18 mmHg) were prepared as has been described by Smith and his co-workers.[11,12] Pseudocumene (b. p. 166—167°C) was prepared by the lithium hydride reduction[13] of 2, 5-dimethylbenzyl chloride (b. p. 99—102°C/15 mmHg), which in turn was obtained by the chloromethylation of *p*-xylene[14]. The *o*-xylene, *m*-xylene, mesitylene and hemimellitene were commercial products.

Measurements.—The infrared spectra were determined on liquid films or on potassium bromide disks, with a Perkin-Elmer Model 021 spectrophotometer. The ultraviolet absorption spectra (above 220 mμ) were measured in methanol solutions with a Hitachi EPS-30 automatic recording spectrophotometer. The NMR spectra were obtained in carbon tetrachloride solutions, with tetramethylsilane as the internal reference, using a JNM-3H 60 spectrometer manufactured by the Japan Electron Optics Laboratory Co., Ltd. The chemical shifts are expressed in τ-units. The NMR spectrum was very helpful in the structure assignment of each isomer obtained; in most cases it permitted an unequivocal choice (Fig. 1).

The General Procedure for Pivaloyl Chloride Acylations.—In a three-necked flask fitted with a thermometer, a reflux condenser and a dropping funnel, finely-powdered aluminum chloride was covered with small amounts of carbon disulfide and then cooled to the temperature of ice-water. The mixture was magnetically-stirred and a solution of pivaloyl chloride and a polymethylbenzene dissolved in carbon disulfide was added drop-by-drop over a period of 20—30 min. As the pivaloyl chloride entered the aluminum chloride suspension, gas evolved immediately. The gas was a mixture of hydrogen chloride, carbon monoxide and isobutylene, the proportions varying markedly with the structure of the aromatic hydrocarbon and the experimental conditions used. After the addition of the pivaloyl chloride, the mixture was stirred for half an hour at room temperature and then decomposed with dilute hydrochloric acid mixed with crushed ice. The organic layer was separated, carbon disulfide was removed by passing a current of air through it, and the residual dark oil was subjected to steam distillation. The oily layer of the steam-distillate was extracted with ether and dried over anhydrous calcium chloride. The ether extract was concentrated, and the residue was fractionated at reduced pressure.

In the distillation of VII, however, so much foaming was encountered that this compound was first chromatographed on a short alumina column, using petroleum ether as an eluant, and then repeatedly crystallized from light-boiling ligroin.

Compounds I, II and V have already been synthesized by Nightingale and his co-workers[15] through quite the same procedure, but the precise physical constants of them have not been described. Compounds III, IV and VII were first synthesized by the present authors.

2, 4-Dimethylpivalophenone (I).—To the stirred suspension of aluminum chloride (30 g.) in carbon disulfide (40 ml.), pivaloyl chloride (10 g.) and *m*-xylene (13.0 g.) dissolved in carbon disulfide (30 ml.) were added at 0—5°C over a 30-min. period. After

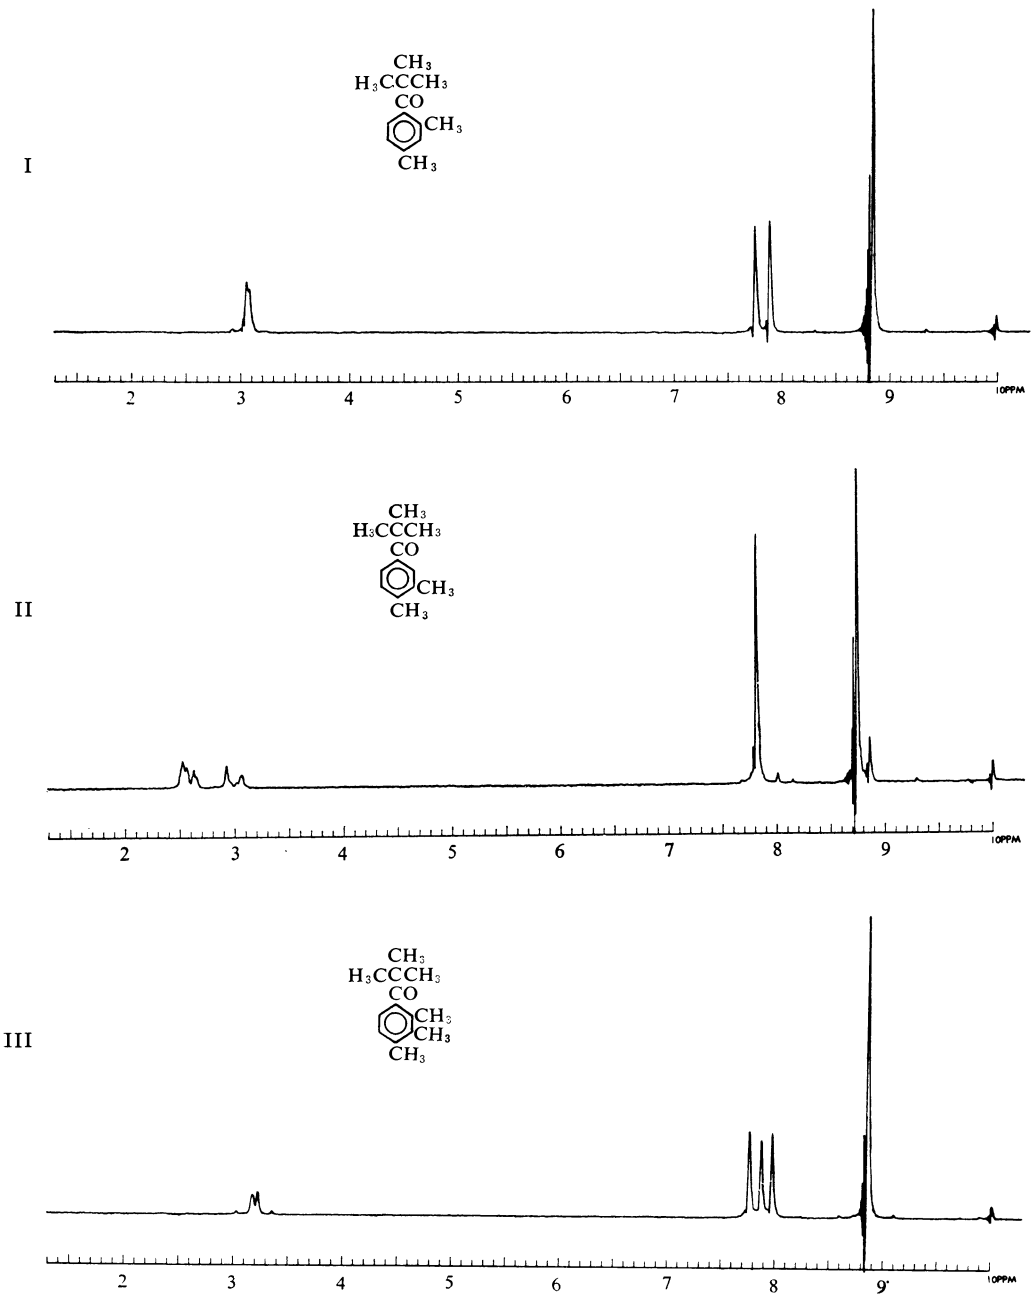

Fig. 1. NMR spectra of polymethylpivalophenones.

1 hr., the mixture was worked up as described above. The distillation of the oily product gave three hydrocarbon fractions: b. p. —90°C/22 mmHg, 1.5 g.; b. p. 93—95°C/22 mmHg, 7.7 g. (5-*t*-butyl-*m*-xylene); b. p. 121—122°C/22 mmHg, 1.5 g., and a ketonic fraction (b. p. 132—133°C/22 mmHg, 6.6 g.). The redistillation of the ketonic fraction yielded 5.6 g. of I, boiling at 131—132°C/21 mmHg.

Found: C, 82.18; H, 9.80. Calcd. for $C_{13}H_{18}O$: C, 82.06; H, 9.54%.

Its infrared bands were at 867 (isolated ring hydrogen), 827 (two adjacent ring hydrogen) and 1664 cm^{-1} (carbonyl). The ultraviolet absorption bands were at 244.5, 271—272 (*infl*)** and 310 mμ (*s*)**. The NMR methyl peaks at were 7.91 (*o*-methyl), 7.76 (*p*-methyl) and 8.85 (*t*-butyl).

3, 4-Dimethylpivalophenone (II).—II was prepared in the manner described above. B. p. 141—143°C/20—21 mmHg. The yield of steam-distilled ketone was a little lower than that of I. The hydrocarbon

** *infl* denotes inflection; *s*, shoulder.

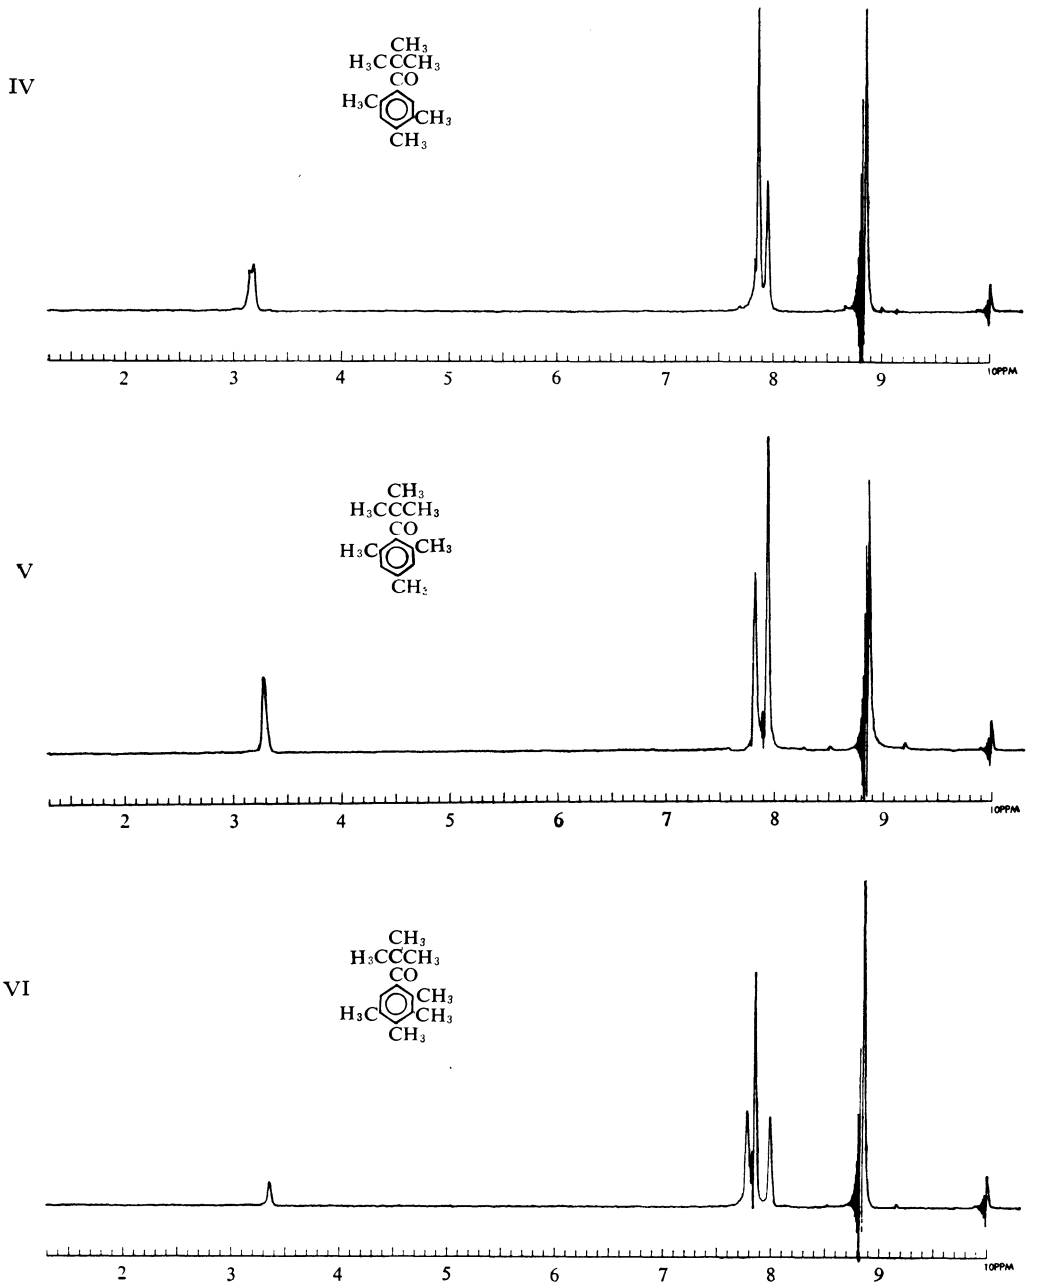

Fig. 1. Continued

fraction was mainly composed of 4-*t*-butyl-*o*-xylene, b. p. 102—103°C/22 mmHg.

Found: C, 82.33; H, 9.65. Calcd. for $C_{13}H_{18}O$: C, 82.06; H, 9.54%.

Strong infrared bands were found at 867 (isolated ring hydrogen), 827 (two adjacent ring hydrogens) and 1665 cm^{-1} (carbonyl). The ultraviolet absorption bands were at 252, 276—277 (*infl*) and 317—318 mμ (*s*). The NMR methyl peaks were at 7.81 (*m*- and *p*-methyl) and 8.74 (*t*-butyl).

2, 3, 4-Trimethylpivalophenone (III).—Hemimellitene (10 g.) was acylated with a mixture of pivaloyl chloride (6.6 g.) and aluminum chloride (20 g.) at 0—3°C by the procedure used above. An ordinary work-up followed by the distillation of the residual oil, gave two hydrocarbon fractions (b. p. 78—79°C/31 mmHg, 2.0 g.; b. p. 125—127°C/31 mmHg, 3.5 g.), a ketonic fraction (b. p. 149—151°C/21 mmHg, 9.5 g.), and a residue (ca. 1.0 g.). After redistillation, the ketone (b. p. 151—152°C/20—21 mmHg, 8.5 g.) solidified to white prisms melting at 39—40°C.

Found: C, 82.47; H, 10.11. Calcd. for $C_{14}H_{20}O$:

VII

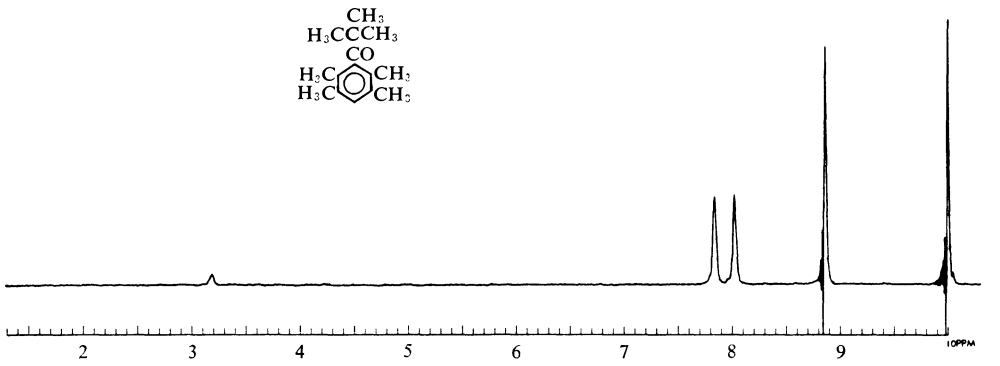

Fig. 1. Continued

C, 82.30; H, 9.87%.

The infrared bands were at 832 (two adjacent hydrogens) and 1685 cm^{-1} (carbonyl). The ultraviolet absorption bands were at 238—242 (broad) and 301—303 mμ (s). The NMR methyl peaks were at 7.76 (*p*-methyl), 7.87 (*m*-methyl), 7.97 (*o*-methyl) and 8.84 (*t*-butyl).

2, 4, 5-Trimethylpivalophenone (IV).—IV was prepared from pseudocumene (15 g.), pivaloyl chloride (10 g.) and aluminum chloride (30 g.). The fractionation of the oily product gave the hydrocarbon mixture (b. p. chiefly 66—68°C/22 mmHg. 2.0 g.) and the ketone (b. p. 152—154°C/30—31 mmHg, 13.7 g.). On standing, the ketone solidified to white prisms melting at 32—33°C.

Found: C, 82.17; H, 9.87. Calcd. for $C_{14}H_{20}O$: C, 82.30; H, 9.87%.

Its infrared bands were at 874 (isolated ring hydrogen) and 1691 cm^{-1} (carbonyl). The ultraviolet absorption bands were at 250, 278 (*s*) and 307 mμ (*infl*). The NMR peaks were at 7.86 (*m*- and *p*-methyl), 7.95 (*o*-methyl) and 8.85 (*t*-butyl).

2, 4, 6-Trimethylpivalophenone (V).—Mesitylene (15.0 g.) was acylated using pivaloyl chloride (10.0 g.) and aluminum chloride (30.0 g.) at 0—5°C. The distillation of the oily product gave two hydrocarbon fractions (b. p. 61—63°C/22 mmHg, 4.5 g.; b. p. chiefly 91—92°C/22 mmHg, 0.5 g.), a ketonic fraction (b. p. 141—143°C/22 mmHg, 10.2 g.) and a residue (ca. 1.0 g.). The redistillation of the ketonic fraction gave 9.5 g. of V, boiling at 142—143°C/22 mmHg, which, on standing in the refrigerator, solidified to white crystals, m. p. 19—21°C.

Found: C, 82.50; H, 10.08. Calcd. for $C_{14}H_{20}O$: C, 82.30; H, 9.87%.

The infrared bands were at 875 (isolated ring hydrogen) and 1682 cm^{-1} (carbonyl). The ultraviolet absorption bands were at 274—276 (*infl*) and 305—306 mμ. The disappearance of the K-band indicates the steric inhibition of the conjugation due to the *o*, *o'*-disubstitution. The NMR methyl peaks were at 7.82 (*p*-methyl), 7.94 (*o*-methyl) and 8.86 (*t*-butyl).

2, 3, 4, 5-Tetramethylpivalophenone (VI).—Prehnitene (15.0 g.) was acylated with pivaloyl chloride (9.0 g.) and aluminum chloride (30 g.) at 0—5°C. The liberation of carbon monoxide was not significant. A similar work-up, followed by the distillation of the product, afforded hydrocarbon fractions (b. p. 85—89°C/25 mmHg, 1.6 g.; b. p. 90—130°C/25 mmHg, 1.0 g.), a ketone (b. p. 161—165°C/21 mmHg, 11.2 g.) and a residue (1.3 g.). The redistillation of the ketonic fraction gave 10.5 g. of pure VI, b. p. 162—163°C/21 mmHg, which readily solidified to prisms and melted at 37—39°C.

Found: C, 82.25; H, 10.45. Calcd. for $C_{15}H_{22}O$: C, 82.51; H, 10.16%.

There were strong infrared bands at 867 (isolated ring hydrogen) and 1691 cm^{-1} (carbonyl). The ultraviolet absorption bands were at around 240—250 (*s*), 275—280 (*infl*) and 310—314 mμ (*infl*). The NMR methyl peaks were at 7.79 (*p*-methyl), 7.86 (*m*-methyl), 7.99 (*o*-methyl) and 8.85 (*t*-butyl).

2, 3, 5, 6-Tetramethylpivalophenone (VII).—Durene (14.0 g.) was acylated with pivaloyl chloride (8.9 g.) and aluminum chloride (30 g.) at 5—10°C. A usual work-up followed by distillation under reduced pressure, was difficult because of the remarkable foaming; thus the oily product was subjected to chromatographic separation on an alumina column (1.8×30 cm.). Elution with petroleum ether afforded a hydrocarbon fraction (b. p. chiefly 98°C/37 mmHg, 2.5 g.), an oily mixture of VI and VII (11.0 g.), and small amounts of yellow needles of an unidentified ketonic substance. After the ketonic mixture had stood in the refrigerator, about 4.0 g. of white crystals separated out; on several recrystallizations from petroleum ether, these gave white needles melting at 104—105°C.

Found: C, 82.66; H, 10.25. Calcd. for $C_{15}H_{22}O$: C, 82.51; H, 10.16%.

The infrared bands were at 868 (isolated ring hydrogen) and 1685 cm^{-1} (carbonyl). The ultaviolet absorption bands were at 272—273 (*s*), 280 and 311 mμ (*s*). Its NMR methyl peaks were at 7.85 (*m*-methyl), 8.03 (*o*-methyl) and 8.86 (*t*-butyl).

The remaining oily part (b.p. 165—167°C/36 mmHg) was found by spectroscopic inspection to be mainly composed of the vicinal product VI.

The yellow needles, after recrystallization from boiling petroleum ether, melted at 183—185°C. They showed a strong absorption at 1685 cm^{-1} (carbonyl).

Found: C, 86.19; H, 8.92%.

The Isomerization of the Ketones.—A mixture of a ketone (3.3 or 4.0 g.), aluminum chloride (10 g.) and carbon disulfide (20 ml.) was agitated for 3—4 hr. at room temperatures and subsequently worked up in the manner described above. VII (4.0 g.) gave about 0.5 g. of a hydrocarbon fraction and 1.7 g. of a ketonic fraction. The spectral data of the latter nearly coincide

with those of the vicinal isomer VI. On the other hand, V (3.3 g.) gave 0.8 g. of the hydrocarbon fraction and 2.0 g. of the ketonic fraction (b. p. 144—146°C/22 mmHg, 2.0 g.). The spectral inspection of the latter disclosed that V was recovered unchanged. On the gas chromatograms of these hydrocarbon fractions simultaneously obtained there were found four or six peaks. In both cases some polymeric by-products were formed.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1207—1211 (1966)

The Alkaline Sulfide Reduction of Aromatic Nitro Compounds. VIII. The Correlation between Sodium Monosulfide and Hydrosulfide in the Reduction of Sodium *m*-Nitrobenzene Sulfonate

By Shizunobu HASHIMOTO and Junzo SUNAMOTO

Department of Applied Chemistry, Doshisha University, Karasuma-imadegawa, Kamikyo-ku, Kyoto

(Received September 14, 1965)

In order to examine the correlation between sodium hydrosulfide and sodium monosulfide, the reduction of sodium *m*-nitrobenzene sulfonate by these aqueous sulfides has been studied kinetically. The rates of the hydrosulfide reduction and the main reaction of the monosulfide reduction were found to be proportional to the concentration of the nitro compound and the square of the concentration of the reducing agent. In the hydrosulfide reduction, the hydroxide ion concentration has a negative effect on the initial state and a positive effect on the final state. The polarographic study on the hydrosulfide reduction confirmed the presence of disulfide ions. From the available data, the correlation among the alkaline sulfides in the reduction was discussed.

The alkaline sulfides may be classified into alkaline hydrosulfide, monosulfide, and polysulfide. In studying the significance of the method of preparation, each stoichiometric equation has been employed for the reduction of aromatic nitro compounds by them, for example:[1]

$$4\,\text{Ar-NO}_2 + 6\,\text{NaSH} + \text{H}_2\text{O} \rightarrow 4\,\text{Ar-NH}_2 + \text{Na}_2\text{S}_2\text{O}_3 \quad (1)$$

$$4\,\text{Ar-NO}_2 + 6\,\text{Na}_2\text{S} + 7\,\text{H}_2\text{O} \rightarrow 4\,\text{Ar-NH}_2 + 3\,\text{Na}_2\text{S}_2\text{O}_3 + 6\,\text{NaOH} \quad (2)$$

$$\text{Ar-NO}_2 + \text{Na}_2\text{S}_2 + \text{H}_2\text{O} \rightarrow \text{Ar-NH}_2 + \text{Na}_2\text{S}_2\text{O}_3 \quad (3)$$

However, it seems reasonable to assume that sodium monosulfide is nothing but sodium hydrosulfide in an aqueous solution, because sodium monosulfide is almost completely hydrolyzed into sodium hydrosulfide and sodium hydroxide in an aqueous solution, as in Eq. 4.[2]

$$\text{Na}_2\text{S} + \text{H}_2\text{O} \rightleftarrows \text{NaSH} + \text{NaOH} \quad (4)$$

In an earlier paper dealing with the polarographic oxidation of sodium sulfides, the relation of their reducing power has discussed.[3] In the present paper the correlation among the sodium sulfides in the reduction of sodium *m*-nitrobenzene sulfonate will be investigated.

Experimental

Materials.—Sodium monosulfide and disulfide were prepared and purified by the method used in the preceding experiment.[3] Sodium hydrosulfide was prepared and purified according to the method given in the literature.[4] Sodium *m*-nitrobenzene sulfonate was the same as that used in the previous report.[5]

Product Study.—The reduction of sodlum *m*-nitrobenzene sulfonate was carried out under the same conditions as those used in the kinetic experiments, after a reaction of a sufficient duration, the resulting solution was acidified with concentrated hydrochloric acid, boiled on a water bath for about 20 min., and filtered. After it had been washed, the filtrate and the washings were combined and diluted with water to the appropriate voulme. From this solution a sample was taken and submitted to the diazometry according to the usual method. At the same time a part of this solution was submitted to paper chromatography. The reaction gave the corresponding amine in a 92.5% yield by the disulfide reduction, in a 95.5% yield by the monosulfide reduction, and in a 97.3% yield by the hydrosulfide reduction.

The paper chromatography of the resulting solution with several solvents, such as 2% hydrochloric acid,

n-butanol - concentrated hydrochloric acid (4 : 1), 2% aqueous ammonia, and pure water, confirmed only the presence of metanilic acid; the insoluble residue in hydrochloric acid was only sulfur.

Procedure for Rate Measurement.—The procedure for the rate measurement and analysis was the same as the method described earlier.[5] The probable error for the determination of the produced amines was ±0.23%.

Procedure for pH Measurement.—A glass electrode and a caromel elelctrode were placed in a reaction flask for the rate measurements; the pH was then followed during the reduction on a Horiba-Hitachi M4-type pH meter.

Polarography on Hydrosulfide Reduction.—Using the same method as in the rate measurements, at appropriate time intervals an aliquot was taken and subjected to a.c. polarography on a Yanagimoto PA-102-type polarography. As the supporting electrolyte, the buffer solution, 0.01 M sodium borate and 0.04 M sodium hydroxide, was used (pH=12.15, as measured by a glass electrode).

Results and Discussion

The differences in the rates of reduction in the initial stage were unexpectedly large when sodium *m*-nitrobenzene sulfonate was reduced by aqueous sodium hydrosulfide, monosulfide, and disulfide. Therefore, these rates could not all be measured under the same reduction conditions; the rates of reduction by monosulfide and hydrosulfide were therefore measured under one set of conditions, while those of reduction by disulfide and hydrosulfide were measured under another set of conditions. These data are compared each other in Fig. 1.

The initial rate of the disulfide reduction was very large and the reaction reached an apparent equilibrium rather early, while in the monosulfide reduction there was an induction period,[5] after which the main reaction proceeded at much the same rate as the disulfide reduction. The hydrosulfide reduction showed a medium reaction rate between the rates of the monosulfide and the disulfide reduction. The order of the apparent rates in the initial stage was $S_2^{2-}>SH^->S^{2-}$, and that at corresponding times after the induction period of the monosulfide reduction was $S^{2-}>SH^->S_2^{2-}$.

Sodium hydrosulfide undergoes ionic dissociation, but it hardly hydrolyzes at all in an aqueous solution.[2] On the other hand, sodium monosulfide undergoes hydrolysis, as has been described above. It may, therefore, be supposed that the difference in the reaction conditions between the monosulfide and the hydrosulfide reductions depends upon the pH of the medium.

A more direct basis for comparison between them is found in the pH dependence of the reaction.

* Gaseous hydrogen sulfide was introduced into the aqueous sodium monosulfide solution till the color of phenolphthalein disappears and excess hydrogen sulfide was removed by nitrogen till the removed gas shows negativity on a lead acetate paper.

The addition of sodium hydroxide in the hydrosulfide reduction made the initial rate slower, while it accelerated the rate of the subsequent reaction. In the reduction by the aqueous monosulfide solution, which absorbed hydrogen sulfide, the induction period disappeared and the rate of the overall reaction became slower, approaching that of the hydrosulfide reduction. The correlation between them is shown in Figs. 2 and 3.

● pH ○ Yield of amine

pH Change During Reduction.—In the alkaline sulfide reduction, the pH changes during the course of the reduction. On the hydrosulfide reduction, the monosulfide reduction, and the disulfide reduction, therefore, the pH values were followed under the conditions indicated in Figs. 4, 5, and 6 respectively.

In the hydrosulfide reduction the pH first increased with the progress of the reduction, but after a while it decreased a little. In the monosulfide reduction the pH continuously increased with the progress of the reaction; indeed, the pH in the induction-period intervals of the reduction increased remarkably. In the disulfide reduction, unlike the monosulfide reduction, the pH only decreased during the course of the reduction.

The rate of the main step in the monosulfide reduction of sodium *m*-nitrobenzene sulfonate depends upon the pH, as we previously reported.[5] Hojyo et al. also presented evidence that the rate of the disulfide reduction of nitrobenzene in an aqueous methanolic solution shows a first-order dependence on the hydroxide ion concentration.[6] On the basis of these data, it is clear that the alkaline-sulfide reductions are always closely connected with the pH of the medium.

In spite of the foregoing results, which show the pH dependence of the rate of alkaline-sulfide reductions, there remains the interesting question of why no induction period appears in the reduction by a hydrosulfide that shows a lower pH value than the monosulfide in an aqueous solution.

The Rate of the Hydrosulfide Reduction.—Since the hydrosulfide hardly hydrolyzes at all in an aqueous solution, it may be assumed that its stoichiometric concentration is almost equal to the kinetically-available concentration. The rate of the hydrosulfide reduction is given by runs in

Table I. The effect of the initial concentration of the nitro compound and sodium hydrosulfide on the apparent third order rate constants (30°C)

3.50	3.60	1.20±0.08
3.50	7.19	1.62±0.08
3.50	10.8	2.95±0.33
6.99	7.19	2.59±0.23

6) M. Hojyo, Y. Takagi, and Y. Ogata, *J. Am. Chem. Soc.*, **82**, 2459 (1960).

which the initial concentrations of the nitro compound and of sodium hydrosulfide have been interchanged. The rate of the reduction is found to be proportional to the concentration of the nitro compound and to the square of the concentration of sodium hydrosulfide:

$$\frac{d(\text{Ar-NH}_2)}{dt} = k(\text{Ar-NO}_2)(\text{NaSH})^2 \qquad (5)$$

The apparent third-order rate constants as calculated by Eq. 5 and the initial concentrations of both reactants are shown in Table I.

The temperature effect obeys the Arrhenius equation, as is shown in Fig. 7; the activation energy was thereby estimated graphically to be $E=$ 9.38 kcal. mol^{-1}.

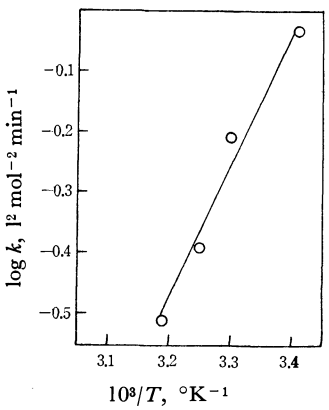

Fig. 7. The temperature dependence of the apparent third order rate constants.

Sodium monosulfide and sodium hydrosulfide are in a hydrolytic equilibrium, as has been described above. If these reducing agents, therefore, are used in the same stoichiometric concentration and compared with each other, the difference in their reduction conditions will be due to the pH in their medium; if the pH change which occurs during the course of the reduction is not considered, the two reactions must be essentially identical in their kinetics. The rate equation in the main step of the monosulfide reduction[5] is, in fact, the same as that given for the hydrosulfide reduction:

$$\frac{d(\text{Ar-NH}_2)}{dt} = k(\text{Ar-NO}_2)(\text{Na}_2\text{S})^2 \qquad (6)$$

A comparison of the apparent third-order rate constants of the hydrosulfide reduction with those of the main step of the monosulfide reduction is shown in Table II. It seems most reasonable to assume that the differences in the rate constants on the two sulfide reductions are due to the hydroxide ion concentration in the medium.

It was previously suggested that the induction period observed in the monosulfide reduction was due to the formation of the sulfide ion radical and its dimerization, as follows:[5]

$$(\text{S}^{2-}\text{-H}_2\text{O}) \xrightarrow[\text{Fe}^{3+}, \text{ or } \text{S}_2\text{O}_3^{2-}, \text{ etc.}]{h\nu,\ O_2} \text{S}^{-}\cdot + \text{H}\cdot + \text{OH}^- \qquad (7)$$

$$\text{S}^{-}\cdot + \text{S}^{-}\cdot \rightarrow (\text{S-S})^{2-} \qquad (8)$$

In view of the above correlation between monosulfide and hydrosulfide, it may similarly be reasonable to assume that the following processes are also involved in the initial stage of the hydrosulfide reduction:

$$\text{SH}^- \xrightarrow{h\nu,\ O_2,\ \text{etc.}} \text{S}^{-}\cdot + \text{H}\cdot \qquad (9)$$

$$\text{S}^{-}\cdot + \text{H}_2 \rightarrow \text{SH}^- + \cdot\text{OH} \qquad (10)$$

$$\text{H}\cdot + \cdot\text{OH} \rightarrow \text{H}_2\text{O} \qquad (11)$$

$$\text{H}\cdot + \cdot\text{H} \rightarrow \text{H}_2 \qquad (12)$$

It appears that the hydrosulfide ion readily gives a sulfide ion radical and a hydrogen radical in the presence of light or oxygen, and that the sulfide ion radical produced immediately dimerizes to give the disulfide ion, as in Eq. 8. The hydrogen radical may couple with the hydroxide radical produced according to Eq. 10 to give water, or dimerize to hydrogen gas. It may be supposed that the hydrogen radical or hydrogen gas produced here is not directly concerned with the reduction of the nitro compound, but further work is in progress on this point and will be reported on at a later date.

On the basis of the results which show that the initial stages in the hydrosulfide reduction and in the monosulfide reduction depend upon the pH of the medium, it may be supposed that this auto-oxidation process of the hydrosulfide ion to the disulfide ion is also affected by the pH and that the rate of the auto-oxidation becomes in accordance with the pH increment.* That is to say, the rate of the formation of the disulfide ion in the aqueous hydrosulfide solution is rapid, but that in the aqueous

monosulfide solution is very slow, because of the high concentration of hydroxide ions. An induction period, therefore, appears only in the monosulfide reduction.

The Polarographic Study of the Hydrosulfide Reduction.—In order to examine the above hypothesis that the disulfide ion will be formed in the hydrosulfide reduction, a. c. polarography was applied to the hydrosulfide reduction of sodium *m*-nitrobenzene sulfonate. As is shown in Table III, the heights of the first, the fourth, and the fifth waves all increased as the reduction proceeded. The increase in the height of the first wave shows the formation of the oxide of sulfide, that is, thiosulfate.[3] The fourth wave was overlapped with the wave of the nitro compound. However, the increase in the height of this wave clearly shows the formation of the polysulfide ions, as is true also with the fifth wave.[3] The polarography of the hydrosulfide reduction confirmed the formation of the disulfide ion and supported the above hypothesis.

Conclusion

Sodium monosulfide and sodium hydrosulfide are in a hydrolytic equilibrium. The reductions by both sulfides, therefore, must be essentially identical in their kinetics. The rate equation in the main reaction of the monosulfide reduction was, in fact, identical with that of the hydrosulfide reduction (cf. Eqs. 5 and 6).

It may be reasonable to assume that the reduction of aromatic nitro compounds by the aqueous monosulfide or the aqueous hydrosulfide proceeds as follows. First, the hydrosulfide ion, as well as the one produced by the hydrolysis of the monosulfide ion in an aqueous solution, gives the sulfide ion radical with light or oxygen and dimerized to the disulfide ion. Secondly, the disulfide ion produced attacks the positively-charged nitrogen atom of the nitro group, because the reducing power of the monosulfide ion or of the hydrosulfide ion is very small in itself.

The hydroxide ion has a negative effect on the first process, involving the formation of the sulfide ion radical and its dimerization, and a positive effect on the second process, which involves the reduction of the nitro group. From these relationships, it is clear that no induction period appears in the hydrosulfide reduction as a result of its low concentration of hydroxide ions at the initial stage.

Hojyo et al. presented evidence that the disulfide reduction of nitrobenzene in an aqueous methanolic solution is given by Eq. 13, in conjunction with the hydrolytic equilibrium of the disulfide ion:[6]

$$-\frac{d(Ar\text{-}NO_2)}{dt}=k(Ar\text{-}NO_2)(S_2^{2-}) \qquad (13)$$

On the basis of the assumptions that the rate of the auto-oxidation of the hydrosulfide ion is rather rapid compared with the rate of the reduction of the nitro group, and that the reduction of the nitro group takes place not by the way of the action of the hydrosulfide ion or the monosulfide ion, but by way of that of the disulfide ion,

i) the auto-oxidation of the sulfide ion;

$$S^{2-}\xrightarrow{H_2O}SH^-\xrightarrow[\text{oxygen, etc.}]{\text{light or}}S_2^{2-}$$

(rather rapidly)

ii) the reduction of the nitro group;

$$S_2^{2-}\xrightarrow{Ar\text{-}NO_2}S_2O_3^{2-} \qquad \text{(slowly)}$$

it is clear that the rate can be expressed by a third-order equation, second order with respect to the hydrosulfide or the monosulfide, and first order with respect to the nitro compound. In this way the relationship between the disulfide reduction and the hydrosulfide (or the monosulfide) reduction can also be explained.

Thanks are due to Mr. Miyoshi Oshima for his assistance in some of the experimental work. The authors are also indebted to the Daiwa Dyestuff Co., Ltd., for its gift of materials.

The Mechanism of the Alkaline Fusion of Benzenesulfonic Acid.[1,2]

By Shigeru OAE, Naomichi FURUKAWA, Masahiro KISE and Mitsuyoshi KAWANISHI

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received September 16, 1965)

Benzenesulfonic acid-1-^{14}C was fused with potassium hydroxide at 320—350°C for five minutes. The phenol obtained was then degraded as usual, and the distribution of carbon-14 in the phenol was determined. Practically all the ^{14}C activity was found at the 1 position of the phenol, which means that there is no migration of the ^{14}C originally labeled at the position 1 or the benzenesulfonic acid. Benzenesulfonic acid was also treated with potassium hydroxide enriched with ^{18}O. The resulting phenol was found to be incorporated, with the same concentration of ^{18}O as that of the ^{18}O enriched water used. The results show that the mechanism of the reaction is of a simple S_N2 type and not of the elimination-addition type involving the benzyne intermediate, while there was no oxygen migration in the reaction.

The alkaline fusion of benzenesulfonic acid was first effected by Wurtz[3] or Kekulé[4] more than a hundred years ago. Since then, the method has been used as a conventional technique for the manufacture of phenol and related hydroxy compounds. Recently, however, the alkaline fusion process has been giving way to other, more simple methods for the production of phenol, and its use is quite limited nowadays. Yet the alkaline fusion is still considered to be one of the best methods to introduce the hydroxyl group into the aromatic ring. As for the reaction mechanism, the alkaline fusion of aromatic sulfonic acids has been classified only as a simple S_N2-type nucleophilic aromatic substitution,[5] without any concrete evidence. However, under strong alkaline conditions such as those employed in this reaction, one can postulate another mechanism involving the formation of a benzyne-type intermediate. It is interesting, in this respect, to compare the alkaline fusion of benzenesulfonic acid with that of halobenzene in a strong alkaline medium such as sodiumamide in liquid ammonia,[6] where the reaction is known to proceed via the initial abstraction of an ortho proton by the strong base, followed by the formation of an unstable intermediate benzyne which reacts very rapidly with a nucleophile to give the final product. In fact, a few previous works have not accepted the simple S_N2-type mechanism for the alkaline fusion reaction.[7] For instance, *p*-benzenedisulfonic acid or *p*-chlorobenzenesulfonic acid have been reported to produce resorsinol to some extent, and hence it has been suggested[8-10] that the alkaline fusion might not be a simple S_N2-type mechanism, but an elimination-addition type process which involves the participation of a benzyne-type intermediate to some extent. Meanwhile, another alternative pathway is also conceivable, the one involving the initial attack of the hydroxide anion on the sulfur atom, followed by the intramolecular migration of the oxygen atom to the benzene ring, thus giving phenol. This mechanism is not unlikely in view

of the fact that the sulfur atom is known to be attacked readily by a strong nucleophile because of its ability to expand the valence shell from an octet to a decet by using its d-orbitals.[11] In fact, in the alkaline fusion of diphenyl sulfone, the sulfur atom is the primary site of the nucleophilic attack by the hydroxide anion.[12] These three postulated mechanisms may be summarized as follows.

One of the most powerful ways to get a clear understanding of the mechanistic information of the alkaline fusion is the isotopic tracer technique. If one uses sodium benzenesulfonate specifically labeled with ^{14}C at its 1 position for the alkaline fusion and traces the ^{14}C radioactivity distribution in the resulting phenol, one can readily discriminate undesirable from desirable mechanistic schemes. If the reaction follows the mechanism I, all the ^{14}C activity originally labeled at benzenesulfonic acid-1-^{14}C will remain at the position 1 in the resulting phenol, whereas if the reaction proceeds through the benzyne-type intermediate, the distribution of the ^{14}C will be completely different from that to be expected from the mechanism I, and exactly a half of the ^{14}C will be found at the position 1 in the phenol, whereas the remaining half will be distributed equally at the 2 and 6 positions. In the meantime, the mechanism III can be tested by the use of $K^{18}OH$. If the reaction follows the path indicated by the mechanism III, the concentration of ^{18}O in the resulting phenol will be considerably lower than that of the potassium hydroxide employed, since the four oxygen atoms attached to the sulfur will be substantially equilibrated before collapsing to form the rearranged phenyl sodium sulfate. If the proton transfer among four oxygen atoms is very fast in the intermediate addition complex, the oxygen-18 content in the resulting phenol will become one-quarter that of the $K^{18}OH$ originally employed.

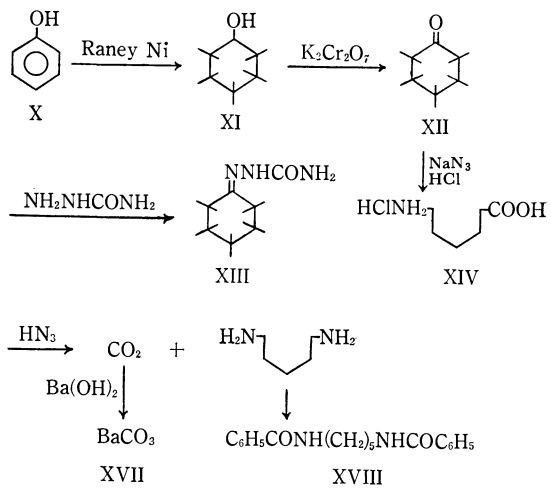
Results and Discussion

Benzensulfonic acid-1-^{14}C was synthesized as is shown in Scheme 1.

The degradative method is shown in Scheme 2.



Scheme 2.

The results derived from the runs are shown in Table I. Cyclohexanonesemicarbazone was chosen as the standard sample for evaluating the activities of all the other products.

The degradation study indicates that practically all the ^{14}C activity of the phenol was found at position 1 where ^{14}C was originally labeled and the

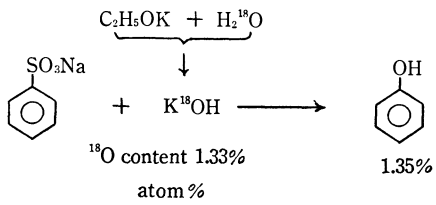
TABLE II. THE ALKALINE FUSION WITH $K^{18}OH$



sulfonic acid group was originally attached. This observation clearly excludes the elimination-addition mechanism involving a benzyne-type intermediate, for it requires a half of the ^{14}C activity to be divided equally at the two ortho positions, and the remaining half to be at the position 1.

When the alkaline fusion of benzenesulfonic acid was carried out with ^{18}O-enriched potassium hydroxide (atom % of ^{18}O: 1.33), the resulting phenol was found to be incorporated with exactly the same concentration of ^{18}O (atom % of ^{18}O: 1.35). This observation does not favor the other alternative mechanism, which involves the initial nucleophilic attack of the hydroxide ion on the sulfur atom of the sulfonic acid, followed by the migration of the phenyl group from the sulfur atom to oxygen, since it is utterly inconceivable that he migration of the phenyl group takes place only at the entering oxygen atom. This fact is consistent with the findings of Makolkin.[13] According to this mechanism, the oxygen-18 concentration in the hydroxyl group of the resulting phenol should be between natural and a one-quarter excess of what was incorporated in the potassium hydroxide used, depending on the amount of proton-transfer during the reaction. The actual finding is not in accord with this prediction, but it is quite consistent with the mechanism of the simple aromatic S_N-reaction. In fact, this simple mechanism is only compatible with the data on the ^{14}C experiments. Therefore, both ^{14}C and ^{18}O tracer experiments unequivocally suggest that the alkaline fusion of benzenesulfonic acid proceeds through the path involving the direct nucleophilic attack of hydroxide on carbon 1, in a simple aromatic S_N-reaction as is shown by eq. I.

Another piece of evidence in support of the aromatic S_N-type mechanism for this reaction may be found in the fact that the alkaline fusion of *p*-toluenesulfonic acid did not give a mixture of *p*- and *m*-cresols, but only the isomer. Thus, the only product of the alkaline fusion of *p*-toluenesulfonic acid was, in all respects, identical to *p*-cresol. The cresol obtained from the alkaline fusion of *p*-toluidine via *p*-toluenesulfinic acid and *p*-toluenesulfonic acid (shown in Scheme 3) was also completely identical with that of an authentic sample prepared from the direct hydrolysis of the diazotized-*p*-toluidine.

13) I. A. Makolkin, *Acta Physicochim.*, **16**, 88 (1942).

In order to obtain further supporting evidence for the direct aromatic S_N mechanism, mesitylenesulfonic acid was subjected to alkaline fusion.[14] Since this compound has no ortho hydrogen available for the elimination of the hydrogen and sulfonic acid groups to form a benzyne-like intermediate, the formation of mesitylenol through the benzyne intermediate is not possible. Yet a substantial amount of mesitylenol was obtained in the ordinary alkaline fusion of mesitylenesulfonic acid. The rather low yield of the phenol, 30%, is probably due to the large steric compression of the transition complex of the reaction. All these observations clearly suggest that the alkaline fusion of these sulfonic acids proceeds through the path involving the nucleophilic replacement the SO_3H group by the hydroxide ion at position 1, much the same as in the usual aromatic S_N reaction of aromatic halides.

Experimental

The preparation of Benzenesulfonic Acid-1-^{14}C. —*Acetic Acid-1-^{14}C.*—Acetic acid-1-^{14}C was prepared following the usual method.[15] A typical example is as follows. A Grignard solution prepared from 1.89 g. of methyl iodide and 291 mg. of magnesium in 50 ml. of dry ether was carboxylated with dried $^{14}CO_2$ generated from 0.655 g. of barium carbonate, which has 1.0 mc. of ^{14}C activity in a vacuum system. Acetic acid-1-^{14}C was converted to sodium acetate. The yield was 0.200 g. (quantitative).

Ethyl Acetate-1-^{14}C.[16]—Sodium acetate-1-^{14}C (0.40 g.) was esterified with 1.5 ml. of freshly-prepared ethyl phosphate. The yield was 0.395 g. (90%).

1-Methyl Cyclohexanol-1-^{14}C.[16]—To the Grignard solution prepared from 32.5 g. of pentamethylenedibromide and 5.22 g. of magnesium, 2.96 g. of ethyl acetate-1-^{14}C in 150 ml. of absolute ether added. After the decomposition of the above Grignard solution with an ammonium chloride solution, 1-methyl cyclohexanol-1-^{14}C was obtained. The yield was 2.82 g., a 97% yield.

16) A. Murray and D. L. Williams, ibid., p. 102.

Toluene-1-^{14}C.[17]—The conversion of 1-methyl-cyclohexanol-1-^{14}C to toluene-1-^{14}C was carried out following the method employed by Sixma et al., using platinum chloride on alumina as the dehydration and dehydrogenation catalyst. From 5.00 g. of 1-methyl cyclohexanol-1-^{14}C, 2.60 g. of toluene-1-^{14}C was obtained (a 65% yield).

Benzoic Acid-1-^{14}C.[16]—Toluene-1-^{14}C (1.53 g.) was oxidized with 7.0 g. of potassium permanganate in an aqueous solution. Benzoic acid (1.47 g.) was thus obtained (a 79% yield). Recrystallization from water gave colorless crystals with a m. p. of 122°C.

Aniline-1-^{14}C.[18]—Benzoic acid-1-^{14}C (6.1 g.) was treated with 5.0 g. of sodium azide in a mixture of 40 ml. of chloroform and 20 ml. of concentrated sulfuric acid; aniline-1-^{14}C (3.9 g.) was thus obtained (a 84% yield). The b. p. was 181—182°C.

Benzenesulfinic Acid-1-^{14}C.[19]—Aniline (3.9 g.) was diazotized with 3.2 g. of sodium nitrite and 5 ml. of concentrated sulfuric acid in 60 ml. of water. The diazonium solution was saturated with sulfur dioxide gas which had been generated from sodium bisulfite and sulfuric acid until the weight of the gas reached to 20 g. Then to this solution was added 25 g. of copper metal which had been freshly prepared from cupric salfate and zinc powder, with the temperature maintained below 5°C. After the gas evolution had ceased, the precipitated copper was filtered and washed with ether several times. The filtrate was then extracted three times with 50 ml. of ether. The combined ether solution was dried over anhydrous magnesium sulfate overnight. Then the ether was evaporated, and benzenesulfinic acid-1-^{14}C was obtained as slightly yellow-colored crystals. The yield was 4.7 g.; 78.3%; m. p. 84°C.

Benzenesulfonic Acid-1-^{14}C.—Benzenesulfinic acid-1-^{14}C (4.7 g.) was suspended in 90 ml. of a 2% hydrogen peroxide solution at room temperature. The mixture was then stirred with a magnetic stirrer at room temperature until the suspended sulfinic acid had been completely dissolved. The solution was kept standing overnight. Then the solution was titrated with a standard sodium hydroxide solution and dried over a water bath. Colorless hair-like crystals of sodium benzenesulfonate-1-^{14}C were thus obtained. The yield was 5.7 g. (100%).

The Alkaline Fusion of Sodium Benzenesulfonate-1-^{14}C.—A typical run was as follows. In a 50-ml. nickel muffle was fused 10 g. of potassium hydroxide. Into this molten potassium hydroxide 3.0 g. of sodium benzenesulfonate-1-^{14}C was stirred with a steel rod equipped with a thermometer. The reaction was carried out at temperatures between 300 and 340°C for 5 min. After that the vessel was rapidly cooled with water. The solidified reactants were dissolved with a concentrated hydrochloric acid solution until the solution had strongly acidified. The aqueous solution was then steam-distilled until the precipitate with bromine did not appear. The distillate was saturated with sodium chloride and then extracted three times with 60 ml. of ether. The ether solution was distilled. The yield of phenol-*x*-^{14}C was 1.1 g. (68%); b. p. 73°C/10 mmHg. Since no detectable change was observed when the experiment was performed under a nitrogen gas stream, the fusion was carried out in the open air.

The Degradation of Phenol-*x*-^{14}C.—The degradation method for phenol-*x*-^{14}C is shown in Scheme 2. A typical run was as follows:

Cyclohexanol-x-^{14}C.[20]—Phenol-*x*-^{14}C was reduced as usual using Raney's nickel as a hydrogenation catalyst in a 100-ml. autoclave. The solvent used was methanol. From 5.0 g. of phenol-*x*-^{14}C, 4.2 g. of cyclohexanol-*x*-^{14}C was obtained (a 78% yield). B. p. 159—162°C.

Cyclohexanone-x-^{14}C.[20]—Cyclohexanol-*x*-^{14}C was oxidized to cyclohexanone-x-^{14}C using with potassium bichromate as the oxidizing agent. From 4.2 g. of cyclohexanol-*x*-^{14}C, 3.5 g. of cyclohexanone-*x*-^{14}C was obtained (81.6%; b. p. 155—159°C). A part of the cyclohexanone was converted to its semicarbazone, which was then used as the standard sample for original ^{14}C activities. M. p. 167—167.5°C.

6-Aminohexanoic Acid-x-^{14}C.[19]—Cyclohexanone-x-^{14}C was converted to 6-aminohexanoic acid according to the Schmidt reaction. Cyclohexanone (2.1 g.) in 30 ml. of water was treated with 7.4 g. of sodium azide; the ε-aminocaprolactum-x-^{14}C obtained was then hydrolyzed to afford 6-aminohexanoic acid-*x*-^{14}C hydrochloride. The hydrochloride was recrystallized from absolute-alcohol-anhydrous ether. The yield was 3.4 g. (90% yield).

The Decarboxylation of 6-Aminohexanoic Acid-*x*-^{14}C.[20]—6-Aminohexanoic acid-*x*-^{14}C hydrochloride (10.7 g.) was treated with 3.7 ml. of concentrated sulfuric acid, the resulting hydrochloride gas was removed by heating the solution up to 70°C under reduced pressure. The residue was placed in 100-ml. three-necked flask and connected to a Schmidt decarboxylation apparatus. To this mixture 20 ml. of 1.17 N hydrazoic acid was added drop wise over a 40-min. period at 40°C, and the $^{14}CO_2$ generated was trapped with 0.25 N barium hydroxide. After the reaction had been completed (the time needed for this was 15 hr.), the apparatus was swept with CO_2-free nitrogen gas. The $Ba^{14}CO_3$ thus precipitated was collected in a dry box and washed with hot water and then with acetone. The yield of barium carbonate was 1.5 g. (84% yield). The residual 1,5-pentanediamine was changed to a dibenzoyl derivative, which was recrystallized four times from ethyl acetate-benzene. M. p. 133—133.5°C.

The Measurement of the Activities.—The activities of the samples were measured using a JRC Aloka-2π-gas flow G. M. counter using Q-gas. Known amounts of the samples were completely oxidized to carbon dioxide following the Van-Slyke wet-combustion method. The carbon dioxide generated was collected as barium carbonate; it was made into pellets and the activity were measured. The samples measured were cyclohexanone semicarbazone (XIII) as a standard total activity, barium carbonate (XV) generated by a Schmidt decarboxylation, and 1, 5-dibenzoyl pentanediamine (XVII). The amounts of pellets of barium carbonate obtained were 124 mg. (95%) from cyclohexanone semicarbazone, 173 mg. from barium carbonate and 151 mg. (97%) from 1, 5-dibenzoylaminopentane. The counting data are shown in Table I.

The Alkaline Fusion of Benzenesulfonic Acid

19) J. D. Roberts, D. A. Semenow, H. E. Simmons, Jr., and L. A. Carlsmith, *J. Am. Chem. Soc.*, **78**, 601 (1956).

20) R. B. Loftfield, *J. Am. Chem. Soc.*, **73**, 4707 (1951).

with $K^{18}OH$.—*The Preparation of Potassium Hydroxide-^{18}O.*—To a solution of 3 g. of potassium in 30 ml. of absolute ethanol, 1.5 ml. of water-^{18}O was added (^{18}O 1.645 atom %; Yeda Research and Development Co., Ltd., Israel). The ethanol and excess water were removed by distillation under reduced pressure, and the residue was dried over phosphorus pentoxide in vacuo. Thus, about 4.0 g. of potassium hydroxide-^{18}O (^{18}O 1.33 atom%) was obtained.

The Potassium Hydroxide-^{18}O Fusion of Sodium Benzenesulfonate.—A mixture of 1 g. of sodium benzenesulfonate and 2 g. of potassium hydroxide-^{18}O was heated at 320—330°C for 5 min. in a steel vessel, and cooled rapidly with tap water. The reaction mixture was then extracted with 50 ml. of hot water and acidified with concentrated hydrochloric acid. After the steam distillation of the mixture, a slight excess of bromine was added to the distillate, resulting in the formation of crude 2, 4, 6-tribromophenol; this was separated by filtration, washed, and dried. Repeated recrystallizations from aqueous ethanol and *n*-hexane afforded about 1.4 g. of colorless needles of a silky luster needles which melted at 92—94°C with sublimation. (Reported[21] m. p. 94—96°C). The atom percentage of ^{18}O was found to be 1.35%.

Attempts to Find Rearranged Products during the Alkaline Fusion of *p*-Toluene Sulfonic Acid.—Samples of *p*-cresols obtained by the following methods were checked by means of an Infrared Spectrum study to see if any rearrangement takes place during the alkaline fusion.

a) Commercially-available p-Cresol was purified by repeated distillation under reduced pressure; a fraction with a b. p. of 105°C/28 mmHg was collected.

b) p-Cresol from p-Toluidine.—*p*-Toludine was converted into its diazonium chloride, which was subsequently warmed on a water bath. Repeated distillation gave a fraction with a b. p. of 102°C/31 mmHg. The *p*-cresol thus obtained was used as a standard smaple for the infrared study.

c) p-Cresol from p-Toluenesulfonic Acid.—Potassium *p*-toluenesulfonate was fused with molten potassium hydroxide in a steel reaction vessel. Cresol was isolated and distilled under reduced pressure to give the main fraction (b. p. 104—105°C/28 mmHg).

d) p-Cresol from p-Toluenesulfonic Acid which had been Synthesized from p-Toluidine.—*p*-Toluidine was diazotized with sodium nitrite, and then converted into *p*-toluenesulfinic acid. *p*-Toluenesulfonic acid was prepared by oxidizing the above sulfinic acid with hydrogen peroxide. The method of alkaline fusion was the same as that described for the sodium benzene sulfonate. The infrared spectra of all these *p*-cresols, prepared by different methods, were consistent in all respects with that of the standard sample. In no case was there found any rearranged isomers or any other product than the starting material.

The Alkaline Fusion of Mesitylenesulfonic Acid.—Mesitylenesulfonic acid was synthesized from mesitylene and concentrated sulfuric acid following the usual procedure[14] (m. p. 76—78°C). To 30 g. of fused potassium hydroxide 12.5 g. of mesitylenesulfonic acid was added at 300—310°C for 5 min. After rapid cooling, the mixture was acidified with hydrochloric acid. Mesitylenol (3.5 g.) was obtained in a relatively low yield (29%); m. p. 70°C (sublimed).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1216—1220 (1966)

The Intermolecular Hydrogen Bonding between Methanol and Triethylamine in Various States

By Etsuko HIRANO and Kunio KOZIMA

Laboratory of Chemical Spectroscopy, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 18, 1965)

The intermolecular hydrogen bond energy between methanol and triethylamine was determined by infrared studies in the vapor state and in solutions. It was also found that, with an increase in the dielectric constant, ε, of the solvents, the free O–H stretching band of methanol shifts to a lower frequency, the molar absorptivity of this band increases, and the hydrogen bond energy of this system decreases. As is well known, the hydrogen-bonded system is mainly stabilized by the contribution of two resonating structures, the non-bonded structure and the charge-transfer structure. It seems probable that the weight of the latter for a relatively weak hydrogen-bonded complex is small. Therefore, if the energies for both resonating structures are assumed to be mainly determined by the electrostatic interaction, the hydrogen bond energy may be expected to be reciprocal to the dielectric constant of the environment. This is actually true within the limits of experimental error in a few solutions. It was also found, however, that the relation cannot be extrapolated to the case of $\varepsilon=1$, i. e., to the case of vapor.

While a considerable number of infrared studies of hydrogen bonding in solutions have been reported, little attention has been paid to the vapor state. It seems that it would be interesting to

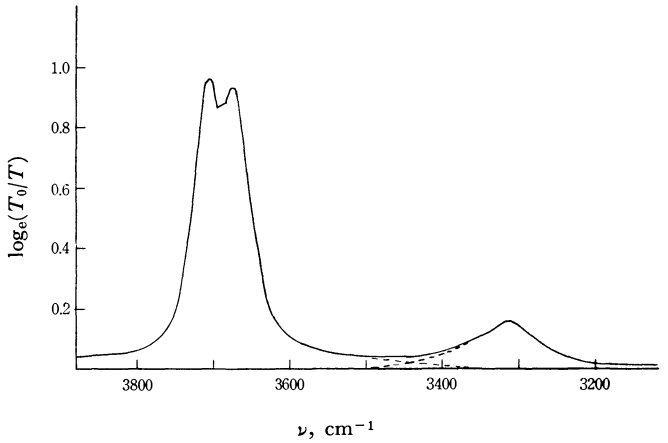

Fig. 1. The infrared spectrum of the O-H stretching band for methanol and the complex in the vapor.

study the hydrogen bonding in the vapor state as well as in solutions for the same substances in order to obtain information about the effect of environment on the hydrogen bonding.

For this study methanol and triethylamine have been chosen as the proton donor and the proton acceptor respectively, and the intermolecular hydrogen bond energy will be measured spectroscopically in the vapor state and in solutions.

Experimental

Materials.—Methanol, triethylamine, carbon tetrachloride, chlorobenzene, dichloromethane, and chloroform were purified by the usual methods[1]; for each substance only that fraction was used which distilled at a constant temperature.

Infrared Spectra.—For the measurements in the vapor state, two thin glass ampules, in which methanol and triethylamine had been sealed separately, were broken in a three-liter spherical, vacuumed flask; the two vapors were thus mixed. The quantity of each substance should be adequately adjusted so as to make each vapor pressure less than its own saturated vapor pressure in the flask. After prolonged mixing, the mixture was expanded into a one-meter vacuumed gas cell for infrared studies.

For the measurements in solutions, a 3.0 mm. fixed cell was used throughout this study.

The spectra were measured over the range from 3000 to 3900 cm^{-1} with a Perkin-Elmer Model 112 Infrared Spectrometer equipped with a lithium fluoride prism for both states.

The temperature of the samples was measured by a copper-constantan thermocouple.

Measurements of the Integrated Intensities.—An infrared spectrum of a mixed vapor of methanol and triethylamine is shown in Fig. 1. The band near 3683 cm^{-1} is due to the hydroxyl stretching vibration of the free methanol molecules, while the band near 3313 cm^{-1} can be assigned to that of the hydrogen-bonded complex of methanol and triethylamine, for this band disappears in the spectrum of pure methanol vapor.

The change in the relative intensities of these bands with the temperature was measured. As the two bands overlap near 3500 cm^{-1}, the observed curve of absorbances was divided into two smooth curves so that their sum was equal to the observed value, as is shown in Fig. 1. The ambiguity in dividing these bands does not seem to have any noticeable influence on the results. The area intensities were obtained by the graphical integration of the absorbances by using a planimeter, since the contours of the bands were not so simple for the vapor. The integrations were carried out from 3150 to 3480 cm^{-1} and from 3500 to 3865 cm^{-1} for the two bands respectively. This sufficiently covers a range of about four times the half-intensity width for each band. The integration outside this

1) J. A. Riddick and E. E. Toops, Jr., "Organic Solvents," Interscience Publishers, New York (1955), p. 445, p. 413 (by the method of Günther et al.), p. 408 (by the method of McAlpine and Smyth), p. 409 (by the method of Maryott et al.), and p. 411 (by the method of Morgan and Lowry).

interval may be neglected without noticeable influence on the evaluation of the relative intensities, because their absorbances at these limits are smaller than one-fifteenth of those at the peaks. The correction for finite slit widths can be neglected for the vapor, because of the breadth of the bands. The results obtained for the vapor are shown in Table I.

For the studies of solutions it did not seem that it would be accurate to determine the concentration of the complex by measuring the intensity of the hydrogen-bonded O-H stretching band, because both O-H stretching bands shift to lower frequencies in solutions than in the vapor and the hydrogen-bonded O-H band overlaps with the C-H stretching bands at the wing. Therefore, the concentration of the complex was estimated by measuring the decrease in the intensity of the free O-H stretching band. For this the intensity of the free O-H stretching band in solutions should be studied first. The methanol solutions used for this purpose were so dilute that the spectra showed no evidence of the band characteristic of the hydrogen bonding. In the solvent of carbon tetrachloride or dichloromethane, the free O-H band was represented by Lorentz's equation. Although in the solvent of chlorobenzene the shape of the band was asymmetric, each side of the band could be represented by the equation. Therefore, the true integrated absorption intensity per mole (the true molar absorptivity), a, corrected for finite slit widths, was calculated by the equation:

$$a = K(1/CL)\log_e(T_0/T)_{max}\Delta\nu^a{}_{1/2}$$

where the letters have their usual meanings.[2] The values of K were obtained from Ramsay's table.[2] For the non-polar solvent of carbon tetrachloride, the area intensity of this band is independent of the temperature. However, for the polar solvent of chlorobenzene or dichloromethane the intensity decreases slightly with an increase in the temperature. The results obtained are shown in Table II and should be used for the evaluation of the concentration of the complex shown in Table III.

The infrared spectra of the mixture of methanol and triethylamine in carbon tetrachloride or dichloromethane also have these bands, of which one is due to the free molecule and the other to the hydrogen-bonded complex. In chlorobenzene, however, the band due to the hydrogen-bonded complex cannot be detected because the band is masked by an absorption of the solvent.

Results and Discussion

The change in the internal energy, ΔE, which is equal to the hydrogen bond energy in its absolute magnitude, can be evaluated by the van't Hoff equation:

$$\mathrm{d}\log_e K_c/\mathrm{d}T = \Delta E/\boldsymbol{R}T^2$$

The equilibrium constant, K_c, is given by:

$$K_c = C_X/(C_D - C_X)(C_A - C_X),$$

where C_D is the initial concentration of methanol, C_A that of triethylamine, and C_X the concentration of the hydrogen-bonded complex.

In the vapor, the area intensity, I_f, of the free O-H stretching band at 20°C and that of that at 35°C were almost the same, within the limits of experimental error. Therefore, it may be a good approximation to take $(C_D - C_X)$ and $(C_A - C_X)$ as constant over this temperature range, since the values of C_X were shown to be very small compared with those of C_D and C_X. On the other hand, the area intensity, I_h, of the O-H stretching band of the complex markedly decreases with a rise in the temperature, as is shown in Table I. Therefore, by measuring this change with the temperature, the ratio of C_X's at two temperatures could be obtained. The fact that the intensity of the band is very sensitive to small variations in the concentration of the complex is due to the marked increase in the molar absorptivity of the O-H stretching band when hydrogen bonding occurs. The evidence for this may be seen in Table IV for the case of the dilute carbon tetrachloride solution. The suffixes f and h refer to the values of the free molecule and of the complex respectively.

The hydrogen bond energy in the vapor can then be evaluated by:

$$\log_e\frac{(K_c)_1}{(K_c)_2} = \log_e\frac{(C_X)_1}{(C_X)_2} = \log_e\frac{(I_h/a_h)_1}{(I_h/a_h)_2} = \frac{-\Delta E}{\boldsymbol{R}}\left(\frac{1}{T_1} - \frac{1}{T_2}\right)$$

The suffixes 1 and 2 refer to the values at the temperatures T_1°K and T_2°K respectively. The values of molar absorptivity, a_h, were cancelled in this equation, because of its independence of the temperature.

The values thus obtained are shown in the last column of Table I. The values of $|\Delta E|$ is larger by about 2.9 kcal./mol. than that for the methanol-ethyl ether complex in the vapor reported by Inskeep et al.[3] This result agrees with the expectation in that the frequency shift of the O-H stretching band, $\Delta\nu_{OH} = (\nu_{OH})_f - (\nu_{OH})_h$, is larger for the former than the latter.

In solutions the C_D and C_A concentrations were obtained by weighing. The C_X concentration could be evaluated by:

$$C_X = C_D - (I_f/a_f L)$$

where I_f is the area intensity of the free O-H stretching band. The equilibrium constants at various temperatures thus obtained are listed in Table III. From these data the hydrogen bond energy* can be calculated; the results are shown in Table V, together with the changes in the free energy and the entropy.

TABLE V. THE PROPERTIES OF THE INTERMOLECULAR HYDROGEN BONDING BETWEEN METHANOL AND TRIETHYLAMINE

State	Solvent	ε	$(\nu_{OH})_f$ cm^{-1}	$\Delta\nu_{OH}$ cm^{-1}	a_f 10^3 darks	$-\Delta E$ kcal./mol.	$-\Delta F$ kcal./mol.	$-\Delta S$ ca.l/mol.·deg.
Vapor		1	3683	370	—	7.6	—	—
Soln.	CCl_4	2.24	3642	430	4.9	6.0	1.2(31°C)	15 (31°C)
	C_6H_5Cl	5.71	3633	—	8.3	4.3	1.1(24°C)	10 (24°C)
	CH_2Cl_2	9.08	3628	328	9.2	3.0	1.1(24°C)	6.4(24°C)

It can be seen from Table V that the free O–H stretching band shifts to a lower frequency and that the molar absorptivity, a_f, of the band increases with an increase in the dielectric constant of the solvents. This fact indicates that the ionic character of the free O–H bond increases with an increase in the dielectric constant of the solvents.

As is well known, the hydrogen-bonded system is mainly stabilized by the contribution of two resonating structures, the non-bonded structure, –O–H···N$\lessgtr$, and the charge-transfer structure, $-O^-\cdots H-{}^+N\lessgtr$. Because the energy of the non-bonded structure is mainly due to the electrostatic interaction, the energy may be reciprocal to the dielectric constant, ε, of environment. As for the charge-transfer structure, it seems to be hard to estimate the effects of a solvent on its energy. However, it seems probable that the weight of the charge-transfer structure for such a relatively weak hydrogen-bonded complex is small[4] and that even for this structure the main part of energy is due to the electrostatic interaction. Therefore, if the energies for both resonating structures are considered to be mainly determined by the electrostatic interaction, the hydrogen bond energy may be expected to be a linear function of $1/\varepsilon$.

It is well known that, with an increase in the strength of hydrogen bonding, the O–H stretching bands in linear hydrogen bonds are progressively lowered in frequency.[5] Therefore, the $\Delta\nu_{OH}$ shift may be considered to be a measure of the strength of the hydrogen bonding.

The data of $\Delta\nu_{OH}$ shown in Table V and the value of $\Delta\nu_{OH}$, 360 cm^{-1}, obtained in the chloroform solution ($\varepsilon = 4.81$) are plotted against $1/\varepsilon$ in Fig. 2-(a). The values for the solutions are represented by a straight line, which is in agreement with the expectation mentioned above.

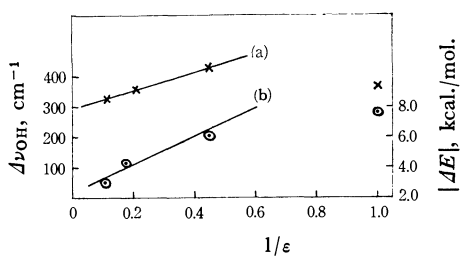

Fig. 2. (a) $\Delta\nu_{OH}$ vs. $1/\varepsilon$
(b) $|\Delta E|$ vs. $1/\varepsilon$

Furthermore, since a direct measure of the strength of the hydrogen bonding is the value of $|\Delta E|$, the values of $|\Delta E|$ are also plotted against $1/\varepsilon$ in Fig. 2-(b). Because of the possibility of experimental error in the evaluation of $|\Delta E|$, it is not conclusive; nevertheless it is very probable that the values of $|\Delta E|$ for the solutions can also be represented by a straight line.

The values of $\Delta\nu_{OH}$ or $|\Delta E|$ for the vapor phase do not fall on the straight line extrapolated from those obtained in the solutions. This fact may be taken as showing that the mechanism of the hydrogen bonding is somewhat different in the vapor from that in the solutions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1221—1227 (1966)

Studies of the Photoreduction of Acridine in Ethanol by the Flash Technique

By Akira KIRA, Shunji KATO*1 and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received October 6, 1965)

With the flash technique, the absorption spectra of the triplet state and of the semireduced form of acridine were observed, and the kinetics of the reactions involving these transient species was investigated. It was established that the photoreduction of acridine in the deaerated ethanol solution proceeds via two paths. One is a path via semireduced acridine; this path is strongly inhibited by the presence of oxygen, which efficiently oxidizes semireduced acridine. In the other path, the final product, acridan, is produced immediately after flashing, with no appreciable transient species being formed. The photoreduction by this path is not affected by the presence of oxygen. It may be presumed that this process is a molecular one between singlet acridine and alcohol. The reactive species in the former path also seems to be the singlet excited state instead of the lowest triplet state.

The photoreduction of acridine in alcohol has recently been studied by several workers,[1-5] but no attempt to elucidate the detailed mechanism seems to have been made except by Kellmann and Dubois[6]. They proposed the possibility of the n-π^* triplet being a reactive species. Here, however, we have paid attention only to the problem of whether the reactive species is the singlet excited state or the lowest triplet state. Our results, particularly those concerning the effect of oxygen on the reaction, have nevertheless revealed another important feature of the reaction mechanism which Kellmann and Dubois did not mention. Hence the authors would like to stress this point in the present stage, postponing a decision whether our "singlet excited state" is a true singlet excited state or an n-π^* triplet state or whether it consists of both these states.

In previous papers[4,5] the steady light photoreduction of acridine in ethanol, methanol and isopropanol was studied in both aerated and deaerated solutions. The quantum yields of the photoreduction for the degassed solutions are 0.13 (ethanol), 0.13 (methanol) and 0.09 (isopropanol), while for the air-saturated solutions, they are 0.043 (ethanol), 0.032 (methanol) and 0.032 (isopropanol). When the concentration of dissolved oxygen is low, the reaction first proceeds at a rate approximately equal to that in the air-saturated solution, but a sharp break becomes apparent at a certain timepoint in the decay curve, after which the rate becomes approximately equal to that of the degassed solution.

On the basis of the above results, a scheme was tentatively proposed in which half-hydrogenated acridine is attacked by oxygen and the resultant $AH\cdots O_2$ reacts bimolecularly in the following two, alternative ways:

$$2AH\cdots O_2 \rightarrow AH_2 + A + 2O_2$$

$$2AH\cdots O_2 \rightarrow 2A + H_2O_2 + O_2$$

The above scheme, however, had no definite experimental evidence; moreover, it was not decided whether the reactive species is the singlet excited state or the triplet state. The purpose of the present paper is to identify the transient species produced during the reaction and to study the kinetics of the elementary reactions which are related with the overall reaction. No transient absorption due to $AH\cdots O$ was observed; indeed, the analysis of the data led to quite a different scheme in which singlet excited acridine reacts with alcohol in two alternative ways. One produces acridan or its derivatives,*2 presumably by a molecular mechanism, while the other produces semireduced acridine as a transient intermediate which, in the presence of oxygen, is easily reoxidized to acridine.

Experimental

Our flash photolysis apparatus is the same as that

*2 As to the final product, it is not certain whether it is acridan or its derivative with a fragment of an alcohol molecule attached to the 9-position. Cf. Ref. 3. Since our main interest is in elucidating the primary processes, we tentatively assume that the product is acridan.

previously described.[7,8] The cells used are 10 cm. long. The procedure for degassing is the same as that described in a previous paper.[4] The samples were illuminated by a 90—125 Joule flash through a ultaviolet filter, which transmits the light from 320 mμ to 400 mμ. The concentration range of acridine examined was from 1×10^{-5} to 1×10^{-4} M, but in most experiments a 3×10^{-5} M solution was used. Under the above conditions, 4—7% of acridine undergoes a permanent change after one flash.

The acridine was recrystallized three times from the water-ethanol mixture. The ethanol was fractionally distilled.

Results

The Quantity of Acridan Produced as a Function of the Oxygen Concentration.— Acridan has a prominent peak at 286 mμ[4]; therefore, the optical density at 290 mμ after flashing was used as a measure of the quantity of acridan produced. This is plotted against the oxygen concentration in Fig. 1. It is evident that above ca. 5×10^{-6} M of oxygen, the yield of acridan is about 1/2.8 of that in the degassed solution, independent of the oxygen concentration. This result agrees quite well with that for the steady-light experiment.[4] The concentrations of acridan in the two cases are 2.2×10^{-6} M and 0.8×10^{-6} M respectively, corresponding to 7 and 2.5% of the original acridine. These refer to the case of the 125 J. flash illumination with the ultraviolet filter.

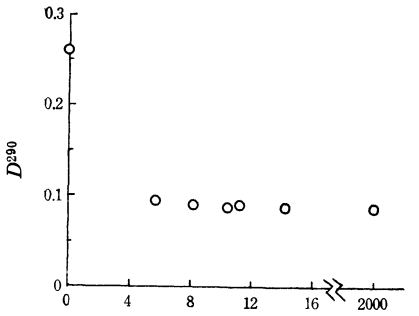

Fig. 1. Effect of oxygen concentration on the quantity of acridan produced by a flash illumination.

The Absorption Spectra of the Transient Intermediates.—The absorption spectra of the transient intermediates are shown in Figs. 2a and 2b. They are assigned as follows.

The band at 440 mμ, with a rather short life time, is attributed to the triplet state A^T, as was done by Jackson and Porter.[9] The molar extinction coefficient of the triplet state, $\varepsilon_A T$, could not be determined since semireduced acridine has an appreciable absorption in the region of the acridine absorption band, as plate 1 shows. $\varepsilon_A T$ in a benzene solution is ca. 7×10^4 M^{-1} cm^{-1}, as will be reported later; this value will be used tentatively when necessary.

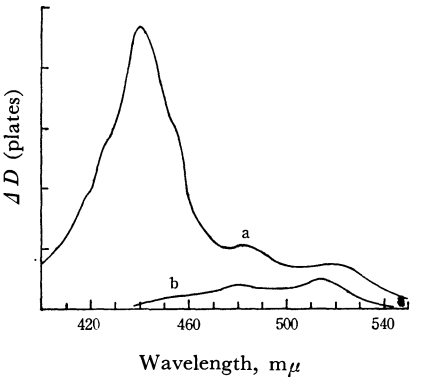

Fig. 2b. Transient absorption spectra in the visible region.
a, 80 μsec. b, 360 μsec.

Jackson and Porter attributed the band at 520 mμ to the triplet state. However, this band, which clearly has a longer life time than that at 440 mμ, must be attributed to a species different from A^T.

The sharp peak at 278 mμ has a rather long life, and as it declines, the abosrption near 290 mμ due to acridan rises. Hence, it can safely be concluded that this is semireduced acridine. A superposing broad absorption band from aronud 290 mμ extending to a shorter wavelength region is assigned to A^T, since its duration is about the

same magnitude as that of 440 mμ.

The air-saturated solution (the oxygen concentration is 2.0×10^{-3} M) does not give any transient absorption spectrum. The solutions containing 10^{-6} M—10^{-5} M of oxygen give an absorption band quite similar to that in the degassed solution, but only to a small extent. No new absorption band appeared. Thus no evidence could be obtained for the formation of such intermediates as $A^{T}\cdots O_2$ and $AH\cdots O_2$.

The Decay of the Triplet State.—The decay of the triplet state was examined by measuring the optical density change at 440 mμ under vairous illuminating conditions. The results are shown in Fig. 3. Evidently the decay curves do not obey a first-order law. The decay at the initial stage becomes faster when the initial concentration of A^{T} is higher. Further, it is seen that the decay curves cross one another. The former finding may imply that a first-order process and a second-order process are superposed. If one plots the apparent first-order rate constant at the initial stage against the optical density, a fairly satisfactory linear relation is obtained. From the slope and the intercept, one gets for the first-order rate constant, $k_1\cong10^{2}$—10^{3} sec^{-3}, and for the second-order rate constant, $2k_2\cong1\times10^{10}$ M^{-1}·sec^{-1}. These are, of course, very rough values, since it is thought that other decay processes are also taking place. Other molecular species which may attack the triplet state of acridine are the ground state acridine, acridan, and semi-

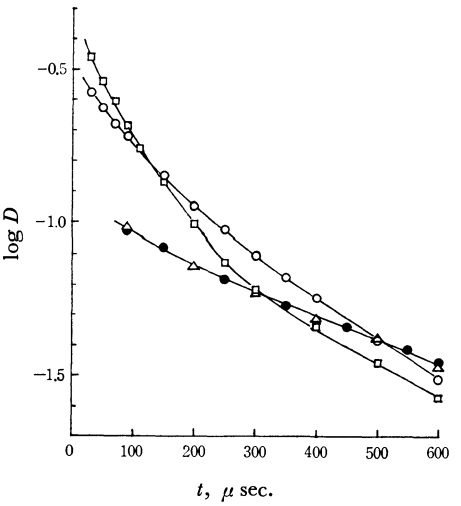

Fig. 3. Decay curves of the absorption at 440 mμ.
The order of the flash intensity is
□ > ○ > △, ●.

reduced acridine. If $A^{T}+A\rightarrow$ occurs with about the equal rate constant as that of $A^{T}+A^{T}\rightarrow$, then the first-order decay curve should be obtained, but this is not the case. $A^{T}+AH_2\rightarrow$ is judged not to contribute so much, because of the following check. In Fig. 3, □, ○ and △ refer to the plots for similar samples illuminated with different intensities, the first with strong, the second with medium, and the third with weak intensities. Plot ● is the one obtained when the sample for ○ was again flashed with the same intensity as that used for △. It may be seen that the ● plot agrees quite well with the △ plot; this rules out the contribution of $A^{T}+AH_2\rightarrow$. Thus, it seems that acridan and the ground-state acridine do not deactivate triplet acridine very much. It may be inferred, however, that $A^{T}+AH\rightarrow$ occurs to some extent, because this process is now the only one left that gives rise to the crossing of the curves. At any rate, the exact analysis of the plots at the present stage of study is very difficult, and no further attempt was undertaken. The above values of k_1 and k_2 are tentative, but it is thought that they are correct in the order of magnitude.

When oxygen is added, the decay of triplet acridine becomes faster with an increase of the oxygen concentration. In the air-saturated solution the absorption at 440 mμ is not observed, even immediately after flashing. When the concentration of oxygen is $\geq1\times10^{-5}$ M, the decay satisfactorily obeys the first-order rate law. In Fig. 4, the first-order rate constants are plotted against the oxygen concentration. The data for 5.7×10^{-6} M of oxygen is somewhat doubtful. From the inclination of the line, the rate constant for $A^{T}+O_2\rightarrow$ can be calculated as $k=2.2\times10^{9}$ M^{-1}·sec^{-1}.

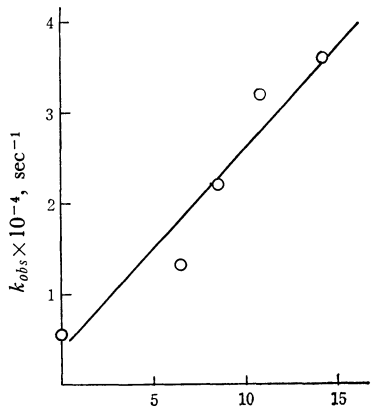

Fig. 4. Effect of oxygen concentration on the first-order rate constant of the triplet state, measured at 440 mμ.

The Decay of Semireduced Acridine and the Rate of the Formation of Acridan.—As Fig. 5 shows, the decline in the optical density at 278 mμ and the rise at 290 mμ proceed in parallel, supporting the view that the $2AH \rightarrow AH_2+A$ reaction is taking place. These curves will be analyzed later, since such an analysis requires some information concerning the reaction mechanism.

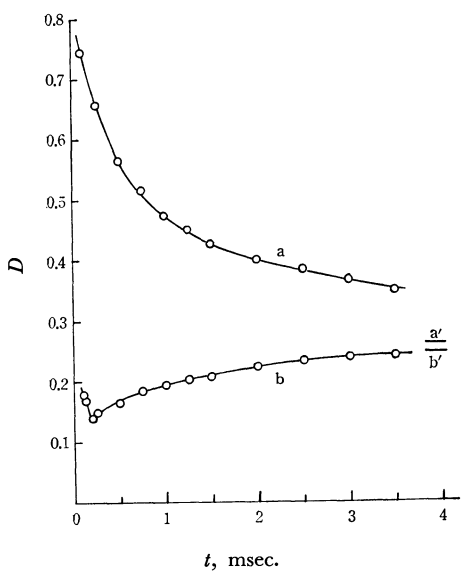

Fig. 5. Change in optical density at (a) 278 mμ and (b) 290 mμ. (a') and (b') refer to a long time after flashing.

When the concentration of oxygen is about 10^{-5} M, the disappearance of the 278 mμ peak is much faster, but this is not accompanied by the production of acridan. In other words, the optical density at 290 mμ remains constant, with

the same value as that for $\gtrsim 5\times10^{-6}$ M oxygen in Fig. 1 (see plate 2). The reaction is a first-order one. Some examples are shown in Fig. 6, where d is $D^{278}_{AH}-D^{278}_{AH_2\cdot\infty}$. In these experiments the concentration of acridine was 3×10^{-5} M and the input for the flash was 125 J.; an ultraviolet filter was used. In Fig. 7, the first-order rate constants are plotted against the oxygen concentration. From the slope one gets $k=1.2\times10^{9}$ M^{-1} sec^{-1}.

Discussion

In connection with the mechanism for the photoreduction in the presence of oxygen assumed in the previous paper, the following two findings are most important: 1) The deactivation of the triplet state by oxygen occurs very fast, with a rate constant of $k=2.2\times10^{9}$ M^{-1} sec^{-1}, and no transient absorption spectrum is observed in the air-saturated solution. 2) In the presence of about 10^{-5} M of oxygen, the reaction between semireduced acridine and oxygen is very rapid, with a rate constant of 1.2×10^{9} M^{-1} sec^{-1}, and there is no formation of acridan. The first finding strongly supports the view that the reactive species in the air-saturated solution is the singlet excited state. Because practically all the triplet state is annihilated by oxygen, there is no room to consider the occurrence of the $A^T+RH_2\rightarrow AH+RH$, $AH+O_2\rightarrow AH\cdots O_2$ reaction. A conceivable different mechanism which can be reconciled with the present kinetic data is the one involving the formation of $A^T\cdots O_2$ (a loose molecular complex which Schenck[10] proposed), which abstracts the hydrogen atom from alcohol. However, this mechanism is also improbable because, according to our unpublished results, triplet acridine in the presence of oxygen at a high concentration does not react with acridan, which is a more powerful hydrogen donor.

Next, judging from the second finding, the singlet state of acridine cannot yield semireduced acridine, and so the only possible mechanism for the air-saturated solution is:

$$A^* + RH_2 \rightarrow A\cdots H_2R \rightarrow AH_2 + R$$

$$(A\cdots H_2R)$$

In the absence of oxygen, an additional reaction involving the formation of semireduced acridine occurs. Thus, the reaction occurs via the two paths.

The remainning problem is now to decide:

1) whether $A\cdots H_2R$, if it is formed, is partially attacked by oxygen or not;

2) whether $A\cdots H_2R$ partially produces half-hydrogenated acridine or not;

$$A\cdots H_2R \rightarrow AH + RH$$

and in addition,

3) whether semireduced acridine is formed via the singlet or the triplet state, or both.

First, the results presented in Fig. 5 will be analyzed. Of all the acridan produced,*3 a 1.8/2.8 part is considered to result from the $2AH\rightarrow AH_2+A$ reaction; it is convenient to discuss only this part. Since the absorption due to the triplet state (T-T absorption) is negligible during the time interval in question, one can write:

$$\overline{D}^{278} = l\{\varepsilon^{278}_{AH}[AH] + \varepsilon^{278}_{AH_2}[AH_2]\} \quad (1)$$

$$\overline{D}^{290} = l\{\varepsilon^{290}_{AH}[AH] + \varepsilon^{290}_{AH_2}[AH_2]\} \quad (2)$$

where l is the length of a cell and $[AH_2]$ is the concentration of acridan produced only via semireduced acridine; accordingly, both $\overline{D}$'s are the differences between the observed optical density and 1/2.8 of the optical density of acridan at a sufficiently long time after flashing, $D_{AH_2\cdot\infty}$. If one assumes the $2AH\rightarrow AH_2+A$ disproportionation reaction, the following relation:

$$[AH]_i = 2[AH_2]_\infty$$

holds, where $[AH]_i$ is the initial concentration of semireduced acridine after flashing and $[AH_2]_\infty$ is the concentration of acridan a long time after flashing. This relation and the values of $D^{278}_\infty \equiv (D^{278}_{AH_2\cdot\infty})$, D^{290}_∞ and $\varepsilon^{290}_{AH_2}=1.2\times10^{4}$ M^{-1} cm^{-1}, combined with Eqs. 1 and 2, enable us to estimate the values of ε^{278}_{AH} and ε^{290}_{AH} to be as follows:

$$\varepsilon^{278}_{AH} = 2.4\times10^{4}\ \text{M}^{-1}\,\text{cm}^{-1}$$

$$\varepsilon^{290}_{AH} = 6\times10^{2}\ \text{M}^{-1}\,\text{cm}^{-1}$$

$$[AH]_i = 2.0\times10^{-6}\ \text{M}$$

Since ε^{290}_{AH} is only 1/20 of $\varepsilon^{290}_{AH_2}$, the optical density in the region of 290 mμ is a measure of the quantity of acridan. The following table gives D_i and D_∞ at three wavelengths for a typical case.

λ, mμ	290	295	300
D_i	0.07	0.07	0.05—0.06
D_∞	0.21	0.19	0.16

Thus $[AH_2]_i$ is about one-third of $[AH_2]_\infty$. This agrees with the ratio of the quantity of acridan produced in the evacuated and in the aerated solutions, leading to the conclusion that one-third of the acridan is produced by the $A^*+RH_2\rightarrow AH_2+R$ reaction and not via semireduced acridine. One can, therefore, safely rule out the possibility of this process:

$$A\cdots H_2R + O_2 \rightarrow A + R + H_2O_2$$

10) G. O. Schenck, *Naturwissenschaften*, **40**, 212 (1953).

*3 In the flash experiment where a large quantity of semireduced acridine is formed, some of the product may be diacridan. However, to make the description simple, we assume that all the product is acridan. Some of the data must be modified if the above situations really hold.

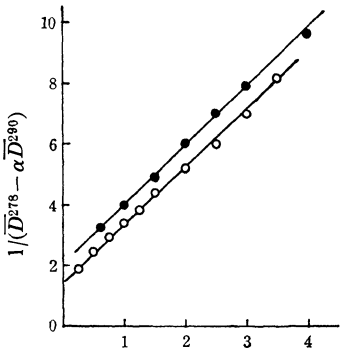

Fig. 8. Second-order decay of semireduced acridine calculated from the decrease of semireduced acridine.
$[A]_0$: ● 2×10^{-5} M, ○ 3×10^{-5} M

Now from Eqs. 1 and 2, one obtains:

$$\overline{D}^{278} - \alpha\overline{D}^{290} = l(\varepsilon_{AH}^{278} - \alpha\varepsilon_{AH}^{290})[AH]$$

where $\alpha \equiv \varepsilon_{AH_2}^{278}/\varepsilon_{AH_2}^{290}$ and where the value of α is approximately one. Hence, $1/(\overline{D}^{278}-\alpha\overline{D}^{290})$ should be linear with time. As Fig. 8 shows, this relation really holds, and the slope gives $2k/l(\varepsilon_{AH}^{278}-\alpha\varepsilon_{AH}^{290})$, where k is the true second-order rate constant for $2AH \rightarrow AH_2+A$. The rate constant, k, obtained is 2.5×10^8 M^{-1} sec^{-1}. This rate constant can also be evaluated by the following independent method. From 1 and 2 one obtains:

$$\overline{D}^{278}\varepsilon_{AH}^{290} - \overline{D}^{290}\varepsilon_{AH}^{278} = l[AH_2]\{\alpha\varepsilon_{AH}^{290} - \varepsilon_{AH}^{278}\}\varepsilon_{AH_2}^{290}$$

By the $[AH]=2\{[AH_2]_\infty-[AH_2]\}$ relation and by taking into account that $\varepsilon_{AH}^{290} \simeq (1/40)\varepsilon_{AH}^{278}$, one can write:

$$[AH] = \frac{2}{l\varepsilon_{AH_2}^{290}}\left\{\overline{D}_\infty^{290} - \overline{D}^{290} + \overline{D}^{278}\frac{\varepsilon_{AH}^{290}}{\varepsilon_{AH}^{278}}\right\}$$

Hence, the rate constant is evaluated from the plot of $1/(\overline{D}_\infty^{290} - \overline{D}^{290} + \overline{D}^{278}\cdot\varepsilon_{AH}^{290}/\varepsilon_{AH}^{278})$ against time.

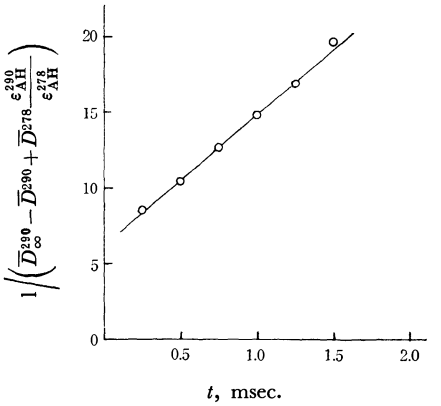

Fig. 9. Second-order decay of semireduced acridine calculated from the increase of acridan.

An example of the plot is given in Fig. 9; from the slope one gets $k=2.5\times10^8$ M^{-1} sec^{-1}, which is in good agreement with the above value.

The success of the above analysis eliminates the participation of the $AH+RH \rightarrow AH_2+R$ reaction, for the following reason. According to Taub and Dorfman,[11] the rate constant, $2k$, for $RH+RH \rightarrow$ is larger than 8×10^8 M^{-1} sec^{-1}; thus, if the above reaction occurs, the second-order rate formula should not hold.

The question whether semireduced acridine is produced in the singlet excited state or in the triplet state of acridine can not be answered clearly in the present stage of study, but the former seems to be more probable. The reason for this is as follows.

First, the value of $[AH]_1$ obtained above (2.0×10^{-6} M) is much larger than the value of $[A^T]_1$ obtained under similar conditions ($\sim9\times10^{-7}$ M). Moreover, it must be taken into account that most of the triplet acridine disappears, at least in the initial stage, according to the $A^T+A^T \rightarrow$ reaction. In agreement with this, the plot in Fig. 8 remains linear, even in the $t<1$ msec. region. Figure 6 also supports this view because, since triplet acridine is deactivated by oxygen very efficiently ($k=2.2\times10^9$ M^{-1} sec^{-1}), the initial concentration of semireduced acridine should largely decrease with the concentration of oxygen if semireduced acridine is really produced via the triplet state.

