Such structural models as GGG'G have not been taken up for other polymers because of the steric impact between the atoms in the helix. However, as we described in the previous paper, the –S–S– structures reduce the steric impact and make these structural models possible for polyalkyl polysulfides. The structural model for polymethylene disulfide was determined to be GG'G in the previous paper. This model is very similar to the present model for polyethylene disulfide. Apparently, therefore, such models as GG'G and GGG'G are characteristic of polyalkyl polysulfides.

For the models proposed by Katz and by Minoura, the internal rotation conformations have not been described explicitly. Therefore, we are able to derive the conformations only from the pictures in their papers.

For Katz's model, the internal rotation conformations appear to be trans, trans, trans and cis along the $-S-CH_2-CH_2-S-S-$ bond sequence of the 2_1 helical model. The skeletal atoms are placed on one common plane and twofold symmetry axes (intersecting the fiber axis at right angles) exist, in contradiction with the results of the present infrared analyses.

In Minoura's model, the internal rotation conformations appear to be gauche, trans, gauche and gauche, and the internal rotation angle around the S–S bond is implicitly assumed to be around 100°C. The helical model of the conformation is 2_1, and twofold symmetry axes (intersecting the helical axis at right angles) again exist. As we have proved in the present work, however, the twofold symmetry axes actually do not exist. Therefore, neither of their models can be accepted.

The authers wish to express their gratitude to Professor Masamichi Tsuboi, Dr. Akiko Y. Hirakawa and Dr. Yoshimasa Kyogoku of the University of Tokyo for the use of their infrared spectrometer, and Mr. Tohoru Chiba of the Toho Rayon Company for measuring the fiber period of the substance. We wish also to thank Professor Tatsuo Miyazawa of the Institute for Protein Reseach, Osaka University, for his encouragement and his invaluable advice throughout this work.

Studies of Polybutenes. III. On the Molecular Motion Studied by Nuclear Magnetic Resonance*

By Shoichi KONDO,† Fumiaki ISHII,† Yasuo CHOKKI,†† Koji TANAKA† and Masatami TAKEDA†

† *Department of Chemistry, Faculty of Science, Tokyo College of Science, Shinjuku-ku, Tokyo*
†† *Takeda Chemical Industries Ltd., Osaka*

(Received December 18, 1965)

The molecular motion of polybutenes of low molecular weights has been studied by observing the NMR line widths and spin-lattice relaxation times at temperatures in the range from −180 to 200°C. The temperature dependence of these values is similar to that of polyisobutylene of a higher molecular weight. The correlation time spectra calculated from the spin-lattice relaxation time and the spin-spin relaxation time shift in the shorter-time direction with the decrease in the molecular weight. The dependence of the correlation frequency upon the temperature is also discussed in terms of the W. L. F. equation.

In previous papers[1,2] the molecular weight and its distribution in some polybutenes have been reported. The molecular weights from 300 to 10000 are situated between the typical high polymer and the monomer. Its chemical constituent is mainly polyisobutylene with some copolymer components of another butenes. It seems that it would be worthwhile to study the state of the molecular motion of these substances at low temperatures and to compare this motion with that of the polyisobutylene of a high molecular weight.[3]

In the present work line-widths and spin-lattice relaxation times were observed as functions of the temperature for three samples with different molecular weights. The glass transition temperatures were determined by dilatometry. On the basis of such observations, the possible transition of the mean correlation frequency with the temperature and the distribution spectra of the correlation frequency have been discussed.

Experimental

Samples.—The samples of the commercial polybutenes used were Indopol from Amoco and Vistanex from Esso Standard. Sample A: Indopol L-10 was selected as a sample of a lower molecular weight, sample B: Indopole H-300 of a medium molecular weight, and sample C: Vistanex LM-MH of a higher molecular weight. The molecular weights of the samples A and B were determined by a cryoscopic method using benzene as a solvent. The glass-transition temperature was determined with an improved dilatometer described by Bekkedahl.[4] *n*-Propylalcohol was used as a confining liquid from −150 to 0°C.

Equipment.—The nuclear magnetic resonance spectrometer used for the line-width measurement was a JNM-BL-1 type apparatus (Japan Electron Co. Ltd.) operating at a fixed frequency of 29 Mc./s. The measurement of the spin-lattice relaxation time was carried out with a spin-echo apparatus (Japan Electron Co. Ltd.) at the resonance frequency of 25 Mc./s. by applying 90°-90° pulse method.