Concluding Remarks.—The elementary reactions substantiated by the present flash photolysis experiment may be summarized as follows:

$$A \xrightarrow{h\nu} A^*$$

$$A^* + RH_2 \rightarrow \left(A\!:\!\overset{H}{\underset{H}{\cdots}}\!:R\right) \rightarrow AH_2 + R \qquad (1)$$

$$\left(A\!:\!\overset{H}{\underset{H}{\cdots}}\!:R\right) \xrightarrow{O_2} A + R + H_2O_2 \qquad (2)$$

$$A^* + RH_2 \rightarrow AH + RH \qquad (3)$$

$$A^* \rightarrow A^T \qquad (4)$$

$$A^T \xrightarrow{k_5} A \qquad (5)$$

$$A^T + A^T \xrightarrow{k_6} (A + A) \qquad (6)$$

$$A^T + RH_2 \not\rightarrow AH + RH \qquad (7)$$

$$A^T + O_2 \xrightarrow{k_8} A + O_2 \qquad (8)$$

$$2AH \xrightarrow{k_9} AH_2 + A \qquad (9)$$

$$AH + O_2 \xrightarrow{k_{10}} A + HO_2 \qquad (10)$$

$$AH + RH \not\rightarrow AH_2 + R \qquad (11)$$

× denotes the non-occurrence of the reaction. The rate constants obtained are:

11) I. A. Taub and L. M. Dorfman, *J. Am. Chem. Soc.*, **84**, 4053 (1962).

$k_5 \cong 10^2 - 10^3$ sec^{-1}

$k_6 \cong 5 \times 10^9$ M^{-1} sec^{-1}

$k_8 = 2.2 \times 10^9$ M^{-1} sec^{-1}

$k_9 = 2.5 \times 10^8$ M^{-1} sec^{-1}

$k_{10} = 1.2 \times 10^9$ M^{-1} sec^{-1}

The scheme for the reaction in the presence of oxygen is 1, this may be a one-step molecular process, with A$\cdots$H$_2$R or the like being its transition state. In the absence of oxygen, the scheme consists of 3 and 9 in addition to 1. However, it can not yet be said certainly that 7 does not occur. It remains to be solved, as was mentioned at the beginning, whether our "singlet excited state" is really a true singlet excited state or an n-π^* triplet state, as Kellmann and Dubois[6] proposed; in any case, however, there is no doubt that the photoreduction of acridine in ethanol occurs via two different paths.

Aldehydes in Lake and Sea Waters

By Eijiro KAMATA

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya

(Received October 20, 1965)

The vertical distribution of aldehydes in Lake Kizaki during summer stagnation is described. Aldehydes are found only in the hypolimnion, not in the upper aerobic water layers. The highest aldehyde content in three series of vertical samples is 0.11 mg./l. in terms of formaldehyde equivalents. It was shown by laboratory experiments that formaldehyde is rapidly decomposed in aerobic lake water, but very slowly in anaerobic lake water. In sea waters, aldehydes are not found in the surface water layer, and no systematic variation is noticed in the verticall distribution.

The decomposition of organic substances to carbon dioxide is an important process in the carbon cycle in natural waters. In order to investigate this process thoroughly, it is first necessary to elucidate the distribution of the organic substances produced and preserved in a water body and its deposits. In this connection we have previously reported on carbohydrates and organic acids in lake waters.[1,2]

In the present paper some results will be given on aldehydes in lake and sea waters and in an interstitial water of a lake mud.

Results and Discussion

Lake Waters and Interstitial Water of Lake Mud.—Three series of the vertical distribution of aldehydes in Lake Kizaki during summer stagnation are given in Table I. Aldehydes are found only in water layers below a depth of 20 m., not in the upper aerobic water layers. The highest aldehyde content is 0.11 mg./l. in terms of formaldehyde equivalents; this is observed in anaerobic water layers near the bottom. The aldehyde content in an interstitial water of the bottom mud is 0.044 mg./l. in terms of formaldehyde equivalents (Table II).

In order to make it clear why aldehydes are found only in the hypolimnion, the decomposition rates of formaldehyde under aerobic or anaerobic conditions at 20°C and 8°C in lake water were assertained.*1 The anaerobic conditions at 8°C refer approximately to the conditions at a depth of 25 m. in the lake. The results are shown in Fig. 1. As is shown in Fig. 1-A, under aerobic conditions at 20°C, 50 μg./l. of formaldehyde is completely decomposed in 30 hr., but under anaerobic conditions at 8°C, 50 μg./l. of formaldehyde invariably remains for 3 days, and then is gradually decomposed and so completely lost over the next 3 days. Even at 20°C the lifetime of formaldehyde under anaerobic conditions is twice that under aerobic conditions. It is clearly demonstrated that formaldehyde is decomposed through microbiological processes by the fact that no decrease in formaldehyde is observed in sterilized lake water*2 over an 8 day period. From these experimental results it may be concluded that aldehydes can not be found in aerobic water layers because of their rapid decomposition rate, while in anaerobic hypolimnion their slow rate of decomposition allows them to be preserved in a detectable concentration. Thus

TABLE II. THE ALDEHYDE CONTENT IN AN INTERSTITIAL WATER OF THE BOTTOM MUD FROM LAKE KIZAKI

Date of sampling: Sept. 21, 1963.
Water content: 78 g./100 g. of fresh mud.
Fe^{2+}: 20 mg./l.
Aldehydes as HCHO: 0.044 mg./l.

aldehydes liberated from organic matters are decomposed to carbon dioxide and can be found in anaerobic hypolimnion as a result of dynamic equilibrium, production-decomposition.

Sea Water.—Sea waters were obtained during the cruise of the Ryofu Maru belonging to the Japan Meteorological Agency made as the JEDS-4 (The Fourth Japanese Deep Sea Expedition). After being frozen, the samples were transported to our laboratory. Table III gives three series of the vertical distribution of aldehydes down to a depth of about 4000 m. The degree of the aldehyde content is expressed by a + sign. A + unit is approximately equivalent to 0.01 mg./l. in terms of formaldehyde equivalents. Aldehydes are not found in the surface water layer. This is caused by the higher temperature and the aerobic conditions. No systematic variation in aldehydes is

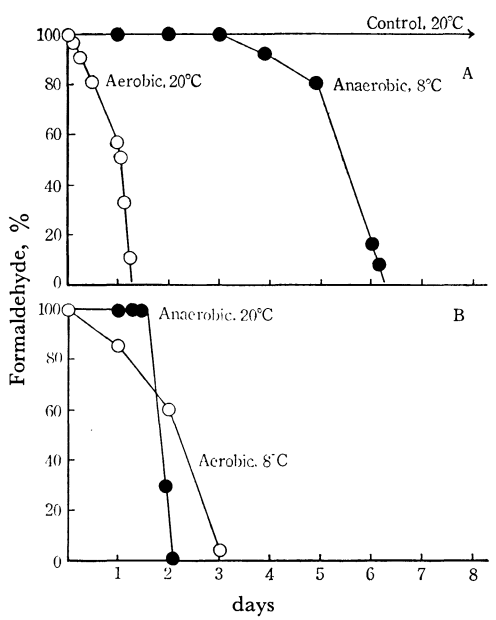

Fig. 1. Decomposition of formaldehyde in lake water under the aerobic or anaerobic condition. The concentration of formaldehyde added, 50 μg./l.

noticed. The lower temperature of the water layers below the surface layer should explain the preservation of a detectable amount of aldehydes.

Experimental

Reagents.—*A Standard Solution of Formaldehyde.*—A stock solution of formaldehyde is standardized by the dimedone method.[3] The aliquot of the stock solution is then used as the standard solution (1 μg./ml.).

3-Methyl-2-benzothiazolone Hydrazone Hydrochloride (MBTH) Reagents.—1) 0.4% aqueous solution. 2) 0.4% (1+1000) hydrochloric acid solution.

1% *Ferric Chloride Solution.*

Saturated Sodium Chloride Solution.

Crystals of Anhydrous Sodium Sulfate.

Organic Solvents.—1) Acetone. 2) A mixed solvent, (1+1) acetone-chloroform.

Apparatus.—Coleman model 14 spectrophotometer. Tokyo Photo-electric Laboratory filter photometer, model 7A (for field work). Sharp TE-10 automatically temperature-controlled water bath.

Procedure 1 (for lake water).—To 10 ml. of a test solution 2 ml. of a 0.4% MBTH aqueous solution is added. After the mixture has stood for 20 min., 0.5 ml. of 1% ferric chloride solution is added. After an additional 10 min., 12.5 ml. of acetone is added. The absorbance is read at the wavelength of 670 mμ within 30 min.

Procedure 2*[3] (for the interstitial water and sea water).—To 9 ml. of a test solution 1 ml. of a saturated sodium chloride solution is added; then 2 ml. of a 0.4% MBTH (1+1000) hydrochloric acid solution is added. After the mixture has stood for 20 min., 0.5 ml. of 1% ferric chloride solution is added. After an additional 10 min., the mixture is transferred into a separatory funnel with 12 ml. of a (1+1) acetone-chloroform solvent and shaken twenty times. The extract is poured into a 10 ml. measuring flask, and the flask is filled up to the mark with the solvent. Then the extract is quickly dehydrated in a stoppered test tube with 6 g. of anhydrous sodium sulfate. The suspended particles in the extract are filtered off through dry filter paper. The absorbance is read at the wavelength of 670 mμ. The color is stable for at least two hours.

For the determination of aldehydes in sea water, 10 ml. of a test solution is used without the addition of the sodium chloride solution.

The Separation of the Interstitial Water from Lake Mud.—A lump of frozen lake mud (~200 g.) is melted and filtered through a Millipore Filter (type HA) under a nitrogen atmosphere.

The author wishes to express his gratitude to Dr. Ken Sugawara, Professor Emeritus of Nagoya University, and to Dr. Yoshio Sugiura and the crew of the Ryofu Maru, the Japan Meteorological Agency, for kindly supplying sea water samples.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1230—1235 (1966)

The Solvation of Ions in Liquid Sulfur Dioxide

By Yasuhiko KONDO, Tsutomu GOTO, Isamu SUO and Niichiro TOKURA

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahiracho, Sendai; Department of Applied Chemistry, Faculty of Engineering, Osaka University, Miyakojima-ku, Osaka

(Received October 20, 1965)

The variation in the density and in the sound velocity with the concentration was measured in a liquid sulfur dioxide solution of electrolytes. The amounts of solvations and the volume changes which accompany the dissolving of the electrolytes were estimated. In liquid sulfur dioxide they were found to be considerably greater than those in water. The relations between the volume changes and the solvations were also discussed.

It has been generally accepted that solvents play an important role in synthetic organic chemistry; in this connection, various attempts have been made to specify the type of effects exerted by solvents on the reaction rates. Liquid sulfur dioxide is a good ionizing aprotic solvent, and various specific phenomena have been found in this solvent.[1-4]

In order to elucidate the effect of this solvent on a chemical reaction and the relation between a chemical reaction and a solvation phenomenon, an attempt has now been made to measure the solvations of ions in liquid sulfur dioxide. In this report, the volume changes and the amounts of solvation will be measured by means of density[5] and compressibility[6] measurements in liquid sulfur dioxide, and the data for various solutes will be compared.

Experimental

Materials.—Liquid sulfur dioxide was dried with phosphorus pentoxide and distilled twice. The electrolytes used were synthesized and dried in vacuo at 60°C and recrystallized three times from solvents indicated by known methods.[7-9]

The Method of Density Measurement.[5]—The volume change, ΔV, which accompanies the dissolving of one mole of a substance may be shown as follows:

$$\begin{aligned}\Delta V &= (\text{Volume of the solution}) \\ &\quad - \{(\text{Volume of the solute}) \\ &\quad + (\text{Volume of the solvent})\} \\ &= \frac{1}{n}\left[\frac{W+w}{D} - \left\{\frac{w}{d_0} + \frac{W}{D_0}\right\}\right] \qquad (1)\end{aligned}$$

where W, w, D_0, d_0, D, n are the weights of a pure solvent and of a solute, the densities of a pure solvent, of a solute and of a solution, and moles of the substance respectively. In the case of solid substances, from the view point of thermodynamics, the volume of a fused substance which is supercooled must be used as the volume of the solute. As for the salt used in this experiment, since it was impossible to measure these densities in a fused state, the densities of the solid states were used in the following calculations. For those which could not be compared with previous results in the literature, the densities were measured by using a pycnometer.

The densities of the solids used in the calculation are: KI: 3.121, $(CH_3)_4NI$: 1.819, $(C_2H_5)_4NI$: 1.552, MePyrI: 1.827, $(C_2H_5)_4NBr$: 1.388, $(C_2H_5)_4NClO_4$: 1.259, $(C_2H_5)_4NCl$: 1.112, $(C_2H_5)_4NPic.$: 1.356, $(CH_3)_4NClO_4$: 1.346, MePyr ClO_4: 1.423.

MePyr=Methylpyridinium Pic.=Picrate

The Measurement of the Densities of Liquid Sulfur Dioxide Solutions of Electrolytes.—A glass float was calibrated to a standard state of pure water using a mixed solution of sulfuric acid and water. The densities of solutions of electrolytes in liquid sulfur dioxide were measured by means of the glass float in a sealed pressure vessel.

The value of the density of liquid sulfur dioxide (d=1.3700 at 25°C) obtained by the present authors differs by 0.1 percent from the value (1.3718) which was obtained by the extrapolation to 25°C of the values quoted from the International Critical Tables.[11a]

Since, however, only a correlation between the densities of solutions and the concentrations of the solutes is needed in this experiment, the values obtained by the present authors were used throughout the calculations in spite of the slight discrepancy mentioned above. The values for densities in aqueous salt solutions used

unit. W: gram, V: ml. mol^{-1} C: mol. l^{-1}, λ: mm.

in the calculations are quoted from the International Critical Tables.[11b,c]

The Method of Compressibility Measurement.[6] —The following equation was used to calculate the amount of solvation from compressibility measurements. If a part of the solvent, v, changes to v' as a result of solvation, the volume of the solution, V, may be expressed as follows,[6] where V_0, V_1, v are the volumes of the solvent before mixing, the solute and the solvent molecules which solvate on the solute respectively:

$$V = V_0 + V_1 - v + v' \tag{2}$$

By using β, an adiabatic compressibility which is determined experimentally by measuring the sound velocity, u, and the density, d, Eq. 4 is obtained from the relation:[6]

$$\beta = \frac{1}{u^2 d} \tag{3}$$

$$V\beta = V_0\beta_0 + V_1\beta_1 - v\beta_0 + v'\beta_0' \tag{4}$$

If it can be assumed that $\beta_1=\beta_0'=0$, Eq. 5 is obtained from Eq. 4.[6] Also, v, the amount of solvation per mole of solute, can be calculated from Eq. 6, where D_0, D, λ_0, λ, C, M, are the densities of pure solvent and of solution, the wavelengths in a pure solvent and in a solution, the concentration of the solute [mol.l^{-1}] and the molecular weight of the solute respectively.[6]

$$V\beta = V_0\beta_0 - v\beta_0 \tag{5}$$

The number of solvation, n, was calculated from Eq. 7,[6] where v_0 is the molar volume of liquid sulfur dioxide at 25°C.

$$v = \frac{1000}{C}\left(\frac{D}{D_0} - \frac{D_0\lambda_0^2}{D\lambda^2}\right) - \frac{M}{D_0} \quad \text{[ml. mol}^{-1}\text{]} \tag{6}$$

$$v = nv_0 \ (v_0 = 46.7 \text{ ml.mol}^{-1} \text{ at } 25°C) \tag{7}$$

The sound velocities in liquid sulfur dioxide and in an electrolyte solution were measured with an ultrasonic interferrometer at a frequency of 1 Mc./sec.

Apparatus.—The interferrometer cell shown in Fig. 1 was made of stainless steel and made it possible to measure the velocity under an equilibrium vapor pressure of liquid sulfur dioxide [ca. 3.5 atom at 25°C].

The reflector was also made of stainless steel; it moves vertically without rotation, and its position was determined by a micrometer with a traveling range of 25 mm. The pressure bottle was attached to the cell in order to keep the pressure equal on both sides of the crystal during the measurement. The sample solution was introduced through the lead pipe after the cell had been evacuated, and the measurements were conducted in a thermostat bath held at 25°C. A typical run is presented in Table I.

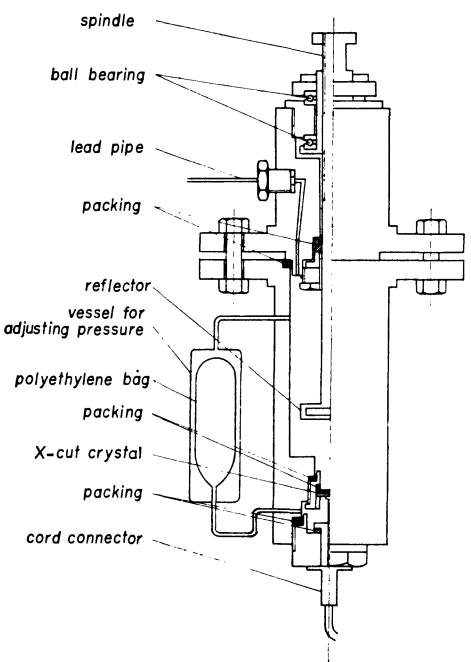

Fig. 1. Ultrasonic interferrometer for use under pressure.

Results and Discussion

Figures 2 and 3 give the results of the measurements of the densities and sound velocities (wavelengths) in liquid sulfur dioxide solutions of electrolytes.

The volume change, ΔV, and the amount of solvation, calculated from Eq. 1 and Eq. 6 respectively, are plotted against the square root of the concentration of the solute in Figs. 4, 5 and 6. It has been said that ΔV and v are linear functions of $C^{1/2}$ in water;[5b,6b,7] it is apparent from Figs. 4, 5 and 6 that a similar relation holds for the results in liquid sulfur dioxide.[4]

Generally, the behavior of an electrolyte in a

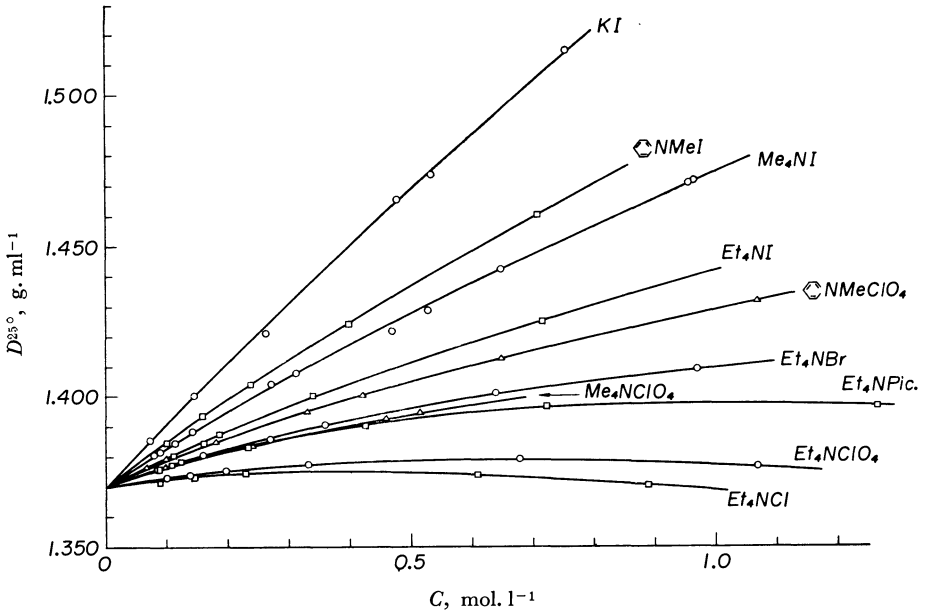

Fig. 2. Variation of the density of electrolyte solution in liq·SO_2 with the concentration of the solute.

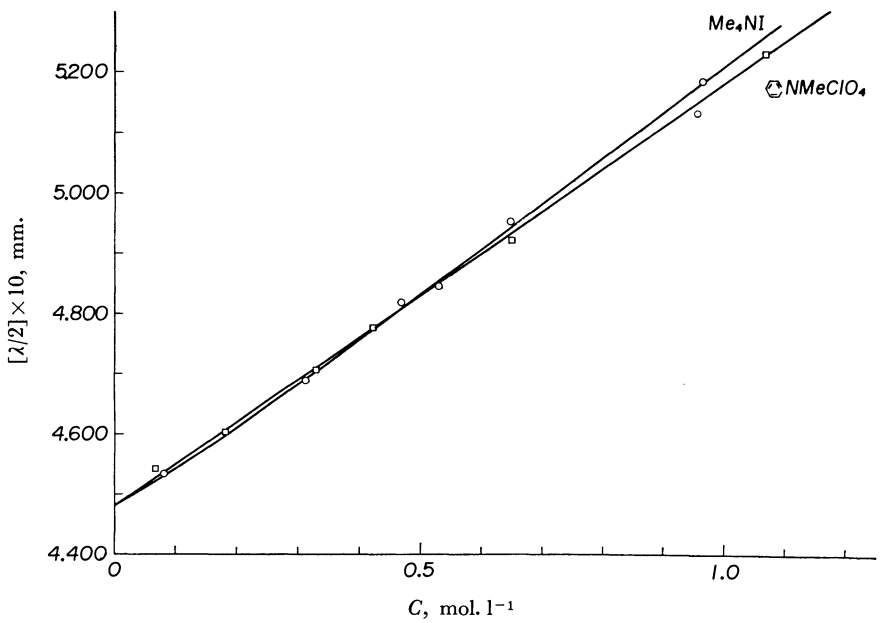

Fig. 3. Variation of wavelength with the concentration of the solute.

non-aqueous solvent is quite different from that in water. It has often been discussed also on the behavior in liquid sulfur dioxide. It was impossible to conduct measurements over the entire range where data are required for a detailed discussion and formulation of an electrolyte, since in this experiment the measurements were limited to the region where ΔV is a linear function of $C^{1/2}$, we did not consider the detailed nature of the electrolyte. The results obtained by extrapolating to a zero concentration of the solute are summarized in Table II.

From the view point of thermodynamics, the standard state of the electrolyte must be a state of fused salt in a supercooled state, and the volume changes which were calculated using the data for the solid state must include those which accompany the fusion of the solid substance.

The differences in the $[-\Delta Ve]$ value between iodides and perchlorates are presented in Table

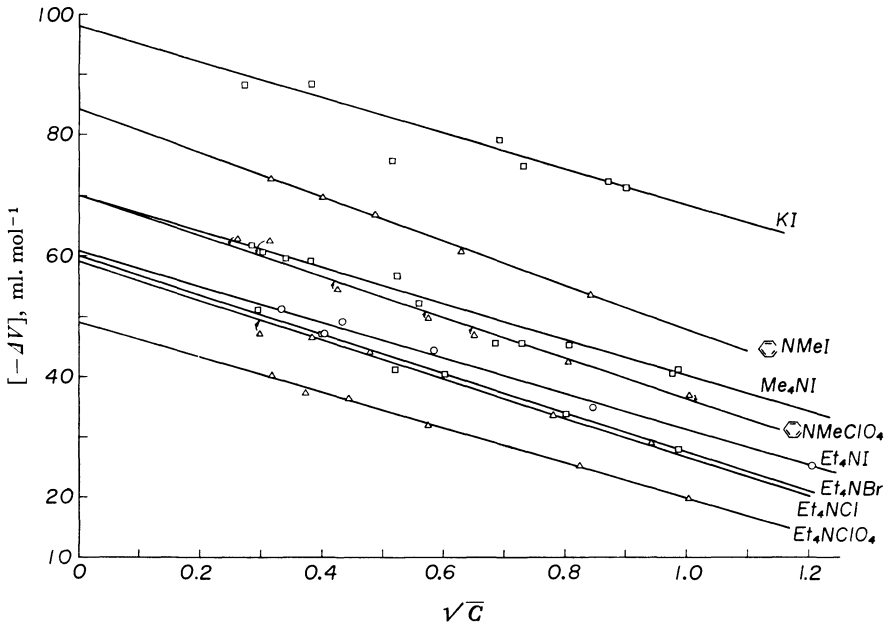

Fig. 4. Plots of the $[-\Delta V]$ value vs. $C^{1/2}$ of the solute.

Table II. Data obtained in this experiment (25°C)

Electrolyte	$[-\Delta Ve]$ ml. mol^{-1}	v ml. mol^{-1}	Number of solvation
KI	98		
MePyrI	84		
Me_4NI	70	375	8
Et_4NI	61		
Et_4NBr	60		
Et_4NCl	59		
$Et_4NPic.$	65		
Et_4NClO_4	49		
$MePyrClO_4$	70	320	6.8
Me_4NClO_4	60		
KI in H_2O	8		
Et_4NCl in H_2O	−13		

Table III. The stoichiometric additivity of the $[-\Delta Ve]$ values

Counter cation	$[-\Delta Ve]_{Iodide}-[-\Delta Ve]_{Perchlorate}$
$MePyr^+$	14 ml. mol^{-1}
Me_4N^+	10 ml. mol^{-1}
Et_4N^+	12 ml. mol^{-1}
Av.	12 ml. mol^{-1}

III. From the table, it is apparent that these differences are constant within the range of ±2 ml. mol^{-1}, which would be within the limit of experimental errors for the measurement in liquid sulfur dioxide. Since the ΔVe value is stoichiometrically additive, as is shown above, it would be possible to use the ΔVe value as a measure of the solvation of the constituent ion. The ΔVe values for the salts which have the same counter ion are compared in Table IV. From Table IV, it may be seen that the important factors influencing the ΔVe values, that is, effecting the solvation of the ion, are the bulkiness and the shape of the ion, which controls the approach of a solvent molecule to the ion.

Table IV. A comparison of the $[-\Delta Ve]$ value for the ion

For iodide

$$\underset{98}{K^+} > \underset{84}{MePyr^+} > \underset{70}{Me_4N^+} > \underset{61}{Et_4N^+}$$

For tetraethyl ammonium

$$\underset{65}{Picrate^-} > \underset{61}{I^-} \geqq \underset{60}{Br^-} \geqq \underset{59}{Cl^-} > \underset{49}{ClO_4^-}$$

As may be seen from Table II, the ΔVe value for potassium iodide in liquid sulfur dioxide is −98, much smaller than that in water, −8. The same relation holds for the value of Et_4NCl (−59 in liquid sulfur dioxide, +15 in water). This suggests that there exists a considerable interaction between the solute and solvent molecules for such a large solute as Et_4NI in liquid sulfur dioxide.

The small $[\Delta Ve]$ value in a sulfur dioxide solution may be explained by the following two points:

1) Sulfur dioxide is slightly associated in the liquid state, as is shown in its low boiling temperature and small vaporizing heat, and it may be easily compressed in the vicinity of the ionic charge.

2) The sulfur dioxide molecule is larger than the water molecule, and the interaction of sulfur dioxide with a large ion such as the tetraethyl ammonium ion may be predominant. The solvation

TABLE V. THE ΔVe VALUE AND THE DISSOCIATION CONST. OF THE SALTS

Salt	Picrate	Iodide	Bromide	Chloride	Perchlorate
$K_d \times 10^4$ for Me_4N^+ ion[4]	19.5	13.9	11.8	10.3	8.4
$[-\Delta Ve]$ for Et_4N^+ ion	65	61	60	59	49

Salt	$MePyr^+$	$Me_4\overset{+}{N}$
$K_d \times 10^4$ for Picrate[4]	29	19.5
$[-\Delta Ve]$ for Perchlorate	70	60

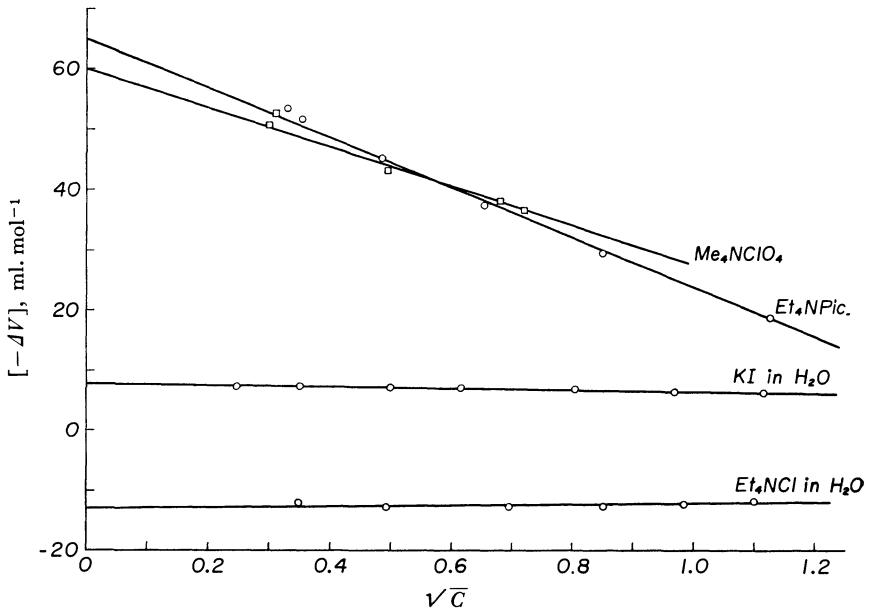

Fig. 5. Plots of the $[-\Delta V]$ value vs. $C^{1/2}$ of the solute.

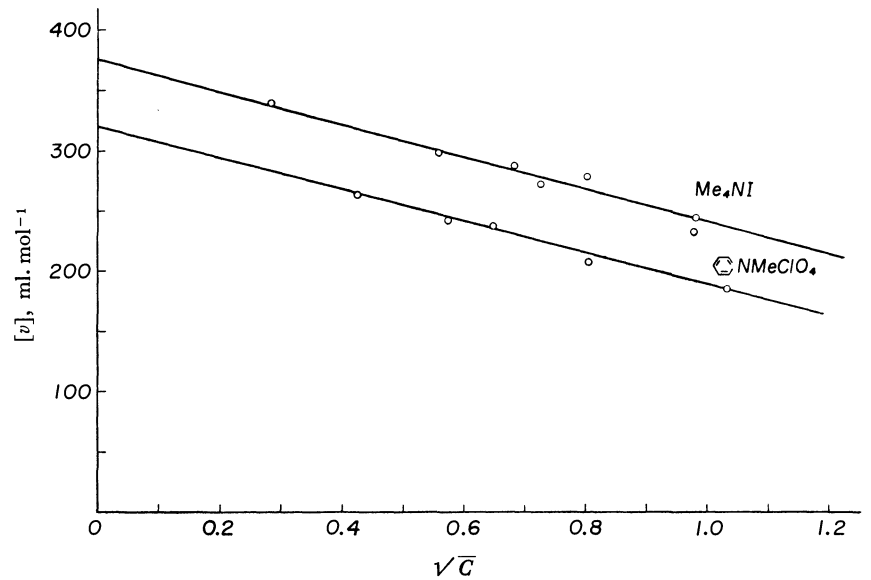

Fig. 6. Plots of the v value vs. $C^{1/2}$ of the solute.

number in a sulfur dioxide solution as calculated from Eq. 6 is eight for Me_4NI and about seven for $MePyr \cdot ClO_4$. Judging from these values it is again likely that such large solutes are considerably solvated in liquid sulfur dioxide.

It is generally accepted that the volume change is a measure of solvent-solute interactions, but this does not necessarily indicate the thermodynamic stability of the solute in the solution. However, as is shown in Table V, in liquid sulfur dioxide the order of the increase in the $[-\Delta Ve]$ value is in accord with that in the K_d value.[4]

It would be reasonable to assume that the $[-\Delta Ve]$ values thus obtained express the thermodynamic behavior of the ion in liquid sulfur dioxide.

Studies of Aminosugars. XI. Configurational Studies of Aminosugar Glycosides and Aminocyclitols by a Copper Complex Method*1

By Sumio UMEZAWA, Tsutomu TSUCHIYA and Kuniaki TATSUTA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received October 23, 1965)

An extensive study has been made of the determination of the rotational shift of aminosugars in three kinds of cuprammonium solutions, i. e., in solutions of tetramminecopper(II) sulfate, ammoniacal cuprous chloride and Cupra B, with special consideration of the spacial relationships between adjacent amino and hydroxyl groups in six-membered chair molecules. This paper is an extension of the work of Reeves which provided a tool for the determination of the spacial relationships between adjacent two-hydroxyl groups. Some significant generalizations have been obtained. About ten derivatives of glucosamine have been prepared, and their structures, as indicated by their rotational shifts, have been discussed. The absolute configurations of *d*- and *l-trans*-2-aminocyclohexanol have been successfully determined.

The optical rotatory behavior of glucopyranosides in a cuprammonium solution was first explained by Reeves[1a] by means of conformational considerations, and his experimental evidence confirmed the predicted favored conformational structures.

The findings of Reeves are concerned with the structural relationship between hydroxyl groups on adjacent carbon atoms. It has been concluded that, in the case of a substance with a six-membered chair form, a pair of adjacent hydroxyl groups in the molecule can form a copper complex when dissolved in "Cupra B,"[1b] and if the pair is located sterically so as to give near the $\pm 60°$ projected angle,[2a] the difference in the molecular rotations of the substance in Cupra B and in water, $\Delta[M]_{\text{Cupra B}}$,[3] is approximately ± 2000.

The present investigation was undertaken to see if a practical method could be worked out for the determination of a configurational relationship between amino and hydroxyl groups on adjacent carbon atoms in a six-membered chair molecule. The need for such a method is keenly felt for the elucidation of the absolute structures of a variety of aminosugar glycosides recently found in the field of antibiotics.

Optical rotatory studies have been carried out with a series of aminosugar derivatives and aminocyclitols in a tetramminecopper(II) sulfate[4] solution (TACu), a solution of cuprous chloride in concentrated aqueous ammonia (CuAm), and a

*1 This constitutes Part XXIV of a series entitled "Studies of Antibiotics and Related Substances," by Sumio Umezawa. A portion of this paper was presented at the 18th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1965. Previous reports on aminosugars: S. Umezawa and Y. Ito, This Bulletin, **34**, 69 (1961); Y. Ito, S. Koto and S. Umezawa, ibid., **35**, 1618 (1962); S. Umezawa, S. Koto and Y. Ito, ibid., **36**, 183 (1963); T. Suami, S. Ogawa and S. Cupra B solution. The results obtained by experiments on a number of substances of known configurations have led to some general conclusions, by which the absolute configurations of *d*- and *l*-*trans*-2-aminocyclohexanol[5] have been successfully determined.

As an example of a configurationally-known substance with a pair of adjacent amino and hydroxyl groups, methyl 2-amino-2-deoxy-4, 6-di-*O*-methyl-β-D-glucopyranoside (I) has been measured for the Δ[M] values in the above-mentioned three kinds of copper solutions; it gave $\Delta[M]_{TACu}$ −930, $\Delta[M]_{CuAm}$ −850 and $\Delta[M]_{Cupra\ B}$ −980 respectively. The projected angle between the adjacent amino and hydroxyl groups of the substance is about −60°.

An *N*-methyl derivative (III) of I, methyl 2-deoxy-4, 6-di-*O*-methyl-2-methylamino-β-D-glucopyranoside, showed nearly the same Δ[M] values as did I (Table I).

Methyl 2-acetamido-2-deoxy-α- and -β-D-glucopyranosides (IV, V), which have a pair of adjacent hydorxyl groups, showed the values of $\Delta[M]_{TACu}\sim 0$, $\Delta[M]_{CuAm}\sim+2200$ and $\Delta[M]_{Cupra\ B}\sim+2200$ respectively. The projected angles between the adjacent hydroxyl groups of both substances are about +60°.

Methyl 2-acetamido-2-deoxy-4, 6-di-*O*-methyl-β-D-glucopyranoside (VI), in which no hydroxyl or amino groups are free except for a hydroxyl group of C-3, showed nearly zero Δ[M] values in the above-mentioned three kinds of copper solutions. Methyl 2-amino-2-deoxy-3-*O*-methyl-β-D-glucopyranoside (VII), which has isolated hydroxyl and amino groups, also showed nearly zero Δ[M] values.

It has been further found that none of the compounds mentioned above showed any change in optical rotations when determined in an aqueous solution of cupric sulfate.

Methyl 2-amino-2-deoxy-α- and -β-D-glucopyranoside (VIII, IX) were also examined. These glucosides contain two kinds of pairs of adjacent groups, a pair of adjacent amino and hydroxyl groups and a pair of adjacent hydroxyl groups; they correspond to the case in which a competitive formation of a copper complex is to be expected between a pair of amino and hydroxyl groups and a pair of hydroxyl groups because these glucosides contain the $-C(OH)-C(OH)-C(NH_2)-$ grouping. It has been found that the corresponding Δ[M] values of VIII and IX are essentially equal, being $\Delta[M]_{TACu}\sim-830$, $\Delta[M]_{CuAm}\sim+1770$ and $\Delta[M]_{Cupra\ B}\sim+1770$ respectively. The negative sign and the magnitude of $\Delta[M]_{TACu}$ indicate that a formation of copper complex occurs with a pair of adjacent amino and hydroxyl groups at C-2 and C-3, not with a pair of hydroxyl groups at C-3 and C-4, and that the projected angle between the amino and hydroxyl groups is −60°. On the contrary, the positive sign and the magnitude of $\Delta[M]_{CuAm}$ and $\Delta[M]_{Cupra\ B}$ indicate that a complex formation occurs with a pair of adjacent hydroxyl groups at C-3 and C-4, and that the projected angle between them is +60° (Chart 1).

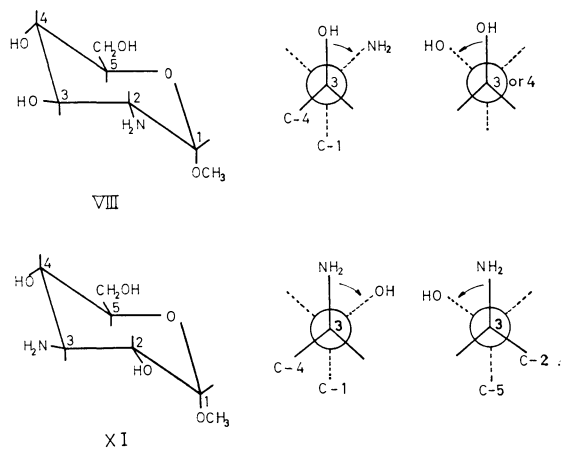

Chart 1.

Methyl α-D-glucopyranoside (X), methyl 3-amino-3-deoxy-α-D-glucopyranoside[6] (XI) and methyl 6-amino-6-deoxy-α-D-glucopyranoside[6] (XII) were further measured for Δ[M]. These glucosides correspond to the cases in which we can pick up two pairs of adjacent hydroxyl groups or adjacent amino and hydroxyl groups, and the projected angles of the two pairs are equal, though opposite in sign. For example, in XI, the projected angular relationship between the amino group at C-3 and the hydroxyl group at C-2 is clockwise and that between the amino group at C-3 and the hydroxyl group at C-4 is counterclockwise. As expected, the experimental values of Δ[M] were all small (Table I); however, $\Delta[M]_{CuAm}$ and $\Delta[M]_{Cupra\ B}$ showed values which, though slight, could not be deemed nearly zero or negligible, suggesting that the complex formation is slightly one-sided. A similar tendency had been observed by Reeves.[2b]

The above observation led to the following generalizations:

(1) TACu shows a significant $\Delta[M]_{TACu}$ value in compounds which have a pair of adjacent amino (or methylamino) and hydroxyl groups in a six-membered chair molecule, but in compounds which have a pair of adjacent hydroxyl groups or isolated hydroxyl or amino groups, $\Delta[M]_{TACu}$ is nearly zero. The sign of $\Delta[M]_{TACu}$ is in accord with the sign conventionally expected from the projected angle

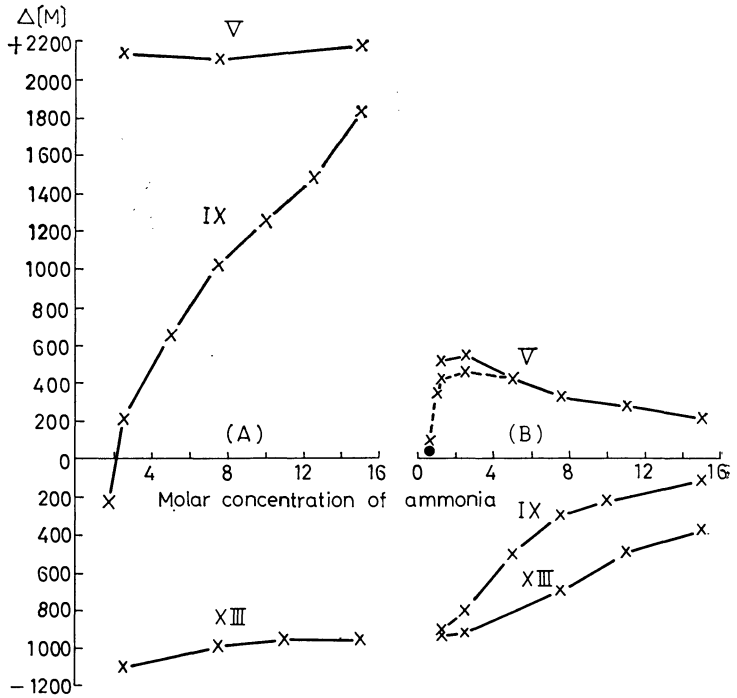

Fig. 1. Effect of the concentration of ammonia on Δ[M] of compounds V, IX and XIII (0.02 mmol.) in solutions (2 ml.) containing cuprous chloride (0.32 mmol.) (A), and cupric chloride (0.32 mmol.) (B). Since the cupric chloride solutions of low concentration of ammonia (<1.5 M ammonia) were not clear, cupric sulfate (0.32 mmol.) was used instead of cupric chloride; this range is represented by a dotted line.
● in B designates $\Delta[M]_{TACu}$ value of V.

made by adjacent hydroxyl groups.[2a] However, the magnitude of the $\Delta[M]_{TACu}$ value of the compounds with a pair of adjacent amino (or methylamino) and hydroxyl groups is about a half of the $\Delta[M]_{CuAm}$ or $\Delta[M]]_{Cupra\ B}$ value of the compounds with a pair of adjacent hydroxyl groups.

(2) Both CuAm and Cupra B show significant $\Delta[M]_{CuAm}$ and $\Delta[M]_{Cupra\ B}$ values in both cases, i. e., in cases of compounds which have a pair of adjacent amino (or methylamino) and hydroxyl groups and in cases of compounds which have a pair of adjacent hydroxyl groups. The sign of these Δ[M] values is again in accord with that conventionally expected from the projected angle. However, the magnitudes of the Δ[M] values in the former cases are about a half of those in the latter cases.

(3) In compounds with pairs both of adjacent amino and hydroxyl groups and of adjacent hydroxyl groups, TACu shows Δ[M] values exclusively corresponding to the pair of the former groups, while CuAm and Cupra B show Δ[M] values exclusively corresponding to the pair of the latter groups.

The above-mentioned generalizations were then successfully applied to an elucidation of the absolute configurations of *d*- and *l-trans*-amino-cyclohexanol.[5] The high negative increment ($\Delta[M]_{TACu}-920$) observed with the former was similar to that observed with I ($\Delta[M]_{TACu}-930$), but of a sign opposite to that of the latter ($\Delta[M]_{TACu}$ +930). Thus, (1s : 2s)-2-aminocyclohexanol (XIII) and (1R : 2R)-2-aminocyclohexanol (XIV) have been assigned to *d*- and *l-trans*-2-aminocyclohexanol respectively.

Discussion

As can be seen from the Table I, TACu has a significant effect in Δ[M], one quite different from that of CuAm and Cupra B, which are essentially similar. It may be considered that the significant difference is due to the formation of a copper(II) complex in the case of TACu and of a Copper(I) complex in the case of CuAm. On the other hand, however, it became of special interest to investigate how the concentration of ammonia affects the Δ[M] value, because either CuAm or Cupra B contains a far larger amount of ammonia than TACu.

Three compounds (V, IX and XIII) were chosen for the investigation. Each of them was dissolved in mixtures of aqueous ammonia of a series of concentrations, and of cuprous or cupric chloride. The Δ[M] values of the resulting solutions are

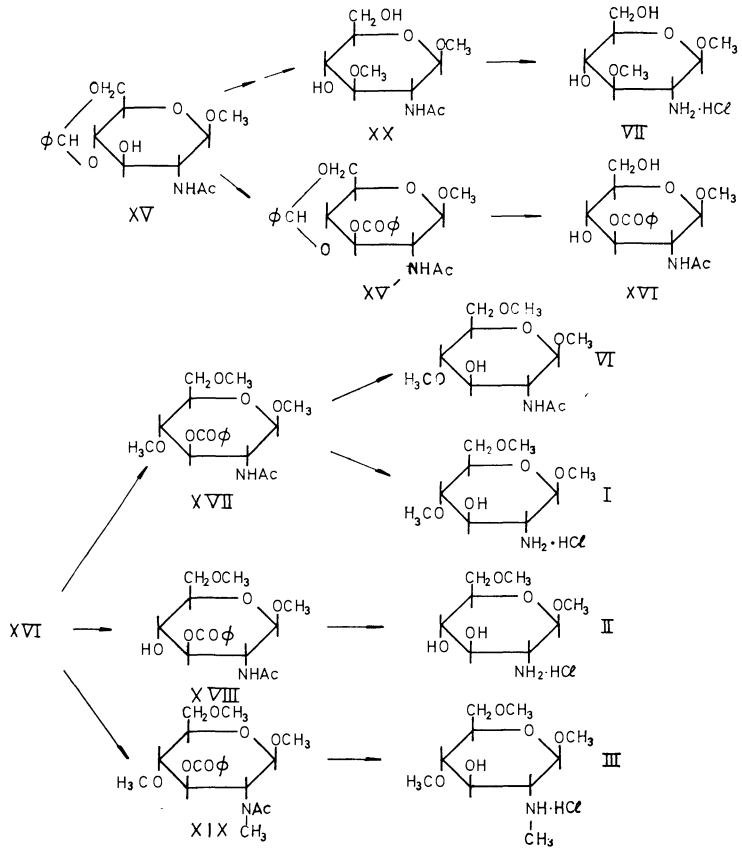

Chart 2. Scheme for the syntheses of derivatives of glucosamine.
Φ: C_6H_5 Ac: $COCH_3$

plotted against the molar concentrations of ammonia in Fig. 1.

As can be seen there, the Δ[M] values of cupric solutions of compounds with a pair of adjacent amino and hydroxyl groups are closely related to the concentration of ammonia. In the cupric chloride - ammonia solutions, the Δ[M] values for IX and XIII are significantly dependent on the concentration of ammonia. The absolute values of IX and XIII increase with the decrease in the concentration of ammonia, reaching a maximum where the concentration of ammonia is nearly equivalent to that in TACu. This indicates that TACu is an excellent reagent for the determination of Δ[M]. The Δ[M] value for V in the cupric solutions showed low values at various concentrations of ammonia.

In the cuprous chloride - ammonia solution, the Δ[M] values for both V and XIII are nearly independent of the concentrations of ammonia between two and fifteen moles, whereas the values for IX increase with the concentration of ammonia, reaching a point where the concentration of ammonia is nearly equivalent to that (14 mol.) in Cupra B. This suggests that, in a region of high concentration of ammonia, a preferential complex-formation occurs with adjacent hydroxyl groups and, as the concentration of ammonia becomes lower, adjacent amino and hydroxyl groups competitively participate in the complex-formation.

Synthesis.—Chart 2 outlines the synthetic steps for the derivatives of glucosamine. Excepting XV and XX, all the derivatives have never been prepared to the authors' knowledge. Methyl 2-amino-2-deoxy-4, 6-di-*O*-methyl-β-D-glucopyranoside (I) has been prepared by starting with methyl 2-acetamido-4, 6-*O*-benzylidene-2-deoxy-β-D-glucopyranoside[7] (XV). The 3-*O*-benzoyl derivative (XV') of XV was debenzylidenated to give methyl 2-acetamido-3-*O*-benzoyl-2-deoxy-β-D-glucopyranoside (XVI). The Purdie methylation of XVI by a general procedure gave methyl 2-acetamido-3-*O*-benzoyl-2-deoxyl-4, 6-di-*O*-methyl-β-D-glucopyranoside (XVII) in a low yield. However, it has been found that the use of a "flash mixer" equipped with an eccentrically-rotating stirrer gave a high yield of XVII, as will be described in the "Experimental" section. The

7) W. Roth and W. Pigman, *J. Am. Chem. Soc.*, **82**, 4608 (1960).

hydrolysis of XVII to I was performed by treatment with hydrazine, a method which was first introduced by Fujinaga and Matsushima[8] for the deacetylation of *N*-acetylated aminosugar glucosides.

In the above methylation, if the reaction period was curtailed, a partially-methylated product, methyl 2-acetamido-3-*O*-benzoyl-2-deoxy-6-*O*-methyl-β-D-glucopyranoside (XVIII), was obtained in addition to XVII, indicating that 6-*O*-methylation occurs easier than 4-*O*-methylation. The evidence for the structure of XVIII was obtained by a study of the infrared and NMR spectra (Fig. 2) and by the determination of three Δ[M] values of the deacetylated product (II) of XVIII (Table I).

Furthermore, it has been found that, if more hours were used in the above methylation, the *N*-methyl derivative of XVII, i. e., methyl 3-*O*-benzoyl-2-deoxy-4,6-di-*O*-methyl-2-*N*-methylacetamido-β-D-glucopyranoside (XIX), was obtained in a low yield. This was then converted to methyl 2-deoxy-4, 6-di-*O*-methyl-2-methylamino-β-D-glucopyranoside (III) by the action of hydrazine.

Methyl 2-acetamido-2-deoxy-4, 6-di-*O*-methyl-β-D-glucopyranoside (VI) was obtained by curtailing the reaction period of XVII with hydrazine for the preparation of I.

Methyl 2-amino-2-deoxy-3-*O*-methyl-β-D-glucopyranoside (VII) was prepared by starting with XV. Methyl 2-acetamido-2-deoxy-3-*O*-methyl-β-D-glucopyranoside (XX) obtained from XV by the method of Roth et al.[7] was treated with hydrazine to give VII. Fujinaga and Matsushima[9] have recently reported that XX can be converted to VII with hydrazine in a low yield; it has been found that the yield of VII can be successfully increased by raising the reaction temperature to about 130°C.

The mixture of α- and β-anomers (VIII and IX) of methyl 2-amino-2-deoxy-D-glucopyranoside was prepared by the route of Irvine et al.[10] However, as an alternative synthesis, the above mixture has been successfully prepared by a direct Fischer method, only raising the reaction temperature to about 150°C. The anomers could be separated by the method of Austin et al.[11] with resin column chromatography using Dowex 1×2. The separation patterns of anomers in the resin chromatography of the two mixtures were nearly the same, giving two clear-cut peaks. The anomers obtained from the both mixtures were proved to be identical in their physical properties.[12]

12) Recently we learned of another method for the preparation of VIII and IX using Amberlite IR-120 (Y. Matsushima and T. Miyazaki, This Bulletin, **38**, 1325 (1965)).

Experimental

The Preparation of Copper Solutions.—Cupra B: This was prepared by the method of Reeves.[1b] CuAm (cuprous chloride in aqueous ammonia): Cuprous chloride (1.60 g.) was dissolved in 15 N ammonia (100 ml.) at 15°C. TACu (tetramminecopper-(II) sulfate solution): Tetramminecopper(II) sulfate ($[Cu(NH_3)_4]SO_4 \cdot H_2O$) (3.95 g.) was dissolved in fresh distilled water (100 ml.).

The Determination of Optical Rotations.—A sample (0.1 mmol.) was dissolved in each of the above-mentioned three copper solutions (10 ml.), placed in a usual optical cell (10 cm. in length, 1—2 ml.), and the optical rotation at 436 mμ was measured at 15°C by the method of symmetrical angles using a Hitachi EPU-2 spectrophotometer coupled with a Hitachi A-2 polarimeter. An aqueous solution of the same sample was prepared, and the optical rotations at 436 and 589 mμ were also measured.

Thin Layer Chromatography and Silica Gel Column Chromatography.—Thin layer chromatography was conducted by the use of silica gel (Daiichi Pure Chemicals Co.); the prepared plate was activated at 110°C and then stored in a desiccator. Coloration was performed with concentrated sulfuric acid or 0.25% ninhydrin in pyridine. Solvent systems used: benzene-ethyl acetate-acetone (1 : 1 : 1) (Solvent I) and benzene-methanol-acetone (1 : 1 : 8) (Solvent II). Silica gel column chromatography was carried out by the use of silica gel (Kanto Chemical Co.) and was activated at 110°C before use.

Methyl 2-Acetamido-4, 6-*O*-benzylidene-3-*O*-benzoyl-2-deoxy-β-D-glucopyranoside (XV′).—According to the procedure used for the preparation of the corresponding α-anomer by Jeanloz,[13] XV′ was prepared from XV in a 60% yield; m. p. 292—294°C, $[\alpha]_{589}^{15}$ −97° (*c* 0.5, chloroform).

Found: C, 64.66; H, 5.89; N, 3.14. Cacld. for $C_{23}H_{25}O_7N$: C, 64.62; H, 5.90; N, 3.28%.

Methyl 2-Acetamido-3-*O*-benzoyl-2-deoxy-β-D-glucopyranoside (XVI).—A mixture of XV′ (380 mg.) and glacial acetic acid (14 ml.) was heated to 80°C, and to this mixture water (9.7 ml.) was added portion by portion. After 30 min. of heating at the same temperature, the mixture was cooled and evaporated to dryness under reduced pressure. To the residue water was again added, and it was again evaporated to dryness; this treatment was thrice repeated. To the residue toluene (3 ml.) was then added and the mixture was evaporated; this treatment was thrice repeated. Finally, the toluene solution was filtered and, after the removal of the solvent, petroleum ether was added to afford crystals of XVI; m. p. 100—102°C (decomp.), $[\alpha]_{589}^{15}$ −47° (*c* 0.5, chloroform).

Found: C, 56.30; H, 6.39. Calcd. for $C_{16}H_{21}O_7N$: C, 56.63; H, 6.24%.

Methyl 2-Acetamido-3-*O*-benzoyl-2-deoxy-4, 6-di-*O*-methyl-β-D-glucopyranoside (XVII), Methyl 2-Acetamido-3-*O*-benzoyl-2-deoxy-6-*O*-methyl-β-D-glucopyranoside (XVIII) and Methyl 3-*O*-Benzoyl-2-

13) The derivative XV′ had been isolated as a minor product from a reaction mixture obtained from methyl 2-acetamido-4, 6-*O*-benzylidene-2-deoxy-α-D-glucopyranoside (R. W. Jeanloz, *J. Am. Chem. Soc.*, **76**, 555 (1954)); reported m. p. 293—295°C, $[\alpha]_D$ −102±2° (*c* 0.73, chloroform).

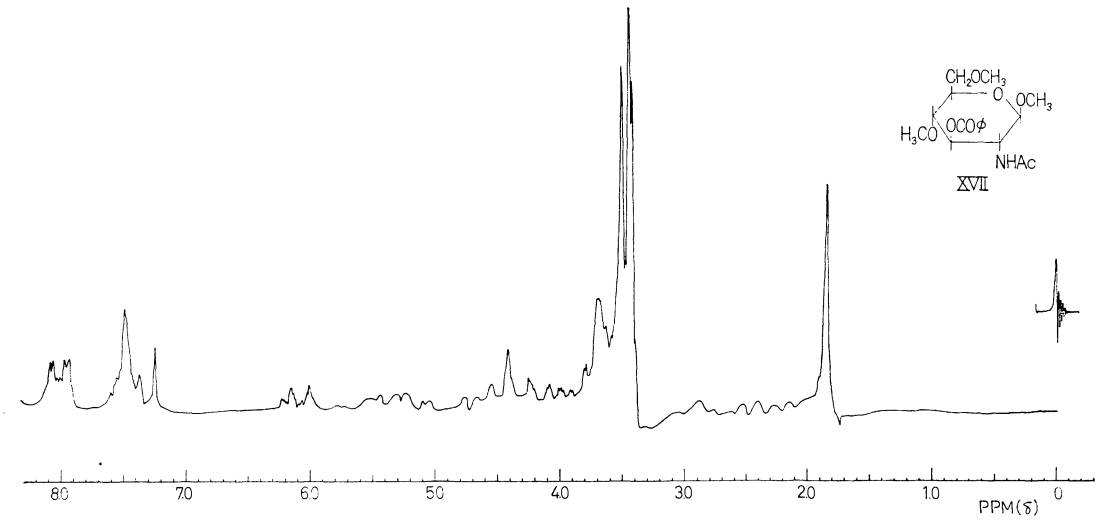

Fig. 2-A. The NMR spectrum at 60 Mc.p.s. of methyl 2-acetamido-3-*O*-benzoyl-2-deoxy-4, 6-di-*O*-methyl-β-D-glucopyranoside (XVII) in deuteriochloroform.

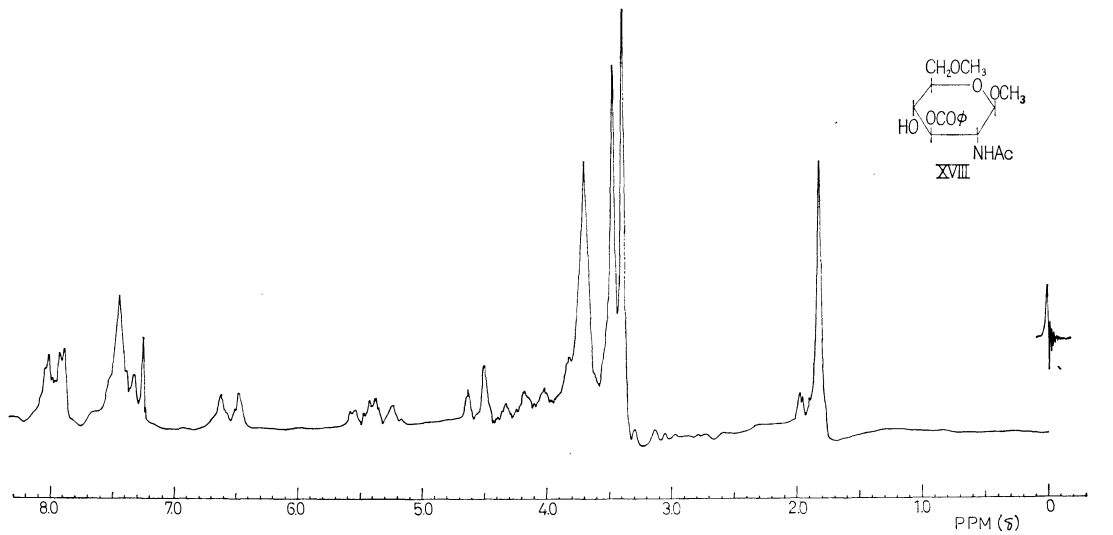

Fig. 2-B. The NMR spectrum at 60 Mc.p.s. of methyl 2-acetamido-3-*O*-benzoyl-2-deoxy-6-*O*-methyl-β-D-glucopyranoside (XVIII) in deuteriochloroform.

deoxy-4, 6-di-*O*-methyl-2-(*N*-methylacetamido)-β-D-glucopyranoside (XIX).—A mixture of methyl 2-acetamido-3-*O*-benzoyl-2-deoxy-β-D-glucopyranoside (XVI) (300 mg.), silver oxide (1.2 g.), methyl iodide (0.9 g.), Drierite (anhydrous calcium sulfate) (0.9 g.) and dry acetone (3 ml.) was placed in a thick, tightly-capped glass tube and agitated vigorously for 6 hr. at room temperature with an eccentrically-rotating stirrer.*2 After filtration, the precipitate was washed with acetone, and the combination of the filtrate and the washings was evaporated to dryness, giving 330 mg. of a solid. In thin layer chromatography with solvent I, the solid was proved to be composed of three components with R_f values of 0.42, 0.58 and 0.90 (minor spot). The solid was dissolved in a solvent mixture of benzene-ethyl acetate-acetone (1 : 1 : 1) and chromatographed on a silica gel column (48×130 mm.) with the same solvent. Every fraction (11 g.) was tested by thin layer chromatography. Substances with R_f values of 0.58 and 0.42 appeared in the fractions of tubes Nos. 16—19 and 22—27 respectively. The former fractions were collected and evaporated to give a residue which crystallized from chloroform, thus affording XVII, 130 mg.; m. p. 167—169°C, $[\alpha]_{589}^{15}$ −11.1° (*c* 0.9, methanol); IR spectrum (KBr disk): 3305 (νNH, sharp), 2940, 2850, 1735 (ester), 1665 (Amide I), 1565 (Amide II), 1455, 1378 cm^{-1}.

Found: C, 58.92; H, 6.85; N, 3.82. Calcd. for $C_{18}H_{25}O_7N$: C, 58.84; H, 6.86; N, 3.81%.

*2 A "Flash Mixer" (Mitamura Riken Kogyo Co.) with an eccentric radius of 1 mm. was used at 2000 r. p. m.

From the latter fractions, XVIII was obtained in the way described above; yield, 115 mg. (hygroscopic); m. p. 179—181°C (sintered once at 75—85°C), $[\alpha]_{589}^{15}$ +17.7° (*c* 1.2, methanol); IR spectrum (KBr disk): 3340, 2920, 2830, 1725, 1660, 1550, 1450, 1375 cm^{-1}.

Found: C, 54.89; H, 6.72; N, 3.74. Calcd. for $C_{17}H_{23}O_7N \cdot H_2O$: C, 54.98; H, 6.79; N, 3.77%.

When the above agitaion with an eccentrically-rotating stirrer was continued for 20 hr., the resulting crude product was composed of two components, R_f 0.59 and 0.90 (minor component). On a silica gel chromatography on the scale described above, the eluted fractions of tubes Nos. 16—21 and 10—12 gave 180 mg. of XVII and 30 mg. of XIX respectively.

When the above agitation was continued for 45 hr., the yield of XIX was increased to 67 mg., ($[\alpha]_{585}^{15}$ −10.5° (*c* 1, methanol); IR spectrum (KBr disk): 2930, 2900, 2830, 1730 (ester), 1690 (Amide I), 1455, 1380 cm^{-1}). No absorption bands corresponding to νNH (~3300) and δNH (~1550, Amide II) were observed, indicating that XIX is a *N*-methylated product.

Found: C, 59.60; H, 6.88; N, 3.54. Calcd. for $C_{19}H_{27}O_7N$: C, 59.83; H, 7.13; N, 3.67%.

The NMR spectra of compounds XVII and XVIII were determined in deuteriochloroform at a frequency of 60 Mc. p. s. with a Varian A60 spectrometer (Fig. 2). Tetramethylsilane was used as an internal reference. The comparison of the relative strength of the peaks at ~6.5 τ (methyl protons of methoxyl groups) with the other peaks [acetoxyl protons at ~8.2 τ, anomeric protons (3.91 τ for XVII and 3.45 τ for XVIII), and aromatic protons] revealed that XVII and XVIII have three and two methoxyl groups respectively.

Methyl 2-Amino-2-deoxy-4, 6-di-*O*-methyl-β-D-glucopyranoside Hydrochloride (I).—A mixture of XVII (60 mg.) and hydrazine hydrate*3 (0.9 ml.) in a sealed tube was heated in a boiling water bath for 17 hr. After the hydrazine had been removed in vacuo, the residue was dissolved in a mixture of benzene-methanol-acetone (1 : 1 : 8) and chromatographed on a silica gel column (27×70 mm.) with the same solvent. A ninhydrin active product was eluted between 40—120 ml. This fraction was evaporated to dryness; the aqueous solution of the residue was passed through a small column of Dowex 1×2 (OH form), and the ninhydrin-active portion was again collected and evaporated to dryness. The residue was dissolved in chloroform and dried over sodium sulfate, and, after filtration, the filtrate was evaporated to dryness. The residue was again dissolved in water, neutralized with hydrochloric acid, treated with active charcoal, and evaporated to give a solid which was crystallized from methanol by adding acetone; yield, 23 mg.; m. p. 203—204°C (decomp.), $[\alpha]_{589}^{15}$ −2.0° (*c* 0.3, water); IR spectrum (KBr disk): 3320, 2900, 1600 ($\delta_{as}NH_3^+$), 1500 (δ_s NH_3^+), 1450, 1400—1370 (3 bands) cm^{-1}.

Found: C, 41.71; H, 7.61; N, 5.41. Calcd. for $C_9H_{19}O_5N \cdot HCl$: C, 41.94; H, 7.81; N, 5.44%.

On thin layer chromatography with solvent II, I showed an R_f of 0.54. To an aqueous solution (2.6 ml.) of the hydrochloride (I) (2.6 mg.) periodic acid (9.1 mg.), was added, and the mixture was allowed to stand at room temperature for 20 hr. A drop of the solution was then subjected to thin layer chromatography. No spot corresponding to I was discerned.

Methyl 2-Amino-2-deoxy-6-*O*-methyl-β-D-glucopyranoside Hydrochloride (II).—A mixture of XVIII (110 mg.) and hydrazine hydrate (1.6 ml.) was treated for 60 hr. as above. The thin layer chromatography of the crude product showed an R_f value of 0.32 with solvent II. Isolation and purification was carried out in the same way as described in the above synthesis of I; yield, 39 mg. (hygroscopic), $[\alpha]_{589}^{15}$ −4.0° (*c* 0.5, water); IR spectrum (KBr disk): ~3300, 2900, 1600, 1510, 1450, 1400—1380 (2 bands) cm^{-1}.

Found: C, 39.62; H, 7.41. Calcd. for $C_8H_{17}O_5N \cdot HCl$: C, 39.43; H, 7.45%.

Methyl 2-Acetamido-2-deoxy-4, 6-di-*O*-methyl-β-D-glucopyranoside (VI).—A mixture of XVII (150 mg.) and hydrazine hydrate (2.3 ml.) in a sealed tube was heated in a boiling water bath for 1.5 hr. The removal of the solvent in vacuo left a solid which, on thin layer chromatography with solvent II, showed a single spot (R_f 0.7). The solid was then dissolved in the same solvent system and chromatographed on a silica gel column (27×200 mm.) with the same solvent. An eluate between 50—80 ml. was evaporated to dryness, and the residue was dissolved in ethanol. The solution was treated with active charcoal and concentrated to a small volume, from which crystals of VI was obtained by the addition of ether; yield, 75 mg.; m. p. 177—179°C (decomp.), $[\alpha]_{589}^{15}$ −23.3° (*c* 0.9, water); IR spectrum (KBr disk): 3500—3400, 3270, 2920, 2820, 1650 (Amide I), 1565 (Amide II), 1450, 1375 cm^{-1}.

Found: C, 50.44; H, 7.74; N, 5.20. Calcd. for $C_{11}H_{21}O_6N$: C, 50.18; H, 8.04; N, 5.32%.

Methyl 2-Deoxy-4, 6-di-*O*-methyl-2-methylamino-β-D-glucopyranoside Hydrochloride (III).—A mixture of XIX (90 mg.) and hydrazine hydrate (1.4 ml.) in a sealed tube was heated in a boiling water bath for 22 hr. The removal of the solvent in vacuo left a solid which, on thin layer chromatography with solvent II, showed a single spot (R_f 0.52).

The solid was then dissolved in the same solvent system and chromatographed on a silica gel column (27×90 mm.) with the same solvent. An eluate between 50—110 ml. was evaporated, and the residue was treated in the way described in the synthesis of I; yield, 39 mg. (hygroscopic); $[\alpha]_{589}^{15}$ −1.1° (*c* 0.5, water); IR spectrum (KBr disk): 3350, 2900, 1600 (δ_{as} NH_3^+), 1505 (δ_s NH_3^+), 1455, 1405 cm^{-1}.

Found: C, 43.81; H, 8.03. Calcd. for $C_{10}H_{21}O_5N \cdot HCl$: C, 44.19; H, 8.16%.

Methyl 2-Amino-2-deoxy-3-*O*-methyl-β-D-glucopyranoside Hydrochloride (VII).—A mixture of methyl 2-acetamido-2-deoxy-3-*O*-methyl-β-D-glucopyranoside*4 (XX) (83 mg.) and hydrazine hydrate (2 ml.) in a sealed tube was heated at 130°C for 40 hr. The removal of the solvent in vacuo left an solid which, on thin layer chromatography with solvent II, showed a single spot (R_f 0.38). (XX showed an R_f of 0.54 with solvent II.) The solid was then dissolved in a mixture of benzene, methanol and acetone (1 : 1 : 8); the mixture was chromatographed on a sillica gel column (27×88 mm.) with the same solvent. An eluate (between 40—100 ml.) was evaporated, and the residue was treated

*3 Commercial hydrazine hydrate (80%) was fractionally distilled; the fraction constant at 119°C was taken for use.

*4 M. p. 221—222°C (decomp.) (lit.[7] m. p. 229°C); $[\alpha]_{589}^{15}$ −46.2°, $[\alpha]_{436}^{15}$ −85.3° (*c* 0.6, water) (lit.,[7] $[\alpha]_D$ −45.9°); Found: C, 48.04; H, 7.57. Calcd. for $C_{10}H_{19}O_6N$: C, 48.17; H, 7.70%.

in the way described in the synthesis of I; yield, 55 mg. (70%). A sample (11 mg.) was recrystallized from ethanol to yield 9 mg. of an analytically-pure sample of VII; m. p. 139—140°C (decomp.). $[\alpha]_{589}^{15}$ +10.3° (*c* 0.3, water); IR spectrum (KBr disk): 3370, 2920, 1600 (δ_{as} NH_3^+), 1500 (δ_s NH_3^+), 1450, 1395 cm^{-1}.

Found: C, 39.54; H, 7.39; N, 5.68. Calcd. for $C_8H_{17}O_5N \cdot HCl$: C, 39.43; H, 7.45; N, 5.75%.

Methyl 2-Amino-2-deoxy-α- and -β-D-glucopyranoside Hydrochloride (VIII and IX).—A mixture of 2-amino-2-deoxy-D-glucose hydrochloride (215 mg.) and 2 N hydrochloric acid in methanol (5 ml.) was placed in a sealed glass tube and heated at 150°C for 4 hr. The resulting solution was evaporated to give a brown syrup, which was then dissolved in water and passed through a small column of Dowex 1×2 (OH form). This solution, after having been treated with active charcoal, was then evaporated to give a syrup; this syrup was then applied to a column (18×270 mm.) of Dowex 1×2 (OH form), and elution was carried out with water. Methyl 2-amino-2-deoxy-α-D-glucopyranoside and methyl 2-amino-2-deoxy-β-D-glucopyranoside emerged in the eluates between 63—69 ml. and between 75—84 ml. respectively. The former fraction was collected, concentrated to a small volume, and neutralized with hydrochloric acid. After evaporation to dryness, the solid obtained was recrystallized from ethanol to give 34 mg. of VIII, m. p. 189°C (decomp.)*5 $[\alpha]_{589}^{15}$ +153° (*c* 0.23, water)*5.

Found: C, 36.78; H, 7.23; N, 5.95. Calcd. for $C_7H_{15}O_5N \cdot HCl$: C, 36.61; H, 7.02; N, 6.10%.

From the latter fraction, by the same procedure as above, IX was obtained, 36 mg., m. p. 188°C (decomp.)*6 $[\alpha]_{589}^{15}$ −20° (*c* 0.23, water)*6.

Found: C, 36.72; H, 7.01; N, 6.14. Calcd. for $C_7H_{15}O_5N \cdot HCl$: C, 36.61; H, 7.02; N, 6.10%.

Methyl 2-Acetamido-2-deoxy-α- and -β-D-glucopyranoside (IV and V).—To an aqueous ethanol (7 : 3) solution of the hydrochloride VIII (1.0 g.), acetic anhydride and powdered barium hydroxide octahydrate were added alternately until the solution became negative to a ninhydrin test; then a little excess of sulfuric acid was added and the mixture was filtered. The filtrate was treated with Dowex 2×8 (OH form) and, after the solvent had been removed, the residue was recrystallized from ethanol to give 680 mg. of IV, m. p. 187—188°C*7 $[\alpha]_{589}^{15}$ +103° (*c* 0.3, water); IR spectrum (KBr disk): 3370, 3300, 2920, 2860, 1655 (Amide I), 1550 (Amide II), 1445, 1375, 900 (Type 1 of pyranose ring), 853 (Type 2a) cm^{-1}.

Found: C, 46.18; H, 7.23; N, 5.87. Calcd. for $C_9H_{17}O_6N$: C, 45.95; H, 7.28; N, 5.95%.

The β-anomer (V) was also prepared from IX (1.0 g.) in the same way as above; yield, 610 mg.; m. p. 199—200°C,*8 $[\alpha]_{589}^{15}$ −48° (*c* 0.3, water);*8 IR spectrum (KBr disk): 3400, 3300, 2930, 2880, 1650 (Amide I), 1555 (Amide II), 1450, 1380, 940 (Type 1 of pyranose ring), 859 (Type 2b) cm^{-1}.

Found: C, 45.94; H, 7.24; N, 5.90. Calcd. for $C_9H_{17}O_6N$: C, 45.95; H, 7.28; N, 5.95%.

***d*- and *l*-*trans*-2-Aminocyclohexanol Hydrochloride (XIII and XIV).**—To an aqueous solution of *d*-*trans*-2-aminocyclohexanol L-(+)-tartrate (200 mg.), 10 ml. of Amberlite IRA-400 (OH form) was added. After filtration, the filtrate was concentrated to a small volume and neutralized with hydrochloric acid. The addition of acetone gave crystals of XIII; yield, 80 mg.; m. p. 157.5—158°C, $[\alpha]_{589}^{15}$ +41.7° (*c* 0.5 water); IR spectrum (KBr disk): 3435, 3330, 2990, 2920, 2840, 1975 (νNH_3^+), 1595 (δ_{as} NH_3^+), 1505 (δ_s NH_3^+), 1465, 1385, 1358 cm^{-1}.

Found: C, 47.63; H, 9.02; N, 9.08. Calcd. for $C_6H_{13}ON \cdot HCl$: C, 47.52; H, 9.31; N, 9.24%.

The hydrochloride (XIV) of the *l*-isomer was prepared from *l*-*trans*-2-aminocyclohexanol L-(+)-tartrate (200 mg.); yield, 77 mg.; m. p. 157.5 −158°C, $[\alpha]_{589}^{15}$ −40.3° (*c* 0.5, water).

Found: C, 47.67; H, 9.17; N, 9.10. Calcd. for $C_6H_{13}ON \cdot HCl$: C, 47.52; H, 9.31; N, 9.24%.

Part of the expenses for this work were defrayed by a grant-in-aid for Scientific Research from the Ministry of Education, which grant is gratefully acknowledged. We are also indebted to Mr. Saburo Nakada of this Laboratory for his microanalysis. The authors also wish to thank Professor Tetsuo Suami of our Department for providing the sample of *d*- and *l*-*trans*-2-aminocyclohexanol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1244—1248 (1966)

Studies of Aminosugars. XII. The Absolute Structure of Kanamycin as Determined by a Copper Complex Method*1

By Sumio UMEZAWA, Kuniaki TATSUTA and Tsutomu TSUCHIYA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received October 23, 1965)

N, *N'*-Dimethyl-di-*O*-methyldeoxystreptamine has been prepared from kanamycin through the hydrolysis of the totally-methylated product of *O*-(3-acetamido-3-deoxy-α-D-glucopyranosyl)-*N*, *N'*-diacetyldeoxystreptamine. On the other hand, *N*, *N'*-dimethyl-4, 5, 6-tri-*O*-methyldeoxystreptamine has been prepared by hydrolysis of the totally-methylated product of *N*, *N'*-diacetyldeoxystreptamine. The shifts in molecular rotations of the both products have then been determined, with solutions of tetramminecopper(II) sulfate, ammoniacal cuprous chloride and Cupra B being substituted for water as the solvent. By the application of the generalizations described in the foregoing paper, it has been found that the former product includes a pair of adjacent methylamino and hydroxyl groups and that the projected angle between them is about +60°. These findings led to the conclusion that the free hydroxyl group in the former product is attached to the C-6 of deoxystreptamine, indicating that, in kanamycin, 6-amino-6-deoxy-α-D-glucosyl and 3-amino-3-deoxy-α-D-glucosyl moieties are attached to the C-4 and C-6 of deoxystreptamine respectively.

In earlier papers, we reported the results of the methylation[1] and partial hydrolysis studies[2] of kanamycin; thus the structure[1a] of kanamycin was deduced, with the reservation that the absolute sequence of the substitution of 3-amino-3-deoxy-D-glucose and 6-amino-6-deoxy-D-glucose at the C-4 and C-6 of deoxystreptamine remained undetermined.

Recently, Hichens and Rinehart[3] successfully applied the cuprammonium method of Reeves[4] to the investigation of the absolute structure of neomycins, paromomycins and kanamycins, by measuring the shift of the molecular rotation, $\Delta[M]_{\text{Cupra B}}$, of *N*, *N'*-diacetyl-6-*O*-methyldeoxystreptamine obtained from neomycin B and C and from paromomycin. Tatsuoka et al.[5] used the same method to elucidate the absolute configuration of kanamycin, measuring the $\Delta[M]_{\text{Cupra B}}$ of tri-*N*-acetyl-kanosaminyl-deoxystreptamine.

The work of Reeves, using "Cupra B," provides a tool for the determination of the stereochemical relationship between adjacent hydroxyl groups. In the preceding paper[6], the determination of $\Delta[M]_{\text{TACu}}$*2 has been introduced as a method for the revelation of the stereochemical relationship between adjacent amino and hydroxyl groups in a molecule of a six-membered chair form; this method involves measuring the shift in the opticalrotation when a tetramminecopper(II) sulfate solution (TACu) is substituted for water as the solvent.

The present report will describe the determination of the absolute structure of kanamycin by the use of TACu in addition to an ammoniacal cuprous chloride solution and "Cupra B." For this purpose, *N*, *N'*-dimethyl-di-*O*-methyldeoxystreptamine (IV) has been prepared, starting from kanamycin, by the route shown in Scheme I(1). Additionally, *N*, *N'*-dimethyl-tri-*O*-methyldeoxystreptamine (VII) has been prepared from deoxystreptamine as a reference substance (Scheme I (2)).

(1) Kanamycin → 6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-deoxystreptamine (I) → 6-*O*-(3-acetamido-3-deoxy-α-D-glucopyranosyl)-*N*, *N'*-diacetyl-deoxystreptamine (II) → 6-*O*-[3-deoxy-2, 4, 6-tri-*O*-methyl-3-(*N*-methylacetamido)-α-D-glucopyranosyl]-*N*,*N'*-diacetyl-*N*, *N'*-dimethyl-4, 5-di-*O*-methyl-deoxystreptamine (III) → *N*, *N'*-dimethyl-4, 5-di-*O*-methyl-deoxystreptamine (IV).

(2) Deoxystreptamine → *N*, *N'*-diacetyl-deoxystreptamine (V) → *N*,*N'*-diacetyl-*N*,*N'*-dimethyl-4, 5, 6-tri-*O*-methyldeoxystreptamine (VI) → *N*, *N'*-dimethyl-4, 5, 6-tri-*O*-methyl-deoxystreptamine (VII).

Scheme 1

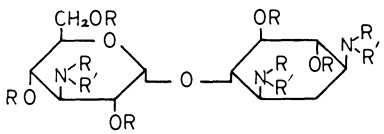
*2 $\Delta[M]_{\text{TACu}} = ([\alpha]_{436}\ \text{TACu} - [\alpha]_{436}\ \text{water}) \times \frac{\text{Mol. wt.}}{100}$

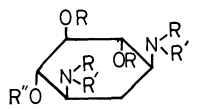
TABLE I.

	$[\alpha]_{589}^{15}$	$[\alpha]_{438}^{15}$	$\Delta[M]_{TACu}$	$\Delta[M]_{CuAm}$	$\Delta[M]_{Cupra\ B}$
IV·2HCl	+14	+30	+1100	+1090	+1110
VII·2HCl	+3	+6	+1	+10	−9
II	+80	+154	+40	+1590	+1420*

* Reported $\Delta[M]_{Cupra\ B}$ +1380 by Tatsuoka et al. (Ref. 5).

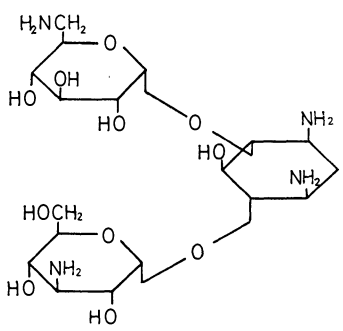


I : R=R'=H
II : R=H; R'=COCH$_3$
III : R=CH$_3$; R'=COCH$_3$



IV : R=CH$_3$; R'=R''=H
V : R=R''=H ; R'=COCH$_3$
VI : R=R''=CH$_3$; R'=COCH$_3$
VII R=R''=CH$_3$; R'=H

The three kinds of $\Delta[M]$ values for IV measured in TACu, CuAm and Cupra B were all approximately +1100, while those for VII were approximately zero, indicating that no complexing occurs between two methylamino groups of the deoxystreptamine moiety VII (Table I). These results, when subjected to the generalizations described in the preceding paper[6], led to the conclusion that the projected angle*3 between adjacent methylamino and hydroxyl groups is about +60° in the molecule of IV, that is, that IV is *N*, *N'*-dimethyl-4, 5-di-*O*-methyldeoxystreptamine; thus, kanamycin is deduced to be 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-6-*O*-(3-amino-3-deoxy-α-D-glucopyranosyl)-deoxystreptamine. This accords with the results obtained by the above-mentioned authors.[3,5] If IV were 5, 6-di-*O*-methyl isomer instead of the substance mentioned above, the $\Delta[M]_{TACu}$ value would be about −1000.



Kanamycin

The three $\Delta[M]$ values for II have also been measured to give an additional proof of the above structure assignment of kanamycin (Table I).

6-*O*-(3-Amino-3-deoxy-α-D-glucopyranosyl)-deoxystreptamine (I), which was first isolated by Maeda et al.,[7] was prepared by the hydrolysis of kanamycin with 3 N hydrochloric acid, heating them at about 100°C for one hour, followed by column chromatography using active carbon and Dowex 1×2; this procedure gave a high yield of I.

The acetylation of I has been effected by the use of acetic anhydride and barium hydroxide, thus giving II. The acetylation of deoxystreptamine briefly run in methanolic acetic anhydride gave V.

As to the methylation of II and V, a modified Purdie method was used; the methylation was effected in a sealed tube at 75—80°C. It has been found that the methylation of acetamino groups was performed as well as that of hydroxyl groups, affording III and VI respectively. This was proved by the determination of the infrared and NMR spectra; after the methylation, the absorption band at 1550 cm^{-1} (Amide II) observed in the infrared spectra of II and V disappeared in those of IV and VII respectively, while, in the NMR spectra of IV and VII, signals for *N*-methyl groups (~7.5τ) were clearly discerned (Fig. 1).

The hydrolysis of III and VI has been carried out in dilute hydrochloric acid, with the application of heat, giving IV and VII respectively.

Experimental

The preparation of a tetramminecopper(II) sulfate solution (TACu) and of cuprous chloride in 15 N aqueous ammonia (CuAm), and the determination of optical rotation were carried out as described in the preceding paper.[6] Paper chromatography was conducted by the descending technique on Toyo filter paper No. 50, and the locations of the substances on the papergrams were established by 0.25% ninhydrin in pyridine. Thin layer chromatography was carried out as described in the preceding paper, and the coloration of substances bearing amino groups was performed with concentrated sulfuric acid or 0.25% ninhydrin in pyridine.

6-*O*-(3-Amino-3-deoxy-α-D-glucopyranosyl)-deoxystreptamine (I).—A solution of a kanamycin base (10 g.) in 3 N hydrochloric acid (150 ml.) was heated in a boiling water bath for 1 hr. and then evaporated under reduced pressure. The resulting syrup was refluxed for 30 min. with dry methanol (500 ml.)

*3 See footnote of Ref. 6.

7) K. Maeda, M. Murase, H. Mawatari and H. Umezawa, *J. Antibiotics*, **A11**, 163 (1958).

containing dry hydrogen chloride (10 g.). By this procedure, aminosugars were converted to their glucosides; this was confirmed by paper chromatography. After the solution had been cooled, dry hydrogen chloride (100 g.) was gradually introduced, with the temperature kept at about −10°C, to precipitate a white solid. This solid was collected, washed with cold methanol and dried (8.5 g.). This was proved by paper chromatography to be composed of approximately equal amounts of I and deoxystreptamine, accompanied by 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-deoxystreptamine (6AD) (minor product) and unchanged kanamycin. The filtrate contained deoxystreptamine, methyl 3-amino-3-deoxy-D-glucoside[8] and methyl 6-amino-6-deoxy-D-glucoside.[8] The solid (8.5 g.) was dissolved in a small quantity of water, placed on a column containing 100 g. of carbon (Wako Pure Chemical Industries, 70—150 mesh, activated at 120°C before use), and developed with water. After an initial portion (600 ml., ninhydrin negative) had been removed, the eluate was cut into 10 g. fractions; deoxystreptamine, 1, 6AD and kanamycin were then eluted in the fractions Nos. 4—18, 16—28, 27—50 and 45—63 respectively. The eluate of Nos. 16—28 was evaporated and dried (3.5 g.). An aqueous solution of the residue was passed through a column of Dowex 1×2 (OH form, 29×500 mm.) and eluted with water. After a small amount of deoxystreptamine had been eluted, the free base of I emerged in a 110—300 ml. portion. This was concentrated to a small volume and neutralized with hydrochloric acid; from the resulting solution, trihydrochloride of I was crystallized by adding methanol and ethanol. Yield, 2.8 g. (31%), m. p. 235—236°C (decomp.) (lit.,[7] 219—219.5°C (decomp.)), $[\alpha]_{589}^{13}$ +75.1°, $[\alpha]_{438}^{13}$ +140.6° (*c* 1.3, water) (lit.,[7] $[\alpha]_{D}^{28}$ +76.1°).

Found: C, 33.43; H, 6.66. Calcd. for $C_{12}H_{25}N_3O_7 \cdot 3HCl$: C, 33.31; H, 6.51%.

6-*O*-(3-Acetamido-3-deoxy-α-D-glucopyranosyl)-*N*, *N*'-diacetyl-deoxystreptamine (II). — Trihydrochloride (500 mg.) of I suspended in aqueous ethanol (7 : 3) was acetylated with acetic anhydride and barium hydroxide. After the solvent had been removed in vacuo, the residue was extracted with ethanol and then evaporated. An aqueous solution of the residue (708 mg.) was treated with Amberlite IRA-400 (OH form) and Amberlite IR-120 (H form) successively. After the solvent had been removed, the residue was crystallized from its methanol solution (1.5 ml.) by adding acetone (5 ml.); it gave 450 mg. of II, which was proved to be pure on thin layer chromatography (R_f, 0.29)*4 with a solvent system of *n*-butanol - pyridine - water - acetic acid (6 : 4 : 3 : 1). A pure sample of II had a m. p. of 238—242°C (decomp.) (lit., m. p. 235—242°C,[5] 176—181°C[9] (decomp.)), $[\alpha]_{589}^{12}$ +80° (*c* 0.45, water) (lit.,[5] $[\alpha]_{D}^{27}$ +72°); IR spectrum (KBr disk): ~3400, 1645 (Amide I), 1557 (Amide II), 1415, 1375 cm^{-1}.

Found: C, 47.16; H, 6.71; N, 8.72. Calcd. for $C_{18}H_{31}N_3O_{10} \cdot 1/2H_2O$: C, 47.16; H, 7.04; N, 9.16%.

6-*O*-(3-Deoxy-2,4,6-tri-*O*-methyl-3-*N*-methylacetamido-α-D-glucopyranosyl)-*N*, *N*'-diacetyl-*N*, *N*'-dimethyl-4, 5-di-*O*-methyl-deoxystreptamine (III). —In a 10 ml.-glass-pressure tube coupled with a pressure gauge there were placed methyl iodide (2.5 g.) and a thoroughly-ground mixture of II (200 mg.) and silver oxide (2.0 g.); the mixture was then heated at 75°C for 3 hr. At the end of this period, the inner pressure reached to 3 atm. After cooling, the whole content was extracted twice with methanol, and the extract was evaporated to dryness. The methylation was repeated several times. During the course of the reaction, in the infrared absorption spectra of the resulting products, the absorption bands at ~3400 cm^{-1} (OH) and ~1550 cm^{-1} (Amide II) gradually faded and those at ~2920 cm^{-1} and 1450 cm^{-1} became clearer, while the absorption at ~1640 cm^{-1} (Amide I) remained unchanged. The final product thus obtained was dissolved in chloroform, and, after filtration, the solution was evaporated to dryness. An aqueous solution of the residue was treated with active charcoal and then evaporated to give a white solid, 187 mg.; m. p. 98—100°C, $[\alpha]_{D}^{18}$ +94° (*c* 1, water). On thin layer chromatography with dioxane, the product showed a single spot with an R_f of 0.2. IR spectrum (KBr disk): 2920, 2815, 1640, 1450, 1410, 1375 cm^{-1}.

Found: C, 55.42; H, 8.47; N, 7.51. Calcd. for $C_{26}H_{47}O_{10}N_3$: C, 55.59; H, 8.43; N, 7.48%.

***N*, *N*'-Dimethyl-4, 5-di-*O*-methyldeoxystreptamine (IV).** — A sample of III (400 mg.) was dissolved in 3 N hydrochloric acid (20 ml.) in a sealed tube and then heated in a boiling water bath for 6 hr. After evaporation in vacuo, the syrup was deacidified by co-evaporation with water. A solution of the residue in a solvent system of *n*-butanol - pyridine - water - acetic acid (6 : 4 : 3 : 1) was chromatographed on a cellulose powder column (45×165 mm.) and eluted with the same solvent. Ninhydrin-active substances emerged in 100—120, 180—240 and 260—380 ml. portions. The last portion, which had no reducing property, was concentrated to a small volume and then again chromatographed through a Dowex 1×2 column (OH form, 8×320 mm.) with water. Ninhydrin-active fractions were collected and evaporated to dryness. The residue was dissolved in chloroform, and, after filtration, the solution was evaporated to dryness (140 mg.). The residue was dissolved in water, neutralized with hydrochloric acid, and evaporated to dryness to give a solid, which was then recrystallized from ethanol to give dihydrochloride of IV; yield, 120 mg.; m. p. 228—231°C (decomp.), $[\alpha]_{589}^{15}$ +13.6° (*c* 0.3 water); IR spectrum (KBr disk): 3360, 2940, 2825, 2740, 2440, 1585 (δNH_2^+), 1465, 1385, 1340 cm^{-1}.

Found: C, 41.00; H, 8.12; N, 9.37. Calcd. for $C_{10}H_{22}O_3N_2 \cdot 2HCl$: C, 41.24; H, 8.31; N, 9.62%.

The NMR spectrum of the base IV was determined at a frequency of 60 Mc.p.s. with a Varian A 60 spectrometer in deuteriochloroform, and also in the same solvent including a few drops of deuteroxide (Fig. 1). Tetramethylsilane was used as the internal reference.

***N*, *N*'-Diacetyldeoxystreptamine (V).**—A deoxystreptamine base (500 mg.) suspended in dry methanol (5 ml.) was vigorously stirred into acetic anhydride (1.3 ml.); the reaction was then continued for 3 hr.

8) H. Ogawa, T. Ito, S. Inoue and S. Kondo, ibid., **A11**, 70, 72 (1958).

*4 The free base I has an R_f value of 0.15 with the same solvent.

9) H. Ogawa, T. Ito, S. Kondo and S. Inoue, *J. Antibiotics*, **A11**, 169 (1958).

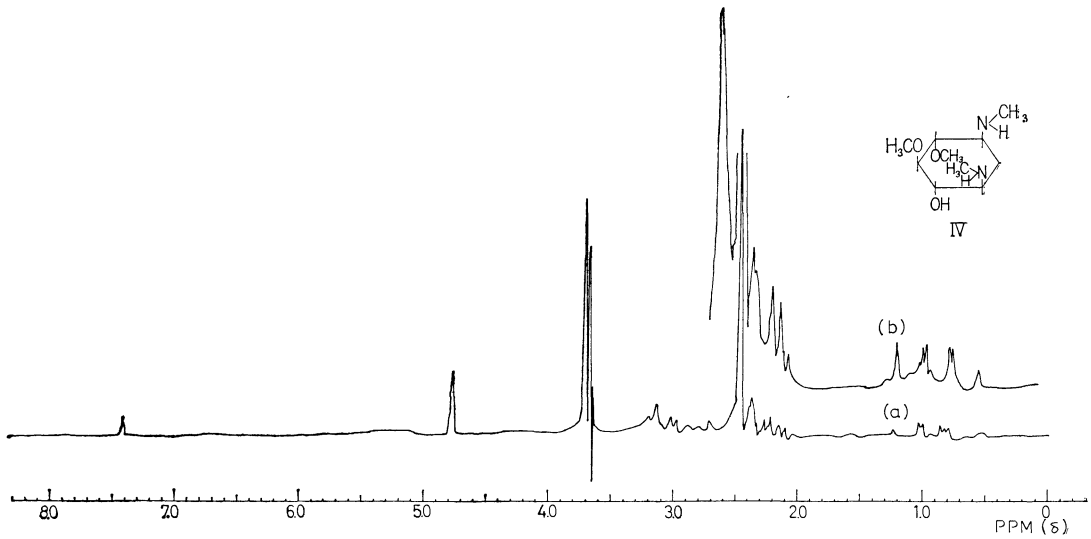


Fig. 1-A. The NMR spectra of *N*, *N'*-dimethyl-4, 5-di-*O*-methyldeoxystreptamine (IV); (a): in the mixture of $CDCl_3$ and a few drops of D_2O, (b): in $CDCl_3$.

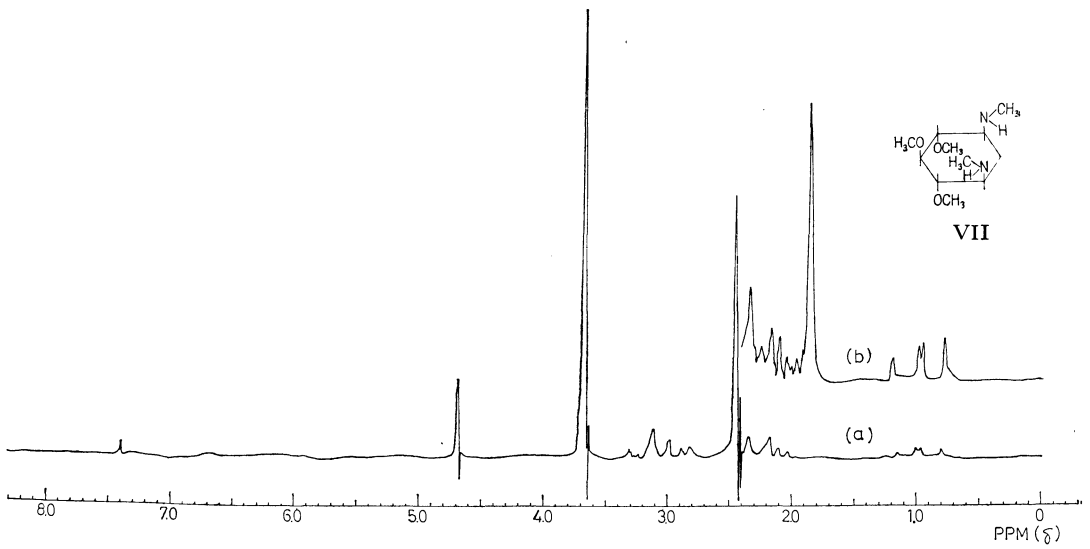

Fig. 1-B. The NMR spectra of *N*, *N'*-dimethyl-4, 5, 6-tri-*O*-methyldeoxystreptamine (VII); (a): in the mixture of $CDCl_3$ and a few drops of D_2O, (b): in $CDCl_3$.