Results and Discussion

Table I gives the molecular weights and the glass transition temperatures for the three samples. The high-resolution nuclear magnetic resonance spectrum of sample C was identical with that of polyisobutylene. The spectrum of the sample B was very similar to that of polyisobutylene except for the appearance of weak absorptions at higher magnetic fields. These absorptions are presented to a larger extent in the spectrum of the sample A.

Table I. Molecular weight and glass transition temperatures of polybutenes

	Sample	M_w	T_g, °C
A	Indopol L-10	310	−106
B	Indopol H-300	1100	−95
C	Vistanex LM-MH	11000	−85

The Temperature Dependence of Line Widths.—The first derivative curve of the absorption spectrum was recorded for the three samples at various temperatures from −180 to 0°C. The line width at the maximum slope is plotted against the temperature in Fig. 1. The general features

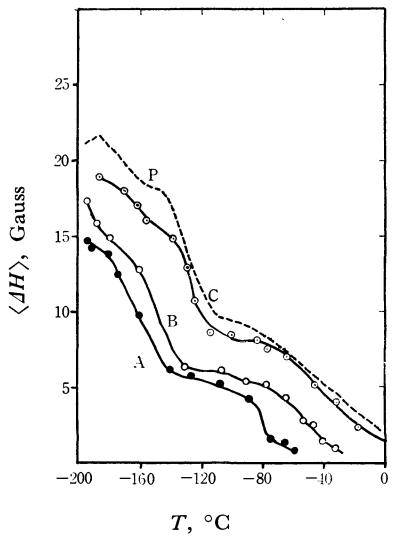

Fig. 1. Plots of line width vs. temperature. P: data by Powles.[3]

of these plots are similar to those of the plots observed on polyisobutylene by Powels.[3] Figure 1 shows two distinct narrowings on each curve. The low-temperature narrowing is due to the onset of a rotational motion around their three-fold axis of methyl groups. However, it may be seen that the temperature of this transition shifts lower as the molecular weight of the samples becomes smaller. This fact suggests that there is some coupling between the rotation of the methyl groups and some modes of the molecular motion of the main chain such as the rotational shear waves which have been suggested from the interpretation of the results of dynamic measurement at low temperatures. The high-temperature narrowing can be attributed to the onset of the segmental motion of these polymers. The temperatures defined as a narrowing center of the line width for samples A, B and C are −80, −54 and −38°C, respectively. The glass-transition temperatures are several tens of degrees lower than the temperatures of the narrowing center.

The Temperature Dependence of the Spin-Lattice Relaxation Time. — The spin-lattice relaxation time T_1 was measured for each sample over the temperature range from −50 to 200°C. An attempt to measure the T_1 at lower temperatures was unsuccessful for the sample C. Plots of the T_1 versus $1/T$ are given in Fig. 2. Two minima have been observed in both curves concerning samples A and B. The low temperature minima are probably associated with the methyl group motion which is in turn related to the above-mentioned line-width narrowing. The high temperature minima correspond to the segmental motion. The temperatures of the T_1 minima are shifted to the lower temperature side with the

4) N. Bekkedahl, *J. Research Natl. Bur. Standard*, **42**, 145 (1949).

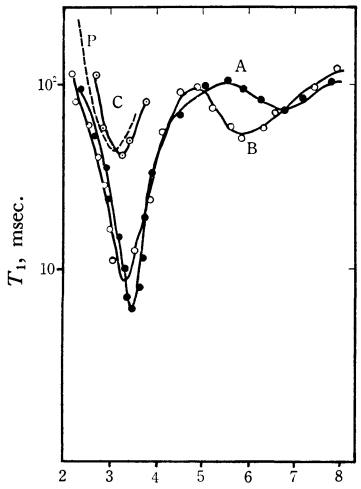

Fig. 2. Spin-lattice relaxation time as a function of temperature.

decrease in the molecular weight. The results of all the samples obtained are summarized in Table II.