The precipitate was filtered, washed with methanol, and then dissolved in water. To the solution, a small quantity of Amberlite IR-120 (H form) was added to remove the unchanged material; after filtration, the solution was concentrated to a small volume, and ethanol was added to cause crystallization. Yield, 570 mg.; m. p. 250°C (lit.,[10] 292—293°C); IR spectrum (KBr disk): 3450, 3340, 3300, 3120, 2900, 1650 (Amide I), 1580 (Amide II), 1445, 1417, 1385 cm^{-1}.

Found: C, 48.55; H, 7.28; N, 11.08. Calcd. for $C_{10}H_{18}O_5N_2$: C, 48.77; H, 7.37; N, 11.38%.

N, N'-Diacetyl-N,N'-dimethyl-4, 5, 6-tri-O-methyldeoxystreptamine (VI).—In a 20 ml.-glass-pressure tube there were placed methyl iodide (7.0 g.) and a thoroughly-ground mixture of V (200 mg.) and silver oxide (7.0 g.); the mixture was then heated at 85°C for 5 hr. After cooling, the reaction mixture was evaporated. The residue was extracted thrice with water, and the combined extracts were evaporated to dryness. The methylation was repeated thrice more. The change in infrared spectra during the repeated methylation was substantially the same as that concerning III. The product was dissolved in chloroform, and, after filtration, the solution was evaporated to give a white solid, 209 mg.; m. p. 207—208°C (decomp.); IR spectrum (KBr disk): 2920,

2820, 1640 (Amide I), 1445, 1410, 1380 cm^{-1}.

Found: C, 56.94; H, 8.92; N, 8.85. Calcd. for $C_{15}H_{28}O_5N_2$: C, 56.73; H, 8.71; N, 8.70%.

***N*, *N'*-Dimethyl-4, 5, 6-tri-*O*-methyl-deoxystreptamine (VII).**—A solution of VI (400 mg.) in 2 N hydrochloric acid (20 ml.) was heated in a boiling water bath for 5 hr. and then concentrated under reduced pressure. The residual syrup was deacidified by co-evaporation with water. A solution of the residue in a small quantity of a solvent mixture of *n*-butanol - pyridine - water - acetic acid (6 : 4 : 3 : 1) was chromatographed on a cellulose powder column (45×250 mm.) with the same solvent, and each fraction (15 ml.) was tested by ninhydrin-coloration. Ninhydrin-active substances were eluted in Tubes Nos. 37—42 and Nos. 47—49. The former fractions were collected, evaporated, and dried. The residue (220 mg.) was dissolved in a small quantity of water and passed through a column of Dowex 1×2 (OH form, 8× 370 mm.) with water. The ninhydrin-active fractions were again collected and evaporated to dryness. The residue was dissolved in chloroform, and, after filtration, the solution was again evaporated to dryness. An aqueous solution of the residue was treated with active charcoal, neutralized with hydrochloric acid, and evaporated. Recrystallization from its methanol solution by adding acetone gave crystalline dihydrochloride of VII; yield, 155 mg.; m. p. 215—216°C (decomp.), $[\alpha]_{589}^{15}$ +3° (*c* 0.3, water). This has an R_{fIV}*5 value of 1.5 on paper chromatography with a solvent system of *t*-amylalcohol - pyridine - water - acetic acid (6 : 4 : 3 : 1). IR spectrum (KBr disk); 3380, 2940, 2820, 2720, 2450, 1610 (δNH_2^+), 1470, 1390 cm^{-1}.

Found: C, 43.19; H, 8.40; N, 8.97. Calcd. for $C_{11}H_{24}O_3N_2 \cdot 2HCl$: C, 43.28; H, 8.58; N, 9.18%.

The NMR spectrum of the base VII was determined as described in the procedure for IV (Fig. 1).

The authors are indebted to Mr. Saburo Nakada of this Laboratory for the microanalysis. This research was supported in part by a grant from the Microbial Chemistry Foundation, to which the authors' thanks are due.

*5 R_{fIV} is an R_f value relative to the R_f value of *N*, *N'*-dimethyl-4, 5-di-*O*-methyldeoxystreptamine (IV), the latter taken as 1.0.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1248—1253 (1966)

A New Mode of the Formation of the Meso-ionic Pyrido[2, 1-b]-3, 4-dihydro-4-oxothiazole: An Attempted Preparation of Pyrido[2, 1-b]-3, 5-dihydro-5-oxothiazole[1-3]

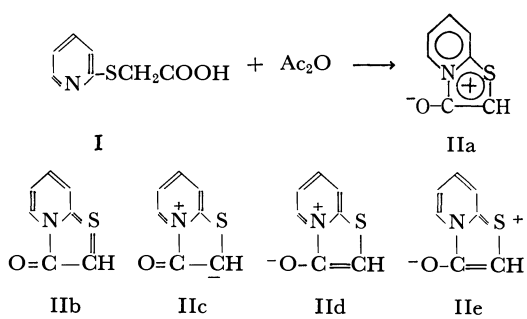
By Hiroshi KATO, Kazuo TANAKA and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 27, 1965)

The acylation of 2-mercaptopyridine gives *S*-acyl derivatives, which, on treatment with chloroacetic acid, give the title compound.

The structure of the reaction product of (2-pyridylthio)acetic acid (I) and acetic anhydride was reinvestigated by Duffin and Kendall[4] and was shown to have a pyrido [2, 1-b]thiazole skeleton (II). This type of ring formation has since then been extended to many aza-heterocyclic systems with a mercapto group *ortho* to the ring nitrogen atom.[6-8]



I IIa

IIb IIc IId IIe

Duffin and Kendall first[5] classified this type of compound as meso-ionic, but later[6] they abandoned this idea in favor of the structure IIb, in which the participation of the sulfur d-orbitals gives rise to a wholly covalently-bonded structure. In our opinion, however, though the structure

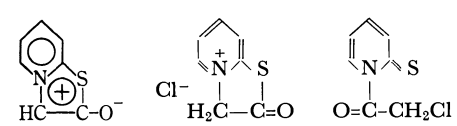
IIb certainly would contribute to some degree to the resonance of this compound, other cannonical structures, such as IIc-e, would also be important participants in the resonance; therefore, we feel it more reasonable to assume the meso-ionic structure for this type of compound.

The present investigation was initiated with the idea of preparing a condensed ring system III, in which the positions of the CH and CO groups in the ring are reversed relative to the structure II. The preparation of such a ring system may be interesting because, for this ring system, no single satisfactory covalently-bonded structure can be devised, even if the sulfur d-orbitals are considered for the bonding. The preparation of such a ring system and comparison of its properties with those of the compound II would give a wealth of information concerning the evaluation of the degree of the contribution of the sulfur d-orbitals to the ring. Uncondensed ring system with the same arrangement of the atoms in the meso-ionic part of the ring as in III has been prepared by Lawson and others,[9] and has been found to be quite stable.

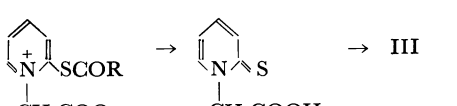
Results and Discussion

As a possible route toward a synthesis of III, we first tried the reaction of 2-mercaptopyridine with chloroacetyl chloride, anticipating the formation of an intermediate, IV. When this reaction was carried out in a dilute aqueous solution of sodium hydroxide, the reaction product was (2-pyridylthio)acetic acid (I). In order to avoid hydrolytic conditions, the same reaction in dry benzene was attempted; the crude reaction product was then treated immediately with acetic anhydride and sodium acetate. The reaction product isolated was compound II. From this result, it seems likely that the reaction first gave an *N*-acylated product (V), which then went through ring closure to give compound II.



III IV V

VI



A similar reaction is reported by Goerdeler et al.,[10] who report that the acylation of thioamides with acyl chlorides gives *N*-acyl derivatives, or that the *S*-acyl derivatives first formed rearrange to give the *N*-acyl derivatives.

In order to secure the pyridine nitrogen atom as the only available position to an attack of chloroacetyl group, we tried to prepare III by the above-described series of reactions. 2-Acylthiopyridines (VI) were prepared by heating 2-mercaptopyridine with acetic anhydride, or by the treatment of sodium 2-pyridylmercaptide with acetyl or benzoyl chloride. Infrared absorptions of the acetylated compound at 1050, 652 and 768 cm^{-1} which have been assigned to a (C=O)S group,[11] the lack of absorptions of a non-aromatic double-bond system between 1600 and 1700 cm^{-1} (1620 and 1623 cm^{-1} have been reported for 2-thiopyridone and *N*-methyl-2-thiopyridone[12]); and a similar absorption pattern of the acetyl derivative to that of 2-methylthiopyridine[13] support the *S*-acetyl structure against the *N*-acetyl structure. Further, they are soluble in dilute hydrochloric acid, from which they can be recovered by rapid and careful neutralization. From this fact, it may be deduced that *S*-acylated 2-mercaptopyridines are not very sensitive to hydrolysis, but they are readily attacked by nucleophilic reagents; 2-acetylthiopyridine, for example, reacts rapidly at room temperature with aniline to form 2-mercaptopyridine and acetanilide. When 2-acetylthiopyridine was warmed with chloroacetic acid in benzene, an exothermic reaction took place to give a resinous product, the treatment of which with water or ethanol created a new precipitate which was identical with II. The same product, II, was formed by a similar reaction of 2-benzoylthiopyridine with chloroacetic acid. In this case, benzoic acid was also formed.

These results suggest a rapid reaction of 2-acylthiopyridines with chloroacetic acid to give (2-pyridylthio)acetyl acylates VIIa or chloride VIIb. To check this possibility, 2-acetylthiopyridine was warmed in benzene with ethyl chloroacetate. The reaction products were ethyl (2-pyridylthio)acetate (VIII) and acetyl chloride, the former being identified by conversion to (2-pyridylthio)acetic acid, and the latter, by conversion to acetanilide.

Of special interest would be the reaction of 2-acylthiopyridines with chloroacetamide, because,

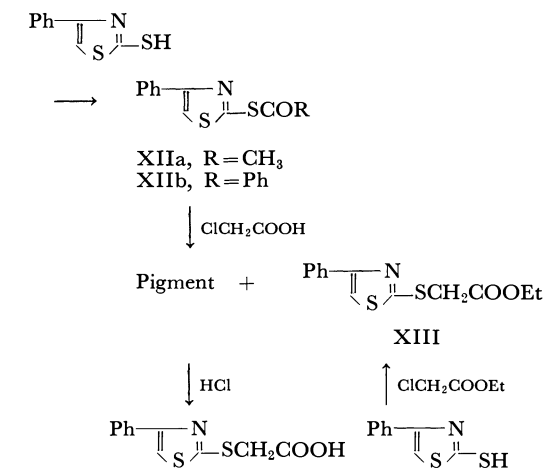
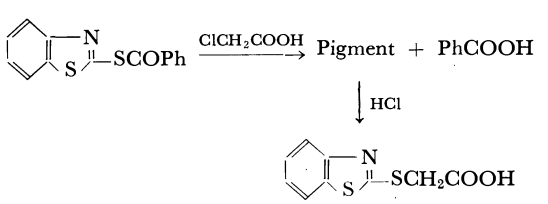
VIII

if a similar type of reaction takes place, it would give an *N*-acyl derivative IX, which would give either compound II by the removal of the acylimino group (route a) or a new meso-ionic compound, X, by dehydration (route b).[14] When 2-acetylthiopyridine was warmed in benzene with chloroacetamide, compound II was formed. The same compound, II, was formed from 2-benzoylthiopyridine. When (2-pyridylthio)acetamide (XI), prepared from 2-mercaptopyridine and chloroacetamide, was treated with acetyl chloride, the same compound, II, was again formed. It has been reported[5] that no reaction occurs upon the treatment of (2-quinolylthio)acetamide with acetic anhydride, though the corresponding anhydro base was formed when (2-quinolylthio)acetic acid was heated with acetic anhydride. This is probably due to an insufficient acylating power of an acid anhydride to give an *N*-acyl derivative, IX.

The foregoing reactions would, in principle, be the same as the reaction of (2-pyridylthio)-acetic acid with an equimolar amount of acyl chloride. This type of reaction was applied to 4-phenyl-2-mercaptothiazole and to 2-mercaptobenzothiazole. With the (thiazolylthio)acetic acids derived from these compounds, it has been reported[7] that the reaction with acetic anhydride always gives intractable red pigments of unknown structures instead of the corresponding meso-ionic rings. The treatment of 4-phenyl-2-mercaptothiazole with acetic anhydride gave the acetyl derivative (XIIa); this derivative, on being warmed with chloroacetic acid in benzene, gave the same pigment as that reported earlier[7] and a compound with the formula $C_{11}H_{11}ON_3S_2$ after recrystallization from ethanol. The latter compound gave a hydrazide with hydrazine hydrate and, on hydrolysis, gave (4-phenylthiazolyl-2-thio)acetic acid. The compound was identified as ethyl (4-phenylthiazolyl-2-thio)acetate (XIII) by comparison with a specimen which was prepared from 4-phenyl-2-mercaptothiazole and ethyl chloroacetate. The same amorphous pigment and benzoic acid were formed by the reaction of chloroacetic acid and 2-benzoylthio-4-phenylthiazole





14) The preparation of this ring system will be the subject of the following paper.

(XIIb), which had been prepared from 4-phenyl-2-mercaptothiazole and benzoyl chloride. The pigment gave (4-phenylthiazolyl-2-thio)acetic acid (XIV) by acid hydrolysis. The fact that an identical substance was formed from both the *S*-acetyl and *S*-benzoyl derivatives shows that these acyl groups are absent in the reaction product; the actual structure of this product, however, still remains to be elucidated. When 2-benzoylthiobenzothiazole was treated with chloroacetic acid in benzene, a red pigment, with a quantitative amount of benzoic acid, and a small amount of 2-mercaptobenzothiazole were formed. The pigment was identical with the reaction product of (2-benzothiazolylthio)acetic acid and acetic anhydride.[7] The red pigment gave a small amount of (2-benzothiazolylthio)acetic acid by acid hydrolysis.

Experimental

All melting points were determined on a micro hot stage and are corrected. All boiling points are uncorrected. The infrared spectra were taken on a Nippon Bunko Spectrophotometer, Model S, equipped with an NaCl prism on KBr tablets, unless otherwise stated.

The Reaction of 2-Mercaptopyridine and Chloroacetyl Chloride.—a) To a solution of 2 g. of 2-mercaptopyridine and 1.4 g. of sodium hydroxide in 50 ml. of water, 4 g. of chloroacetyl chloride was added in one portion with cooling and vigorous stirring. The stirring was continued until the excess chloroacetyl chloride had been decomposed. The crystals which separated out were collected and were recrystallized from ethanol to give 2.3 g. of yellow crystals with a green fluorescence, m. p. 130°C. Recrystallization from ethanol raised the m. p. to 136—137°C. This substance is soluble in 5% aqueous sodium bicarbonate. The melting point of this substance was undepressed on admixture with an authentic specimen of (2-pyridylthio)acetic acid (I).

b) An aqueous solution of 2 g. of 2-mercaptopyridine and 0.8 g. of sodium hydroxide was concentrated to dryness under reduced pressure. Benzene was added to the residue, and to this suspension was added 2.2 g. of chloroacetyl chloride in one portion with cooling and stirring. After thirty minutes, the dark green precipitate was collected and then warmed on a water bath for thirty minutes with a mixture of acetic acid, acetic anhydride and anhydrous sodium acetate. The mixture was concentrated under reduced pressure, the residue was treated with ice water, and the greenish yellow precipitate was collected and recrystallized from ethanol to give 0.5 g. of yellow silky needles, m. p. 189°C, undepressed on admixture with an authentic specimen of pyrido[2,1-b]-3,4-dihydro-4-oxothiazole (II).

Found: C, 55.24; H, 3.60; N, 9.23. Calcd. for C_7H_5ONS (II): C, 55.63; H, 3.34; N, 9.27%.

2-Acetylthiopyridine (VI, R=CH_3).—a) A mixture of 14 g. of 2-mercaptopyridine and 26 ml. of acetic anhydride was refluxed for one hour. The excess acetic anhydride and acetic acid were then distilled off under reduced pressure, and the residual oil was distilled to give 13 g. of a yellow liquid, boiling at 96—99°C/3.5 mmHg.

Found: C, 54.56; H, 4.86; N, 9.30. Calcd. for C_7H_7ONS: C, 54.90; H, 4.61; N, 9.15%.

This substance is soluble in dilute hydrochloric acid. IR (liquid film); strong absorptions at 1708, 1578, 1450, 1420, 1350, 1110, 1050, 991, 952 and 768 cm^{-1}.

b) An aqueous solution of 0.8 g. of sodium hydroxide and 2.2 g. of 2-mercaptopyridine was concentrated to dryness under reduced pressure. The residue was suspended on benzene, and to this suspension was added 2 ml. of acetyl chloride under stirring and cooling. After an hour, water was added to this suspension, and the solution was neutralized with sodium bicarbonate. The benzene layer was separated, and the aqueous layer was extracted with ether. The combined extracts were dried over sodium sulfate and distilled under reduced pressure to give 2 g. of the same substance as that prepared by the preceding procedure.

2-Benzoylthiopyridine (VI, R=C_6H_5).—An aqueous solution of 4.1 g. of sodium hydroxide and 11.6 g. of 2-mercaptopyridine was concentrated to dryness under reduced pressure. The residue was suspended on dry benzene, and 15 g. of benzoyl chloride was stirred into this suspension with cooling. The newly-formed precipitate was filtered off, and the filtrate was distilled under reduced pressure to give 7.3 g. of a colorless liquid boiling at 171.6—172°C/3 mmHg; this liquid soon solidified to white needles, m. p. 44—45°C. This substance is soluble in dilute hydrochloric acid.

Found: C, 66.67; H, 4.39; N, 6.48. Calcd. for $C_{12}H_9ONS$: C, 66.97; H, 4.22; N, 6.51%.

The Reaction of 2-Acetylthiopyridine with Aniline.—To a solution of 1 g. of 2-acetylthiopyridine in 10 ml. of benzene, 1 ml. of aniline was added with cooling by an ice bath. After thirty minutes, benzene was removed by distillation under reduced pressure. The residual oil solidified upon the addition of petroleum ether. It was then washed with 5% hydrochloric acid, and the residue (0.7 g., m. p. 115°C) was recrystallized from water to give 0.4 g. of colorless leaflets, m. p. 116°C, undepressed on admixture with an authentic specimen of acetanilide.

The hydrochloric acid washings were neutralized with sodium bicarbonate and were extracted with chloroform. The chloroform extracts were dried over magnesium sulfate and concentrated, and the residue was recrystallized from benzene to give 0.2 g. of yellow prisms, melting at 129—130°C, undepressed on admixture with an authentic specimen of 2-mercaptopyridine.

The Reaction of 2-Acetylthiopyridine and Chloroacetic Acid.—To a solution of 0.5 g. of 2-acetylthiopyridine in dry benzene, 0.31 g. of chloroacetic acid was added; then the mixture was slightly warmed on a water bath. An exothermic reaction took place, and an oily substance separated out. After five minutes, the benzene layer was decanted and, on the addition of ethanol, the oily substance solidified to give a yellowish-green powder. This powder was collected by filtration, suspended on water, and neutralized with sodium bicarbonate. The yellow suspension which resulted was collected and recrystallized from ethanol to give 0.3 g. of yellow silky needles, melting at 181—183°C,

undepressed on admixture with an authentic specimen of pyrido[2, 1-b]-3, 4-dihydro-4-oxothiazole.

Found: C, 55.24; H, 3.60; N, 9.23. Calcd. for C_7H_5ONS (II): C, 55.63; H, 3.34; N, 9.27%.

The Reaction of 2-Benzoylthiopyridine and Chloroacetic Acid.—To a solution of 0.5g. of 2-benzoylthiopyridine in 2 ml. of dry benzene, 0.22 g. of chloroacetic acid was added. The mixture was then warmed on a water bath for five minutes. When the oily substance which separated out was worked up by essentially the same procedure as that described above, 0.1 g. of yellow silky needles were obtained; the m. p. and mixed m. p. with II was 178—179°C.

The benzene mother liquor of the above experiment was extracted wtih an aqueous solution of sodium bicarbonate, and the aqueous extract was acidified with hydrochloric acid to give 0.1 g. of benzoic acid.

The Reaction of 2-Acetylthiopyridine and Ethyl Chloroacetate.—A solution of 1.53 g. of 2-benzoylthiopyridine and 1.23 g. of ethyl chloroacetate in 10 ml. of benzene was gently boiled on a water bath and the heating was so adjusted that a small but steady amount of a distillate came out through a short air condenser. The distillate, with a peculiar odor of acetyl chloride, was poured into a solution of 1 g. of aniline in 2 ml. of benzene. The crystals which separated out were collected and washed with a small amount of water to afford 0.75 g. of white crystals, m. p. 108—110°C. One crystallization from hot water gave pure acetanilide as colorless leaflets, m. p. 114°C, undepressed on admixture with an authentic specimen.

The reaction mixture of the above experiment was concentrated under reduced pressure, and the viscous oily residue which could not be crystallized was washed with 5% aqueous sodium bicarbonate and warmed with 10 ml. of 10% hydrochloric acid on a water bath for thirty minutes. The mixture was then concentrated under reduced pressure, and the residue was extracted with aqueous sodium bicarbonate. The extract was washed with benzene and was neutralized with hydrochloric acid to give 1.0 g. of yellow crystals melting at 133—134°C. One recrystallization from ethanol gave a pure sample of (2-pyridylthio)acetic acid, melting at 136°C, undepressed on admixture with an authentic specimen.

The Reaction of 2-Acetylthiopyridine with Chloroacetamide.—A solution of 1.5 g. of 2-acetylthiopyridine and 0.94 g. of chloroacetamide in 10 ml. of dry benzene was refluxed for thirty minutes on a water bath. The residue which separated out was collected, washed with ethanol and water, and neutralized with sodium bicarbonate. The green precipitate was recrystallized from benzene to give 0.35 g. of orange silky needles, melting at 181—183°C. The melting point of this substance was undepressed on admixture with an authentic specimen of II.

Found: N, 9.13. Calcd. for C_7H_5ONS: N, 9.27%.

The Reaction of 2-Benzoylthiopyridine with Chloroacetamide.—A solution of 2.15 g. of 2-benzoylthiopyridine and 0.94 g. of chloroacetamide in 5 ml. of benzene was refluxed on a water bath for one hour. The green precipitate which separated out was worked up by the procedure described in the above experiment, to give 0.1 g. of greenish yellow needles of II, m. p. 181—183°C, undepressed on admixture with an authentic specimen.

Found: N, 8.96. Calcd. for C_7H_5ONS: N, 9.27%.

(2-Pyridylthio)acetamide (XI).—To a solution of 1 g. of 2-mercaptopyridine and 0.36 g. of sodium hydroxide in 4 ml. of ethanol, 0.48 g. of chloroacetamide was added with cooling and stirring. The precipitate which separated out was filtered off, the filtrate was concentrated under reduced pressure, and the residue was recrystallized from benzene to give 1.5 g. of white leaflets, m. p. 80°C.

Found: C, 49.88; H, 4.88; N, 16.88. Calcd. for $C_7H_8ON_2S$: C, 50.00; H, 4.80; N, 16.66%.

The Reaction of (2-Pyridylthio)acetamide and Acetyl Chloride.—A solution of 0.9 g. of (2-pyridylthio)acetamide and 0.5 g. of acetyl chloride in 5 ml. of benzene was refluxed for one hour. The precipitate which separated out was collected, washed with aqueous sodium bicarbonate, and recrystallized from benzene to give 0.36 g. of greenish yellow needles, m. p. 181—183°C undepressed on admixture with an authentic specimen of II.

4-Phenyl-2-acetylthiothiazole (XIIa).—A mixture of 2 g. of 4-phenyl-2-mercaptothiazole and 4 ml. of acetic anhydride was refluxed for one hour, the resultant solution was concentrated under reduced pressure, and the residue was recrystallized from benzene to give 1.8 g. of white plates melting at 89°C (yield, 77%).

Found: C, 55.94; H, 4.06; N, 5.94. Calcd. for $C_{11}H_9ONS_2$: C, 56.17; H, 3.86; N, 5.96%.

The Reaction of 4-Phenyl-2-acetylthiothiazole with Chloroacetic Acid.—A mixture of 10 g. of 4-phenyl-2-acetylthiothiazole and 4.7 g. of chloroacetic acid in 20 ml. of benzene was warmed on a water bath for one hour. Ethanol was added to the mixture, and the red amorphous powder which separated out was collected and recrystallized from pyridine to give 5 g. of a red amorphous powder, m. p. 185°C.

Found: C, 56.37; H, 3.64; N, 6.16%.

The infrared spectrum of this substance was identical with that of the reaction product between (4-phenylthiazolyl-2-thio)acetic acid and acetic anhydride.[7]

The filtrate of the above experiment was concentrated under reduced pressure, and the residue was purified by column chromatography (alumina-benzene) and recrystallized from ethanol to give 3.6 g. of colorless prisms, m. p. 62°C, undepressed on admixture with ethyl (4-phenylthiazolyl-2-thio)acetate (XIII) prepared by the method described below.

Found: C, 55.74; H, 4.91; N, 4.91. Calcd. for $C_{13}H_{13}O_2NS$: C, 55.91; H, 4.70; N, 5.02%.

Hydrazide: white needles, m. p. 105—106°C, undepressed on admixture with a sample prepared by another route (see below).

Found: N, 15.97. Calcd. for $C_{11}H_{11}ON_3S_2$: N, 15.84%.

Ethyl (4-Phenylthiazolyl-2-thio)acetate (XIII).—To a solution of 5 g. of 4-phenyl-2-mercaptothiazole and 1.5 g. of potassium hydroxide in 50 ml. of ethanol, there was added 3.2 g. of ethyl chloroacetate with stirring and cooling. The precipitate was removed by filtration, the filtrate was concentrated, and the residue was recrystallized from ethanol to give 5.5 g. of white needles, m. p. 62—63°C.

Found: N, 15.97. Calcd. for $C_{13}H_{13}O_2NS_2$: N, 5.02%.

Hydrazide: white needles, m. p. 105—106°C.

4-Phenyl-2-benzoylthiothiazole (XIIb).—A mixture of 2 g. of 4-phenyl-2-mercaptothiazole and 3 ml. of benzoyl chloride was gently refluxed for one hour. After cooling, the crystals which separated out were collected and recrystallized from benzene to give 2.3 g. of pale yellow crystals, m. p. 95—96°C (yield, 81%).

Found: C, 64.89; H, 3.72; N, 4.48. Calcd. for $C_{16}H_{11}ONS_2$: C, 64.64; H, 3.72; N, 4.71%.

The Reaction of 4-Phenyl-2-benzoylthiothiazole with Chloroacetic Acid.—When 4-phenyl-2-benzoylthiothiazole was treated with chloroacetic acid under conditions similar to those in the case of 2-acetylthio derivative, the same red pigment (identical in infrared spectrum with that from 2-acetylthio derivative) was isolated. From the mother liquor of the reaction medium, a quantitative amount of benzoic acid was isolated.

The Acid Hydrolysis of the Red Pigment.—The red substance isolated from the preceding experiment (0.5 g.) was refluxed for one hour in 20 ml. of concentrated hydrochloric acid, and then the reaction mixture was concentrated under reduced pressure. The residue was extracted with aqueous sodium bicarbonate, and the extracts were acidified by the addition of hydrochloric acid. The crystals (0.2 g.) which separated out were recrystallized from ethanol to give white needles, m. p. 91—92°C, undepressed on admixture with an authentic specimen of (4-phenylthiazolyl-2-thio)acetic acid.[7]

The Reaction of 2-Benzoylthiobenzothiazole with Chloroacetic Acid.—A mixture of 10 g. of 2-benzoylthiobenzothiazole and 3.5 g. of chloroacetic acid in 20 ml. of benzene was warmed at 60°C for one and a half hours, and then the benzene was removed under reduced pressure. The red residue was washed with ether and ethanol, and then recrystallized from ethanol to give 4.6 g. of fine red needles, m. p. 234°C. The infrared spectrum of this substance was identical with that of the reaction product between (benzothiazolyl-2-thio)acetic acid and acetic anhydride.[7]

Found: C, 53.05; H, 2.56; N, 6.34%.

The ether washings of the above experiment were extracted with aqueous sodium bicarbonate, the extract was acidified with hydrochloric acid, and the crystals which separated out were collected and recrystallized from water to give 1.5 g. of benzoic acid as white leaflets melting at 122°C, undepressed on admixture with an authentic specimen of benzoic acid.

The ether layer separated from sodium bicarbonate washing was concentrated, and the residue was extracted with ethanol to give a small amount of an amorphous yellow powder melting at 179—180°C, undepressed on admixture with an authentic specimen of 2-mecrapto-benzothiazole.

Found: N, 8.70. Calcd. for $C_7H_5NS_2$: N, 8.38%.

The Acid Hydrolysis of the Red Pigment.—The red pigment obtained by the above-described experiment (0.5 g.) was refluxed in 10 ml. of concentrated hydrochloric acid for one hour, and then the mixture was concentrated under reduced pressure. The residue was extracted with aqueous sodium bicarbonate, the extract was acidified with hydrochloric acid, and the precipitate which separated out was recrystallized from ethanol to give 0.1 g. of (benzothiazolyl-2-thio)acetic acid, melting at 156°C, undepressed on admixture with an authentic specimen.

The Synthesis of Pyrido[2, 1-b]-3, 4-dihydro-4-iminothiazole Derivatives. A New Meso-ionic Heterocyclic System[1,2]

By Hiroshi KATO and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received October 27, 1965)

The action of acyl chlorides on 2-pyridylthioacetonitrile and related compounds gives the corresponding *N*-acylated pyrido[2, 1-b]-3, 4-dihydro-4-iminothiazoles and related compounds.

In the preceding paper of this series,[1] the formation of pyrido[2, 1-b]-3, 4-dihydro-4-oxothiazole (I) by a new mode of formation was reported. Although a considerable amount of work has been reported on this ring system, the corresponding imino derivatives (e. g., II) were not known when this investigation was completed.[3] An attempt to prepare this compound by the reaction of (2-pyridylthio)acetamide and acetyl chloride gave the oxo derivative I, as we have reported.[1] In the present communication, we will report the successful preparation of *N*-acyl-pyrido[2, 1-b]-3, 4-dihydro-4-iminothiazoles (II) and related compounds.

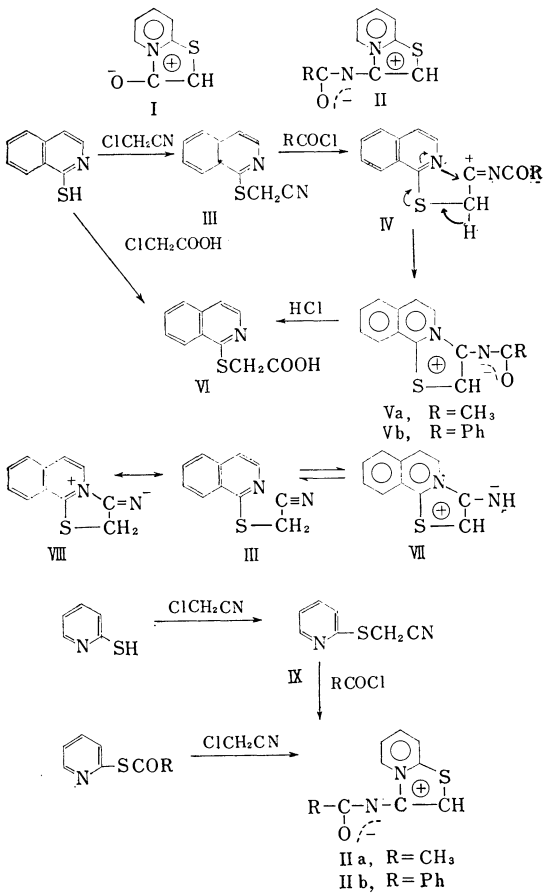
1) Studies on Meso-ionic Compounds. Part XXV. Part XXIV: H. Kato, K. Tanaka and M. Ohta, This Bulletin, **39**, 1248 (1966).

2) For a preliminary communication, see H. Kato, K. Tanaka and M. Ohta, ibid., **35**, 1901 (1962).

3) As a result of our preliminary communication,[2] a number of condensed and uncondensed compounds of this type have been prepared in this laboratory: H. Chosho, K. Ichimura and M. Ohta, This Bulletin, **37**, 1670 (1964); K. Ichimura and M. Ohta, ibid., **38**, 707 (1965).

Results and Discussion

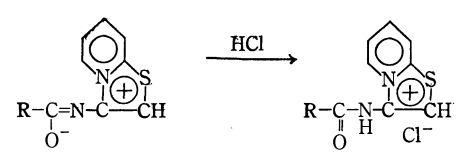
The reaction of 1-mercaptoisoquinoline and chloroacetonitrile gave 1-isoquinolylthioacetonitrile



(III). The presence of a nitrile group was revealed by an infrared absorption at 2240 cm^{-1}. No ring closure took place when it was treated with hydrogen chloride[4] or acetic anhydride. Successful ring closures with these reagents to give meso-ionic compounds have been reported in the case of *N*-nitroso-*N*-phenylglycinonitrile (with hydrogen chloride)[5] and *N*-benzyl-2-pyridylaminoacetonitrile (with acetic anhydride).[6] On heating a benzene solution of 1-isoquinolylthioacetonitrile with acetyl chloride, a hydrochloride was formed, which gave a free base with the empirical formula $C_{13}H_{12}ON_2S$ on treatment with alkali. A similar reaction occurred with benzoyl chloride to give a free base, $C_{18}H_{12}ON_2S$. The infrared absorption at 2240 cm^{-1} has disappeared in these compounds, suggesting that the nitrile group has participated in the reaction. From the above results and known analogous ring formation reactions, it may safely be deduced that the reaction products are *N*-acetyl and *N*-benzoyl-isoquinolo[1, 2-b]-3, 4-dihydro-4-iminothiazole (Va and Vb). The formation of this compound can reasonably be explained by considering the attack of an acyl cation on the nitrile group to give the intermediate cation IV, followed by ring formation and a proton removal to give the products V shown in the above chart. Since the ring nitrogen atom is by far the more basic than the nitrile nitrogen atom, a strong acid such as hydrogen chloride preferably would add to the ring nitrogen atom rather than to the nitrile nitrogen atom to facilitate the polarization, thus resulting in the loss of the nucleophilic aptitude of the ring nitrogen atom. Such is evidently not the case with *N*-nitroso-*N*-substituted glycinonitrile, which gives a sydnone-imine derivative when treated with hydrogen chloride. The failure of ring formation with acetic anhydride is probably due to its poor acylating power in forming the intermediate IV. The fact that it does not give the product with acetic anhydride and the presence of the infrared absorption of III at 2240 cm^{-1} further show the absence of an equilibrium between the open-chain (III) and cyclic (VII) isomers, and even the absence of an intramolecular interaction such as III↔VIII, which is sometimes to be found in structurally similar systems.[7]

This meso-ionic system seems rather stable, and when the *N*-benzoyl derivative Vb was treated with phenylhydrazine, aniline, chromic acid or zinc powder in acetic or hydrochloric acid, or when heated in acetic acid, no reaction took place and the starting material was recovered unchanged. Sydnone-imines which are structurally similar to compound V are quite stable to strong acidic conditions, but the hydrolysis of the *N*-benzoyl derivative Vb by hydrochloric acid caused a cleavage of the ring to give benzoic acid and (1-isoquinolylthio)acetic acid (VI). The structure of the reaction product was established by preparing the compound independently from 1-mercaptoisoquinoline and chloroacetic acid.

The treatment of 2-mercaptopyridine with chloroacetonitrile gave 2-pyridylthioacetonitrile (IX), which, by the action of acetyl and benzoyl chloride, gave *N*-acetyl- and *N*-benzoyl-pyrido-[2, 1-b]-3, 4-dihydro-4-iminothiazole (IIa and IIb) respectively. The same compounds, IIa and IIb, were obtained by the action of 2-acetylthio- and 2-benzoylthio-pyridine and chloroacetonitrile, albeit in lower yields. The mode of formation



4) It was later found[3] that an uncondensed ring system could be prepared by the action of hydrogen chloride.

6) N. W. Bristow, P. T. Charlton, D. A. Peak and W. F. Short, *J. Chem. Soc.*, **1954**, 616.

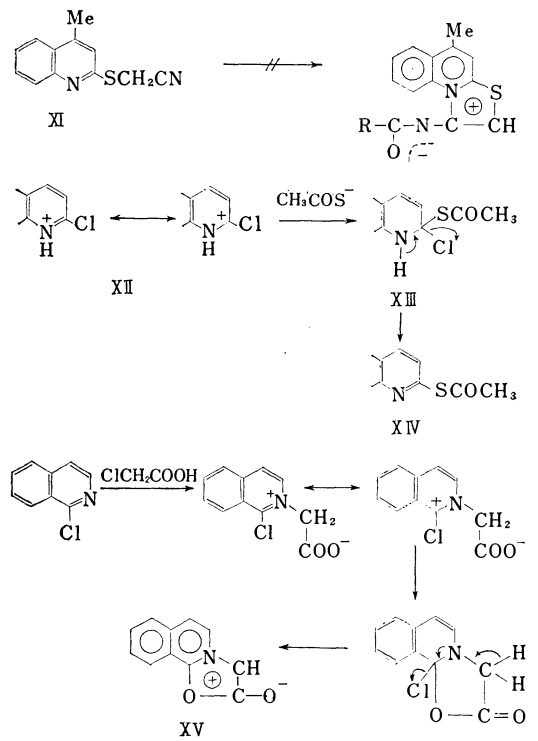
7) See, e.g., M. Ohta and H. Kato, *J. Chem. Soc. Japan, Pure Chem. Sect.* (*Nippon Kagaku Zasshi*), **86**, 661 (1965).

in the latter case would be essentially the same as that of the formation of the corresponding oxo compound I from 2-acylthiopyridine and chloroacetic acid.

Mention should be made of the infrared spectra of these compounds. Neither of the *N*-acetyl free bases, IIa or Va, shows any absorption in the normal amide carbonyl region. This is in marked contrast to the corresponding oxo ring system (e. g., I), which shows an alsmost normal carbonyl absorption at 1675 cm^{-1}, suggesting that the carbonyl groups of II and V are very strongly polarized; it supports further the rather superficial similarity of the oxo and imino-type meso-ionic compounds, as has been discussed elsewhere in the case of sydnones and sydnone-imines.[7,8] In contrast to the common idea, these "amides," II and V, are soluble in dilute hydrochloric acid and form stable hydrochlorides. The infrared absorption of IIa hydrochloride shows a strong absorption due to an amide group at 1702 cm^{-1}. This fact, and the absorption centered at 3180 cm^{-1} show that the proton is attached neither to the ring nitrogen atom nor to the polarized carbonyl oxygen, but to the exocyclic "amide" nitrogen atom, to give a tropylium salt-like structure, X.

A similar treatment of 2-mercapto-4-lepidine with chloroacetonitrile gave 4-lepidly-2-thioacetonitrile (XI), this, however, did not give the expected corresponding imino derivative by the action of acyl chlorides. Since the basicity of this compound is considered to lie between, or to be nearly equal to, those of the pyridyl and isoquinolyl derivatives, this anomalous behavior is certainly not related to the basicity of this compound. (The pK_a's of 2-methylthiopyridine, 2-methylthioquinoline and 1-methylthioisoquinoline are reported to be 3.62, 3.71 and 3.93 respectively.[9]) This result may most reasonably be explained by considering a steric hindrance between the *N*-acyl group and the hydrogen atom of the 8-position of the quinoline nucleus. A similar effect has been observed in an attempted synthesis of the oxo analogue; though (2-quinolylthio)-acetic acid gave the corresponding oxo-compound, when the 8-position of the quinoline ring was substituted, no ring formation took place.[10] In the present case, a study of a model indicates that even a small atom like hydrogen at that position is bulky enough to interact with relatively bulky acyl groups.

It was found that the chlorine atoms of 1-chloroisoquinoline and 2-chloro-4-lepidine are active enough to give, on brief heating with mercaptoacetic acid, almost a quantitative yield of the corresponding mercapto derivatives which are required as the starting materials in this study. This phenomenon can reasonably be explained by considering an attack of the acetothioxy anion on protonated azines XII to give XIII, followed by the removal of a molecule of hydrogen chloride to give XIV, which later gives the mercapto derivatives by hydrolysis or thioacetolysis. This fact led us to try to prepare a new meso-ionic compound, XV, by the following sequence of reactions. When 1-chloroisoquinoline and chloroacetic acid were heated in benzene, the reaction product was isocarbostyril, showing that the attack of chloroacetic acid at the 1-position of the isoquinoline ring precedes the formation of the quaternary salt formation.



Experimental

All melting points were determined on a micro hot stage and are corrected. Boiling points are uncorrected. The infrared spectra were taken on a Nippon Bunko Infrared Spectrometer, Model S, equipped with an NaCl prism on KBr tablets.

1-Isoquinolylthioacetonitrile (III).—To a solution of 1.24 g. of sodium hydroxide and 5 g. of 1-mercaptoisoquinoline in 50 ml. of ethanol, a solution of 2.35 g. of chloroacetonitrile in 10 ml. of ethanol was added; the mixture was then warmed on a water bath for twenty minutes. The precipitate which separated out was filtered off, the filtrate was concentrated under reduced pressure, and the pale yellow plates which separated out on cooling were collected (4 g., m. p. 95.0—95.5°C) and recrystallized from ethanol to give white plates, m. p. 95.5°C. IR, 2240 cm^{-1}.

9) A. Albert and G. B. Barlin, *J. Chem. Soc.*, **1959**, 2384.
10) G. F. Duffin and J. D. Kendall, ibid., **1951**, 734.

Found: C, 65.91; H, 3.84; N, 14.27. Calcd. for $C_{11}H_8NS_2$: C, 65.99; H, 4.03; N, 13.99%.

***N*-Acetyl-isoquinolo[1, 2-b]-3, 4-dihydro-4-iminothiazole (Va).**—To a solution of 1 g. of 1-isoquinolylthioacetonitrile in 6 ml. of benzene, a solution of 0.4 g. of acetyl chloride in 4 ml. of benzene was added; the mixture was then refluxed on a water bath for one hour. The pale yellow precipitate was collected (1.2 g., m. p. 255—256°C) and dissolved in water. The aqueous solution was made alkaline with sodium bicarbonate and was extracted with chloroform. The chloroform extract was dried over sodium sulfate and concentrated, and the yellow fine needles which separated out were collected (0.4 g., m. p. 210—212°C). Recrystallization from benzene afforded 0.2 g. of yellow prisms, melting at 215°C. This substance is soluble in dilute hydrochloric acid. IR: no absorption around 2240 cm^{-1}.

Found: C, 64.25; H, 4.40; N, 11.59. Calcd. for $C_{13}H_{10}ON_2S$: C, 64.46; H, 4.16; N, 11.59%.

***N*-Benzoyl-isoquinolo[1,2-b]-4,3-dihydro-4-iminothiazole (Vb).**—To a solution of 1 g. of 1-isoquinolylthioacetonitrile in 10 ml. of benzene 0.7 g. of benzoyl chloride was added. The mixture was then refluxed on a water bath for ten minutes. The benzene was evaporated, and the residue was warmed on the water bath for another two hours. The dark mass which formed was tritulated with 5 ml. of ethanol, and the solid was collected by filtration to afford 1.25 g. of a brown powder (m. p. 255—260°C). This was dissolved in water, the solution was made alkaline with sodium bicarbonate, and the precipitate which formed was collected to give 1.13 g. of a yellow powder, melting at 271°C. One recrystallization from *n*-butanol gave 0.88 g. of yellow leaflets melting at 273°C. This substance is soluble in 10% hydrochloric acid.

Found: C, 71.30; H, 3.81; N, 9.49. Calcd. for $C_{18}H_{12}ON_2S$: C, 71.04; H, 3.98; N, 9.21%.

The Acid Hydrolysis of the *N*-Benzoyl Compound Vb.—A solution of 1 g. of *N*-benzoyl-isoquinolo[1, 2-b]-3, 4-dihydro-4-iminothiazole in 50 ml. of 10% hydrochloric acid was heated on a water bath for one hour. After cooling, the crystals (portion A) which separated out were collected, and the filtrate was concentrated under reduced pressure. The residue was washed with aqueous sodium bicarbonate and recrystallized from ethanol-ligroin to give 0.25 g. of silky white needles melting at 96°C. The melting point of this substance was not depressed on admixture with a sample of (1-isoquinolylthio)acetic acid prepared by the method to be described below.

Found: N, 6.62. Calcd. for $C_{11}H_9O_2NS$: N, 6.39%.

The sodium bicarbonate washings were acidified with hydrochloric acid, and the crystals which separated out were added to portion A and recrystallized from water to give 0.35 g. of colorless needles; these needles were identified as benzoic acid by their melting point (122°C) and mixed melting point with an authentic sample of benzoic acid.

(1-Isoquinolylthio)acetic Acid (VI).—Into a solution of 0.8 g. of 1-mercaptoisoquinoline and 0.4 g. of sodium hydroxide in a mixture of 20 ml. of ethanol and 2 ml. of water, 0.5 g. of chloroacetic acid was stirred. After two hours, the precipitate of sodium chloride was filtered off; the new crystals which separated out on cooling were collected and dissolved in water, and the aqueous solution was acidified with acetic acid. The crystals which separated out were recrystallized from ethanol-ligroin to give 0.5 g. of silky white needles melting at 98°C.

Found: N, 6.53. Calcd. for $C_{11}H_9O_2NS$: N, 6.39%.

2-Pyridylthio acetonitrile (IX).—Into a solution of 9.3 g. of 2-mercaptopyridine and 5.3 g. of sodium hydroxide in 50 ml. of ethanol, 6.3 g. of chloroacetonitrile was stirred while the solution was being cooled. The precipitate of sodium chloride was removed by filtration, and the filtrate was concentrated and distilled under reduced pressure to give 9.5 g. of a yellow liquid boiling at 118—120°C/3 mmHg.

Found: C, 55.03; H, 3.90; N, 18.26. Calcd. for $C_7H_6N_2S$: C, 56.00; H, 4.03; N, 18.66%.

This substance darkened quite rapidly, and no good analytical agreement was obtained on several repeated analyses.

***N*-Acetyl-pyrido[2, 1-b]-3, 4-dihydro-4-iminothiazole (IIa).**—a) A solution of 2 g. of 2-pyridylthioacetonitrile and 0.95 ml. of acetyl chloride in 10 ml. of benzene was refluxed on a water bath for one hour. The precipitate which formed was then collected to give 3.0 g. of a yellow powder. Recrystallization from ethanol afforded 2.1 g. of yellow prisms melting at 250°C. IR: 1702 cm^{-1}.

Found: N, 12.04. Calcd. for $C_9H_9ON_2SCl$: N, 12.25%.

This substance was dissolved in water, made alkaline with potassium carbonate, and extracted with chloroform. The chloroform extracts were concentrated, and the residue was recrystallized from benzene to give 1.3 g. of yellow needles, melting at 73—74°C.

Found: C, 51.52; H, 5.06; N, 13.58. Calcd. for $C_9H_8ON_2S+H_2O$: C, 51.42; H, 4.80; N, 13.33%.

After being dried at 60°C under a vacuum for a day:

Found: N, 14.02. Calcd. for $C_9H_8ON_2S$: N, 14.58%. This substance is soluble in dilute hydrochloric acid. IR: no strong absorption between 1700—1600 cm^{-1}.

b) A solution of 1 g. of 2-acetylthiopyridine and 0.5 g. of chloroacetonitrile in 3 ml. of benzene was refluxed on a water bath for one hour. The crystals which separated out were collected to give 0.9 g. of a dark yellow powder, which was then recrystallized from ethanol to give 0.45 g. of orange needles, m. p. 252—254°C (decomp.).

Found: N, 12.03. Calcd. for $C_9H_9ON_2SCl$: N, 12.25%.

***N*-Benzoyl-pyrido[2, 1-b]-3, 4-dihydro-4-iminothiazole (IIb).**—a) A solution of 2 g. of 2-pyridylthioacetonitrile and 1.54 ml. of benzoyl chloride in 10 ml. of benzene was refluxed for one hour on a water bath. The benzene was then evaporated, and the residue was warmed on a water bath for another thirty minutes. The crystals which separated out on cooling were collected to give 3 g. of a pale yellow powder. This substance was suspended in water and made basic with sodium bicarbonate. The resultant solid was collected to give 2.35 g. of a brown powder, which was recrystallized from ethanol to give 1.75 g. of yellow needles with a green fluorescence, m. p. 206°C.

Found: C, 66.14; H, 3.75; N, 10.76. Calcd. for $C_{14}H_{10}ON_2S$: C, 66.13; H, 3.96; N, 11.02%.

b) A solution of 2 g. of 2-benzoylthiopyridine and 0.7 g. of chloroacetonitrile was refluxed on a water

bath for twelve hours. After cooling, the yellow precipitate was collected to give 0.25 g. of yellow crystals, which were basified with sodium bicarbonate and recrystallized from ethanol to give 0.1 g. of yellow needles, m. p. 206°C, undepressed on admixture with a sample prepared by Method a).

4-Lepidyl-2-thioacetonitrile (XI).—Into a solution of 3.2 g. of 2-mercapto-4-lepidine and 0.74 g. of sodium hydroxide in 30 ml. of ethanol, 1.4 g. of chloroacetonitrile was added dropwise with cooling and stirring. The precipitate of sodium chloride was filtered off, and the filtrate was concentrated to give 4.1 g. of pale yellow needles melting at 64—65°C. Recrystallization from ethanol afforded colorless needles melting at 65°C.

Found: C, 67.28; H, 4.71; N, 13.09. Calcd. for $C_{12}H_{10}ON_2S$: C, 67.28; H, 4.71; N, 13.08%.

The Attempted Preparation of *N*-Acyl-4-lepido-[2, 1-b]-3, 4-dihydro-4-iminothiazole.—A solution of 1.3 g. of 4-lepidyl-2-thioacetonitrile and 0.58 g. of acetyl chloride in 5 ml. of benzene was refluxed for one hour on a water bath. The precipitate which separated out was collected (0.8 g.) and recrystallized from ethanol to give yellow needles. It was suspended on water, made alkaline with potassium carbonate, and extracted with chloroform. The chloroform extract was then concentrated under reduced pressure, and the residue was recrystallized from ligroin to give colorless needles melting at 65—66°C, undepressed on admixture with 4-lepidyl-2-thioacetonitrile.

When 4-lepidyl-2-thioacetonitrile was treated with benzoyl chloride in benzene, the starting material was recovered unchanged after it had been heated on a water bath for five hours.

1-Mercaptoisoquinoline.—a) To a suspension of 2 g. of isoquinoline in 5 ml. of water, 0.94 g. of thioacetic acid was added, and the mixture was warmed for thirty minutes on a water bath. The crystals which separated out were collected to give 1.75 g. of yellow prisms melting at 171°C. One recrystallization from ethanol gave yellow prisms, m. p. 171°C.

b) An exothermic reaction occurred when 2 g. of 1-chloroisoquinoline was mixed with 2 ml. of thioacetic acid. After it had been warmed on a water bath for ten minutes, the mixture was cooled and the pale yellow prisms which separated out were collected (1.8 g., m. p. 166°C) and recrystallized from ethanol to give 1.65 g. of yellow prisms, m. p. 170°C.

2-Mercapto-4-lepidine.—a) To a suspension of 0.5 g. of 2-chloro-4-lepidine in 10 ml. of water, 0.22 g. of thioacetic acid was added and the mixture was warmed on a water bath for thirty minutes. The crystals which separated out were collected to give 0.45 g. of yellow needles, melting at 260°C.

b) A mixture of 0.5 g. of 2-chloro-4-lepidine and 1 ml. of thioacetic acid was warmed on a water bath for thirty minutes. The mixture was concentrated under reduced pressure, and the residue was washed with water to give 0.5 g. of yellow needles, melting at 261°C.

The Reaction of 1-Chloroisoquinoline and Chloroacetic Acid.—A solution of 1 g. of 1-chloroisoquinoline and 0.6 g. of chloroacetic acid in 10 ml. of benzene was refluxed on a water bath for two hours. Benzene was distilled off under reduced pressure, and the residue which solidified was recrystallized from ethanol to afford 0.3 g. of pale yellow needles, m. p. 210—211°C, undepressed on admixture with an authentic specimen of isocarbostyrile.

We warmly appreciate the technical assistance of Mr. Kazuo Tanaka in a part of the experiment reported here. This work was supported in part by The Kawakami Foundation, to which our thanks are due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1257—1261 (1966)

Studies of the Mixed Amino-acid Complexes of Cobalt(III). I. The Geometrical Isomers of the [Co en gly (chelate)] Series

By Nobuko MATSUOKA, Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received October 28, 1965)

Five new complexes of the [Co en gly (chelate)] type, i. e., *mer(N)*- and *fac(N)*-[Co en gly CO_3], *mer(N)*- and *fac(N)*-[Co en gly ox] and *mer(N)*-[Co en gly malo], have been derived from a new dinitro complex, *cis*-[Co en gly $(NO_2)_2$], through an intermediate complex, [Co en gly Cl (OH_2)]Cl. The geometrical structures of these complexes have been determined on the basis of the processes of their derivation and their absorption spectra. Two new bisglycinato complexes, *trans(O)*- and *cis(O)*-[Co en gly_2]I·H_2O, have been prepared from *mer(N)*- and *fac(N)*-[Co en gly CO_3] respectively.

Recently the mixed amino-acid complexes of cobalt(III) have been recognized as interesting in relation to the optical rotatory dispersion or the circular dichroism studies of metal complexes,

and several reports have appeared.[1-6] However, only a few mixed amino-acid complexes have been known; they belong to the [Co^{III} N_4O_2]- or the [Co^{III} N_3O_3]-type. In particular, we know of extremely few examples of pairs of geometrical isomers, for example, the *trans(O)*- and *cis(O)*-isomers of a [Co N_4O_2] complex or the *mer(N)*- and *fac(N)*-isomers of a [Co N_3O_3] complex.

In the present paper, five new complexes of the [Co en gly (chelate)] type, including two pairs of geometrical isomers, and a pair of the *trans(O)*- and *cis(O)*-isomers of [Co en gly_2]X, will be reported on. All of these new complexes will be derived from a new starting material, [Co en gly $(NO_2)_2$]. The absorption spectra of these complexes will then be discussed in the same way as in a previous paper.[7]

Experimental

Preparation.—*1) Dinitroglycinatoethylenediaminecobalt(III):* [$Co(NO_2)_2$ gly en].—A solution containing 25 g. of potassium nitrite in 30 ml. of water was added to a solution containing 20 g. of cobalt(II) chloride hexahydrate in 20 ml. of water, and then 7 g. of glycine in 40 ml. of water and 6 g. of 93% aqueous ethylenediamine were added to the solution in this order. The dark brown solution was oxidized by bubbling air in for about ten hours, whereupon the desired complex separated as yellow precipitates. The crude complex was filtered and washed with a small quantity of water, and then with ethanol, and dried in air. This complex is sparingly soluble in water at room temperature, moderately soluble in hot water, and insoluble in methanol, ethanol, acetone and benzene. The pure crystals were obtained by recrystallization from hot water. Yield, 18 g.

Found: C, 17.33; H, 4.44; N, 24.30. Calcd. for [$Co(NO_2)_2(C_2H_4NO_2)(C_2H_8N_2)$]: C, 16.85; H, 4.24; N, 24.57%.

The following three complexes, 2—4), were prepared by the same method as above using racemic alanine and racemic propylenediamine.

2) Dinitroalaninatoethylenediaminecobalt(III): [$Co(NO_2)_2$ ala en].—Found: C, 20.21; H, 4.64; N, 23.26. Calcd. for [$Co(NO_2)_2(C_3H_6NO_2)(C_2H_8N_2)$]: C, 20.08; H, 4.72; N, 23.41%.

3) Dinitroglycinatopropylenediaminecobalt(III): [$Co(NO_2)_2$ gly pn].—Found: C, 20.29; H, 4.66; N, 23.39. Calcd. for [$Co(NO_2)_2(C_2H_4NO_2)(C_3H_{10}N_2)$]: C, 20.08; H, 4.72; N, 23.41%.

4) Dinitroalaninatopropylenediaminecobalt(III): [$Co(NO_2)_2$ ala pn].—Found: C, 23.06; H, 5.06; N, 22.26. Calcd. for [$Co(NO_2)_2(C_3H_6NO_2)(C_3H_{10}N_2)$]: C, 23.01; H, 5.15; N, 22.36%.

5) Potassium Dinitrobisglycinatocobaltate(III): K[Co $(NO_2)_2$ gly_2]. Potassium nitrite (50 g.) in 70 ml. of water and glycine (26 g.) in 150 ml. of water were added in this order to a solution containing 40 g. of cobalt(II) chloride hexahydrate in 50 ml. of water. The dark brown solution was then oxidized by bubbling air in for about three hours. After the addition of 200 ml. of ethanol, the solution was kept in a refrigerator overnight. The yellow brown crystals were filtered and recrystallized from hot water. They were dried by heating at 105°C. Yield, 30 g.

Found: C, 13.99; H, 2.85; N, 17.13. Calcd. for K[$Co(NO_2)_2(C_2H_4NO_2)_2$]: C, 14.21; H, 2.38; N, 16.57%.

6) Chloroglycinatoaquoethylenediaminecobalt(III) Chloride: [Co Cl gly (OH_2) en]Cl.—The ground sample of the [Co $(NO_2)_2$ gly en] complex (20 g.) was suspended in 50 ml. of concentrated hydrochloric acid and warmed on a water bath. The yellowish suspension began to dissolve with the bubbling of nitrogen dioxide, and the mixture became violet. After the bubbling of gas had ceased, the violet solution was cooled to room temperature. The violet crystalline complex deposited was then filtered and washed with diluted hydrochloric acid (1 : 1) and dried in air. This complex is soluble in water, with an accompanying aquation but insoluble in ethanol and methanol. Yield, 14 g.

Found: C, 16.86; H, 5.06; N, 14.79. Calcd. for [Co Cl $(C_2H_4NO_2)OH_2(C_2H_8N_2)$]Cl: C, 17.03; H, 5.00; N, 14.90%.

7) Diisothiocyanatoglycinatoethylenediaminecobalt(III): [Co $(NCS)_2$ gly en].—To a solution of 2 g. of potassium thiocyanate in 20 ml. of water, 2 g. of [Co Cl gly (OH_2) en]Cl was added, and the mixture was warmed on a water bath. The color of the solution changed from violet to dark red, and the red crystals began to deposit. After the solution had been cooled to room temperature, the crystals were separated and washed with a little water, and then with ethanol, and dried in air. This complex is insoluble in water, ethanol and methanol. Yield, 2 g.

Found: C, 23.54; H, 3.97; N, 22.22. Calcd. for [$Co(NCS)_2(C_2H_4NO_2)(C_2H_8N_2)$]: C, 23.30; H, 3.91; N, 22.65%.

8) The mer(N) or Violet Form of Carbonatoglycinatoethylenediaminecobalt(III) Monohydrate: mer(N)-[Co CO_3 gly en]·H_2O. — In 100 ml. of water 10 g. of [Co Cl gly (OH_2) en]Cl and 10 g. of potassium hydrogen carbonate were dissolved; the mixture was then heated on a water bath for an hour. The solution was cooled to room temperature, and 50 ml. of ethanol was added to it. Some violet crystals began to separate in this step. After the solution had been kept in a refrigerator overnight, a large amount of the violet crystals, which were contaminated with a little amount of the reddish violet *fac(N)*-form, was obtained. The pure violet needles were obtained by recrystallization from hot water, washed with ethanol, and dried in air. This complex is insoluble in methanol and ethanol. Yield, 6.8 g.

Found: C, 22.14; H, 5.24; N, 15.23. Calcd. for [$Co\ CO_3(C_2H_4NO_2)(C_2H_8N_2)$]·$H_2O$: C, 22.15; H, 5.20; N, 15.50%.

9) The fac(N) or Red Form of Carbonatoglycinatoethylenediaminecobalt(III): *fac(N)*-[Co CO_3 gly en]. — Five grams of [Co Cl gly (OH_2) en]Cl were dissolved in a solution of 5 g. of potassium hydrogen carbonate

in 100 ml. of water. The solution was heated on a water bath for an hour and then cooled to room temperature. After about 20 ml. of methanol had been added to the solution, it was allowed to stand for about ten hours. The crude complex deposited as reddish violet crystals. This was recrystallized from water by the usual procedure. Yield, 0.2 g.

Found: C, 23.62; H, 4.98; N, 16.71. Calcd. for $[Co\,CO_3(C_2H_4NO_2)(C_2H_8N_2)]$: C, 23.73; H, 4.78; N, 16.60%.

10) The mer(N) or Violet Form of Oxalatoglycinato-ethylenediaminecobalt(III): mer(N)-[Co ox gly en].—In 20 ml. of warm water 4 g. of potassium oxalate and 5 g. of [Co Cl gly (OH_2) en]Cl were dissolved, and the mixture was heated on a water bath. After about 5 min. the desired complex gradually separated as reddish-violet needle crystals. This was recrystallized from hot water. Yield, 4 g.

Found: C, 25.66; H, 4.33; N, 14.98. Calcd. for $[Co\,(C_2O_4)(C_2H_4NO_2)(C_2H_8N_2)]$: C, 25.63; H, 4.30; N, 14.95%.

This complex was also prepared from *mer(N)*-[Co CO_3 gly en] and oxalic acid.

11) The fac(N) or Red Form of Oxalatoglycinato-ethylenediaminecobalt(III): fac(N)-[Co ox gly en].—This complex was prepared from *fac(N)*-[Co CO_3 gly en] and oxalic acid by the same method as that used for *mer(N)*-[Co ox gly en]. The pure complex was obtained as a pink powder. Yield, 0.1 g. from 0.5 g. of the carbonato complex.

Found: C, 25.54; H, 4.29; N, 14.89. Calcd. for $[Co\,(C_2O_4)(C_2H_4NO_2)(C_2H_8N_2)]$: C, 25.63; H, 4.30; N, 14.95%.

12) mer(N)-Malonatoglycinatoethylenediaminecobalt(III): mer(N)-[Co malo gly en].—To a solution of 2.5 g. of malonic acid in 50 ml. of water, 5 g. of *mer(N)*-[Co CO_3 gly en] was added and heated on a water bath. After the bubbling of carbon dioxide had finished, the solution was heated for more about one hour. It was then cooled and allowed to stand overnight. Reddish-violet crystals were recrystallized from water. Yield, 3.8 g. The same product was also obtained from the *fac(N)* carbonato complex.

Found: C, 28.42; H, 4.80; N, 14.18. Calcd. for $[Co(C_3H_2O_4)(C_2H_4NO_2)(C_2H_8N_2)]$: C, 28.49; H, 4.78; N, 14.24%.

13) trans(O)-Bisglycinatoethylenediaminecobalt (III) Iodide Monohydrate: trans(O)-[Co gly_2 en]$I\cdot H_2O$.—Two grams of *mer(N)*-[Co CO_3 gly en] was added to a solution containing 1.2 g. of glycine in 20 ml. of water. The solution was evaporated to 5 ml. on a water bath at about 70°C and filtered in hot. The filtrate was cooled to room temperature. After a calculated amount of potassium iodide had been added to the solution, dark red crystals began to separate. The mixture was kept in a refrigerator overnight. The recrystallization was made from water by the usual procedure.

Found: C, 17.78; H, 4.51; N, 13.61. Calcd. for $[Co\,(C_2H_4NO_2)_2(C_2H_8N_2)]I\cdot H_2O$: C, 17.48; H, 4.40; N, 13.62%.

14) cis(O)-Bisglycinatoethylenediaminecobalt(III) Iodide Monohydrate: cis(O)-[Co gly_2 en]$I\cdot H_2O$.—This complex was obtained by the same method as that used for the *trans(O)*-isomer, using *fac(N)*-[Co CO_3 gly en] instead of the *mer(N)*-isomer. After a little red precipitate produced by the addition of a calculated amount of potassium iodide had been filtered off, a small quantity of ethanol was added to the filtrate; the solution was then kept in a refrigerator overnight. The pinkish red powder deposited was recrystallized from water.

Found: C, 17.46; H, 4.34; N, 13.80. Calcd. for $[Co(C_2H_4NO_2)_2(C_2H_8N_2)]I\cdot H_2O$: C, 17.48; H, 4.40; N, 13.62%.

Measurements.—The absorption spectra were measured by a Beckman DU spectrophotometer at room temperature. The concentrations of the solutions varied from 1.0×10^{-2} to 0.5×10^{-4} F.

Results and Discussion

As a representative absorption spectrum of the complexes of the dinitro(amino-acidato)diamine type, the curve of [Co en gly$(NO_2)_2$], which was used as the starting compound in the preparations of the [Co en gly (chelate)] series, is shown in Fig. 1,

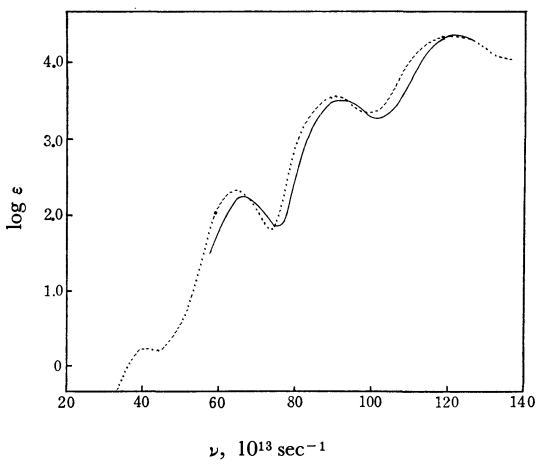

Fig. 1. Absorption curves of ——[Co en gly $(NO_2)_2$] and ·····K[Co $gly_2(NO_2)_2$].

in which the curve of a new bisglycinato complex, K[Co gly_2 $(NO_2)_2$], is also plotted. Previously one of the present authors[8] showed that the so-called nitro specific band of a *trans*-dinitrocobalt(III) complex was located at about 350—335 mμ, while, on the other hand, the band of the corresponding *cis*-dinitro complex was located at about 335—320 mμ. Judging from the positions of the nitro specific band of the present complexes, which are at 325 and 332 mμ for [Co en gly $(NO_2)_2$] and K[Co gly_2 $(NO_2)_2$] respectively, it may be considered that the two coordinated NO_2^- ligands of both the complexes are in the *cis* positions.

By warming up the starting complex, [Co en gly $(NO_2)_2$], with concentrated hydrochloric acid, the two coordinated NO_2^- ligands are easily freed from the cobalt(III) ion without the decomposition of the two chelate rings, while the two glycine

Complex	A-band ν_{max} (log ε_{max})	I-band ν_{max} (log ε_{max})	II-band ν_{max} (log ε_{max})
mer(N)-[Co en gly CO_3]	{31.0 (0.04) {34.9 (0.01)	56.6 (2.07)	81.1 (2.17)
fac(N)-[Co en gly CO_3]	33.0 (0.17)	56.6 (2.17)	80.4 (2.13)
mer(N)-[Co en gly ox]	ca. 35 (0.15)	57.7 (1.96)	81.1 (2.23)
fac(N)-[Co en gly ox]		57.7 (2.13)	81.1 (2.24)
mer(N)-[Co en gly malo]		58.3 (1.95)	80.6 (2.13)
mer(N)-[Co gly_3][9]	29.8 ($\bar{1}$.82)	55.7 (2.00)	80.6 (2.18)
fac(N)-[Co gly_3][9]	33.0 (0.02)	57.7 (2.20)	80.2 (2.15)

The frequencies are given in 10^{13} sec^{-1}.

rings of K[Co gly_2 $(NO_2)_2$] are decomposed by such treatment. The complex salt resulting from the treatment of [Co en gly $(NO_2)_2$] is quantitatively obtained as a violet crystalline powder. The analytical data show that this complex has one water molecule which is not removed even by heating at 105°C for a few days. It may be assumed that this water molecule is coordinated to the cobalt(III) ion.

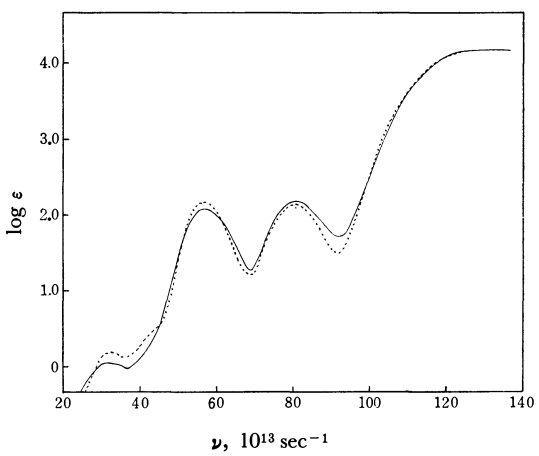

Fig. 3. Absorption curves of —— *mer(N)*- and ····· *fac(N)*-[Co en gly CO_3].

From the reaction of [Co en gly Cl (OH_2)]Cl with potassium hydrogen carbonate, two kinds of the carbonato complex, the violet form and the red form, are obtained. Now, the [Co en gly (CO_3)] complex may be expected to have two geometrical isomers, *mer(N)* and *fac(N)*, as is seen in Fig. 2. The absorption curves and the numerical data of both the isomers are shown in Fig. 3 and Table I. The first absorption band of the violet isomer is broader in shape and lower in intensity than that of the red isomer. It has been well established that the first band of a *mer(N)*-isomer of the complex of the [Co N_3O_3] type is broadened by the overlap of the split three absorption components and that the degenerate first band of a *fac(N)*-isomer is higher in intensity than that of the *mer(N)*-isomer.[7] Consequently, it may be concluded that the violet isomer of [Co en gly CO_3] is a *mer(N)*-form, and the red one, a *fac(N)*-form.

As is shown in Fig. 4 and Table I, the absorption curves of the two isomers of [Co en gly ox] show the same trends in the first bands as those of the *mer(N)*- and *fac(N)*-isomers of [Co en gly CO_3]. Furthermore, the violet oxalato isomer is derived from *mer(N)*-[Co en gly CO_3], and the red one, from *fac(N)*-[Co en gly CO_3]. These facts confirm

TABLE II. ABSORPTION DATA OF BIS(AMINO-ACIDATO) SERIES

Complex ion	A-band ν_{max} (log ε_{max})	I-band ε_{max} (log ε_{max})	II-band ν_{max} (log ε_{max})
trans(O)-[Co en gly_2]$^+$	31.6 ($\bar{1}$.90)	56.6 (1.94) 66.0 (1.64)	83.3 (2.12)
cis(O)-[Co en gly_2]$^+$	37.0 ($\bar{1}$.90)	59.8 (2.09)	83.3 (2.13)
trans(O)-[Co en (β-ala)$_2$]$^+$ [2]		55.2 (2.00) 65.8 (1.61)	82.8 (1.94)

The frequencies are given in 10^{13} sec^{-1}.

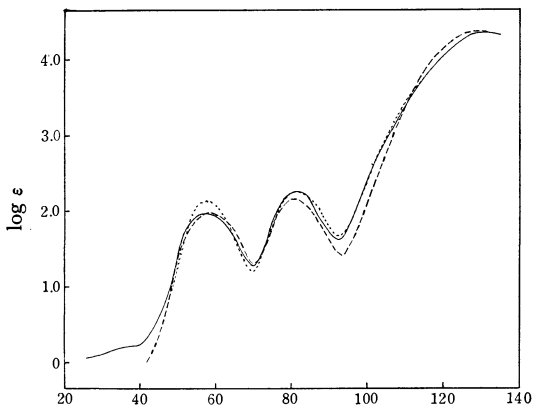

Fig. 4. Absorption curves of —— *mer(N)*- and ····· *fac(N)*-[Co en gly ox] and ---- *mer(N)*-[Co en gly malo].

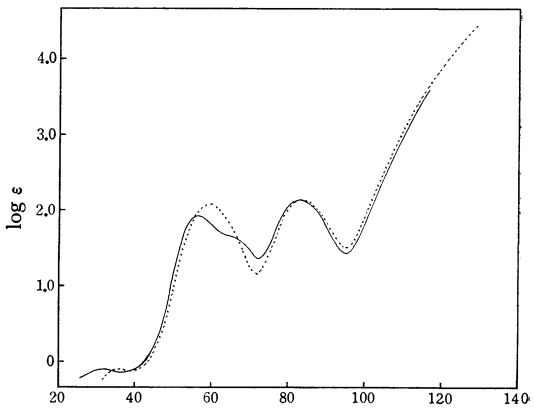

Fig. 5. Absorption curves of —— *trans(O)*- and ····· *cis(O)*-[Co en gly_2]I·H_2O.

that the violet [Co en gly ox] is of the *mer(N)* - form, and the red one, of the *fac(N)*-form.

The complexes which are derived from *mer(N)*- and *fac(N)*-[Co en gly CO_3] by the reaction with malonic acid are identical. From the fact that the first band of this complex agrees with that of *mer(N)*-[Co en gly ox], as is seen in Fig. 4, the *mer(N)* structure is assigned to this complex.

Three geometrical isomers, *trans(O)*-, *β-cis(O)*- and *β-cis(O)*-forms,* are expected for the [Co en gly_2]$^+$ ion. The *trans(O)*- and *α-cis(O)*-[Co en gly_2]$^+$ ions will be derived from *mer(N)*-[Co en gly CO_3] if the substitution reaction of the CO_3^{2-} ligand by the gly^- ion proceeds with the retention of the geometrical configuration of the [Co en gly —] part, while the *α-cis(O)*- and the *β-cis(O)*-[Co en gly_2]$^+$ ions are derived from *fac(N)*-[Co en gly CO_3], as is shown in Fig. 2.

In fact, the dark red complex is derived from *mer(N)*-[Co en gly CO_3], accompanied by a small quantity of a pinkish red complex, while from *fac(N)*-[Co en gly CO_3] the pinkish red complex, which is more soluble than the dark red one, is derived. The first absorption band of the dark red complex splits into two distinct components (Fig. 5 and Table II). This splitting pattern agrees well with the data[2,10] of the other *trans(O)*-[Co N_4O_2] complexes and with the pattern which is to be expected for the *trans* form from the semi-empirical molecular orbital calculations.[11] The first absorption band of the pinkish red complex is normal in shape; it may reasonably be considered that the pinkish red complex is *cis(O)*-[Co en gly_2]$^+$. It is difficult, however, on the basis of only the absorption spectrum, to discriminate between *α-cis(O)*- and *β-cis(O)*-structures.

* The prefix *α* denote that the two nitrogen atoms of the coordinated amino-acid ions occupy the *trans*-positions, and prefix *β* the *cis*-positions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1262—1269 (1966)

Electronic Spectra and Electronic Structures of α- and β-Nitronaphthalenes and 1, 8-Dinitronaphthalene

By Maomi KOJIMA and Saburo NAGAKURA

The Institute of Physical and Chemical Research, Komagome, Bunkyo-ku, Tokyo

(Received October 29, 1965)

The absorption spectra of α-, β-nitronaphthalenes and 1, 8-dinitronaphthalene were measured in the near and vacuum ultraviolet regions. The peak wavelengths are as follows: α-nitronaphthalene, 213, 243 and 326.5 mμ; β-nitronaphthalene, 210.5, 259.5, 303 and 342 mμ; 1, 8-dinitronaphthalene, 199.5, 229.5 and 303 mμ. The transition energies and oscillator strengths were calculated with these three molecules by considering the configurational interaction among the ground, locally-excited and charge-transfer configurations. By combining the theoretical results with the observed peak wavelengths and the oscillator strengths, the nature of the electronic excitations corresponding to the observed absorption bands was clarified. Concerning 1, 8-dinitro-naphthalene, the twisting angle between the nitro groups and the naphthalene ring was estimated to be 60—70° by comparing the observed peak wavelengths and intensities with the calculated values. The effect of solvents on the absorption spectrum of 1, 8-dinitronaphthalene was found to be explained by the energy change in the charge-transfer configurations caused by the polarity of solvents. By considering the contribution of the charge-transfer configurations in the ground state, the increment in the dipole moment due to the delocalization of π-electrons was estimated for α- and β-nitronaphthalenes and 1, 8-dinitronaphthalene. The estimated dipole moment could explain the fact that the observed dipole moment of β-nitronaphthalene is greater than that of α-nitronaphthalene.

In previous papers,[1,2] we studied the electronic spectra and the electronic structures of nitrobenzene, nitromesitylene and 1, 5-dinitronaphthalene from both experimental and theoretical points of view. Concerning nitrobenzene,[1] a new band characteristic of the charge-transfer interaction between the benzene ring as an electron donor and the nitro group as an electron acceptor was observed at 240 mμ. This band almost completely disappeared in nitromesitylene, in which the nitro group is twisted from the benzene ring plane and in which, therefore, the resonance interaction is largely prohibited. In addition to this, the theoretical consideration based on the configurational interaction calculation and the direction of the transition moment measured by Labhart[3] lead to the conclusion that the 240 mμ band of nitrobenzene is an intramolecular charge-transfer absorption. A similar study has also been made with 1, 5-dinitronaphthalene.[2]

In the present study, we have undertaken to study the electronic spectra and electronic structures of α- and β-nitronaphthalenes and 1, 8-dinitronaphthalene by measuring the absorption spectra in the near and vacuum ultraviolet regions. Particularly, concerning 1, 8-dinitronaphthalene, the relation between the electronic spectra and the twisting angle of the nitro groups from the naphthalene ring plane was investigated, with the result that the twisting angle is 60—70° in solution.

Experimental

Materials.—Commercial 1, 8-dinitronaphthalene was purified by repeating recrystallizations from methanol and ethanol (m. p. 167°C).

Purified samples of α- and β-nitronaphthalenes were kindly presented by Mr. Akira Ishitani.* The *n*-heptane and methanol used as solvents were purified by the method described in the literature.[4,5] Commercial acetonitrile (OK type Special Grade, manufactured by the Asahi Chemical Industry, Ltd.) was first refluxed over calcium hydride for ten hours and then roughly distilled. The distillate was refluxed again over phosphorus pentoxide for half an hour and distilled. Finally it was distilled again from calcium hydride.

Measurements.—The absorption spectra of mononitro- and dinitronaphthalenes in the wavelength region of 190—500 mμ were measured with a Cary recording spectrophotometer, model 14. The absorption measurements of the acetonitrile solutions in the 180—200 mμ region were made with a vacuum ultraviolet spectrophotometer constructed in our

The experimental values were observed in the *n*-heptane solution.

*1 Since 1, 8-dinitronaphthalene is hardly soluble in *n*-heptane and the concentration of the *n*-heptane solution could not be determined accurately, all the molar extinction coefficient values are adjusted on the assumption that the values of the peak molar extinction coefficient of the longest wavelength band in the *n*-heptane solution coincides with that observed with the methanol solution. This may cause the errors of the order of 10%.

*2 Values calculated with $\theta=60°$.

*3 The other transitions are all forbidden.

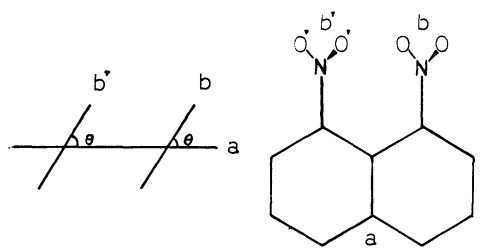

Fig. 4. 1,8-dinitronaphthalene with a hypothetical molecular symmetry C_2.
a: naphthalene ring plane
b, b': nitro group plane
θ: twisting angle

(*f*) values are also tabulated. In some cases, several bands overlap with each other and so we can not determine the oscillator strength value separately for each band. In these cases, the sums of the oscillator strengths for the overlapped bands are shown.

Theoretical

The π-electron structures of α- and β-nitronaphthalene and 1, 8-dinitronaphthalene were studied theoretically by the method used in the cases of 1, 5-dinitronaphthalene,[2] nitrobenzene and nitromesitylene.[1] That is to say, the respective nitronaphthalene molecules were separated into the naphthalene ring and the nitro groups, and the molecular orbitals of the components were evaluated by combining the results of the MO calculations with the experimental data of the electronic spectra. Thereafter, the interaction between the components was considered in terms of the configurational interaction among the ground, locally excited and charge-transfer configurations.

Concerning the geometrical configurations of the three molecules under consideration, no experimental data were found, so we assumed them to be follows: in β-nitronaphthalene, the nitro group is coplanar with the naphthalene ring plane; on the other hand, in α-nitronaphthalene, the nitro group is twisted from the aromatic ring plane by 49°, as in the case of 1, 5-dinitronaphthalene[7]; in 1, 8-dinitronaphthalene, the angle between the nitro group and the naphthalene ring plane may be assumed to change from 90° to 49° with a molecular symmetry (C_2) (see Fig. 4) and the calculation of the electronic structure was made with four values of the angle (49°, 60°, 70°, 80°). The other data necessary for the calculations were taken to be equal to the experimental data observed with 1, 5-dinitronaphthalene.[7] The C–N, N–O and C–C bond lengths were taken to be equal to 1.486 Å, 1.207 Å and 1.405 Å respectively, the C–C bond length being an averaged value for the ring

$H_{II\cdot X}=0.0064\beta'_{CN}$	$H_{VI\cdot X}=0.2055\beta'_{CN}$
$H_{III\cdot IX}=0.0910\beta'_{CN}$	$H_{VII\cdot VIII}=-0.2288$ eV.
$H_{III\cdot X}=0.1660\beta'_{CN}$	$H_{VII\cdot IX}=0.0309\beta'_{CN}$
$H_{IV\cdot IX}=-0.1969\beta'_{CN}$	$H_{VII\cdot X}=0.2010\beta'_{CN}$
$H_{IV\cdot X}=0.0097\beta'_{CN}$	$H_{IX\cdot X}=0.0997$ eV.

($\beta'_{CN}=-1.57$ eV.)

The other off-diagonal matrix elements are zero.

Table VI. The off-diagonal matrix elements used for the calculation of β-nitronaphthalene

$H_{I\cdot IX}=-0.2595\beta_{CN}$	$H_{V\cdot VIII}=-0.1080$ eV.
$H_{I\cdot X}=0.3988\beta_{CN}$	$H_{V\cdot IX}=0.0859\beta_{CN}$
$H_{II\cdot VIII}=0.1190$eV.	$H_{V\cdot X}=-0.0097\beta_{CN}$
$H_{II\cdot IX}=-0.1782\beta_{CN}$	$H_{VI\cdot IX}=-0.1836\beta_{CN}$
$H_{II\cdot X}=0.0705\beta_{CN}$	$H_{VI\cdot X}=-0.1270\beta_{CN}$
$H_{III\cdot IX}=-0.1017\beta_{CN}$	$H_{VII\cdot VIII}=-0.1334$ eV.
$H_{III\cdot X}=-0.0921\beta_{CN}$	$H_{VII\cdot IX}=0.1693\beta_{CN}$
$H_{IV\cdot IX}=0.0855\beta_{CN}$	$H_{VII\cdot X}=-0.1243\beta_{CN}$
$H_{IV\cdot X}=-0.0158\beta_{CN}$	$H_{IX\cdot X}=0.2211$ eV.

($\beta_{CN}=-2.4$ eV.)

The other off-diagonal matrix elements are zero.

C–C bonds.

We took the energy of the ground configuration as the standard. Beside this, several locally excited configurations and the two types of charge-transfer configurations were taken into account.

The diagonal and off-diagonal matrix elements of the total electronic Hamiltonian were evaluated according to the methods presented by Pariser and Parr,[8] by Longuet-Higgins and Murrell[9] and by Pople[10]. They are shown in Tables IV—VII. The secular equations were solved by the aid of an electronic computer, FACOM 202, located at the Institute for Solid State Physics.

The finally-obtained energy levels and wave functions are shown in Tables VIII—X.

Discussion

α-Nitronaphthalene.—It is seen from Fig. 1 that the absorption spectrum of α-nitronaphthalene consists of three bands in the observed wavelength region. They appear at 213, 243 and 326.5,

* Mean values weighted by calculated oscillator strengths for all the transitions assigned to a band.
** Sum of the calculated oscillator strength values classified to the same observed band.
(The numbers in bracket correspond to the 303.0 mμ band 229.4 mμ band and 199.6 mμ band (observed with the *n*-heptane solution), respectively.)

mμ. From a comparison of the observed absorption spectrum with the theoretical results, the broad 326.5 mμ band may be considered to include the two overlapped bands corresponding to the $W_0\rightarrow W_1$ and $W_0\rightarrow W_2$ transitions. The wave functions, Ψ_1 and Ψ_2, given in Table VIII show that the former corresponds to the $A_{1g}^-\rightarrow B_{3u}^-$ transition of naphthalene, while the latter contains the $A_{1g}^-\rightarrow B_{2u}^-$ transition of naphthalene and the CT_5-type charge-transfer transition in almost equal proportions. As is revealed by the calculated oscillator strengths given in Table I, the $W_0\rightarrow W_1$ transition is weaker than the $W_0\rightarrow W_2$ transition.

The 243 mμ band may be ascribed to the $W_0\rightarrow W_3$ and $W_0\rightarrow W_4$ transitions. In view of the calculated oscillator strength values given in Table I, this band may be assigned substantially to the W_0—W_4 transition, which results mainly from the CT_4-type charge-transfer transition.

The strong band at 213 mμ seems to include various transitions, transitions from the ground state, W_0, to the W_5, W_6, W_7, W_8 and W_9 states. An inspection of the calculated oscillator strengths given in Table I reveals that the $W_0\rightarrow W_5$ and $W_0\rightarrow$

W_8 transition bands are weak and may be covered by the other transition bands. The $W_0 \rightarrow W_6$ transition is mainly composed of the $A_{1g}^- \rightarrow B_{3u}^+$ and $A_{1g}^- \rightarrow A_{1g}^+$ transitions. The $W_0 \rightarrow W_7$ transition has a complicated character and comes from the $A_{1g}^- \rightarrow B_{1g}^-$, $A_{1g}^- \rightarrow B_{3u}^+$ and $A_{1g}^- \rightarrow A_{1g}^-$ transitions, besides the local transition within the nitro group and CT_4-type charge-transfer transitions. The $W_0 \rightarrow W_9$ transition results largely from the local excitation within the nitro group. The tail at the shorter wavelength side of the 213 mμ band might be due to this transition.

β-Nitronaphthalene.—The absorption spectrum of β-nitronaphthalene shown in Fig. 2 consists of four bands in near and vacuum ultraviolet regions down to 180 mμ. They appear at 210.5, 259.5, 303 and 342 mμ.

The 342 mμ band may safely be assigned to the $W_0' \rightarrow W_1'$ transition. The wave function, Ψ_1', given in Table IX shows that the band may be regarded as the shifted band of the $A_{1g}^- \rightarrow B_{3u}^-$ transition band of naphthalene.

The 303 mμ band can be assigned to the $W_0' \rightarrow W_2'$ transition. Its character is, for the most part, that of the shifted band of the $A_{1g}^- \rightarrow B_{2u}^+$ transition of naphthalene, though it also includes, to some extent, the $A_{1g}^- \rightarrow B_{3u}^-$ and CT_5-type charge-transfer transitions.

The $W_0' \rightarrow W_1'$ and $W_0' \rightarrow W_2'$ transitions of β-nitronaphthalene are similar to, respectively, the $W_0 \rightarrow W_1$ and $W_0 \rightarrow W_2$ transitions of α-nitronaphthalene in their nature. Therefore, it may be said that the overlapping bands at 326.5 mμ in α-nitronaphthalene appear separately at 342 and 303 mμ in β-nitronaphthalene. This difference can be explained satisfactorily by the present theoretical treatment. That is to say, the B_{2u}^+ locally excited configuration is stabilized by the contribution of the charge-transfer configurations to a greater extent in the W_1' state of β-nitronaphthalene than in the W_1 state of α-nitronaphthalene; the reverse is the case for the W_2 and W_2' states.

The 259.5 mμ band is undoubtedly due to the $W_0' \rightarrow W_3'$ transition. From the wave function, Ψ_3', given in Table IX, this transition is known to result mainly from the $A_{1g}^- \rightarrow B_{2u}^+$ and CT_5-type transitions. This transition corresponds to the $W_0 \rightarrow W_3$ transition of α-nitronaphthalene, whose transition probability is very small.

The 210.5 mμ band may be regarded as overlapping bands corresponding to the $W_0' \rightarrow W_4'$, $W_0' \rightarrow W_5'$, $W_0' \rightarrow W_6'$, $W_0' \rightarrow W_7'$ and $W_0' \rightarrow W_8'$ transitions. An inspection of the calculated oscillator strength values given in Table IX shows that this band consists substantially of the $W_0' \rightarrow W_5'$ and $W_0' \rightarrow W_6'$ transitions. The $W_0' \rightarrow W_4'$, $W_0' \rightarrow W_7'$ and $W_0' \rightarrow W_8'$ transitions are very weak in intensity. Roughly speaking, the $W_0' \rightarrow W_5'$ and $W_0' \rightarrow W_6'$ transitions of β-nitronaphthalene correspond to the $A_{1g}^- \rightarrow A_{1g}^-$ and $A_{1g}^- \rightarrow B_{1g}^-$ transitions of naphthalene respectively, though the $A_{1g}^- \rightarrow B_{3u}^+$ transition of naphthalene also contributes considerably to these two transitions. The tail at the shorter wavelength side of the 210.5 mμ band might be due to the $W_0' \rightarrow W_9'$ transition. Table IX shows that the upper state of this transition is mainly composed of the local excitation within the nitro group (50%) and of the local excitation ($A_{1g}^- \rightarrow B_{3u}^+$) within the naphthalene ring (25%).

1, 8-Dinitronaphthalene. — As is shown in Fig. 3, the absorption spectrum of 1, 8-dinitronaphthalene consists of three bands in the observed wavelength region. They appear at 199.5, 229.5 and 303 mμ.

The Determination of the Angle between the Naphthalene Ring and the Nitro Groups.—In order to evaluate the twisting angle between the nitro groups and the naphthalene ring, we calculated the transition energies and oscillator strengths for the four angles of 49°, 60°, 70° and 80°. Each of the observed bands consists of multiple transitions. Therefore, the mean value of the calculated transition energies, weighted by the calculated oscillator strengths, was evaluated for each observed band. Consequently, the deviation, δw_i, between the observed and calculated transition energies could be obtained for each band. The minimum sum of the $|\delta w_i|$ values for the three observed bands was found to be that for the angle of 70°. From the comparison between the calculated and observed oscillator strengths, the most suitable value of the angle was determined to be 60°. Therefore, it is most probable that the angle between the naphthalene ring plane and the nitro groups in 1, 8-dinitronaphthalene is 60°—70° in solution. This value seems reasonable in view of the fact that the nitro groups are twisted by 49° from the naphthalene ring in 1, 5-dinitronaphthalene.[7]

The Assignment of the Absorption Bands.—The 303 mμ band may safely be assigned to the $W_0'' \rightarrow W_2''$ and $W_0'' \rightarrow W_3''$ transitions. Judging from the calculated oscillator strengths, the latter transition band may be considered to be hidden under the former. The latter mainly consists of the CT_5-type charge-transfer transition. An inspection of Ψ_2'' given in Table X shows that the $W_0'' \rightarrow W_2''$ transition is a mixture of the $A_{1g}^- \rightarrow B_{2u}^+$ transition of naphthalene and the charge-transfer (CT_5-type) transition.

In view of the oscillator strength values of the $W_0'' \rightarrow W_6''$ and $W_0'' \rightarrow W_7''$ transitions, the character of the 229.5 mμ band comes mostly from the former. The latter is composed of the shifted $A_{1g}^- \rightarrow B_{1g}^-$ transition. The $W_0'' \rightarrow W_6''$ transition consists mainly of the CT_4-type charge-transfer

13) G. D. Nordheim and H. S. Sponer, *Discussions Faraday Soc.*, **9**, 19 (1950).

band, although it also includes the $A_{1g}^{-} \rightarrow B_{3u}^{+}$ transition to some extent. The 199.5 mμ band may owe its character chiefly to the $W_0'' \rightarrow W_{10}''$, $W_0'' \rightarrow W_{11}''$ and $W_0'' \rightarrow W_{12}''$ transitions. The $W_0'' \rightarrow W_{11}''$ transition is very weak in comparison with the other two. The $W_0'' \rightarrow W_{10}''$ transition may be regarded as a mixture of the $A_{1g}^{-} \rightarrow B_{3u}^{+}$ and CT_4-type transitions. The $W_0'' \rightarrow W_{12}''$ transition corresponds to the local excitation of the NO_2 groups.

The Solvent Effect on the Absorption Bands.—Figure 3 shows that the 199.5 mμ and 229.5 mμ bands of 1, 8-dinitronaphthalene are sensitive to the polarity of the solvent; these bands change not only in the peak wavelength but also in the intensity with the polarity of the solvent. These tendencies are tabulated in Table XI. In order to explain the solvent effect, we calculated the energy levels and wave functions, changing the energy values of the two types of charge-transfer configurations, H_{CT_5} and H_{CT_4}. The results are shown in Table XII. It is seen that the decrease in the energies of the two types of charge-transfer configurations brings about a decrease in the transition energies (mean values) corresponding to the three absorption bands at 199.5, 229.5 and 303 mμ, and that it causes a decrease and an increase in the oscillator strength values of the 229.5 mμ and 199.5 mμ bands respectively. On the other hand, the oscillator strength of the 303 mμ band is insensitive to the solvent. These theoretical results satisfactorily explain the observed solvent effects shown in Table XI. Thus the absorption spectrum of 1, 8-dinitronaphthalene may be regarded as a typical example showing conspicuous solvent effects through the energy change of the charge-transfer configurations.

Dipole Moments of α- and β- Nitronaphthalenes.—According to the present theoretical consideration, the contributions of the charge-transfer configurations in the ground state are 2.1% and 4.4% for α- and β- nitronaphthalenes respectively. From this it may be expected that the dipole moments due to π-electrons would be greater in β-nitronaphthalene than in α-nitronaphthalene. In fact, the dipole moments of α- and β-nitronaphthalenes were observed to be 3.62—3.88D and 4.36—4.4D respectively.[14] In order to treat the problem more quantitatively, we calculated the dipole moments of these compounds by considering the additional moment due to the contribution of the charge-transfer configurations.[15] Consequently, the dipole moments of α- and β-nitronaphthalenes were calculated to be 3.52 and 4.10D respectively. Therefore, it may be said that the present theoretical treatment can explain quantitatively, or at least semi-quantitatively, the difference in the dipole moment between α- and β-nitronaphthalenes. A similar calculation was made for the dipole moment of 1, 8-dinitronaphthalene, with the result of 6.77D. This value also coincides well with the observed value, 7.1—7.87D.[14]

14) L. G. Wesson, "Tables of Electric Dipole Moments," The Technology Press, Massachusetts Institute of Technology, Cambridge, Massachusetts (1948), pp. 13, 45.

15) The dipole moments of the charge-transfer configurations were evaluated to be as follows from the π-electron distribution of each CT configuration:

α-Nitronaphthalene CT_4, CT_5; 16.40D

β-Nitronaphthalene CT_4, CT_5; 20.74D

From these values and the contribution of each charge-transfer configuration in the ground state, the additional dipole moments due to resonance interaction are evaluated to be 0.36 and 0.92 D for α- and β-nitronaphthalenes respectively. By combining these additional dipole moments with the observed dipole moment of nitromethane, 3.2D, the dipole moments of α- and β-nitronaphthalenes were evaluated to be 3.52 and 4.10D respectively.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1269—1273 (1966)

The Reaction of the Exo-cyclic Imino Group of "4-Thiazone Imine"[1)]

By Masaki OHTA, Kei YOSHIDA and Shigeru SATO

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 1, 1965)

In order to accumulate further information about the properties of meso-ionic compounds with an exo-cyclic imino group, the reactivity of an exo-cyclic imino group of thiazone imine as compared with that of sydnone imine was investigated. Moreover, for the purpose of the pharmacological test, 2, 3-disubstituted thiazone imine hydrochlorides and their *N*-acetyl derivatives were prepared.

Meso-ionic compounds of various ring systems with an exo-cyclic imino group have been reported in the literatures; of these, sydnone imine has been most extensively investigated. The stabilities of the free bases of these meso-ionic compounds differ markedly, depending on the ring systems. In some

cases, as in "nitron", free bases can be obtained in a stable form, but sydnone imine or "thiazone imine", which we reported on previously,[2] is unstable and can not be obtained as a free base; it exists only in the form of a salt or an *N*-acyl derivative. Furthermore, the reactivity of the exo-cyclic imino group varies according to the ring system and appreciably differs from that of a usual imino group, which suggests the presence of intrinsic characteristics of the meso-ionic ring. The structure of meso-ionic compounds other than sydnone imine has scarcely been investigated; there remain many points for discussion concerning the representation of these compounds. In some cases, the representation of one specific polar structure might be satisfactory, although as a common feature the compounds can be regarded as resonance hybrids consisting of many polar structures. The structure of the hydrochloride of thiazone imine, which we considered as a meso-ionic compound, may be represented not only by formulae I and II, but also by the quaternary salt structure III, as will be shown below. The hydrochloride of an *N*-acyl derivative of thiazone imine may similarly be represented by IV, V, VI, etc.

The present investigation of the reactivity of the exo-cyclic imino group of thiazone imine, as compared with that of sydnone imine, was undertaken in order to accumulate further information about the structure of thiazone imine. Moreover, stimulated by the recent interest in pharmacological activities,[3] we synthesized 2, 3-disubstituted thiazone imine derivatives for the pharmacological test and also for the purpose of testing the applicability of the methods reported in a previous paper.[2]

Two procedures for the synthesis of thiazone imine derivatives are available: the ring closure of intermediate nitriles prepared by refluxing a benzene solution of chloroacetonitrile and *N*-monosubstituted thioamides by treatment with hydrogen chloride (method A), and a one-step condensation of thioamides and chloroacetonitrile by heating, with or without diphenyl as a diluent (method B).

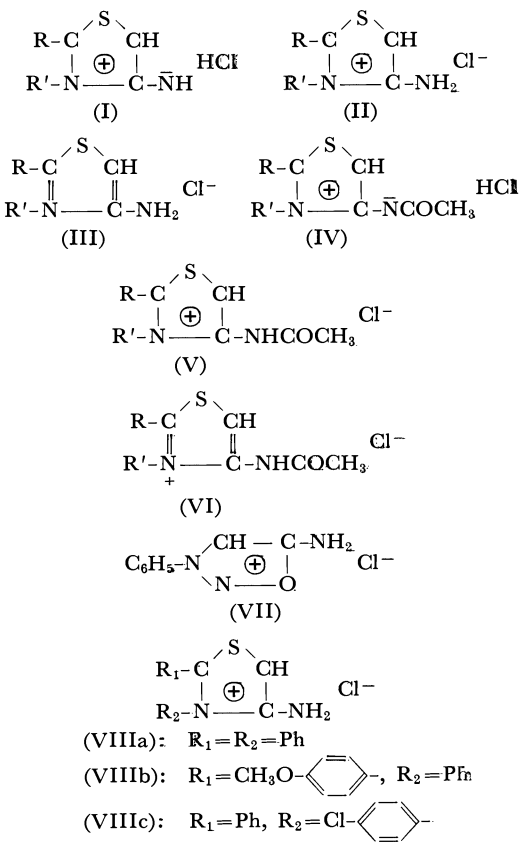

Fig. 1.

The data on the newly-synthesized thiazone imine hydrochlorides are summarized in Table I. Compounds No. 1 and No. 2 were prepared by both methods A and B, and the others, by only method B; an attempt to isolate the intermediates was in vain to give the starting materials. The reaction of thioformanilide and chloroacetonitrile to prepare 3-phenyl-thiazone imine hydrochloride could not be accomplished by method B. The reaction of thiocaprolactam with chloroacetonitrile by

method B to prepare 2, 3-cyclopentamethylene thiazone imine salt gave *S*-acetoamido-isothiocaprolactam hydrochloride. These facts suggest that, in thiazone imine salt, the ring is stabilized by conjugation with aromatic substituents.

As a preliminary work for the subsequent experiments, the stability of the salt and bases of 2, 3-diphenyl thiazone imine was examined. Concerning the stability of sydnone imine, we[4] and Daeniker[3] have reported that its hydrochloride VII is quite stable when heated with water or dilute hydrochloric acid, while its free base can not be obtained by neutralization, which resulted only in decomposition yielding the nitrosoacetonitrile derivative. When an aqueous solution of sydnone imine hydrochloride is neutralized with sodium bicarbonate, a solution of bicarbonate of sydnone imine is formed; this solution, although it is decomposed on heating and carbon dioxide is evolved, can be used immediately for further experiments such as the preparation of *N*-acyl-derivatives. On the other hand, 2, 3-diphenyl-4-thiazone imine hydrochloride (VIIIa) is converted to the acid amide derivative by heating it in 10% hydrochloric acid at 100°C. When an aqueous solution of VIIIa was allowed to stand for a long period, heated at 100°C or neutralized with sodium bicarbonate, a tarry substance was separated out; from this substance nothing could be isolated in a pure state. However, an intermediate nitrile, *S*-cyanomethyl-isothiobenzoyl-*p*-chloroanilide, was isolated from the neutralization products of 2-phenyl-3-(*p*-chlorophenyl)-4-thiazone imine hydrochloride (VIIIc). The above facts indicate that the decomposition of VIIIa does not proceed through a simple reversed process of its formation and that VII is more sensitive to hydrolytic attack than is sydnone imine hydrochloride.

In the studies of reactions at the exo-cyclic imino group of thiazone imine hydrochloride, manipulations in an aqueous or alkaline media seem undesirable. Therefore, taking the results obtained here into consideration, several reactions of VIII under special conditions were examined.

VII can be acetylated with acetic anhydride or acyl chloride by usual methods. In contrast to sydnone imine, VIIIa can not be benzoylated with benzoyl chloride in pyridine, and VIII is recovered unchanged. The acetylation of VIIIa by heating it with acetic anhydride at 100°C for many hours in either the absence or the presence of pyridine gave an acetyl derivative, but the yield was not satisfactory. The use of boron trifluoride as a condensing agent shortened the reaction time considerably and gave a better yield. The data on newly synthesized *N*-acetyl-derivatives of 2, 3-disubstituted-4-thiazone imine hydrochlorides are summarized in Table II. However, the applicability of the method to the synthesis of various acyl-derivatives is extremely limited due to the necessity of using an acid anhydride. We have now found that acylation can be easily accomplished by the simple heating of VIIIa with acid chloride without a solvent or in an inert solvent; by this method various acyl derivatives are obtained in good yields. In a similar way, VII is easily acylated with aliphatic acid chloride, but not with aromatic acid chloride, presumably because of the high reaction temperature, which causes the decomposition of VII.

The carbamoylation and thiocarbamoylation of VII were also attempted. Phenylcarbamoyl and thiocarbamoyl derivatives are unknown. When VII was treated with potassium cyanate in water at room temperature overnight, the *N*-carbamoyl derivative (IX) of VII was obtained, along with a small quantity of *N*-nitroso-*N*-phenyl-glycinonitrile. Under similar conditions, VII and sodium thiocyanate gave only thiocyanate salts of sydnone imine X. All attempts to convert this into the thiocarbamoyl derivative (XI) were unsuccessful. In the case of VIIIa and VIIIb, the reaction with potassium cyanate in a chloroform solution under reflux produced the *N*-carbamoyl derivative, XIIa and XIIb. The reaction of VIIIa with sodium thiocyanate in water gave thiocyanate salts of thiazone imine XIII, which forms the same picrate

4) H. Kato, M. Hashimoto and M. Ohta, *J. Chem. Soc. Japan, Pure Chem. Sect.* (*Nippon kagaku Zassi*), **78**, 707 (1957).

as that obtained from VIII. Attempts to isomerize the thiocyanate of thiazone imine into a thiocarbamoyl derivative XIV were unsuccessful.

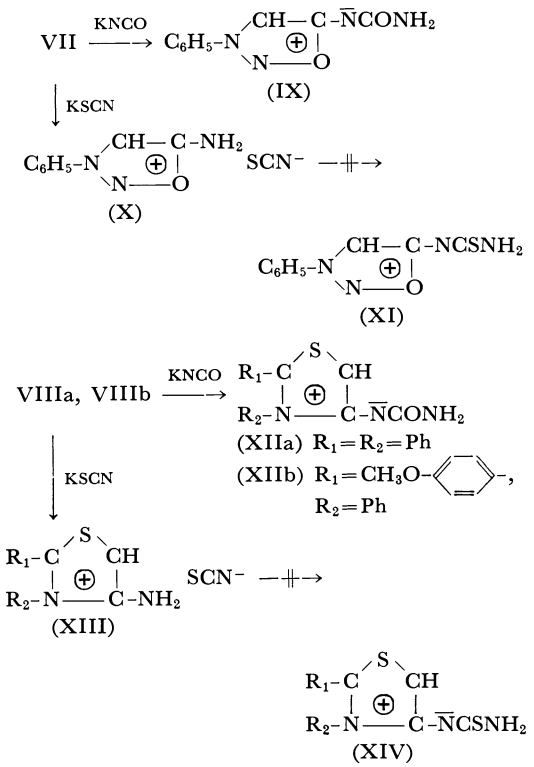

Fig. 2.

Experimental

The Preparation of 2-Phenyl-3-*p*-chlorophenyl-4-thiazone Imine Hydrochloride (VIIIc) by Method A.—A solution of 45 g. of thiobenzoyl-*p*-chloroanilide, 14 g. of chloroacetonitrile and 23 g. of triethylamine in 300 ml. of benzene was refluxed for 3 hr. After the solution had cooled, the precipitated triethylamine hydrochloride was filtered off, and benzene was removed by evaporating it under reduced pressure. The oily residue crystallized after the solution had then stood overnight. The recrystallization from methanol gave *S*-cyanomethyl-isothiobenzoyl-*p*-chloroanilide as white prisms; m. p. 118°C. The yield was 55 g.

Found: C, 62.82; H, 4.01; N, 9.82. Calcd. for $C_{15}H_{11}ClN_2S$: C, 62.94; H, 3.85; N, 9.79%.

Into the solution of 55 g. of *S*-cyanomethyl-isothiobenzoyl-*p*-chloroanilide in 300 ml. of dry acetone, 30 ml. of 30% alcoholic hydrogen chloride was added under cooling in an ice-water bath. The yellow crystals of VIIIc which precipitated were recrystallized from ethanol. *S*-Cyanomethyl-isothiobenzoyl-*o*-chloroanilide (m. p. 80°C) and 2-phenyl-3-*o*-chlorophenylthizaone imine hydrochloride were prepared in the same way.

The Preparation of 2, 3-Disubstituted-4-thiazone Imine Hydrochloride by Method B.—In order to avoid needless repetition, the experimental conditions for carrying out these reactions have been generalized. A mixture of *N*-substituted thioamides, a slight excess over the calculated amount of chloroacetonitrile and an equal amount of diphenyl was heated at 100—120°C in an oil bath. First the reaction mixture melted to a clear solution, and then, as the reaction proceeded, the hydrochloride began to crystallize out. Usually, the reaction is accompanied by a considerable temperature elevation which must be controlled by cooling. After ten to twenty minutes heating, acetone was added to the cooled mixture, and the insoluble crystals were collected by filtration and washed with an acetone-ether mixture. The products can be recrystallized from an ethanolic solution by gradually adding ether.

The Preparation of *N*-Acetyl-2, 3-disubstituted-4-thiazone Imine Hydrochloride.—The experimental conditions for carrying out these reactions have been generalized.

A suspension of 2, 3-disubstituted-4-thiazone imine hydrochloride in about ten times as much acetic anhydride by weight containing a small amount of boron trifluoride etherate was heated at 100°C while being stirred. The reaction times are shown in Table I.

Into the cooled solution, ether was added and the precipitates were collected by filtration and recrystallized from ethanol.

The Reaction of VIIIc and Sodium Bicarbonate.—Into the solution of 1 g. of VIIIc in 10 ml. of water, 5 ml. of 5% sodium bicarbonate solution was added. The solution was allowed to stand overnight. During this time a brown solid was separated out; it was then recrystallized from methanol. 0.3 g. of *S*-cyanomethyl-isothiobenzoyl-*p*-chloroanilide (m. p. 118°C) was thus obtained.

The Acylation of Sydnone- and Thiazone Imine Hydrochlorides with Acyl Chloride.—*General Procedure.* Sydnone- or thiazone imine hydrochloride was heated with an excess of acyl chloride without a solvent or in an inert solvent such as toluene, and the hydrochloride of the acyl derivative was collected by filtration, washed with benzene, and recrystallized from an appropriate solvent.

The following acyl derivatives were prepared by this method: Acetyl-: m. p. 290°C (decomp.). Free base: m. p. 198°C (decomp.). Propionyl-: m. p. 220°C (decomp.).

Found: N, 7.60; Calcd. for $C_{18}H_{17}ClN_2OS$: N, 8.10%.

Benzoyl-: m. p. 223°C (decomp.). Free base: m. p. 212°C (decomp.). Cinnamoyl-: m. p. 272°C (decomp.). Found: N, 6.70; Calcd. for $C_{23}H_{19}ClN_2OS$: N, 6.72%.

The Reaction of Thiocaprolactam with Chloroacetonitrile.—Two grams of thiocaprolactam with 1.2 g. of chloroacetonitrile was heated at 100°C on a water bath. The reaction was completed in several minutes, yielding a viscous oil which solidified when left standing at room temperature. Acetone was added, and the insoluble products were collected by filtration. Recrystallization from benzene-ethanol gave *S*-carbamoylmethyl-isothiocaprolactam hydrochloride as colorless prisms. Yield, 1.6 g; m. p. 158—159°C.

Found: C, 43.54; H, 6.52; N, 12.57. Calcd. for $C_{18}H_{13}ClN_2S$: C, 43.14; H. 6.74; N, 12.48%.

***N*-Carbamoyl-3-phenyl-sydnone Imine (IX).**—One gram of VII was dissolved in water, and then an aqueous solution of 0.4 g. of potassium cyanate was added. After the solution had been allowed to stand

overnight, the pale yellow precipitates were collected by filtration and recrystallized from ethanol to give IX as yellow crystals, m. p. 153°C (decomp.).

Found: C, 52.91; H, 4.17; N, 27.38. Calcd. for $C_8H_8N_4O_2$: C, 52.94; H, 3.95; N, 27.44.%

3-Phenylsydnone Imine Thiocyanate (X).—Into an aqueous solution of 1 g. of VII, a solution of 0.42 g. of sodium thiocyanate was added. The precipitate was immediately separated out and recrystallized from ethanol to give pale yellow needles, m. p. 155°C (decomp.).

Found: C, 49.57; H, 3.66; N, 25.30. Calcd. for $C_8H_8N_4OS$: C, 49.09; H, 3.66; N, 25.45%.

This was not converted into *N*-thiocarbamoyl-3-phenylsydnone imine when heated.

***N*-Carbamoyl-2, 3-diphenylthiazone Imine (XIIa).**—One gram of VIIIa and 0.9 g. of pulverized potassium cyanate were refluxed in 80 ml. of chloroform for 5 hr. After the solvent had been removed under reduced pressure, the residue was recrystallized from ethanol to give XIIa as yellow crystals, m. p. 275°C (decomp.).

Found: C, 65.02; H, 4.48; N, 14.38. Calcd. for $C_{16}H_{13}N_3OS$: C, 65.08; H, 4.44; N, 14.23%.

2, 3-Diphenylthiazone Imine Thiocyanate (XIIIa).—To an aqueous solution of 1 g. of VIIIa, a solution of 0.3 g. of sodium thiocyanate was added. The yellow precipitate which was immediately separated out was collected and recrystallized from 70% aqueous ethanol to give yellow needles, m. p. 113°C (decomp.).

Found: C, 65.02; H, 4.48; N, 14.38. Calcd. for $C_{16}H_{13}N_3S_2$: C, 65.08; H, 4.34; N, 13.49%.

This thiocyanate could not be converted into *N*-thiocarbamoyl-2, 3-diphenylthiazone imine by heating it.

***N*-Carbamoyl-2-(*o*-methoxyphenyl)-3-phenylthiazone Imine (XIIb).**—One gram of VIIIb was dissolved in chloroform, and then 0.75 g. of powdered potassium cyanate was added. After the mixture had been allowed to stand overnight at room temperature, it was evaporated under reduced pressure to yield a crystalline residue. The residue was recrystallized from ethanol to give yellow scales, m.p. 287°C (decomp.).

Found: N, 14.41. Calcd. for $C_{17}H_{15}N_3O_2S$: N, 13.59%.

2-(*p*-Methoxyphenyl)-3-phenylthiazone Imine Thiocyanate (XIIIb).—When an aqueous solution of 1 g. of VIIIb, a solution of 0.3 g. of sodium thiocyanate was added, yellow crystals were crystallized out immediately. Recrystallization from ethanol gave yellow needles, m. p. 163°C (decomp.).

Found: N, 12.39. Calcd. for $C_{17}H_{15}N_3OS_2$: N, 12.30%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1273—1279 (1966)

Amino Acid-Carbohydrate Coordinated Compounds.* II. The Synthesis and the Stability of 3-*O*-Aminoacyl-D-glucoses**

By Nobutoshi MURAMATSU

Central Research Laboratory, Ajinomoto Co., Kawasaki

(Received November 2, 1965)

3-*O*-Aminoacyl-D-glucoses (amino acids; Gly, L-Ala, L-Lys, L-Asp (α and β) and L-Glu (α and γ)) have been prepared by the condensation of 1, 2; 5, 6-di-*O*-isopropylidene-D-glucose with suitably protected amino acid derivatives in the presence of *N*, *N'*-dicyclohexylcarbodiimide, followed by the removal of the protected groups. The effect of free amino and carboxyl groups on the stability of these compounds has been clarified.

In the investigations of the mode of the linkage of amino acids to carbohydrates in glycoproteins, a few reports[1,2] on the synthesis of 6-*O*-aminoacyl-D-glucoses have been presented, with it taken as a low molecular model compound for the examination of the stability of the glycopeptide linkage. Suzuki et al.[1] synthesized 6-*O*-(*N*-benzyloxycarbonyl=Cbz)aminoacyl-D-glucoses by the condensation of 1, 2 ; 3, 5-di-*O*-benzylidene-D-glucose with *N*-Cbz-amino acids (Gly, L-Lys, L-Asp-α-benzyl and L-Asp-β-benzyl) in the presence of *N*, *N'*-dicyclohexylcarbodiimide (the DCC method), followed by the hydrolytic removal of benzylidene groups. Kochetkov et al.[2] developed the direct synthesis of the compounds by the condensation of unprotected glucose with *N*-Cbz-amino acids (Gly, DL-Ala, DL-Val, DL-Norleu, β-Ala and ε-amino caproic acid) by the DCC method. The removal of the Cbz-group from these compounds by catalytic hydrogenolysis in neutral media causes the ester bond to break; only in acidic media it is successfully accomplished. Kochetkov et al.[3] clarified the effect of the amino group in the aminoacyl group on the stability of these compounds.

This paper will deal with the preparation and the stability of 3-*O*-aminoacyl-D-glucoses (amino acids; Gly, L-Ala, L-Lys, L-Asp-α-benzyl, L-Asp-β-benzyl, L-Glu-α-benzyl and L-Glu-γ-benzyl). According to Kochetkov's report[2] 3-*O*-*N*-Cbz aminoacyl-D-glucose was formed as a minor product of these condensations. It was identified with the authentic sample by a synthesis using the condensation of 1, 2 ; 5, 6-di-*O*-isopropylidene-D-glucose with *N*-Cbz-glycine, followed by the removal of the isopropylidene groups. The procedure employed in one of the author's reports[4] was used here. Equal moles of 1, 2 ; 5, 6-di-*O*-isopropylidene-D-glucose[5] and suitably protected *N*-Cbz-amino acid derivatives were condensed in the presence of DCC in absolute pyridine.

After the filtration, the precipitated *N*, *N'*-dicylohexylurea was washed with excess benzene. The combined mixture of the filtrate and the washings was washed with dilute hydrochloric acid, aqueous sodium bicarbonate and water, and then dried over sodium sulfate. The benzene layer was evaporated under reduced pressure to a thick syrup, and crystallized by trituation with petroleum ether. The 1, 2 ; 5, 6-di-*O*-isopropylidene-3 - *O* - *N* -Cbz-aminoacyl-D-glucoses (I) thus obtained gave negative silver ammonia and ninhydrin reactions, and exhibited absorption bands characteristic of ester carbonyl at 1740—1755 cm^{-1} and the bands characteristic of urethane carbonyl at 1675—1710cm^{-1} in the infrared spectra. The hydrolysis of isopropylidene groups of I in 75% acetic acid at 80°C for two or three hours gave 3-*O*-*N*-Cbz-aminoacyl-D-glucoses (II). Although II was purified by cellulose powder chromatography, only a few compounds could be obtained as crystals. These compounds gave positive silver ammonia and negative ninhydrin reactions. The compound II was converted to 3-*O*-aminoacyl-D-glucoses (III) by hydrogenolysis in aqueous methanol in the presence of Pd-C. In the case of neutral and basic aminoacyl-derivatives, III was obtained as oxalate. The compound III gave positive silver ammonia and ninhydrin reactions. The structure of III was confirmed by periodate oxidation, in which the consumption of the periodate was three moles per mole of III. 1, 2 : 5, 6-di-*O*-isopropylidene - 3 - *O* - aminoacyl-D-glucose (IV) was obtained from I by the procedure described above. The physical properties of I, II, III and IV are summarized in Table I.

The stability of these compounds was investigated at various pH values under the experimental conditions shown in Table II.

Table II. Conditions on hydrolysis for the investigation on the stability of ester bond

Temperature: 40°C
Concentration: 0.02 mol.
PH: 1, 2.2, 3, 4, 5, 6, 8.
Buffer: McIlvain's Buffer.
Separation of the degradation products:
Paper chromatography: Solv. *n*-BuOH sat. with H_2O
Paper electrophoresis: Solv. Pyridine : HOAc : H_2O (2 ml. : 4 ml. : 1000 ml.)
Determination of the degradation products:
D-Glucose: Anthrone method
Amino acids: Bioassay

The hydrolysis was carried out in the concentration of 0.02 mmol. in order to obtain the half-life periods and rate constants as the first order reaction.[3] As an example, diagrams of reaction time-liberated glucose in the hydrolysis of 3-*O*-L-alanyl-D-glucose at pH 6 and 1 are shown in Fig. 1. In the case of pH 1, the half-life period was calculated by the extrapolation of the data. The half-life periods of various compounds at pH 6 and 1 are listed in Table III.

In order to compare the stability of the neutral and basic amino acid esters, the half-life periods of 3-*O*-L-alanyl-D-glucose and of 3-*O*-L-lysyl-D-glucose are plotted against the individual pH values in Fig. 2. Figure 3 shows the half-life period of the acidic amino acid esters; 3-*O*-α-L-aspartyl-D-glucose and 3-*O*-β-L-aspartyl-D-glucose.

IV-b		—	31/4	1.1

Discussion

The neutral and the basic 3-*O*-aminoacyl-D-glucoses gave similar curves, as is shown in Fig. 2. In the region of pH 4—7, their stabilities are almost identical. This reflects the effect of the α-amino group mainly, while the ε-amino group in the L-lysyl ester has almost no effect. In the region of pH 1—3, however, 3-*O*-L-lysyl-D-glucose is more stable than 3-*O*-L-alanyl-D-glucose. This may be understood in terms of Kochetkov's interpretation[3] that the protonation on the free amino

group prevents the attack of the proton on the ester bond. This tendency is more prominent in the case of the L-lysyl ester because it has two amino groups.

The acidic amino acid esters, as described in Fig. 3, show almost the same stability as the neutral and the basic amino acid esters in the region of pH 5—7. The difference in stability between 3-*O*-β-L-aspartyl-D-glucose and 3-*O*-α-L-aspartyl-D-glucose in the region of pH 4—6 is caused by the interrelation of distance between the ester bond and the amino group. In more acidic media below pH 4, these acidic amino acid esters are extremely stable. This may be explained by the hydride ion formation of the intramolecular carbonyl group with the amino group, which reduces the effect of the amino group. The effects of both the stability and the instability of the free amino group on these compounds are unambiguous in view of the fact that the half-life periods of 3-*O*-L-alanyl-D-glucose and 3-*O*-*N*-Cbz-L-alanyl-D-glucose at pH 1 and 6 (shown in Table III) are interchanged alternately.

On the other hand, the interaction of the amino and the carbonyl groups in these aminoacyl sugars must be considered to be one of the factors causing instability, in addition to the effect of the amino group mentioned above. The half-life period of 1, 2 ; 5, 6-di-*O*-isopropylidene-3-*O*-L-alanyl-D-glucose at pH 6 listed in Table III is almost the same value as that of 3-*O*-L-alanyl-D-glucose, this seems to be negative evidence for the deduction above. However, such an estimation should be based upon a comparison of the corresponding derivatives with the same conformations. This aspect is now under examination.

Experimental

For paper chromatography and paper electrophoresis "Toyo Roshi filter paper No. 51A" was used. The paper chromatography technique used was the ascending procedure using the buffer cited in Table II. Paper electrophoresis was carried out using the buffer of pH 4 cited in Table II, the condition selected was 26.7 V./cm. The R_f values for paper chromatography and the mobilities for electrophoresis may be summarized as follows: These spots were detected with silver ammonia[3] (free carbonyl), ninhydrin (amino) and Rydn reactions[6] (imino). The melting points are not corrected.

1, 2 ; 5, 6-Di-*O*-isopropylidene-3-*O*-*N*-benzyloxycarbonyl-aminoacyl-D-glucoses (I).—DCC (0.011 mol.) was added to a solution of *N*-Cbz-amino acid derivatives (0.01 mol.) in dry pyridine (100 ml.) which had been cooled to 0°C, 1, 2 ; 5, 6-di-*O*-isopropylidene-D-glucose (0.01 mol.) was added to the mixture a few minutes later, and then the solution was kept at room temperature overnight. The precipitated *N, N'*-dicyclohexylurea was filtered and washed with benzene (150 ml.). The mixture of the filtrate and the washings was washed several times with 5% hydrochloric acid, 2% sodium bicarbonate solution and water, then dried over anhydrous sodium sulfate, and evaporated to a syrup under reduced pressure. The syrup thus obtained was dissolved in ether and treated with petroleum ether until it became turbid; then it was left in a refrigerator. The crude crystals were recrystallized from ethyl acetate and water. The physical constants of 1, 2 ; 5, 6-di-*O*-isopropylidene-3-*O*-*N*-Cbz-aminoacyl-D-glucoses (I) prepared by this method are presented in Table I.

3-*O*-*N*-Benzyloxycarbonyl-aminoacyl-D-glucoses (II).—A solution of 1, 2 ; 5, 6-di-*O*-isopropylidene-3-*O*-*N*-Cbz-aminoacyl-D-glucose (I) (0.01 mol.) in 75% acetic acid (40 ml.) was refluxed for three hours, and then the solution was evaporated to a syrup under reduced pressure. In this syrup, 3-*O*-*N*-Cbz-aminoacyl-D-glucose, D-glucose resulting from the hydrolysis of the ester bond, and an unknown substance which is perhaps the partial-hydrolysed product "1, 2-*O*-isopropylidene-3-*O*-*N*-Cbz-aminoacyl-D-glucose" were detected by paper chromatography. The purification of 3-*O*-*N*-Cbz-aminoacyl-D-glucose was attempted by partition chromatography over cellulose powder (Tokyo Roshi: Grade B) as an adsorbent and *n*-butyl alcohol saturated with water as the effluent. Each fraction was detected by paper chromatography. The elution pattern is shown in Fig. 4. The fractions of the peak of A were collected and evaporated under reduced pressure, and a syrup of 3-*O*-*N*-Cbz-aminoacyl-D-glucose was obtained. Among these a few compounds were crystallized from ethyl acetate. The physical constants of 3-*O*-*N*-Cbz-aminoacyl-D-glucoses are presented in Table I.

3-*O*-Aminoacyl-D-glucoses (III).—*a) The Case of Neutral and Basic Amino Esters.*—To a solution of 3-*O*-*N*-Cbz-aminoacyl-D-glucose (0.005 mol.) in methanol (50 ml.), oxalic acid (0.01 mol.) and 10% Pd-C (2 g.) suspended in water were added; the mixture was then subjected to hydrogenolysis. Hydrogen gas was bubbled into the stirred mixture at room temperature until no carbondioxide was detected in the exhaust. This

Fig. 4.

took about 4—5 hr. The catalyst was removed by filtration and washed with water. The filtrate and the washings were combined and evaporated to a syrup under reduced pressure below 40°C. The syrup was dissolved in methanol and crystallized with the addition of acetone. Recrystallization was then repeated with the same procedure. The yields of these products were about 60—70%.

b) The Case of Acidic Amino Acid Esters.—In this case oxalic acid is not necessary. The other procedures were conducted with the method described above. The yields were 55—85%. The physical constants of 3-*O*-aminoacyl-D-glucoses are presented in Table I.

1, 2 ; 5, 6-Di-*O*-isopropylidene-3-*O*-aminoacyl-D-glucoses (IV).—Compounds I were hydrogenolysed with the procedure mentioned above and so transformed to 1, 2 ; 5, 6-di-*O*-isopropylidene-3-*O*-aminoacyl-D-glucose (IV). In these cases, after the filtration of the catalyst, the filtrate was concentrated and crystallized from methanol or methanol and ether. The physical constants of 1, 2 ; 5, 6-di-*O*-isopropylidene-3-*O*-aminoacyl-D-glucoses are presented in Table I.

General Procedure for the Investigation of Hydrolysis.—A 0.02 mol. solution of 3-*O*-aminoacyl-D-glucoses in an appropriate buffer was soaked into a thermostat controlled at 40°C; 0.05 ml. portions of the solution were sampled intermittently; they are spotted along Line A in Fig. 5. At the same time, the standard solution of D-glucose or amino acid was spotted on the paper at Point B. The spots were developed on paper electrophoresis. The part containing the degradation product was excised along Line A and eluted with 10 ml. of water as shown in Fig. 6.[7] D-

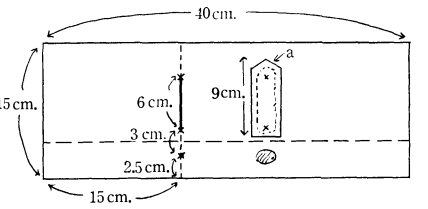

Fig. 5.

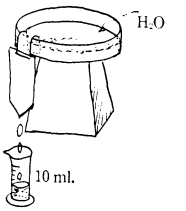

Fig. 6.

Glucose was estimated by the Anthron method[8] and amino acid by bioassay[9] using the eluted solution.[10] The recovery of the method was 100±6%, and the reference sample was made by the procedure described above using non-spotted paper.

a) Neutral and Basic Amino Acid Esters.—In these cases the hydrolysis was pursued by the estimation of D-glucose, as the mobility of D-glucose was different from that of 3-*O*-aminoacyl-D-glucoses. For example, in Table IV and Fig. 1 the progress of the hydrolysis of 3-*O*-L-alanyl-D-glucose at pH 6 and 1 is shown. In this case 3-*O*-L-alanyl-D-glucose was weighed (6.0 mg.) and dissolved in 1 ml. of a buffer. The final value of the D-glucose liberated should be 36 γ in 0.01 ml. of the solution. Figure 2 was the result of plotting the half-life period against the pH values.

b) Acidic Amino Acid Esters.—In this case the hydrolysis could not be pursued by the estimation of D-glucose, for the mobility of 3-*O*-aminoacyl-D-glucose was similar to that of D-glucose. Therefore, it was pursued by the estimation of amino acid by the bioassay method, as the mobility of the amino acid was different from that of 3-*O*-aminoacyl-D-glucose. The half-life periods at all the pH values are shown in Fig. 3.

c) The Hydrolysis of 3-O-N-Benzyloxycarbonyl-L-alanyl-D-glucose.—In this case the hydrolysis was pursued by the estimation of D-glucose after the development of the spot by paper chromatography.

d) The Hydrolysis of 1, 2 ; 5, 6-*Di-O-isopropylidene-3-O-L-alanyl-D-glucose.*—In this case the hydrolysis was

7) Dipping of the filter paper into water is practically effective for the estimation of amino acids.

Vinyl-substituted Polysilanes

By Hideki SAKURAI, Kenji TOMINAGA and Makoto KUMADA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received November 4, 1965)

1-Vinylheptamethyltrisilane, 2-vinylheptamethyltrisilane and vinylpentamethyldisilane have been prepared from the corresponding chlorosilanes and vinylmagnesium chloride. In these compounds, intense absorption maxima were observed in the ultraviolet region, and both the λ_{max} and ε increased with an increase in the chain length. Nuclear magnetic resonance and infrared data are also recorded here. Free radical copolymerizations were carried out with styrene and with acrylonitrile, and the monomer reactivity ratios of vinylpentamethyldisilane and 2-vinylheptamethyltrisilane were determined. It has been concluded that the 3d orbital resonance is not important for the stabilization of an odd electron adjacent to the silicon atom in the free radical intermediate in copolymerization in spite of spectral and chemical evidence of enhanced conjugation between the vinyl group and the polysilanyl group.

In their studies of the copolymerization of vinyltriethoxysilane and vinyltrimethylsilane, Scott and Price reported a very low resonance stabilization factor, Q.[1] The low values of Q for both monomers (0.03—0.035) were further supported by the ultraviolet spectra of these compounds, which disclosed only a little conjugation between the vinyl group and the silicon atom. On the other hand, for vinyl sulfides[2] it was concluded, from the large Q values and the relatively intense ultraviolet absorption band, that a sulfide sulfur atom could conjugate with a p electron, either in the free radical intermediate or in the excited state, possibly through 2p-3p conjugation but *not through 2p-3d conjugation.*[1]

Recently, Hague and Prince[3] described an absorption at 246.5 mμ for hexaphenyldisilane and explained this absorption as due to an interaction between phenyl groups through the silicon-silicon bond. Subsequently, it was reported from this laboratory[4,4a] that polysilanes with phenyl or vinyl groups, unlike monosilanes, have a very intense absorption in the ultraviolet region, and it was proposed that the silicon-silicon bond itself is a chromophore, making an enhanced conjugation with pi-electron systems. This interesting ultraviolet property of polysilanes has also been studied independently by Gilman et al.[5,6] In relation to these findings our primary interest was to investigate if the enhanced conjugation of the disilanyl group with the ethylenic double bond influences the copolymerization characteristics and other properties of these vinylpolysilanes.

In the present paper we wish to describe the results of the preparation, spectral study and copolymerization study of vinyl-substituted polysilanes.

Results and Discussion

Vinylpentamethyldisilane (I), 1-vinylheptamethyltrisilane (II), and 2-vinylheptamethyltrisilane (III) were prepared from vinylmagnesium chloride and the corresponding chloropolysilanes in tetrahydrofuran. These three compounds were all colorless liquids and showed no tendency to spontaneous polymerization. Chernyshev et al.[7] reported on the preparation of vinylpentamethyldisilane, together with related disilanyl compounds.

M_2	M_1	r_1	r_2	Q_2	e_2
I	Styrene	50±10	0	0.02	−0.6
	Acrylonitrile	3±1	0		
III	Styrene	38±5	0	0.02	−0.7
	Acrylonitrile	2±1	0		

They gave 120—121°C as the boiling point of vinylpentamethyldisilane, but our repeated preparation of this compound disclosed its boiling point to be 131°C.

Table I lists the ultraviolet spectral properties observed for I, II and III, together with vinyltrimethylsilane (IV), vinyltriethoxysilane (V), 1, 2-divinyltetramethyldisilane (VI) and 1, 4-divinyloctamethyltetrasilane (VII). With an increase in the number of silicon atoms, the position of the absorption maximum shifted to a longer wavelength and the molar extinction coefficient increased regularly. This is a tendency which was also observed with phenylsubstituted polysilanes[3,6)] and with permethylated polysilanes.[6)]

Recently West[8)] illustrated the effect of metalloid substitution on the electronic spectra of simple chromophores using a qualitative molecular orbital theory. Since the electronic absorption of a simple olefin must be associated with only a transition from bonding pi-orbitals to antibonding pi-orbitals (π-π^* transitions) and since the resonant interaction of a vacant silicon d_π orbital is expected to be stronger with the antibonding orbital than with the bonding orbital,[8)] the increasing bathochromic shift with an increase in the chain length of vinylpolysilanes may be a reflection of the lowering of the d_π level by the catenation of the silicon atom. As has been observed for 1-phenylheptamethyltrisilane,[3)] it is interesting to note that vinylheptamethyltrisilanes possess two absorption maxima (or shoulders). All permethylated straight-chain polysilanes except hexamethyldisilane have been reported[6)] to possess a characteristic absorption in

8) R. West, *J. Organometal. Chem.*, **3**, 314 (1965).

the normal ultraviolet region. Since octamethyltrisilane was found to have an absorption maximum at 215.0 mμ, the broad shoulder observed at 216—218 mμ for II and III may be attributed to the absorption of the trisilane chain itself, which originates in a different sort of transition, independent of the π-π^* transition.

The infrared absorption bands associated with the vinyl group are given in Table II. Significant shifts in CH_2 deformation and C=C stretching frequencies from normal positions in analogous carbon compounds were observed. Potts and Nyquist[9] pointed out that the out-of-plane CH_2 deformation frequencies in substituted ethylenes of the Y–CH=CH_2 type are sensitive to the nature of the substituent, Y. Thus, the CH_2 deformation band shifts to a higher frequency when the pi-electron-attracting power of Y becomes greater. As can be seen from Table II, the out-of-plane CH_2 deformation frequencies of the vinyl group for I, II and III shift from the normal frequency of the CH_2 deformation band to a frequency higher by 35 cm^{-1}. This abnormally high frequency of the CH_2 deformation may be explained by the interaction of silicon with an unsaturated system through a dative p_π-d_π overlap.[10] In a series of vinylsilanes of the $R_3SiCH=CH_2$ type, Eisch and Trainor[10] also found a correlation between the position of the CH_2 deformation frequency and the electron-withdrawing power of R as measured by σ_p or σ.* Although this interesting correlation may not be directly applicable to the vinylpolysilane system, it is likely that the electron-releasing inductive character of the pentamethyldisilanyl group is slightly greater than that of the trimethylsilyl group.

Table III lists the proton magnetic resonance data for carbon tetrachloride solutions of some vinyl-substituted silanes. The deshielding effect of the vinyl group on the proton of the methyl groups bound to silicon was observed to be transmitted along the polysilane chain. As the same trend was also observed for phenyl-substituted polysilanes,[11] these results suggest some d_π-d_π double-bond character of the polysilane chain. As one can see from Table III, only two kinds of methyl peaks were observed for II. It had been found[11] that internal Si-CH_3 groups were more shielded than terminal Si-CH_3 groups* in octamethyltrisilane, although inner Si-CH_3 groups were generally more deshielded than outer Si-CH_3 groups in homologous permethylated straight polysilanes.[11,12] Therefore, the peak of the internal $Si(CH_3)_2$, rather than of the $Si(CH_3)_2$ attached to the vinyl group, was supposed to fall at the position for the terminal $Si(CH_3)_3$.

The copolymerizations of both I (M_2) and III (M'_2) with styrene (M_1) and with acrylonitrile (M'_1) were carried out at 60°C. From the composition analyses of the resulting copolymers, the monomer reactivity ratios were determined. These copolymerization characteristics are summarized in Table IV.

The values of Q for both monomers are low and in the same range of magnitude as for many other vinyl-substituted monosilanes.[13] This fact suggests that the 3d orbital resonance is not important for the stabilization of an odd electron adjacent to the silicon atom in the free radical intermediate in the copolymerization in spite of spectral and chemical evidence of enhanced conjugation between the vinyl group and the polysilanyl group. The more negative e values of both monomers than the value for trimethylvinylsilane could be ascribed to a slightly greater electron-releasing character of the disilanyl group and of the 2-trisilanyl group. This observation is compatible with the infrared spectral evidence.

Experimental

Boiling points are uncorrected. NMR spectra were obtained in carbon tetrachloride solution with a Varian A-60 spectrometer. Tetramethylsliane or cyclohexane was used as an internal standard. The infrared spectra were obtained with a Nippon Bunko DS-402G Grating Infrared Spectrophotometer. The ultraviolet spectra were obtained with a Shimadzu SV-50A Automatic Recording Spectrophotometer.

1-Chloroheptamethyltrisilane,[14] 2-chloroheptamethyltrisilane[14] and chloropentamethyldisilane[15] were prepared as reported previously. Styrene was distilled under reduced pressure in a stream of nitrogen after steam distillation. Acrylonitrile was redistilled through a 30-cm. column packed with glass helicoils under nitrogen.

Vinylpentamethyldisilane. — In a 2-l. flask equipped with a stirrer, a reflux condenser filled with dry-ice and a gas inlet tube, 32 g. (1.32 g.-atoms) of magnesium turnings and 700 ml. of tetrahydrofuran freshly distilled from lithium aluminum hydride were placed. A few drops of ethyl iodide, together with a crystal of iodine, was added to initiate the reaction. To the stirred solution there was then added through a gas inlet vinyl chloride, which had been previously passed through a saturated solution of sodium hydroxide, a Drielite tube and a phosphorus pentoxide tube. When the Grignard preparation was complete, the condenser was replaced with a water condenser and chloropentamethyldisilane (171.5 g., 1.03 mol.), dissolved in an equal volume of tetrahydrofuran, was added at such a rate that a gentle reflux was maintained. After this addition was complete (after one hour), the reaction

mixture was refluxed for further 20 hr. It was subsequently cooled and hydrolyzed by the addition of a saturated aqueous solution of ammonium chloride. The organic layer was separated, washed, and distilled to remove the solvent. The residue was then fractionally distilled through a 30-cm. column packed with glass helices to give 99 g. (60.8%) of vinylpentamethyldisilane, b. p. 131—132°C, n_D^{20} 1.4497, d_4^{20} 0.7673 (lit.,[7] b, p. 120—121°C, n_D^{20}, 1.4441, d_4^{20} 0.7621).

1-Vinylheptamethyltrisilane.—To a stirred solution of vinylmagnesium chloride prepared from 5 g. (0.2 g.-atom) of magnesium and vinyl chloride in 200 ml. of tetrahydrofuran in the same manner as described above there was added, drop by drop, 31 g. (0.14 mol.) of 1-chloroheptamethyltrisilane over a 40-min. period. After the addition was complete, the reaction mixture was refluxed for 5 hr.; then the solvent was distilled off through a short column to ensure a complete reaction and the residual mass was hydrolyzed with an aqueous solution of ammonium chloride. After the usual treatment simple distillation gave 26 g. of a practically pure liquid (on v. p. c.) boiling over the range of 70—79°C (16 mmHg). Fractional distillation gave 18 g. (59%) of 1-vinylheptamethyltrisilane, b. p. 79°C (16 mmHg), n_D^{20} 1.4741, d_4^{20} 0.7972. (Found: C, 49.32; H, 10.83; MR_D, 76.35. Calcd. for $C_9H_{24}Si_3$: C, 49.92; H, 11.17%; MR_D, 76.32.)

2 - Vinylheptamethyltrisilane. — Vinylmagnesium chloride was prepared from 15 g. (0.62 g.-atom) of magnesium and vinyl chloride in 300 ml. of tetrahydrofuran. 2-Chloroheptamethyltrisilane (37 g., 0.16 mol.) was added drop by drop to the Grignard reagent over a period of 40 min. After the treatment in virtually the same manner as with 1-vinylheptamethyltrisilane, 21 g. (61%) of 2-vinylheptamethyltrisilane was obtained as a colorless liquid, b. p. 75°C (17 mmHg), n_D^{20}, 1.4761, d_4^{20}, 0.7945. (Found: C, 50.04; H, 10.99; MR_D, 76.89. Calcd. for $C_9H_{24}Si_3$: C, 49.92; H, 11.17%; MR_D, 76.32.)

Copolymerization Procedure. — The copolymerizations of pairs of monomers were carried out at 60±0.1°C in sealed glass tubes which had been degassed three times on a vacuum line. Benzene and dimethylformamide were used as the solvent for the copolymerization with styrene and with acrylonitrile respectively, while azobisisobutyronitrile (0.5 mol. per cent to the total of monomers) was used as the initiator. Polymerization was interrupted when it was estimated that 5—10% of the copolymer had been formed. The copolymers were then precipitated by pouring the reaction mixture into 200 ml. of cold methanol. The resultant copolymers were further purified by repeated reprecipitations and were subjected analysis; the results are listed in Tables V, VI, VII and VIII.

From the data of analysis the monomer reactivity ratios, r_1 and r_2, were estimated by the intersection method using Eq. 1. The r_2 values in each case were virtually zero, so the Q and e values were calculated by solving Eqs. 2 and 3:

$$r_2 = \frac{M_1}{M_2}\left[\frac{dM_2}{dM_1}\left(1+\frac{M_1}{M_2}\,r_1\right)-1\right] \quad (1)$$

$$r_1 = \frac{Q_1}{Q_2}\exp\left[-e_1(e_1-e_2)\right] \quad (2)$$

$$r'_1 = \frac{Q'_1}{Q_2}\exp\left[-e'_1(e'_1-e_2)\right] \quad (3)$$

The authors are indebted to Dr. Kazuo Tori of The Shionogi Research Laboratory for NMR to Mr. Tadao Kobatake and Mr. Katsuhiko Sato for their microanalyses, and to the Tokyo Shibaura Electric Co., Ltd., for its gifts of chlorosilanes and a methylchlorosilane residue.

This research was supported in part by a grant-in-aid of the Ministry of Education and by the Kawakami Memorial Foundation, to which the authors' thanks are due.

Organic Sulfur Compounds. IV. The Reactions of Arylsulfonic Acids with Alkyl Chlorocarbonates

By Asami YAMAMOTO* and Michio KOBAYASHI**

Department of Chemistry, Yokohama City University, Matsuura-machi, Kanazawa-ku, Yokohama

(Received November 15, 1965)

The reactions of *p*-toluenesulfonic acid salt with alkyl chlorocarbonates have been investigated and their mechanism discussed. The reactions were slow at low temperature, and the intermediates, sulfonic carbonic anhydrides, could be isolated. When heated, these mixed anhydrides decomposed to alkyl sulfonates and carbon dioxide. *p*-Toluenesulfonic acid-^{18}O was prepared and its reaction with ethyl chlorocarbonate examined. All three oxygen atoms of the sulfonic acid were retained in the ethyl sulfonate formed. The reaction of isobutyl chlorocarbonate with silver *p*-toluenesulfonate gave a mixture of isobutyl- and *s*-butyl sulfonate. On the basis of these experiments, the mechanism involving the free alkyl cation has been proposed for the decomposition of the sulfonic-carbonic anhydrides.

Alkyl and aryl chlorocarbonates have been known to react with the carboxylic acid salts to form the carboxylic-carbonic anhydrides, which have drawn much attention recently.[1-6] The chlorocarbonates also give the nitric-carbonic anhydrides with silver nitrate; the decomposition of the anhydrides to nitric esters and carbon dioxide has been the subject of several recent publications.[7-9] Although many other reactions of the chlorocarbonates have been reported,[10] little is known about their reaction with sulfonic acid. In this paper, studies of the reaction of *p*-toluenesulfonic acid salt with alkyl chlorocarbonates will be described.

Results and Discussion

When ethyl chlorocarbonate (Ib) was added to a solution of silver *p*-toluenesulfonate (II) in acetonitrile at room temperature, the reaction proceeded very slowly with the precipitation of silver chloride. When this solution was warmed, a copious formation of carbon dioxide was observed and ethyl *p*-toluenesulfonate (IIIb) was isolated from the reaction mixture in 35% yield.

At room temperature this reaction was very slow; it was only one-third completed after 17 days, as estimated by the yield of silver chloride precipitated. The reaction mixture was concentrated under reduced pressure, the residue was extracted with methylene chloride, and its infrared spectrum (Fig. 1) was measured to show the presence of a strong carbonyl band in the 1786 cm^{-1} region which could not be attributed to the unchanged ethyl chlorocarbonate. By the evaporation of the solvent in a vacuum, a colorless oil was obtained. The similarity of its infrared spectrum to that of the corresponding methyl ester (IVa) described below suggested that this oil was carboethoxy *p*-toluenesulfonate (IVb). When this oil was heated on a water-bath, carbon dioxide was evolved and the infrared spectrum of the residue showed no C=O absorption. By the elution chromatography, pure IIIb was isolated.

$$RSO_3Ag + \underset{\underset{\text{I}}{\overset{\|}{O}}}{Cl\text{-}C\text{-}OR'} \rightarrow \underset{\text{IV}}{R\text{-}\overset{\uparrow}{\underset{\downarrow}{S}}(=O)\text{-}O\text{-}\underset{\underset{O}{\|}}{C}\text{-}OR'} + AgCl \qquad (1)$$

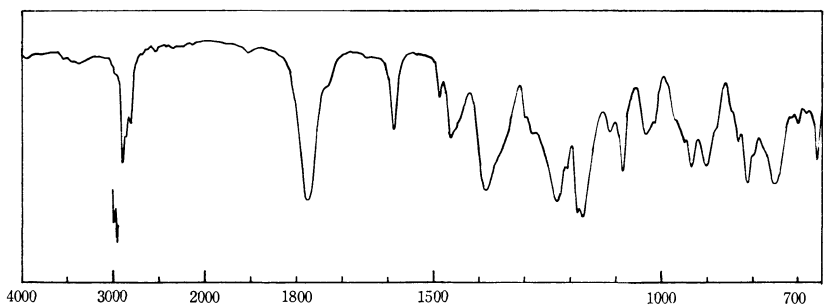

Fig. 3. Infrared spectrum of $CH_3C_6H_4SO_2$-O-C(=O)-O-Bu^i capillary film.

A similar treatment of methyl chlorocarbonate (Ia) with II in acetonitrile gave carbomethoxy *p*-toluenesulfonate (IVa) as colorless crystals in 10% yield. This compound has been prepared recently in a completely different way.[11] The infrared spectrum of our sample is shown in Fig. 2. Unexpectedly, this compound was rather stable in a pure state, but it decomposed to methyl *p*-toluenesulfonate (IIIa) when heated at 120—140°C for 5 hr. When warmed with water, it was hydrolyzed to form a clear solution of the sulfonic acid.

The reaction of silver nitrate with alkyl chlorocarbonate has been reported to be catalyzed by pyridine.[8] The reaction of Ib with II in the presence of pyridine was carried out in the hope of accelerating the rate of an otherwise very slow formation of the mixed anhydride (IVb), but it was found that in the presence of pyridine merely the decomposition of Ib occurred, while the sulfonic acid remained unchanged, indicating the absence of any catalytic effect of the tertiary base.

The same mixed anhydride (IVa) was expected to be formed by the reaction of *p*-toluenesulfonyl chloride with sodium methyl carbonate (V) as is shown below:

11) R. J. Crawford and R. Raap, *J. Org. Chem.*, **28**, 2419 (1963).

$$RSO_2Cl + NaO\text{-}C(=O)\text{-}OCH_3 \rightarrow$$

V

$$RSO_2\text{-}O\text{-}C(=O)\text{-}OCH_3 + NaCl \quad (3)$$

(R=*p*-tolyl)

Equimolecular amounts of tosyl chloride and V were treated in acetonitrile for one week, and the insoluble powder was filtered off. The solvent was removed by vacuum distillation and the residue was dissolved in methylene chloride. The infrared spectrum of this solution showed strong absorption bands at 1830 and 1790 cm^{-1} which were attributed to dimethyl pyrocarbonate (VI). Upon evaporation, a mixture of methyl *p*-toluenesulfonate and this pyrocarbonate, but no mixed anhydride (IVa), was obtained. Probably, once formed, IVa reacted with the unchanged V to give VI according to the reaction 4:

$$RSO_2\text{-}O\text{-}C(=O)\text{-}OCH_3 + NaO\text{-}C(=O)\text{-}OCH_3 \rightarrow$$

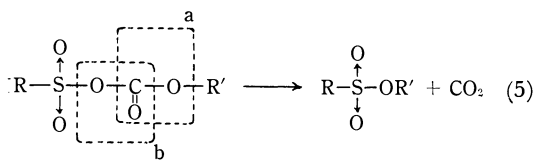
IVa V

$$RSO_3Na + CH_3O\text{-}C(=O)\text{-}O\text{-}C(=O)\text{-}OCH_3 \quad (4)$$

VI

The preparation of diethyl pyrocarbonate from 2 mol. of sodium ethyl carbonate and one mole of tosyl chloride, reported in a recent publication,[12] may be based on the formation of IVb as an intermediate.

There are two possibilities in the decomposition of the sulfonic carboxylic anhydride (IV) to alkyl sulfonate, namely path a and path b, as is shown below:

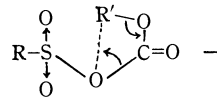


(5)

Path a is alkyl-oxygen splitting, while path b alkoxycarbonyl splitting. This problem has been solved by the isotope labeling. If the sulfonic acid containing the heavy oxygen is used, path a should give the sulfonic ester which retains all three oxygen atoms. On the other hand, path b would lead to the sulfonic ester, which should have 2 out of the 3 oxygen atoms which originally exist in the sulfonic acid.

p-Toluenesulfonic acid-^{18}O was prepared from tosyl chloride and $H_2{}^{18}O$. The reaction of its silver salt with Ib gave ethyl *p*-toluenesulfonate-^{18}O, which ^{18}O atom% was the same as that of the ethyl ester prepared by the direct alkylation of the same silver salt with ethyl bromide.[13] This finding definitely shows that the path a is the only way of cleavage.

However, there remained another question to solve concerning the mechanism of the decomposition of the mixed anhydride IV. The alkyl-oxygen splitting of IV could occur by either the intramolecular four-center cyclic mechanism (reaction 6) or the free alkyl carbonium ion mechanism (reaction 7):



(6)

$$RSO_2\text{-}O\text{-}C(=O)\text{-}OR' \rightarrow RSO_3^- + CO_2 + R'^+ \quad (7)$$

To solve this question, the reaction of isobutyl chlorocarbonate (Ic) and II was investigated. If the free alkyl cation, isobutyl carbonium ion in this case, was formed, the rearrangement to *s*-butyl and *t*-butyl carbonium ion would be expected, finally resulting in the formation of *s*-butyl *p*-toluenesulfonate. *t*-Butyl *p*-toluenesulfonate is unstable and is not expected to survive under the reaction conditions.

When an equimolecular amounts of Ic and II were treated at room temperature in acetonitrile, a slow reaction started, forming a compound which was believed to be carboisobutoxy *p*-toluenesulfonate (IVc). Its decomposition gave a mixture of isobutyl *p*-toluenesulfonate and *s*-butyl *p*-toluenesulfonate in a 0.8 : 1.0 mol. ratio, with a quantity of isobutene and free *p*-toluenesulfonic acid. Isobutene was considered to be derived from the *t*-butyl cation.

Therefore, the following mechanism is proposed to the decomposition of the mixed anhydride IVc:

$$RSO_3Ag + ClC\text{-}OBu\text{-}i \rightarrow$$

$$RSO_2\text{-}O\text{-}C(=O)\text{-}OBu\text{-}i + AgCl \quad (8)$$

IVc

$$IVc \rightarrow [RSO_3^-][O \equiv C \cdots OBu\text{-}i]^+ \quad (9)$$

$$[O \equiv C \cdots OBu\text{-}i] \rightarrow CO_2 + i\text{-}Bu^+ \quad (10)$$

$$i\text{-}Bu^+ \rightleftarrows s\text{-}Bu^+ \rightleftarrows t\text{-}Bu^+ \quad (11)$$

$$RSO_3^- + i\text{-}Bu^+ \rightarrow RSO_3Bu\text{-}i \quad (12)$$

$$RSO_3^- + s\text{-}Bu^+ \rightarrow RSO_3Bu\text{-}s \quad (13)$$

12) L. Rosnati, *Chem. Ber.*, **96**, 3098 (1963).

13) W. D. Emmons and A. F. Ferris, *J. Am. Chem. Soc.*, **75**, 2257 (1953).

$$RSO_3^- + t\text{-}Bu^+ \rightarrow RSO_3H + (CH_3)_2C{=}CH_2 \quad (14)$$

When the reaction temperature was raised, a reaction giving the sulfonic anhydride (VII) occurred, along with the decomposition to the alkyl sulfonate. The most probable reaction to form VII would be the disproportionation of the mixed anhydride IV (reaction 15), but no detailed discussion of this reaction will be given at the present stage since only a slight amount of diisobutyl carbonate was detected among the products.

$$RSO_2\text{-}O\text{-}\underset{\underset{O}{\|}}{C}\text{-}OBu\text{-}i \rightarrow$$

IVc

$$^1/_2(RSO_2)_2O + ^1/_2(i\text{-}BuO)_2CO + ^1/_2CO_2 \quad (15)$$

VII

Experimental

Materials. — Silver *p*-toluenesulfonate (II) was prepared from silver oxide and *p*-toluenesulfonic acid, recrystallized from distillled water, and dried in a vacuum. Methyl chlorocarbonate (Ia) and ethyl chlorocarbonate (Ib) were commercial products and purified by distillation. Isobutyl chlorocarbonate (Ic) was prepared from phosgen and isobutyl alcohol in chloroform, b. p. 126—128°C. $\nu_{C=O}$ absorption band in 1780 cm^{-1} (neat). Isobutyl *p*-toluenesulfonate was prepared from tosyl chloride and isobutyl alcohol in the presence of pyridine, b. p. 161—165°C/3—4 mmHg. IR 1372 (antisymm. s-o), 1192, 1180 (symm. s-o), 982, 944, 818 cm^{-1} (in CCl_4 or CH_2Cl_2). *s*-Butyl *p*-toluenesulfonate was prepared from *s*-butyl alcohol in a similar way and purified by rapid elution chromatography over silica gel with petroleum ether - benzene mixture, since the repeated attempts to purify it by vacuum distillation resulted in a partial decomposition. IR 1370, 1192, 1180, 910, 819 cm^{-1} (in CH_2Cl_2).

The Reaction of Silver *p*-Toluenesulfonate with Ethyl Chlorocarbonate.—*Reaction at the Boiling Point.*—To a solution of 11.5 g. of II in 40 ml. of warm acetonitrile 4.0 g. of Ib diluted with 3 ml. of the same solvent was added. The precipitation of silver chloride proceeded slowly, along with a slow evolution of carbon dioxide (50 ml. in one night; calculated volume, 870 ml.). This mixture was refluxed until the evolution of gas ceased. The total gas volume was 800 ml., and the weight of silver chloride was 5.1 g. (90% of the theoretical yield). Acetonitrile was expelled from the filtrate by vacuum distillation, and the residue was taken up in benzene to remove the unchanged II, washed with aqueous sodium carbonate, and dried over magnesium sulfate. The evaporation of the solvent from this solution and the recrystallization of the residue gave 2.0 g. of IIIb, m. p. 32—34°C, in a 30% yield of the theoretical.

Reaction at Room Temperature.—To a solution of 7.0 g. of II in 35 ml. of acetonitrile 2.7 g. of Ib in 10 ml. of acetonitrile was added drop by drop; the mixture was then left at room temperature for 17 days. The solvent and all other volatile materials were removed by vacuum distillation at room temperature, and the residue was dissolved in 50 ml. of methylene chloride and filtered. Its infrared spectrum is shown in Fig. 1. From the yield of silver chloride, 1.2 g., the reaction was estimated to have been 1/3 completed. The evaporation of this solution under reduced pressure gave a sirup which showed the same infrared spectrum as in Fig. 1, suggesting the presence of carboethoxy *p*-toluenesulfonate (IVb)[11] contaminated with some ethyl *p*-toluenesulfonate. When heated, this sirup formed carbon dioxide, and the residue gave pure IIIb by column chromatography over alumina with benzene.

The Reaction of II with Methyl Chlorocarbonate.—The reaction of II (7.0 g.) with Ia (2.3 g.) was carried out in a way similar to that described above for the ethyl ester. After 17 days at room temperature, silver chloride was filtered off and the volatile matter was expelled from the filtrated by vacuum distillation at room temperature. To the residue 50 ml. of methylene chloride was added and the infrared spectrum was measured; we thus found a strong C=O band at 1790 cm^{-1}. From the yield of silver chloride, 1.2 g., and also from the intensity of the above C=O band, a 35% conversion was estimated. Upon the evaporation of the solvent in a vacuum and the recrystallization of the residue from a mixture of *n*-hexane: benzene (2 : 1), 0.65 g. of IVa was obtained as a colorless prism, m. p. 57—59°C (lit.[11] 60—61°C). Heating at 120°C for 20 min. produced no change in the infrared spectrum of IVa, while heating at 120—140°C for 5 hr. resulted in a complete decomposition to methyl *p*-toluenesulfonate.

The Reaction of *p*-Toluenesulfonyl Chloride with Sodium Methyl Carbonate (V).—When 9 g. of tosyl chloride was mixed with 4.0 g. of V, prepared by passing carbon dioxide into a solution of sodium methoxide in methanol and by the evaporation of the reaction mixture in a vacuum to complete dryness, an exothermic reaction started at once. The mixture was cooled immediately, diluted with 30 ml. of acetonitrile, and kept at room temperature for one week. The insoluble powder was filtered off, and the solvent was removed in vacuo. The residue was dissolved in methylene chloride and its infrared spectrum examined; this spectrum exhibited strong absorptions at 1830 and 1790 cm^{-1}, corresponding to those of methyl pyrocarbonate. The work-up of this solution gave methyl *p*-toluenesulfonate too, but no IVa.

The Preparation of Silver *p*-Toluenesulfonate-^{18}O.—A mixture of 20 g. of tosyl chloride and 5 ml. of $H_2{}^{18}O$ (^{18}O: 1.5 atom%) was heated in a water bath for 2 days; the contents of the flask were thereby solidified. Another few milliliters of $H_2{}^{18}O$ and 10 ml. of anhydrous dioxane were added to this solid, and the homogeneous mixture was heated for sevaral hours. The volatile matter was expelled by vacuum evaporation, and distilled water was added to the residue. The water was then distilled off in vacuo to ensure the removal of the hydrogen chloride formed. Finally the residue was dissolved in 100 ml. of distilled water and warmed with 13 g. of silver oxide. This solution was filtered while hot, and the filtrate was cooled in ice water to deposit the desired salt. The concentration of the mother liquid gave a second croup. Recrystallized silver salt was dried in a vacuum, powdered, and dried again in vacuo.

The Preparation of Ethyl *p*-Toluenesulfonate-^{18}O.—To a solution of 5.0 g. of silver *p*-toluenesulfonate-^{18}O in 20 ml. of warm acetonitrile, 4.0 g. of ethyl bromide was added; the reaction mixture was then refluxed for one hour and cooled. After another hour at room temperature, the mixture was filtered and the solvent was distilled off from the filtrate. The crystalline residue was recrystallized from petroleum ether to give 2.4 g. of ethyl *p*-toluenesulfonate-^{18}O. The ^{18}O atom% of this ester was 0.61%.

The Reaction of Silver *p*-Toluenesulfonate-^{18}O with Ib.—A solution of 5.5 g. of Ib (1.4 mol. equivalent) in 5 ml. of acetonitrile was added to a solution of 10.0 g. of silver salt-^{18}O in 40 ml. of acetonitrile at 95°C. The precipitation of silver chloride started at once. The total volume of the evolved gas was 950 ml.; it thus exceeded the calculated volume, 860 ml. The infrared spectrum of the filtrate indicated the presence of some diethyl carbonate ($\nu_{C=O}$, 1740 cm^{-1}). Acetonitrile was removed from the filtrate by vacuum distillation, and the residue was taken up in methylene chloride to free it from unchanged silver sulfonate. The evaporation of this solution, the repeated extraction of the residue with petrolum ether, and finally filtration chromatography through alumina gave 0.4 g. of ethyl *p*-toluenesulfonate-^{18}O, m. p. 31°C. The ^{18}O atom% of this ester was 0.62%.

The Reaction of II with Isobutyl Chlorocarbonate.—*i) Reaction at Room Temperature.*—To a solution of 7.0 g. of II in 30 ml. of acetonitrile, 3.4 g. of Ic in 10 ml. of the same solvent was added. No change was observed. The mixture was then kept at room temperature for 8 days, and the precipitated silver chloride (1.0 g., 1/3 of the calculated) was filtered off. Acetonitrile was removed in a vacuum, and the residue was dissolved in methylene chloride and filtered from the unchanged II. The solvent was distilled off in vacuo, and the residue was warmed with a mixture of benzene-petroleum ether (1 : 2). Upon cooling, some colorless crystals separated; they were identified as *p*-toluenesulfonic acid. The filtrate and the insoluble matter in the solvent mixture were combined, diluted with ether, washed with a sodium carbonate solution and water, and dried over magnesium sulfate. Upon the evaporation of the solvent in vacuo, a colorless sirup was obtained which exhibited a strong C=O absorption in the infrared spectrum (Fig. 3), suggesting the presence of carboisobutoxy *p*-toluenesulfonate (IVc), probably contaminated with some butyl *p*-toluenesulfonate. All attempts to isolate the mixed anhydride (IVc) in the crystalline form were unsuccessful. After one week at room temperature, the sirup was dissolved in ether, treated with an excess of *p*-phenylenediamine to decompose the unchanged IVc to *N*-carboisobutoxy *p*-phenylenediamine and the sulfonic acid, washed with diluted sulfuric acid, filtered through decolorizing carbon, and finally evaporated. The oil thus obtained in a small yield was a mixture of isobutyl and *s*-butyl *p*-toluenesulfonate, plus a slight amount of diisobutyl carbonate. The ratio of isobutyl sulfonate to *s*-butyl sulfonate was estimated by infrared spectroscopy to be 0.79: 1.00. The low yield of butyl *p*-toluenesulfonates was attributed to the too mild decomposition conditions (one week at room temperature).

ii) Reaction at Boiling Point.—A solution of 7.0 g. of II and 3.7 g. of Ic in 40 ml. of acetonitrile was refluxed until the evolution of gas (total 565 ml., nearly 1 mol.) ceased. The presence of isobutene in gas was confirmed by converting it into dibromide (identified by boiling point and infrared spectrum). Acetonitrile was removed under reduced pressure, and the residue was taken up in methylene chloride, filtered, washed with dilute sodium carbonate solution, and dried over magnesium sulfate. Upon the evaporation of the solvent, a mixture of *p*-toluenesulfonic anhydride (VII) and its free acid was crystallized. The infrared spectrum of the filtrate indicated that the yield of butyl *p*-toluenesulfonates was very low, if there was any at all. An attempt to isolate them from the filtrate by column chromatography was unsuccessful.

iii) Reaction at a Moderate Temperature.—A solution of 7.0 g. of II and 3.4 g. of Ic in 30 ml. of acetonitrile was warmed at 40—60°C for several hours; a gaseous mixture of carbon dioxide and isobutene (identified as dibromide) evolved. Treatment similar to that in i) gave an oil which again exhibited a strong C=O band at 1788 cm^{-1}. Excess aniline was added to this oil to form a semisolid mixture, which left the white crystals undissolved upon the addition of diluted nitric acid. The recrystallization of these crystals from petroleum ether gave carboisobutoxyaniline, m. p. 82—84°C; melting point upon admixture with authentic specimen, 82—83°C. The acidic aqueous filtrate gave only a trace of silver chloride with a silver nitrate solution. Therefore, the presence of the C=O absorption band and the formation of urethan could not be attributed to the presence of the unchanged Ic in the oil. The concentration of the petroleum ether mother filtrate from urethan and treatment with active carbon gave a mixture of isobutyl and *s*-butyl *p*-toluenesulfonate. The mole ratio of *iso* : *sec.* was estimated by infrared spectroscopy to be 0.86 : 1.00. By elution chromatography over silica gel with petroleum ether-benzene, these two esters could be separated (the isobutyl ester was eluted first), from each other, and the formation of *s*-butyl ester was confirmed. From the yield of carboisobutoxyaniline and butyl sulfonates, about half of the mixed anhydride IVc was considered to have decomposed to butyl sulfonates.

The Preparation of Carboisobutoxyaniline.—When an excess of aniline was added to 0.3 g. of Ic, the reaction occurred immediately, giving a solid mass. The addition of diluted nitric acid to this mass left undissolved crystals; they were recrystallized from 10 ml. of petroleum ether to give the desired product, m. p. 85—86°C (lit. 80 or 86°C). Its high yield indicated the absence of any appreciable *s*-butyl chlorocarbonate as an impurity in the sample used for the present study.

The authors are grateful to Professor Shigeru Oae of Osaka City University for his donation of heavy oxygen water, and to Dr. Reiko Kiritani of the Radiation Center of Osaka Prefecture for her ^{18}O analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1288—1292 (1966)

Organic Sulfur Compounds. V. Reactions of Arylsulfonic Acids with Alkyl and Aryl Chlorosulfites

By Asami YAMAMOTO* and Michio KOBAYASHI**

Department of Chemistry, Yokohama City University, Mutsuura-machi, Kanazawa-ku, Yokohama

(Received December 14, 1965)

Silver *p*-toluenesulfonate has been found to react with alkyl and aryl chlorosulfite to give *p*-toluenesulfonic esters. Mixed anhydrides of the sulfonic acid and monoalkyl or monoaryl sulfite were postulated as the intermediates. No rearrangement of the alkyl group was observed during the reaction. The reaction mechanism was studied by means of the ^{18}O tracer technique.

The reaction of arylsulfonic acid with alkyl chlorocarbonates was described in a previous paper.[1] Studies of the reactions of *p*-toluenesulfonic acid with alkyl and aryl chlorosulfites will be reported in this paper.

Results and Discussion

The Reaction of Alkyl Chlorosulfites.—Ethyl chlorosulfite (Ia) reacted with silver *p*-toluenesulfonate (II) in acetonitrile at room temperature to precipitate silver chloride quantitatively. Upon the warming of the filtrate, sulfur dioxide evolved and ethyl *p*-toluenesulfonate (IIIa) was obtained in a 30% yield. *p*-Toluenesulfonic anhydride (IV) and *p*-toluenesulfonic acid were by-products.

A mixed anhydride (Va) of the sulfonic acid and monoalkyl sulfite, namely, ethoxysulfinyl *p*-toluenesulfonate, may be postulated as a probable intermediate:

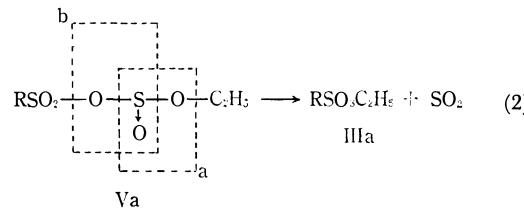
$$RSO_3Ag + Cl\text{-}S\text{-}OC_2H_5 \rightarrow \underset{\underset{\text{Ia}}{\downarrow O}}{} \quad RSO_2\text{-}O\text{-}S\text{-}OC_2H_5 + AgCl \qquad (1)$$
$$\underset{\underset{\text{Va}}{\downarrow O}}{}$$

(R = *p*-tolyl)

Although the formation of Va could not be verified, the presence of analogous mixed anhydrides in the case of isobutyl and phenyl derivatives was supported by infrared spectra, as will be described below.

There seem to be two reactions, one to lead to the formation of the alkyl sulfonate and another to produce the sulfonic anhydride. These two reactions will be considered separately in the following discussion.

Alkyl Sulfonate Formation.—i) The Mode of the Cleavage of the Mixed Anhydride.—There are two possible modes of cleavage by which Va can give ethyl sulfonate IIIa, namely, alkyl-oxygen splitting (path a) and alkoxy-sulfonyl splitting (path b):



(2)

In a similar decomposition of the mixed anhydride of *p*-toluenesulfonic acid and monoalkyl carbonate[1] alkyl-oxygen splitting has been established, while alkoxy-acyl splitting has been established as taking place in the cases of the mixed anhydride of *p*-toluenesulfinic acid and monoalkyl sulfite[2] and of the carbonic-carboxylic anhydride.[3] On the other hand, 75% alkoxy-acyl splitting and 25% alkyl-oxygen splitting were observed in the nitric-carbonic anhydride.[4]

When the reaction of silver *p*-toluenesulfonate-^{18}O and ethyl chlorosulfite was carried out, the resultant ethyl *p*-toluenesulfonate-^{18}O was found to retain all three oxygen atoms originally present in silver sulfonate. Therefore, alkyl-oxygen cleavage (path a) is definitely established for the reaction 2.

ii) Mechanism.—Several mechanisms may be formulated for the reaction 2, every one of them consistent with the alkyl-oxygen splitting. At first, the mechanism shown below involving a free alkyl cation was considered to be the most plausible:

$$RSO_2\text{-}O\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}O\text{-}R' \longrightarrow [RSO_3^-][O{=}S^{+}{-}O{-}R']^+ \quad (3)$$

VI

$$[R'{-}O{=}S{\equiv}O]^+ \longrightarrow SO_2 + R'^+ \quad (4)$$

$$RSO_3^- + R'^+ \longrightarrow RSO_3R' \quad (5)$$

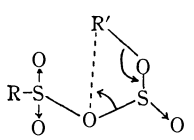
(R = *p*-tolyl, R' = alkyl)

In hope of confirming this assumption, the reaction of II with isobutyl chlorosulfite (Ib) was investigated. If a free isobutyl cation was formed over the intermediate Vb (V: R'=isobutyl) as is shown in the reactions 3 and 4, its facile rearrangement to *s*-butyl and *t*-butyl carbonium ion would lead to the formation of *s*-butyl *p*-toluenesulfonate, as is found in the decomposition of carboisobutoxy *p*-toluenesulfonate.[1]

In repeated attempts, however, the isolation of *s*-butyl *p*-toluenesulfonate was always unsuccessful. In the ester fraction, isobutyl sulfite and isobutyl *p*-toluenesulfonate (IIb) were detected, in yields varying according to the reaction conditions.

Thus, a free alkyl cation mechanism (reactions 3, 4 and 5) can find no experimental support for the decomposition of alkoxysulfinyl arylsulfonate V. This contrasts clearly with the decomposition of the formally analogous sulfonic-carbonic anhydride.[1]

The following three mechanisms, involving no free alkyl cation formation, could be presumed:



$$\longrightarrow RSO_3R' + SO_2 \quad (6)$$

$$RSO_3^- + [R'{-}O{=}S{\equiv}O]^+ \longrightarrow$$

VI

$$RSO_3R' + SO_2 \quad (7)$$

and finally:

$$RSO_3^- + R'\text{-}O\text{-}\underset{\underset{O}{\downarrow}}{\overset{\overset{O}{\uparrow}}{S}}\text{-}O\text{-}\underset{\underset{O}{\downarrow}}{\overset{\overset{O}{\uparrow}}{S}}\text{-}R \rightarrow$$

V

$$RSO_3R' + [RSO_2\text{-}O\text{-}SO_2]^- \quad (8)$$

VII

$$VII \rightarrow RSO_3^- + SO_2 \quad (9)$$

Of these three mechanisms, the second (reaction 7) and third (reaction sequence 8 and 9) belong to the S_N2 type, whereas the first one (reaction 6) is a S_Ni type four center cyclic mechanism. The study of the reaction of an optically active chlorosulfite with II would help to decide which mechanism should be chosen.

The mechanism of the Formation of the Sulfonic Anhydride.—The formation of IV and isobutyl sulfite suggests the occurrence of the disproportionation reaction (10) in the decomposition of the mixed anhydride V:

$$RSO_2\text{-}O\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}OR' \rightarrow$$

$$1/2(RSO_2)_2O + 1/2(R'O)_2SO + 1/2SO_2 \quad (10)$$

For the mechanism of this reaction, the following ionic chain reaction sequence seems to be plausible:

$$V \longrightarrow RSO_3^- + [O{=}S^{+}{-}OR']^+ \quad (3)$$

VI

$$RSO_3^- + V \longrightarrow (RSO_2)_2O + \left[R'O\text{-}S\begin{matrix}O\\O\end{matrix}\right]^- \quad (11)$$

$$[R'O\text{-}SO_2^-] \longrightarrow R'O^- + SO_2 \quad (12)$$

$$R'O^- + V \longrightarrow RSO_3^- + (R'O)_2SO \quad (13)$$

The attack on V by $R'O^-$ anion might occur on the sulfone group, not on the sulfinyl group, as is shown below:

$$R'O^- + V \rightarrow RSO_3R' + [R'O\text{-}SO_2^-] \quad (14)$$

However, if this is the case, the resultant sulfonic ester should retain only two out of the three oxygen atoms of the sulfonic acid; this is contrary to the experimental evidence obtained with ^{18}O, at least for alkyl chlorosulfite.

Another mechanism, which postulates the intermediate formation of a sulfonyl cation (VIII), could be formulated for the disproportionation reaction 10:

$$RSO_2^+ + V \longrightarrow (RSO_2)_2O + [R'O{=}S{\equiv}O]^+ \quad (15)$$

VIII VI

$$VI + V \longrightarrow (R'O)_2SO + [RSO_2{-}O{=}S{\equiv}O]^+ \quad (16)$$

IX

$$IX \longrightarrow RSO_2^+ + SO_2 \quad (17)$$

Although the sulfonyl cation VIII has been postulated in the Friedel-Crafts' sulfonylation[5] and in the reaction of tosyl chloride with Lewis acids[6], its formation as a free molecular species seems rather doubtful.[7]

While the anionoid attack of $R'O^-$ on V (reaction 13) is considered to occur on the sulfinyl group, as has been stated above, the other anionoid attack by RSO_3^- on V seems to occur only on the sulfonyl group (reaction 11). Probably the attack

O

by RSO_3^- could take place on sulfinyl sulfur too, but with the net result of a simple exchange of RSO_3^- (18):

$$RSO_3^- \cdots\rightarrow \underset{\underset{OR'}{\downarrow}}{\overset{\overset{O}{\uparrow}}{S}}\text{-O-}O_2SR \rightarrow \underset{\underset{OR'}{\downarrow}}{\overset{\overset{O}{\downarrow}}{RSO_2\text{-O-S}}} + RSO_3^- \qquad (18)$$

A Question about the Existence of the Mixed Anhydride V.—For the formation of the alkyl sulfonate in the reaction of II with alkyl chlorosulfite, the following mechanism, which could take place without the formation of the intermediate V, can be postulated:

$$\underset{\underset{O}{\downarrow}}{Cl\text{-S-}OR'} + Ag^+ \longrightarrow AgCl + \underset{VI}{\left[O{=}S{=}OR'\right]^+} \qquad (19)$$

$$RSO_3^- + VI \longrightarrow RSO_3R' + SO_2 \qquad (7)$$

The reaction sequence 19 and 7 is analogous to the one, which has been proposed[4] and later denied on the basis of kinetic evidence for the formation of the nitric ester from silver nitrate and alkyl chlorocarbonate.[8]

In order to verify the formation of an intermediate Vb and to support our postulation against the above mechanism (19 and 7), the reaction between II and Ib was carried out at 0°C and the solvent was distilled off in a vacuum at 0°C. The infrared spectrum of the residue in methylene chloride (Fig. 1) was rather close to that of *s*-butyl *p*-toluenesulfonate, but upon the treatment of this solution with ice water, isobutyl sulfite and a small amount of isobutyl *p*-toluenesulfonate were obtained without any trace of *s*-butyl *p*-toluenesulfonate. This experiment was repeated three times. Since a similar spectrum was recorded in every case, this spectrum is now believed to be attributable to Vb. The evaporation of the methylene chloride solution in a vacuum resulted in an oily residue containing crystals of the sulfonic anhydride IV. The work-up of this residue gave isobutyl sulfite in a good yield and isobutyl *p*-toluenesulfonate as a minor product. These products were considered to have been produced from Vb during the evaporation and/or the subsequent work-up.

8) D. N. Kevill and G. H. Johnson, *J. Am. Chem. Soc.*, **87**, 928 (1965).

The Reaction of Phenyl Chlorosulfite.—As has been described above, the decomposition of the sulfonic-monoalkylsulfurous anhydride V and sulfonic-carbonic anhydride proceeds by alkyl-oxygen cleavage, while the decomposition of the carbonic-carboxylic anhydride and of the sulfinic-monoalkylsulfurous anhydride proceeds by alkoxy-acyl cleavage. These facts correspond to the other facts that the alkyl sulfonate was hydrolyzed by alkyl-oxygen splitting,[9] while alkyl sulfinate[10] and carboxylic ester[11] were hydrolyzed by alkoxy-acyl splitting. Therefore, it seems that it would be interesting to examine the mode of the decomposition of phenoxysulfinyl *p*-toluenesulfonate Vc, since aryl sulfonate has been known to undergo aryloxy-sulfonyl splitting[12] upon hydrolysis.

The reaction of silver *p*-toluenesulfonate-^{18}O with phenyl chlorosulfite was carried out in order to answer this question. Although the yield of the expected phenyl *p*-toluenesulfonate-^{18}O was low, its ^{18}O atom% was exactly 2/3 of that of the starting silver sulfonate. Consequently, phenoxy-acyl cleavage is operative in the decomposition of Vc; this again corresponds to the mode of the hydrolysis.

$$RS^{18}O_2\text{-}^{18}O\text{-}S\text{-}OC_6H_5 \rightarrow \underset{\underset{O}{\downarrow}}{} \quad RS^{18}O_2OC_6H_5 + SO^{18}O \qquad (20)$$

The infrared spectrum of an intermediate, believed to be Vc, was observed in acetonitrile (Fig. 2). After boiling for 9 hr., this solution was evaporated under reduced pressure. From the residue, *p*-toluenesulfonic acid and a lot of a resinous material were obtained, besides phenyl *p*-toluenesulfonate.

The mechanism of the decomposition of Vc has not yet been determined. Mechanism 14 could be applied to reaction 20, but the formation of the phenoxy anion would lead to the formation of diphenyl sulfite, at least as a by-product. Actually, however, none of this compound was detected. Instead, a large amount of a resinous material with an unknown structure was produced, as has been described above.

Experimental

Materials.—Ethyl chlorosulfite (Ia), b. p. 59°C/85 mmHg, was prepared from ethyl alcohol and thionyl chloride. Isobutyl chlorosulfite, b. p. 61°C/25 mmHg, was obtained in a similar way. Phenyl chlorosulfite, b. p. 105—107°C/10 mmHg, was synthesized from phenol and 4 mol. of thionyl chloride.[13] *p*-Toluenesulfonic acid-^{18}O was the same sample as was used in a previous paper.[1] The ^{18}O atom% was 0.61%. The preparation of isobutyl- and *s*-butyl *p*-toluenesulfonates was also described in the same report.[1]

The Reaction of Silver p-Toluenesulfonate (II) and Ethyl Chlorosulfite (Ia).—To a solution of 13.5 g. of II in 50 ml. of acetonitrile, there was added, drop by drop, 7.0 g. of Ia in 10 ml. of acetonitrile; the precipitate of silver chloride appeared at once. The mixture was then left for 35 min., and silver chloride was filtered off. Its weight was 6.7 g. (97%). After the filtrate had been warmed on a water bath for several hours and left overnight, the solvent was distilled off in vacuo. The residue was dissolved in ether, washed with water, and evaporated to give 3.45 g. of IIIa, m. p. 32—34°C, in a 36% yield.

Reaction of Silver p-Toluenesulfonate-^{18}O with Ia.—The reaction of 4.5 g. of Ia with 9.2 g. of silver *p*-toluenesulfonate-^{18}O in 40 ml. of acetonitrile was carried out in a way similar to that described above. The solvent was expelled in a vacuum, the residue was dissolved in benzene, and silver chloride (4.5 g.; 100%) was filtered off. The filtrate was washed with a sodium carbonate solution, dried, and evaporated. The oily residue was then extracted with petroleum ether to give 4.2 g. of ethyl *p*-toluenesulfonate-^{18}O, m. p. 32—33°C. Upon recrystallization, 3.0 g. (46%) of the pure ester was obtained. The ^{18}O atom% of this sample was 0.62%. From the insoluble part in petroleum ether, 1.6 g. of *p*-toluenesulfonic anhydride-^{18}O was obtained as colorless crystals, (m. p. 122—124°C; lit. 122—125°C) in a yield 30% of the theoretical yield.

The Reaction of II with Isobutyl Chlorosulfite Ib.—i) Reaction at 0°C.—A solution of 3.5 g. of Ib in a few milliliters of acetonitrile was added, drop by drop, to an ice-cooled solution of 7.0 g. of II in 30 ml. of the same solvent. After the reaction mixture has been cooled in ice water for a few hours, acetonitrile was distilled off in vacuo at 0°C to leave the colorless oil; it turned purple overnight. This oil was dissolved in methylene chloride, filtered, and evaporated in vacuo to give a mixture of crystals and oil. The crystals were separated by filtration and identified as IV. Oil was extracted with petroleum ether, and 0.5 g. of *p*-toluenesulfonic acid was obtained from the insoluble part. The soluble part was chromatographed over alumina with petroleum ether, (b. p. under 40°C) to afford 0.9 g. of diisobutyl sulfite (40% of the theoretical yield) from the early eluent and 0.3 g. of isobutyl *p*-toluenesulfonate (IIIb) (6%). Although every fraction in elution chromatography was examined by infrared spectroscopy, there was no indication of the presence of *s*-butyl *p*-toluenesulfonate.

ii) The Identification of the Intermediate.—The reaction was carried out with the same amounts of the reactants and in a manner similar to that described above. After the solvent had been removed in vacuo, the residue was taken up in methylene chloride and filtered. The infrared spectrum of the filtrate is shown in Fig. 1. This solution was poured into ice water; the organic layer was washed with 5% sodium carbonate and water successively, and dried over potassium carbonate, and then its infrared spectrum was measured again. Although the infrared spectrum in Fig. 1 was similar to that of *s*-butyl *p*-toluenesulfonate, the second infrared spectrum, taken after the hydrolysis with ice water,

showed only a very weak absorption of the sulfonic ester in the 1380 cm^{-1} region. The main product was identified as diisobutyl sulfite. In a separate experiment, a specimen of *s*-butyl *p*-toluenesulfonate was treated with a sodium carbonate solution and potassium carbonate, as described above; no appreciable decomposition was found to be effected by such purification procedure.

iii) The Hydrolysis of the Intermediate.—A reaction with the same amounts of the reactants as in i) was carried out, and then the reaction mixture was decomposed with ice water after 20 min. at 0°C. The organic matter was extracted with 200 ml. of methylene chloride, washed with water and 5% sodium carbonate, and dried over magnesium sulfate; the solvent was then removed in vacuo to give a colorless oil, which was shown by infrared spectrum to be pure diisobutyl sulfite. Upon distillation, 1.7 g. of sulfite was isolated at 100°C/20 mmHg in a 78% yield. Since no *p*-toluenesulfonic anhydride was detected among the products, this sulfite was considered to be produced by the interaction of Vb with isobutyl alcohol, one of the products of the hydrolysis of Vb, not by the disproportionation reaction (11).

The Reaction of Phenyl Chlorosulfite (Ic) with II.—i) The Identification of an Intermediate.—A solution of 4.0 g. of Ic in a few milliliters of acetonitrile was added, drop by drop, to a solution of 6.0 g. of II in 30 ml. of the same solvent at room temperature; thereupon silver chloride began to precipitate immediately. The mixture was filtered through a fritted glass funnel, and the infrared spectrum of the filtrate was recorded (Fig. 2). This solution was then refluxed in an oil bath for 9 hr., and the solvent was removed in vacuo. The viscous residue was extracted repeatedly with carbon tetrachloride to leave a mixture of *p*-toluenesulfonic acid and a resinous matter. The extract was evaporated, and the residue (2.2 g.) was chromatographed over alumina with benzene to give 1.1 g. of phenyl *p*-toluenesulfonate (identified by melting point and infrared), in 21% yield.

ii) Reaction at the Boiling Point.—To a solution of 2.2 g. of II in 10 ml. of acetonitrile, 1.5 g. of Ic in a few milliliters of the same solvent was added at room temperature. The reaction mixture was refluxed without the filtration of the precipitated silver chloride for 2 hr. The next day, then, the solution was filtered and the solvent was distilled off from the filtrate in a vacuum. The crystalline residue was dissolved in ether to remove some insoluble matter and again evaporated. There was a strong smell of sulfur dioxide. The residue was extracted with benzene, and the soluble part was chromatographed to afford 0.5 g. of phenyl *p*-toluenesulfonate (25%). From the insoluble part in benzene, 0.5 g. of *p*-toluenesulfonic acid was isolated (35%).

The Reaction of Silver p-Toluenesulfonate-^{18}O with Ic.—A solution of 1.5 g. of Ic in a few milliliters of acetonitrile was added to a solution of 2.2 g. of silver sulfonate ^{18}O in 10 ml. of the same solvent over a 1.5 hr. period; then the mixture was refluxed for a few hours. Silver chloride was filtered off, and the solvent was removed from the filtrate by distillation. The residue was taken up in 70 ml. of benzene, washed with a sodium carbonate solution and water successively, and dried over magnesium sulfate. Upon elution chromatography over alumina with benzene, 0.2 g. of phenyl *p*-toluenesulfonate-^{18}O was obtained. The ^{18}O atom% of this ester was 0.49%. (The calculated atom% based on 2/3 retention was 0.48%).

Thanks are due to Dr. Reiko Kiritani of the Radiation Center of Osaka Prefecture for the analysis of ^{18}O, and to Professor Shigeru Oae of Osaka City University for the donation of the heavy oxygen water.

Organic Sulfur Compounds. VI. The Reactions of Arylsulfinic Acids with Alkyl Chlorocarbonates

By Michio KOBAYASHI* and Miki TERAO

Department of Chemistry, Yokohama City University, Matsuura-machi, Kanazawa-ku, Yokohama

(Received November 8, 1965)

The reactions of the arylsulfinic acid salts with alkyl chlorocarbonates in various alcohols as solvents gave the alkyl sulfinates, in which the alkoxyl groups originated from the solvent alcohols, not from the chlorocarbonates. Sodium *p*-toluenesulfinate-^{18}O and ethyl chlorocarbonate in a large excess of methanol gave methyl *p*-toluenesulfinate-^{18}O, which was shown to contain about half of the ^{18}O atoms of the starting salt. The mixed anhydride of sulfinic acid and monoalkyl carbonate is postulated as an intermediate, the alcoholysis of which would give the sulfinate ester. Reactions have been studied also in the nonhydroxylic solvents.

The formation of sulfinic esters by the reaction of sodium sulfinates with alkyl chlorocarbonates in alcohols has long been known.[1,2] In solvents other than alcohol, the reaction was reported to

2) R. Otto, ibid., **26**, 308 (1893).

be low and to stop in an early stage.[1] The reaction proceeded also without any solvent, but the yield and the purity of the resultant sulfinate ester were low.[3]

$$RSO_2Na + ClCO_2R' = \underset{\underset{O}{\downarrow}}{RS\text{-}OR'} + CO_2 + NaCl \quad (1)$$

In this paper, studies of the reactions of sodium arylsulfinates with alkyl chlorocarbonates in various solvents will be described.

Results

Sodium *p*-toluenesulfinate (I) reacted with ethyl chlorocarbonate (II) without solvent at room temperature very slowly. The reaction was accompanied by the evolution of carbon dioxide in a 40—60 mol. % yield, but the yield of ethyl *p*-toluenesulfinate (III) was only 10—18%, with the by-production of sulfinyl sulfone (IV) in a low yield. When dioxane was the solvent, hardly any sulfinate ester formation was observed and thiolsulfonate (V) was the chief product. Warming the reaction mixture at 70°C did not improve the result, although carbon dioxide evolution could reach a peak of 30 mol. % under some conditions.

In acetonitrile, the yields of the sulfinic ester depended on the reaction period; it was nearly 0% in 1—15 hr., 22% in 2 days. 13% in 5 days, and 39% in 8 days (with carbon dioxide in 35%) at room temperature. In pyridine, which dissolved sodium sulfinate partly, the reaction was rapid and the yield of the sulfinic ester was increased to 30% of the theoretical yield. When ethyl chlorocarbonate was added to a solution of free *p*-toluenesulfinic acid in anhydrous pyridine, carbon dioxide evolved immediately and ethyl sulfinate was obtained in a 42% yield. In a similar way, ethyl *p*-nitrobenzenesulfinate was prepared in a 43% yield.

Reactions between sodium sulfinate and chlorocarbonates in a large excess of alcohols were very rapid, and the yields of the sulfinic esters were usually satisfactory. For instance, the reaction of I with ethyl chlorocarbonate in ethanol gave ethyl *p*-toluenesulfinate in yields 36—62% of the theoretical yield. In a large excess of methanol, the reaction between ethyl chlorocarbonate and sodium *p*-toluenesulfinate was also very rapid, but in this case the ester formed was methyl *p*-toluenesulfinate, not the ethyl ester. The yield was 69—73%.

When I was treated with ethyl chlorocarbonate in *n*-butyl alcohol, *n*-butyl *p*-toluenesulfinate was obtained in 57 mol. %. The use of isopropyl alcohol as the solvent gave isopropyl *p*-toluenesulfinate in 20 mol. %. No sulfinic ester, neither ethyl nor *t*-butyl, was formed in *t*-butyl alcohol. Allyl alcohol gave allyl *p*-toluenesulfinate in a 55% yield. In carbitol, the reaction proceeded rapidly at room temperature, but no ethyl sulfinate formation was observed and carbitol sulfinate decomposed during the vacuum distillation.