TABLE II. TEMPERATURES AND VALUES OF T_1 MINIMA

Sample	T, °C	T_1, msec.	T, °C	T_1, msec.
A	12	6.4	−120	73.2
B	19	8.3	−90	65.4
C	44	42	—	—

The Temperature Dependence of the Correlation Frequency and Its Distribution.— The motional effects of the spin-lattice relaxation time T_1 and the spin-spin relaxation time T_2 for a coupling of nuclei were interpreted by the following equations:[5]

$$1/T_1 = 2/3 \cdot \Delta\omega_2^2\{\tau/(1+\omega^2\tau^2)+4\tau/(1+\omega^2\tau^2)\}$$

$$1/T_2 = \Delta\omega_2 \cdot 1/\alpha \cdot \tan^{-1}(\alpha\tau/T_2)$$

where α is the numerical coefficient nearly equal to unity and $\Delta\omega_2^2$ is the second moment in units of angular frequency. In the case of the polymers, however, a simple application of the above equations does not give a reasonable temperature dependence of the correlation frequency. One of the main reasons for this may be the neglect of the distribution of correlation frequencies. It is often necessary to postulate the distribution in order to explain the dynamic and dielectric behavior of the polymer. As the values of T_1 and T_2 as a function of the temperature were obtained from measurements at a fixed frequency, it is impossible to get the distribution from the isochronal NMR data alone. Therefore, we have to reduce the data of the temperature dependence to those of frequency dependence in some way. In dynamic and dielectric studies the relation between the frequency and the temperature can be explained by the W. L. F. equation which is widely used in discussing the segmental motion of the amorphous polymers. Slichter and Davis[6] have shown on the basis of their observation of the frequency dependence of the $T_{1\,\min}$ value for natural rubber, that the relation between the frequency and the temperature in the spin-lattice relaxation process can be explained by the W. L. F. equation. The shift factor which relates the correlation frequency at the temperature T with that at the reference temperature T_s can be expressed by the form:

$$\log a(T) = \log\{\tau(T)/\tau(T_s)\}$$
$$= -8.86(T-T_s)/101.6+T-T_s$$

where T_s is chosen 50°C higher than the glass-transition temperature. In Fig. 3, the smooth curves passing through the point of each T_2 show the temperature dependence of the correlation frequency using the shift factor. It may be seen that the application of the W. L. F. equation can not describe this case completely since all the ν_c points at $T_{1\,\min}$ appear somewhat below each curve. However, that equation can be used for most practical purposes.

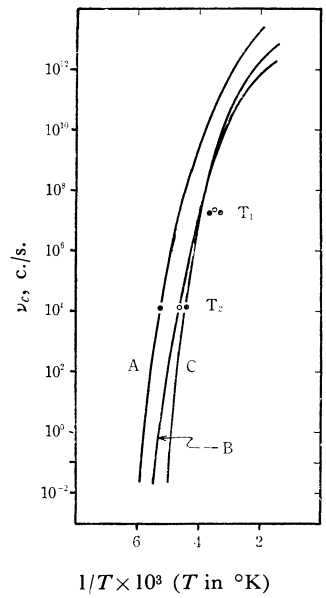

Fig. 3. Correlation frequencies as a function of temperature.

It has been proposed by Miyake[7] that the correlation-time spectra can be obtained from the

5) R. Kubo and K. Tomita, *J. Phys. Soc. Japan*, **9**, 888 (1954).
6) W. P. Slichter and D. D. Davis, *J. Appl. Phys.*, **34**, 98 (1963).
7) A. Miyake, *Rep. Prog. Poly. Phys. Japan*, **4**, 36 (1961).

observed values of T_1 and T_2 as a function of the temperature when the W. L. F. equation is applicable to the case of nuclear magnetic resonance. According to his method the correlation time spectra calculated from the observed values of T_1 and T_2 are shown in Fig. 5 using the following equation:

$$I\{\sqrt{1/2}\omega_0 a(T)\} \simeq 0.733\omega_0/\Delta\omega_2^2 T_1$$

$$I\{T_2/a(T)\} \simeq 4.60(T_2^\circ/T_2) \times \{1-\mathrm{d}\log a(T)/\mathrm{d}\log T_2\}^{-1}$$

in which T_2° is the particular value of T_2 when the temperature is sufficiently low and no motional narrowing is observed. It may be seen that the correlation time spectra for T_1 in Fig. 4 are slightly affected by the molecular weight while those of T_2 in Fig. 5 depend very much on the molecular weight. The dependence of the correlation-time spectra upon the molecular wieght seems to suggest that not only the micro-brownian motion but also the macro-brownian motion may be related to the distribution spectrum. This seems to be consistent with the fact that the curve of T_1 vs. $1/T$ in the sample A has a sharper and deeper minimum than in the sample C, and that the glass-transition temperature increases with the increase in the molecular weight.