From the above results, the reaction of sulfinate salts with ethyl chlorocarbonate in the primary or secondary alcohols was shown to form, not ethyl sulfinate, but alkyl sulfinates containing the alkyl group of the solvent alcohols.

These alkyl sulfinates might be the result of the ester exchange between ethyl sulfinate, a possible primary product, and the solvent alcohols. However, the reaction of sodium *p*-toluenesulfinate and ethyl chlorocarbonate in a mixture of ethyl *p*-toluenesulfinate of a 1/2 mol. equivalent of the sodium salt and a large excess of methanol gave a sulfinate ester mixture, which contained the same amount of ethyl *p*-toluenesulfinate as in the beginning and methyl *p*-toluenesulfinate in 42 mol. %. Under similar conditions without added ethyl sulfinate, the yield of methyl sulfinate from methyl chlorocarbonate and I in methanol was 42% of the theoretical yield. Therefore, it can be concluded that almost no ester exchange occurred under these reaction conditions, and the various alkyl sulfinates mentioned above may safely be regarded as the primary reaction products.

To confirm this point, the reaction of sodium *p*-toluenesulfinate with ethyl chlorocarbonate in dioxane containing 1 mol. of methanol was carried out; the sulfinate ester mixture, consisting of 82 mol. % of the methyl ester and 18 mol. % of the ethyl ester was thus found to be formed in 60% combined yield. On the other hand, the reaction of sodium *p*-toluenesulfinate and methyl chlorocarbonate in a mixture of 1 mol. of ethanol and a large volume of dioxane gave a mixture of methyl sulfinate and ethyl sulfinate in nearly the same molar ratio. In order to compare the relative reactivities of methanol and ethanol, the reaction of ethyl chlorocarbonate with I in a large excess of an equimolecular mixture of methanol and ethanol was carried out, resulting in the formation of a mixture of methyl- and ethyl-sulfinate in a 2 : 1 molar ratio.

These findings clearly indicate that the alkyl group of the alcohol used as a solvent entered into the resultant sulfinate ester, as is shown below:

$$RSO_2Na + ClCO_2C_2H_5 + R'OH = \underset{\underset{O}{\downarrow}}{RS\text{-}OR'} + CO_2 + NaCl + C_2H_5OH \quad (2)$$

Whether this alkyl group entered into the ester in company with the oxygen atom should be clarified by the isotope labeling method. Sodium *p*-toluenesulfinate-^{18}O was prepared by the reaction of $H_2{}^{18}O$ with *p*-toluenesulfinyl chloride or by the hydrolysis of ethyl *p*-toluenesulfinate with sodium hydroxide in $H_2{}^{18}O$.

3) A. J. H. Houssa and H. Phillips, *J. Chem. Soc.*, **1929**, 2510.

$$\begin{matrix} CH_3C_6H_5S\text{-}Cl + H_2{}^{18}O \\ \quad\quad\downarrow \\ \quad\quad O \end{matrix} = CH_3C_6H_5S{}^{18}OOH + HCl = \quad (3)$$

$$\begin{matrix} CH_3C_6H_5S\text{-}OC_2H_5 + H_2{}^{18}O \\ \quad\quad\downarrow \\ \quad\quad O \end{matrix} CH_3C_6H_5S{}^{18}OOH + C_2H_5OH \quad (4)$$

Bunton and his collaborator[4] established that the hydrolysis of alkyl sulfinate proceeded with an alkoxy-sulfinyl splitting; this was indicated by the absence of heavy oxygen atom in the alcohol formed in the reaction 4. We have confirmed this point by detecting the presence of ^{18}O in nearly the calculated amount in the sulfinic acid formed.

The reaction of sodium *p*-toluenesulfinate-^{18}O containing 0.65 atom % of ^{18}O with ethyl chlorocarbonate in a large excess of methanol gave methyl *p*-toluenesulfinate-^{18}O, the ^{18}O atom % of which was found to be 0.41%. This finding clearly indicated that the methoxyl group of the sulfinate ester came from methanol used as a solvent. (The calculated ^{18}O atom % based on the reaction shown below is 0.427%.)

$$\begin{matrix} RS{}^{18}O_2Na + ClCO_2C_2H_5 + CH_3OH = \\ RS\text{-}OCH_3 + CO{}^{18}O + NaCl + C_2H_5OH \\ \quad\downarrow \\ \quad {}^{18}O \end{matrix} \quad (5)$$

This alkoxy-acyl binding in the sulfinate ester formation corresponds well to the alkoxy-acyl splitting in the hydrolysis mentioned above.

Discussion

From the experimental results, the differences between the reaction in the alcoholic solvents and that in the non-hydroxylic solvents are clearly indicated. In primary or secondary alcohols, the reaction is fast, the yields of the sulfinate esters are high, and the alkoxy group of the solvent is introduced into the ester. On the other hand, the reaction is slow, the yield of the ester is very low, sometimes almost zero, and the sulfinate ester produced contains an alkyl radical of chlorocarbonates in a non-hydroxylic solvent other than pyridine. Pyridine is exceptional; in it the reaction proceeds rapidly and the ester yields are high.

Since no ester formation was observed when the sodium sulfinate was treated with alcohols, there should be some intermediates which react with alcohols to give the sulfinate esters. Sulfinic carbonic anhydride VI, which has been suggested[3] in the reaction without alcohol, is considered to be the most probable such intermediate:

$$RSO_2Na + ClCO_2R' = \underset{\substack{\downarrow \\ O}}{\overset{\substack{\downarrow \\ O}}{R\text{-}S\text{-}O\text{-}C\text{-}OR'}} + NaCl \quad (6)$$

VI

Among similar mixed anhydrides, several carboxylic sulfurous anhydrides VII have been known,[5] and the probable existence of the sulfinic carboxylic anhydrides VIII has been pointed out.[6]

$$\underset{\substack{\downarrow \\ O}}{\overset{\substack{\downarrow \\ O}}{R\text{-}O\text{-}S\text{-}O\text{-}C\text{-}R'}} \quad \underset{\substack{\downarrow \\ O}}{\overset{\substack{\downarrow \\ O}}{R\text{-}S\text{-}O\text{-}C\text{-}R'}} \quad \underset{\substack{\downarrow \\ O}}{\overset{\substack{\uparrow \\ O}}{R\text{-}S\text{-}S\text{-}R}}$$

VII VIII IV

The decomposition of VI would give the sulfinic ester thus:

$$\underset{\substack{\downarrow \\ O}}{\overset{\substack{\downarrow \\ O}}{R\text{-}S\text{-}O\text{-}C\text{-}OR'}} = \underset{\substack{\downarrow \\ O}}{R\text{-}S\text{-}OR'} + CO_2 \quad (7)$$

This decomposition seems to be base-catalyzed, since in pyridine the formation of carbon dioxide is very rapid. In other non-hydroxylic solvents, the reaction 7 is slow compared to such side reactions as 8, where the primary product, sulfinic anhydride (X), takes well-known, complicated courses to give the sulfinyl sulfone or thiolsulfonate[6]:

$$\begin{matrix} R\text{-}S\text{-}O\text{-}C\text{-}OR' + RSO_2{}^- = \\ \quad\downarrow\quad\downarrow \\ \quad O\quad O \end{matrix}$$

$$\underset{\substack{\downarrow \quad \downarrow \\ O \quad O}}{R\text{-}S\text{-}O\text{-}S\text{-}R} + [{}^-O_2C\text{-}OR'] \quad (8)$$

X

In the hydroxylic solvents, the intermediate VI suffers attack by the solvent molecules, ahead of the decomposition 7, as follows:

$$VI + R''OH \longrightarrow \underset{\substack{\downarrow \quad \downarrow \\ O \quad O}}{R\text{-}S\text{-}O\text{-}C\text{-}OR'} \longrightarrow R\text{-}S\text{-}OR'' + HO_2C\text{-}OR' \quad (9)$$

$$[HO_2C\text{-}OR'] \rightarrow CO_2 + R'OH \quad (10)$$

This alcoholysis may also be base-catalyzed. The alcohol liberated in the reaction 10 could participate in the alcoholysis too; this evidently explains why the ester mixture is always afforded in the reaction in dioxane containing an equimolecular amount of alcohol. If the reactivity of two alcohols, one added and one liberated, are equal, an ester mixture containing 75 mol. % of the ester of the added alcohol and 25 mol. % of that of the liberated alcohol may be expected. Actually, methanol has a greater reactivity than ethanol, as is

4) C. A. Bunton and B. N. Hendy, *J. Chem. Soc.*, **1962**, 2562.
5) Part II of this series. M. Kobayashi and A. Yamamoto, This Bulletin, **39**, 961 (1966).
6) Part III of this series. M. Kobayashi, ibid., **39**, 967 (1966).

indicated by the competitive alcoholysis; this causes the formation of an ester mixture richer in methyl ester than had been calculated.

In the reaction of sodium *p*-toluenesulfinate-^{18}O, the labeled, mixed anhydride (XI) is alcoholized to give the alkyl sulfinate-[sulfinyl ^{18}O], which should retain half of the heavy oxygen atom in the original sodium sulfinate:

$$\underset{\underset{^{18}O}{\downarrow}}{R\text{-}S\text{-}^{18}O\text{-}\overset{\overset{O}{\|}}{C}\text{-}OR'} + R''OH$$

XI

$$\rightarrow R\text{-}\underset{\underset{^{18}O}{\downarrow}}{S}\text{-}OR'' + CO^{18}O + R'OH \qquad (11)$$

Experimental

Materials.—Dioxane was purified as usual[7] and dried over sodium. Acetonitrile was refluxed over phosphorus pentoxide until a colorless product was obtained and then rectified. The alcohols were dehydrated by distillation from lithium hydride.

The Reaction of Sodium *p*-Toluenesulfinate (I) with Ethyl Chlorocarbonate (II). Without a Solvent.—To 4.0 g. of finely-powdered, anhydrous sodium salt (I) 2.4 g. of II was added at room temperature. About 330 ml. of carbon dioxide (60 mol. %) evolved slowly over 3 hr. The reaction mixture was then extracted with petroleum ether, and the extract concentrated and vacuum distilled to give 0.66 g. of ethyl *p*-toluenesulfinate (III) in a 18% yield. Most of the insoluble white powder in petroleum ether was soluble in water, but 0.2 g. of *p*-tolylsulfinyl *p*-tolylsulfone (IV: R=*p*-tolyl) remained. This was identified by melting point and mixture melting point determinations (87—90°C).

The General Procedure of the Reactions in Solvents Other Than Alcohols or Pyridine.—An equimolecular amount of II was stirred into a suspension of I; then the mixture was kept for an appropriate reaction period, from a few hours to several days, at room temperature. Water and petroleum ether were added to the resulting jelly, and the organic layer was separated, dried over magnesium sulfate, and subjected to vacuum distillation to give III. It was identified by its infrared spectrum and b. p. (102—106°C/5 mmHg, 98—102°C/3 mmHg).

Reaction in Pyridine.—A suspension of 4.0 g. of I in 30 ml. of pyridine was boiled once to effect the partial solution and then cooled to room temperature. To this mixture 3.2 g. of II was added, drop by drop, during which process the evolution of slight heat and 450 ml. of carbon dioxide was observed. After dilution with water, the product was extracted with petroleum ether, washed with dilute hydrochloric acid and water, dried, and distilled in vacuo to give 1.3 g. of III (30%).

Reactions in Alcohols.—i) In 30 ml. of methanol 5.0 g. of I was shaken to effect the partial solution. When 3.1 g. of II was added, drop by drop, to this solution, cooled with ice water, carbon dioxide formed immediately. After a few hours the reaction mixture was then diluted with water and extracted with petroleum ether. Vacuum distillation gave 3.3 g. of methyl *p*-toluenesulfinate at 90°C/3 mmHg in 69% yield.

ii) To a suspension of 17.5 g. of I in 100 ml. of ethanol 10.8 g. of II was added. Treatment similar to that above gave 6.7 g. of III at 98—102°C/3 mmHg in 36% yield.

iii) A suspension of 5.0 g. of I in 30 ml. of *n*-butanol was treated with 3.0 g. of III as described in i). After 15 hr. at room temperature, 4.3 g. of *n*-butyl *p*-toluenesulfinate was isolated; b. p. 118—120°C/3 mmHg in 57% yield.

iv) From 5.0 g. of I in 30 ml. of allyl alcohol and 3.0 g. of II, 3.0 g. of allyl *p*-toluenesulfinate, b. p. 98—102°C/3 mmHg, was obtained in 55% yield after one day's reaction.

v) A suspension of 5.0 g. of I in a mixture of 0.9 g. of methanol and 30 ml. of dioxane was treated with 3.0 g. of II at room temperature. After 10 min., the reaction started, accompanied by the evolution of carbon dioxide. The yield of the sulfinate ester mixture was 2.8 g. after 40 hr. Using the 970 cm^{-1} absorption band for methyl *p*-toluenesulfinate and the 884 cm^{-1} band for the ethyl ester, the composition of this ester mixture was estimated as 82 mol.% the methyl ester and 18 mol.% the ethyl ester by infrared spectrum, the total yield being 60% of the theoretical.

vi) When 2.8 g. of methyl chlorocarbonate was added to 5.0 g. of I in a mixture of 1.8 ml. of ethanol and 30 ml. of dioxane, 200 ml. of carbon dioxide (30%) evolved in 5 min. The reaction mixture afforded the sulfinate ester mixture, the composition of which was found by its infrared spectrum to be 48 mol.% the methyl ester and 52 mol.% the ethyl ester in a total yield 30% of the theoretical.

vii) The reaction of 5.0 g. of I and 3.0 g. of II in a mixture of 2.0 g. of III and 30 ml. of methanol gave 4.0 g. of the sulfinate ester mixture, b. p. 92—104°C/3 mmHg. Its infrared spectrum revealed the presence of 2.1 g. of III and 1.9 g. of methyl sulfinate (43% of the theoretical yield) in this mixture.

viii) Reaction in an equimolecular mixture of methanol and ethanol: To 7.0 g. of I in a mixture of 16 g. of methanol and 23 g. of ethanol, 4.5 g. of II was added with cooling in ice water. After one hour, the reaction mixtue was diluted with an excess of water and extracted with 60 ml. of carbon tetrachloride. The extract was found by infrared spectroscopy to contain 2.25 g. of methyl *p*-toluenesulfinate and 1.25 g. of III. The relative reactivity of methanol and ethanol for this reaction was calculated to be 2 : 1 from this competitive reaction.

Reaction in Pyridine.—i) When 2.5 g. of II was added, drop by drop, to a solution of 3.0 g. of *p*-toluenesulfinic acid in 20 ml. of anhydrous pyridine, the reaction occurred immediately, with the evolution of carbon dioxide and with the precipitation of pyridine hydrochloride. From the reaction mixture, 1.5 g. of III was obtained in 42% yield.

ii) When 2.0 g. of *p*-nitrobenzenesulfinic acid (10.7 mmol.) was added to 15 ml. of pyridine, a red suspension was obtained. The addition of 5.5 g. (50.7 mmol.) of II to this suspension over 40 min. caused the formation of 320 ml. (13.3 mml.) of carbon dioxide. The pale brown reaction mixture was then

7) A. Weissberger and E. S. Proskauer, "Organic Solvents," 2nd Ed. (1955).

diluted with water and extracted by petroleum ether; the extract was washed with diluted hydrochloric acid and water, dried over magnesium sulfate, and evaporated. The recrystallization of the residue from petroleum ether gave 1.0 g. of ethyl *p*-nitrobenzenesulfinate, m. p. 48.5—50.5°C, in 34% yield.

Sodium *p*-Toluenesulfinate-^{18}O.—i) To 11.5 g. of *p*-toluenesulfinyl chloride[8] 2.5 g. of $H_2{}^{18}O$ (^{18}O= 1.5 atom %) was slowly added with ice cooling. After 2 hr., the white reaction product mass was neutralized with 5 g. of sodium hydroxide in a few milliliters of light water; the crystals thus formed were recrystallized from distilled water to give 7.6 g. of sodium *p*-toluenesulfinate dihydrate, which was dehydrated in vacuo. The ^{18}O atom % of this salt was 0.86%. (The calculated value is 0.86%.)

ii) A mixture of 6.7 g. of III and 1.44 g. of sodium hydroxide in 6.00 ml. of $H_2{}^{18}O$ (1.5 atom % ^{18}O) was stirred with a magnetic stirrer for 2 hr., and cooled in an ice bath; the resultant crystals were filtered through a fritted-glass funnel to give 7.0 g. of the labeled dihydrate of I, which was then dehydrated in vacuo at 110°C for one hour. The ^{18}O atom % of this anhydrous salt was 0.65%, lower than the calculated value, 0.71%.

Ethyl *p*-Toluenesulfinate - [sulfinyl ^{18}O]. — A suspension of 5.0 g. of the labeled sodium sulfinate prepared as above ii) in 30 ml. of methanol was treated with 3.0 g. of II; after 3 hr., the reaction mixture was extracted by petroleum ether. The vacuum distillation of the extract after drying over magnesium sulfate gave 3.5 g. of methyl *p*-toluenesulfinate-[sulfinyl ^{18}O] in 74% yield. The ^{18}O atom % of this specimen was 0.41%. (The caluclated value, based on the reaction 5, was 0.43%).

Thanks are due to Dr. Teijiro Kitao and Miss Reiko Kiritani of the Radiation Center of Osaka Prefecture for their analyses of ^{18}O, and also to Professor Shigeru Oae of Osaka City University for his donation of the heavy oxygen water.

Organic Sulfur Compounds. VIII. The Formation of Sulfinate Esters by the Alkylation of Sulfinic Acid Salts

By Michio KOBAYASHI*

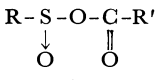
Department of Chemistry, Yokohama City University, Mutsuura-machi, Kanazawa-ku, Yokohama

(Received December 3, 1965)

The alkylation of the sulfinic acid salts with triethyloxonium fluoroborate results in the formation of the ethyl sulfinates, not in the usual sulfone formation.

Sulfinic acid salts are known to react with many alkylating reagents to give the sulfones; indeed, this reaction is one of the established methods for the preparation of sulfones.[1]

Although the fact that the electronegativity of an oxygen atom is higher than that of sulfur suggests the localization of the negative charge mainly on the oxygen atoms in a sulfinate anion, every reported alkylation of the sulfinic acid salts has taken place on the sulfur atom, thus resulting in the formation of the sulfones; this mode of *S*-alkylation has been believed to be the general one for the sulfinate anion.



(I)

In the course of our study of the reaction of the sulfinic acid salt with carboxylic chloride, the formation of a sulfinic carboxylic anhydride (I) as an intermediate has been deduced.[2] This means an *O*-alkylation in the sulfinate anion. Since the above reaction is a very rapid one (completed in a few minutes even at −70°C) compared to the usual slow alkylation of the sulfinic acid salts to form the sulfones, it occurred to the author that a highly-reactive alkylating reagent may attack the sulfinate anion on oxygen atom to give a sulfinic ester.

Triethyloxonium fluoroborate is known to be a very efficient ethylating reagent.[3] When the reaction of sodium *p*-toluenesulfinate with this oxonium salt was attempted, the formation of ethyl *p*-toluenesulfinate in an almost quantitative yield was observed. The ethylation of a pyridinium *p*-nitrobenzenesulfinate with the same reagent also gave ethyl sulfinate. No sulfone formation was detected. Therefore, it may be concluded that,

with a highly-reactive alkylating reagent, the attack on the sulfinate anion proceeds in a kinetically controlled manner to give a relatively unstable sulfinate ester, while in the reaction with weak alkylating reagents a thermodynamically controlled attack gives more stable isomeric sulfones. A similar idea concerning the dual nature of the electrophilic attack on the ambident anions has been well established by Kornblum and his coworhers in the cases of active methylene compounds.[4]

Experimental

Ethyl *p*-Toluenesulfinate.—Into a solution of 3.5 g. of triethyloxonium fluoroborate[5] in 20 ml. of methylene chloride, 3.0 g. of finely-powdered anhydrous sodium *p*-toluenesulfinate in several portions was vigorously stirred over a 5 minute period. The reaction proceeded quickly, with a slight evolution of heat. After 30 ml., the reaction mixture was repeatedly shaken with a large volume of water and the organic layer was dried over magnesium sulfate. The infrared spectrum of an aliquot of this solution indicated the formation of 2.92 g. of ethyl *p*-toluenesulfinate in 95% yield. The vacuum distillation of the remaining part of the solution gave the pure ethyl ester, b. p. 100°C/1 mmHg.

Ethyl *p*-Nitrobenzenesulfinate.—When 0.45 g. of dry pyridine in 20 ml. of methylene chloride was added to a suspension of 0.92 g. of *p*-nitrobenzenesulfinic acid in 50 ml. of the same solvent, a yellow solution was obtained. The addition of 2 g. (excess) of triethyloxonium fluoroborate in 20 ml. of methylene chloride to the above solution with the stirring over a 2 minute period resulted in the decolorization of the solution and the precipitation of white crystals. After 5 min., the reaction mixture was poured into a lot of water, and the methylene chloride layer was separated, dried, and evaporated. The pale yellow residue was recrystallized from petroleum ether to give 0.39 g. of ethyl *p*-nitrobenzenesulfinate, m. p. 48—50°C (lit.[6] 49—51°C) in 37% yield. Its identity was confirmed by its infrared spectrum.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1297—1301 (1966)

The Preparation of 2-Alkoxy-1, 3, 2-oxazaphospholidines and Some Reactions

By Teruaki MUKAIYAMA and Yasuto KODAIRA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 16, 1965)

The preparation of 2-alkoxy-1, 3, 2-oxazaphospholidines and some reactions will be described. 2-Alkoxy-1, 3, 2-oxazaphospholidines were prepared either from ethyl phosphorodichloridite and aminoethanols or, more conveniently, from tris[diethylamino]phosphite, aminoethanols and alcohols. 2-Alkoxy-1, 3, 2-oxazaphospholidines reacted easily with alcohols or *p*-toluenesulfonic acid monohydrate to give dialkyl aminoethyl phosphites or alkyl aminoethyl phosphite by the ring-opening at the P–N linkage of the phospholidines. It was oxidized by means of sulfur or nitrogen tetroxide to give 2-thione or 2-one in high yields. Further, it was found that it reacted with ethyl isocyanate to form 1 : 1 adducts. The structure of the adducts was confirmed, by a study of its chemical transformations, to be a seven-membered cyclic compound. It also reacted with carbon dioxide at about 120°C to yield the phosphorous-containing polyamide.

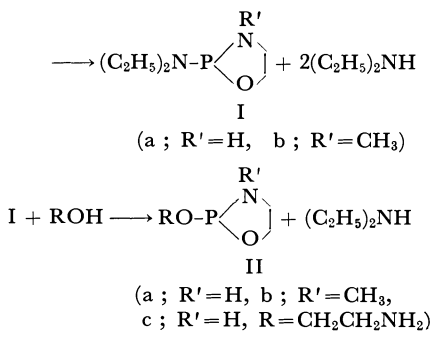
It has been reported in a previous paper[1] that 2, 3-diphenyl-1, 3, 2-oxazaphospholidine can be prepared by treating phenyl phosphinous dichloride with 2-phenylaminoethanol in the presence of two molecular equivalents of triethylamine.

It was also found by the present work that 2-alkoxy-3-methyl-1, 3, 2-oxazaphospholidine (IIb) can be prepared in a 69% yield from ethyl phosphorodichloridite and 2-methylaminoethanol. However, 2-alkoxy-1, 3, 2-oxazaphospholidine (IIa) could not be obtained by the use of 2-aminoethanol, which has a primary amino group, whereas 2-(2-aminoethyl)-1, 3, 2-oxazaphospholidine (IIc)[2] resulted in a 25% yield. It was further established that the phospholidines can be conveniently prepared from aminoethanols and tris[diethylamino]-phosphite. Various 2-alkoxy-1, 3, 2-oxazaphospholidines (II) were synthesized by the reaction

1) T. Mukaiyama and Y. Yokota, This Bulletin, **38**, 858 (1965).

2) R. Burgada, *Ann. Chim.*, **8**, 348 (1963).

of alcohols with 2-diethylamino-1, 3, 2-oxazaphospholidine (I), which had been prepared from tris-[diethylamino]phosphite and aminoethanols, as is shown in the following scheme. These results

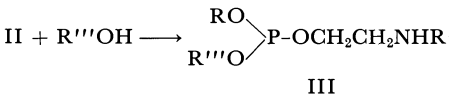


are summarized in Table I.

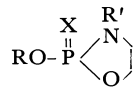
TABLE I. PREPARATION OF 2-ALKOXY-1, 3, 2-OXAZAPHOSPHOLIDINES

Alcohol	B. p. °C/mmHg	Yield %	Anal. N, % Calcd.	Found
C_2H_5OH	62—67/17	80	9.40	9.16
n-C_3H_7OH	83—85/20	79	8.59	8.70
i-C_3H_7OH	57—60/10	66	8.59	8.38
n-C_4H_9OH	98—100/21	77	7.91	8.16
t-C_4H_9OH	75—86/15	80	7.91	8.05
CH_2=$CHCH_2OH$	75—77/13	76	8.69	8.75
$CH_3NHCH_2CH_2OH$	105—107/0.14	80	15.73	15.91

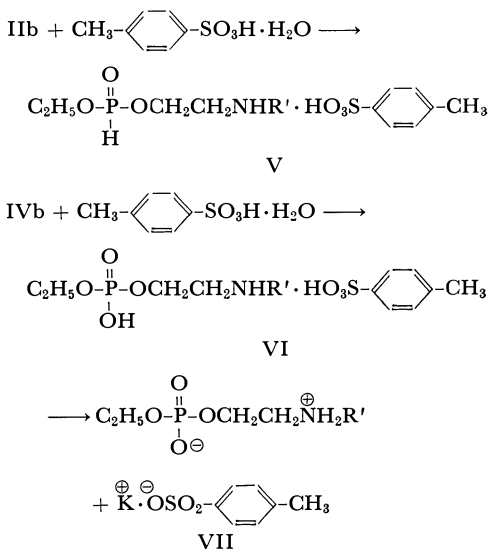
The phospholidines react with alcohols in refluxing benzene to give dialkyl 2-aminoethyl phosphites (III) in excellent yields by ring opening at the P–N linkage of the phospholidine. These results are summarized in Table II.



The phospholidines were oxidized easily by means of sulfur in benzene at room temperature or by means of nitrogen tetroxide in dichloromethane at −78°C, thus forming 2-alkoxy-1, 3, 2-oxazaphospholidine-2-thione (IVa) or 2-one (IVb) in 86% or 61% yields respectively.



When the phospholidines were treated with an equimolecular amount of p-toluenesulfonic acid monohydrate in benzene at room temperature, a ring-opening reaction took place exclusively at the P–N linkage of the phospholidine, giving the p-toluenesulfonium salt of ethyl 2-methylaminoethyl phosphite (V) in a quantitative yield. In a similar way, the p-toluenesulfonium salt of ethyl 2-methylaminoethyl phosphate (VI) was obtained in an excellent yield from IVb. It was then converted to the ethyl 2-methylaminoethyl phosphate (VII), which was identified as a barium salt, by treating it with barium hydroxide in an ethanol solution.

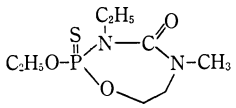


The phospholidines react with an equimolecular amount of ethyl isocyanate at about 110—120°C, resulting in the formation of 1 : 1 adducts (VIII).

TABLE II. REACTION OF 2-ETHOXY-1, 3, 2-OXAZAPHOSPHOLIDINES WITH ALCOHOLS

R′	R‴OH	B. p. °C/mmHg	Yield %	Anal. N, % Calcd.	Found
CH_3	C_2H_5OH	50—51/1	67	7.18	7.25
CH_3	n-C_3H_7OH	52—53/1	68	6.70	6.76
CH_3	i-C_3H_7OH	79—83/7	73	6.70	6.74
CH_3	t-C_4H_9OH	44—47/6	46	6.28	6.29
CH_3	CH_2=$CHCH_2OH$	72—84/2	84	6.76	6.59
H	C_2H_5OH	50—52/2	56	7.73	7.76
H	n-C_3H_7OH	60—63/1	75	7.18	7.37
CH_3	$CH_3NHCH_2CH_2OH$	77—83/4	58	12.50	13.32

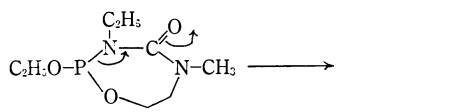
The structures of these adducts VIII were confirmed to be seven-membered cyclic ureid derivatives (XI) by the following spectral data and their chemical transformations. The infrared spectra of these adducts (VIII) showed an absorption at 1660 cm^{-1} due to the ureid carbonyl group. VIII was oxidized exothermally by means of sulfur in a benzene solution at room temperature to yield IX in a 89% yield. This was in turn hydrolyzed to the *p*-toluenesulfonium salt (X) by ring opening when treated with *p*-toluenesulfonic acid monohydrate in refluxing benzene.



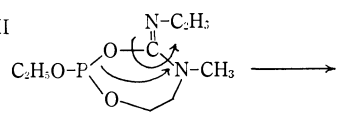
IX

X

When heated at about 180°C, the adducts decomposed to give ethyl isonitrile (XIII) and oxazaphospholidine-2-one (IVb) by way of an internal nucleophilic displacement, as is shown below.



XI



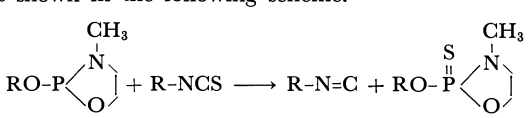
XII

IVb + $C_2H_5N{=}C$

XIII

On the other hand, the reaction of phenyl isocyanate and the phospholidine at 110—120°C gave an undistillable oily substance, which decomposed to give a small amount of phenyl isonitrile and oxazaphospholidine-2-one (IVb) along with a glassy, hygroscopic resinous substance.

Similarly, isonitriles and oxazaphospholidine-2-thione were prepared when ethyl isothiocyanate or phenyl isothiocyanate was heated with II, as is shown in the following scheme.



2-Ethoxy-1, 3, 2-oxazaphospholidine (IIa) absorbed carbon dioxide at 0°C, giving a viscous oily adduct (XIV) with infrared absorptions at 1650 and 1565 cm^{-1} due to the amide carbonyl group. When XIV was heated under reduced pressure, 35% of the IIa was recovered, whereas when it was heated at 110—120°C in a sealed tube or under a carbon dioxide atmosphere, a glassy, hygroscopic polymer (XV), m. p. 186—188°C, was produced.

XV

Experimental

All melting points and boiling points are uncorrected.

Solvents and Reagents.—The solvents and alcohols were dried and purified by ordinary procedures.

The Preparation of 2-Alkoxy-3-methyl-1, 3, 2-oxazaphospholidine (IIb).—A mixture of 2-methylaminoethanol (3.75 g., 0.05 mol.) and triethylamine (15.45 g., 0.125 mol.) was added, drop by drop, into a solution of ethyl dichloro phosphite (7.35 g., 0.05 mol.) in 100 ml. of ether at 0°C with stirring. After the solution had been stirred for 2 hr. at room temperature, the precipitate of triethylammonium hydrochloride was filtered and washed twice with ether (10 ml.). After the ether had been removed under reduced pressure, 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine (IIb) (b. p. 62—67°C/17 mmHg, 3.1 g., 69%) was obtained.

Found : N, 9.16. Calcd. for $C_5H_{12}O_2NP$: N, 9.40%.

The Reaction of Ethyl Dichloro Phosphite with 2-Aminoethanol. — A mixture of 2-aminoethanol (3.05 g., 0.05 mol.) and triethylamine (10.1 g., 0.10 mol.) was added, drop by drop, into a solution of ethyl dichloro phosphite (7.35 g., 0.05 mol.) in 70 ml. of ether at 0°C with stirring. After the mixture had been stirred for 2 hr. at room temperature, the precipitate of triethylammonium hydrochloride was removed from the reaction mixture. The removal of the solvent from the filtrate under reduced pressure gave an oily product which crystallized after it had been allowed to stand overnight. The needle crystalline of 2-(2-aminoethyl)-1, 3, 2-oxazaphospholidine (IIc) (m. p. 106—120°C, 3.7 g., 25%) was collected. Recrystallization from benzene gave an analytical sample (m. p. 116°C).

Found : N, 9.45. Calcd. for $C_4H_{11}O_2N_2P$: N, 9.33%.

The vaccum distillation of the filtrate gave an unidentified oil (b. p. 80—86°C/0.05 mmHg, 0.82 g.).

The Preparation of 2-Diethylamino-3-methyl-1, 3, 2-oxazaphospholidine (Ib).—A solution of tris[diethylamino]phosphite (4.94 g., 0.02 mol.) and 2-methylaminoethanol (1.50 g., 0.02 mol.) in 30 ml. of benzene was refluxed for 3 hr. After the benzene and diethylamine had been removed under reduced pressure, 2-diethylamino-3-methyl-1, 3, 2-oxazaphospholidine (b. p. 88—90°C/3 mmHg, 2.1 g., 60%) was obtained by vacuum distillation.

Found: N, 15.91. Calcd. for $C_7H_{17}ON_2P$: N, 15.91%.

The Preparation of 2-Diethylamino-1, 3, 2-oxazaphospholidine (Ia).—By a procedure analogous to that mentioned above, 2-diethylamino-1, 3, 2-oxazaphospholidine (b. p. 91—97°C/5 mmHg, 1.52 g., 47%) was obtained from the reaction of tris[diethylamino]-phosphite (4.94 g., 0.02 mol.) and 2-aminoethanol (1.42 g., 0.02 mol.). A small amount of the needle crystalline of 2-(2-aminoethyl)-1, 3, 2-oxazaphospholidine was also obtained as a by-product.

Found: N, 17.29. Calcd. for $C_6H_{15}ON_2P$: N, 16.95%.

The Preparation of 2-Alkoxy-1, 3, 2-oxazaphospholidines.—A solution of 2-diethylamino-2-methyl-1, 3, 2-oxazaphospholidine (1.76 g., 0.01 mol.) and ethanol (0.46 g., 0.01 mol.) in 20 ml. of benzene was refluxed for 2 hr. After the benzene and diethylamine had been removed under reduced pressure, 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine (b. p. 62—67°C/17 mmHg, 1.19 g., 80%) was obtained by vacuum distillation.

In a similar fashion, the reaction of various alcohols and 2-diethylamino-1, 3, 2-oxazaphospholidine gave the corresponding 2-alkoxy-1, 3, 2-oxazaphospholidines. The results are summarized in Table I.

The Reaction of 2-Ethoxy-1, 3, 2-oxazaphospholidine with Alcohols.— A solution of 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine (1.49 g., 0.01 mol.) and ethanol (0.46 g., 0.01 mol.) in 15 ml. of benzene was refluxed for 2 hr. After the solvent had been removed under reduced pressure, 2-methylaminoethyl diethyl phosphite (b. p. 49—51°C/1 mmHg, 1.3 g., 67%) was obtained by vacuum distillation.

In a similar fashion, the reaction of various alcohols and 2-ethoxy-1, 3, 2-oxazaphospholidines gave the corresponding dialkyl 2-aminoethyl phosphites, as is shown in Table II.

The Oxidation of 2-Ethoxy-3-methyl-1, 3, 2-oxazaphospholidine by Means of Sulfur.—Into a solution of 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine (1.49 g., 0.01 mol.) in 20 ml. of benzene was added sulfur in small portions with stirring at room temperature. After the stirring had been continued for an additional hour, the unreacted sulfur was removed by filtration. Benzene was removed from the filtrate under reduced pressure and the residue was distilled in a vaccum, giving 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine-2-thione (b. p. 76—78°C/0.12 mmHg, 1.56 g., 86%).

Found: N, 7.53. Calcd. for $C_5H_{12}O_2SNP$: N, 7.73%.

The Oxidation of 2-Ethoxy-3-methyl-1, 3, 2-oxazaphospholidine by Means of Nitrogen Tetroxide.—Into a solution of 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine (1.49 g., 0.01 mol.) in 15 ml. of dichloromethane there was added, drop by drop, a solution of nitrogen tetroxide in dichloromethane at −78°C with stirring; this was continued until the solution turned blue. After the solvent had been removed under reduced pressure, 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine-2-one (b. p. 90—91°C/0.2 mmHg, 1.0 g., 61%) was obtained.

Found: N, 8.52. Calcd. for $C_5H_{12}O_3NP$: N, 8.48%.

The Reaction of 2-Ethoxy-3-methyl-1, 3, 2-oxazaphospholidine with *p*-Toluenesulfonic Acid Monohydrate.—A solution of 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine (1.49 g., 0.01 mol.) and *p*-toluenesulfonic acid monohydrate (1.90 g., 0.01 mol.) in 15 ml. of benzene was refluxed for an hour. A transparent viscous oil separated from the reaction mixture. After the mixture had been kept standing overnight at room temperature, the benzene was removed by decantation. The oil was then rinsed three times with benzene (10 ml.) in order to remove the by-products; this gave the *p*-toluenesulfonium salt of ethyl 2-methylamino phosphite (3.30 g., 97%).

Found: N, 4.37. Calcd. for $C_{12}H_{22}O_6NP$: N, 4.31%.

The Reaction of 2-Ethoxy-3-methyl-1, 3, 2-oxazaphospholidine-2-one with *p*-Toluenesulfonic Acid Monohydrate.—Into a solution of 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine-2-one (6.60 g., 0.04 mol.) in 50 ml. of benzene was added *p*-toluenesulfonic acid monohydrate (7.60 g., 0.04 mol.) in small portions with stirring at room temperature. After stirring had been continued for an additional 2 hr., the reaction mixture was kept standing overnight at room temperature. A transparent viscous oil thereupon separated from the reaction mixture. The benzene was removed by decantation and the oil was rinsed three times with benzene (10 ml.), thus giving *p*-toluenesulfonium salt of ethyl 2-methylaminoethyl phosphate (14.0 g., 98%).

Into a solution of the salt in 50 ml. of ethanol, a solution of potassium hydroxide (2.24 g., 0.04 mol.) in 50 ml. of ethanol was added, drop by drop, with stirring. A white precipitate, the potassium salt of *p*-toluenesulfonic acid (8.40 g., 74%), was then collected by filtration. To the filtrate there was added an aqueous solution of barium hydroxide; this gave a white precipitate of the barium salt of ethyl 2-methylaminoethyl phosphate (9.2 g., 52%).

Found: C, 22.33; H, 5.59; N, 4.73. Calcd. for $C_{10}H_{30}O_{10}N_2P_2Ba$: C, 22.07; H, 5.61; N, 5.21%.

The Reaction of 2-Ethoxy-3-methyl-1, 3, 2-oxazaphospholidine with Ethyl Isocyanate.—A mixture of 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine (1.49 g., 0.01 mol.) and ethyl isocyanate (0.71 g., 0.01 mol.) was heated at 110—120°C for 4 hr. in a sealed tube. The reaction mixture was then distilled under reduced pressure, thus obtaining a 1 : 1 adduct (b. p. 80—83°C/0.11 mmHg, 1.57 g., 68%). Its infrared spectrum showed absorptions at 1700 and 1660 cm^{-1}.

Found: N, 12.69. Calcd. for $C_8H_{17}O_3N_2P$: N, 12.71%.

The Oxidation of the Adduct by Means of Sulfur.—Into a solution of the adduct (2.20 g.) in 20 ml. of benzene was added sulfur in small portions with stirring at room temperature. After it had been stirred for additional 30 min., the reaction mixture was kept standing overnight. After the solvent had been removed under reduced pressure, IX (b. p. 111—126°C/

0.09 mmHg, 2.24 g., 89%) was obtained by vacuum distillation.

Found: N, 11.40. Calcd. for $C_8H_{17}O_2SN_2P$: N, 11.11%.

The Hydrolysis of IX by Means of *p*-Toluenesulfonic Acid Monohydrate.—Into a solution of IX (1.09 g.) in 10 ml. of benzene was added *p*-toluenesulfonic acid monohydrate (0.95 g.) with stirring at room temperature. The reaction soon started, with a liberation of heat. After stirring had been continued for 30 min., the reaction mixture was further refluxed for 2 hr., whereupon a transparent viscous oil was separated from the reaction mixture. After the solvent had been removed by decantation, the oil was rinsed twice with benzene (10 ml.). The *p*-toluenesulfonium salt of the thiophosphate X (2.04 g., 100%) was obtained.

Found: N, 6.89. Calcd. for $C_{15}H_{27}O_7N_2SP$: N, 6.83%.

The Thermal Decomposition of the Adduct.—The adduct (2.20 g.) was heated at 180°C for 2 hr. under nitrogen. The vacuum distillation of the adduct gave 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine-2-one (b. p. 85—93°C/0.2 mmHg, 0.2 g.) and ethyl isonitrile (about 0.5 g.) which was trapped in dry-ice acetone bath, a resinous solid remained in a Claisen flask.

The Reaction of 2-Ethoxy-1, 3, 2-oxazaphospholidine with Ethyl Isocyanate.—A solution of 2-ethoxy-1, 3, 2-oxazaphospholidine (1.35 g., 0.01 mol.) and ethyl isocyanate (0.71 g., 0.01 mol.) in 15 ml. of benzene was refluxed for 2 hr. After the benzene had been removed under reduced pressure, an adduct (b. p. 107—110°C/0.15 mmHg, 1.32 g., 64%) was obtained by vacuum distillation. Its infrared spectrum showed absorptions at 1700 and 1650 cm^{-1}.

Found: N, 13.51. Calcd. for $C_7H_{15}O_3N_2P$: N, 13.59%.

The Reaction of 2-Ethoxy-3-methyl-1, 3, 2-oxazaphospholidine with Phenyl Isocyanate.—A mixture of 2-ethoxy-3-methyl-1, 3, 2-oxzaphospholidine (1.49 g., 0.01 mol.) and phenyl isocyanate (1.19 g., 0.01 mol.) was heated at 110—120°C for 4 hr. in a sealed tube. The fractional distillation of the mixture gave phenyl isonitrile (0.3 g.) and 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine-2-one (0.2 g.), along with a large amount of a transparent, hygroscopic resinous solid.

The Reaction of 2-Ethoxy-3-methyl-1, 3, 2-oxazaphospholidine with Phenyl Isothiocyanate and Ethyl Isothiocyanate.—A mixture of 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine (1.49 g., 0.01 mol.) and phenyl isothiocyanate (1.35 g., 0.01 mol.) was heated at 110—120°C for 4 hr. in a sealed tube. The fractional distillation of the mixture gave phenyl isonitrile (b. p. 65—72°C/28 mmHg, 0.45 g., 45%) and 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine-2-thione (b. p. 77—78°C/0.16 mmHg, 1.12 g., 62%). Similarly, the reaction of ethyl isothiocyanate (0.87 g., 0.01 mol.) and 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine (1.49 g., 0.01 mol.) gave ethyl isonitrile and 2-ethoxy-3-methyl-1, 3, 2-oxazaphospholidine-2-thione (1.40 g., 77%).

The Reaction of 2-Ethoxy-1, 3, 2-oxazaphospholidine with Carbon Dioxide.—A) 2-Ethoxy-1, 3, 2-oxazaphospholidine (2.31 g., 0.018 mol.) absorbed 0.24 g. of carbon dioxide under atmospheric pressure at 0°C, giving a transparent viscous oil. Its infrared spectrum showed absorptions at 1650 and 1565 cm^{-1}. The fractional distillation of the oily adduct recovered 2-ethoxy-1, 3, 2-oxazaphospholidine (0.8 g., 35%). A white glassy hygroscopic solid was obtained when the oily adduct was heated at 110—120°C for 6 hr. in a sealed tube. The resultant polymer was crushed, refluxed in 15 ml. of benzene, and collected (m. p. 186—188°C, 1.15 g.). Its infrared spectrum showed absorptions at 1650 and 1560 (CONH), 1220 (P=O), 1050 (POC) cm^{-1}. It did not dissolve in water, dichloromethane, benzene, acetonitrile or *o*-dichlorobenzene.

From the benzene extract, 0.9 g. of 2-ethoxy-1, 3, 2-oxazaphospholidine (b. p. 75—83°C/21 mmHg) was recovered.

B) 2-Ethoxy-1, 3, 2-oxazaphospholidine (3.0 g.) was heated at 110—120°C for 3 hr. under a carbon dioxide atmosphere of 55 kg./cm^2 in an autoclave. After the mixture had been kept standing overnight, a white glassy, hygroscopic solid was obtained. The polymer was crushed, refluxed in 20 ml. of benzene, and collected by filtration (m. p. 179—183°C, 3.7 g.). Its infrared spectrum showed absorptions at 1650 and 1540 (CONH), 1220 (P=O), and 1050 (POC) cm^{-1}.

The authors wish to express their hearty thanks to Dr. Oyo Mitsunobu for his helpful suggestion and Miss Keiko Nakamura for her microanalyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1302—1306 (1966)

The Sensitive Gas Chromatography of Para-, Orthohydrogen, Hydrogen Deuteride and Deuterium[1)]

By Iwao YASUMORI and Seigo OHNO

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received November 17, 1965)

A sensitive gas chromatograph of the reduced-pressure type was devised to analyze hydrogen nuclear spin isomers and isotopes, and its characteristics were studied in order to obtain the optimum conditions for analysis. It was shown that the para and ortho composition of 0.01 ml. S. T. P. of normal hydrogen could be determined within an accuracy of 1% by employing an alumina column cooled at −196°C, while the composition of 0.02 ml. S. T. P. of the equilibrated mixture of hydrogen, hydrogen deuteride and deuterium at 25°C could be determined within the same accuracy by employing an alumina column coated with manganese chloride. The alumina column was no longer capable of separating the spin isomers when it was treated above 350°C. Kinetic studies of the hydrogen-deuterium equilibration (21°C) and of the orthohydrogen conversion (−196°C), using the alumina as a catalyst, revealed that this strong activation creates active sites for the equilibration and the magnetic conversion which makes the peak separation obscure. The nature of these active centers was briefly discussed.

Since the nuclear spin isomers of hydrogen, para- and orthohydrogen, and isotopic molecules, including deuterium and tritium, were found, the method of measuring the thermal conductivity, originally developed by Farkas, has long been used for the analysis of their mixture, while mass spectrometry has been used for the analysis of the isotopes. These methods of analysis, however, are somewhat unsatisfactory, apart from their lack of convenience, the applicability of the thermal conductivity method is practically limited to the binary mixtures, while the mass spectroscopy can not be used for the analysis of the spin isomers.

Recently Kwan et al. and a number of other investigators have reported that it is possible to separate these isomers or isotopic molecules by gas chromatography when a column packing such as alumina is operated at a low temperature of liquid nitrogen.[2-11)] Moreover, the simultaneous separation of these four modifications, para-, orthohydrogen, hydrogen deuteride and deuterium molecules, has been successful.[12,13)] This method, therefore, may be a useful alternative to the current ones for the analysis if the present ambiguity in accuracy and the low sensitivity are improved, all the results reported hitherto, except for those in Venugopalan and Kutschke's work,[11)] indicate that it is necessary, for the quantitative determination of the composition, to use a gaseous sample of more than one milliliter at a standard temperature and pressure. In order to follow the change in composition at low pressure, it is desirable to develop a highly-sensitive apparatus which can work with a sample of several hundredths of a milliliter. For this purpose, a gas chromatograph of the reduced-pressure type was adopted, and the optimum conditions for the analysis were examined using the equilibrium mixture of hydrogen modifications.

The present paper will present the details of this method and also some information about the catalytic activities of gamma-alumina in the ortho-parahydrogen conversion and in the hydrogen-deuterium equilibration reactions which were studied by its application.

Experimental

Apparatus and Procedure.—A gas chromatograph of the reduced-pressure type was used in this study; a schematic diagram of it is shown in Fig. 1. The helium employed as the carrier gas was adjusted to atmospheric pressure by a bubbler (A) and was then purified over a Linde molecular sieve 13X trap (C) at −196°C. Gas sampling was performed by a gas pipette (D). In most experiments, an alumina column

was used for the separation of isomers, and an alumina column coated with manganese chloride, for that of isotopes at −196°C. A Linde molecular sieve 13X column was also examined in order to compare it with the characteristics of these column packings. The eluted hydrogen samples were converted into water vapor on a cupric oxide column (F) heated at 750°C and were detected by a katharometer (G) made of stainless steel block with paths for the gas flow (5 mm. in diameter) and coiled tungsten filaments (30 ohms) in it. In order to avoid the condensation of water vapor, the katharometer was kept at 45°C, and the path between the combustion column and the katharometer, at 110°C. In order to maximize the sensitivity, the pressure in the katharometer was adjusted by a pressure drop (J) to 55—60 mmHg, which is the lowest value where the drifts of base lines are negligible.

Kinetic studies of the orthohydrogen conversion at −196°C and the hydrogen-deuterium equilibration at 21°C were made using column packings as catalysts. A reaction vessel of about 950 ml. with a circulator was connected with the gas pipette (D). The gases were left in contact with the catalyst for a suitable time and then led to the gas chromatograph for analysis. Prior to each experiment, the catalyst was degassed for 5 hr. at a definite temperature in vacuo better than 10^{-6} mmHg.

Materials.—Hydrogen was purified by diffusing it through a heated palladium thimble, while high purity deuterium purchased from the Takachiho Chemical Co. which contained hydrogen deuteride 0.7%, was used without further purification. Tank helium was passed through a trap filled with a Linde molecular sieve 13X immersed in liquid nitrogen in order to remove oxygen and other condensables; it was then used as the carrier gas.

Preparation of Columns.—Aluminum hydroxide prepared by the hydrolysis of distilled aluminum isopropoxide was dried at 500°C for 10 hr. in a current of dried air and was then left in contact with water vapor overnight. The alumina (80—100 mesh) thus obtained was packed into a glass tube (1.7 m. long and 2 mm. in inside diameter) and was treated in a current of helium under various conditions. The spectroscopic analysis of the alumina indicated that it contained iron 0.019%, manganese 0.002% and chromium 0.005% by weight. An X-ray diffraction study showed that this alumina had gamma structure.

The column for the separation of isotopes was prepared in the following way. Five grams of the alumina were immersed in 100 ml. of a 0.075 mol./l. manganese chloride solution overnight. The alumina was quickly washed with distilled water, dried at 200°C for 10 hr., packed into a glass tube (2.2 m. × 2 mm.), and then treated in a current of helium at 200°C for 25 hr. A Linde molecular sieve 13X (30—60 mesh) was also used as a column; it was packed into a glass tube (1.7 m. × 3 mm.) and treated in a current of helium at 100°C for 20 hr. The spectroscipic analysis of the molecular sieve indicated that it contained iron 0.12%, manganese 0.005% and chromium 0.005% by weight.

Results and Discussion

The Determination of Para- and Orthohydrogen.—As is shown in Fig. 2, chromatograms with two well-separated peaks were obtained by using an alumina column which was activated at 100—150°C. It was observed that the shape of the peaks at the beginning of activation was appreciably asymmetrical, but after activation for more than 20 hr. it became almost symmetrical. This treatment made it possible to evaluate the peak area by a rather simple method—by multiplying the height by the half-width of the peak. A column which was strongly activated at higher temperatures (350°C) no longer had the function

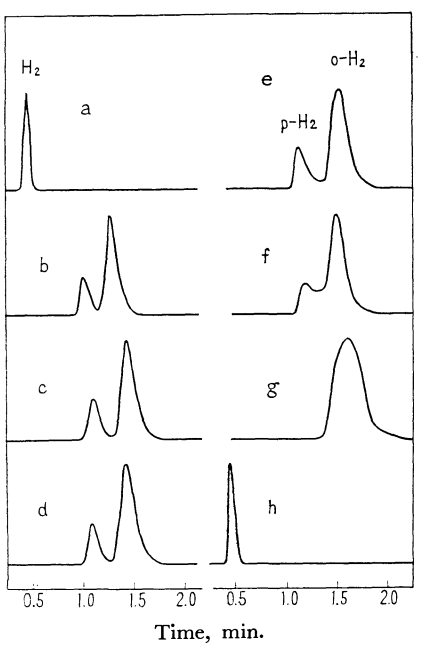

Fig. 2. Chromatograms of normal hydrogen on an alumina column activated at various temperatures.
Column: alumina (80—100 mesh, 1.7 m. × 2 mm.; −196°C) activated at a, 20°C, b, 100°C, c, 120°C; d, 150°C; e, 200°C, f, 270°C; g, 350°C; for 9 hr. and h, kept in contact with water vapor after activating at 350°C. Flow rate of carrier: 100 ml./min.

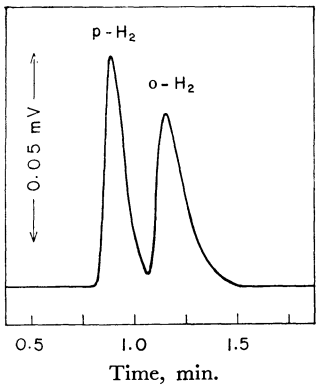

Fig. 3. Chromatogram of para-riched hydrogen equilibrated at −196°C.
Column: alumina (80—100 mesh, 1.7 m × 2 mm; −196°C) activated at 100°C for 45 hr.
Flow rate of carrier: 100 ml./min.
Sample: 0.015 ml.

of separation. However, it was easily recovered by the adsorption of water vapor. Figure 3 shows a chromatogram of the para-riched hydrogen obtained by the use of an alumina column. From a comparison of peak areas, it was established that the first-eluted peak corresponds to parahydrogen and the second peak, to orthohydrogen.

Figure 4 shows the calibration lines for these isomers. There was a good linear relationship between the peak area and the volume for each isomer; this relationship held up to 0.2 ml. of the sample. It was also shown that, for the analysis of normal hydrogen (para: ortho=1 : 3), it is sufficient to use more than 0.01 ml. of the sample,

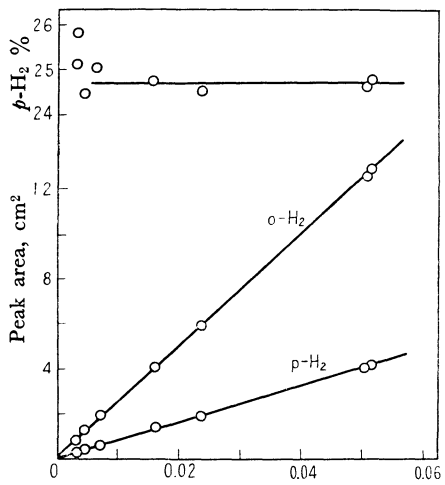

Fig. 4. Calibration lines for para- and ortho-hydrogen.

Flow rate of carrier: 100 ml./min.

and that the estimated mole fraction of the isomers agreed with the expected value within an accuracy of 1%.

The Linde molecular sieve 13X column has some unsatisfactory points. It gives not only longer retention times, but also a lower sensitivity than alumina. Moreover, the observed ratio of ortho to para in normal hydrogen becomes 2.88±0.03, which is lower than the expected value, 3.00. This is, as will be seen later, a result of the fact that the interconversion catalyzed by some paramagnetic impurities, mainly iron (0.12%), proceeds within the column. Therefore, it is advisable to employ highly-purified alumina as the column packing for the quantitative separation of para- and orthohydrogen.

The Determination of Hydrogen, Hydrogen Deuteride and Deuterium.—Analogous to the case of para- and orthohydrogen, well-separated chromatograms for isotopes were also obtained by using an alumina column coated with manganese chloride; they are shown in Fig. 5. The specific peak area which is defined as that for a unit volume of the sample, had the same value for both hydrogen and deuterium within the range of experimental error. Therefore, the ratio of the peak area for hydrogen isotopes corresponded practically to their mole ratios.

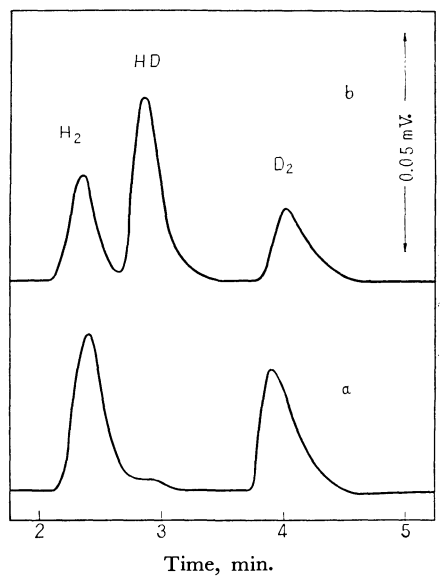

Fig. 5. Chromatograms of mixture of hydrogen, hydrogen deuteride and deuterium.
Column: alumina coated with manganese chloride and activated at 200°C for 25 hr. (80—100 mesh, 2.2 m. × 2 mm.; −196°C)
Flow rate of carrier: 90 ml./min.
a, mixture of hydrogen and deuterium (0.02 ml.) ($H_2/D_2=1.076$)
b, equilibrated mixture of hydrogen, hydrogen deuteride and deuterium at 25°C (0.022 ml.)

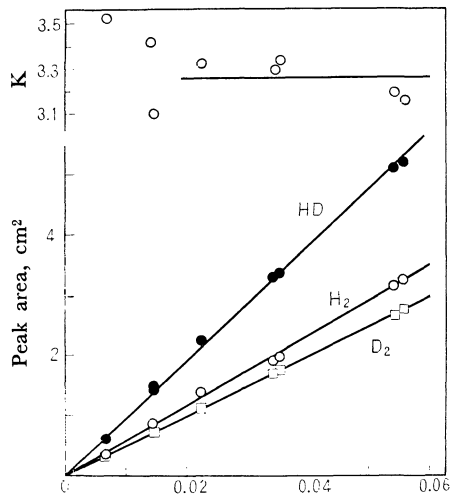

Fig. 6. Calibration lines for mixture of hydrogen, hydrogen deuteride and deuterium equilibrated at 25°C.
Column: alumina coated with manganese chloride and activated at 200°C for 25 hr.
(80—100 mesh, 2.2 m. × 2 mm.; −196°C)
Flow rate of carrier: 90 ml./min.

Figure 6 includes the calibration lines for these isotopes, which also held a good linear relationship between the peak area and the volume for each species. In this case of an isotopic mixture, it was verified, using an equilibrated mixture of hydrogen, hydrogen deuteride and deuterium at 25°C as the sample, that 0.02 ml. of a gaseous sample is sufficient for the quantitative determination of the composition within an accuracy of 1%. The observed value of the equilibrium constant, 3.26± 0.1, agreed with the calculated value, 3.268, within an accuracy of 3%. This improvement in sensitivity is mainly due to the lowering of the pressure of the carrier gas at which the katharomeer and to the conversion of eluted hydrogen into water, which amplifies the difference in thermal conductivity between the sample and the carrier gas.

Since a microthermal conductivity method can analyze 0.01—0.03 ml. of a sample,[14] the present method may be a useful alternative.

Orthohydrogen Conversion and Hydrogen-Deuterium Equilibration on Column Packings.—As is shown in Fig. 2, the separating power of alumina varied greatly according to the temperature at which alumina was activated. It has been reported that on separation occurs on a strongly-activated column; this is due to rapid interconversion between the isomers within the column.[7] In order to get further proof of this, kinetic studies of orthohydrogen conversion and also of hydrogen-deuterium equilibration were performed, using column packings as the catalysts.

The time course in all cases of constant pressure followed the first-order law; therefore, the rate constant may be expressed as:

$$k_e = (1/t) \ln (C_0/C_t) \text{ min}^{-1}$$

where C_0 or C_t is the excess concentration of species at time zero, or t, over the equilibrium value at the experimental temperature. The absolute rate constant was calculated to be:

$$k_m = k_e pV/60AkT \text{ molecules} \cdot \text{cm}^{-2} \text{ sec}^{-1}$$

where p is the gas pressure; V, the reaction volume at the temperature, T; A, the surface area of the catalyst, and k, Bolzmann's constant.

Figure 7 shows the specific activities for the conversion (−196°C) and for the equilibration (21°C) of catalysts which were subjected to the evacuation at various temperatures. Not all catalysts showed activity for the equilibration at −196°C. Therefore, the conversion proceeding at that temperature is of a physical nature.

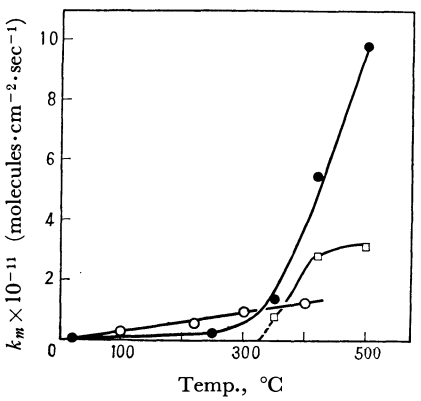

Fig. 7. Effect of evacuating temperature on the specific activities of catalysts.
● conversion on alumina at −196°C
○ conversion on molecular sieve 13X at −196°C
□ equilibration on alumina at 21°C

When the alumina was evacuated at temperatures higher than 350°C, the conversion activity increased abruptly; the equilibration activity also became appreciable at 21°C. On the contrary, the conversion activity of the molecular sieve 13X gradually increased with the evacuating temperatures, and the equilibration did not occur at temperatures up to 100°C.

As may be seen in Fig. 7, the activity of the physical conversion increases in two stages with the evacuating temperatures. The transition point between these stages nearly corresponds to the temperature at which the separated peaks begin to merge with each other, as is shown in Fig. 2. It may, therefore, be suggested that this phenomenon

14) H. Melville and B. G. Gowenlock, "Experimental Methods in Gas Reaction," Macmillan and Co., London (1964), p. 239.

results from the rapid interconversion within the column.

In order to get insight into this phenomenon, the effect of paramagnetic impurities was roughly examined by applying Wigner's theory. The activity of neodymium oxide in the parahydrogen conversion[15] was taken as a reference, and it was assumed that the conversion proceeds over the ferric ions on the surface of alumina the concentration of which is the same as that in bulk, and that the accessible distances between hydrogen molecules and active centers for γ-alumina and neodymium oxide are similar. The concentration of ferric ions is, therefore, given by the expression:

$$[Fe_2O_3]/[Nd_2O_3] = \{\mu(Nd^{3+})/\mu(Fe^{3+})\}^2 k_m(Fe^{3+})/k_m(Nd^{3+})$$

where $\mu(Fe^{3+})$ and $\mu(Nd^{3+})$ represent the magnetic monents of the cations. Thus the value of the concentration was estimated to be 0.04% by the evacuation at 250°C and 1.7% by that at 500°C. The former value agrees approximately with the observed iron content (0.019%), while the latter can not be explained from only its existence, even if all the ferric ions are exposed on the surface. Moreover, highly-purified alumina (Fe, Cu, Mg, and Mn$<$1 p. p. m.) which had been carefully prepared by three distillations of aluminum isopropoxide showed no activity in the evacuation at 250°C, but a high activity at 500°C, corresponding to a ferric ion content of 9.5%. Therefore, the first, gradual increase in activity is due to the exposure of paramagnetic impurities caused by dehydration, while the second, aburpt increase implies that "paramagnetic" sites of a different origin are created on the surface of γ-alumina.

Eley et al. have reported that α-alumina evacuated at 550°C has active sites for the H_2–D_2 equilibration and for the magnetic conversion, and also that new thermolabile paramagnetic sites are created by γ-ray irradiation.[16] Therefore, it is conceivable that α- and γ-alumina behave similarly in the catalysis of these reactions.

Further studies of the nature of these sites on γ-alumina are in progress; details will be reported later.

The authors wish to express their thanks to Professor Takao Kwan of the University of Tokyo for his helpful discussions and also to Professor Tadao Shiba of Tokyo Institute of Technology for the generous gift of alumina which made this work possible.

Rearrangements of Tertiary Amine Oxide. XV.[1] The Reaction of Heterocyclic *N*-Oxides with *p*-Nitrobenzenesulfinyl Chloride

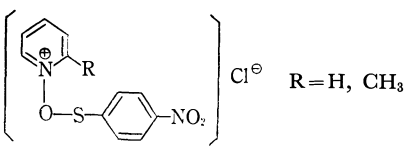
By Shigeru OAE and Katuyata IKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received November 24, 1965)

In the reaction of pyridine and α-picoline *N*-oxide with *p*-nitrobenzenesulfinyl chloride, the N–O bond of the intermediate salt appears to cleave homolytically, as in the case of *N*-oxide with *p*-nitrobenzenesulfenyl chloride, and the *p*-nitrosulfonyl radical which arises from the homolytic cleavage of the N–O bond is considered to be so stable that only the secondary reaction products from the sulfonyl radical, and no heteroring-substituted products, are obtained. It is the same in the case of unsubstituted benzenesulfinyl chloride.

We have reported earlier that, in the reaction of *p*-nitrobenzenesulfenyl chloride with pyridine and α-picoline *N*-oxides, the N-O bond of the incipient salt I was homoliticaly cleaved, giving only reduced pyridine bases, while neither ring-substituted rearrangement products nor unreacted *N*-oxides were obtained.[2]

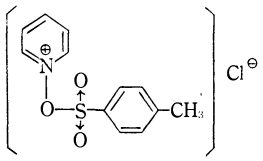


I

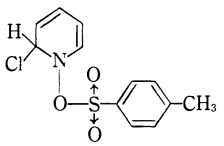
On the other hand, the reactions of pyridine and isoquinoline *N*-oxide with tosyl chloride gave ring-substituted rearrangement products, apparently

1) Part XIV: S. Oae and S. Kozuka, *Tetrahedron*, **21**, 1971 (1965).
2) S. Oae and K. Ikura, This Bulletin, **38**, 58 (1965).

formed through the heterolytic cleavage of the N–O linkage of the intermediate IIA, formed by the nuclear addition of Cl ion to the II salt.[3]



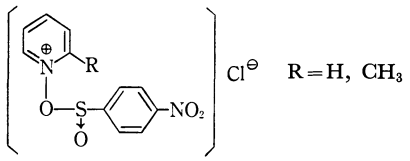
II



IIA

The marked difference between these two reactions may lie in the difference in the reacting organic sulfur chlorides. Namely, the former, *p*-nitrobenzenesulfenyl chloride, is electronically neutral, while the latter has the positive character of the sulfur atom, which would cause a facile heterolytic cleavage of the N–O bond. This may lead to the idea that sulfinyl chlorides, which has a more positive sulfur atom than sulfenyl chlorides and a less positive sulfur atom than sulfonyl chlorides, would give rise to a reaction between the two above reactions.

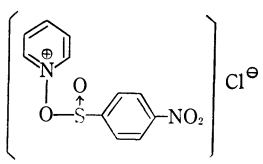
Thus we have investigated the reaction of *p*-nitrobenzenesulfinylchloride with pyridine and α-picoline *N*-oxides, a reaction which involves the incipient formation of the III salt.



III

Results and Discussion

p-Nitrobenzenesulfinyl chloride was prepared by chlorinating *p*, *p*'-dinitrodiphenyldisulfide in glacial acetic acid with chlorine gas, and it was identified by means of the reaction product with acetone, which has the analytical composition of the α-sulfinylacetone. When equivalent amounts of pyridine *N*-oxide and *p*-nitrobenzenesulfinyl chloride were mixed in a benzene solution, colorless crystalline precipitates were formed immediately, with an evolution of heat. The crystals, which are very hygroscopic, have the analytical composition of the salt IV, as is shown below:



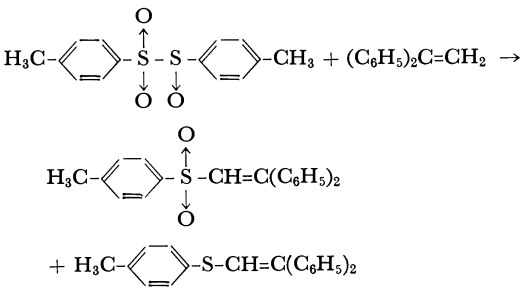
IV

The IV salt was obtained after the thorough removal of the solvent benzene under the vaccum; the salt was then heated at 180—200°C for two hours under a nitrogen stream. It began to melt at around 80°C, but no color change was observed until around 180°C; at around 180°C the salt started to melt, giving a dark, oily mass, and sulfur dioxide was evolved.

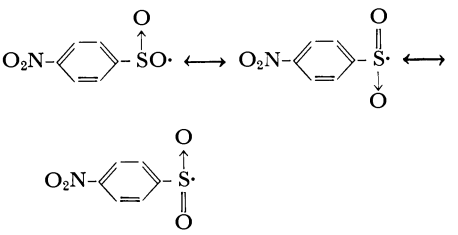
Among the reaction products isolated were pyridine, *p*-nitrochlorobenzene, *p*-nitrobenzenesulfonic acid, and *p*, *p*'-dinitrodiphenyldisulfide.

Neither a ring-substituted rearrangement product nor unreacted pyridine *N*-oxide was isolated among the products. These reaction products and their distributions seem to indicate that this reaction is also initiated by the cleavage of the N–O bond of the IV salt, just as in the case of *N*-oxide with *p*-nitrobenzenesulfenyl chloride, and not like the case of *N*-oxide with tosyl chloride. Here again the sulfonyl radical, V, which was presumed to be formed at first by the cleavage of the N–O bond of the IV salt, is apparently stable.

The existence of this radical was reported previously by Kice[4] and Overberger[5]. Namely, Kice has reported that the thermal decomposition of aromatic sulfinyl sulfonate gives the tolyl sulfonyl radical, which can be trapped with gulvinoxyl. He has also shown that the radical can add to an olefine to give a stable addition product, as is shown below:



This radical stability may be due to the 3d-orbital resonance of the sulfur atom as follows.

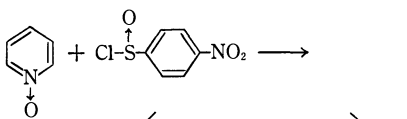


If the reaction would follow a path similar to that of pyridine *N*-oxide with tosyl chloride, one

3) S. Oae, T. Kitao and Y. Kitaoka, *Tetrahedron*, **19**, 827 (1963).
4) J. L. Kice and N. E. Pawlowski, *J. Am. Chem. Soc.*, **86**, 4898 (1964).
5) C. G. Overberger and A. J. Rosenthal, ibid., **82**, 117 (1960).

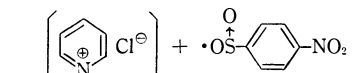
would expect some pyridine ring-substituted compound among the product mixture, for the heterolytically-cleaved species, presumably the nitrobenzene sulfonium ion, is considered to react with the other cleaved partner to give perhaps a very stable sulfonyl product.

In this reaction, however, there was apparently no formation of any heteroring-substituted product, and the yield of the pyridine recovered was nearly quantitative. The entire reaction is quite similar to the reaction with *p*-nitrobenzenesulfenyl chloride. These findings, and the results of the previous work on the thermal decomposition of aromatic sulfinyl sulfonate, seems to favor the homolytic cleavage of the N–O bond of the IV salt. Thus, the overall reaction scheme may be formulated nicely as below:

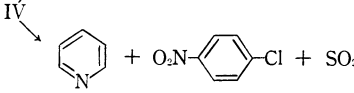


(1)

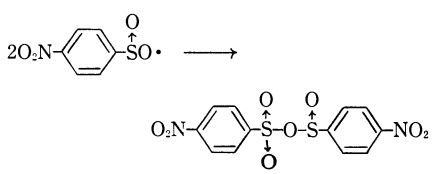
IV



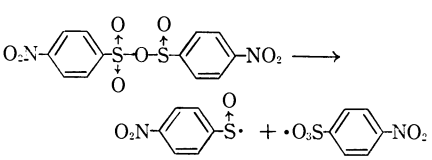
(2)



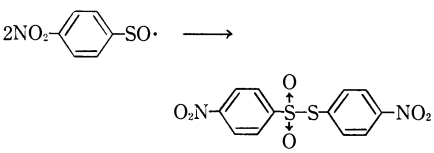
(3)



(4)

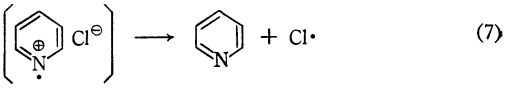


(5)

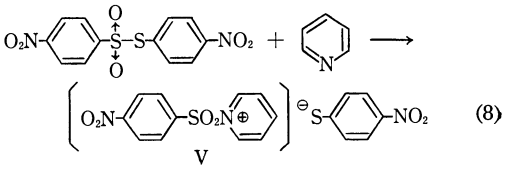


(6)

p-Nitrochlorobenzene was probably formed by step 3. Here again the *p*-nitrochlorobenzene was

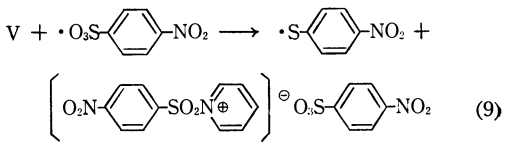


(7)

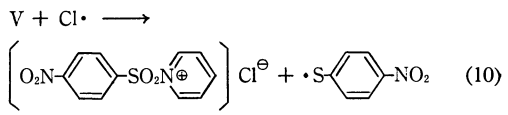


(8)

V

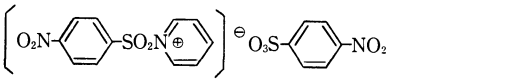


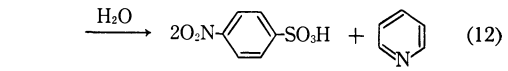
(9)



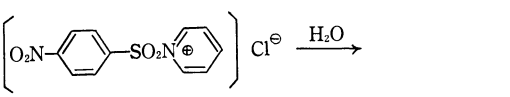
(10)

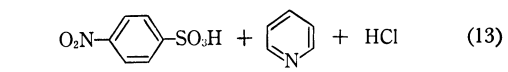
(11)





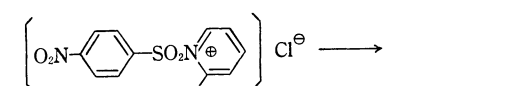
(12)

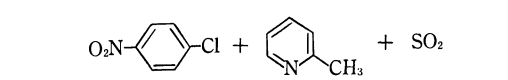




(13)

obtained as in the case of the reaction of *p*-nitrobenzenesulfenyl chloride with α-picoline *N*-oxide, where the formation of *p*-nitrochlorobenzene was considered to proceed through the following pathway:[2]



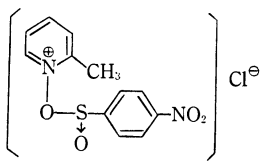


In this reaction the amount of this compound actually isolated was rather large as compared to those of the disulfide and *p*-nitrobenzenesulfonic acid.

About the formation of the radical, (O_2N–  –$SO_3\cdot$) is now yet questionable, but if step

5 is assumed, the reaction products are cleverly explained, and this radical might be occur with the charge transfer with V, as is shown by step 9.

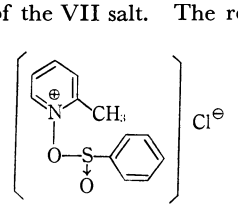
The same reaction was applied to α-picoline N-oxide. In this case, too, equimolar amounts of α-picoline N-oxide and p-nitrobenzenesulfinyl-chloride were mixed in a benzene solution. White crystalline precipitates gradually formed, with an evolution of heat; these precipitates changed to a dark oil during the removal of the solvent. The dark oil was found by analysis to have the composition derived from the VI salt.



VI

This salt was heated at 140—150°C for two hours under a nitrogen stream. The evolution of hydrogen chloride began at around 140°C, and sulfur dioxide gas was also observed during the heating, although the amounts of both gases were small. The reaction products isolated were α-picoline, p,p'-dinitrodiphenyl disulfide, and p-nitrobenzenesulfonic acid. Here again an undetectable amount of any hetero ring-substituted products was obtained among the reaction products in spite of the noticeable amounts of hydrogen chloride evolved. Here, p-nitrochlorobenzene was not obtained. However, the amount of disulfide was larger than in the case of pyridine N-oxide. Judging from these reaction products, therefore, the reaction also seems to proceed via a similar homolytic cleavage of the N–O bond of the VI salt, and the overall reaction scheme may be considered to be quite analogous to the one previously postulated for that with pyridine N-oxide except for step 3.

We have also extended the reaction to unsubstituted benzenesulfinyl chloride with α-picoline N-oxide. When equimolar amounts of α-picoline N-oxide and benzenesulfinyl chloride were mixed in a benzene solution, heat evolved and a dark red oil was gradually precipitated. Apparently the decomposition of the conceivable incipient salt was very facile, and the resultant dark oil was a reacted mixture. However, in this case, it is considered that the reaction proceeds through the formation of the VII salt. The reaction products isolated were α-picoline, diphenyl disulfide, and benzenesulfonic acid.



VII

This reaction was also considered to proceed like the other two reactions.

Experimental

The Preparation of p-Nitrobenzenesulfinyl Chloride.—p,p'-Dinitrodiphenyl disulfide was mixed with exactly twice as much glacial acetic acid in chloroform, and chlorine gas was introduced at −5——10°C until no hydrogen chloride evolution was recognized. Then the chloroform and acetyl chloride formed were thoroughly removed in vacuo at room temperature.

The residue formed cubic crystals. This was used for the succeeding reaction without further purification; m. p. 58—60°C.

Found: N, 7.12. Calcd. for $C_6H_4NO_3SCl$: N, 6.81%.

This chloride was identified by reacting it with acetone at room temperature until its derivatives were produced. The product has the correct analytical composition of the α-sulfinylacetone, O_2N-C$_6$H$_3$(-SO-)-SCH_2COCH_3; m.p. 66—67°C.

Found: C, 47.56; H, 4.02; N, 6.64; S, 14.90. Calcd. for α-sulfinylacetone: C , 47.56; H, 3.99; N, 6.16; S, 14.11%.

The Reaction of Pyridine N-Oxide with p-Nitrobenzenesulfinyl Chloride.—When both a benzenes solution of pyridine N-oxide (1.00 g.) and p-nitrobenzenesulfinyl chloride (2.00 g.) were mixed at room temperature, the white salt, IV, precipitated at once. Then the solvent was removed in vacuo at room temperature, and the residue was heated at around 180—200°C for two hours under a nitrogen stream. The reaction mixture became a dark, oily mass, and sulfur dioxide was evolved. After the reaction, dilute hydrochloric acid was added, and the mixture was extracted with chloroform.

The removal of the solvent chloroform gave p-nitrochlorobenzene (1.10 g.) and p,p'-dinitrodiphenyl disulfide (0.05 g.).

The aqueous layer was made neutral with sodium carbonate and extracted with chloroform. The removal of the solvent gave pyridine (0.6 g.). Then, a 10% ethanol solution of benzylisothiourea hydrochloride salt was added to the aqueous mother solution, from which pyridine had already been recovered, and the crystals thus precipitated was collected and recrystallized from a water-ethanol mixture. These crystals were thiuronium salt of p-nitrobenzenesulfonic acid (0.78 g.).

The sulfur dioxide was trapped by passing it through a solution of barium hydroxide; the quantity of SO_2 was 0.36 g.

The Isolation of 1-p-Nitrobenzenesulfinylpyridinium Salt IV.—The hygroscopic crystalline precipitate obtained by reacting p-nitrobenzenesulfinyl chloride and pyridine N-oxide was washed with ethanol, dried, and analyzed; m. p. 98—100°C.

Found: C, N, 9.62. Calcd. for $C_{11}H_9N_2O_4SCl$: N, 9.32%.

The Reaction of α-Picoline N-Oxide with p-Nitrobenzenesulfinyl Chloride. — α-Picoline N-

oxide (2.0 g.) and *p*-nitrobenzenesulfinyl chloride (4.0 g.) were used. The colorless salt which was gradually precipitated changed to a dark oil during the removal of the solvent. After the solvent had been removed, the dark oil was heated at 140—150°C for two hours under a nitrogen stream. The treatment of the reaction products was exactly the same as in the case of pyridine *N*-oxide.

The product from the chloroform layer was *p*, *p*'-dinitrodiphenyl disulfide (2.1 g.). From the aqueous layer α-picoline (1.3 g.) and *p*-nitrobenzenesulfonic acid (1.6 g.) were obtained.

The Isolation of 1-*p*-Nitrobenzenesulfinyl-2-picolinium Salt VI.—The dark oil precipitate obtained by reacting *p*-nitrobenzenesulfinyl chloride and α-picoline *N*-oxide was washed well with water and recrystallized from a water-ethanol mixture; m. p. 174—177°C.

Found: N, 9.09. Calcd. for $C_{12}H_{11}N_2O_4SCl$: N, 8.90%.

The Reaction of α-Picoline *N*-Oxide with Phenylsulfinyl Chloride.—α-Picoline *N*-oxide (1.5 g.) and phenylsulfinyl chloride (2.1 g.) were reacted as usual in a benzene solution. Apparently the reaction got started immediately, forming no precipitated salt, but a dark red oil was gradually precipitated while the solvent was bing removed with a vigorous reaction. Then the dark oil was heated an additional hour at around 160°C. The treatment of the reaction products was exactly the same as in the above two cases.

The product from the chloroform layer was diphenyl disulfide (1.1 g.). From the aqueous layer, α-picoline (1.0 g.) and benzenesulfonic acid (0.8 g.) were obtained.

All the compounds were identified by mixed melting point, infrared spectra, and elemental analyses.

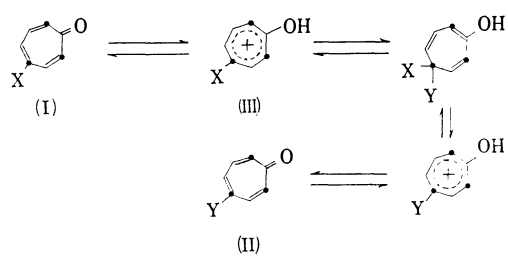
(Received November 24, 1965)

The acid hydrolysis of some polyhalotropones and some reactions of the products were investigated. The treatment of 2, 5-dichlorotropone with hydrochloric or sulfuric acid afforded 2-chloro-5-hydroxytropone (I) and a small amount of 5-chlorotropolone. The compound I gives only one kind of the methyl ether and one kind of the acetyl or benzoyl derivative. From the methyl ether, 5-amino- and 5-methylamino-2-chlorotropone were derived. The methoxyl and the amino groups of these compounds are reactive to alkaline hydrolysis, giving I without any of the skeletal rearrangement usually observed in the alkaline treatment of similar 2-halotropones. The hydrolysis of 2, 4, 7-tribromotropone with hydrochloric acid gave 3, 6-dichlorotropolone and 7-chloro-4-hydroxytropolone.

It is known[1] that 2-halotropones react with alkalis to give benzoic acid derivatives mainly, besides a small amount of tropolones, and that polyhalotropones, under similar treatment, afford benzoic acid and salicylaldehyde derivatives, in addition to considerable amounts of tropolones in some cases.

However, on being heated with strong acids, halotropones, (for example, I; X=halogen), are converted into a conjugated acid cation (III), whose hydrolysis yields hydroxytropone (II; Y=OH) without any rearrangement to benzenoid compounds. When hydrogen halides are used



in this reaction, the exchange of the halogen atom often occurs and a different halotropone (II; Y=halogen) may be obtained besides the products of hydrolysis.[1] Apparently, in the acid treatment of halotropones, halogen atoms located at the 3- or 4-position undergo such reactions easier than those at the 2-position. This is probably due not only to steric interference but also to facile anionoid attack at positions β or δ to the conjugated unsaturated ketone.

*1 Presented at the 14th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1961.

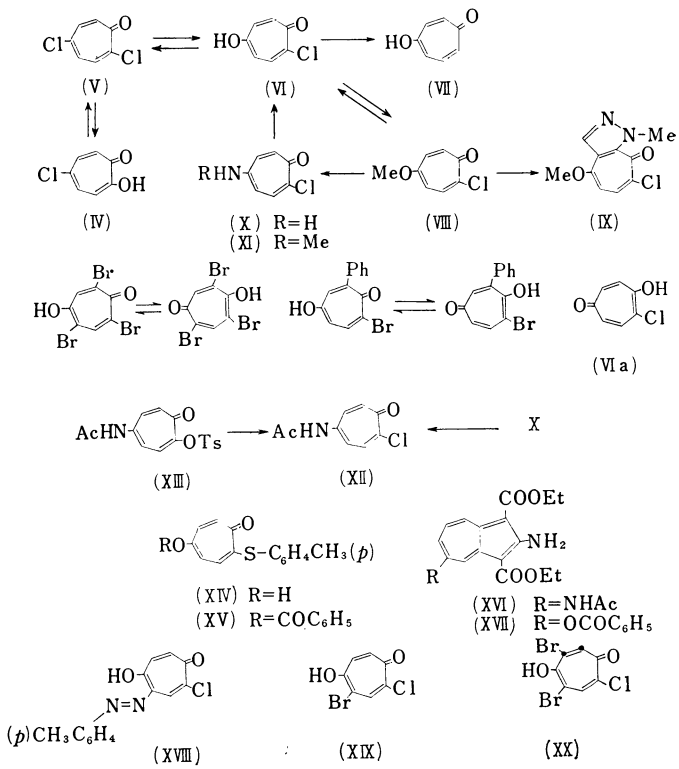
1) T. Nozoe, "Non-Benzenoid Aromatic Compounds," Ed. by D. Ginsburg, Interscience Publishers, New York (1959), p. 410; T. Nozoe et al., "Dai Yuki Kagaku (Comprehensive Organic Chemistry)," Vol. 13, Asakura-Shoten, Tokyo (1960), pp. 181, 217.



For instance, the conversion[2] of 4-bromotropone into 4-hydroxy- or 4-chlorotropone, when it was heated with hydrochloric acid in acetic acid, occured more easily than the conversion of 2-bromotropone into 2-chloro- or 2-hydroxytropone under the same conditions. 3-Bromo-2-chlorotropone gave 2-chloro-3-hydroxytropone and 2, 3-dichlorotropone by a similar treatment, but it did not afford any 3-chlorotropolone.[3] On being heated with concentrated sulfuric acid, 2, 4, 7-tribromotropone[4] and 2-phenyl-4, 5, 7-tribromotropone[5] yielded 4-hydroxy-2, 5, 7-tribromotropone and 5, 7-dibromo-4-hydroxy-2-phenyltropone respectively. The former compound must have been produced by the bromination of 2, 7-dibromo-4-hydroxytropone with bromine that had been generated from the sulfuric acid oxidation of the hydrobromic acid liberated by the initial hydrolysis of 2, 4, 7-tribromotropone.*3

This paper is one of a series devoted to an investigation of the order of relative ease with which halotropones undergo hydrolysis or halogen exchange, and to the utilization of such results in the preparation of 3- or 4-hydroxytropones, whose syntheses have otherwise been difficult. For the present paper, the acid hydrolysis of 2, 5-dichlorotropone and 2, 4, 7-tribromotropone has been investigated, and some reactions of the products have been studied.

2, 5-Dichlorotropone (V),[6] obtained by the reaction of 5-chlorotropolone (IV) and thionyl chloride, on being heated with concentrated hydrochloric acid or concentrated sulfuric acid in acetic acid afforded a considerable amount of pale yellow crystals (VI), m. p. 218°C, and a small amount of 5-chlorotropolone (IV).

The compound VI is acidic and shows a pale green coloration with ferric chloride, but with ferric or cupric ion it does not form a chelate complex which is soluble in chloroform, as is the case with tropolone.

The infrared absorption spectrum of VI in KBr shows OH bands at 3020, 2660 and 2550 cm^{-1} which are assumed to be due to intermolecular hydrogen bonding similar to that found with 4-hydroxytropone.[7,8] The ultraviolet absorption spectrum (Fig. 1) of VI exhibits maxima.

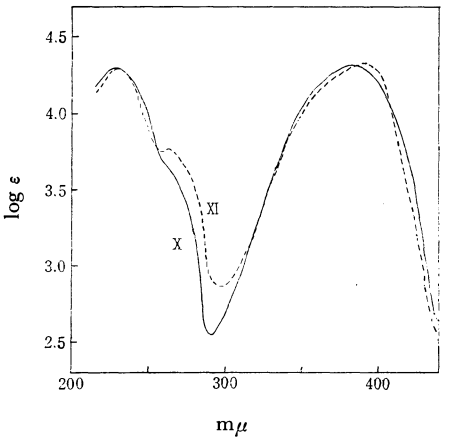

Fig. 2. Ultraviolet absorption spectra of X and XI in methanol.

at wavelengths similar to those observed in the spectrum of 2-bromo-5-hydroxytropone.[7] In addition to the abvoe spectroscopic evidence, VI affords 4-hydroxytropone (VII)[2a,7] on catalytic hydrogenation; therefore, it must be 2-chloro-5-hydroxytropone.

Nozoe et al.[9] and Muroi[10] have reported that a tautomeric relationship exists between 4-hydroxy-2, 5, 7-tribromotropone and 5-hydroxy-2, 4, 6-tribromotropone, and between 5, 7-dibromo-4-hydroxy-2-phenyltropone and 2, 4-dibromo-5-hydroxy-6-phenyltropone, and that in each case the tautomers gave different methyl ethers when allowed to react with diazomethane.

It was thought that VI might also exist as an equilibrium mixture of 2-chloro-5-hydroxytropone and 4-chloro-5-hydroxytropone (VIa); however, the treatment of VI with thionyl chloride afforded only 2, 5-dichlorotropone, and no isomeric 4, 5-dichlorotropone was obtained. Furthermore, compound VI yielded only one acetate, one benzoate and one tosylate, and with diazomethane it afforded only one methyl ether (VIII), besides a nitrogen-containing compound (IX).

Since Nozoe et al.[11] have found that the reaction of halotropones or 4-hydroxytropone with diazomethane gives pyrazolotropone (1-methyl-8-oxocyclohepta[d]pyrazole) derivatives, and since IX was also obtained by the action of diazomethane on the methyl ether (VIII), IX must be the pyrazolotropone derivative, as is shown in the scheme.

The methoxy compound (VIII) was easily hydrolyzed by alkali to give VI. VIII reacts with ammonia and methylamine to afford amino and methylamino compounds (X and XI) respectively; these compounds, on alkaline hydrolysis, yield VI, a reaction similar to the hydrolysis of 2-aminotropone. The ultraviolet absorption spectrum of amino compounds (Fig. 2) are quite different from that of 2-aminotropone,[12] but they are similar to that of 4-aminotropone.[13] The Acetylation of X afforded 5-acetamido-2-chloro tropone (XII), which was also obtained by the action[14] of hydrochloric acid on 5-acetamido-2-tosyloxytropone (XIII); therefore, it is clear that VIII and X are 2-chloro-5-methoxy- and 5-amino-2-chlorotropone respectively.

It is known that 5-methoxy-2, 4, 7-tribromotropone,[4] 2, 4-dibromo-5-methoxytropone[15] and 7-bromo-4-methoxy-2-phenyltropone[10] give only the corresponding rearranged compounds, i. e., anisic acid derivatives, upon treatment with alkali or alkoxide, but not the products of a simple hydrolysis, i. e., 4-hydroxytropone derivatives. In contrast to the above, it is noteworthy that the alkaline treatment of the methoxy compound (VIII) afforded only hydroxytropone (VI).

As has been mentioned above, the methoxyl group of VIII underwent anionoid substitution reaction; however, the reaction of *p*-tolylthiophenol with 2-chloro-5-hydroxytropone (VI) or its benzoyl derivative yielded 2-(*p*-tolylthio)tropone derivatives (XIV or XV respectively). 5-Acetamido-2-chlorotropone (XII) and the benzoyl derivative of VI reacted with ethyl cyanoacetate, in the same way as do 2-chlorotropones, to give 5-acetamido-[16] and 5-benzoyloxyazulene derivatives (XVI and XVII respectively).

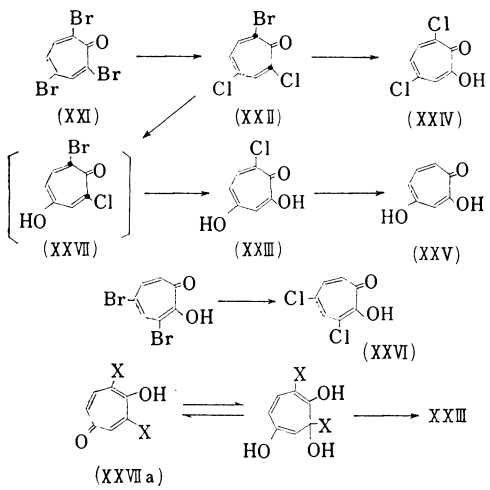
With diazotized *p*-toluidine, 2-chloro-5-hydroxytropone (VI) reacted, similarly to 4-hydroxytropone, to give the azo compound (XVIII), The bromination of VI yielded 4-bromo-2-chloro-5-hydroxytropone (XIX) and 4, 6(or 4, 7)-dibromo-2-chloro-5-hydroxytropone (XX). The structures of these compounds were assumed to be as above from the reactivity of 4-hydroxytropone[2a]; however, the position of the second bromine atom in XX was not clarified.

When 2, 4, 7-tribromotropone (XXI) was heated with hydrochloric acid in acetic acid at 100°C for one hour, it gave dichloromonobromotropone (XXII), whereas the same solution, on being heated at 135°C for 10 hr., afforded 70% of chlorodihydroxytropone (XXIII) and 10% of dichlorohydroxytropone (XXIV). The compounds XXIII and XXIV were also obtained by a similar acid treatment of XXII. The dihydroxytropone (XXIII) was identified as 7-chloro-4-hydroxytropolone since, on hydrogenolysis, it



gave 4-hydroxytropolone (XXV).[17] Compound XXIV was not identical with 3, 5-dichlorotropolone (XXVI), obtained by the anionoid substitution of 3, 5-dibromotropolone[18] with hydrochloric acid; therefore, it must be 3, 6-dichlorotropolone.

During the treatment of polyhalotropones with acids, the halogen at the γ-position (C_4) undergoes anionoid substitution more easily than that at the α-position (C_2 or C_7); therefore, XXII is assumed to be 7-bromo-2, 4-dichloro- or 2-bromo-4, 7-dichlorotropone.

As has been shown above, the vigorous treatment of XXI or XXII with hydrochloric acid caused the hydrolysis of the halogens at the 2- and 4-positions, but not at the 7-position. This may indicate that the 2- and 4-positions, in both XXI and XXII, are more reactive than the 7-position.

It is considered that XXII undergoes a competitive hydrolysis of the halogen at the 2- and 4-positions to give XXIV and XXVII, and that there is no further hydrolysis of XXIV under these reaction conditions, whereas the further hydrolysis of XXVII proceeds through its tautomeric form (XXXVIIa) to yield XXIII.

Further investigations are being undertaken to clarify the above reaction path, and to study the reactivity of the 4-hydroxy- and 2, 4-dihydroxytropones which were obtained in this work.

Experimental*4

The Treatment of 2, 5-Dichlorotropone (V) with Hydrochloric Acid.—a) A solution of 2, 5-dichlorotropone (2 g.) in acetic acid (15 ml.) containing water (0.1 ml.) was saturated with hydrogen chloride gas; the solution was then kept at 110°C for 10 hr. in a sealed tube. The solvent was removed, and the residue was extracted with benzene. The insoluble part (1.65 g.) was recrystallized from ethanol to give 2-chloro-5-hydroxytropone (VI) as yellow needles, m. p. 217—218°C.

Found: C, 53.69; H, 3.16. Calcd. for $C_7H_5O_2Cl$: C, 53.69; H, 3.20%.

λ_{max}^{MeOH} mμ (log ε): 220(4.27), 350(4.14).

$\lambda_{max}^{0.1N\ NaOH}$ mμ (log ε): 228(4.33), 260^{sh} (3.52), 381-(4.37).

From the benzene-soluble part, 5-chlorotropolone (IV) (200 mg.) was obtained after being recrystallized from methanol.

b) After a solution of 2, 5-dichlorotropone (3 g.) in acetic acid (27 ml.) and concentrated hydrochloric acid (15 ml.) in a sealed tube had been allowed to stand at 100°C for 10 hr., the solvent was evaporated. By treating the residue described above, 2.2 g. of VI and 300 mg. of IV were obtained.

The Treatment of 2, 4, 7-Tribromotropone (XXI) with Hydrochloric Acid.—a) A solution of 2, 4, 7-tribromotropone (500 mg.) in acetic acid (10 ml.) saturated with hydrochloric acid gas was kept in a sealed tube at 100°C for 10 hr. The colorless needles precipitated out by cooling the solution in an ice box were recrystallized from cyclohexane, yielding colorless needles (XXII), m. p. 149—150°C.

Found: C, 32.70; H, 1.25. Calcd. for $C_7H_3OBrCl_2$: C, 32.12; H, 1.91%.

b) A solution of XXI (500 mg.) in a mixture of acetic acid (4 ml.) and concentrated hydrochloric acid (3 ml.) was kept in a sealed tube at 135—140°C for 10 hr. The residue which was obtained by removing the solvent was dissolved in water and extracted with benzene and then with ethyl acetate. The yellow powder obtained from the extract with ethyl acetate was washed with benzene, and the insoluble part (130 mg.) was recrystallized from dilute ethanol giving yellow long prisms, 3-chloro-6-hydroxytropolone

*4 All melting points are uncorrected.

(XXIII), m. p. 242°C.

Found: C, 48.71; H, 3.13. Calcd. for $C_7H_5O_3Cl$: C, 48.72; H, 2.92%.

λ_{max}^{MeOH} mμ (log ε): 255(4.47), 340(3.81), 367(3.93).

The residue obtained by removing the solvent from the benzene extract was recrystallized from cyclohexane affording crystals of 3, 6-dichlorotropolone (XXIV), m. p. 129—130°C.

Found: C, 44.26; H, 2.36. Calcd. for $C_7H_4O_2Cl_2$: C, 44.02; H, 2.11%.

λ_{max}^{MeOH} mμ (log ε): 252(4.39), 336(3.98), 377(3.75), 388(3.75), 397^{sh}(3.68), 428(3.31).

The Treatment of XXII with Hydrochloric Acid.—A solution of XXII (500 mg.) in acetic acid (5 ml.) and concentrated hydrochloric acid (3 ml.) was heated around 140°C for 10 hr. in a sealed tube. The solvents were removed under reduced pressure, and the residue was separated into a soluble part (260 mg.) and an insoluble part in benzene. The former was sublimed under reduced pressure to give 114 mg. of sublimate, which was then recrystallized from dilute ethanol to give XXIII, m. p. 240—242°C. The insoluble part in benzene was sublimed in vacuo to afford 30 mg. of the sublimate, which was then recrystallized from methanol, giving XXIV, m. p. 129—130°C. The infrared spectra of both of the compounds were superimposable upon those of XXIII and XXIV respectively, which had been obtained before.

The Reduction of 7-Chloro-4-hydroxytropolone (XXIII).—A solution of XXIII (50 mg.) and sodium acetate (25 mg.) in ethanol (6 ml.) was submitted to catalytic hydrogenation in the presence of 5% Pd-C (20 mg.); 9 ml. of hydrogen was thus absorbed. The residue obtained by removing the solvent was sublimed in vacuo, yielding yellow crystals, m. p. 191—194°C. Recrystallization from acetic acid gave yellow crystals (10 mg.), m. p. 221—223°C, these crystals showed no depression of melting point on admixture with 4-hydroxytropolone (XXV), m. p. 225—226°C, obtained by the alkaline hydrolysis of 3-bromotropolone.[9]

3, 5-Dichlorotropolone. — A solution of 3, 5-dibromotropolone (100 mg.) in acetic acid (4 ml.) and concentrated hydrochloric acid (3 ml.) was refluxed for 10 hr. The solvent was removed, and the residue was recrystallized from benzene-cyclohexane, affording micro needles of 3, 5-dichlorotropolone (XXVI), m. p. 138—139°C.

Found: C, 44.00; H, 2.50. Calcd. for $C_7H_4O_2Cl_2$: C, 44.02; H, 2.11%.

The Reduction of 2-Chloro-5-hydroxytropone (VI).—A solution of VI (100 mg.) and sodium acetate (55 mg.) in methanol (9 ml.) was submitted to catalytic hydrogenation using 5% Pd-C (40 mg.) as a catalyst; 13 ml. of hydrogen was thus absorbed. The removal of the solvent left yellow crystals, which were then sublimed under reduced pressure. The recrystallization of the sublimate from methanol afforded yellow needles (50 mg.), m. p. 210°C (decomp.), which showed no depression of melting point on admixture with authentic 4-hydroxytropone (VII).

5-Acetoxy-2-chlorotropone.—After a solution of 2-chloro-5-hydroxytropone (100 mg.) and acetic anhydride (3 ml.) had been heated at 110°C for one hour, the solution was poured onto ice and extracted with benzene; the extract was dried over sodium sulfate, and the solvent was removed. The residue was recrystallized from cyclohexane, giving 5-acetoxy-2-chlorotropone (80 mg.) as colorless needles, m. p. 101.5—102°C.

Found: C, 54.81; H, 3.34. Calcd. for $C_9H_7O_3Cl$: C, 54.42; H, 3.55%.

5-Benzoyloxy-2-chlorotropone.—To a solution of 2-chloro-5-hydroxytropone (500 mg.) in pyridine (4 ml.), benzoyl chloride (450 mg.) was added, the mixture was then poured onto ice. The crystals (800 mg.) which precipitated out were recrystallized from ethanol to afford 5-benzoyloxy-2-chlorotropone (650 mg.) as colorless needles, m. p. 153—154°C.

Found: C, 64.48; H, 3.31. Calcd. for $C_{14}H_9O_3Cl$: C, 64.50; H, 3.48%.

2-Chloro-5-tosyloxytropone.—To a solution of 2-chloro-5-hydroxytropone (600 mg.) in pyridine (6 ml.), *p*-toluenesulfonyl chloride (740 mg.) was added. After having been allowed to stand at room temperature for 20 min., the solution was poured onto ice to give colorless crystals (680 mg.), m. p. 110—115°C. Recrystallization from ethanol afforded 2-chloro-5-tosyloxytropone (600 mg.) as colorless needles, m. p. 119—120°C.

Found: C, 54.46; H, 3.30. Calcd. for $C_{14}H_{11}O_4SCl$: C, 54.11; H, 3.57%.

The Reaction of VI with Thionyl Chloride.—By gentle refluxing the suspended mixture of VI (100 mg.) in thionyl chloride (2 ml.), VI was gradually dissolved. After 30 min., the excess thionyl chloride was removed in vacuo; the residue was extracted with benzene, and the extract was washed with water and dried. The crystals which were obtained after passing the benzene solution through an alumina column were sublimed and then recrystallized from cyclohexane, yielding pale yellow needles (65 mg.). This crystals showed no depression of melting point on admixture with 2, 5-dichlorotropone.

The Methylation of VI with Diazomethane.—To a suspension of VI (2 g.) in ether (30 ml.), an ethereal solution of diazomethane prepared from *N*-nitrosomethylurea (2 g.) was added; the mixture was then allowed to stand in an ice box for 50 hr. The starting material (700 mg.) was recovered as an insoluble part by filtration, the solvent was removed from the filtrate in vacuo, and the residue was dissolved in ether and passed through an alumina column. From the rapidly-eluted fraction by ether, crystals (1.1 g.), m. p. 85—90°C, were obtained, and recrystallization from cyclohexane afforded colorless plates, m. p. 91—92°C, of 2-chloro-5-methoxytropone (VIII).

Found: C, 56.42; H, 3.99. Calcd. for $C_8H_7O_2Cl$: C, 56.34; H, 4.04%.

λ_{max}^{MeOH} mμ (log ε): 225(4.25), 338(4.13).

From the latter fraction of elution, crystals (50 mg.), m. p. 190—193°C, were obtained. Recrystallization from ethanol gave colorless needles (IX), m. p. 195—196°C.

Found: C, 53.80; H, 3.84; N, 12.24. Calcd. for $C_{10}H_9O_2N_2Cl$: C, 53.47; H, 4.04; N, 12.48%.

5-Hydroxy-2-(*p*-tolylthio)tropone (XIV).—A solution of VI (156 mg.), *p*-thiocresol (152 mg.) and sodium hydroxide (45 mg.) in ethanol (20 ml.) was refluxed for 30 min. A small amount of the precipitate was removed, and the filtrate was evaporated, leaving a yellow solid, which was then washed with water and

recrystallized from methanol, yielding 95 mg. of yellow micro prisms (XIV), m. p. 231—232°C (decomp.).

Found: C, 68.76; H, 4.72. Calcd. for $C_{14}H_{12}O_2S$: C, 68.84; H, 4.95%.

5-Benzoyloxy-2-(*p*-tolylthio)tropone (XV). — A solution of 5-benzoyloxy-2-chlorotropone (245 mg.), *p*-thiocresol (152 mg.) and sodium hydroxide (45 mg.) in ethanol (20 ml.) was refluxed for 10 hr. The solvent was removed, and the residue was dissolved in water, extracted with benzene, and dried. The crystals obtained by removing the benzene were recrystallized from methanol; 150 mg. of greenish yellow plates (XV), m. p. 159—160°C, were thus obtained.

Found: C, 72.59; H, 4.57. Calcd. for $C_{21}H_{16}O_3S$: C, 72.40; H, 4.63%.

5-Amino-2-chlorotropone (X).—a) A solution of 2-chloro-5-methoxytropone (VIII) (100 mg.) in ethanol (20 ml.) saturated with ammonia was allowed to stand at room temperature for 3 days. The removal of the solvent afforded crystals (90 mg.), m. p. 187—190°C, which were then recrystallized from methanol, giving 5-amino-2-chlorotropone (X) as yellow needles, m. p. 204—205°C.

Found: C, 53.75; H, 3.85; N, 9.21. Calcd. for C_7H_6ONCl: C, 54.04; H, 3.89; N, 9.00%.

λ_{max}^{MeOH} mμ (log ε): 230(4.28), 260^{sh}(3.67), 383(4.32).

b) After a mixture of VIII (200 mg.) and liquid ammonia (5 ml.) had been kept at room temperature overnight, the excess ammonia was removed. The residue was dissolved in chloroform, passed through an alumina column, and recrystallization from methanol gave yellow needles (80 mg), m. p. 203—204°C, which showed no depression of melting point on admixture with 5-amino-2-chlorotropone obtained in procedure a).

2-Chloro-5-methylaminotropone (XI). — A solution of VIII (130 mg.) and a 28% aqueous solution of methylamine (0.2 ml.) in methanol (3 ml.) was kept at room temperature for 4 days. The solvent was removed, and the residue was recrystallized from ethanol-ether, giving 2-chloro-5-methylaminotropone (80 mg.) as yellow plates, m. p. 148—149°C.

Found: C, 56.98; H, 4.79; N, 8.20. Calcd. for C_8H_8ONCl: C, 56.65; H, 4.77; N, 8.26%.

λ_{max}^{MeOH} mμ (log ε): 230(4.29), 365(3.75), 390(4.32).

5-Acetamido-2-chlorotropone (XII).—a) After a solution of X (50 mg.) in acetic anhydride (0.5 ml.) had been refluxed for 10 min., the acetic anhydride was removed; the recrystallization of the residue from ethanol afforded XII (50 mg.) as colorless needles, m. p. 210—212°C.

Found: C, 54.56; H, 4.03; N, 7.09. Calcd. for $C_9H_8O_2NCl$: C, 54.70; H, 4.03; N, 7.09%.

λ_{max}^{MeOH} mμ (log ε): 223(4.23); 248(4.15), 269^{sh}(3.91), 350(4.17), 370^{sh}(4.06).

b) After a suspension of 5-acetamido-2-tosyloxytropone (220 mg.) in dioxane (10 ml.) had been saturated with dry hydrogen chloride gas, it was warmed at 80°C for 5 min. The tosyloxytropone had disappeared; it was replaced by colorless crystals. After the reaction mixture had been cooled in an ice box for 2 hr., the precipitate was filtered, affording colorless crystals (120 mg.), which were then recrystallized from ethanol to gave colorless needles, m. p. 210—212°C; these needles showed no depression of melting point on admixture with the sample obtained in procedure a).

5-Acetamido-2-tosyloxytropone (XIII).—To a solution of 5-acetamidotropolone (550 mg.) in pyridine (2.5 ml.), *p*-toluenesulfonyl chloride (1 g.) was added, and the mixture was heated at 80°C for one hour. Water (50 ml.) was added, and the precipitate was filtered, washed with water, and recrystallized from ethanol to give 1.1 g. of XIII as pale yellow micro plates, m. p. 177—178°C.

Found: C, 57.26; H, 4.65; N, 3.90. Calcd. for $C_{16}H_{15}O_5NS$: C, 57.66; H, 4.54; N, 4.20.

λ_{max}^{MeOH} mμ (log ε): 228(4.42), 262^{sh}(4.03), 344(4.16).

Diethyl 2-Amino-5-acetamidoazulene-1, 3-dicarboxylate (XVI).—To a solution of ethyl cyanoacetate (180 mg.) in a sodium ethoxide solution prepared from ethanol (10 ml.) and sodium (20 mg.), XII (140 mg.) was added; the mixture was then kept at room temperature for 3 days. The solvent was removed in vacuo, water was added, and the insoluble part was recrystallized from ethanol, giving yellow crystals (110 mg.), m. p. 178—180°C. This was identified as diethyl 2-amino-5-acetamidoazulene-1, 3-dicarboxylate[16] by a mixed melting point determination and by a comparison of their infrared spectra.

Diethyl 2-Amino-5-benzoyloxyazulene-1, 3-dicarboxylate (XVII).—To a solution of sodium ethoxide prepared from 70 mg. of sodium in anhydrous ethanol (20 ml.), ethyl cyanoacetate (560 mg.) and 5-benzoyloxy-2-chlorotropone (520 mg.) were added. After the mixture had been kept at room temperature for a day, the solvent was removed, water was added, and the solution was extracted with chloroform and then dried. The extract was passed through an alumina column, and 100 mg. of yellow crystals, m. p. 124—127°C, were obtained. Recrystallization from ether gave yellow crystals (XVII), m. p. 129—130°C.

Found: C, 67.65; H, 5.19; N, 2.91. Calcd. for $C_{23}H_{21}O_6N$: C, 67.80; H, 5.20; N, 3.44%.

λ_{max}^{MeOH} mμ (log ε): 245(4.66), 317(4.78), 327(4.88), 370(3.94), 390(3.96), 450(3.44).

When the original water layer was acidified with 2 N sulfuric acid, 180 mg. of a precipitate was obtained. This precipitate was dissolved in methanol and treated with charcoal; yellow crystals, m. p. over 300°C, were thus obtained. The structure of these crystals was not determined.

2-Chloro-5-hydroxy-4-(*p*-tolylazo)tropone (XVIII). — To a stirred solution of VI (156 mg.) and potassium hydroxide (80 mg.) in water (3 ml.), diazotized *p*-toluidine prepared from 118 mg. of *p*-toluidine was added drop by drop. The precipitate was filtered and washed with water, giving 250 mg. of a reddish solid. Recrystallization from benzene-cyclohexane afforded deep red micro needles (XVIII), m. p. 176—177°C.

Found: C, 61.56; H, 3.65; N, 10.45. Calcd. for $C_{14}H_{11}O_2N_2Cl$: C, 61.20; H, 4.04; N, 10.21%.

The Bromination of 2-Chloro-5-hydroxytropone. —To a stirred solution of VI (312 mg.) in acetic acid (8 ml.), bromine (700 mg.) in acetic acid (1 ml.) was added drop by drop at room temperature. The reaction mixture was then allowed to stand overnight, giving 320 mg. of a precipitate. The recrystallization of the precipitate from dilute ethanol afforded pale yellow needles of 2-bromo-4-chloro-5-hydroxytropone (XIX), m. p. 178—179°C.

Found: C, 35.27; H, 2.20; Calcd. for $C_7H_4O_2ClBr$: C, 35.70; H, 1.64%.

The filtrate obtained from the original reaction mixture was evaporated, and the residue was extracted with ethyl acetate. Crystals obtained from the extract were recrystallized from dilute ethanol, affording pale yellow crystals (XX), m. p. 211—212°C.

Found: C, 28.07; H, 1.63. Calcd. for $C_7H_3O_2ClBr_2$: C, 26.72; H, 0.96%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1316—1322 (1966)

The Crystal and Molecular Structure of the Dehydrated Tetramer of 1, 2-Dimethyldisilanetetraol, $(CH_3)_8Si_8O_8$

By Taiichi HIGUCHI and Akira SHIMADA

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received November 30, 1965)

The crystal and molecular structure of $(CH_3)_8Si_8O_8$ has been determined by means of the Patterson projections and refined by the two-dimensional Fourier technique and the least-squares method. The space group is $P4/nnc$, with four molecules per unit cell. The unit cell constants are $a=11.73\pm0.02$ Å, and $c=17.17\pm0.02$ Å. The skeleton of a molecule consists of two "crown-shaped" $(-Si-O-)_4$ rings which are crystallographically independent of each other and are connected by four Si–Si bonds along the c axis. The four six-membered $(-Si-Si-O-)_2$ rings thus formed have boat forms. Hence, a molecule forms a cage-like conformation with an approximate symmetry of $4/mmm$. Each molecule in the unit cell is surrounded by four adjacent molecules related with centers of symmetry; these molecules form, in a sense, a layer perpendicular to the c axis.

In structural investigations of cyclic organosilicon compounds, some interesting characteristics have been elucidated.[1-8] Thus, several types of rings have been reported to exist in those compounds containing Si–O, Si–Si, or Si–N bonds. Planar conformations are found in $(-Si-O-)_3$ and $(-Si-N-)_2$ skeletons,[3,7] and the $(-Si-Si-O-)_2$ ring has a chair form close to a plane.[6] As for an eight-membered ring system, the $(Si-O-)_4$ skeleton exists either in a puckered ring of a $\bar{1}$ symmetry[4] or in a "crown-shaped" ring,[5] while $(-Si-N-)_4$ skeletons have "chair" and "cradle" forms.[8] In view of the strain associated with these ring conformations, the valence angle of the oxygen or nitrogen atom with two silicon atoms shows a wide range of variation; the former bond angle especially is reported to be larger than the corresponding angle in common organic compounds.

The dehydrated tetramer of 1, 2-dimethyldisilanetetraol, $(CH_3)_8Si_8O_8$ (I), herein reported on, was isolated by Kumada[9] from acid hydrolyzates of 1, 1, 2, 2-tetraethoxydimethyldisilane, $(C_2H_5O)_2$-$CH_3SiSiCH_3(OC_2H_5)_2$. Purely chemical studies had suggested that this new compound has a cage-like configuration, as is shown in Fig. 1. This

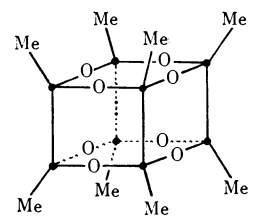

Fig. 1. Dehydrated tetramer of 1,2-dimethyldisilanetetraol, $(CH_3)_8Si_8O_8$.
Me: CH_3, ●: Si.

configuration may be considered to consist of two eight-membered $(-Si-O-)_4$ rings and four six-membered $(-Si-Si-O-)_2$ rings. In this respect, this molecule may be closely related to bistetramethyldisilanylenedioxide, $((CH_3)_4Si_2O)_2$,[6] and octa-(methylsilsesquioxane), $(CH_3SiO_{1.5})_8$ (III),[5] the molecular structures of which have already been established, by X-ray analyses, to be shown in Figs. 2(a) and (b).

The present X-ray work was undertaken to confirm this molecular configuration, with the

hope that such information will contribute to the structural chemistry of organosilicon compounds in connection with the various problems mentioned above. The structural information regarding the silicon-oxygen configuration obtained by this work will also be useful in discussing the course of polymerization reactions and the conditions under which linear polymers can be terminated by ring formation.[10]

Experimental

The specimens were kindly prepared and supplied by Professor Makoto Kumada of Kyoto University.[9] They are soluble in most organic solvents and are recrystallized several times from the solution in chloroform. The crystals thus obtained were colorless cubes. They were decomposed so quickly because of the moisture that they were sealed into thin-walled glass capillary tubes.

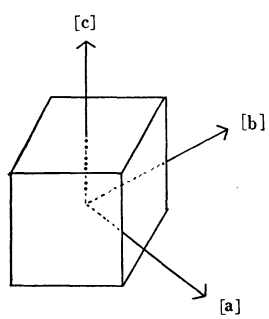

Fig. 3. The relation of principal axes to the crystal form.

Oscillation and Weissenberg photographs were taken with Cu$K\alpha$ radiation. These photographs indicate that the crystal has the Laue symmetry, $4/mmm$, and that the unit cell dimensions are $a=11.73\pm0.02$ Å and $c=17.17\pm0.02$ Å. The relation of principal axes to the crystal form is shown in Fig. 3.

There are four molecules per unit cell. The physical constants are found to be as follows: m. p. 320°C, mol. wt.=473.0, $D_{obs}=1.30$ g. cm^{-3}, and $D_{calcd}=1.33$g. cm^{-3}. The following types of reflections were systematically absent: $(hk0)$ with $h+k$ odd, $(h0l)$ with $h+l$ odd, and (hhl) with l odd. The corresponding space group is $P4/nnc$. The time of exposure was limited because of the decomposition of crystals, and it was very difficult to obtain three-dimensional intensity data. The equatorial and 1st-layer Weissenberg photographs around the b- and c-axes were taken by the multiple-film technique. The relative intensities of the reflections were measured by a visual comparison with calibrated intensity strips. The usual Lorentz and polarization corrections were applied to the measured intensities. No correction was made for absorption (the linear absorption coefficient for Cu$K\alpha$ radiation, $\mu=46.5$ cm^{-1}). The observed structure factors were brought to an absolute scale, primarily by means of Wilson's method.[11]

Structure Determination

Since the unit cell contains four molecules, the centers of the four molecules in each unit cell are located at fourfold positions; three sets of these positions are listed for the $P4/nnc$ space group, with reference to the origin at $\bar{1}$, in the *International Tables for X-ray Crystallography*. Positions $4(c)$ and $4(d)$ seem to be unwise choices, since they require that the centers of adjacent molecules be separated by half a length of the c axis, but no trains of peaks perpendicular to the c axis exist near at $U=0$ and $W=1/2$ of the Patterson map $P(UW)$. The $4(e)$ position, on the other hand, is suitable for the packing of molecules and it seems to explain the Patterson peaks; therefore, it was chosen for the center of a molecule. In this position the center of a molecule lies at the fourfold axis. The asymmetric unit consists of a quarter of one molecule, namely, two silicon atoms, two oxygen atoms and two methyl groups. Hence, eighteen parameters must be determined in this analysis, hydrogen atoms not being considered.

The first clue to the structure determination was obtained from the Patterson function, $P(UV)$, onto the (001) plane, which showed interatomic vectors between oxygen and silicon atoms as well as between silicon atoms. These vector peaks were easily interpreted with the aid of the fact that the molecule has a fourfold symmetry with conventional bond distances. These approximate positions of the $(-Si-O-)_8$ skeleton gave a fairly

good agreement between calculated and observed structure factors.

The electron-density projection along c axis was then synthesized. It revealed the positions of four sets of silicon and oxygen atoms which are related by a fourfold axis and form squares respectively. Two methyl groups could also be found in the second electron-density projection. However, the heavy overlapping of all silicon and oxygen atoms prevented us from proceeding with a further refinement of this projection. A Patterson projection along the b axis gave some information about the z parameters of silicon and oxygen atoms, and the electron-density projection along the b axis was computed. This electron-density map along the b axis, together with the aid of the projection along the c axis, was sufficient to give all of the atomic positions except those of hydrogen atoms. The coordinates of the atoms were then refined by trial and error method, and later by successive Fourier syntheses. After these procedures, the (F_o-F_c) syntheses were applied in order to refine the coordinates and temperature factors further. At this stage of the structure determination, the reliability factors for $(hk0)$

The value of index followed by an asterisk indicates reflection below the observable limit. The value of F_o in this case is minimumum observed value.

and ($h0l$) reflections were found to be 12.9% and 22.8% respectively, the isotropic temperature factors being $B_C=3.5$, $B_O=3.5$ and $B_{Si}=3.0$ for carbon, oxygen and silicon atoms.

The least-squares method was applied in the next stage of the refinement. After nine cycles of the refinement of the positional and isotropic temperature factor parameters, the reliability factors for the final parameters dropped to 14.0%, with only observed reflections. The value of F_o listed for the unobserved reflections (marked with an asterisk in Table II) is $F_{min}/2$; this value was used in the least-squares refinements. The calculations of the structure factors were made with an IBM 1401 computer. The least-squares refinements were carried out with the program written by Mr. Noritake Yasuoka[12] for an OKITAC-5090D electronic computer. In these calculations, the Hartree-Fock atomic scattering curves were used for carbon and oxygen atoms, and Slater's curve for silicon atoms, the contribution of hydrogen atoms being disregarded. The final atomic coordinates and isotropic temperature factors are listed in Table I. The final electron-density maps along the c and b axes are shown in Figs. 4 and 5, where the final positions of atoms are marked with crosses. The observed and calculated structure factors are given in Table II.

Results and Discussion

Some intersesting results were revealed in this structural work, although the poor experimental data resulting from the decomposition of crystals and the exclusion of many hydrogen atoms in the calculation of structure factors might not permit us to discuss the details of structural features. The conformation of a molecule and the molecular arrangement in the crystal, together with intermolecular distances, may be seen in Figs. 6 and 7, which represent the c and b axes projections for this crystal. Table III lists the independent bond lengths, the bond angles and the non-bonded interatomic distances in a molecule. Table IV compares the bond lengths and angles found in this analysis with those found in the related compounds.

The skeleton of a molecule consists of two eight-membered $(-Si-O-)_4$ rings which are crystallographically independent of each other and which are connected by four Si-Si bonds along the c axis. Hence, the molecule forms a cage-like conformation with the approximate symmetry of $4/mmm$ predicted by chemical grounds. Two sets of four silicon atoms which are related by a fourfold axis form two square planes (3.04 Å × 3.04 Å, 3.01 Å × 3.01 Å) perpendicular to the c axis. Similarly, two sets of four oxygen atoms form two square planes, the sides of which are 2.69 Å and 2.62 Å. All of these planes are parallel to one another. The distance between two "silicon-square planes" is 2.36Å, while that between two "oxygen-square planes" is 3.33Å. The distances between the silicon-square plane and the oxygen-square plane are 0.52Å and 0.46Å respectively. Consequently, each of two $(-Si-O-)_4$ rings form a "crown-shaped" eight-membered ring. In this respect, the conformation of these rings is similar to that in octa-(methylsilsesquioxane) (III),[5] although the corresponding interplanar distance is 0.34Å in the latter. However, it differs from that in octamethylcyclotetrasiloxane (IV),[4] the puckered ring of $\bar{1}$ symmetry with a dihedral angle of 150° between the silicon- and oxygen-planes.

On the other hand, a set of the other four silicon atoms, Si(1), Si(1′), Si(2′) and Si(2), forms a plane approximately parallel to the c axis, and the best least-squares plane A, calculated by the program of Mr. Tsunehiro Takano for a NEAC 2101 computer, has the following equation:

$$0.4986x - y + 0.0061z - 0.2237 = 0$$

Table V shows the deviation of atoms from this plane, the individual atoms lying out of the plane by only insignificant amounts. The equation of a plane B through the Si(1), O(1), and Si(1′) atoms is:

$$0.4946x - y + 0.8315z - 0.0224 = 0$$

while that of a plane C through the Si(2), O(2), and Si(2′) atoms is:

TABLE V. DEVIATION OF ATOMS FROM THE BEST PLANE (Si(1), Si(1'), Si(2'), Si(2))

Atom	Deviation, Å	Atom	Deviation, Å
Si(1)	−0.005	Si(2')	−0.005
Si(1')	0.005	O(1)	0.381
Si(2)	0.005	O(2)	0.350

$$0.5026x - y - 0.8479z + 1.5828 = 0$$

The dihedral angle between the two planes, A and B, is 144°, while that between the two planes, A and C, is 143°. Thus, the skeleton of the ring, Si(1), O(1), Si(1'), Si(2'), O(2) and Si(2), has a boat form, whereas the ring in compound II has a chair form, with a dihedral angle of 170°. The adoption of a crown-shaped conformation by eight-membered rings would necessitate these four six-membered rings having boat forms.

The Si-Si bond distance, 2.36Å, in the molecule is almost the same as the 2.34Å and 2.35Å distances found in metallic silicon and II. The differences in non-equivalent Si-O distances, Si-C distances and Si-O-Si bond angle would probably not be significant, the mean values being 1.63Å, 1.88Å and 136°. The mean Si-O bond lengths agree well with those reported by other investigators.[1-6] The mean Si-C distance agrees with those found for II and spirosiloxane.[2] The bond distances calculated from the sum of covalent radii with electronegativity[13] corrections are Si-O=1.76Å and Si-C=1.88Å; the latter value is in good agreement with those found here, although the deviations of the Si-C bond lengths from the everage bond length are not small. The Si-O-Si bond angles are significantly smaller than those of II, III and IV, but they are the same as that in hexamethylcyclotrisiloxane. The corresponding angle in the spirosiloxane is 130°. The Si-N-Si angle of octamethylcyclotetrasilazane is 132°.[8] These shorter bond lengths and the larger bond angles around the oxygen atoms might confirm that the Si-O-Si configuration is more flexible than the corresponding one in carbon compounds, probably due to the existence of an ionic character and the contribution of the *d*-orbital to Si-O bonds. The bond angles around the silicon atoms are almost tetrahedral.

Each molecule in the unit cell is surrounded by four adjacent molecules related by centers of symmetry; these molecules form, in a sense, a layer perpendicular to the *c* axis. They are held together in such a way that a methyl group on one silicon atom is located just upon the six-membered ring of an adjacent molecule. This molecular arrangement in a layer might suggest polar interaction between the methyl group and the oxygen atom. Each layer seems to be held together along the *c* axis by only van der Waals forces; this mode of molecular packing in the crystal is in good agreement with the fact that this crystal has a cleavage perpendicular to the *c* axis.

The authors wish to express their gratitude to Professor Makoto Kumada and Dr. Mitsuo Ishikawa of Kyoto University for kindly supplying the samples for this study, to Mr. Noritake Yasuoka of the Osaka Industrial Research Institute and Dr. Tsunehiro Takano of Osaka University for their programs of electronic computer calculation, and to the Oki Electric Industry Co., Ltd., for the use of their electronic computer. The present study was partly supported by a scientific research grant from the Ministry of Education.

The Studies of the Cage Effect of Solvents. VI. The Photolysis of Methylazoethane in *n*-Heptane

By Shin'ichi FUJITA, Sukeya KODAMA and Osamu TOYAMA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai, Osaka

(Received December 8, 1965)

Methylazoethane was photolyzed in *n*-heptane in order to study the effect of a solvent cage quantitatively; the results obtained were then compared with those for azomethane and azoethane previously studied. By using styrene as a scavenger for radicals, it was demonstrated that a large fraction (90% at −75°C and 58% at 100°C) of a pair of methyl and ethyl radicals formed by the decomposition of a molecule of methylazoethane combines to form propane or disproportionates to form methane and ethylene in an original solvent cage. The ratio of the rate constant for the disproportionation to that for the combination is small, and it decreases with a rise in the temperature, as was previously found for azoethane. The effect of the temperature on the yields of the products of cage reactions in the present work and in the previous work with azomethane and azoethane shows that the combination of ethyl radicals and the cross-combination of methyl and ethyl radicals in a solution require appreciable activation energies, even if that for the combination of methyl radicals is zero.

The photolysis of methylazoethane in a solution yields a pair of methyl and ethyl radicals in a solvent cage. The ratios of their subsequent combination and disproportionation have recently been investigated by Szwarc and his co-workers.[1] In the present work, the photolysis of the same substrate in *n*-heptane has been studied in order to elucidate the general kinetics, including the cage reactions mentioned above, and in order to compare the results with those previously obtained for azomethane[2] and azoethane[3].

Experimental

Materials.—Methylazoethane was prepared by the thermal decomposition of the methylazoethane-cuprous chloride which had been obtained by the ethylation and oxidation of methylhydrazine sulfate,[4] in a way similar to that used for azomethane.[5] Since the prepared gas was about 2% azomethane, it was purified by a gas chromatographycal method with a column of dimethylformamide on activated alumina and was stored in a dark-colored reservoir. It was further purified before each use by condensation and evacuation at −140°C.

There has to date been no report on the properties of methylazoethane. We have now determined a few of them. The plot of the logarithmic vapor pressure vs. $1/T$ gives a good linear relation in the range from −48 to 20°C and is represented by $\log P = 7.78 - 1487/T$ The normal boiling point is calculated as 30.3°C from the equation. The molecular extinction coefficient,

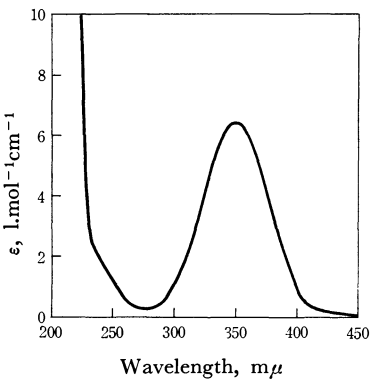

Fig. 1. Absorption spectrum of methylazoethane vapor at 29°C.

calculated from $\log(I/I_0) = -\varepsilon cd$ and with the optical densities determined in the gas phase, is illustrated in Fig. 1. The value for the absorption maximum situated at 352 mμ is 6.44 l. mol^{-1} cm^{-1}.

In this work *n*-heptane was used as the solvent for the reasons described in a previous paper[3] for azoethane, and styrene was used as the scavenger for radicals. They were taken from commercial samples which had been found to be gas chromatographically pure, and were subjected before use to thrice-repeated bulb-to-bulb distillation using a dry ice - acetone bath.

Procedure.—The apparatus was similar to that used for azomethane and previously described.[2] The reaction cells were glass cylinders about 3.6 cm. in diameter, 1.0 cm. long and about 10 cc. in volume. The full arc from a high-pressure mercury lamp, Mazda

SHL-100UV, was used for the photolysis in most experiments. The effective wavelength range seems to be restricted to 300—400 mμ, judging from the light absorption by methylazoethane and the transmission through the cell. In order to check the effect of the wavelength, a few experiments were carried out with a UV-Dl filter which transmits only the 366 mμ line. The extent of photolytic conversion in each run was usually about 5%. After the required time of irradiation, the reaction cell was opened to the analytical system, which consisted of traps set at −145°C and −210°C. The products of the photolysis were nitrogen, methane, ethane, ethylene and propane. After the gaseous components had been separated from the solution by thrice-repeated bulb-to-bulb distillation and by an autodistillation vessel[6] at the dry ice - acetone temperature, methylazoethane was condensed at −145°C and ethane, ethylene and propane were trapped at −210°C. Noncondensable products, nitrogen and methane, were introduced into a Toepler guage and the volume of the mixture was determined. Each component was further analyzed by a gas chromatograph with a 2 m. silica gel column. The fraction trapped at −210°C was dealt with similarly. The column used for it was a series consisting of 2 m. of activated alumina with 2% squalane and 2 m. of ethylene glycol saturated with silver nitrate on celite at room temperature.

Results

Table I shows the results of photolysis in the absence of styrene at 0°C. As will be shown below, $(C_2H_4+C_3H_8)/N_2$ is a measure of the cage effect, and $(CH_4+C_3H_8)/N_2$ and $(C_2H_6+C_2H_4+C_3H_8)/N_2$ represent the material balances with reference to methyl and ethyl radicals respectively. It may be seen in the table that the irradiation of filtered light (366 mμ) produces little change in the yields of gaseous products, as would be expected from the effective wavelength range for the unfiltered light mentioned above. Table I further shows that the variation in light intensity or in the rate of nitrogen formation is almost without effect on the relative yields of gaseous products.

Table II shows the effect of the temperature in

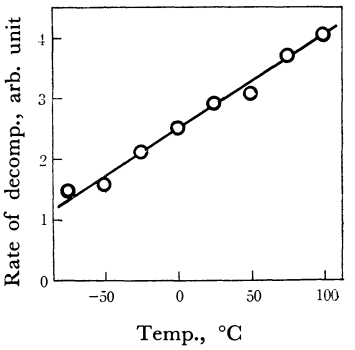

Fig. 2. Dependence of the decomposition rate on temperature.

6) J. Smid, A. Rembaum and M. Szwarc, *J. Am. Chem. Soc.*, **78**, 3315 (1956).

the presence of styrene. The ethane yields were found to be negligible in this case; in the two runs carried out at −75 and 100°C, they were 0.21 and 0.48% respectively. The formation of butane was negligible even in the absence of styrene. Figure 2 shows the effect of the temperature on the rate of photolysis; this effect may be taken as reflecting the dependence of the quantum yield on the temperature, although the latter quantity was not measured in this work.

Discussion

Mechanism.—A comparison of the results obtained in this work with those previously obtained for azomethane[2] and azoethane[3] suggests that the following reaction scheme is probable for the present photolysis:

$$CH_3N_2C_2H_5 + h\nu \rightarrow CH_3N_2C_2H_5^* \quad (1)$$

$$CH_3N_2C_2H_5^* + M \rightarrow CH_3N_2C_2H_5 + M \quad (2)$$

$$CH_3N_2C_2H_5^* \rightarrow [CH_3 + N_2 + C_2H_5] \quad (3)$$

$$[CH_3 + N_2 + C_2H_5] \rightarrow C_3H_8 + N_2 \quad (4)$$

$$\rightarrow CH_4 + C_2H_4 + N_2 \quad (5)$$

$$\rightarrow CH_3 + N_2 + C_2H_5 \quad (6)$$

$$CH_3 + RH \rightarrow CH_4 + R \quad (7)$$

$$C_2H_5 + RH \rightarrow C_2H_6 + R \quad (8)$$

$$CH_3 \text{ (or } C_2H_5) + CH_3N_2C_2H_5 \rightarrow \text{addition products} \quad (9)$$

$$CH_3 \text{ (or } C_2H_5) + R \rightarrow CH_3R \text{ or } (C_2H_5R) \quad (10)$$

Reaction 1 represents the formation of excited molecules of the substrate by light absorption; reaction 2, their deactivation by solvent molecules, and reaction 3, the formation of a pair of methyl and ethyl radicals in a solvent cage by the decomposition of the excited molecule. Reactions 4 and 5 are, respectively, the combination and disproportionation of such a pair of radicals in the original solvent cage, while reaction 6 represents the separation of these radicals by diffusion prior to their combination or disproportionation. The remaining reactions are those for the methyl and ethyl radicals thus separated.

Figure 2 shows that the quantum yield of the photolysis falls off with a lowering of the temperature. Such a behavior is similar to that found for azoethane[3] and may be accounted for by reactions 2 and 3, provided that the latter reaction requires an appreciable activation energy.

A comparison between Tables I and II shows that the yields of propane and ethylene are not affected by the presence of styrene, and that, consequently, these gaseous products are formed only by cage reactions 4 and 5. The sum of relative yields, $(C_3H_8+C_2H_4)/N_2$, thus gives the fraction of the radicals that react in the solvent cage in reactions 4 and 5. Table II shows that this fraction is nearly 90% at −75°C, but that it falls to about 60% at 100°C, indicating that the escape of radicals from the solvent cage by diffusion is favored at elevated temperatures.

In the presence of a sufficient concentration of styrene, the reaction scheme given above requires that methane be formed solely by reaction 5, and that, consequently, the yield of methane equal that of ethylene. Table II shows that these yields are in fact nearly equal to each other at low temperatures, while above room temperature there is a substantial difference between them. This presumably indicates that, at high temperatures, a part of the methane comes from the hydrogen atom abstraction by the methyl radical from the solvent molecule constituting the cage.

A comparison between Tables I and II further shows that the yield of methane was reduced by the addition of from 25% to 4% of styrene at 0°C. Similarly, the yield of ethane was reduced from 13% to a negligibly small value at 0°C. These observations may be explained by reactions 7 and 8. As may be seen from the figures given above, the yield of methane in reaction 7 is higher than that of ethane in reaction 8. Consequently, the material balance for methyl radicals as represented by $(CH_4+C_3H_8)/N_2$ is higher than that for ethyl radicals, $(C_2H_6+C_2H_4+C_3H_8)/N_2$ (Table I). These findings probably reflect the lesser ability of ethyl radicals to abstract hydrogen atoms from solvent molecules; this fact was previously inferred from the results of the photolysis of azoethane in solution.

The losses in the material balances for methyl and ethyl radicals may be accounted for by reactions 9 and 10. Their relative weights in importance are however not clear from this work.

Rate Constant Ratios of Cage Reactions.—When reactions 4—6 are regarded as ordinary elementary steps, it follows that:

$$k_5/k_4 = (C_2H_4)_s/(C_3H_8)_s$$

$$k_6/k_4 = [(N_2)_s - (C_2H_4)_s - (C_3H_8)_s]/(C_3H_8)_s$$

$$k_6/k_5 = [(N_2)_s - (C_2H_4)_s - (C_3H_8)_s]/(C_2H_4)_s$$

where the suffix s denotes the presence of styrene. On applying these equations to the experimental results, we obtain the Arrhenius plots shown in Figs. 3 and 4. The plot for k_5/k_4 is linear, but those for k_6/k_4 and k_6/k_5 show deviations above room temperature, as was the case with azoethane. These deviations presumably arise from the inadequacy of the crude representation given in reaction 6 for the escape of radicals from a solvent cage at high temperatures.

Table III shows the Arrhenius parameters determined from Figs. 3 and 4; for the latter figure these quantities refer to the linear portions of the plots. The table also contains the corresponding

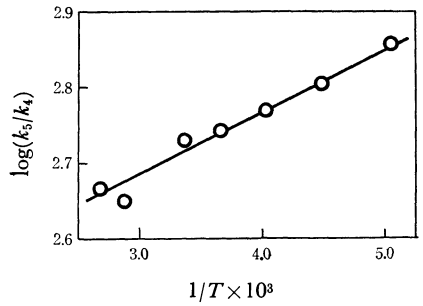

Fig. 3. Arrhenius plot for k_5/k_4.

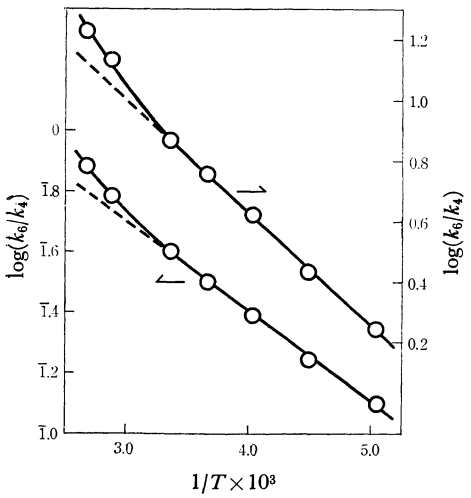

Fig. 4. Arrhenius plots for k_6/k_4 and k_6/k_5.

values for azomethane[7] and azoethane[3]. It may be seen in the table that E_5-E_4 is slightly negative for methylazoethane as well as for azoethane. These results are in agreement with those obtained and discussed in detail by Szwarc and his co-workers.[1,8]

The energy differences, E_6-E_4 and E_6-E_5, on the other hand, are definitely positive, indicating that the effect of the temperature on the cage reactions is largely controlled by the energy of activation for the diffusion of radicals.

Table III shows that E_6-E_4 decreases in the order of azomethane, methylazoethane, and azoethane. If the value of E_4 were zero for all of the methyl-methyl, methyl-ethyl and ethyl-ethyl combination, the trend in the values of E_6-E_4 would mean a greater activation energy for the diffusion of methyl radicals than that for ethyl radicals, contrary to what would be expected. Table III, therefore, leads to the conclusion that the combination of ethyl radicals and the cross-combination of methyl and ethyl radicals require activation energies greater than about 0.5 and 0.2 kcal./mol. respectively at least. This conclusion is compatible with previously-reported values. The activation energy for the combination of ethyl radicals has been reported as 2 kcal./mol. in the gas phase[9] and as 0.8 kcal./mol. in solution,[10] while that for methyl radicals is regarded as approximately zero in the gas phase.[11]

7) In the previous work with azomethane no experiment was carried out in *n*-heptane. The values for azomethane listed in the table are those determined in this work by photolyzing azomethane in *n*-heptane.

NOTES

Reactions of Coordinated Organic Ligands with Cupric Bromide

By Robert H. BARKER, Michinobu KATO,* G. W. MCLAUGHLIN and Hans B. JONASSEN

Department of Chemistry, Tulane University, New Orleans, Louisiana, U. S. A.

(Received June 5, 1965)

Metal halides, such as cupric bromide, are known to act as halogenating agents for ketones and reactive aromatics. We have now been able to extend these reactions to include the halogenation of some coordinated organic nuclei.

The treatment of the copper(II) chelate of 8-hydroxyquinoline with cupric bromide in absolute alcohol produces a mixture of products. Hydrolysis with hydrochloric acid yields 5, 7-dibromo-8-hydroxyquinoline,[1] plus some monobrominated material.

The copper(II) chelate of salicylaldehyde is brominated in a similar fashion to yield 5-bromosalicylaldehyde upon acid hydrolysis.

Several metal acetylacetonates also undergo this type of reaction. The treatment of bis(2, 4-pentanedionato)copper(II) with cupric bromide produced bis(3-bromo-2, 4-pentanedionato)copper-(II) very rapidly. The cobalt(III) and chromium-(III) chelates of acetylacetone were brominated in the same manner as the copper(II) complex, except that the reaction proceeded somewhat more slowly. Substitution occurred only on the number 3 carbon of the ligands. No detectable amounts of bis(3-bromo-2, 4-pentanedionato)copper(II) were found to result from these reactions which might be formed through ligand exchange in a solution.[2] We have found that the copper(II) complexes readily form from the free ligand and cupric bromide under the conditions of the bromination, whereas the cobalt(III) and chromium(III) complexes do not. In agreement with a variety of such brominations reported by Collman et al.,[3] the bromination of these trivalent metal chelates may involve direct electrophilic substitution on the chelate ring.

Experimental

The Bromination of Bis(8-hydroxyquinolinato)-copper(II) and Bis(salicylaldehydato)copper(II).—A mixture of one of the metal chelates (0.01 mol.) of 8-hydroxyquinoline (A) or salicylaldehyde (B) and cupric bromide (0.02 mol.) in 100 ml. of absolute ethanol was stirred for 1 hr. at 50—60°C. (A): The reaction mixture was collected on a filter and dissolved in 6 N hydrochloric acid by being warmed. The resulting solution was saturated with hydrogen sulfide to precipitate cupric sulfide and then filtered. The free base of 5, 7-dibromo-8-hydroxyquinoline was recovered from the aqueous filtrate and recrystallized from *N*, *N*-dimethylformamide. It was identified by comparing its infrared spectrum with that of standard spectra shown in the Sadtler catalog (No. 7168); yield, 30%. (B): The reaction mixture was collected on a filter. The evaporation of the filtrate left some residue. These materials were put together and dissolved in 6 N hydrochloric acid to give a precipitate. An alcoholic extract of the precipitate gave needles of 5-bromosalicylaldehyde (yield, 35%), identified by a comparison of its m. p. (105°C) (Beilstein's Handbook) and infrared spectrum (Sadtler No. 5769) with those of a standard sample.

The Bromination of the Metal Acetylacetonates.—A mixture of one of the complexes (0.0075 mol.) and well-dried cupric bromide (0.018 mol.) in 100 ml. of absolute ethanol was stirred for 30 min. at room temperature. After filtration to remove the cuprous bromide formed during the reaction, the filtrate was evaporated to dryness under reduced pressure. Recrystallization from chloroform and heptane produced the pure product in the copper(II) series (yield, ca. 20%), but cobalt-(III) and chromium(III) products required further purification by chromatography on alumina in order to remove small amounts of mono- and dibrominated materials from them. Each compound was identified by a comparison of its melting point and infrared spectra with those in the literature[3]; yields after chromatography: 10% for the chromium(III) complex and 17% for the cobalt(III) complex.

The Infrared Absorption Spectrum of the Vinyl Chloride - Vinyl Acetate Copolymer and Its Tacticity

By Tsugio TAKEUCHI and Sadao MORI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received June 9, 1965)

We have already reported a method for the infrared analysis of the vinyl chloride - vinyl acetate copolymer.[1] In that paper we suggested the possibility of discriminating between the copolymer and a mixture of the homopolymer of vinyl chloride and that of vinyl acetate (henceforth referred to as PVC and PVAc respectively); no difference in the frequencies of the absorption bands was observed, but the absorption intensities of some bands of the copolymer were markedly different from those of a mixture with the same composition. In this paper the infrared spectra in the 400—700 cm^{-1} range of the same samples will be measured. We will also study the relation between the vinyl acetate content of the copolymer and the tacticity of its vinyl chloride part. The crystallinity of the copolymer will also be discussed.

Experimental

The infrared spectra of the polymers were observed by means of a Nihon-Bunko double-beam infrared spectrophotometer, Model DS-402G. The samples of PVC, PVAc and the copolymers were the same as those used in a previous experiment.[1] The polymer films were obtained from the tetrahydrofuran solutions of the polymers by evaporating the solvent on mercury under reduced pressure.

Results and Discussion

The Infrared Absorption Spectra and Relative Absorption Intensities.—Shimanouchi et al.[2,3] have assigned the bands of PVC at 638 cm^{-1} and 615 cm^{-1} to the C–Cl stretching frequencies associated with the syndiotactic structure, an extended chain, and the band at 690 cm^{-1} to the isotactic structure, a three-fold helix. They have also concluded that the bands at 690 cm^{-1} and 615 cm^{-1} are due to the amorphous region of the polymer, and the band at 638 cm^{-1} to the crystalline region.

Three bands, at 690 cm^{-1}, 637 cm^{-1} and 615 cm^{-1}, were observed in the spectra of the copolymers and the mixtures. They were inferred to arise as follows: the 690 cm^{-1} band from the C–Cl vibration, and the 637 cm^{-1} band and the 615 cm^{-1} band from the vibrations of C–Cl and the acetyl group.[2,4] In Fig. 1 the ratios of the absorbance at 690 cm^{-1} to that at 637 cm^{-1}, of that at 637 cm^{-1} to that at 615 cm^{-1}, and of that at 690 cm^{-1} to that at 615 cm are plotted against the vinyl acetate content. It may be seen that there are great differences in the absorbance ratios between the copolymer and the mixture, the difference in the absorbance ratio of the 690 cm^{-1} and 637 cm^{-1} bands being the most noticeable.

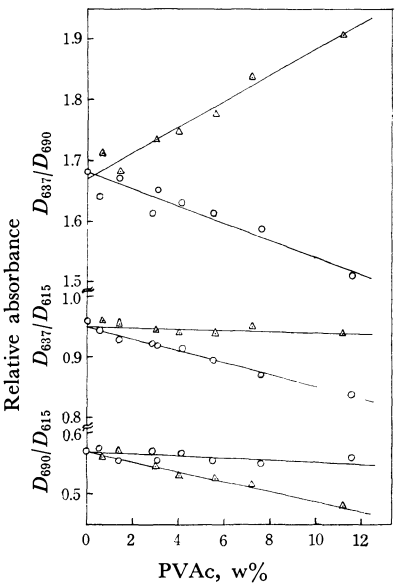

Fig. 1. Relative absorbances of the 690, 637 and 615 cm^{-1} bands.
○—○: Copoymers
△—△: Mixtures

The Tacticity of the Copolymer.—On the basis of the differences in absorbance ratio between the copolymer and the mixture, the tendency of the crystallinity and the tacticity of the copolymer to change with an increase in the vinyl acetate content of the copolymer was considered.

Figure 2 shows that the absorption intensity of the band at 690 cm^{-1} of the copolymers decreases less than that of the mixtures as the vinyl acetate content increases. If the intensity of the 690 cm^{-1}

band is not subjected to the influence of the copolymerization of PVAc, it might be possible to explain this result qualitatively in terms of the fact that the amorphous content of the isotactic region of the vinyl chloride part increases as the vinyl acetate content increases. As the bands at 637 cm^{-1} and 615 cm^{-1} were assigned to the bands due to the vibrations of both the acetyl group of PVAc and the C–Cl of PVC, it might not be appropriate to discuss the tacticity of the copolymer quantitatively. However, the relative absorbance of the 637 cm^{-1} band to the 615 cm^{-1} band of the copolymer was smaller than that of the mixture; this means that the absorption intensity at 637 cm^{-1} of the copolymer decreased, or that at 615 cm^{-1} increased, more than those of the mixture. If the influence

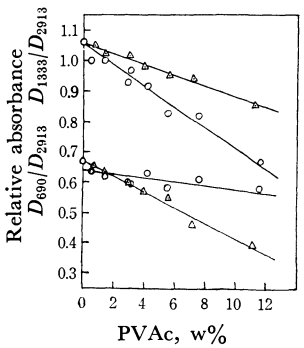

Fig. 2. Relative absorbances of 1333 and 690 cm^{-1} bands to the 2913 cm^{-1} band.[1)]

○—○: Copolymers △—△: Mixtures

of the copolymerization of PVAc is disregarded, it should be possible to explain these results by concluding that the crystalline content of the syndiotactic region of vinyl chloride decreases, or that the amorphous content of the syndiotactic region of the vinyl chloride part increases, as the copolymerization degree of vinyl acetate increases.

The band at 1333 cm^{-1} of PVC was considered to be the crystalline band[1)]; its absorbance of the copolymer decreased much more than that of the mixture as the vinyl acetate content increased (see Fig. 2). It was clear that the degree of crystallinity of the copolymer was smaller than that of a mixture of two homopolymers of the same composition. This fact was confirmed by the finding that the densities of the copolymers were smaller than those of the mixtures calculated from the densities of PVC and PVAc.

Grisenthwaite and Hunter[5)] have pointed out that the degree of crystallinity and the content of the syndiotactic region of the amorphous part of PVC increase as the polymerization temperature is lowered; basides, its isotactic region decreases. The results presented above lead to the following, differing conclusions: the degree of the crystallinity of the copolymer decreases as the vinyl acetate content increases, while the isotactic region of the amorphous vinyl chloride part increases.

The Mechanism of the Oxidative Decarboxylation of Benzoic Acid*

By Shigeru OAE, Takao WATANABE and Naomichi FURUKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received July 12, 1965)

The oxidative decarboxylation of benzoic acids with copper has been known as a method to produce phenols.[1] Although its precise mechanism is not clear, it has been suggested that the reaction involves the initial formation of cupric benzoate between two molecules of benzoic acid and cupric oxide, followed by the intramolecular attack of the carboxyl oxygen at the ortho-position of the other benzene ring, producing, via the equilibrium formation of a six-membered cyclic intermediate, phenyl benzoate, which is presumed to be the precursor of phenol.[2] In this case the oxygen atom of the phenol formed is expected to come from the carboxyl group. Meanwhile, if salicylic acid is formed by the pyrolysis of basic cupric benzoate,[3] the oxygen atom of the resulting phenol is likely to come from the water used. Another possibility is that the oxygen atom in the resulting phenol originates in the air. Thus, we have undertaken the pyrolysis of ^{18}O-labeled benzoic acid and traced the origin of the oxygen atom in the resulting phenol.

Experimental

Benzoic Acid Labeled with ^{18}O.—A mixture of 3.5 g. of benzoyl chloride and 2 ml. of $H_2{}^{18}O$ was refluxed until no hydrogen chloride gas evolved. After the mixture had then cooled, colorless crystalline

precipitates were filtered, washed with a small amount of water, and then recrystallized from water. The yield was 2.6 g. (84.9%); m. p. 123°C.

The Decarboxylation of ^{18}O-Labeled Benzoic Acid.—The apparatus used for the reaction is shown in Fig. 1. In a generator an air-steam mixture was prepared by bubbling air into hot water. The air-steam mixture was thus generated at the rate of 0.5—0.6 l./hr., the temperature of the water being kept at 80—90°C. As a reaction vessel, it is convenient to use a three-necked flask equipped with an air-steam-mixture-inlet tube, a thermometer, and a reflux condenser packed with glass beads and heated by an electric furnace, the temperature being kept at 130—140°C. The upper end of the reflux condenser was connected to a receiver. Phenol, water and other volatile products were collected in a receiver, and the carbon dioxide generated was entrapped by passing it through a barium hydroxide solution. A typical run for decarboxylation was as follows. In a reaction vessel, a mixture of 2.0 g. of ^{18}O-labeled benzoic acid, 40 mg. of cupric oxide and 68 mg. of magnesium oxide was charged and heated to 230—240°C by stirring it with a magnetic stirrer. The air-steam mixture was then introduced. After treatment for 5 hr., an excess of bromine water was added to the receiver flask. By this method, 1.5 g. of tribromophenol was obtained, in a 29% yield, when mixed with an authentic sample, its melting point did not drop. A brownish residue in a reaction vessel was washed with water and ether. Crude benzoic acid (0.95 g.) was thus recovered, while phenyl benzoate was obtained as a by-product. The overall yield was 53%.

^{18}O-Analysis.—^{18}O analyses of phenol, the recovered benzoic acid and carbon dioxide were carried out as usual by changing each sample into carbon dioxide gas, which was then subjected to mass spectrometry.

The Reaction of Phenol with Water.—Control experiments were carried out in order to test the oxygen exchange between phenol and $H_2{}^{18}O$ under the same reaction conditions. After phenol had been recovered as its 2, 4, 6-tribromide, the ^{18}O-content of the phenol was analyzed by the same procedure. The ^{18}O-concentration was found to be 0.20 atom%, which is that of the natural abundance of ^{18}O. The results showed no ^{18}O exchange between phenol and water.

Discussion

The analytical data on the ^{18}O content of the resulting phenols and benzoic acids, both those initially-employed and those recovered, are summarized in Table I.

Most of the ^{18}O initially-labeled in the carboxyl group was found in the phenol produced, except when the reaction was carried out with the extensive introduction of a steam. However, in every run, a small decrease in the ^{18}O content of the products was observed, especially in the recovered benzoic acid. This is presumably because of an oxygen exchange between ^{18}O-labeled benzoic acid and water during the reaction. These observations are clearly in accord with the mechanism involving the formation of phenol via the cyclic intermediate. As is shown by the run 3 in Table I, the intervention of another possible reaction, i e., that of the basic salt of benzoic acid, is conceivable in this case, since the basic salt is presumably formed quite readily in the presence of an excess of water. Accordingly, it seems that only a minor portion of the reaction proceeds through a path involving the basic salt, while the major part of the reaction proceeds through an ordinary process with cupric salt of benzoic acid, with the ^{18}O concentration gradually reduced during the reaction.

Table I. ^{18}O Contents of benzoic acid and phenol in the decarboxylation of ^{18}O-labeled benzoic acid (^{18}O-atom%)

Run	Benzoic acid		CO_2	Phenol
	Initial	Recovered		
1a)	1.05	0.93	0.81	1.02
2a)	1.25	0.99	—	1.01
3b)	0.87	0.46	0.33	0.42

a) The reaction was carried out at 230—240°C for 5 hr.

The Sheet Scintillation Counting of Tritium in Surface Films*

By Mitsuo MURAMATSU and Noboru TOKUNAGA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo
Japan Radiation and Medical Electronics, Inc., Mitaka, Tokyo

(Received August 10, 1965)

Because of the extremely soft nature of β-rays, tritium is expected to be the most effective radioactive tracer for elucidating the mechanism of such surface-chemical processes as the adsorption of detergents at the solution/gas interface, as well as for studying the nature of solid surfaces. Thus, the adsorbed amount of tritiated sodium dodecyl sulfate was determined with a 2π proportional counter, with humidified hydrocarbon gas flowing over the detergent solution.[1] The surface roughness of solid samples was determined by measuring the radioactivity of a tritiated specimen.[2] Similar techniques have been employed in studying the behavior of tritiated lauric acid in thin layers on metal[3] and that of hydrocarbons on metallic[4] and aqueous[5] hypophases.

All these experiments have been carried out with a windowless flow counter of a limited size. In these experiments, therefore, the experimental devices had to be small enough to fit into the counter; they can not include, for example, a trough for insoluble monolayers. In addition, the surface is inevitably exposed to the hydrocarbon gas, which in some cases dissolves in the hypophase.[6] To avoid these difficulties, an attempt has been made to develop a method of scintillation counting which does not require a flowing gas and where the space for the sample is not limited.

Experimental

The counting probe consisted mainly of a sheet of plastic scintillator and a photomultiplier tube (EMI 9536s). To minimize the optical loss due to total reflection, coupling of the sheet to the tube window was achieved with silicone oil of the same refractive index, 1.60, as that of the scintillator sheet. The assembled probe was placed, at a distance of 1 mm., face to face with a thin film (0.17—0.85 μg./cm^2) of an extremely pure sample of stearic-9, 10-^{3}H, ^{3}H acid (9.5 c./mol.)[7] spread over the circular range (1.13 cm^2) of a concentric aluminum disk. The whole assembly was thermostated to $\pm$0.5°C throughout the measured temperature range of —5 to 10°C.

The output pulses led to a linear amplifier (Aloka LA-10; maximum amplification, 30000), then to a pulse height analyzer (Aloka PA-22, 2 channel) for counting.

Two types of plastic scintillator sheets were used in the experiments. The sheets of the Pilot Scintillator B, which contained *p*, *p'*-diphenylstilbene as a scintillator, were obtained from the Pilot Chemicals, Inc., Watertown, Mass., U. S. A. The other type, containing terphenyl, was kindly supplied by the Matsushita Denko K. K., Osaka.

Results and Discussion

The background values were generally high, because of the low discrimination levels which we inevitably chose for counting the pulses of tritium β-rays. Therefore, attempts were made to overcome the difficulty by the aid of optical coupling

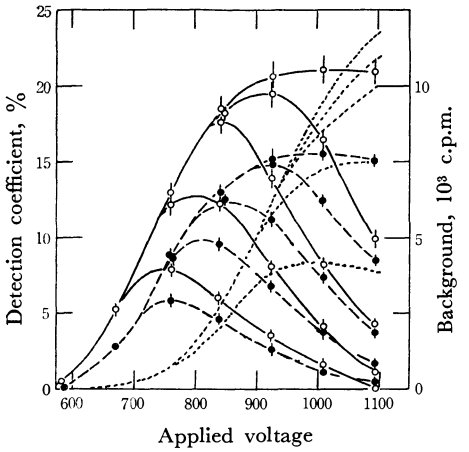

Fig. 2. Voltage dependences of background (dotted lines) and of detection coefficient with the Pilot Scintillator B sheet with (full) or without (chained) optical coupling.

Temperature, 10°C; window width, down to up, 5—12.5, 5—25, 5—50, 5—100 and 5—∞ Volts.

Each point expresses the average from 5—10 independent experiments.

for the efficient transformation of the optical scintillae into electronic pulses. Figures 1 and 2 show the counting characteristics for terphenyl and the Pilot Scintillator B sheets, respectively, with and without an optical coupling at 10°C. It can be seen in the figures that the coupling has caused a shift of the curve to lower voltage and has increased the detection coefficient. Accordingly, the background value at a 10% detection coefficient, for example, was decreased by the coupling from 2600 to 650 c.p.m. with the terphenyl sheet (Fig.1) and 1000 to 330 c. p. m. with the Pilot Scintillator B sheet (Fig. 2).

Precise experiments using 0.01—0.25 mm.-thick scintillator sheets have shown that the counting characteristics do not depend on the thickness.

The lowering of the temperature causes a remarkable decrease in the background, especially in the high voltage region, but it has little influence upon the detection coefficient. For obtaining a 10% detection coefficient, for instance, the background values were 90 c.p.m. at −5°C and 700 c.p.m. at 10°C. Similar or more exaggerated difference was found for obtaining another value of the detection coefficient. Very low temperature, however, could not be used, especially for adsorption experiments with an aqueous system.

Figure 3 shows the effect of sample thickness on the count rate, obtained at the applied voltage in order to give the maximum detection coefficient for each window width using a Pilot Scintillator B at 10°C. The linearity is fairly good, regardless of the counting conditions. If we assume the 20 Å²/molecule to be the cross-sectional area of

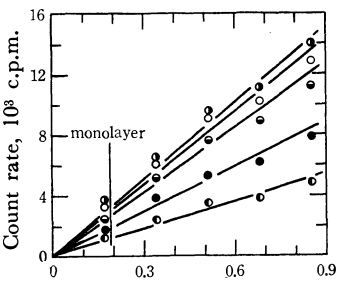

Fig. 3. Effect of sample thickness on count rate. Temperature, 10°C; scintillator, optically coupled Pilot Scintillator B.

Window width and applied voltage; ◐, 5—12.5 V. and 755 V.; ●, 5—25 V. and 800 V.; ◒, 5—50 V. and 840 V.; ○, 5—100 V. and9 25V.; and ◑, 5—∞ V. and 1010 V.

stearic acid, 1200 c.p.m. for a 5—12.5 V. window width would, for example, be obtained as the net count rate of a monolayer of tritiated stearic acid spread over a circle of 1.13 cm.² in area. Therefore, if we would have a monolayer of the same substance with the same specific activity spread on a surfac wider than the tube window, we could expect ca. 21600 c.p.m. as the net count rate, A, due to the tritium in the monolayer,* the value being much more than the background, B, 490 c.p.m. in this case. Figure 4 illustrates the values of A and B/A as a function of B under counting conditions which give a maximum detection coefficient for each window width. The

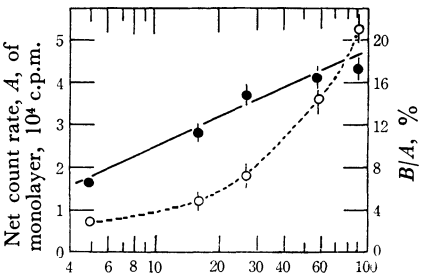

Fig. 4. Net count rate, A, (●) of stearic acid monolayer and the B/A ratio (○) as a function of background, B, at 10°C. Scintillator, optically coupled Pilot Scintillator B; window width, left to right, 5—12.5, 5—25, 5—50, 5—100 and 5—∞ V.

Each point expresses the average from 5 independent experiments.

* It was confirmed that the geometric factor for a point source does not depend on its radial position, almost up to the edge of the scintillator sheet. The constancy of the factor is due to the short distance (1mm.) between the sheet and the sample and, possibly, to the structure of the Venetian-blind-type phototube to which our photomultiplier belongs.

figure shows that the value of B/A increases remarkably with an increase in the background, showing the better conditions obtainable with a narrower window width and, correspondingly, with a lower voltage. It must also be mentioned that the temperature dependence of the background is decreased markedly by a decrease in the applied voltage and by a narrowing of the window width.

The sheet scintillation, which was first reported for counting tritiated hydrogen[8] and for the low-background counting of hard β-rays[9] will thus be of great use in determining the amount of a tritiated substance present in very thin layers at the air/water interface of any size available. It will enable us to determine simultaneously the radioactivity and such other properties as surface pressure and potential.

The authors wish to thank Mr. Nobuo Motida, President of JRME, for his interest in this work.

Syntheses and Structures of Acetylformoin and Related Compounds. V. *p-t*-Butylbenzoylformoin and *t*-Toluylformoin

By Sadao KIMURA, Yo MIYAGI and Ryozo GOTO

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received August 19, 1965)

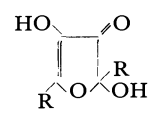
In our earlier investigations[1] it has been reported that α-ketoaldehydes undergo a self-condensation similar to benzoin condensation to give formoins, for which several structures are possible. The results may be summarized as follow: structure I is preferred in solutions in alcohols and ethers; structure II is preferred in solutions in chloroform and carbon tetrachloride; the structure in the solid state is dependent on the substituent R. The two struc tures have been found to have quite different spectral characteristics. Compound

$$2\ \mathrm{RCOCHO} \xrightarrow{\mathrm{CN^-}} \mathrm{RCOCH(OH)COCOR}$$

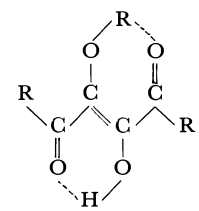
I shows $\nu_{C=C}$ at ca. 1605, $\nu_{C=O}$ a ca. 1685, and two bands of ν_{OH} between 3000and 4000 cm^{-1} in the solid state, and $\nu_{C=C}$ at ca. 1615, $\nu_{C=O}$ at ca. 1705 and one band of ν_{OH} between 3500 and 3800 cm^{-1} in a solution. Compound II shows $\nu_{C=C}$ at ca. 1620 cm^{-1} and no discernible bands of ν_{OH} and $\nu_{C=C}$ in either state. λ_{max} is located ca. 360 and 240 mμ in compound I and ca. 400 and 300 mμ in compound II when R is the phenyl group.

In this paper the authors will report on the condensation products of *p-t*-butylphenylglyoxal and *t*-tolylglyoxal, namely, *p-t*-butylbenzoylformoin (BBF) and *t*-toluylformoin (TF).[2] The glyoxals prepared by the selenium oxide oxidation of the *p*-substituted acetophenones were subjected to condensation in an aqueous alcoholic solution containing sodium cyanide.

It has been established by elementary analysis and molecular weight determination that the product is composed of two molecules of the glyoxal.



I



II

The infrared spectrum of BBF has the spectral characteristics of structure I in the solid state: $\nu_{C=C}$ 1593, $\nu_{C=O}$ 1680 and ν_{OH} 3100 and 3300 cm^{-1}. In THF or ethanol it also shows the spectral properties of structure I: $\nu_{C=C}$ 1625, $\nu_{C=O}$ 1700 and ν_{OH} 3260 cm^{-1}; λ_{max}^{EtOH} 358 (ε, 13700) and 245 (ε, 12500) mμ.

When BBF is dissolved in chloroform in air, it is rapidly oxidized to give a red solution as benzoylformoin.[1d] For this reason, the ultraviolet spectrum in this solvent was measured in a cell sealed in vacuc. The situation is rather complicated, as in the case cf benzoylformoin. In ethanol-free chloroform, λ_{max}'s are located at 400 and 300 mμ, indicating structure II. The solution in ethanol-containing (ca. 1%) chloroform shows λ_{max} 371 and 245 mμ. However, it can not be thereby concluded that this spectrum indicates structure II, for benzoylformoin may react with ethanol in chloroform to give *O*-ethyl

1) a) R. Goto, Y. Miyagi and H. Inokawa, This Bulletin, **36**, 147 (1963); b) Y. Miyagi and R. Goto, ibid., **36**, 650; c) Ibid., **36**, 921; d) Y. Miyagi, ibid., **37**, 12 (1964).

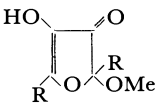
2) TF was first synthesized by Abenius and Söderbaum (*Ber.*, **25**, 3473 (1892)), but its structure needs to be investigated further.

benzoylformoin II (R=OH, R'=Et).[3]

When the ultraviolet spectrum is quickly recorded in the 340—420 mμ range, it is found that the absorption arises around 370 mμ immediately after dissolving in ethanol-free chloroform and that it shifts to 405 mμ in about five minutes. This fact indicates that the structure of BBF, which is I soon after dissolving, turns to II by a quick shift of the equilibrium between I and II.

TF also has the spectral properties of structure I in the solid state and in solution in THF and ethanol: $\nu_{C=C}$ 1598, $\nu_{C=O}$ 1693, and ν_{OH} 3240 and 3520 cm^{-1} in the solid state; $\nu_{C=C}$ 1630, $\nu_{C=O}$ 1705 and ν_{OH} 3280 and 3540 cm^{-1} in THF; λ_{max}^{EtOH} 355 (ε, 11100) and 245 (ε, 11100) mμ.

The ultraviolet spectrum of TF in chloroform is also complicated. In ethanol-free chloroform, λ_{max} is located at 400 mμ. In ethanol-containing chloroform it shifts to 380 mμ, a position a little longer in wavelength than the band of BBF in this solvent, 371 mμ. Moreover, a shoulder is observed on the longer wavelength side of the 380 mμ band. This spectrum indicates the presence of a mixture of two components. One of these may be established as II with certainty. However, the other component can not be concluded unequivocally to be I for the same reason as has held in the case of BBF.



III

As does benzoylformoin,[1b-c,4] BBF and TF undergo methanolysis by methanolic hydrogen chloride to give *O*-methyl dericatives with spectral properties similar to those of structure I. Since etherification by alcoholic hydrogen chloride is characteristic of glycosidic linkage, the structure of these *O*-methyl derivatives may be established as III.

The situation is now being investigated in more detail.

Experimental

Glyoxals.—*p-t*-Butylacetophenone[5] and *p*-methylacetophenone[6] were oxidized with selenium oxide by the general procedure[7] to *p-t*-butylphenylglyoxal and *p*-tolylglyoxal respectively. The latter was isolated as a hydrate, m. p. 105.5—106.5°C. The former, however, failed to give a hydrate.

***p-t*-Butylbenzoylformoin (BBF).**—Crude *p-t*-butylphenylglyoxal was redistilled to give a yellow liquid boiling at 99—104°C/4 mmHg. After 10 g. of this had been dissolved in 80% aqueous ethanol (65 ml.), to this solution an aqueous solution (5 ml.) containing 0.2 g. of sodium cyanide was added. The color of the solution turned a reddish yellow, and yellow crystals were deposited. After 2 hr., the crystals were filtered off, which were dissolved in warm ethanol and recrystallized by adding water: yield, 7 g.; m. p. 168.5—169.0°C.

Found: C, 75.43; H, 7.44; mol. wt. (Rast), 400. Calcd. for $C_{24}H_{28}O_4$: C, 75.76; H, 7.42%; mol. wt., 380.

***p*-Toluylformoin (TF).**—The procedure was the same as above except that glyoxal hydrate was used instead of the glyoxal monomer. Yellow needles: recrystallized from 50% aqueous ethanol; m. p. 154—159°C (lit. 161°C[2]). Found: C, 72.98; H, 5.15; mol. wt. (Rast), 298. Calcd. for $C_{18}H_{16}O_4$: C, 72.96; H, 5.44%; mol. wt., 296.

***O*-Methyl *p-t*-Butylbenzoylformoin.**—BBF (3 g.) was dissolved in 10% methanolic hydrogen chloride (50 ml). Immediately pale yellow crystals were deposited. The whole mixture was allowed to stand overnight in a refrigerator. Crystals were collected and recrystallized from methanol; yield, 2.5 g.; m. p. 206—207°C; ν_{max}^{Nujol} 1615, 1690 and 3360 cm^{-1}; λ_{max}^{EtOH} 358 (ε, 12900) and 245 (ε, 12000) mμ.

Found: C, 75.95; H, 7.81; CH_3O, 7.73. Calcd. for $C_{25}H_{30}O_4$: C, 76.11; H, 7.67; CH_3O, 7.68%.

***O*-Methyl *p*-Toluylformoin.**—The procedure was the same as above. Pale yellow needles, recrystallized from methanol; m. p. 195—196°.2C; ν_{max}^{Nujol} 1615, 1690 and 3400 cm^{-1}; ν_{max}^{EtOH} 358 (ε, 12400) and 245 (ε, 11300) mμ.

Found: C, 73.38; H, 5.81; CH_3O, 10.18. Calcd. for $C_{19}H_{18}O_4$: C, 73.53; H, 5.85; CH_3O, 10.00%.

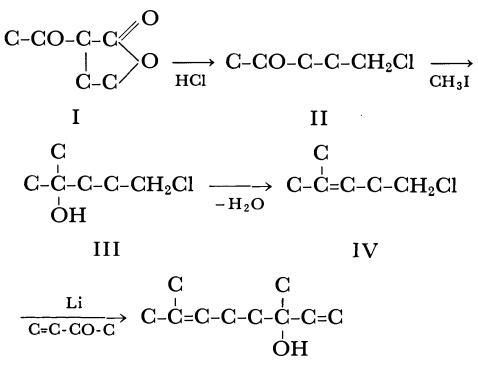
The Synthesis of Linalool

By Kyoichi SUGA, Shoji WATANABE and Imako OKOSHI

Department of Applied Chemistry, Faculty of Engineering, Chiba University, Yayoicho, Chiba

(Received August 20, 1965)

Linalool is widely used in perfumery. Various methods have been used successfully for the synthesis of linalool. The authors will now describe a new method of preparing linalool from α-acetyl-γ-butyrolactone (I), which is an intermediate of vitamin B_1[1]. This new method is shown in the following scheme:



5-Chloro-2-pentanone (II) was prepared by the action of aquous hydrochloric acid[2] on I in a good yield. The ketone (II) with methylmagnesium iodide gave the alcohol 1-chloro-4-methyl-4-hydroxy-pentane (III) in a 60% yield. The alcohol (III) was then dehydrated easily by potassium bisulfate to 1-chloro-4-methyl-3-pentene (IV). The alkenyl lithium from the chloride (IV) reacted with methylvinyl ketone to give linalool (V). The identity of V was confirmed by comparing its infrared absorption spectrum and its gas liquid chromatography with those of authentic linalool.

Similarly, dihydrolinalool was prepared from the alkenyl lithium of the chloride (IV) and ethyl methyl ketone.

Experimental

α-Acetyl-γ-butyrolactone (I). — It was obtained from the Sankyo Co., Ltd., and from the Takasago Perfumery Co., Ltd.

5-Chloro-2-pentanone (II).—A mixture of 45 ml. of concentrated hydrochloric acid, 53 ml. of water, and 38.4 g. (0.3 mol.) of I was placed in a 200 cc. distilling flask fitted with a condenser and a receiver immersed in an ice-water bath. The reaction mixture was heated for 10 min., and then distilled as rapidly as possible. After 90 ml. of distillate had been collected, 50 ml. of water was added to the distilling flask and another 30 ml. of distillate was collected. The yellow organic layer was extracted with ether. The ether extracts were dried over calcium chloride. Fractional distillation gave a crude II (28 g., yield 78%). It was redistilled for characterization, b. p. 70—72°C/12 mmHg; n_D^{25} 1.4371 (reported[2] 70—72°C/12 mmHg, n_D^{25} 1.4371).

1-Chloro-4-methyl-4-hydroxypentane (III).—Methylmagnesium iodide, obtained from magnesium (4 g.) and methyl iodide (22 g.) in ether (200 ml.), was cooled to 0°C and stirred during the addition (10 min.) of II (20 g.) in ether (100 ml.). After a further 60 min., acetic acid (25 ml.) in ether (50 ml.) was added. The mixture was then stirred with water (200 ml.), and the aqueous layer was extracted with ether. The ether extracts were washed with aqueous sodium hydrogen carbonate, dried over anhydrous sodium sulfate, and distilled to give 1-chloro-4-methyl-4-hydroxypentane (III) (8 g.), b. p. 80—83°C/16 mmHg; d_4^{20} 1.1091; n_D^{20} 1.4522; IR: ν_{max} 3380 cm^{-1} (OH), ν_{max} 1120 cm^{-1} (a tertiary OH), the gas chromatogram showed a single peak.

1-Chloro-4-methyl-3-pentene (IV). — The above chloride (III) (8 g.) was heated at 160°C with fine-powdered potassium bisulfate (2 g.). After an hour 10 ml. of water was added, and the mixture was extracted with ether. The ether extracts were dried over anhydrous sodium sulfate. Fractional distillation gave 1-chloro-4-methyl-3-pentene (IV) (4.5 g.), b. p. 125—130°C; d_4^{20} 0.9721; n_D^{20} 1.4414; IR: ν_{max} 890 cm^{-1} (-C=CH); gas chromatography showed a single peak.

Linalool (IV).—Lithium (0.47 g.; thin strips freshly cut) and ether (50 cc.) under nitrogen were stirred during the slow addition of 1-chloro-4-methyl-3-pentene (IV) (4 g.) in ether (60 cc.). When reaction began, a cooling bath (−20°C) was applied. Stirring was then continued at −15°C until nearly all the lithium had reacted (2 hr.). To the solution at −70°C, methyl vinyl ketone (2.3 g.) in ether (10 cc.) was added (5 min.). Twelve hours later a 50% alcoholic solution (10 cc.) in ether was added, and the mixture was treated as usual. Fractional distillation gave 3 g. of linalool (V), b. p. 78—80°C/6 mmHg; d_4^{15} 0.8702; n_D^{0} 1.4681; IR: 3400 cm^{-1} (OH), 1120 cm^{-1} (a tertiary OH), 890 cm^{-1} (-C=CH-), 910 and 990 cm^{-1} ($-CH=CH_2$).

Its nature was confirmed by comparing its infrared absorption spectrum and gas chromatography with those of an authentic sample. (Found: C, 77.80; H, 11.73%).

Dihydrolinalool (VI).—Much as has been described above, dihydrolinalool was prepared from 1-chloro-4-methyl-3-pentene (IV) and ethyl methyl ketone. The dihydrolinalool so prepared had the following

Studies of Some Radical Transfer Reactions. II.† Electron Transfer Reactions Involving Halide and Oxalate Ions with OH Radicals during the Aqueous Polymerization of Methylmethacrylate

By Mihir K. SAHA, Premamoy GHOSH* and Santi R. PALIT

Indian Association for the Cultivation of Science, Jadavpur, Calcutta 32, India

(Received September 28, 1965)

Hydroxyl radicals (OH·) in solution may possible participate in electron transfer reactions with some anions (X^-) present in the same medium, thereby losing their radical nature and being replaced by new radicals (X·) derived from the anions in question:

$$OH\cdot + X^- \rightarrow OH^- + X\cdot$$

In polymerization experiments in such systems, the occurrence of the above type of radical transfer reactions may easily be traced by the analysis of the polymer endgroups. The present paper will report the results of our investigation of such reactions involving halide (F^-, Cl^- and Br^-) and oxalate ions with OH· radicals in aqueous media, based on the analysis of the endgroup of the polymethylmethacrylate prepared in such systems.

Experimental

The aqueous polymerization of purified methylmethacrylate (MMA) was carried out in Pyrex flasks under a nitrogen atmosphere at room temperature; it was initiated by OH radicals derived either by the photolysis of H_2O_2 in ultraviolet light or by redox reaction with Fe^{2+} ions in the dark. Sodium fluoride, potassium chloride and potassium bromide were separately added at varied concentrations in the polymerization media. The PMMA samples obtained after the completion of polymerization were filtered, washed, and then dried in an air oven at 45°C.

The polymers were then heated with pyridine in sealed tubes in order to transform any halogen atom endgroups presumably incorporated in them to quaternary pyridinium halide endgroups. The quaternised polymers were then properly purified of pyridine and dried. Tests for halogen in the polymers were then carried out by the dye-partition technique, using an aqueous disulfine blue reagent. Quantitative analysis was carried out spectrophotometrically.[1] The determination of the carboxyl endgroup in polymers obtained in the presence of oxalate ions was carried out by the dye interaction test using a Rhodamine reagent.[2]

Results and Discussion

The hydrogen peroxide-initiated polymerization of MMA in the presence of the halide salts in aqueous media proceeds with certain characteristics, the polymers being obtained in a coarse precipitated form. The increase in the salt concentration results in an increase in the induction period, probably due to some replacement of the active OH· radicals by the less active halogen atoms according to the above reaction. The increase in salt concentration also leads to an appreciable decrease in the yield of the polymer. No polymerization occurs in the presence of potassium iodide, probably because of the fast oxidation of the iodide ion by the active OH· radicals with the liberation of iodine, which acts as a strong inhibitor. The general features of polymerization in the presence of oxalate ion in aqueous media are more or less the same as in presence of F^-, Cl^- or Br^- ions.

The polymers obtained with the use of H_2O_2 as the initiator in aqueous media have been found, by the application of the sensitive dye technique,[3] to bear an OH endgroup only to the extent of about 1 per chain. However, when prepared in the presence of the halide ions (F^- Cl^- and Br^-), they also give a positive response to the dye partition

test with aqueous disulfine blue reagents for halogen atom endgroups (transformed to quaternary halide groups) (Table I). For quantitative purposes, it is assumed that the different pyridinium halides (fluoride, chloride and bromide) groups are all equally responsive to the appropriate dye test; the spectrophotometric determinations are based on a comparison of the experimental optical density values with the same calibration curve of a particular model compound. There is, of course, some uncertainty about the quantitative values for halogen contents in the polymers, as these are highly contingent upon the very slow and sluggish process of quaternisation,[4,5] which is slower and more sluggish than usual in the present case as the concentration of halogens, (appearing only at chain ends) in the polymer is extermely low. The process of quaternisation may be completed to varying extents in different samples. Due to these limitations, a proper order in halogen content in the polymers as determined from any consideration is probably far from expectation; in fact, none is realised by our experiments. However, qualitatively the dye techniques employed for the endgroup characterisation of the polymers obtained

in the present set of experiments give a simple and sound demonstration of the radical transfer reaction between OH· radicals and F^-, Cl^- and Br^- ions in aqueous media.

It is known that chloride ions inhibit the reactions of OH· radicals, and this can be explained on the basis of radical ion transfer reaction under discussion.[6-9] Expectedly, the effect is greater with bromide ion. However, with fluoride ions with a very high affinity for electrons, a similar effect appears to be much less favoured,[10] if not improbable. A fairly positive test for fluorine-atom endgroups in polymers prepared in the presence of fluoride ions indicates, however, the occurrence of the electron transfer reaction between the OH· radical and the F^- ion.

Much as hadide ions, oxalate ions also take part in electron transfer reaction with OH· radicals; this is clearly indicated by the presence of carboxyl endgroups in the respective polymers (Table II). The generation of carboxyl radicals probably occurs by means of the following mechanism:

$$\mathrm{OH\cdot} + \begin{matrix}\mathrm{COO^-}\\ |\\ \mathrm{COO^-}\end{matrix} \rightarrow \begin{matrix}\mathrm{COO\cdot}\\ |\\ \mathrm{COO^-}\end{matrix} + \mathrm{OH^-}$$

$$\downarrow$$

$$\mathrm{CO_2} + \mathrm{\dot{C}OO^-}$$

The Copolymerization of Trimethylethylene and Tetramethylethylene with Maleic Anhydride*

By Shunsuke MURAHASHI, and Shun'ichi NOZAKURA

Department of Polymer Science, Faculty of Science, Osaka University, Toyonaka, Osaka

and Katsutoshi YASUFUKU

Institute of Physical & Chemical Research, Bunkyo-ku, Tokyo

(Received October 11, 1965)

In a previous paper,[1] it was reported that *cis*-butene-2 was more reactive than the *trans*-isomer in the copolymerization with maleic anhydride (MAn). We wish now to report the copolymerization behavior of trimethylethylene and tetramethylethylene with MAn in comparison with that of butene-2. Trimethylethylene was readily copolymerized with MAn to give a copolymer with a relatively high molecular weight, whereas tetramethylethylene gave practically no copolymer with MAn.

Momoners were copolymerized at 60°C in benzene in the presence of 2, 2'-azobisisobutyronitrile as an initiator. Conversions were less than 5% in all cases. Copolymers were purified by repeated reprecipitation from an acetone solution with dry ether. The copolymer compositions were calculated from the analysis with correction for absorbed water. Specific viscosities were measured in acetone at 30°C, using an Ostwald viscometer. The results are shown in Fig. 1.

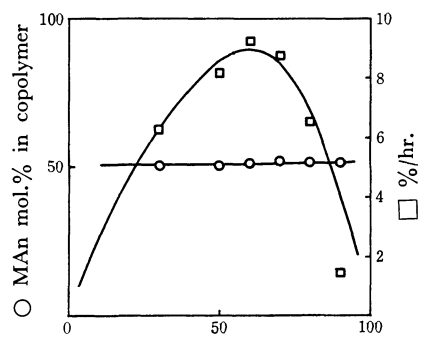

Fig. 1. Copolymerization of trimethylethylene (M_2) with MAn (M_1). $[M_1+M_2]=2.0$ mol./l., [AIBN]=0.01 mol./l. in benzene at 60°C.

The resulting copolymers of trimethylethylene with MAn were found to have a 1 : 1 molar composition and almost identical specific viscosities (0.14—0.18, $c=0.3$ g./dl.), independent of the monomer compositions. It was observed that

	0.8	0.08	185—190	0.016±0.005
	0.6	0.07	175—185	0.030±0.009
	10.0	0.18	245—250	0.005±0.002
	0	—	~150	—

* $c=0.3$ g./dl.

the rate of copolymerization reached a maximum value at the monomer composition of about 60 mol.% of MAn. A distinct yellow coloration was observed on mixing tetramethylethylene with MAn, suggesting the formation of a charge transfer complex between monomers. However, this system did not give an appreciable amount of copolymer by the usual procedure. A very slow polymerization was recognized from the facts that a slight volume contraction was observed in a dilatometric measurement and that a trace of colored noncrystalline powder (soft. p. ~150°C) was obtained by the careful treatment of the contents of the dilatometer.

Table I gives a comparison of the copolymerization behavior of trimethylethylene, tetramethylethylene, *cis*- and *trans*-butene-2[1] with MAn under similar conditions. Trimethylethylene, in comparison with butenes, copolymerized with a higher rate and with a greater tendency to alternation with MAn, yielding copolymers of higher specific viscosities. This result was rather unexpected, but it was rationalized as follows. The higher reactivity of trimethylethylene compared with butene-2 may be due to the increase in the electron density of the C=C double bond by the substitution of one more methyl group, since the MAn radical is partially positive in character. Also, the increase in the resonance stability of the resulting radical might have contributed to the reactivity. The increase in steric hindrance due to the additional methyl group might not play a significant role in this case.

The introduction of the fourth methyl group resulted in a further increase in the electron density, as is shown in the yellow coloration of a charge transfer complex. The low reactivity of tetramethylethylene, however, suggests the overwhelming effect of the steric inhibition of four methyl groups. Similar behavior of the multi-substituted ethylenes had been found in the copolymerizations of chlorinated ethylenes with various monomers.[2]

T-E_γ Charts of Short-Lived Nuclides Formed by Neutron Activation

By Minoru OKADA*

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received October 11, 1965)

Whenever γ-active radionuclides formed by nuclear-reactor exposure are dealt with, it is useful to identify the nuclides by using a chart in which the half-life, T, is plotted against the γ-ray energy, E_γ. For the half-life range from 36 sec. to 10^4 hr., T-E_γ charts have been made by Westermark and Sjöstrand.[1] Recently, however, nuclides with shorter half-lives have become familiar in rapid radioactivation analysis. Therefore, a T-E_γ chart for shorter half-lives is needed. Since neutrons in nuclear reactors exhibit an extremely broad energy range, from zero to at least 15 MeV.,[2] various types of neutron reactions are likely to occur simultaneously. The charts presented here include the nuclides formed by these reactions.

The data have been taken from the table of the "Short-Lived Nuclides"[3]. The reactions considered are: (n, γ), (n, n'), (γ, γ'), (n, p), (n, α), $(n, 2n)$, (γ, n), $(n, n'\alpha)$, (n, pn), (n, t), $(n, {}^3\mathrm{He})$ and $(n, 2p)$. The charts show nuclides formed from naturally-occurring elements; they do not include the following:

(a) Nuclides formed by secondary nuclear reactions, e. g., $^{28}\mathrm{Al}(t, p)^{28}\mathrm{Mg}$ with lithium present.

(b) Nuclides formed by multiple neutron capture.

(c) Fission products.

Annihilation radiations are included in the charts unless they are very weak. X-rays are omitted. Whenever possible, the most intense γ-ray has been especially labeled in the charts.

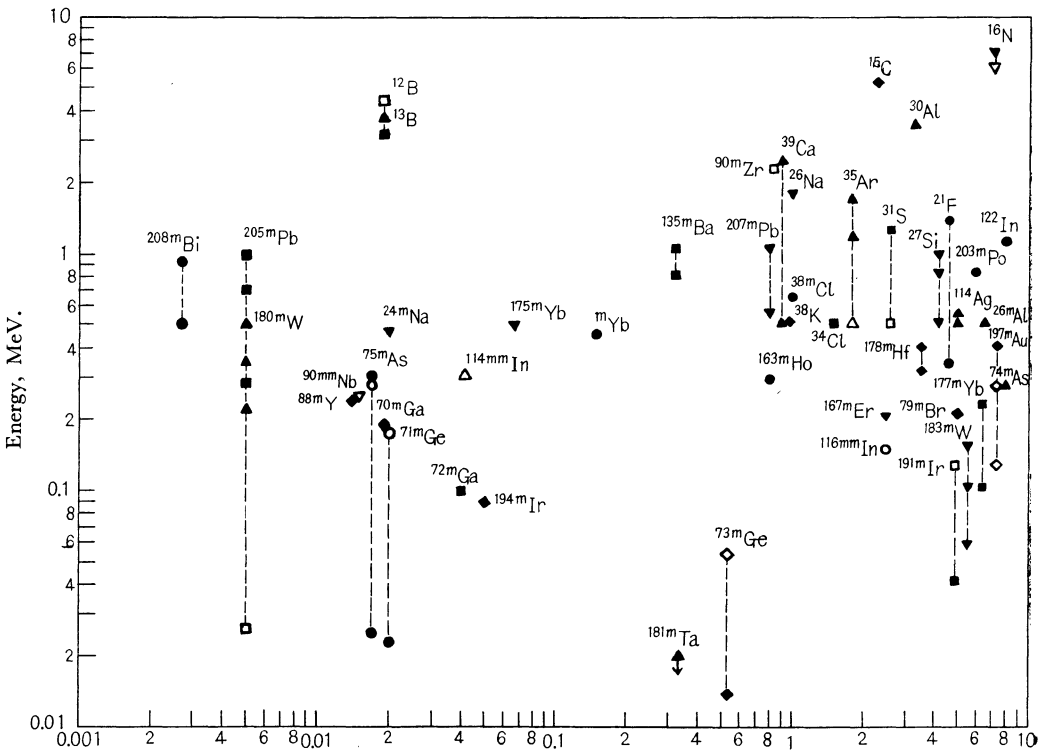

Fig. 1. T-E_γ chart No. I covering half-lives of 0.001—10 sec. The most intense γ-rays are labeled with open circles, open triangles, etc. If several γ-rays are emitted from the same nuclide, dots connect the corresponding points. Arrow in the charts shows that the true value should appear on the direction but only a limit is known.

The Reaction of Benzenediazonium-2-carboxylate with Acrylonitrile and Ethyl Acrylate

By Tsutomu MATSUDA and Tetsuo MITSUYASU

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

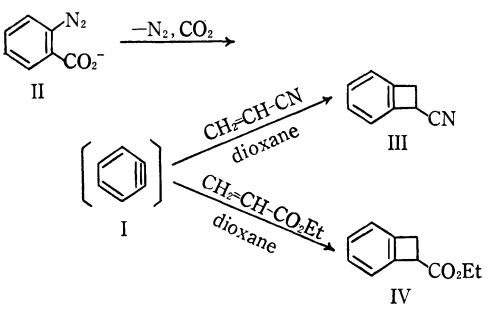
(Received October 23, 1965)

Stiles et al.[1] have reported a new route for obtaining the benzyne intermediate (I) by the thermal decomposition of benzenediazonium-2-carboxylate (II); they confirmed its formation by studying a Diels-Alder reaction with furan and anthracene. This procedure to obtain I has several advantages over the method usually adopted, in which aryl halides are reacted with strong bases, alkali metals or organometallic compounds in the presence of appropriate substrates. First, I can be allowed to react in situ with the compounds which have functional groups that are sensitive to strong bases or organometallic reagents. Second, the reaction may be carried out in various solvent.

In the course of our study of the chemical behavior of I in this route, we found that 1, 2-cycloaddition of I, with acrylonitrile and ethyl acrylate, proceeded to give benzocyclobutene derivatives under some conditions.

Stiles et al. carried out their experiment on I in non-polar solvents, such as benzene or furan. However, the reaction of II with either acrylonitrile or ethyl acrylate at 50—60°C for 6 hr. resulted in excessive polymerization, and no other isolable product was obtained. In view of the salt-like nature of II, we felt that the use of some polar solvent in place of a non-polar solvent would give rise to a better result. Although dimethylformamide and II, when treated at 55—60°C for 6 hr., afforded salicylaldehyde in a 18% yield[2] (as identified by a study of its infrared spectrum and that of its semicarbazone), dioxane was found to be a favorable solvent. Thus, the reaction of II and furan in dioxane at 50—55°C for 13 hr. gave a 65% yield of 1, 4-dihydronaphthalene-1, 4-endoxide, m. p. 55.5—56.1°C (lit.[1] 55.2—56.2°C). A comparable yield was, therefore, attained in a much shorter reaction time than that reported by Stiles et al. The following experiments were, then, all carried out in dioxane.

A suspension of 10.9 g. of freshly-prepared II in a mixture of 5.74 g. of acrylonitrile and 150 ml. of dioxane was stirred under nitrogen at 50—55°C



for 6 hr. After the dioxane and acrylonitrile had been distilled off under a vacuum, the flash distillation of the residue gave a yellow liquid, b. p. 48—86°C/0.6 mmHg; 1.92 g. (20%). The redistilled product, b. p. 54—55°C/0.3 mmHg; n_D^{26} 1.5442, which was found to be pure by gas chromatographic analysis, showed a C=N stretching band at 2250 cm^{-1}, and both its ultraviolet absorption and its NMR spectrum [(p. p. m. from TMS and relative areas), 7.14 (4.3), 4.09 (1.0): quartet, and 3.45 (1.9): triplet], were found to be consistent with the structure of 1-cyano benzocyclobutene (III). Further proof of the structure was obtained by the hydrolysis of the nitrile to the carboxyamide, m. p. 155.1—155.6°C (lit.[3] 155—156°C) and to the carboxylic acid, m. p. 74.8—75.4°C (lit.[3] 74.0—75.5°C).

In nearly the same procedure, the reaction of II, 2.09 g., and freshly-distilled ethyl acrylate, 2.0 g., in 50 ml. of dioxane at 50—55°C for 6 hr. gave a raw product, b. p. 82—108°C/3.5 mmHg; 0.25 g. (8%), and a considerable amount of a residue. The separation of the main constituent (90%) of the product by the gas chromatographic method gave nearly pure ethyl benzocyclobutene-1-carboxylate (IV); its identity was confirmed by a comparison of its infrared specturm with that of the authentic ester, prepared by the esterification of benzocyclobutene-1-carboxylic acid.

The reaction of II with maleic anhydride in dioxane was examined, but phenol was the only product identified.

Organic Sulfur Compounds. VII. The Reaction of Methyl *p*-Toluenesulfinate-[sulfinyl-^{18}O] with Phenylmagnesium Bromide

By Michio KOBAYASHI* and Miki TERAO

Department of Chemistry, Yokohama City University, Mutsuura-machi, Kanazawa-ku, Yokohama

(Received November 1, 1965)

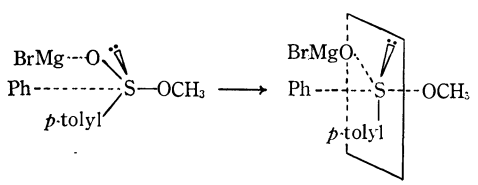
The formation of sulfoxides from the sulfinic esters and Grignard reagents has been long known.[1] Recently this method has been utilized for the preparation of the optically active sulfoxides from *l*-menthyl sulfinates and Grignard reagents.[2] Since the configuration of the resulted sulfoxide is opposite to that of the starting sulfinate ester, this reaction has been considered to proceed by a S_N2 type nucleophilic attack on the sulfur atom, with an inversion and displacement of the alkoxide anion[3]:

$$R\text{-}\underset{\underset{O}{\downarrow}}{S}\text{-}OR' + R''MgBr \rightarrow R\text{-}\underset{\underset{O}{\downarrow}}{\overset{\overset{R''}{|}}{S}} + R'OMgBr \quad (1)$$

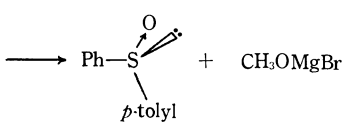
However, it has not yet been experimentally established which oxygen atom of the sulfinate ester is replaced. This point should be clarified by an examination of the reaction of a Grignard reagent with sulfinate ester-[sulfinyl-^{18}O].

Methyl *p*-toluenesulfinate-[sulfinyl-^{18}O], prepared by the reaction of sodium *p*-toluenesulfinate-^{18}O and ethyl chlorocarbonate in methanol,[4] was therefore treated with phenylmagnesium bromide to give phenyl *p*-tolyl sulfoxide. The excess atom percentage of ^{18}O of this sulfoxide was found to be exactly twice that of the starting methyl sulfinate. This fact can best be explained by postulating the retention of the sulfinyl oxygen atom of the methyl ester in the sulfoxide formed.

The above result is consistent with the currently accepted S_N2 mechanism which may be depicted thus:

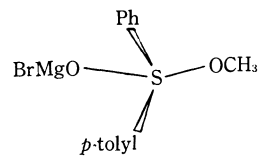


(transition state)



(2)

On the other hand, the coordination of the bromomagnesium cation with the sulfinyl oxygen atom of the ester could result in the formation of the sulfonium cation, in which a lone pair electron may enter the 3s orbital and in which three 3p orbitals are available for the formation of three single bonds. The attack of the anionoid phenyl group on the sulfur atom of this cation may occur from the unhindered open side, to give a tetrahedral intermediate (I) using a 3d orbital:



(I)

Similar tetrahedral intermediates with a lone pair in a 3s orbital have been postulated in the reaction of triphenylsulfonium bromide with phenyllithium or *n*-butyllithium.[5]

The elimination of a methoxide anion from I would lead to the sulfoxide with an inverted configuration. Therefore, both the above experimental results and the asymmetric syntheses in the literature can be explained by either the S_N2 mechanism or the tetrahedral intermediate mechanism. The S_N2 mechanism seems to be most plausible in the analogous ester exchange reaction of the sulfinate esters,[6] but in those cases the formation of the sulfonium cation, in which the positive charge on the sulfur atom could cause the $3p^3$ electronic structure discussed above, is impossible.

Experimental

Methyl *p*-Toluenesulfinate-[sulfinyl-^{18}O]. — Prepared from sodium *p*-toluenesulfinate-^{18}O and ethyl

chlorocarbonate in methanol.[4] The ^{18}O atom percentage of this ester was 0.41%.

Phenyl *p*-Tolyl Sulfoxide-^{18}O.—A Grignard reagent prepared from 5.0 g. of bromobenzene and 0.8 g. of magnesium in 20 ml. of ether was added, drop by drop to 2.0 g. of methyl *p*-toluenesulfinate-^{18}O in 30 ml. of benzene. An excess of 3 N hydrochloric acid was then added to the reaction mixture to dissolve the white precipitate, and the organic layer was separated, washed with alkali and water, and dried over magnesium sulfate. The solvent was evaporated, and the oily residue was dissolved in warm petroleum ether and kept overnight. The colorless crystals of sulfoxide which separated were purified by elution chromatography over alumina with benzene to give an analytical sample. The atom percentage of ^{18}O in this product was 0.62%. The calculated ^{18}O atom%, based on the assumption of a reaction of the sulfinyl oxygen of the ester, is 0.61%.

The Electrical Conduction of Organic Dye Complex Salt between Cationic and Anionic Dyes*

By Shigekazu KUSABAYASHI,** Akimasa TANIGUCHI and Hiroshi MIKAWA**

The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received November 8, 1965)

Many investigations have been made into the semiconducting properties of organic dyes. All classes of the dyes—cationic, anionic or non-ionic—exhibit a small conductivity in the dark. In all these ionic dyes but oxalate, the anion of the cationic dye and the cation of the anionic dye consist of inorganic ions. Concerning the cationic dyes with the triphenylmethane structure, Nelson reports that the dark conductivity is greatly changed by a change of anion.[1]

It is supposed that cationic and anionic dyes together make a salt which is composed of organic cations and organic anions, many combinations of the two dye ions being possible. The present paper will deal with the dark conductivity of some organic dye complex salts.

Experimental

Material.—Malachite green, crystal violet and methylene blue were selected as the cationic dyes, and eosine Y, erythrosine, rose bengal and acid rhodamine were selected as the anionic dyes. All the dyes except erythrosine were recrystallized three times; erythrosine was purified by repeated precipitations.

Organic dye complex salts were prepared by dissolving both component dyes in water at room temperature. To take the dye complex salt between malachite green and eosine as an example, it was prepared as follows. A 2/100 molar aqueous solution of malachite green and a 1/100 molar aqueous solution of eosine are stirred together, and then stirring is continued for another hour. The crystalline product thus obtained is washed with water until the washed water is almost colorless, and recrystallized twice from alcohol. Organic dye complex salts obtained in the same way are tabulated in Table I.

Measurement. — The electrical resistivity was measured on a compressed disk made under 5 t/cm^2 in a vacuum, with silver electrodes by the DC method.

Results and Discussion

The mole ratio between the components of the dye complex salts, as calculated from the carbon percentage, does not always agree with the theoretical composition anticipated from the chemical structures of the component dyes. However, the composition of the dye complex salts is supposed to be as shown in the first column of Table I. Seyewetz[2] and Pelet-Jolivet[3] have reported that a 2 mol. portion of fuchsine combines with 1 mol. of eosine or erythrosine, and also that methylene blue makes a product of a definite composition with eosine.

The absorption sepctra of complex salts were measured in an alcohol solution. Generally, the wavelengths of the absorption peaks were nearly identical with those of the components.

Some absorption spectra of the solid film were also measured. Of these, the absorption spectrum of $(MB)_2(RB)$ is shown in Fig. 1; it is quite different from that of a solution. Its longest-wavelength absorption band is split into two bands in spite of the fact that no splitting is found in the solid absorptions of the two component dyes.

Electrical Property.—The relation between the current and the applied voltage obeyed Ohm's

law. In $(CV)_2(RB)$, for example, the relation obeyed Ohm's law up to 3460 V./cm. at least. In (MG)(AR), however, the current is proportional to the voltage to the power of 1.5. The resistivity at 20°C (ρ_{20}) and the band gap energy (ε), as calculated from the temperature dependence of the resistivity by the equation $\rho=\rho_0\exp(\varepsilon/2kT)$, are tabulated in Table I. The values of the resistivity and the band gap energy for dye complex salts fall in the 10^9—10^{15} Ωcm. and 1.1—2.3 eV. ranges respectively. The values of ρ_{20} and ε change with the change in the partner ion in dye complex salt. Generally the complex salts of methylene blue have low values in ρ_{20} and ε.

The authors wish to express their thanks to Mr. Tsuneyo Shishido for his elementary analyses.

SHORT COMMUNICATIONS

Lithium Aluminum Oxyfluoride Spinel

By Hiroaki YANAGIDA, Goro YAMAGUCHI and Yuzo ONO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received March 7, 1966)

Kordes[1] obtained a spinel-like mineral from a mixture of lithium fluoride and aluminum oxide by heating it to 1300°C. He supposed that a $LiF\text{-}Al_2O_3$ spinel form exists. However, he determined the mineral obtained at 1300°C to be $Li_2O\text{-}5Al_2O_3$, which did not contain fluorine; he did not mention the composition of the products at lower temperatures further. All of the spinel structures previously investigated contain only oxygen or sulfur as an anion, except for the aluminum oxynitride spinel, $AlN\text{-}Al_2O_3$, investigated by Yamaguchi and Yanagida[2] and by Adams, AuCoin and Wolff.[3] It may be supposed, from a consideration of the ionic radii, that there exists a spinel form, $LiF\text{-}Al_2O_3$, which contains fluorine as an anion, in comparison with $MgO\text{-}Al_2O_3$ or $AlN\text{-}Al_2O_3$.

TABLE I. DIFFERENCES BETWEEN THE TWO SPINELS

	I $Li_2O\cdot 5Al_2O_3$	II The spinel obtained from $LiF\text{-}Al_2O_3$
Starting materials	Li_2CO_3 + $\gamma\text{-}Al_2O_3\cdot 3H_2O$	LiF 40 mol.%-$\gamma\text{-}Al_2O_3\cdot 3H_2O$
Temp.	>900°C	800—900°C
Lattice dimention	$a=7.906$ Å	$a=7.922$Å
Super lattice peaks		
(2,1,1)	12.7	—
(2,1,0)	16.5	4.4
(1,1,0)	11.6	4.0
F content by NMR	none	present at least 11%

Mixtures of fine-grained $\gamma\text{-}Al_2O_3\text{-}3H_2O$ or $\alpha\text{-}Al_2O_3$ and chemically pure lithium fluoride or lithium carbonate were heated at 600—1200°C for 0.5—3 hr. in an electric furnace in air. The products were then washed with hydrochloric acid to eliminate a trace of contamination by lithium fluoride and were analyzed by powder X-ray diffraction.

The single spinel phase was formed from the mixtures of lithium fluoride (35—40 mol. percent) and $\gamma\text{-}Al_2O_3\text{-}3H_2O$ (60—65 mol. percent) heated at 800—900°C for more than an hour. This spinel phase was then compared with the lithium aluminum oxide spinel, $Li_2O\text{-}5Al_2O_3$ (denoted as I in Table I). The cubic lattice dimensions, the intensity ratios of such super lattice lines[4] as (2, 1, 1), (2, 1, 0), (1, 1, 0) to a normal line (3, 1, 1), are distinctly different in the two spinels. This shows that the II spinel in Table I is to be distinguished from the I spinel.

The semi-quantitative analysis of fluorine was carried out by broad-line NMR using a mixture of AlF_3 and $\alpha\text{-}Al_2O_3$ as a reference. It was ascertained that the II spinel contained more than 11 percent fluorine, which corresponded to about 70 percent of the value calculated from the $LiF\text{-}Al_2O_3$ formula.

Thus, it is suggested that the II spinel obtained in the present work may either be in a spinel formula, $LiF\text{-}(1+x)Al_2O_3$, or in a solid solution of $LiF\text{-}Al_2O_3$ and $Li_2O\text{-}5Al_2O_3$. The true formula will be determined after an exact quantitative analysis of fluorine, which is now being attempted by the present authors using different methods.

Molecular and Intramolecular Relaxation in Several Biphenyls

By N. K. MEHROTRA and M. C. SAXENA

Physics Department, Lucknow University, Lucknow, India

(Received February 7, 1966)

The relaxation times of some biphenyls have been determined in the 3 cm. microwave region at a temperature of 20°C, using benzene as the solvent. It has been concluded from the smaller values of the relaxation time that the molecules are relaxed by both molecular and intramolecular rotations.

DiCarlo and Smyth[1] have determined the relaxation times of diphenyl sulphide, diphenyl methane and triphenyl amine. Kalman and Smyth[2] have investigated 4-bromobiphenyl in making a study of its dielectric dispersion. However, apparently no attempt has yet been made to study the mechanism of intramolecular rotation in the many biphenyls with different dipole-bearing groups. The aim of the present investigation is to get an idea about the nature of the molecular unit responsible for group rotation in *o*-aminobiphenyl, *p*-aminobiphenyl and 3, 5-dinitro-2-hydroxybiphenyl.

The free energies of the activation for dipole orientation and viscous flow have been calculated at the same temperature, using Eyring's[3] relations and estimated values of the constants A and B.

The relaxation times are determined by means of the fixed frequency method of Gopala Krishna.[4] The standing-wave technique of Von Hippel and Roberts[5] has been used for the measurements of the dielectric constant, ε', and the loss factor, ε''.

All the substances used were of pure quality L. R. grade and were obtained from the British Drug House. The purest-quality benzene obtained from the British Drug House was distilled before use.

The observed values of the relaxation time, along with the values of the activation energy, are given in Table I.

It may be seen from Table I that the relaxation time of *o*-aminobiphenyl is greater than that of *p*-aminobiphenyl, although the size of the two molecules is the same. This difference in the relaxation time can be explained by considering intramolecular group rotation. The polar $-NH_2$ group, which is capable of rotation round its bond with the ring, experiences a greater steric hindrance to rotation at the ortho position than at the para position. Further, however, while the molar volumes of the two molecules may be approximately same, the volumes swept out for dipole orientation by the two molecules must be different.

The relaxation time of 3, 5-dinitro-2-hydroxybiphenyl is found to be greater than those of *o*-amino- and *p*-aminobiphenyls. This may be due to the fact that there is a greater steric hindrance to the rotation of the –OH group at the position 2 due to the presence of a $-NO_2$ group at the position 3. Further, the observed larger value of relaxation time is in accordance with the bigger size of the molecule due to the presence of two nitro groups.

It may, therefore, be concluded from the rotations of the $-NH_2$ and –OH groups that the molecules are relaxed predominantly by the process of intramolecular rotations, resulting in a decrease in the observed relaxation time.

The value of the free energy of activation for *o*-aminobiphenyl has been found to be greater than that of *p*-aminobiphenyl, suggesting that the inner friction experienced by the former molecule is greater than that of the latter.

The free energies of activation for a viscous flow (H_η) are always found to be greater than those for the dielectric relaxation (H_τ). This is in conformity with the finding of Franklin and his coworkers[6] that H_τ and H_η are nearly equal only in the case of low viscosity solvents. A similar result was also obtained by Ahmad and Sharma[7] in the case of solutions of nitrotoluenes and *o*-chlorotoluene in cyclohexane.

TABLE I. VALUES OF THE RELAXATION TIME (τ) AND THE FREE ENERGIES OF ACTIVATION FOR DIPOLE ORIENTATION AND VISCOUS FLOW

Compound	$\tau \times 10^{12}$ sec.	H_τ kcal./mol.	H_η kcal./mol.	H_η/H_τ
(1) *o*-Amino-biphenyl	7.47	2.23	2.90	1.30
(2) *p*-Amino-biphenyl	6.64	2.16	2.90	1.34
(3) 3, 5-dinitro-2-hydroxy-biphenyl	9.96	2.39	2.90	1.21

The Temperature Dependence of the Absorption Spectra of Wurster's Blue-type Ion Radicals

By Ko UEMURA, Shigeki NAKAYAMA, Yukiko SEO, Keisuke SUZUKI and Yuzuru OOSHIKA

Faculty of Science, Kwansei Gakuin University, Nishinomiya

(Received March 12, 1966)

Hausser and Murrell[1] suggested dimer formation in Wurster's Blue solution and assigned the 12000 cm^{-1} band appearing at the temperature of liquid nitrogen to a charge-transfer absorption. We ourselves have previously studied the absorption spectra of *p*-phenylenediamine bromide (I), *N*, *N*-dimethyl-*p*-phenylenediamine (Wurster's Red) perchlorate (II), and *N*, *N*, *N'*, *N'*-tetramethyl-*p*-phenylenediamine (Wurster's Blue) perchlorate solutions (III).[2,3]

The spectra of solutions and solids of I and III are shown in Figs. 1 and 2, respectively. The

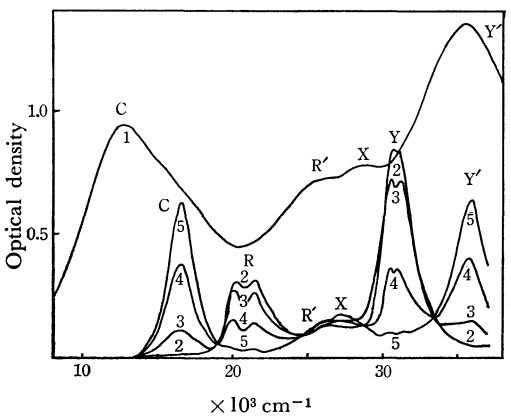

Fig. 1. Spectra of *p*-phenylenediamine radicals. Curve 1: solid (22°C), 2: solution (22°C), 3: solution (−78°C), 4: solution (−99°C), 5; solution (−129°C). Stoichiometric concentration ca. 4×10^{-5} mol./l. Optical path length 1.00 cm. Volume changes of the cell and the solution by cooling were calibrated.

spectra of II are very similar to those of I except for a slight red shift. The concentration dependence of the intensities of the above three compounds can be interpreted as due to the $2R^{+}+X^{-}\rightleftarrows(R_2X)^{+}$ equilibrium, assuming that the R and Y bands are to be attributed to the monomer, and R', Y', and C, to the dimer. The heats of dimerization are approximately 8, 10, and 5 kcal./mol. for I, II, and III, respectively. The weak binding in III is probably due to the increased steric repulsion between the methyl groups. The similarity of the solid

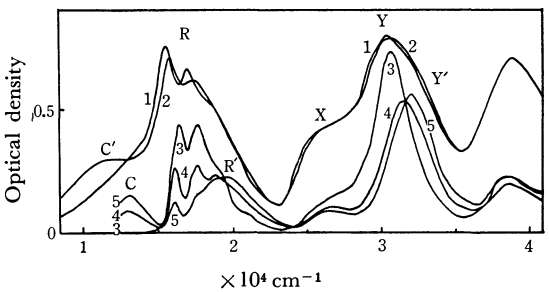

Fig. 2. Spectra of Wurster's Blue. Curve 1: solid (22°C), 2: solid (−196°C), 3: solution (22°C), 4: solution (−149°C), 5: solution (−160°C). Stoichiometric concentration of the solution: 7.58×10^{-5} mol./l. Solvent: ether-alcohol (1 : 2). Optical path length: 0.50 cm. Volume changes of the cell and the solution by cooling were calibrated.

spectra of I and II to those of the dimer suggests that the radicals exist as dimers in the solids; this is in accordance with ESR studies in this laboratory. The spectra of the solid of III at room temperature resemble those of the monomer, but this does not necessarily mean that the spectra are to be attributed to the monomer, for the main features of the spectra are preserved at low temperatures, where a weak charge-transfer band, C', is observed. Two types of models have been proposed for the low temperature solid of III, i. e., the doublet$\rightleftarrows$singlet[1] and singlet$\rightleftarrows$triplet[4] models. The concentration of the singlet dimer at the nitrogen temperature estimated from the magnetic susceptibility[5] is larger than 85%. The contradiction between the spectroscopic and magnetic data may be eliminated by assuming that the dimers are so loosely bound that the electronic states of the radicals are only slightly perturbed by the dimerization. This "loosely bound" model explains that the low temperature solid spectra are similar to the monomer spectra accompanied by a weak charge-transfer band.[6]

A detailed report will be published later elsewhere.

6) Boyd and Phillips recently obtained solution spectra of TCNQ anion radical and analyzed their results by assuming the simple dimerization equilibrium. Their heat of dimerization is of the same order of magnitude with those of II and III (*J. Chem. Phys.*, **43**, 2927 (1965)).

Hydrazine Formation in the γ-Radiolysis of an Aqueous Solution of Ammonia

By Akihisa SAKUMOTO

Tokai Research Establishment, Japan Atomic Energy Research Institute, Tokai, Ibaraki-ken

(Received March 15, 1966)

The effect of additives on the γ-radiolysis of liquid ammonia has been studied by only a few investigators.[1,2] In the present work, the hydrazine formation in the γ-radiolysis of a mixture of liquid ammonia and water at a high-dose irradiation was studied. Hydrazine was determined by the Watt and Chrisp method.[3] Figure 1 shows the relationships between the yield of hydrazine and the concentration of ammonia at room temperature and at -50°C. At the irradiation temperature of -50°C, the yield of hydrazine increases gradually to a maximum value at about 85 mol. %, and then decreases with an increase in the concentration of ammonia. On the other hand, the maximum yield of hydrazine is obtained at about 50 mol. % of ammonia when irradiation is performed at room temperature. The yield of hydrazine at -50°C is larger than that at room temperature at 100 mol. % of ammonia. The dashed lines represent the yield of hydrazine which may be expected if the formation of hydrazine is unaffected by the presence of water.

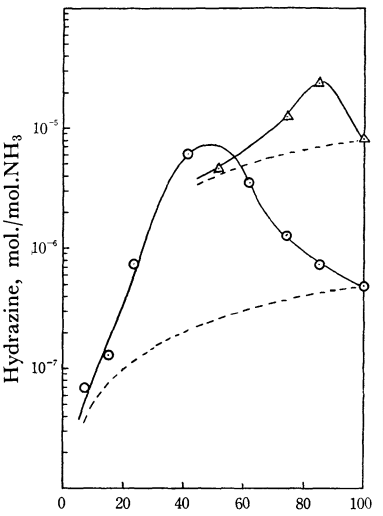

Fig. 1. Yield of hydrazine as a function of ammonia concentration at room temperature and at -50 ± 2°C when irradiated to a total dose of 9.15×10^6 r. at a dose rate of 4.5×10^4 r./hr.
○ Room temperature
△ -50 ± 2°C

As is shown in Fig. 1, the observed yields of hydrazine are larger than those to be expected from the molar fraction of ammonia and water. This indicates that the formation of hydrazine is influenced in some way by the interaction of ammonia with water. From the ionization potential[4] and the proton affinity[5] for ammonia, the proton transfer to ammonia may be expected to occur:

$$NH_3 + H_2O^+ \rightarrow NH_4^+ + OH \qquad (1)$$

though another possibility cannot be excluded:

$$NH_3 + H_3O^+ \rightarrow NH_4^+ + H_2O$$

The enhancement in the yield of hydrazine can be explained if the neutralization of NH_4^+ were to produce amino radicals as follows:

$$NH_4^+ + e^-_{amm}(\text{or } e^-_{aq}) \rightarrow \cdot NH_2 + H_2 \qquad (2)$$

$$\cdot NH_2 + \cdot NH_2 \rightarrow N_2H_4 \qquad (3)$$

On the basis of the above mechanism, we may say that the addition of ammonium ion would also contribute to the increment in the formation of hydrazine.

The details of this will be described elsewhere.

The Base-catalyzed Dimerization of 1, 4-Cyclohexadienes[1]

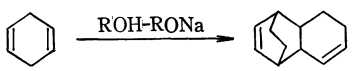
By Ken-ichi MORITA and Zennosuke SUZUKI

The Basic Research Laboratories, Toyo Rayon Company, Ltd., Kamakura

(Received March 15, 1966)

Hoffmann et al.[2] have reported that the treatment of 1, 4-cyclohexadiene (I) with *t*-butoxide in dimethylsulfoxide at 55°C gave a mixture of benzene and cyclohexene in a quantitative yield, while an analogous reaction in *t*-butyl alcohol as a solvent has afforded a mixture of I and 1,3-cyclohexadiene.[3] We now wish to report a base-catalyzed dimerization of 1, 4-cyclohexadinene derivatives in alcoholic solvents at an elevated temperature.

The reaction of 1, 4-cyclohexadiene (I) in alcoholic solvents such as methanol, ethylene glycol or *t*-amyl alcohol in the presence of a base such as potassium alkoxide, sodium alkoxide, potassium hydroxide or sodium hydroxide (10^{-1} to 10^{-3} mol.) at 200—230°C for 15 to 20 hr. afforded dicyclohexadiene (II),[4,8] b. p. 60—61°C/2 mmHg; n_D^{20} 1.5263, in 20 to 30% yields, and a mixture (60—70%) of benzene, cyclohexene and cyclohexadienes.



I II

An analogous base-catalyzed dimerization of dihydrotoluene[9] at 250—255°C for 17 hr. furnished a dimeric mixture of dihydrotoluene, b. p. 75—77°C/4 mmHg, in 20 to 25% yields. The treatment of 2-methoxy-1, 4-cyclohexadiene[9] (III) (7 g.) with 1 ml. of 10% potassium *t*-amyloxide (in *t*-amyl alcohol) in a glass ampoule[10] at 220°C for 24 hr. furnished a dimer V, $C_{14}H_{20}O_2$, (24%); b. p. 110—115°C/2 mmHg; $\nu_{C=C}^{film}$ 1669 cm^{-1}, 1-methoxy-1, 3-cyclohexadiene (IV) (19%), and a mixture (14%) of anisol, III, 1-methoxycyclohexene and benzene. Compound V was identical with a sample prepared in a 16% yield[12] (conversion) by the thermal dimerization of IV[11] at 200—220°C for 32 hr. An acid hydrolysis of V gave the keto ether VI, $C_{13}H_{18}O_2$, $\nu_{C=O}^{film}$ 1715, ν_{OMe}^{film} 1109 cm^{-1}; semicarbazone, m. p. 220—220.5°C decomp. The hydrogenation of VI over a palladium catalyst afforded VII, $C_{13}H_{20}O_2$; b. p. 135—137°C/2 mmHg, $\nu_{C=O}^{film}$ 1714 cm^{-1}, ν_{OMe}^{film} 1109 cm^{-1}. The reaction of pyrrolidyl enamine of 4-methoxybicyclo[2.2.2]octan-2-one (VIII)[14] with methyl vinyl ketone afforded IX., b. p. 145—147°C/1.4 mmHg; τ 6.85 (OMe); 4.37 (doublet, J= 2.5 c. p. s; a vinyl proton); $\nu_{C=O}^{film}$ 1665, $\nu_{C=C}^{film}$ 1632, ν_{OMe}^{film} 1102 cm^{-1}; semicarbazone, m. p. 204—205°C. The hydrogenation of IX over a palladium catalyst gave X, b. p. 135—136°C/2 mmHg, $\nu_{C=O}^{film}$ 1714 cm^{-1}, ν_{OMe}^{film} 1109 cm^{-1}; semicarbazone, m. p. 206—207°C (decomp.).[15] The infrared spectra of VII and X were similar, but some difference was noted in the fingerprint region.

2) J. E. Hoffmann, P. A. Argabright and A. Schriesheim, *Tetrahedron Letters*, **1964**, 1005.

3) Cf. R. B. Bates, R. H. Carnigham and C. E. Staples, *J. Am. Chem. Soc.*, **85**, 3032 (1963).

4) The identity was established by a comparison of the infrared spectra and the retention time of v. p. c. with those of a sample prepared according to the method of Kazanskii and Svirskaya,[5] who obtained dicyclohexadiene (II), b. p. 110—111°C/14mmHg; n_D^{20} 1.5269 in a 50% yield by the Diels-Alder dimerization of 1,3-cyclohexadiene. Since 1,4-cyclohexadiene (I) can readily be prepared from benzene,[6,7] the method described in this paper provides a convenient way to prepare II. It should be noted that a large amount of polymers have been obtained as by-products in the case of the thermal dimerization of 1,3-cyclohexadiene, whereas only a small amount of polymers were formed in the base-catalyzed dimerization of 1,4-cyclohexadiene.

5) B. A. Kazanskii and P. I. Svirskaya, *J. Gen. Chem., USSR*, **29**, 2550 (1959). See also K. Alder and G. Stein, *Ann.*, **496**, 197 (1932).

Reaction of Tropone with Cyclopentadiene

By Shô Itô,*1 Yutaka Fujise, Tomoko Okuda and Yoshiko Inoue

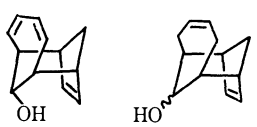
Department of Chemistry, Tohoku Uaiversity, Katahira-cho, Sendai

(Received March 30, 1966)

The Diels-Alder reaction of tropone was reported by Nozoe et al.[1] and the structure of the adduct with maleic anhydride was established. However, the nature of the product which results from the reaction of tropone as a dienophile has not been clarified, although a few reactions have been carried out.[2,3] We wish to present evidence for the structure of the adduct obtained from the reaction of tropone and cyclopentadiene; the reaction comprising the first example of a concerted 6+4 cycloaddition.[4]

Heating of tropone and cyclopentadiene at 80°C in benzene for 5 hr. yielded the 1 : 1 adduct I, m. p. 70—71.5°C (Found: C, 83.78; H, 6.98. Calcd. for $C_{12}H_{12}O$: C, 83.68; H, 7.02%. UV λ_{max}^{MeOH} 238 ($\varepsilon=2840$), 248 (3370), 257 (4520), 266 (4630), 300 mμ (480), IR ν_{max}^{KBr} 1715 cm^{-1}, MS *m/e*: 172 (M^+), 107 (base peak), 78, 66, 39. 2, 4-DNP., 185°C (decomp.) (Found: C, 61.32; H, 4.75. Calcd. for $C_{18}H_{16}O_4N_4$: C, 61.36; H, 4.58%. UV λ_{max}^{MeOH} 365 mμ ($\varepsilon=19100$)). These spectral observations confirm the molecular formula and indicate the presence of an isolated carbonyl group and a conjugated diene system. The NMR spectrum of I in benzene exhibited signals at 1.22 (1H, sextet, $J=11.3$, 4.8), 2.12 (1H, d. $J=11.0$), 2.54 (2H, br.s.), 3.03 (2H, m.), and 5.03—5.88 p. p. m. (6H, m.) supporting structure Ib or Ic rather than Ia.

Ia Ib Ic



II III

Although the reduction of I with sodium borohydride or sodium in ethanol failed to take place, reduction with lithium aluminum hydride in tetrahydrofuran yielded an alcohol II, m. p. 32.5—34.5°C (Found: C, 82.88; H, 7.99, Calcd. for $C_{12}H_{14}O$: C, 82.72; H, 8.10%. UV λ_{max}^{MeOH} 243 ($\varepsilon=4552$, sh.), 252(5720), 262(5668), 273 mμ (3173), IR ν^{KBr} 3490 cm^{-1}. NMR δ^{CDCl_3} 1.49 (1H, m.), 2.21 (1H, d. $J=10.4$), 2.74 (5H, br.m.), 3.90 (1H, br.), 5.83 (4H, m.), 6.21 p. p. m. (2H, br.s.)). From a comparison of the NMR spectra of I and II in deuterochloroform, it is apparent that the methylene protons in I are practically unaffected by the anisotropy of the carbonyl group, a finding in accord with structure Ib but not Ic; an appreciable shift of these protons would be expected in the latter. The fact that the protons on the isolated double bond absorb at appreciably higher field in the case of I (5.99 p. p. m.) than in the case of II (6.27 p.p.m.) is also in accord with structure Ib. Thus the structure Ib was concluded as the correct representation of the structure of I.

Reduction of I with sodium in *n*-butanol yielded the corresponding dihydroalcohol 3, m. p. 95—97°C (Found: C, 81.89; H, 9.10. Calcd. for $C_{12}H_{16}O$: C, 81.77; H, 9.15%) which showed only end absorption in its ultraviolet spectrum. NMR δ^{CDCl_3} 1.1—2.6 (11H, br. m.), 3.97 (1H, br.), 5.53 (2H, br.s.), 5.97 (2H, s.). The stereochemistry of the hydroxyl group in II is tentatively assigned by analogy with the cases of norbornyl derivatives.[5] The structure Ib assigned for the adduct is in agreement with the prediction[4] of Hoffmann and Woodward for concerted cycloaddition.*2

Magnetic Properties of Bis(imidazolato)copper(II)

By Motomichi INOUE, Michihiko KISHITA and Masaji KUBO

Department of Chemistry, Nagoya University, Chikusa, Nagoya

(Received April 7, 1966)

In a preceding paper,[1] we have reported that bis(imidazolato)copper(II) forms three modifications differing in their magnetic moments: a blue modification (1.57 Bohr magnetons), a green modification (1.62 B. M.), and a brown modification (1.46 B. M.). The subnormal magnetic moments suggest the existence of spin interaction between copper atoms in these modifications. In order to obtain further information, we have determined the temperature dependence of magnetic susceptibilities of these compounds.

The magnetic susceptibilities and the moments are shown in Figs. 1 and 2, respectively, as functions of temperature. The susceptibility of the blue modification obeys the Curie-Weiss law over a temperature range of 80—300°K. The Curie constant is 0.491 e. m. u. °K/mol. and the Weiss constant is −171°K. The magnetic behavior of the green modification conforms to the Curie-Weiss law above 170°K with a Curie constant of 0.460 and a Weiss constant of −118°K, but shows an appreciable deviation below 170°K. The broken curve in Fig. 1 was calculated assuming the validity of the Curie-Weiss law with the aforementioned parameters. The large Weiss constants indicate the existence of strong interaction between copper atoms through imidazole rings.

The brown modification definitely differs from other modifications in the magnetic behavior. Its magnetic susceptibility curve resembles the theoretical curve of isolated clusters,[2] but does not agree with Bleaney-Bowers' expression.[3] This fact suggests that in this modification a polymeric structure is involved rather than a binuclear structure.

The Indirect Gas Chromatographic Determination of Palladium in an Aqueous Solution

By Tadashi KOGA and Tadashi HARA

Department of Chemical Engineering, Faculty of Engineering, Doshisha University, Kyoto

(Received April 11, 1966)

In conventional gas chromatographic determinations of non-volatile substances, the constituents have always been converted into their volatile forms; therefore, metal ions have been converted into their β-diketone chelates.[1] Practical analyses of metal ions, however, require operations of several steps and involve serious problems, such as the interference of an excess chelating agent or solvent and decompositions of the metal chelates.

The present paper will offer a simple and indirect method for the determination of palladium ion in an aqueous solution. In this method a mixture of propylene and propane in a definite volume ratio is placed in contact with a perchloric acid solution containing palladium ions, and the resultant gas is analyzed by a gas chromatograph, using propane as an internal standard. Since the reaction between propylene and palladium ions proceeds quantitatively and very fast to form metallic palladium, a linear relationship is held in an acidic solution between the amounts of propylene and the palladium ions.

A mixture of propylene and propane in a 1 : 1 vol. ratio is stored in a balloon, and an aliquot of it is used for each experiment. In order to determine the amount of palladium, 1 ml. of the mixed gas is placed in the gas sampler A, and then A is connected, as is shown in Fig. 1, with the tube, B, in which a palladium solution has previously been charged. After the different ingredients have been in contact with one another at room temperature for some time, the gas is collected in A. The tube is removed and the gas is analyzed under the following conditions: 30 ml./min. of H_2 as the carrier gas; activated alumina as the stationary phase; a 0.4×225 cm. column (70°C), and a thermal coductivity cell as the detector. The relative retention volumes of propane and propylene are 162 and 300 ml. respectively. Up to 480 p. p. m. of palladium gives a straight line against the ratio of the peak area of propylene/propane (Fig. 2).

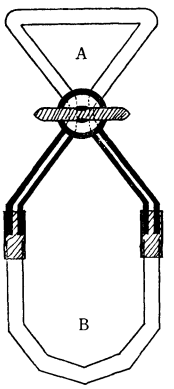

Fig. 1. Gas sampler and tube.
A: Gas sampler B: Tube

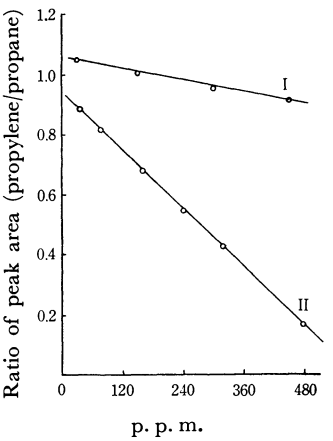

Fig. 2. Calibration curves.
I: Ag^+, II: Pd^{2+}.

The present method is not interfered with by platinum(II) copper(I) mercury(II), or nickel(II) ions which have d^8 or d^{10} electrons and which more or less show affinities for olefins, but it is slightly interfered with by a large amount of silver ions.

An analysis can be made in about 15 min.

A Novel Synthesis of 1, 4-Diketone

By Akira TAKEDA, Hiroyuki HOSISIMA, and Sigeru TORII

Department of Industrial Chemistry, School of Engineering, Okayama University, Tsushima, Okayama

(Received April 11, 1966)

Recently some new ways of preparing dihydrojasmone (I) have been reported in the literature.[1-4] One of the key routes to I is the cyclization of 2, 5-undecadione (II)[2,5,6] or its homologue[7], and so much attention has been paid to the preparation of this diketone (II). In this paper we will describe a synthesis of II via the ω-methylsulfinylmethyl ketone derivative (IV), which is obtainable by the reaction of ethyl γ-ethyleneketaldecanoate (III) with methylsulfinyl carbanion.[8]

The conversion of γ-ketodecanoic acid[9] to the ethyleneketal ester (III), b. p. 117°C/2 mmHg, n_D^{20} 1.4450. Found: C, 65.15; H, 9.99. Calcd. for $C_{14}H_{26}O_4$: C, 65.09; H, 10.14%, IR: 1730 (ester C=O), and 1180, 1140, 1095, and 1045 cm^{-1} (ketal), was carried out by boiling it with ethyl γ-ketodecanoate and ethylene glycol in the presence of *p*-toluenesulfonic acid.[4] The ketal ester (III) was treated with a solution of the methylsulfinyl carbanion (two equivalents) in dimethylsulfoxide-tetrahydrofuran at 0°C under nitrogen.[8] The β-ketosulfoxide (IV) thus produced boiled at 110—120°C/0.08 mmHg (partly isomerized) and gradually solidified, IR: 1705 (C=O) and 1040 cm^{-1} (S=O). The reduction of the crude IV with aluminum amalgam[8] in 90% tetrahydrofuran-10% water gave 5-ethyleneketal-2-undecanone (V), 40% (based on III); b. p. 110°C/2 mmHg, n_D^{20} 1.4648, IR: 1713 (C=O), 1170, 1145, 1100, and 1060 cm^{-1} (ketal). Found: C, 68.29; H, 10.32. Calcd. for $C_{13}H_{24}O_3$: C, 68.38; H, 10.59%. The ketal ketone (V), when heated with dilute acid for 2 hr., was converted into the diketone (II) in a good yield, b. p. 118—120°C/10 mmHg (lit.[5] b. p. 141°C/14 mmHg); IR: 1710 cm^{-1} (C=O). Further evidence for II was obtained by its cyclization to dihydrojasmone (I), whose structure was identified by means of the infrared and mixed-melting-point determination of the 2, 4-dinitrophenylhydrazone of I.[1]

During the course of reaction, the ketonic compounds were purified by using a Girard P reagent. The retention times of the intermediates were as follows (Hitachi F6-D, Chromosorb W (NAW), Silicone SE-30 column, 1 m. long, 0.7 atm. N_2, at 160°C): ethyl γ-ketodecanoate, 14 min.; the ketal ester (III), 38 min.; the ketal ketone (V), 19 min., and the diketone (II), 8 min.

The Photoinduced Isomerization of Anthrone to Anthranol

By Nobuaki KANAMARU and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Azabu, Tokyo

(Received May 12, 1966)

The photoinduced isomerization reaction from anthrone to anthranol was observed in several solvents, such as ethanol, ether, *n*-heptane and acetonitrile; the yield was large in the former two solvents, and very small in the latter two. Detailed experiments were done only in the case of the ether solution, on which we will report here.

By the irradiation of the degassed ether solution of anthrone by a light flash, anthrone was isomerized to anthranol. This may be clearly seen from Fig. 1, where the absorption spectrum (curve 1) of anthrone (~300 mμ) changes into that (curve 3) of anthranol (~370 mμ) after the irradiation.

The absorption spectrum immediately (~25 μ sec.) after the irradiation by the flash was photographed by the aid of the flash-spectroscopy technique; a new absorption band thus appeared at 340 mμ. This band may be expected to be due to the reaction intermediate from the facts that the 300 mμ band of anthrone disappears with the appearance of the new 340 mμ band and that, furthermore, the 370 mμ band of anthranol appears as the 340 mμ band disappears.

The 340 mμ band of the intermediate was found to be similar in position and shape to the spectrum of the benzophenone ketyl radical observed by Porter et al.[1,2] (curve 4 in Fig. 1). Therefore, the 340 mμ band may safely be assigned to the anthrone ketyl radical, whose π electron structure is very similar to that of the benzophenone ketyl radical. This shows that the abstraction of the hydrogen by the anthrone from solvent molecules occurs as the first step of the reaction. This conclusion seems to be supported also by the experimental fact that the yield of anthranol is large in ethanol and ether, solvents whose hydrogen is rather easily abstracted.

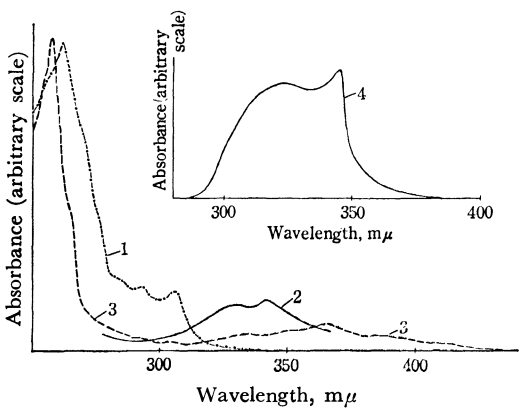

Fig. 1. Absorption spectra (curves 1—3) of the ether solution of anthrone under various conditions and the absorption spectrum (curve 4) of the benzophenone ketyl radical.
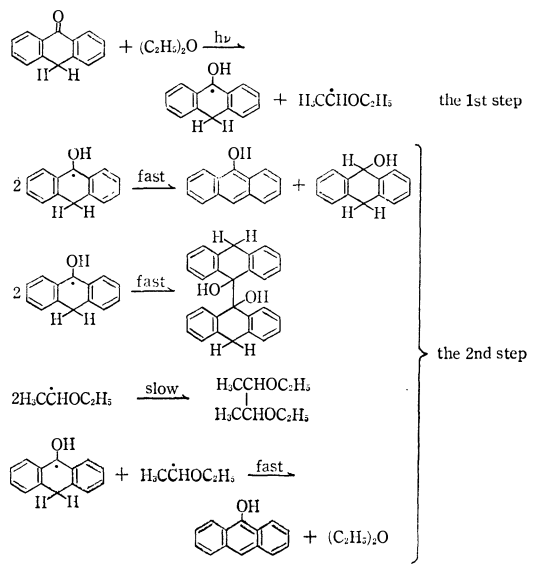
1. before irradiation
2. immediately (25 μsec.) after irradiation
3. (a few minutes) after irradiation
4. benzophenone ketyl radical[1,2]

The second step of the isomerization reaction, namely, the change of the ketyl radical to anthranol, was detected photoelectrically by measuring the absorption intensity of the 340 mμ band of the intermediate. The results show that the intermediate decays at the initial stage, following the second-order reaction formula, with the rate constant of about 10^7 mol^{-1} sec^{-1}, and at the next stage, following the first-order reaction formula.

The formation of the intermediate ketyl radical and its decay curve observed by the present authors can be explained satisfactorily in terms of the following reaction scheme:



The details of the present study will be published in the future.

Reply to Torkar and Krishner's Comment on "A New Alumina Hydrate, Tohdite"

By Goro YAMAGUCHI, Hiroshi YANAGIDA and Shuichiro ONO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received March 1, 1966)

In reply to Torkar and Krishner's comment on our article "A New Alumina Hydrate, Tohdite," we would like to mention as follows.[1]

In our article we gave the chemical composition $5Al_2O_3 \cdot H_2O$ as well as the atomic arrangement of the alumina hydrate. We now realize that at least two articles appeared on the alumina hydrate in question before the publication of our article.[2,3] In these articles, however, the chemical composition and the structure are not explicitly stated. Because of the fact that the alumina hydrate has a spinel structure of low symmetry, a further investigation will be of value.[4]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1357—1364 (1966)

The Oligomerization of Butadiene with Iron Complex Catalysts. II. The Effects of Additives

By Masanobu HIDAI, Katsumi TAMAI, Yasuzo UCHIDA and Akira MISONO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received October 2, 1964)

In the oligomerization of butadiene with the catalyst composed of iron(III) acetylacetonate and triethylaluminum, the degree of digomerization and the structures of the oligomers were strongly affected by the addition of an electron donor as a catalyst component. When triphenylphosphine was added, linear dimers composed of 3-methylhepta-1, 4, 6-triene and *n*-octa-1, 3, 6-triene were formed, while the addition of 2, 2'-dipyridyl produced cyclic dimers composed of cycloocta-1, 5-diene and 4-vinylcyclohex-1-ene. Besides the above donors, triphenylphosphite, tri(*o*-tolyl)-phosphite, tri(*p*-tolyl)phosphite, phosphorus trichloride, triethylamine and pyridine as monodentate, and *o*-phenanthroline, 2(2'-pyridyl)imidazoline and oxine as bidentate ligands, were tried, and the effects of those donors upon the reaction were studied. The transition states in these catalyst systems were also considered by means of studies of the effects of the molar ratio of catalyst components and by the measurements of infrared, ESR and visible light absorption spectra or magnetic susceptibilities of the reaction solutions.

Introduction

In a previous report[1] the authors mentioned that butadiene trimerized to *n*-dodeca-1, 3, 6, 10-tetraene with the catalyst prepared from the reaction of iron(III) acetylacetonate and triethylaluminum in the presence of butadiene. The formation of the *n*-dodecatetraene was considered to proceed through an intermediate complex in which three molecules of butadiene are coordinated to a low valent iron atom. It may, then, be expected that if a proper electron donor is added to the system, the donor will occupy one or more coordination sites around the low valent iron atom corresponding to the available coordinating sites of the electron donor and its amount, and that, hence, the degree of oligomerization and the structure of the oligomers will be changed. During the course of our study, it was found that butadiene dimerizes selectively to 3-methylhepta-1, 4, 6-triene with a catalyst combining iron(III) acetylacetonate, triethylaluminum and triphenylphosphine; on the other hand, butadiene dimerized selectively to cycloocta-1, 5-diene and 4-vinylcyclohex-1-ene with the catalyst prepared from the reaction of iron(III) acetylacetonate, triethylaluminum and 2, 2'-dipyridyl. In this report, besides the above donors, phosphorus trichloride, triphenylphosphite, tri(*o*-tolyl)phosphite, tri(*p*-tolyl)phosphite, triethylamine and pyridine as monodentate and *o*-phenanthroline, 2(2'-pyridyl)-imidazoline and oxine as bidentate ligands were used, and the effects of these donors upon the products were studied. The nature of the catalyst systems was also discussed by measuring the infrared spectra, the visible light absorption spectra, the ESR spectra and the magnetic susceptibilities of the reaction solutions.

Experimental

Reagents.—The methods of preparing or purifying butadiene, benzene, triethylaluminum and iron(III) acetylacetonate were the same as those mentioned in the previous paper.[1] The electron donors, such as triethylamine, phosphorus trichloride, triphenylphosphine, 2, 2'-dipyridyl, *o*-phenanthroline and oxine, were those of commercial reagents. Triphenylphosphite, tri(*o*-tolyl)phosphite, tri(*p*-tolyl)phosphite and 2(2'-pyridyl)imidazoline were prepared by usual methods.

Procedure.—The reaction was usually carried out with a 30-ml.glass tube. In a typical reaction, benzene (9.2 g.), butadiene (3.0 g.), and triethylaluminum (0.1 g.) were added in this order to the tube which had been charged with iron(III) acetylacetonate (0.10 g.) and a calculated amount of an electron donor. Butadiene, benzene and triethylaluminum were added in a dry nitrogen atomosphere. The tube was cooled during the operations to prevent the evaporation of butadiene. The tube was then closed by fusing and kept at 50°C during the reaction. The reaction products were then analyzed by gas chromatography. The columns and the conditions employed were the same as those described in the previous paper.[1]

For the isolation and confirmation of the reaction products, the reaction was carried out in a 200-ml. glass autoclave. The reaction solution was first washed with dilute hydrochloric acid and then with water. After the solution had been dried with anhydrous sodium sulfate, it was distilled under a nitrogen atmosphere. Products of a high purity were obtained

by preparative gas chromatography. The infrared spectra, visible light absorption spectra, ESR spectra and magnetic susceptibilities of the reaction solutions were measured in order to study the reaction intermediates in these catalyst systems. These measurements were carried out in the same way as has been described in the previous paper.[1)]

Results

In order to examine the effects of electron donors on the reaction, a series of reactions with various catalyst systems were carried out. The main products formed by the catalysts with various electron donors are listed in Table I.

The Addition of Monodentate Ligands.—*The Addition of Triethylamine.*—The addition of triethylamine did not affect the composition of the products. The conversion of butadiene was slightly decreased by the addition of triethylamine, but the selectivity of the formation of *n*-dodecatetraene was the same as in the case of an iron(III) acetylacetonate and triethylaluminum system.

The Addition of Triphenylphosphine.—When more than one mole of triphenylphosphine was added to one mole of iron(III) acetylacetonate, butadiene dimerized selectively. The dimers were identified as 3-methylhepta-1, 4, 6-triene and *n*-octa-1, 3, 6-triene by the measurements of the retention times by means of gas chromatography and a study of the infrared spectra. The relationship between the conversion of butadiene or the yield of the dimers and the molar ratio of triphenylphosphine to iron(III) acetylacetonate is shown in Fig. 1. When one mole of triphenylphosphine was added to one mole of iron(III) acetylacetonate (the molar ratio of triethylaluminum to iron(III) acetylacetonate was 3 to 1), the products lower than the trimer were methylheptatriene and *n*-octatriene, and no linear trimers formed by the catalyst without triphenylphosphine could be observed. The conversion of butadiene and the dimer formation increased until the molar ratio of the donor to iron(III) acetylacetonate reached 4—5, although the selectivity of dimer formation decreased slightly. When more than 5 times as much triphenylphosphine as iron(III) acetylacetonate was added, the formation of

dimers was rather depressed, although the conversion of butadiene was increased. In this case liquid polybutadiene was formed as a by-product. On the other hand, both the conversion of butadiene and the dimer formation were also affected by the amount of triethylaluminum added, as is shown in Fig. 2. In the case of the catalyst composition in which 3 times as much triphenylphosphine as iron(III) acetylacetonate was added, both the conversion of butadiene and the yield of dimers reached maxima at the point in which the ratio of triethylaluminum to iron(III) acetylacetonate was three. When more than 3 times as much triethylaluminum as iron(III) acetylacetonate was used, the conversion of butadiene and the dimer formation were rather depressed. It is remarkable that in the catalyst system in which more than 3 times as much triphenylphosphine as iron(III) acetylacetonate was added, the effect of triethylaluminum in depressing the methylheptatriene formation became smaller as the amount of triphenylphosphine added was increased.

The Addition of Phosphites.—By the addition of triphenylphosphite, tri(*o*-tolyl)phosphite, and tri(*p*-tolyl)phosphite, polybutadiene was formed as a main product. In the case of tri(*o*-tolyl)phosphite, the reaction was vigorous as compared with other phosphites, and the polybutadiene formed was solid, although in the case of triphenylphosphite and tri(*p*-tolyl)phosphite the polybutadiene formed was liquid.

Addition of Other Donors.—When one mole of phosphorus trichloride was added to one mole of iron(III) acetylacetonate, the reaction was strongly inhibited. The addition of pyridine also stopped the reaction.

The Addition of Bidentate Ligands. — *The Addition of 2, 2'-Dipyridyl.*—When more than one mole of 2, 2'-dipyridyl was added to one mole of iron(III) acetylacetonate, butadiene dimerized selectively. The dimers were identified as cycloocta-1, 5-diene and 4-vinylcyclohex-1-ene (in the ratio 3 : 1) by the measurements of the retention times by means of gas chromatography and a study of the infrared spectra. The relationship between the conversion of butadiene or the yields of the dimers and the molar ratio of 2, 2'-dipyridyl to iron(III) acetylacetonate is given in Fig. 3. When the molar ratio of 2, 2'-dipyridyl to iron(III) acetylacetonate was 1, for example, after 4-hrs.' reaction at 50°C, 73% of the butadiene reacted, of which 45% was changed to cycloocta-1, 5-diene and 15% to 4-vinylcyclohex-1-ene. All the products except the dimers were polybutadiene, and no *n*-dodecatetraene formed by the catalyst without

2, 2'-dipyridyl was observed. When the molar ratio of 2, 2'-dipyridyl to iron(III) acetylacetonate became more than 1, both the conversion of butadiene and the yield of the dimers were decreased. In Fig. 4 is shown the effect of triethylaluminum added. When more than 3 times as much triethylaluminum as iron(III) acetylacetonate was added, the conversion of butadiene increased, but the polymerization became dominant and the yield of dimers was decreased. The same phenomenon had been observed in the case of the linear trimerization of butadiene with a catalyst composed of triethylaluminum and iron(III) acetylacetonate.

The Addition of o-Phenanthroline. — The addition of *o*-phenanthroline also gave the cyclic dimers as in the case of 2, 2'-dipyridyl, but the selectivity of dimer formation was lower than in the case of the catalyst system with 2, 2'-dipyridyl.

The Addition of 2(2'-Pyridyl)imidazoline or Oxine.— Upon the addition of 2(2'-pyridyl)imidazoline, only polymerization took place. On the other hand, when oxine was added as a catalyst component, the reaction almost the same as in the system without oxine.

Discussion

In the series of reactions described above, not only the dimerization or trimerization of butadiene took place; polymerization also occurred as a result of the change of catalyst components. As was reported in a previous paper,[2] the essential reaction of catalyst components to form active species is the reduction of iron(III) acetylacetonate with triethylaluminum to a low valent state, estimated as zero valent. We consider that the coordination of a donor as a catalyst component to the reduced iron atom changes the active complex form. If some kinds of complex formation are realized among butadiene, an electron donor, and iron atom, then the magnetic properties of the resultant system must differ from those of the system without the electron donor. With this in mind, the magnetic susceptibilities of the reaction solutions were measured. The results are listed in Table II. As was mentioned in the previous papers,[1,2] when triethylaluminum was added to a benzene solution of iron(III) acetylacetonate, Fe^{3+} was reduced to Fe^{2+} and then to a zero valent state. The resultant solution was unstable, and immediately a black precipitate appeared. The system showed the ferromagnetism of an effective magnetic moment of 11—18 B. M., probably caused by the metallic iron. In the presence of butadiene, the solution became reddish brown and showed the paramagnetism of an effective magnetic moment of 4—5 B. M. A shoulder absorption was found at about 400—450 mμ in the visible light absorption spectrum; this absorption has been observed in bis-butadiene dicobalt tetracarbonyl and butadiene iron tricarbonyl.[3] From these results, a paramagnetic intermediate complex in which butadiene is coordinate to the zero valent iron atom may be expected.

A Reaction Solution with a Catalyst Composed of Iron(III) Acetylacetonate, Triethylaluminum and Triphenylphosphine.—In this case, when triphenylphosphine was added, even if in the absence of butadiene, the value of the magnetic susceptibility of the solution decreased, as is shown in Table II-3. When butadiene was present before the addition of triethylaluminum, the reaction solution was bright brown and showed an effective magnetic moment of about 1 B. M.; this finding supported the coordination of both butadiene and triphenylphosphine to the reduced iron atom. In this case a shoulder absorption at 400—420 mμ was also observed. From the observation of the infrared spectra in the potassium bromide region of the reaction solution with various contents of triphenylphosphine, it was observed that, when the ratio of triphenylphosphine to iron(III) acetylacetonate was equal to 0.6 and 1, the absorption at near 500 cm^{-1} characteristic of triphenylphosphine did not appear and that, when the ratio was larger than 1, this absorption appeared and increased with an increase in the ratio of triphenylphosphine to iron(III) acetylacetonate (shown in Figs. 5-1 and 5-2). On the other hand, when the ratio was 0.6, new absorptions at 512 and 538 cm^{-1} appeared. These absorptions became strong when the ratio approached 1. However, the absorptions almost did not change at all when the ratio increased above 1. These new absorptions at 512 and 538 cm^{-1} were also observed in a triphenylphosphine iron complex

isolated from the solution containing diethylmonoethoxyaluminum, iron(III) acetylacetonate and triphenylphosphine. Therefore, these absorptions were supposed to be characteristic of triphenylphosphine coordinated to an iron atom. From these results it was considered that one molecule of triphenylphosphine is coordinate to the reduced iron atom in the reaction solution, even if an excess of triphenylphosphine is present in the solution.

The effect of amounts of triphenylphosphine on the reaction can be explained by the following consideration. In the reaction system composed of iron(III) acetylacetonate, triethylaluminum and triphenylphosphine, the iron atom coordinated by triphenylphosphine and butadiene is solvated by a solvent or by an aluminum compound such as diethylaluminum acetylacetonate and stabilized as a homogeneous solution. When more than one mole of triphenylphosphine to one mole of iron(III) acetylacetonate is present in the solution, the excess of triphenylphosphine which is not coordinate to the iron atom interacts with the aluminum compound surrounding the iron-butadiene-triphenylphosphine intermediate. This causes a change in solvation and a resultant change in the oligomerization reaction. The phenomena that an excess of triethylaluminum depresses the reaction may also be explained as the solvation of the aluminum compound to the reaction intermediate complex. In the case of a large excess of triphenylphosphine in the solution, the excess of triethylaluminum does not affect the reaction course. It may be supposed that the excess triphenylphosphine reacts with triethylaluminum and that the resultant compound is probably not so active as to affect the solvation conditions surrounding the intermediate. Therefore, the reaction was almost the same as the one catalyzed by the system which did not contain an excess of triethylaluminum.

These solvation effects will also affect the magnetic properties of the solution. However, the

(mol. ratio)

accuracy of the measurement of the magnetic susceptibility does not allow any further discussion. The ESR observation of the reaction solution with various ratios of catalyst components is shown in Fig. 6. When triphenylphosphine : iron(III) acetylacetonate : triethylaluminum was 1 : 1 : 3, a broad signal due to the iron atom was observed at the *g*-value of 2.08. This signal was sharpened by the further addition of triphenylphosphine. When the amount of triethylaluminum increased, the absorption became broad again, and upon the further addition of excess triphenylphosphine, the absorption became sharp again. These phenomena may be supposed to be due to the change in coordination or solvation conditions around the iron atom and to be consistent with the above explanation.

The Reaction Solutions with Other Monodentate Ligands.—The addition of triethylamine did not affect the reaction. The effective magnetic moment of the solution was about 4, which is almost the same as that of the reaction solution containing iron(III) acetylacetonate, butadiene and triethylaluminum. From this result, it may be supposed that triethylamine does not coordinate to a low valent iron atom in the system.

When phosphite compounds were added to the catalyst system, the main product was a polymer. In these cases, the reaction solutions were almost diamagnetic and the coordination of phosphites to iron atom may be supposed.

The Reaction Solution with 2, 2'-Dipyridyl.—The magnetic susceptibility of the reaction solution became smaller than the case without a donor, and the difference was greater as the amount of 2, 2'-dipyridyl increased. This suggests that 2, 2'-dipyridyl coordinates to the iron atom in the reaction system. Actually, in the reaction between iron(III) acetylacetonate, 2, 2'-dipyridyl and diethylmonoethoxyaluminum in ether, the diethyl bis-2, 2'-dipyridyl iron complex was isolated. This complex showed catalytic activity in the cyclic dimerization of butadiene.[4] When butadiene was reacted with the complex, 2, 2'-dipyridyl was isolated from the reaction solution. On the other hand, the best ratio of 2, 2'-dipyridyl to iron(III) acetylacetonate was 1 for the cyclooctadiene formation. From these results, a paramagnetic complex in which butadiene and one molecule of 2, 2'-dipyridyl coordinated to the iron atom may be supposed to be an intermediate of this reaction.

The Elucidation of the Transition State and the Effect of Electron Donors.—From the above-mentioned experimental results and discussions, it was concluded that, by the addition of an adequate electron donor as a catalyst component, the oligomerization of butadiene with an iron complex catalyst was strongly affected. It was also found that, for the formation of the linear dimers, the addition of a monodentate ligand such as triphenylphosphine was effective, while for the formation of the cyclic dimers, such bidentate ligands as 2, 2'-dipyridyl or *o*-phenanthroline were effective.

During the course of his study of the oligomerization of butadiene, Dr. Wilke[5] isolated a complex, $NiC_{12}H_{18}$, in which three molecules of butadiene were changed to a C_{12} chain by the formation of one trans double bond and two terminal π-allyl groups. He also isolated a complex, $Ni(PR_3)C_8H_{12}$, in which two molecules of butadiene were changed to a C_8 chain by the formation of two terminal π-allyl groups. It was suggested that the former complex was the intermediate complex for the all-trans-cyclododecatriene formation in the reaction of butadiene with the catalyst composed of nickel acetylacetonate and triethylaluminum, while the latter complex was the intermediate complex for the cyclic dimerization of butadiene with the catalyst composed of nickel acetylacetonate, triphenylphosphine and triethylaluminum. According to his view, three molecules of butadiene approach the nickel atom to form the cyclic trimer through the $NiC_{12}H_{18}$ complex. In the case of the catalyst composed of nickel acetylacetonate, triphenylphosphine and triethylaluminum, one of the coordination sites of nickel is occupied by triphenylphosphine; therefore, only two molecules of butadiene can approach the reaction field, so the dimers are formed through the $Ni(PPh_3)C_8H_{12}$ complex. The degree of the oligomerization of products by the iron complex catalyst can be similarly explained. The formation of the cyclic dimers with the combined catalyst of iron(III) acetylacetonate, 2, 2'-dipyridyl and triethylaluminum can be explained by considering that the donor occupies two coordination sites of the low valent iron atom and that two molecules of butadiene approach the iron atom to form the cyclic dimers through a $Fe(dipy)C_8H_{12}$ complex. The formation of methylheptatriene can also be explained in the same way. Two molecules of butadiene approach the iron atom to which one molecule of triphenylphosphine is coordinated.

Besides the above-mentioned discussions about the number of coordination sites of metal, the sort or the nature of donor must be considered. The polymerization proceeds by some electron donors, while by the other donors the reaction was inhibited or specific oligomerization occurred. These are considered to be due to the difference in the strength of the coordination of a donor to metal and the resultant change in bond strength between the butadiene and the metal. The ligands which are

found experimentally to stabilize the lower valency states of the transition metals are collected in Table III.[6] It will be noted that each of these ligands has available acceptor orbitals for π electrons and that other ligands, which do not have these acceptor orbitals, are much less effective stabilizers of low valencies, though they have similar properties in every other way. Thus, it may readily be understood that the reaction of butadiene by the combined catalyst of iron(III) acetylacetonate and triethylaluminum was not affected by the addition of triethylamine, which does not have available acceptor orbitals for π electrons, but it was affected by the addition of an electron donor, such as 2, 2'-dipyridyl, triphenylphosphine, phosphorus trichloride, or triphenylphosphite, which has acceptor orbitals. Moreover, it will be noted that such ligands as 2, 2'-dipyridyl or triphenylphosphine, by the addition of which an active complex for dimerization is formed, are moderate as acceptors for π electrons, while triphenylphosphite, by which an active complex for polymerization is formed, is strong as an acceptor, and phosphorus trichloride, by the addition of which the reaction of butadiene is stopped, is a very strong acceptor for π electrons. Thus, a ligand which is coordinated to the low valent iron atom and forms an active complex for the dimerization of butadiene, must have available acceptor orbitals for π electrons of adequate energy levels.

A Comparison of Equations for Powder Compression

By Kimio KAWAKITA and Yuhbun TSUTSUMI

Department of Chemistry, Faculty of Engineering, Hosei University, Koganei-shi, Tokyo

(Received December 21, 1964)

Several equations representing the relation between the pressure and the apparent volume of a powdered mass under compression, as proposed by various authors, sometimes have essentially the same form as one other, and sometimes have contradictory characters. Various equations can be modified so as to be a function of the porosity and thus compared with each other. As a result, they can be classified into two types by means of the gradient of the porosity with the pressure ($-dn/dP$, n=porosity). One is $-dn/dP=kn^x$ (Athy: $x=1$, Kawakita: $x=2$), and the other is $-dn/dP=k(1-n)^y/P^z$ (Smith: $y=0$, $z=2/3$, Nutting: $y=1$, $z\fallingdotseq 1$, Balshin: $y=2$, $z\sim 1$, Terzaghi: $y=2$, $z\sim 1$, Jones: $y=3$, $z=1$), where k is a constant and x, y and z are parameters. In Kawakita's equation the rate of the decrease of the porosity is considerably larger in an early period of compaction than in Athy's equation. The second type of equation indicates that a major part of the porosity disappears at lower pressures.

The compacting behavior of a powdered mass was previously analyzed by Kawakita,[1-2] one of the present authors. He proposed an empirical Eq. 1:

$$C=\frac{V_0-V}{V_0}=\frac{abP}{1+bP} \qquad (1)$$

where C=the relative reduction of the volume by compression; V_0=the initial apparent volume; V=the volume under the applied pressure P, and a and b=constants.

The constant a corresponds to the limiting value of the relative reduction of the volume by compression: it should be equal to the initial porosity of a powdered mass, as expressed by Eq. 2:

$$a=C_\infty=\frac{V_0-V_\infty}{V_0} \qquad (2)$$

where V_∞ is the net volume of the powder. The b constant should be equal to the reciprocal of the pressure when the value, C, reaches one-half of the limiting value ($C=C_\infty/2$).

Several equations of other types have also been proposed for the powder compression by various

Table I. Powder compression equations

Author	Equation	Remarks
Balshin	$\ln P = -L \cdot V_r + C$	P=applied pressure, V_r=specific volume, L, C=constants
Smith	$\rho - \rho_0 = C_f \cdot P^{1/3}$	ρ=apparent density, ρ_0=initial apparent density, C_f=compressibility factor
Murray	$\ln\left(\frac{1}{1-D_E}\right) = \frac{\sqrt{2\gamma}\, n^{1/3}}{\sigma_0}\left(\frac{D_E}{1-D_E}\right)^{1/3} 4\pi^{1/3} + \frac{P}{\sqrt{2\sigma_0}}$	D_E=relative density at pressure P, γ=surface tension, n=number of pores in unit volume, σ_0=yield strength at compressing temperature
Ballhausen	$\ln\left(\frac{D}{1-D}\right) \propto P$	D=relative density at pressure P
Konopicky	$\ln\left(\frac{1}{1-D}\right) = kP + \ln\left(\frac{1}{1-D_0}\right)$	D=relative density at pressure P, D_0=relative density at zero pressure, k=constant
Jones	$\frac{dP}{dW} = -kPW$	P=applied pressure, W=relative apparent volume, k=constant
Burr	$D = f_1(P) + f_2(P) + f_3(P) + A$	D=relative apparent density, f_1, f_2, f_3=functions of pressure P, A=constant
Athy	$n = n_0 \cdot \exp(-bx)$	n=porosity, n_0=average porosity of surface clays, b=constant, x=depth of burial
Nutting	$\varepsilon = \psi^{-1} t^{\kappa} f^{\beta}$	ε=volumetric strain, f=compressive stress, t=time, ψ, β, κ=constants
Tanimoto	$\delta = \frac{1-\mu}{E}\sigma + \frac{\sigma \varepsilon_m + A\varepsilon_0}{\sigma + A}$	δ=change of volume, E=elastic factor, σ=compressive stress, ε_m=initial void, ε_0=strain at initial state, μ, A=constants
Terzaghi	$\varepsilon = -\alpha \ln(P+P_c) - \beta(P+P_c) - \gamma P + C$	ε=ratio of porosity, P=applied pressure, $\alpha, \beta, \gamma, P_c, C$=constants
Cooper	$\overset{*}{V} = a_1 \cdot \exp(-k_1/P) + a_2 \cdot \exp(-k_2/P)$	$\overset{*}{V}$=fractional compaction, P=applied pressure, a_1, a_2=fractional coefficients, k_1, k_2=constants
Kawakita	$C = \frac{abP}{1+bP}$	P=applied pressure, C=relative reduction of volume, a, b=constants

Equations from Balshin's to Konopicky's are from Ref. 11, Jones' and Burr's are from Ref. 12, Athy's, Nutting's, Tanimoto's, Terzaghi's and Cooper's are from Refs. 13, 14, 15, 16 and 18 respectively.

investigators, and some of them have been used in practice, though only in a few cases. This paper will deal with our attempt to compare these equations.

Powder Compression Equations.—So far as we are aware, the following equations have been reported (Table I[11-18]).

In order to make a comparison of these equations, each of them should be rewritten by the same notations (Table II).

Burr's equation was not evaluated since no representation was given for the pressure functions. As for Nutting's equation, which includes a time-dependent factor, the measuring time was taken as a constant. In Athy's equation we substituted the depth of burial, x, with a pressure term, P.

Murray's, Konopicky's and Tanimoto's Equations.—Murray's equation is rather complicated:

$$\ln\left(\frac{V}{V-V_\infty}\right) = c_4\left(\frac{V_\infty}{V-V_\infty}\right)^{1/3} + c_5 P$$

However, if the first term of the right side is the constant (k), we find:

$$\frac{V-V_\infty}{V} = k \cdot e^{-c_5 P}$$

which is the same in form as Athy's equation. It is possible, therefore, to say that Murray's equation is a sort of modification of Athy's.

The equations of Balshin, Smith, Murray, Ballhausen and Konopicky were evaluated in the light of experimental data provided by Heckel.[11] He concluded that Konopicky's equation agreed best with the data. We have previously stated[9] that Konopicky's equation could be regarded as the same as that of Athy.

Tanimoto's equation may be rewritten as follows:

$$\frac{V_0 - V}{V_0} = \frac{\beta P + \gamma P^2}{1 + \alpha P}$$

TABLE II. VARIOUS EQUATIONS REPRESENTED BY THE SAME NOTATIONS

Balshin	$\ln P = -c_1 \frac{V}{V_\infty} + c_2$
Smith	$\frac{1}{V} - \frac{1}{V_0} = c_3 \cdot P^{1/3}$
Murray	$\ln\left(\frac{V}{V-V_\infty}\right) = c_4\left(\frac{V_\infty}{V-V_\infty}\right)^{1/3} + c_5 P$
Ballhausen	$\ln\left(\frac{V_\infty}{V-V_\infty}\right) = c_6 P + \ln c_7$
Konopicky	$\ln\left(\frac{V}{V-V_\infty}\right) = c_8 P + \ln\left(\frac{V_0}{V_0-V_\infty}\right)$
Jones	$\ln P = -c_9\left(\frac{V}{V_\infty}\right)^2 + c_{10}$
Athy	$\frac{V-V_\infty}{V} = \frac{V_0-V_\infty}{V_0} \cdot e^{-c_{11}P}$
Nutting	$\ln\left(\frac{V_0}{V}\right) = c_{12}P^{c_{13}}$
Tanimoto	$\frac{V_0-V}{V_0} = \frac{c_{14}P}{V_0} + \frac{c_{16}P}{P+c_{15}}$
Terzaghi	$\frac{V-V_\infty}{V_\infty} = -c_{17}\ln(P+c_{18}) - c_{19}(P+c_{18}) - c_{20}P + c_{21}$
Cooper	$\frac{V_0-V}{V_0-V_\infty} = c_{22} \cdot e^{-c_{23}/P} + c_{24} \cdot {}^{-c_{25}/P}$
Kawakita	$\frac{V_0-V}{V_0} = \frac{c_{25}c_{26}P}{1+c_{26}P}$

V_0=initial apparent volume of powder
V=volume of powder under the applied pressure P
V_∞=net volume of powder
c_1—c_{26} are the constants.

where α, β and γ are the constants. This equation contains the self-contradiction that the volume of powder, V, should approach $-\infty$ at the region of large pressure as a result of the γP^2 term. Our experimental data[10] of the tablet compression of many kinds of powder were applied to this equation, and the coefficients, α, β and γ, were calculated by the method of least squares. As a result, the value of γ was smaller than one several thousandth of the value of either α or β on every occasion. Practically, then, the value of γ can be regarded as zero. If the constant γ is zero, Tanimoto's equation should be the same in form as Kawakita's equation.

A Comparison of Equations Expressed in Terms of Porosity.—Excepting the equations of Murray, Konopicky and Tanimoto, each equation shown in Table II was modified so as to include the same porosity term as a scale.

The apparent compacting volume, V, can be derived from each equation; this volume is used to express the porosity term, $(V-V_\infty)/V$. The results obtained are given in Table III. In Cooper's equation, we considered only the first term in the right side.

As is demonstrated in Table III, Balshin's and Jones' equations can only be applied in some limited ranges of pressure, because the degree of porosity must assume an unreasonable value, 100%, if the compacting pressure is either very low or very high. Similarly, Smith's, Nutting's, Terzaghi's and Cooper's equations cannot be applied to the higher pressure range. Thus, concerning the change in porosity, it is shown that only Ballhausen's, Athy's and Kawakita's equations are applicable over the entire range of pressure.

Porosity Gradient with Applied Pressure.—With regard to the rate of porosity change as a function of the pressure, some differences exist among the equations in question, as is shown below.

TABLE III. COMPARISON OF POROSITIES DERIVED FROM VARIOUS EQUATIONS

Author	Porosity (n=)	$P \to 0$	$P \to \infty$	Necessary condition
Balshin	$1-\frac{c_1}{c_2-\ln P}$	1	1	$c_1 \neq 0$
Smith	$n_0 - c_3 V_\infty P^{1/3}$	n_0	$-\infty$ ($c_3>0$) $+\infty$ ($c_3<0$)	$c_3 \neq 0$
Ballhausen	$\frac{1}{1+c_7 \cdot \exp(c_6 P)}$	$\frac{1}{1+c_7}$	0	$c_6 \neq 0$ $c_7 \neq 0$
Jones	$1-\left(\frac{c_9}{c_{10}-\ln P}\right)^{1/2}$	1	1	$c_9 \neq 0$
Athy	$n_0 \cdot e^{-c_{11}P}$	n_0	0	$c_{11} \neq 0$
Nutting	$1-\left(\frac{V_\infty}{V_0}\right)e^{c_{12}P^{c_{13}}}$	n_0	n_0 ($c_{13}<0$) $-\infty$ ($c_{12}>0, c_{13}>0$) 1 ($c_{12}<0, c_{13}>0$)	$c_{12} \neq 0$ $c_{13} \neq 0$
Terzaghi	$1-\frac{1}{1-c_{17}\ln(P+c_{18})-c'_{19}(P+c_{18})+c'_{21}}$	$1-\frac{1}{1-c_{17}\ln c_{18}-c'_{19}c_{18}+c'_{21}}$	1	
Cooper	$1-\frac{(V_\infty/V_0)}{1-n_0 c_{22} \cdot \exp(-c_{23}/P)}$	n_0	$\frac{1-c_{22}}{(1/n_0)-c_{22}}$	$c_{22} \neq 0$ $c_{23} \neq 0$
Kawakita	$\frac{n_0}{1+(V_\infty/V_0)c_{26}P}$	n_0	0	$c_{26} \neq 0$

n=porosity, n_0=initial porosity

$$\text{Balshin} : -\frac{dn}{dP} = a\cdot(1-n)^2P^{-1}$$

$$\text{Smith} : -\frac{dn}{dP} = b\cdot P^{-2/3}$$

$$\text{Ballhausen}: -\frac{dn}{dP} = c\cdot(1-n)\cdot n$$

$$\text{Jones} : -\frac{dn}{dP} = d\cdot(1-n)^3\cdot P^{-1}$$

$$\text{Athy} : -\frac{dn}{dP} = e\cdot n$$

$$\text{Nutting} : -\frac{dn}{dP} = f\cdot(1-n)\cdot P^{c_{13}-1}$$

$$\text{Terzaghi} : -\frac{dn}{dP} = (1-n)^2\cdot\left(\frac{c_{17}}{P+c_{18}}+c_{19}\right)$$

$$\text{Cooper} : -\frac{dn}{dP} = g\cdot\frac{(1-n)}{P^2}\cdot(n_0-n)$$

$$\text{Kawakita} : -\frac{dn}{dP} = h\cdot n^2$$

where n is the porosity at the applied pressure, P; n_0, the initial porosity, and a, b, c, d, e, f, g and h are the constants. According to Neumann,[17] the c_{13} value in Nutting's equation is very small, that is, the order of 0.1. Furthermore, Terzaghi's equation becomes identical with Balshin's if the c_{18} and c_{19} constants are very small.

Thus, these equations may be represented by two different types of equations:

$$\text{(I)}: -\frac{dn}{dP} = k\cdot n^x : \text{Athy } (x=1),\ \text{Kawakita } (x=2)$$

$$\text{(II)}: -\frac{dn}{dP} = k\cdot\frac{(1-n)^y}{P^z}: \text{Smith } (y=0,\ z=2/3),\ \text{Nutting } (y=1,\ z\fallingdotseq 1),\ \text{Balshin } (y=2,\ z=1),\ \text{Terzaghi } (y=2,\ z\sim 1),\ \text{Jones } (y=3,\ z=1)$$

where k is a proportional constant. Ballhausen's equation is a multiplication of the types I and II ($x=1$, $y=1$, $z=0$). Cooper's equation is the sum of the type II and the type I×II.

From these equations we note that the rate of the change in porosity due to the pressure is related to the ratio of the void to the volume of powder in Athy's and Kawakita's equations, while it is related to the applied pressure and the ratio of the net volume in the other equations.

Figures 1(A) and (B) illustrate the porosity change as a function of the pressure. In these figures we picked out Athy's ($x=1$) and Kawakita's ($x=2$) equations from the type I, Smith's ($y=0$), Nutting's ($y=1$), Balshin's ($y=2$) and Jones' ($y=3$) equations from the type II, and Ballhausen's from the type I×II.

The initial porosity was taken to be 80 and 40% for A and B respectively, while at 3000 kg./cm² it was taken to be 10% in both cases. Even if these percentages are taken otherwise, the general trend of the curves should be the same.

When we made Fig. 1, we used the value of 0.1 for c_{13} in Nutting's equation. In the case of Balshin's and Jones' equations, we constructed the curves for the pressure higher than 0.001 kg./cm², because in both equations the porosity become 100% when the pressure was zero.

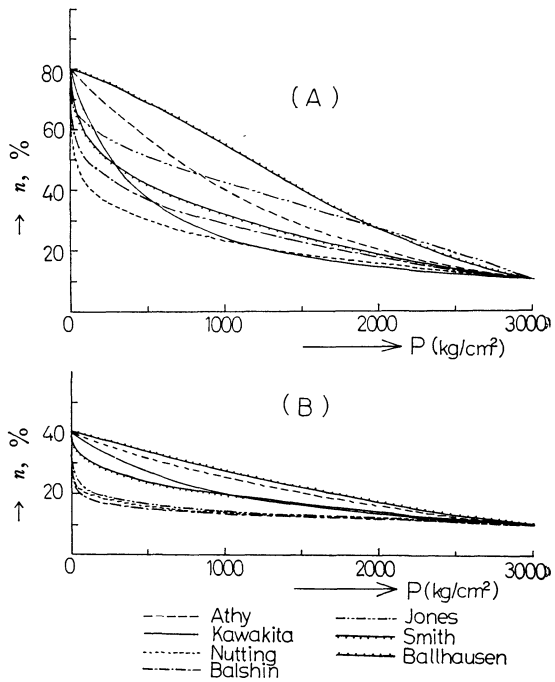

Fig. 1 (A), (B). Comparison of various equations using the term of porosity.

It may, thus, be concluded from Fig. 1 that Ballhausen's equation predicts the most gradual decrease in porosity as the pressure increases, and that the next most gradual decrease is in Athy's equation. Kawakita's equation indicates a considerable decrease in porosity in an early period of compaction. The other equations show that a major portion of the porosity disappears at lower pressures.

According to our experiments on tablet compression,[10] powder of common nonspherical particles changed its porosity largely in an early period of compaction; its compacting behavior was in good agreement with Kawakita's equation. On the other hand, powder of spherical glass or metal particles did not change its porosity appreciably as a result of the pressure; therefore, Athy's equation became applicable.

Finally, the compacting behavior of powder depends remarkably on the experimental conditions and on the physical properties of particles;

therefore, it is difficult to find a single equation which is in exact accord with the experimental data on different kinds of powder and different experimental conditions.

The authors wish to thank Dr. R. E. Collins (University of Houston), who visited Japan in 1964, for his valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1368—1372 (1966)

The Non-Newtonian Flow of Poly(Dimethyl Siloxane)

By Yoshio Ito

Department of Chemistry, Faculty of Science, Niigata University, Niigata

(Received February 22, 1965)

The non-Newtonian flow of poly(dimethyl siloxanes) with a wide variety of degrees of polymerization (Z), 31.6 to 6.02×10^3, was studied by using short capillary viscosimeters. Measurements were performed in the range of rate of shear from 10^{-1} to 3×10^6 sec^{-1}. It was found that the flow behavior was markedly affected by the value Z of the test materials. That is, the flow was practically Newtonian over the entire range of shear rates when Z was less than 1.55×10^2. For higher values of Z, however, typical non-Newtonian behavior was observed in the range of moderate shear rates. At extremely high shear rates, the materials with $Z=3.23\times10^2$ to 2.63×10^3 exhibit the upper (or second) Newtonian flow, but the materials with still higher values of Z exhibit the spiral flow. It was also found that the Shishido equation (*J. Chem. Soc. Japan, Pure Chem. Sect. (Nippon Kagaku Zasshi)*, **84**, 889 (1963)) was applicable to this polymer in describing the observed viscosity vs. shear rate dependence. Finally, an empirical method was proposed for estimating the upper Newtonian viscosity value from the viscosities at zero shear stress and at the inflection point of the flow curve.

Recently, the flow behavior of molten polymers or polymer solutions in short capillaries has attracted the attention of many investigators. This is because: (a) the flow data at a very high shear stress or shear rate are obtainable by this means if an adequate end correction is made to the capillary length, and (b) the data obtained can be used to evaluate the various rheological properties of polymer systems.

Shishido[1-4] proposed a semi-empirical theory for the non-Newtonian flow on the assumption that the viscosity of the fluid is closely related to the deformation of the polymer molecules caused by shear stress; he applied this theory to dilute and concentrated solutions of high polymers.

This paper will present the results of the application of his theory to poly(dimethyl siloxanes) of various molecular weights in the molten state. The measurements cover a wide range of shear stress, from the lower (or first) Newtonian region up to the upper (or second) Newtonian region.

Experimental

The poly(dimethyl siloxanes) used in this study were obtained from the Shin-Etsu Chemical Industry Co., Ltd. The degree of polymerization (Z) were calculated from the zero shear viscosities (η_0) by using the relationship given in Refs. 5 and 6. These values of η_0 and Z are given in Table I.

The viscosity measurements were performed with extrusion capillary viscosimeters[1] driven by nitrogen pressure. The lengths (l) and radii (r) and the ratios between them (l/r) of the capillaries used are listed in Table II. The temperature was kept at 35°C throughout the measurements. The extruding pressure was adjustable up to 150 kg./cm^2.

Results and Discussion

The End Correction of Capillary.—For the flow of a Newtonian fluid in a long capillary, the maximum shear rate (D_N) and shear stress (τ') (at the wall of the capillary) are given by:

$$D_N = 4Q/\pi r^3 \quad (1)$$

$$\tau' = Pr/2l \quad (2)$$

where r and l are the radius and the length of the capillary respectively, Q is the output rate of the fluid, and P is the applied pressure corrected by the kinetic energy effect.

Z	0.0265_0	0.0818	3.09

Considering the entrance effect (Couette correction) ($c=0.65$)[1-3] and the elastic effect (e), we may obtain, instead of Eq. 2, the following relationship for a non-Newtonian fluid passing through a comparatively short capillary:

$$\tau = P/2(l/r+c+e) \qquad (3)$$

where $(c+e)$ is the total end correction and τ is the corrected shear stress. The total end correction can be determined by extrapolating the plot of P versus l/r to the zero value of P at a constant shear rate (D_N). This is the usual method for determining the end correction. Figure 1 shows such plots obtained for Shin-Etsu Silicone KF96H-(10000).

An approximate method for obtaining the end correction, e, has been proposed by Shishido on the basis of his empirical theory of the non-Newtonian flow of polymer solutions.[1-4] This method has been applied to our molten polymers. The results are shown in Fig. 2, where the approximate estimates of e obtained by the Shishido method (open circles) are compared with the ordinary estimates obtained by the above extrapolation method (solid curve). The agreement between the

two estimates was satisfactory over a wide range of shear rate, D.

Flow Curve.—After the end correction is established, it is possible to calculate the corrected flow curve, i. e., the τ vs. D relationship, which should be independent of the l/r values of the capillaries used. The results obtained for the present samples are shown in Fig. 3, where the non-Newtonian shear rate (D) was calculated by:

$$D=(D_N/4)(3+\mathrm{d}\log D_N/\mathrm{d}\log\tau) \qquad (4)^{7)}$$

From Fig. 3, it may be seen that the siloxanes with degrees of polymerization less than 1.55×10^2 exhibit Newtonian behavior. For the materials with a higher degree of polymerization, i. e., from 3.23×10^2 to 8.7×10^2, typical non-Newtonian behavior is observed at moderate shear rates. These materials exhibit the upper (or second) Newtonian flow at extremely high shear rates. The materials of still higher degrees of polymerization, i. e., 1.15×10^3 to 2.63×10^3, do not exhibit the upper Newtonian flow, probably because of the disturbance by the spiral flow. The dotted parts of the flow curves for the materials with $Z=3.31\times10^3$, 5.25×10^3, and 6.02×10^3 indicate this range of spiral flow. When the spiral flow occurs instead of the upper Newtonian flow, the apparent viscosity becomes smaller for the materials with higher degrees of polymerization than for those with lower degrees of polymerization, as is shown in Fig. 3. Such inversion must be physically nonsensical; accordingly, we shall omit these parts of the flow curves from the following discussions.

Flow Equation.—Shishido's proposed equations for the non-Newtonian flow of a polymer solution are:[1)]

$$(\eta_{app}-\eta^*)/(\eta_0-\eta^*)=\exp(-S) \qquad (5)$$

$$1/S=1/S_\infty+(1/\tau-1/\tau_c)/S_\infty\beta \qquad (6)$$

where τ is the shear stress; η_{app}, the apparent viscosity; η^*, the viscosity of the solvent, and η_0, the viscosity at zero shear stress. The symbol S represents the strain exerted on each polymer molecule; S_∞, the value of S in the flow of the upper Newtonian range; β, the flexibility parameter of the polymer molecule, and τ_c, the critical shear stress above which S attains its saturated value (S_∞). These equations may also be applicable to molten polymers. In this case, η^* is zero, Eq. 5 is then reduced to:

$$\eta_{app}/\eta_0=\exp(-S) \qquad (7)$$

Figure 4 shows the plots of $1/S$ versus $1/\tau$ for the present samples under the conditions of normal flow. It may be seen that Eqs. 6 and 7 are approximately valid for these molten polymers. The rheological values obtained from the relation between $1/S$ and $1/\tau$ are listed in Table III, where S_∞^{cal} and η_∞^{cal} are estimated to be as follows. Denote by S_{inf}^{exp} the value of S at the inflection point on the curve of $\log\tau$ versus $\log D$. The

ratios of S_∞ to S_{inf}^{exp} may then be determined for our samples, e, f and g, the upper Newtonian region of which has been experimentally established (see Fig. 3). Thus, we find that $S_\infty/S_{inf}^{exp} \doteqdot 1.7$ independent of the degree of polymerization. The relations between S_∞ and S_{inf}^{exp} of other polymer systems are available from the literature; they are shown in Fig. 5. This figure clearly suggests that the S_∞/S_{inf}^{exp} ratio is practically a constant, 1.7, independent of the polymer and solvent species. Accordingly, if the curve of $\log \tau$ versus $\log D$ is available up to its inflection point, S_∞ can be determined to be $1.7S_{inf}^{exp}$. The values of S_∞ thus

obtained for the present samples are plotted in Fig. 6 against the degree of polymerization (Z). From the figure, we find that:

$$S_\infty = 3.62\times10^{-3}\times Z^{0.92} \quad (8)$$

Accordingly, by using Eq. 7 or Eq. 8 and the relations of η_0 and Z in Refs. 5 and 6, the η_∞ (upper Newtonian viscosity) value can be estimated from η_0 and S_∞, or directly from Z. The values of β are calculated from $S_\infty\beta$ by using S_{inf}^{exp} for the siloxanes with degrees of polymerization from 3.23×10^2 to 8.70×10^2, and by using S_∞^{cal} for the siloxanes with degrees of polymerization from 1.15×10^3 to 2.63×10^3.

Shearing Strain, Pressure Loss and End Correction in the Capillary Flow.—From the theory[1-3] previously proposed, the relations among strain (S), end correction (e), shear stress (τ), and pressure loss (P_{loss}) are:

$$2e = \sqrt{2}S/[1-(1-1/\beta\tau_c)S/S_\infty] \quad (9)$$

$$P_{loss} = \sqrt{2}\beta S_\infty \tau^2 \quad (10)$$

$$= (2\sqrt{2}e^2)/(\beta S_\infty) = (2e)^2/(\sqrt{2}\beta S_\infty) \quad (11)$$

Equations 9, 10, and 11 were examined for the present cases. The solid curves in Fig. 7 indicate the results calculated from Eq. 9 by using the β, τ_c, and S_∞ values obtained experimentally. The experimental results (various point marks) and the theoretical results (solid curve) are substantially in accordance with each other. Two kinds of

βS_∞ values, obtained graphically by using Eqs. 10 and 11, are given in Table III, together with the βS_∞ value obtained from the slope of the plot of $1/S$ versus $1/\tau$. These three kinds of βS_∞ values are in agreement with one another. These results show that the above relations proposed[3] for polymer solutions are also applicable to the molten state of poly(dimethyl siloxanes).

Summary

The non-Newtonian flow of poly(dimethyl siloxanes) of various mol. wts. has been studied with a short capillary viscosimeter. The experiment has covered a wide range of shear rate, from 10^{-1} to 3×10^6 sec^{-1}. The results are as follows:

1) The flow behavior of the sample changes with the degree of polymerization. For the siloxanes with degrees of polymerization less than 1.55×10^2, the flow of the fluid is Newtonian throughout the whole range of shear rates; in the cases of the siloxanes with degrees of polymerization from 3.23×10^2 to 2.63×10^3, however, the flow is non-Newtonian at moderate shear rates; it again becomes Newtonian at high shear rates. With degrees of polymerization of more than 3.31×10^3, the spiral flow rises to a high shear rate.

2) The flow behavior of the sample is expressed by modifying Shishido's equation proposed for non-Newtonian polymer solutions.

3) When the flow curve observed contains its inflection point, the upper Newtonian viscosity can be estimated by a new method proposed here.

4) The relations among the end correction of capillary, the pressure loss and the shear stress proposed by Shishido for polymer solutions are applicable to poly(dimethyl siloxane) also.

The author wishes to express his deep appreciation to Professor Dr. Shunsuke Shishido for many helpful discussions and suggestion made during this work. He also wishes to thank Mr. Hiroshi Kondo for his assistance in the experimental work. Finally, this research was supported in part by a grant-in-aid for Fundamental Scientific Research, for which the author is grateful.

A Spectroscopic Study of Alkylnitrobenzene Anion Radicals

By Yasuto NAKAI

Central Research Laboratory, Sumitomo Chemical Co., Ltd., Takatsuki, Osaka

(Received August 30, 1965)

A series of alkylnitrobenzene anion radicals has been studied by both electron spin resonance and infrared spectroscopy. It has been shown that there is a relationship between the magnitude of the nitrogen hyperfine splitting constant and the steric effect of the bulky alkyl group adjacent to the nitro group. In addition to the physical deformation factors, the effects of solvents, counter-ions, and temperature variation have been discussed. In the infrared spectra, the differences between anion radicals and neutral molecules have been found to be small, except for the change in the absorption intensity of the nitro-group stretching vibration.

The facility with which aromatic nitro compounds can accept an electron and the stability of the resulting radical anions have been reported on in a number of recent studies. A previous study

has also been made of nitrobiphenyl anion radicals in the presence of alkali metal cations by means of electron spin resonance spectroscopy.[1] In this study the unique behavior of the nitro group in conjugate hydrocarbon systems with single-ring structures will be investigated.

The steric influences of substituents, chiefly alkyl groups, on such properties of aromatic nitro compounds as the ultraviolet spectrum, the infrared spectrum, the dipole moment, the molecular refraction, the basicity, and the reaction rate have been reported. In connection with these investigations, the question naturally arises whether the steric influence can also be detected for anion radicals, because there is an expected tendency towards coplanarity due to the additional pi-electron in the case of anion radical systems.

The structural nature of the negatively-charged molecules has been discussed mostly in electron spin resonance studies, whereas little information gained from other spectroscopic studies, particularly from infrared spectroscopy, has so far been made available.

Experimental

Solvents were dehydrated thoroughly and then redistilled in vacuo to remove the molecular oxygen. Each alkali metal was purified by repeated distillations in vacuo. Since the same procedure could not be applied to alkaline earth metals, each granular alkaline earth metal was cut or ground in order to obtain fresh surfaces; each metal was washed with carbon tetrachloride, dried in vacuo, and then amalgamated in order to facilitate the reducing activity.

For the study of the anion radicals by infrared spectroscopy, a special vacuum-tight rock-salt cell 0.1 mm. thick was connected to a glass system in which the anion radicals were produced (a detailed account of the latter has been given elesewhere[2]). The connection was made with polyethylene tubing which could withstand atmospheric pressure and was yet soft enough so that the sample solution could be forced into the optical cell by simply pressing the tubing. When the maximum resolution was required, a Model 521 Perkin-Elmer grating spectrophotometer at the Institute for Chemical Research of Kyoto University was used.

The ESR spectrometer employed was a high-resolution apparatus (JES-3B type) of the Japan Electron Optics Lab. Co., Ltd. The magnetic field was modulated at a frequency of 100 kc./sec. and at a modulation width of 0.1 gauss.

Results and Discussion

Analysis of Infrared Spectra.—The infrared spectra in the range from 800 to 2000 cm^{-1} contain distinct absorption bands corresponding to the symmetric stretching vibration and the asymmetric vibration of the nitro group, with frequencies at about 1350 and 1530 cm^{-1} respectively.[3] The frequencies at the maxima of these bands were carefully determined for each neutral compound, using nitrobenzene as a standard. The frequency of the asymmetric stretching vibration is practically the same for all the compounds investigated, as Table I shows. In other words, the variation in the values observed seems to be independent of the size of the alkyl groups adjacent to the nitro group. On the other hand, the frequencies of the symmetric stretching vibrations of the nitro group vary appreciably.

The spectra for the anion radical solution in dioxane in the presence of the potassium cation were measured for *o*-isopropyl-, *o*-*t*-butyl-, 2, 4, 6-trimethyl-, and 2, 4, 6-tri-*t*-butylnitrobenzenes. In each case the same solution was remeasured after the anion radical had been oxidized, by exposure to air, in order to reform the original neutral species.

Differences between the reduced and unreduced states were evidenced in the infrared spectra by the enhanced absoprtion associated with the asymmetric vibrations, but there was no shift in the frequency within the resolution of the instrument. If the decrease in the frequency of the symmetric stretching vibration is directly related to the coplanarity of the nitro group with the aromatic ring, as has been suggested by Wepster et al.,[4] the present results might predict that the configurations of the neutral molecule and its anion radical are similar. This matter will be discussed in the next section.

The Steric Effect of Alkyl Groups.—The sterically induced decoupling of the nitro group

pi-electron system from the aromatic pi-electron system has been postulated solely on the basis of an interpretation of the electron spin resonance spectra.[5] On the basis of the observed changes in the nitrogen hyperfine splitting constants, a simple model involving hindered rotation in nitro aromatic anion radicals may be suggested. In this model the nitro group is twisted around the C–N bond.

Since the amount of twisting is likely to be similar in the anion radicals and in the neutral molecules, we have anticipated and found a linear relation between the nitrogen hyperfine splitting constants, a_N, and the shift of the symmetric stretching vibration frequency, as is shown in Fig. 1.

The decrease in the C–N bond order was also deduced from the ultraviolet absorption at 250 mμ by the equation of Braude[6] :

$$\varepsilon/\varepsilon_0 = \cos^2\theta \qquad (1)$$

where ε and ε_0 are the molar extinction coefficients for alkylnitrobenzene and nitrobenzene respectively, and where θ is the angle of twist of the nitrogroup out of the plane of the benzene ring. The ratio versus a_N is again plotted in Fig. 2.

The fact that the value of a_N extrapolated to $\theta = 90°$ falls in the range of a_N values characteristic of aliphatic nitro anion radicals confirms the expectation of the absence of conjugation between the nitro group and any groups to which it is bonded. In other words, the unpaired electron appears to be completely localized on the nitro group in this case.

For monoalkylnitrobenzenes, however, neither the infrared nor the ultraviolet spectroscopic data conform to the proportionality behavior shown in Figs. 1 and 2. For example, the nitrogen hyperfine splitting constant for *o*-*t*-butylnitrobenzene anion is 13.0 gauss, while the steric deformation predicted by Eq. 1 is 65 degrees, a value which cannot be predicted from Fig. 2. The cause of this deviation may be as follows. The resonance interaction of the nitro group with the benzene

ring is believed to be such as to constrain the nitrogen and the two oxygens to lie on the same plane, or such as to minimize the out-of-plane deflection, even in the presence of an alkyl group on one side, by bending the two groups away from each other, particularly in the case of the anion radicals. In those cases where the nitro group has alkyl groups on both sides, such bending is prevented, regardless of whether it is the neutral molecule or the radical anion. Thus, the changes in the observables in optical spectroscopy may be directly related to the extent of twisting. Any shift in the nitro-group absorption bands in the infrared spectra would reflect the twisting in the case of the monoalkylnitrobenzenes, but in the case of anion radicals, the shift may reflect both twisting and bending. Since the infrared spectra have not shed light on structural differences between the neutral molecule and the radical anion, as has been described in the last section, electron spin resonance spectra still seem to be a valuable source of infromation on the extent of intramolecular rotation for radical anions.[7]

The Computation of Hyperfine Splitting Constants.—Spin density (ρ) calculations based on the simple Hückel LCAO approximations have been carried out for a variety of parameters in the C–N bond integral expressed in the equation:

$$\beta_{NC} = \beta^0_{NC} \cos\theta \qquad (2)$$

The nitrogen hyperfine splitting constants computed

by the equations[8,9]:

$$a_N = 99.0\,\rho_N - 71.6\,\rho_O \quad (3)$$

$$a_N = Q_N\rho_N = 49\,\rho_N \quad (4)$$

are compared with the experimental values in Table II.

Analysis of the ESR Spectra.—An electron spin resonance spectrum always consists of three well-defined groups of lines corresponding to the interaction with a ^{14}N nucleus if a proper radical concentration is maintained, as is illustrated in Fig. 3. Without deuterium substitutions, the alkyl-proton splittings cannot be distinguished from the ring-proton splittings. The reliable computation of hyperfine components is prevented by linewidth alternations, and by the overlap of the spectral lines due to the presence of cation-paired and isolated radical anions.[10] Efforts to observe the hyperfine splitting of the tertiary-butyl group which has been observed for those derivatives of phenoxyl[11] have been fruitless. The hyperfine splitting of ^{13}C and ^{17}O nuclei are shown in Fig. 4.

The Effect of Metal Cations on the Spectra.—The nitrogen hyperfine splitting constant (a_N) increases with the reciprocal of the cationic radius (r) or with the electronic charge of the cation (z) in solution. A tight ion-pair formation may be directly predicted by a comparison with meta-substituted nitrobenzenes which follows the equation:[12]

$$a_N = \text{constant} \times z/(r + 0.6) \quad (5)$$

Equation 5 is consistent with the presence of a rather loose ion-pair (a solvent shared to a limited extent), in contrast to the results of the present investigation.

of the solvent molecule may release the ion-pair, pulling the metal cation away from the anion radical as well as inducing a more unpaired electron spin on the bulky aromatic ring so as to decrease that on the nitro group. This result is to be contrasted with those with phenoxyls[11] or diphenyl nitric oxide,[13] which are supposed not to be present as ion-pairs in the solution.

The Effect of Temperature Variation.— The nitrogen hyperfine splitting constant increases once below room temperature to a maximum in the temperature range from 0 to −10°C, and then it decreases at a rate of about a hundredth of a gauss per degree.

(Received September 20, 1965)

The electronic structures of dimers containing boron and aluminum atoms, i. e., B_2H_6, $B_2H_2(CH_3)_4$, Al_2Cl_6, $Al_2Cl_2(CH_3)_4$ and $Al_2(CH_3)_6$, are investigated by an extended Hückel method. The calculations show that the central linkages are weak and that their bonding natures are very different from those of the bonds between the metals and terminal atoms. Judging from the orbital energies and populations, these dimers still hold a strong acidity, like that in the monomers, an acidity which depends mainly on the existence of the almost unfilled $p\pi$ orbitals of the metal atoms, where the electrons occupying the lower vacant orbitals in these dimers are almost localized. The results are compared with other calculations and experimental results. It is, further, shown by examining the electronic structures of two hypothetical compounds that these dimers can be easily formed by using the vacant valence orbitals of the metal atoms, and that the metal-metal bonds in some dimers are considerably strong.

The structures of dimers containing boron or aluminum atoms have attracted the interest of many researchers. The bridged model has been applied to the structures of these dimers, and several interpretations have been attempted.[1]

In the present paper, we will treat these dimers by the extended Hückel method proposed by Hoffmann.[2] In our previous paper, Part I,[3] the electronic structures of monomers and ions, including boron or aluminum atoms, were considered by the same method. These dimer compounds are the so-called "electron-deficient compounds," and the usual concept of the electron-pair bond fails as a basis for an interpretation of their electronic structures. Hoffmann's method represents the molecular orbitals (MO) in terms of the linear combinations of the atomic orbitals (AO) of all the valence electrons of the atoms in the compounds; therefore, it is not necessary to predetermine the hybridizations or the orientations of the base orbitals. For this reason, this approximate method is suitable for the treatment of those compounds which have unusual valencies or configurations.

The dimer compounds to be studied in the present paper are B_2H_6, $B_2H_2(CH_3)_4$, Al_2Cl_6, $Al_2(CH_3)_4Cl_2$, $Al_2(CH_3)_6$, and some related compounds. Their electronic structures will be calculated, and,

$Al_2(CH_3)_6$	0.985	5.090	5.011	0.384	0.188

* The notations, M, X and Y refer to those given in Fig. 1.

** The values correspond to the hydrogen atom and the chlorine atom in $BH(CH_3)_2$ and in $AlCl(CH_3)_2$ respectively.

especially, the nature of the bonds and some physico-chemical properties will be discussed.

The values of the parameters used in this paper (the Coulomb and resonance integrals) were given in Part I of this series.[3] The coordinates of the above compounds are shown in Fig. 1, where the notation M denotes the boron or aluminum atom; Y, the bridge atom or group, and X, the terminal atom or group. The two M and four X atoms are on the XY plane, and the two Y atoms are on the Z-axis (one in the + region and the other in the − region). The px, py and pz orbitals of each atom have their positive parts in the X, Y and Z directions, respectively, of the coordinates in Fig. 1. The bond distances and bond angles are estimated with reference to the values given in Ref. 4. For the sake of simplicity in the calculation, however, the values listed in Ref. 4 have been modified slightly; for all the methyl groups, the valence angle is assumed to be tetrahedral, and the C–H bond distance is set equal to 1.09 Å throughout the calculations. The adopted values are summarized in Table I.

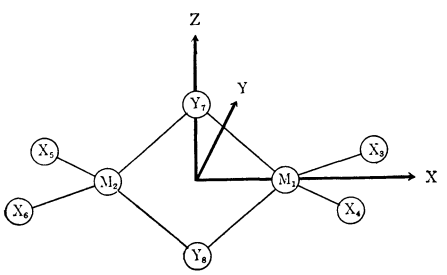

Fig. 1. The coordinates of dimers.

The Electronic Structures of the Dimers

Population Analysis. — The calculated values of the atomic populations of the atom A, M(A), and those of the atom bond populations between A and B atoms, M(A-B),[5] are listed in Fig. 2, where the M(A) values are represented by the numbers on the atom A, and the M(A-B) values, by those between the A–B bond (the values of the hydrogen atoms in the methyl groups are omitted for the sake of simplicity). The results given in Fig. 2 show that the M(A) and M(A-B) values in these dimers are similar to those in their monomers as given in Table II (the values of which are taken from our previous paper),[3] except for the quantities related to the bridge atoms or groups.

They also show that two types of bonds exist in these dimeric compounds; one is the M–X bond (corresponding to M and X in

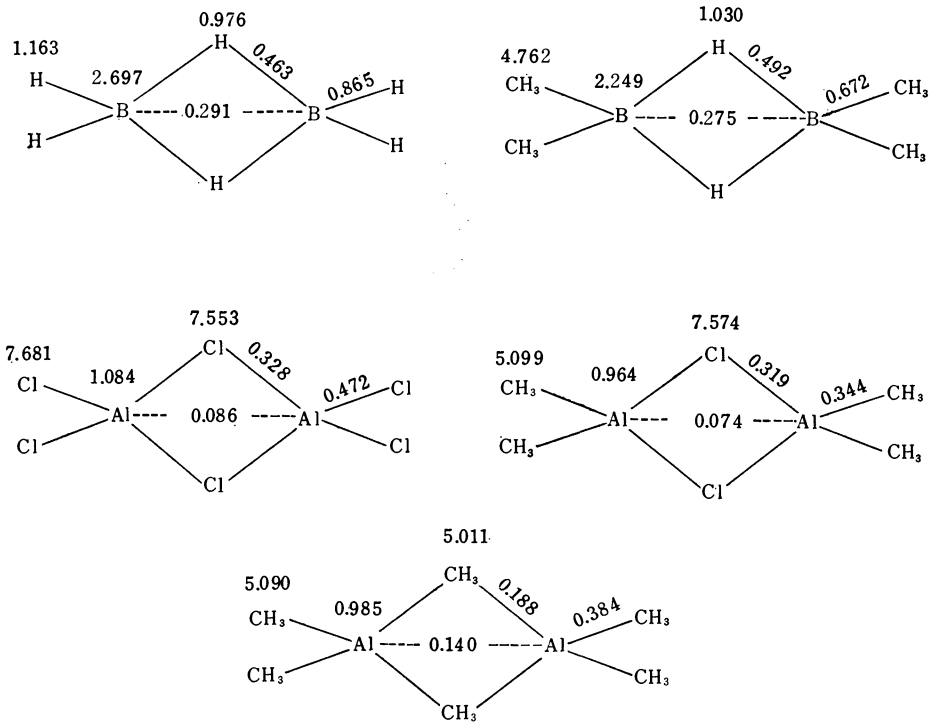

Fig. 2. The M(A) and M(A–B) values of dimers.

Fig. 1), which is nearly the same as the normal electron-pair bond, and the other is the M–Y bond (Y in Fig. 1), which is weak and which may be called a "semi-bond." For example, the calculated values of M(B–H_T) (where H_T indicates the terminal hydrogen) are 0.852 in BH_3 and 0.865 in B_2H_6, while that of M(B–H_B) (H_B denotes the bridge hydrogen) is 0.463. For $Al(CH_3)_3$, the values of M(Al–C_T) are 0.382 in the monomer and 0.384 in the dimer, while the M(Al–C_B) value is 0.188.

As to the M(A) values in M_2A_6-type compounds, those of the atoms in the bridge are slightly smaller than those of the terminal atoms. However, this result is partly in conflict with other results, as is mentioned below. For B_2H_6, our result leads to the $M(H_T) > M(H_B)$ relation, whereas the results of an LCAO SCF calculation by Yamazaki indicate $M(H_T) < M(H_B)$;[6] Yamazaki's findings agree with the experimental findings. On the other hand, it was reported, for Al_2Br_6, on the basis of a PQR measurement,[7] that the charges in the bridge bromine atoms are smaller than those in the terminal atoms; in this case, accordingly, this tendency may agree with our finding for Al_2Cl_6.

Our M(A) and M(A–B) values and some orbital energies for B_2H_6 are listed in Table III, together with the results obtained by Yamazaki. Except for the $M(H_B)$ and some MO energy values, the agreement between them is satisfactory.

Table III. Comparison of the calculated results for B_2H_6

		Present	Yazaki's SCF
M(A)	M(B)	2.697	2.78

$B_2H_2(CH_3)_4$**: $0.826(Z_{B1}-Z_{B2})-0.095(Z_{C3}+Z_{C4}-Z_{C5}-Z_{C6})$

Al_2Cl_6: $0.879(Z_{A11}-Z_{A12})-0.193(Z_{C13}+Z_{C14}-Z_{C15}-Z_{C16})-0.483(X_{C17}-XC_{18})$

$Al_2Cl_2(CH_3)_4$**: $0.900(Z_{A11}-Z_{A12})-0.153(Z_{C3}+Z_{C4}-Z_{C5}-Z_{C6})-0.459(X_{C17}-X_{C18})$

* The numbers in the suffices are given in Fig. 1 and the notations Z_{B1} and Z_{B2} denote the pz orbitals of the boron 1 and 2 atoms respectively, and so on.

** For the sake of simplicity, the values of the hydrogen atoms in the methyl groups and the smaller ones ($<10^{-2}$) are neglected.

to the monomers. This rising trend of the LV levels indicates that the dimeric compounds have an appreciable nucleophilic character, like that in the monomers pointed out in Part I.[3] Furthermore, the nucleophilic character of these dimers depends mainly on the existence of the almost unfilled $p\pi$ orbital of the metal atom, as may be seen in Table V, in which the values of the AO coefficients of the LV orbitals in some dimers are presented. It is there shown that the electrons in these orbitals are largely localized on the $p\pi$ orbitals of the metal atom, and that the anti-bonding character is strongest in the metal-metal bonds. Accordingly, the nucleophilic reagents or electron donors may coordinate with the metal atoms in the dimers, and the transfered electrons may primarily cause the metal-metal bonds to weaken or break. This result agrees with experience.[1]

Some Physico-chemical Properties. — The force constants of various Al-dimers have been evaluated;[8] the magnitudes have been shown to be parallel with those of the bond populations.[9]

TABLE VI. THE M(A-B) VALUES AND THE FORCE CONSTANTS OF Al-DIMERS

(a) Al-Al Bond

	M*	K**
Al_2Cl_6	−0.086	0

$Al_2(CH_3)_6$	0.140	0.50

(b) Al-Cl Bond

	Terminal		Bridge	
	M	K	M	K
Al_2Cl_6	0.472	2.35	0.328	1.05
$Al_2Cl_2(CH_3)_4$	—	—	0.319	1.05

(c) Al-C Bond

	Terminal		Bridge	
	M	K	M	K
$Al_2Cl_2(CH_3)_4$	0.344	2.05	—	—
$Al_2(CH_3)_6$	0.384	2.05	0.188	0.83

* The atom bond population, M(A-B).

** The force constant (in the units of md./Å) taken from Ref. 8.

Those values are summarized in Table VI. It has been pointed out recently that the observed ^{13}C–H spin-spin coupling constants are proportional to the values of the square of the bond order, p, between the ls AO of the hydrogen and the 2s AO of the carbon atom.[10] For B_2H_6, the ^{11}B–H_T and ^{11}B–H_B coupling constants have been measured as 137 c.p.s. and 48 c.p.s. respectively.[11] The calculated p^2 values, 0.149 and 0.029 respectively, are in accordance with the above experimental values. For $Al_2(CH_3)_6$, the NMR signals of the bridge methyl protons are observed in the lower field, and those of the terminal methyl protons in the higher field, at a low temperature.[12] The values for the charges of the bridge and the terminal hydrogens are similar to each other. Thus, the experimental results can not be explained by our calculated charges of hydrogens.*

The Nature of the Bonds in Dimers

The above discussions point out that the M(A–B) values of the metal-terminal atom bond are very different from those of the metal-bridge atom bonds.

* The proton chemical shift is influenced by other factors, such as the magnetic anisotropy of the adjacent carbon atom. Hence, it is impossible at the present stage to determine whether or not our result is valid.

The difference between these bonds will be examined further in this section by means of the values of the AO bond population, N(r–s). For instance, the N(s–s)/M(A–B) ratio, where N(s–s) denotes the AO bond population between the valence s AO's belonging to the A and B atoms, may be used as a measure of this difference. In other words, these values represent the s-nature of the bond X–Y. For B_2H_6, the values obtained are 0.27 for the $B–H_B$ bond and 0.37 for the $B–H_T$ bond. For Al_2Cl_6, the values are 0.20 for the $Al–Cl_B$ bond and 0.29 for the $Al–Cl_T$ bond. For $Al_2(CH_3)_6$, the values are 0.14 for the $Al–C_B$ bond and 0.20 for the $Al–C_T$ bond. Thus, the s-natures of these two bonds in the dimers are clearly different from each other; therefore, if one wants to use the hybrids of the metal atoms to explain the electronic structures of these dimers, at least two kinds of hybrids should be used. A similar point has already been made in Ref. 6.

For a further discussion of these points, two hypothetical compounds are considered. One is the compound which is produced by the symmetrical cleavage of the dimer without changing other conditions; it is named the "deformed monomer." The other is the compound which is produced by omitting the two bridge atoms or groups from the dimers; it is named the "omitted dimer." The shapes of these two compounds and the calculated M(A) and M(A–B) values are given in Fig. 3, in which the deformed monomer is indicated by MX_2Y, and the omitted dimer, by M_2X_4 (the notations M, X and Y are given in Fig. 1).

Some information can be drawn from the results in Fig. 3. For the deformed monomers, the M(M–Y) values (where Y is situated at the same position as the bridge atom in the dimer) are not appreciably different from the M(M–X) values (where X is the terminal atom in the dimer);

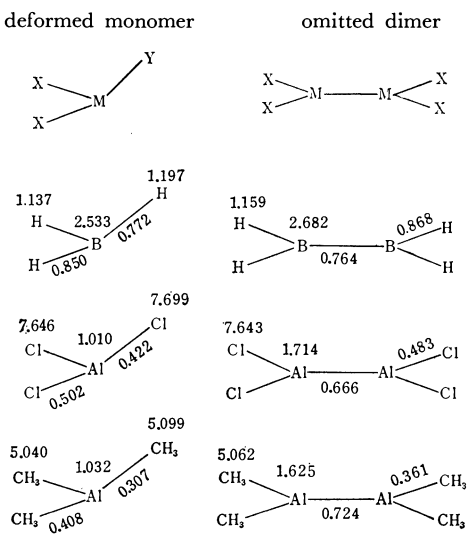

Fig. 3. The M(A) and M(A–B) values of the deformed monomers and omitted dimers.

upon dimerization, though, the M(M–Y) values decrease largely, while the M(M–X) values remain almost constant. For instance, the M(M–Y) values are 0.772 in the deformed BH_3 monomer and 0.463 in the dimer, while the M(M–X) values are 0.850 in the deformed monomer and 0.865 in the dimer. In the deformed monomers, the M(Y) values are slightly larger than the M(X) values; this tendency is reversed in the dimers, as has already been shown. Thus, as a result of the dimer formation the metal-bridge atom bonds become very weak, and a small amount of charge transfer may occur from the "bridge" atom to the other deformed monomer. As to the result for the omitted dimers, the M(M–M) values are quite large, showing that the metal-metal bonds are normal covalent bonds, such as those in B_2Cl_4.[3] The M(A) and M(A–B) values of the other parts are mostly comparable to the corresponding values in the normal dimers. For B_2H_4, the M(B–B) value is 0.764; this value decreases to 0.291 in B_2H_6. For Al_2Cl_4, the M(Al–Al) value is 0.666, and for Al_2Cl_6, –0.086, showing that the Al–Al bond becomes anti-bonding. Thus, as a result of the addition of the two bridge atoms to the omitted dimers, the metal-metal bonds become very weak.

Table VII presents the calculated values of the AO population, N(r). Those of the AO bond population, N(r–s), are given in Table VIII for various compounds including the boron atoms. The results in these tables indicate that the py orbital of the boron atom takes part in the boron-terminal hydrogen bonding, and that the pz and px orbitals take part in the boron-bridge hydrogen and the boron-boron bondings respectively.* In addition, the N(r) values of the px and pz orbitals of the boron atoms vary considerably, while the M(B) values do not change significantly, with the change in the structure from monomer to dimer. The changes in the configuration seem to take place easily by means of the rearrangement of valence electrons in an atom, since the valence orbital (in

Table VII. The N(r) values of the boron atoms in various compounds

	$N(S_B)$	$N(X_B)$	$N(Y_B)$	$N(Z_B)$	M(B)*
B_2H_4	0.979	0.893	0.811	0	2.683
B_2H_6	0.833	0.588	0.811	0.464	2.696
deformed BH_3	0.911	0.554	0.825	0.242	2.532
BH_3	0.912	0.825	0.825	0	2.562

* The notations $N(S_B)$ and $N(X_B)$ denote the atomic orbital populations of the 2s AO and the 2px AO of the boron atom respectively, and so on.

* From the results in Table VIII, it may be seen that the B–B bond in B_2H_6 has some π character; the same tendency is observed for the other M–M bonds in dimeric forms.

TABLE VIII. THE N(r–s) VALUES OF VARIOUS B-COMPOUNDS

a) B_2H_6

s \ r	S_{B1}	X_{B1}	Y_{B1}	Z_{B1}*
S_{B2}	−0.012	0.034	—	—
X_{B2}	0.034	0.166	—	—
Y_{B2}	—	—	−0.028	—
Z_{B2}	—	—	—	0.096

Z_{B2}	—	—	—	—
h_T	0.332	0.120	0.416	—

c) Deformed BH_3

s \ r	S_{B1}	X_{B1}	Y_{B1}	Z_{B1}
h_T	0.332	0.108	0.410	—
h_B	0.334	0.310	0	0.228

* The notations, S_{B1}, X_{B1}···Z_{B1} denote the 2s, 2px···2pz orbitals of the boron atom 1, and h_T and h_B are the 1s orbital of the terminal and bridge hydrogen atoms respectively.

this case, the pz orbital of the boron atom)** remains unoccupied.

Figure 4 lists the correlations between the orbitals in the omitted and normal BH_3 dimers. In B_2H_4, the HO orbital is mainly the σ-type bonding orbital between the boron atoms, while the LV orbital is the π-type bonding orbital between the boron atoms. When hydrogens are added to the bridge, these HO and LV orbitals are stabilized remarkably,

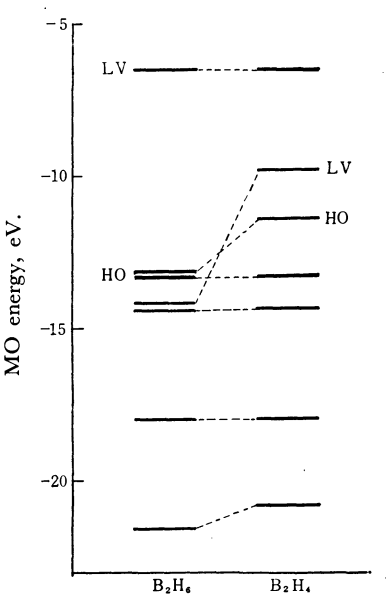

Fig. 4. The MO energies of B_2H_6 and B_2H_4.

and the LV orbital turns out to be the occupied orbital of the BH_3 dimer. These results agree with the tendency of the N(r) values; further, this change in the LV orbital may indicate that the bridge hydrogens are caught by the vacant pπ orbitals of the boron atoms.

Accordingly, our results may be summarized as follows:

1) In a dimer such as the M_2X_6 type, at least two kinds of M–X bonds exist.

2) The metal-terminal atom bonds are almost unchanged upon changes in the structure.

3) The metal-bridge atom bonds become quite weaker.

4) The metal-metal bonds are strong in some dimers.

5) The unfilled p orbitals of the metal atoms play an improtant role in the structural changes.

The calculations were carried out on the IBM 7090 computer of the Japan IBM Co., by the permission of the UNICON Committee, whose kindness we acknowledge.

* For the compounds with boron and hydrogen atoms, these results appear more clearly, since the electronegativities of the B and H atoms are almost equal to each other, and the effect of the migration of the electron between the atoms is negligible.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1383—1387 (1966)

The Refined Calculation of the Band-gap Energy of Tetramethylammonium Pentaiodide

By Shigekazu KUSABAYASHI,†,* Hiroshi MIKAWA,†,*
Misako KONDA†† and Masano HAYASHI†,*

† *The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka*
†† *Japan Atomic Energy Research Institute, Tokai, Ibaraki*

(Received October 18, 1965)

The band-gap energy has been calculated by a tight-binding approximation in a previous report. Although the value thus calculated coincided rather well with the experimental value, it might yet be possible that the band-gap energy will change appreciably when the interactions of all the energy levels are considered at one time. It was, therefore, calculated by the following method, which considers in principle all the level interactions. A repeating unit is composed of 30 atomic orbitals. Each atomic wave function makes three-dimensional Bloch functions. The crystal wave function is set up in the form of a linear combination of these 30 Bloch functions. The energy is then calculated by applying the variation principle and by using the Hückel approximation. The band-gap energy thus calculated is 1.20 eV. This value is near the experimental value, 1.36 eV.; it was also close to the previous result, 1.26 eV., thus confirming the previous calculations. The consideration of the band-widths and the density of the state may interpret the experimental results on the sign of the carrier. The results offer additional support for our previous conclusion regarding the conduction mechanism.

In a previous paper,[1] the band-gap energy of tetramethylammonium pentaiodide was calculated by a tight-binding approximation. The value thus calculated was 1.26 eV., which was satisfactorily near the experimental value, 1.36 eV., obtained from the conductivity measurements.[2] The method used was, briefly, as follows: The iodine framework in the crystal was looked upon as being constructed by repeated translations of a group of two pentaiodide ions (the repeating unit). The wave function of a repeating unit was calculated by Hückel approximation, the resonance integrals between iodine 5 p orbitals being estimated empirically from the data for the gaseous iodine molecule. The wave functions of the crystal were set up in the form of a Bloch function from the wave functions of the repeating unit. No mutual interactions of the Bloch functions of different energies were taken into consideration; thus, interactions between the levels with different energies were neglected.

Although the value thus calculated coincided rather well with the experimental value, it might yet be possible the band-gap energy will change appreciably when the interactions of all the energy levels are taken into consideration at one time.

We have, therefore, attempted in the present paper to calculate the band-gap energy of tetramethylammonium pentaiodide by another method, one which, in principle, takes all the level interactions into consideration (see Appendix).

Method

To solve the problem of the one-electron energy of a three-dimensional crystal from a general point of view, we have modified and extended the method which has previously been used to calculate the energy gap of one-dimensional macromolecules with conjugated double bonds[3] and which has also been used in calculating the band structure of a one-dimensional polynucleotide model.[4]

Primitive translations are denoted by $\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{c}$, and the numbering of the elementary cells, by N. It is assumed that one molecule composed of n atomic orbitals is contained in each elementary cell. The n atomic orbitals of a molecule are denoted by $\varphi_1, \varphi_2, \cdots, \varphi_l, \cdots, \varphi_n$, which make three-dimensional Bloch functions extending over the whole crystal.

$$\psi_{l\boldsymbol{k}}(\boldsymbol{r}) = \sum_{j=1}^{N} \exp(i\boldsymbol{k}\boldsymbol{R}_j)\varphi_l(\boldsymbol{r}-\boldsymbol{R}_j) \quad (l=1,2,\cdots,n)$$

where j is the numbering of the molecules and l, the numbering of the atomic orbitals in a molecule.

The crystal wave function is then set up in the form of a linear combination of these n Bloch functions;

$$\Psi_{\boldsymbol{k}}(\boldsymbol{r}) = \sum_{l=1}^{n} C_l \phi_{l\boldsymbol{k}}$$

By applying the variation principle and using the Hückel approximation, one arrives at a system of secular equations as usual. The following matrix eigenvalue problem for the determination of the possible energies of the electrons is obtained:

$$\boldsymbol{\gamma C} = \lambda \boldsymbol{C}$$

where an element of the matrix, $\boldsymbol{\gamma}$, is:

$$\begin{aligned}\gamma_{lm} = \beta_{lm} &+ \{\bar{\beta}^{a}_{lm} \exp(-i\boldsymbol{ka}) + \overset{+}{\beta}{}^{a}_{lm} \exp(i\boldsymbol{ka})\} \\ &+ \{\bar{\beta}^{b}_{lm} \exp(-i\boldsymbol{kb}) + \overset{+}{\beta}{}^{b}_{lm} \exp(i\boldsymbol{kb})\} \\ &+ \{\bar{\beta}^{c}_{lm} \exp(-i\boldsymbol{kc}) + \overset{+}{\beta}{}^{c}_{lm} \exp(i\boldsymbol{kc})\}\end{aligned}$$

Here, β_{lm} is a resonance integral between atomic orbitals, l and m, in the same molecule, and β_{ll} in the diagonal element of the matrix, $\boldsymbol{\gamma}$, is the Coulomb integral of the atomic orbital, l; $\bar{\beta}^{a}_{lm}$ is a resonance integral between the l atomic orbital of the $\boldsymbol{R}_j$ molecule and the m atomic orbital of the $\boldsymbol{R}_j - \boldsymbol{a}$ molecule; $\overset{+}{\beta}{}^{a}_{lm}$ is a resonance integral between the l atomic orbital of the $\boldsymbol{R}_j$ molecule and the m atomic orbital of the $\boldsymbol{R}_j + \boldsymbol{a}$ molecule, and $\bar{\beta}^{b}_{lm} \cdots \overset{+}{\beta}{}^{c}_{lm}$ have similar meanings. The nearest neighboring molecules of a molecule $\boldsymbol{R}_j$ are assumed to be $\boldsymbol{R}_j \pm \boldsymbol{a}$, $\boldsymbol{R}_j \pm \boldsymbol{b}$, and $\boldsymbol{R}_j \pm \boldsymbol{c}$.

The matrix, $\boldsymbol{\gamma}$, is shown to be Hermitian. Column vector $\boldsymbol{C}$ is set equal to $\boldsymbol{u} + i\boldsymbol{v}$. Then, the $\gamma_{lm}C_m$ term of the secular equations is:

$$\gamma_{lm}C_m = (A_{lm}u_m - B_{lm}v_m) + i(B_{lm}u_m + A_{lm}v_m)$$

where:

$$\begin{aligned}A_{lm} &= \beta_{lm} + (\overset{+}{\beta}{}^{a}_{lm} + \bar{\beta}^{a}_{lm}) \cos \boldsymbol{ka} \\ &\quad + (\overset{+}{\beta}{}^{b}_{lm} + \bar{\beta}^{b}_{lm}) \cos \boldsymbol{kb} + (\overset{+}{\beta}{}^{c}_{lm} + \bar{\beta}^{c}_{lm}) \cos \boldsymbol{kc} \\ B_{lm} &= (\overset{+}{\beta}{}^{a}_{lm} - \bar{\beta}^{a}_{lm}) \sin \boldsymbol{ka} + (\overset{+}{\beta}{}^{b}_{lm} - \bar{\beta}^{b}_{lm}) \sin \boldsymbol{kb} \\ &\quad + (\overset{+}{\beta}{}^{c}_{lm} - \bar{\beta}^{c}_{lm}) \sin \boldsymbol{kc}\end{aligned}$$

By separating further the secular equation into the real part and the imaginary part, and by equating both to zero, one obtains secular equations of the $2n$ order.

The equations can be considered as the partitioned forms of a real eigenvalue problem of twice the original size:

$$\begin{pmatrix} \boldsymbol{A} & -\boldsymbol{B} \\ \boldsymbol{B} & \boldsymbol{A} \end{pmatrix} \begin{pmatrix} \boldsymbol{u} \\ \boldsymbol{v} \end{pmatrix} = \lambda \begin{pmatrix} \boldsymbol{u} \\ \boldsymbol{v} \end{pmatrix}$$

This matrix is also Hermitian. In solving this problem, each eigenvalue appears twice.

In the actual calculation of tetramethylammonium pentaiodide, the same parameter values as in the previous paper were used. Each resonance integral was estimated on the basis of the relation:

$$\beta' = \beta \frac{S'/(1+S')}{S/(1+S)}$$

where β' and S' are resonance and overlap integrals respectively between the interesting orbitals, and β and S are the resonance and overlap integrals respectively for a standard. The values of β and S are those for $(5p\sigma, 5p\sigma)$ at the interatomic distance, 2.68 Å, of an iodine molecule. The appropriate overlap integrals between the interesting orbitals were calculated by Mulliken's formulas[5] for Slater-AO overlap integrals for $t=0$, taking the geometry of the atomic orbitals in crystal into consideration.

As has been stated before, the iodine framework in the crystal can be looked upon as being constructed simply by repeated translations of a group of two pentaiodide ions; this repeating unit is looked upon as a molecule. There are 30 Slater-type 5p atomic orbitals belonging to the 10 iodine atoms in a repeating unit. The nearest neighboring repeating units are located in the five directions, $\boldsymbol{a}$, $\boldsymbol{b}$, $\boldsymbol{c}$, $\boldsymbol{a}-\boldsymbol{b}$ and $\boldsymbol{b}+\boldsymbol{c}$.

Therefore, in our case, a 60-order matrix must be set up for each parametric $\boldsymbol{k}$ value, and then solved for eigenvalues.

Results and Discussion

A special computer program was set up, and the calculations of the eigenvalues for nearly one hundred different $\boldsymbol{k}$ values were performed with an IBM 7044 electronic computer. The maximum

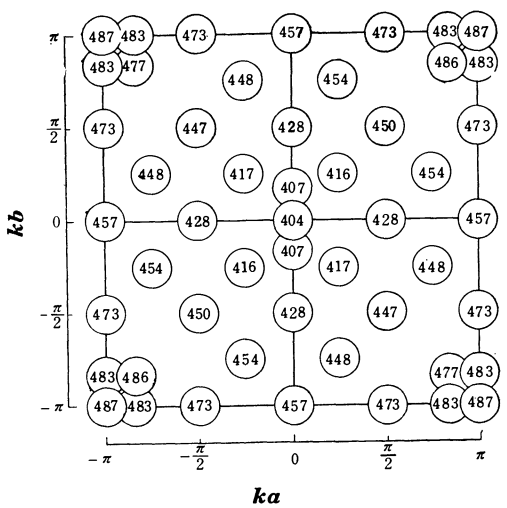

Fig. 1. Maximum energy value of filled band at $\boldsymbol{kc}=0$. $(-10^{-3}\beta$ unit).

5) R. S. Mulliken, C. A. Rieke, D. Orloff and H. Orloff, *J. Chem. Phys.*, **17**, 1248 (1949).

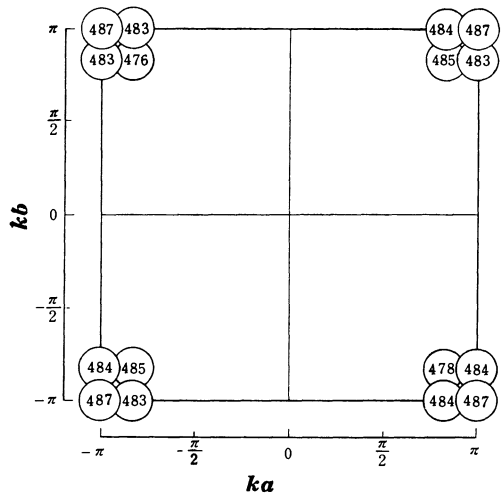

Fig. 2. Maximum energy value of filled band at $kc=\pi/6$. ($-10^{-3}\beta$ unit)

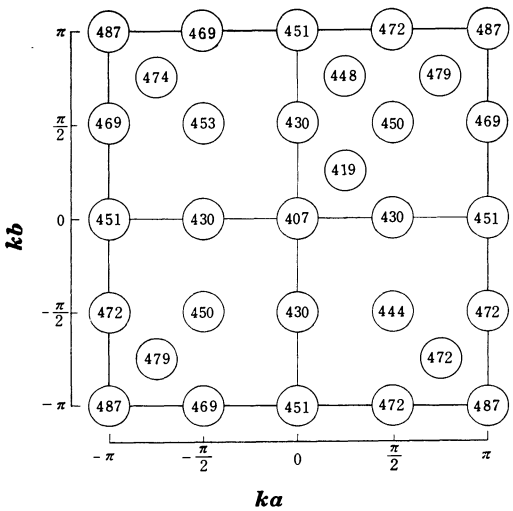

Fig. 3. Maximum energy value of filled band at $kc=\pi/2$. ($-10^{-3}\beta$ unit).

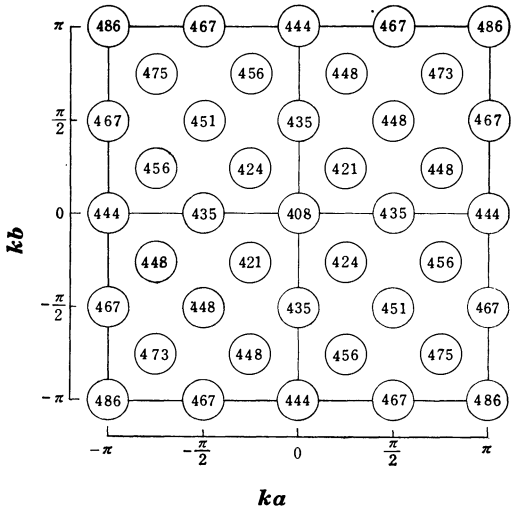

Fig. 4. Maximum energy value of filled band at $kc=\pi$. ($-10^{-3}\beta$ unit)

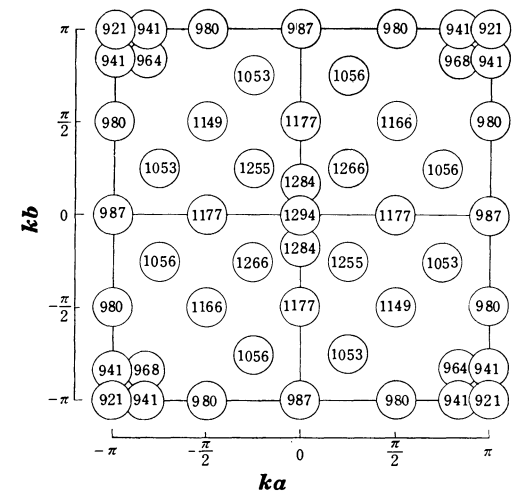

Fig. 5. Minimum energy value of unfilled band at $kc=0$. ($-10^{-3}\beta$ unit)

energy values of the filled bands are shown in Figs. 1—4, while the minimum energy values of the unfilled band are shown in Figs. 5—8. It seems that the energy values do not change much with the variation in kc value, and that the point of ($ka=\pi$, $kb=\pi$, $kc=0$) or some points closed to (π, π, 0) give the lower limit of the unfilled band and the upper limit of the filled band.

The band-gap energy is found to be 0.434β by using the value of (π, π, 0). The substitution of the $\beta=-2.76$ eV. from a previous assumption[1] into 0.434β gives 1.20 eV. This value is near the experimental value of 1.36 eV., and it is also close to 1.26 eV., the value obtained in the previous calculation.

The present method gives information about the band-gap energy, but the characteristics of each level are still not clear, as it is not possible to know $E(k)$ in an analytical form nor the functional forms of wave functions. As is shown in Fig. 9, 22 levels are filled by electrons and as a whole form a hole band, while the upper 4 levels are all vacant and form an electron band. It is found that the width of the electron band is nearly the same as that obtained in the previous report, but the width of the hole band is about 5 times as large as the previous result. (In the previous paper, it was thought tentatively that the hole band was constructed by an overlap of the upper 8 filled bands.) After all, the width of the hole band is about 3 times as large as the width of the electron band.

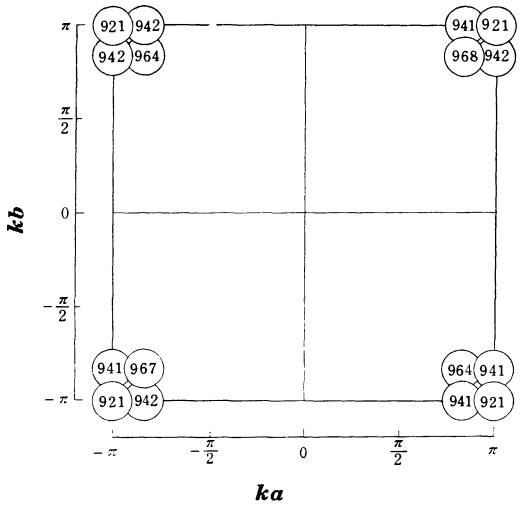

Fig. 6. Minimum energy value of unfilled band at $kc=\pi/6$. ($-10^{-3}\beta$ unit)

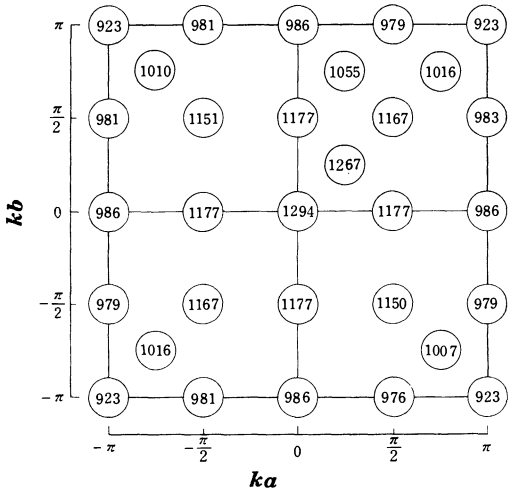

Fig. 7. Minimum energy value of unfilled band at $kc=\pi/2$. ($-10^{-3}\beta$ unit)

As for mobility, no experimental data has yet been obtained. Preliminary thermoelectric power measurements showed that the sign of the carrier was positive.[2] The fact that the width and the density of states in the hole band are much larger than those in the electron band might explain the experimental finding on the sign of the carrier.

Although the method used in the present calculations is more reliable than the previous method, the results are very near the previous results. This tends to confirm the prevoius calculation. Moreover, the results presented here are in agreement with the experimental results. They support our previous conclusion that the iodine framework in the crystal structure is of primary importance in determining the conductivity. They also offer additional support for the idea that the band

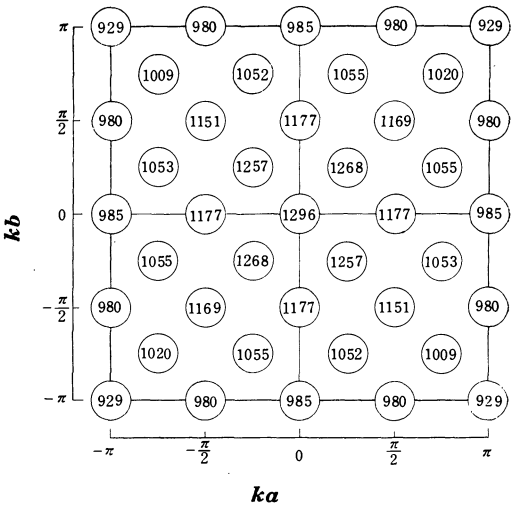

Fig. 8. Minimum energy value of unfilled band at $kc=\pi$. ($-10^{-3}\beta$ unit)

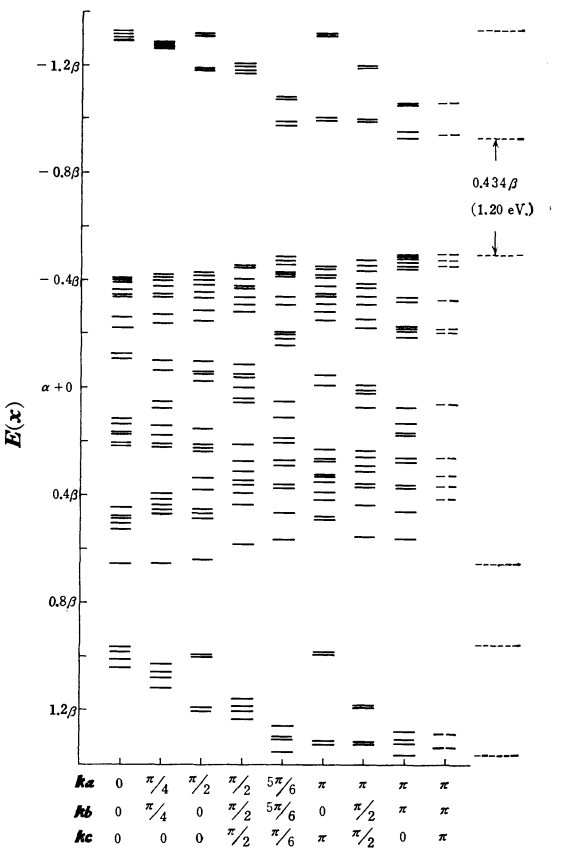

Fig. 9. Energy bands of pentaiodide. (α is the coulomb energy of the iodine 5p atomic orbital.)

model is applicable to the conduction mechanism of tetramethylammonium pentaiodide.

Appendix

The molecular orbital function, Φ^t, is approximated with a linear combination of atomic orbitals, φ_l;

$$\Phi^t = \sum_{l=1}^{n} a_l^t \varphi_l \tag{1}$$

where a_l^t is the coefficient of the lth atomic orbital of the tth level in the jth molecule. By multiplying both sides of (1) with $\exp(i\boldsymbol{k}\boldsymbol{R}_j)$, and by summing them up with respect to j,

$$\sum_{j=1}^{N} \Phi_{j\boldsymbol{k}}^t = \sum_{l=1}^{n} a_l^t \left(\sum_{j=1}^{N} \varphi_{l\boldsymbol{k}}\right) \tag{2}$$

where $\sum_{j=1}^{N} \Phi_{j\boldsymbol{k}}^t$ and $\sum_{j=1}^{N} \varphi_{l\boldsymbol{k}}$ are Bloch functions derived from the tth molecular orbital and from the atomic orbital respectively. In order to take all the level interactions into consideration, both sides of (2) are multiplied with an arbitrary coefficient, c^t, and the values from 1 to n are summed up with respect to t; hence,

$$\sum_{t=1}^{n} c^t \left(\sum_{j=1}^{N} \Phi_{j\boldsymbol{k}}^t\right) = \sum_{t=1}^{n} \sum_{l=1}^{n} c^t a_l^t \left(\sum_{j=1}^{N} \varphi_{l\boldsymbol{k}}\right)$$

As $\sum_{t=1}^{n} c^t a_l^t$ is an arbitrary parameter, one obtains:

$$\sum_{t=1}^{n} c^t \left(\sum_{j=1}^{N} \Phi_{j\boldsymbol{k}}^t\right) = \sum_{l=1}^{n} c_l' \left(\sum_{j=1}^{N} \varphi_{l\boldsymbol{k}}\right)$$

This formula indicates that the linear combination of the Bloch functions derived from each atomic orbital is equivalent to the case of the linear combination of the Bloch functions derived from each molecular orbital (level), i.e., to the case where all level interactions are taken into consideration.

The authors wish to express their thanks to Professor Junjiro Kanamori of Osaka University for his kind discussion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1387—1391 (1966)

The Rotatory Dispersion and Stereochemistry of Organic Compounds. X.[1] Nitrates of α-Hydroxy-carboxylic Acids

By Yojiro TSUZUKI, Koko TANABE, Kikuhiko OKAMOTO and Michiyo FUKUBAYASHI

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received October 19, 1965)

The rotatory dispersion (RD) and ultraviolet absorption of some α-hydroxy-carboxylic acids and their nitrates have been measured and analyzed. A distinct relation has been found between the configuration and the sign of the Cotton effect; namely, nitrates of α-D-hydroxy-carboxylic acids (R-configuration) show positive Cotton effects, while those of α-L-hydroxy-carboxylic acids (S-configuration) show negative Cotton effects. Thus a rotatory contribution by the nitrates of the α-hydroxyl group has been suggested, though it is opposite in sign to the xanthates of the α-hydroxy-carboxylic acids.

In previous papers[1,2] it has been reported, with various nitrates of glucose, that a regular relation exists between the configuration of the carbon atom carrying a nitrate chromophore and the sign of the Cotton effect; namely, α-glucosides with a nitrate chromophore in the D-configuration show negative Cotton effects, while the sign of the Cotton effects of the corresponding β-glucosides is positive. On the contrary, α-glucosides with a nitrate chromophore in the L-configuration show positive Cotton effects, while the sign of the Cotton effects of the corresponding β-glucosides is negative.

This paper will report similar studies made on the nitrate esters of some aliphatic α-hydroxy-carboxylic acids (compounds II—IV, VI, VII, IX—X, XII), namely, tartaric, malic and lactic acids and their alkyl esters, in order to find the sign of the rotatory contribution of the hydroxyl group and, at the same time, to learn that of the carboxyl group, and thus to confirm the view already expressed in earlier papers[3] that the OH group of α-hydroxy-carboxylic acids of the D-configuration contributes to a positive rotation and the COOH group to a negative rotation.

Results and Discussion

Figure 1 collects the RD curves of the derivatives of D(+)-tartaric acid observed in methanol as well

Table I. Hydroxy-carboxylic acids and their Nitrates

Compound		
I	Diethyl D(+)-tartrate	$COOC_2H_5$ $H-C-OH$ $HO-C-H$ $COOC_2H_5$
II	Diethyl D(+)-tartrate mononitrate	$COOC_2H_5$ $H-C-ONO_2$ $HO-C-H$ $COOC_2H_5$
III	Diethyl D(+)-tartrate dinitrate	$COOC_2H_5$ $H-C-ONO_2$ $O_2NO-C-H$ $COOC_2H_5$
IV	D(+)-Tartaric acid dinitrate	$COOH$ $H-C-ONO_2$ $O_2NO-C-H$ $COOH$
V	Dimethyl D(+)-tartrate	$COOCH_3$ $H-C-OH$ $HO-C-H$ $COOCH_3$
VI	Dimethyl D(+)-tartrate mononitrate	$COOCH_3$ $H-C-ONO_2$ $HO-C-H$ $COOCH_3$
VII	Dimethyl D(+)-tartrate dinitrate	$COOCH_3$ $H-C-ONO_2$ $O_2NO-C-H$ $COOCH_3$
VIII	Diethyl L(−)-malate	$COOC_2H_5$ $HO-C-H$ $CH_2COOC_2H_5$
IX	Diethyl L(−)-malate nitrate	$COOC_2H_5$ $O_2NO-C-H$ $CH_2COOC_2H_5$
X	L(−)-Malic acid nitrate	$COOH$ $O_2NO-C-H$ CH_2COOH
XI	Ethyl D(−)-lactate	$COOC_2H_5$ $H-C-OH$ CH_3
XII	Ethyl D(−)-lactate nitrate	$COOC_2H_5$ $H-C-ONO_2$ CH_3

as in dioxane. The mononitrate (compound II) exhibits a positive Cotton effect with a peak at

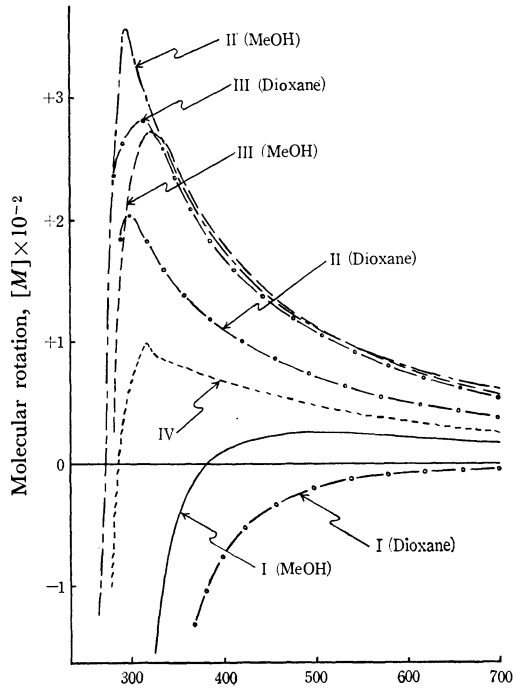

Fig. 1. RD of I—IV.

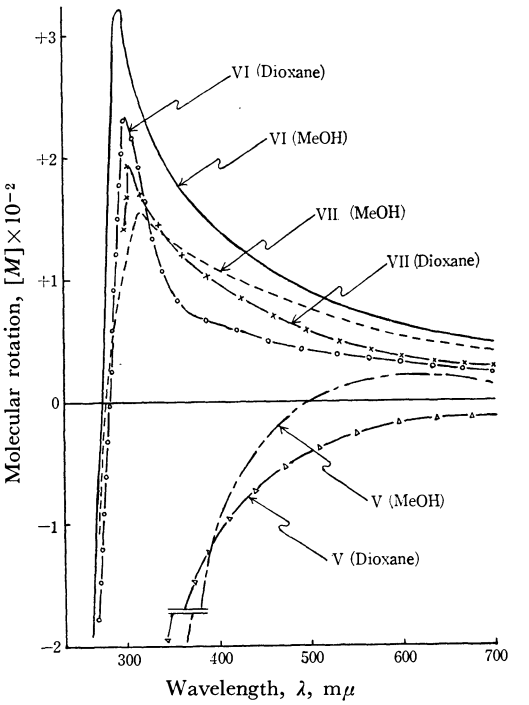

Fig. 2. RD of V—VII.

294 mμ, and the dinitrates (compounds III and IV) also show positive Cotton effects, the peaks of which both appear at 315 mμ. It should, however, be remarked that some anomalies are visible on

the RD curves of these two dinitrates in the region from 330 to 430 mμ, anomalies which can apparently be related to the ultraviolet multiple absorption curves (III and IV) shown in Fig. 4, but the region of the absorption (320—380 mμ) is considerably red-shifted as compared with the peak of the Cotton effect.

In contrast to the dinitrates, a larger decrease in rotation is observed in dioxane than in methanol with the mononitrate (Fig. 1); this decrease is likely to be due to intramolecular hydrogen bond formation in non-polar solvents, as has already been suggested.[3a] Here the intramolecular hydrogen bond may be formed between the OH group and either the carbalkoxy or the nitrate group, whereby the rotatory contribution of the OH group is reduced to a more or less large extent. At any rate, the positive sign of the Cotton effect of the three nitrates agrees with the R-configuration assigned according to the rule of Cahn et al.[4]

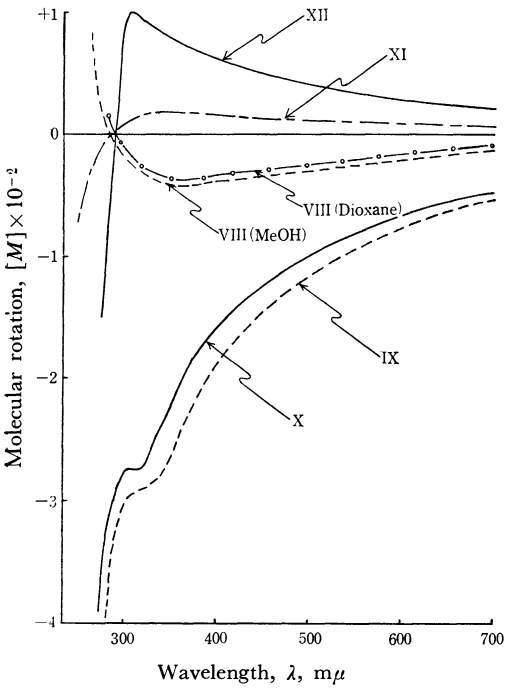

Fig. 3. RD of VIII—XII.

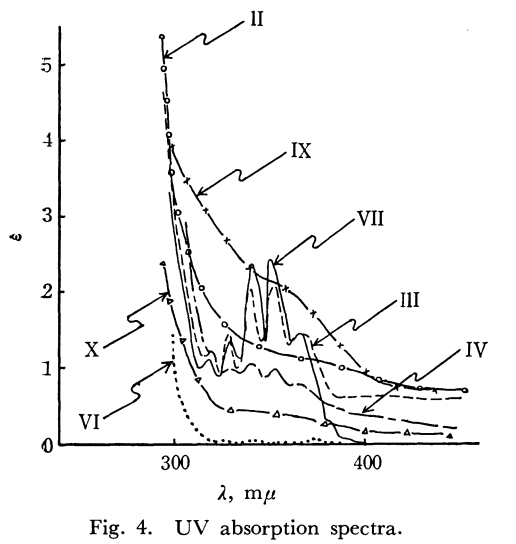

Fig. 4. UV absorption spectra.

In Fig. 2 are shown the RD curves of the mono- and dinitrates of dimethyl D(+)-tartrates (V—VI), observed both in methanol and dioxane. They are not essentially different in their main features from those of Fig. 1. However, the rotation increases in the positive direction in the order:

$$COOH < COOCH_3 < COOC_2H_5$$

Figure 3 gives the RD curves of the three derivatives of L(−)-malic acid (VIII—X), as well as those of D(−)-lactic acid (XI—XII). The nitrate of diethyl L(−)-malate (IX) has a feeble negative Cotton effect, with a shoulder in the region from 300 to 320 mμ, the peak being at 303 mμ and the trough at 310 mμ, while the RD curve (IX) can be expressed by the following Drude equation:

$$[M] = \frac{-0.723}{\lambda^2-(0.313)^2} + \frac{-23.82}{\lambda^2-(0.169)^2} \qquad (1)$$

The negative sign of the Cotton effect can also be confirmed by the negative dispersion constant ($A=-0.723$) of the first term of Eq. 1 as well as by the S-configuration of the asymmetric center. The ultraviolet absorption spectrum does not show a fine structure, as do those of the nitrates of tartaric acid, and it has a slight shoulder at 325—380 mμ (IX in Fig. 4).

Thus, it may be concluded that the nitrates of α-hydroxy-carboxylic acids of the D-type (R-configuration) show positive Cotton effects, whereas the nitrates of the L-type (S-configuration) exhibit negative Cotton effects.

It is noteworthy that this conclusion is just the opposite of the observations[5] that all the xanthates of L-hydroxy-carboxylic acids show positive Cotton effects, while those of D-acids exhibit negative Cotton effects. A similar "inversion" of the sign of rotation has been observed in the xanthates of various derivatives of monosaccharides.[6]

As to the correlation between the RD curve and the configuration, lactic acid is expected to provide

Table II. Dispersion data and Constants

$$[M]=\frac{A_1}{\lambda^2-\lambda_1^2}+\frac{A_2}{\lambda^2-\lambda_2^2}$$

Compound	Drude's equation				$\lambda_{RD}(\mu)$	Sign of Cotton effect	Configuration[4]
	A_1	A_2	$\lambda_1(\mu)$	$\lambda_2(\mu)$			
I	−34.20	+44.68	0.237	0.173			
II	+ 1.29	+27.03	0.312	0.076	0.294	+	R
III	+ 0.815	+29.37	0.303	0.160	0.315	+	R
IV	+ 0.440	+10.3	0.310	0.150	0.315	+	R
V	−36.98	+42.28	0.237	0.173			
VI	+ 0.10	+25.10	0.305	0.207	0.296	+	R
VII	+ 1.58	+15.21	0.300	0.159	0.315	+	R
VIII	+ 2.24	−11.13	0.255	0.000		+	R
XI	− 0.723	−23.82	0.313	0.169		−	S
X	− 1.36	−23.20	0.288	0.000		−	S
XI	− 0.733	+ 3.186	0.255	0.099			
XII	+ 0.496	+ 8.50	0.309	0.158	0.310	+	R

an interesting problem. As may be seen in Fig. 3, ethyl D(−)-lactate really shows a RD curve (XI) quite similar in shape to those of alkyl D(+)-tartrates (I in Fig. 1 and V in Fig. 2); this fact may easily be understood since the lactate coincides with the tartrates in configuration, so that a positive Cotton effect may be expected of the nitrate of D(−)-lactic acid; really, this has already been confirmed with the nitrate of ethyl D(−)-lactate (XII).

Dispersion Constants

The data of the RD measurements were calculated according to a two-term expression of the Drude equation:

$$[M]=\frac{A}{\lambda^2-\lambda_1^2}+\frac{B}{\lambda^2-\lambda_2^2} \qquad (2)$$

They have been found to conform to the equation tolerably well, with two exceptions (compounds VIII and X), which can rather better be expressed by an abbreviated form ($\lambda_2=0$).

The dispersion constants of these compounds thus computed are given in Table II, together with some other data on the Cotton effect and on the configuration of the chromophore-bearing asymmetric center.

Experimental

The nitrates of the hydroxy-carboxylic acids and their esters were prepared according to the methods of the literature. The rotatory dispersion was measured with a Rudolph spectropolarimeter over the region from 250 to 700 mμ. The ultraviolet absorption was measured with a Hitachi EPU-II self-recording spectrophotometer. The dispersion constants of the Drude equations were calculated from the data by means of the least-square method with a Fuji FACOM 201 electronic computer.

Diethyl D(+)-Tartrate (Compound I)[7].—Colorless syrup, b. p. 157—158°C/11 mmHg. The RD was measured at 17°C in methanol (*c*, 1.3758). $[\alpha]_{700}^{17}$ +8.31°, $[\alpha]_{600}$ +10.7°, $[\alpha]_{589}$ +10.9°, $[\alpha]_{500}$ +14.3°, $[\alpha]_{400}$ +7.12°, $[\alpha]_{350}$ −21.5°, $[\alpha]_{320}$ −75.0°.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1391—1397 (1966)

The Rotatory Dispersion and Stereochemistry of Organic Compounds. XI.[1] The Nitrates of Some Hexoses

By Yojiro TSUZUKI, Koko TANABE, Kikuhiko OKAMOTO and Noriko YAMADA

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received December 18, 1965)

The rotatory dispersions (RD) and the ultraviolet absorptions of eight nitrates of galactopyranoside, altropyranosides, glucofuranoside, mannopyranosides and of glucopyranosides, and also of five hexosepyranosides, have been measured. Studies have also been made of the correlation between the configuration and the Cotton effect, the sign of which has been determined by the RD curve as well as by the dispersion constant computed from the dispersion data, and in some cases by means of the circular dichroism (CD). All the findings and conclusions are consistent with the generalized rule originally found with glucose derivatives (Y. Tsuzuki, K. Tanabe and K. Okamoto, This Bulletin, **39**, 761 (1966)). The rule has been shown to be extensively applicable to several hexoses; namely, α-glycosides with a C–ONO_2 chromophore of an α(or D)-configuration show negative Cotton effects, and those with a C–ONO_2 group of a β(or L)-configuration exhibit positive Cotton effects, while with nitrates of β-glycosides the signs of the Cotton effects are exactly reversed (ref. Conclusion).

As has already been reported,[2] the nitrates of glucopyranoside show curves of a rotatory dispersion (RD) with a Cotton effect, and a distinct, regular relationship was observed between the sign of the Cotton effect and the configuration of the nitrates.

In this paper it will be reported that the same regular relation can be observed between the configuration and the rotatory dispersion of eight nitrates of altropyranosides, mannopyranosides, glucopyranosides and a glucofuranoside (Table I); moreover, the RD curves of five other hexose derivatives (Table II) will be described and discussed with reference to the background rotations of the nitrates, and, further the RD curves, of five other nitrates already reported on will be referred to, namely, those of pentaacetyl-α-D-glucopyranose[2] (compound XIV), 2, 3, 4, 6-tetra-*O*-acetyl-1-*O*-nitro-α-D-glucopyranose (compound XV), methyl 4 : 6-*O*-benzylidene-α-D-glucopyranoside 3-nitrate[2] (compound XVI), 1, 2 : 5, 6-*O*-diisopropylidene-D-glucofuranose[3] (compound XVII) and of methyl

4 : 6-*O*-benzylidene-α-D-glucopyranoside 2 : 3-dinitrate[2] (compound XVIII).

Results and Discussion

Figure 1 gives the RD curve of 2, 3, 4, 6-tetra-*O*-acetyl-α-D-galactopyranoside-1-nitrate (compound I), whose inflection below 280 mμ indicates no clear sign of the Cotton effect. However, from the positive curve of the circular dichroism (CD) of I (Fig. 1), the weak Cotton effect can be concluded to be positive in sign. This is in harmony with the convention of Cahn et al.,[4] for the C_1-configuration of I is of an R-conformation.

The RD curve (I) above the absorption region

TABLE II. BACKGROUND'S COMPOUNDS

Number	Name	Structure
IX	Pentaacetyl-α-D-galactopyranose	X	Methyl α-D-mannopyranoside	XI	Methyl 4 : 6-*O*-benzylidene-α-D-altropyranoside	XII	Methyl 4 : 6-*O*-ethylidene-α-D-glucopyranoside	XIII	Methyl β-D-glucopyranoside	

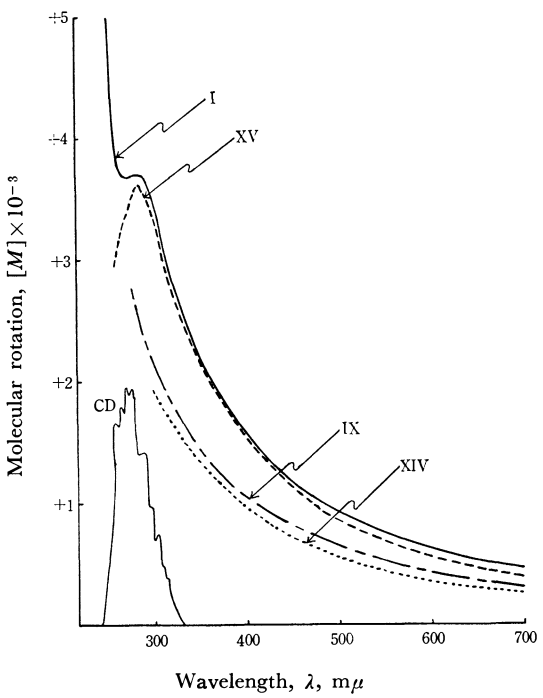

Fig. 1. RD of C_1-nitrates of hexoses (I, IV) and CD of I.

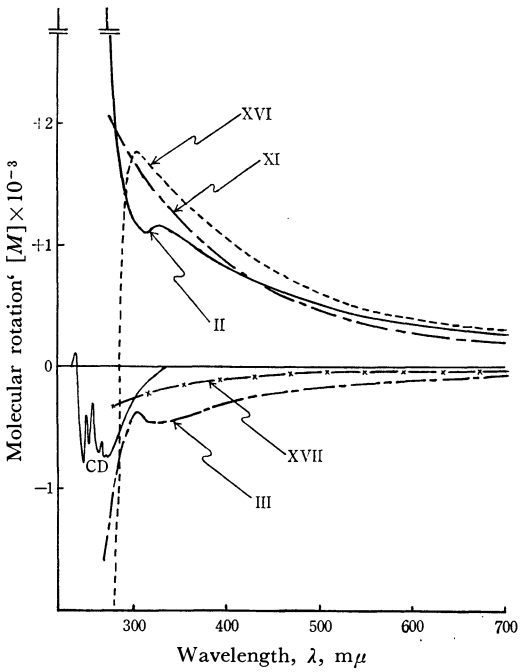

Fig. 2. RD of C_3-nitrates of hexoses (II, III, XVI) and CD of II.

(265—300 mμ) approximates that of 2, 3, 4, 6-tetra-*O*-acetyl-1-*O*-nitro-α-D-glucopyranose (compound XV), which has been reported to show a positive Cotton effect in nearly the same region, the peak of which lies at 285 mμ.[2] These two pyranosides differ only in C_4-OAc configuration; namely, the acetoxyl group is axial in the galactopyranoside (I) and equatorial in the glucopyranoside (XV). They conform to the isorotation

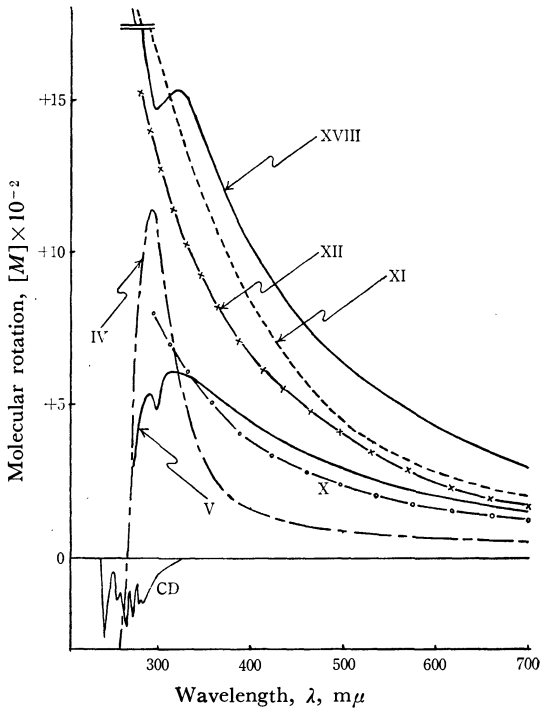

Fig. 3. RD of 2,3-dinitrates of hexoses and CD of V.

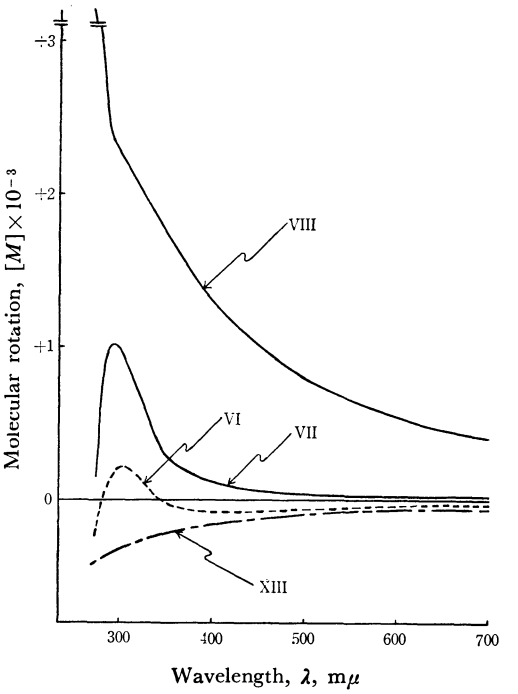

Fig. 4. RD of tri- (VI) and tetranitrates (VII, VIII) of methyl glucopyranosides.

rule of Hudson. The ultraviolet absorption of compound I (Fig. 5) due to the $n\rightarrow\pi^*$ transition of the nitrate group coincides in position with the Cotton effect.

The background optical rotations of compounds I and XV are given, respectively, as the plain curves IX and XIV in Fig. 1; from these it may be seen that the α-C_1-ONO_2 group makes a greater positive rotatory contribution than the α-C_1-OAc.

Figure 2 shows the RD curves of three C_3-ONO_2 derivatives (II, III and XVI). In contrast to methyl 4 : 6-*O*-benzylidene-α-D-glucopyranoside-3-nitrate (XVI),[2] which exhibits a sharp positive Cotton effect with a peak at 300 mμ, methyl 4 : 6-*O*-benzylidene-α-D-altropyranoside 3-nitrate (compound II), which is the C_3-ONO_2, C_2-OH diastereomer of XVI, shows a very weak Cotton effect around 315—320 mμ, the sign of which was determined to be negative by observing the CD curve (Fig. 2), which proved to be negative in sign. That the negative Cotton effect is located at a longer wavelength (315 mμ) is considered to be due to some steric interaction between the C_3–ONO_2 and α-C_1-OMe groups, for the ultraviolet absorption (II) is observed at nearly the same position as the other nitrates (Fig. 6).

The RD curve of the compound III with a furanose ring shows a positive Cotton effect, as may be seen in the negative domain of Fig. 2, with a peak, at 295 mμ, the sign of which coincides with that of the C_3-nitrate of glucose (XVI). Their C_3-ONO_2 configurations are both in the β-position, although their ring structures are different; the sign of the Cotton effect (due to the nitrate group) seems to be independent of the ring structure.

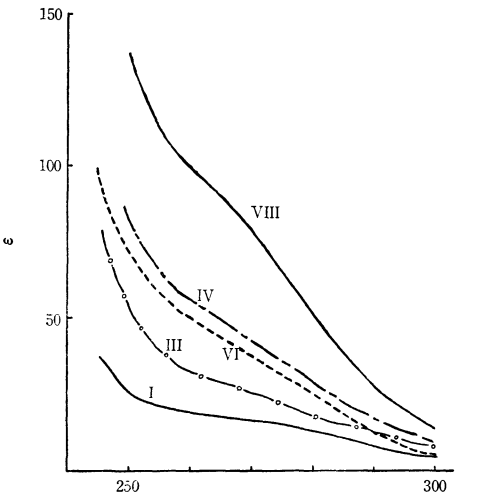

Fig. 5. UV absorption spectra of nitrates.

Mention should also be made that the corresponding xanthate[3] exhibits a positive Cotton effect, just as the nitrate (III) does, although their effects are quite different in strength.

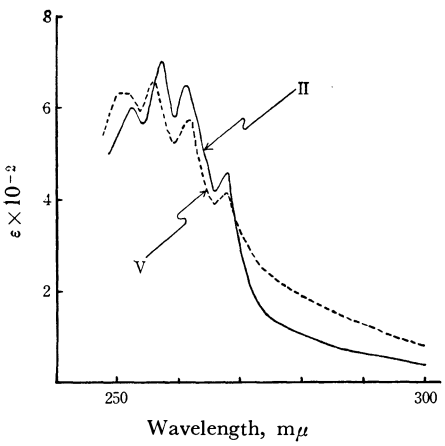

Fig. 6. UV absorption spectra of II and V.

Figure 3 gives the RD curves of some 2, 3-dinitrates. A distinct positive Cotton effect, with a peak at 293 mμ, is seen in methyl 4 : 6-*O*-ethylidene-α-D-mannopyranoside 2 : 3-dinitrate (IV), since the C_2-ONO_2 and C_3-ONO_2, both of the L-configuration, contribute to the positive Cotton effect; this is in conformity with the principle established in an earlier paper[2] (see Table IV of this paper).

The compound XVIII (Fig. 3), which is the C_2-epimer of compound IV, shows, as has been reported,[2] a higher dextrorotation, one due to the contribution of the C_2-group of the D-configuration, but it also exhibits a negative Cotton effect, with a trough at 300 mμ due to the predominating vicinal effect of the C_2-ONO_2 group over that of the C_3-ONO_2 group.

The complex Cotton effect seen in Fig. 3 is exhibited by the RD curve of methyl 4 : 6-*O*-benzylidene-α-D-altropyranoside 2 : 3-dinitrate (V), whose C_2-ONO_2, being of the L-type, contributes to a positive Cotton effect, while the C_3-ONO_2 of the D-type causes a negative Cotton effect. It is most likely that the peak at 290 mμ is responsible for the C_2-ONO_2 group, and that the somewhat wide trough extending from 300 to 310 mμ is an expression of a Cotton effect due to the C_3-ONO_2 chromophore. The sign of this chromophore is probably negative, for the CD curve (Fig. 3) seems to be negative in sign, but the complicated nature of the curve permits no hasty conclusion. Figure 3 also gives the RD curves of the compounds X—XII in order that information on the background rotations of the three 2, 3-dinitrates (IV, V and XVIII) can be obtained by comparing their RD curves.

The RD curve of IV is lower than the background curve of X above the absorption region; because both of the C_2- and C_3-nitrate groups are of the L-type, they contribute to a greater negative rotation than do the corresponding C_2- and C_3-hydroxy groups. The background rotation of XI is also more enhanced than the RD curve of the corresponding 2, 3-dinitrate (V) of the L-type, since the C_2-nitrate group of the L-type is a dominant contributor to a negative rotation as compared to the C_3-nitrate group of the D-type, which might contribute to a positive rotation.

On the contrary, the dinitrate (XVIII),[2] with a C_2-nitrate of the D-type, exhibits in the transparent region a higher positive rotation than does the corresponding background compound (XII) in spite of the presence of the levorotatory C_3-nitrate group.

Figure 4 gives the RD curves of the tri- and tetranitrates of methyl glucopyranosides. Methyl 6-*O*-acetyl-2, 3, 4-tri-*O*-nitro-β-D-glucopyranoside (VI) shows a weak positive Cotton effect, with a broad peak around 295 mμ. This feature is in good harmony with the fact that methyl 4 : 6-*O*-ethylidene-β-D-glucopyranoside 2 : 3-dinitrate, as has already been reported,[2] shows a similar RD curve, with a weak positive Cotton effect.

As may be seen from Fig. 4, a distinct positive Cotton effect is exhibited by the tetranitrate (VII) (methyl 2, 3, 4, 6-tetra-*O*-nitro-β-D-glucopyranoside), whose RD curve has a peak at 290 mμ, whereas its α-anomer (VIII) shows no clear Cotton effect, but only a shoulder around 285—325 mμ. From the regularity already stated, it may be expected that the C_2-ONO_2 and C_4-ONO_2 chromophores, both of the D-configuration (VIII), would give rise to negative Cotton effects; in reality, however, they appear to have been suppressed by the overwhelming, dextrorotatory contribution of the α-C_1-OMe group. The negative plain curve of XIX shows that the β-C_1-OMe group, as a powerful levorotatory contributor, even predominates over the α-C_2-OH group, which would contribute to a strong dextrorotation.

As to the effect of the C_6-ONO_2-chromophore, it can safely be concluded, by comparing several glucopyranose nitrates (compounds VI and VII in this paper, compounds XIV and XV in Part IX[2]), that the C_6-ONO_2 group contributes more or less to positive rotation.

Figures 5 and 6 give the ultraviolet spectra of the eight nitrates described in this paper. As has arleady been reported,[2,5] sugar nitrates usually exhibit weak shoulders ($\varepsilon < 100$) in the region from 250 to 280 mμ of the ultraviolet absorption spectra; this region nearly coincide with the regions of absorption found by a study of their RD curves. However, a somewhat anomalous behavior appears in the ultrariolet absorptions of the compounds II and V (Fig. 6), which occur in the region from 270 to 290 mμ, presumably as a result of the absorption of the phenyl group superposed upon the absorption of the nitrate chromophore around 250—280 mμ.

Table III. Dispersion data and constants

Nitrate	Drude's equation			$\lambda_{RD}(\mu)$	Sign of Cotton effect	Configuration of C_1
	A	B	$\lambda_0(\mu)$			
I	+35.8	+179	0.244	0.280	+	α
II	− 1.58	+130	0.276	0.315	−	α
III	+ 4.21	− 47.0	0.296	0.295	+	α
IV	+ 8.80	+ 11.7	0.275	0.293	+	α
VI	+ 5.51	− 22.0	0.285	0.295	+	β
VII	+ 8.91	− 2.27	0.296	0.290	+	β
VIII	− 3.21	+201	0.299	0.290—0.310 (shoulder)	−	α

Dispersion Constants

It has been found that the data obtained by the RD measurements conform well to the simplified two-term equation of Drude:

$$[M] = \frac{A}{\lambda^2-\lambda_0^2} + \frac{B}{\lambda^2} \qquad (1)$$

The results of calculation, the signs of the Cotton effect and the C_1-configurations are collected in Table III. As may be seen in Table III, the sign of the A-value agrees with that of the Cotton effect in every case, while the absolute value of A well expresses the intensity of the Cotton effect, in harmony with the RD curve.

Here it is worthy of remark that the compound VIII has only a small A value, but its negative sign (−3.21) undoubtedly shows that the Cotton effect is also negative. In reality, however, the sign of its Cotton effect cannot readily be determined by the RD curve, which shows only a shoulder in the absorption region. This slight negative Cotton effect supports the view that the C_2-ONO_2 chromophore of the D-configuration in α-glucosides is a dominant contributor to a negative Cotton effect; this is in conformity with the general rule previously proposed by the present authors.[1]

The B-value in general represents the background rotation, the positive sign of which corresponds to the α-C_1-configuration, and the negative sign, to the β-C_1-configuration. Apparently this regularity does not hold with the compound III, but even so it is not necessarily an exception, for this furanoside 3-nitrate (III) is bridged, between C_1 and C_2, by an isopropylidene radical.

The value of λ_{RD} in Table III represents the position of the peak or the trough of the RD curve; the real absorption center is presumed to be located in a region of a somewhat shorter wavelength. This may be seen from the ultraviolet absorption curve, and the results of calculation really support this reasoning.

Conclusion

As has been stated above, the regular rule established in a previous paper,[2] a rule as to the correlation between the sign of the Cotton effect and the configuration, holds true with the nitrates shown in Table I. The conclusions are summarized in Table IV.

Table IV. The configurations and the signs of the Cotton effect of nitrates of glucosides

C_1-Configuration of glucosides	Configuration of C-ONO_2	Sign of the Cotton effect	Contribution of the rotation
α-Anomer	D or α	−	+
α-Anomer	L or β	+	−
β-Anomer	D or α	+	+
β-Anomer	L or β	−	−

In conclusion, it should also be pointed out that the regular relation observed between the sign of the Cotton effect and the configuration with the nitrates of some α-hydroxy-carboxylic acids[1] corresponds to the case of the β-anomer shown in Table III, and that, conversely, the similar rule found with sugar xanthates[3,6] corresponds to the case of the α-anomer.

Experimental

The derivatives of sugars were prepared according to the methods of the literature. The rotatory dispersion was measured with a Rudolph spectropolarimeter over the wavelength region from about 260 mμ to 700 mμ. The circular dichroism curves were obtained using a JASCO optical rotatory dispersion recorder of the ORD/UV-5 type. The ultraviolet absorption was measured with a self-recording spectrophotometer of the Hitachi EPU-II type. The dispersion constants of the Drude equation were computed from the data by means of the least-square method with an electronic computer of the Fuji FACOM 201 type.

On the Carbon-13 Chemical Shifts of Saturated Hydrocarbons

By Teijiro YONEZAWA, Isao MORISHIMA and Hiroshi KATO

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received October 23, 1965)

A molecular orbital interpretation of the carbon-13 chemical shifts of saturated hydrocarbons is presented. The shielding constant of the carbon atom is shown to be roughly proportional to the excess charge densities of 2p electrons, which is in accordance with experiments. The so-called β- and γ-effects in the carbon-13 chemical shifts are explained on the basis of an MO theory.

Recently carbon-13 nuclear magnetic resonance studies of various compounds have been carried out systematically.[1] In a series of aromatic compounds, many workers have observed a direct relationship between the cabron-13 chemical shift and the π-electron charge density; a theoretical basis for this relation has been given by Karplus and Pople.[2] However, there have been few theoretical interpretations[3] of carbon-13 chemical shifts of saturated hydrocarbons. Carbon-13 chemical shifts of linear and some branched alkanes with a range of about 40 p.p.m. have been found to conform with a simple additivity law.[4] This empirical linear expression, of the type given by Eq. 1

$$\delta^{13}\mathrm{C}(j) = \delta^{13}\mathrm{C}(\mathrm{CH_4}) + \sum_i N_{ij}\delta_i \qquad (1)$$

has yet to be interpreted theoretically. The chemical shift for methane is $\delta^{13}\mathrm{C}(\mathrm{CH_4})$, and the substituent parameters, δ_i, reflect the effect of a carbon atom in the ith position upon the carbon-13 being investigated, where i denotes the α, β, γ, δ and ε carbon atoms. N_{ij} is the number of ith carbon atoms relative to the jth carbon. In the present paper, an attempt is made to give a molecular orbital interpretation of the carbon-13 chemical shift of these compounds.

Theoretical

The nuclear magnetic shielding constant, σ, may be conveniently expressed as a sum of diamagnetic and paramagnetic terms:[5]

$$\sigma = \sigma_\mathrm{d} + \sigma_\mathrm{p} \qquad (2)$$

where:

$$\sigma_\mathrm{d} = (e^2/3mc^2)\sum_i \langle\psi_0|r_i^{-1}|\psi_0\rangle$$

$$\sigma_\mathrm{p} = (\sigma_\mathrm{pxx} + \sigma_\mathrm{pyy} + \sigma_\mathrm{pzz})/3 \qquad (3)$$

$$\sigma_\mathrm{pzz} = -(e^2/2m^2c^2)\sum_{n\neq 0}(E_n - E_0)^{-1} \times [\langle\psi_0|\sum_i l_z^{(i)}|\psi_n\rangle\langle\psi_n|\sum_j l_z^{(j)} r_j^{-3}|\psi_0\rangle + \langle\psi_0|\sum_j l_z^{(j)} r_j^{-3}|\psi_n\rangle\langle\psi_n|\sum_i l_z^{(i)}|\psi_0\rangle] \qquad (4)$$

where $l_z^{(i)}$ is the Z-component of the orbital angular momentum of the ith electron, r_i distant from the nucleus in question, and where ψ_0 and ψ_n are the wave functions of the ground and the n-th excited states, with the energies E_0 and E_n respectively. The approximate values of σ_d can be calculated with the Slater atomic orbitals for the carbon sp^3 hybridized atomic orbital. The diamagnetic shielding constant, σ'_d, per 2s or 2p electron becomes:

$$\sigma'_\mathrm{d}(\text{2s or 2p electron}) = 4.45\,Z^* \text{ (p.p.m.)} \qquad (5)$$

where Z^* is the "effective nuclear charge" estimated according to Slater's rules. Since these yield a Z^* value of 3.25 for a neutral carbon atom, by taking into account a screening per 2s or 2p electron of 0.35 we can write Z^* for a carbon atom, A, in a molecule as:

$$Z^* = 3.25 - 0.35(q^\mathrm{A} - 4) \qquad (6)$$

where q^A is the σ-electron density on the atom. Since σ_d is due to four valence electrons of a carbon atom, we obtain

$$\sigma'_\mathrm{d} = 4.45\,Z^* q^\mathrm{A} \qquad (7)\dagger$$

where q^A is the electron density around the carbon atom A and where, for a neutral carbon ($q^\mathrm{A}=4$), σ'_d is 57.2. The increase in σ'_d if a 2s or a 2p electron is added is 16 p. p. m., about 50% of

† σ_d is associated with all electrons, whereas σ'_d is associated only with valence electrons.

the observed effect. However, the change in the calculated σ-electron density in this study is at most 0.3, while the effect due to the diamagnetic term is calculated to be about 4.8 p. p. m. Thus, the diamagnetic shielding, σ'_d, cannot make a principal contribution in the σ-frame carbon compounds. An approximate formula for σ_p may be obtained[2,3,6] by treating $E_n - E_0$ as a constant ΔE in Eq. 4 and by using the LCAO molecular orbital, where each molecular orbital is expressed as a linear combination of valence-shell atomic orbitals:

$$\sigma_p^A = -[2e^2h^2/3m^2c^2(\Delta E)]\langle r^{-3}\rangle_{2p}(P_1 - P_2 - P_3) \quad (8)$$

where:

$$P_1 = (P_{xx} + P_{yy} + P_{zz})_{AA}$$
$$P_2 = (P_{xx}P_{yy} + P_{yy}P_{zz} + P_{zz}P_{xx})_{AA}/2$$
$$P_3 = \sum_{B(\neq)A} (P_{xx}P_{yy} + P_{yy}P_{zz} + P_{zz}P_{xx})_{AB}/2$$

In this formulation, $(P_{xx})_{AB}$, for example, designates:

$$(P_{xx})_{AB} = 2\sum_i^{occ} C_{xA}{}^i C_{xB}{}^i \quad (9)$$

where $C_{xA}{}^i$ is the coefficient of the $2P_x$ atomic orbital of the carbon, A, in the ith molecular orbitals. It corresponds to the electron desnity (A=B of the $2P_x$ AO or bond order matrix (A$\neq$B) between two $2P_x$ orbitals of the A and B atoms. P_1 is the 2P electron density on the carbon A and has a value of 3 in the neutral carbon. The $\langle r^{-3}\rangle_{2P}$ factor, which is the mean inverse cube radius for carbon 2P orbitals, depends on the local electron desity on the carbon atom.[2] For a Slater 2P orbital, $\langle r^{-3}\rangle_{2P}$ is found to be:

$$\langle r^{-3}\rangle_{2P} = \frac{1}{24a_0{}^3}[3.25 - 0.35(P_1 - 3)]^3 \quad (10)$$

where a_0 is the Bohr radius and $(P_1 - 3)$ is the excess charge density of the 2P electron.

For the calculation of P_1 and P_2, we use a simple LCAO MO theory for the σ-electron developed by Fukui, Kato and Yonezawa.[7] A molecular orbital, φ, is expressed as a linear combination of the sp^3 hybridized orbital of the carbon atom, $\chi_{C,i}$ and the ls orbital of the hydrogen atom, $\chi_{H,l}$, as is shown by the expression:

$$\varphi = \sum_i^n C_i\chi_{C,i} + \sum_l^n C_l\chi_{H,l}$$

The coulomb and resonance integrals are given by the following:

$$\langle\chi_{C,i}|H|\chi_{C,i}\rangle = \alpha$$
$$\langle\chi_{H,l}|H|\chi_{H,l}\rangle = \alpha + a\beta$$
$$\langle\chi_{C,i}|H|\chi_{C,i+1}\rangle = \beta$$

between two sp^3 orbitals of two adjacent carbon atoms:

$$\langle\chi_{C,i}|H|\chi_{C,i} + 1\rangle = m\beta$$

between two sp^3 orbitals to one and the same carbon atom:

$$\langle\chi_{C,j}|H|\chi_{H,j+1}\rangle = b\beta$$

where a is taken as -0.2; m, as 0.34, and b, as 1.1[7]. In solving the secular equation, we neglected the overlap integrals. Then the electron density, q_r, of the rth atomic orbital is defined by:

$$q_r = 2\sum_i^{ooc} C_{ir}{}^2$$