Kinetic Studies of the Oxidation of Uranium Iodides by Oxygen

By Muneo HANDA

Division of Fuel Research and Development, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki

(Received December 20, 1965)

The kinetics of the oxidations of uranium tetraiodide and of triiodide by oxygen were studied over the temperature ranges from 55.0 to 66.5°C and from 88.5 to 103.5°C respectively. The experiments were carried out with an apparatus in which the column of a gas chromatograph was replaced by an electric furance and traps of water vapor, oxygen and iodine. Most of the experiments were performed with the same partial pressure of oxygen (64 mmHg) and total flow rate (60 ml. per min.). The activation energies for the reaction of oxygen with uranium tetraiodide and triiodide were, respectively, 21.1 and 22.5 kcal. per mole. The rate of the formation of uranium trioxide was in agreement with the kinetics to be expected for reaction between a gas and a solid at a continuously diminishing spherical interface.

A study of the rates of reaction between uranium iodides and various gases, such as oxygen, hydrogen, and water vapor, provides information about the chemical behavior of fission iodine in a reactor fuel.[1-3] Before the present study was made, however, no fundamental data on the kinetics of

1) S. Yajima, K. Shiba and M. Handa, This Bulletin, **36**, 253 (1963).
2) S. Yajima, K. Shiba and M. Handa, ibid., **36**, 258 (1963).
3) S. Yajima, K. Shiba and M. Handa, ibid., **38**, 278 (1965).

the reaction were available, since uranium iodides are very unstable and must be handled in an inert gas atmosphere or in vacuo.[4]

The present work was therefore undertaken in an attempt to elucidate the kinetics and, if possible, the mechanism of the oxidation of uranium iodides by oxygen. The experiment was carried out with an apparatus in which the column of a gas chromatograph was replaced by an electric furnace and traps of water vapor, oxygen and iodine. This apparatus made it possible to carry out easily and precisely kinetic studies of a sample which could not be treated in the atmosphere.

From the X-ray analysis of the oxidation products, it was found that the reactions between uranium iodides and oxygen proceeded according to the following chemical equations:[5]

$$2UI_4 + 3O_2 = 2UO_3 + 4I_2 \quad (1)$$

$$2UI_3 + 3O_2 = 2UO_3 + 3I_2 \quad (2)$$

(The reaction temperature was below 200°C.)

$$3UI_4 + 4O_2 = U_3O_8 + 6I_2 \quad (3)$$

$$6UI_3 + 8O_2 = 2U_3O_8 + 9I_2 \quad (4)$$

(The reaction temperature was 600°C.)

Reaction 1 occurred with appreciable velocities when the temperature was raised to about 60°C. On the other hand, Reaction 2 proceeded rapidly at about 100°C or above. When uranium iodides were oxidized at 600°C in air, the uranium trioxide produced was decomposed to triuranium octoxide. The chemical reactions are shown in Eqs. 3 and 4. The kinetics of Reaction 1 has been studied over the temperature range from 55.0 to 66.5°C, and that of Reaction 2, over the range from 88.5 to 103.5°C. The rate of the formation of uranium trioxide was in agreement with the kinetics to be expected for a reaction between a gas and a solid at a continuously diminishing spherical interface. The activation energies for Reactions 1 and 2 were 21.1 and 22.5 kcal. per mole respectively.

Experimental and Results

The Preparation of the Samples.—*Uranium Tetraiodide Packed in a Silica Breakable.*—Uranium tetraiodide was prepared by the direct combination of uranium metal and iodine, using the method reported by Gregory.[6] The reaction was slow, but the product prepared in this way was pure uranium tetraiodide. The iodine/uranium ratio in the uranium tetraiodide was 4.00±0.02. The melting point of the uranium tetraiodide measured in an inert gas atmosphere was 506°C, a value approximately agreed with the 508°C reported in the literature.[4,7] The uranium tetraiodide was ground into powder of from 200 to 400 mesh with a glass mortar in a glove box filled with purified helium. About 200 mg. of the uranium tetraiodide was packed in a silica breakable in a way similar to that described in a previous paper.[3]

Uranium Triiodide Packed in a Silica Breakable.—Uranium triiodide was prepared by heating a stoichiometic mixture of the uranium tetraiodide and uranium metal powder at 750°C for 24 hr. The product was then purified by using a thermochromatograph[3] with pure helium as the carrier. The uranium triiodide deposited on the wall of the thermochromato-tube heated at 700—800°C

was taken out and transferred into a glove box. The uranium triiodide was then ground into powder of from 200 to 400 mesh and packed in a silica breakable in a way similar to that used for uranium tetraiodide. The iodine/uranium ratio in the uranium triiodide was 3.00±0.02. The melting point measured in an inert gas atmosphere was 788°C, nearly equal to the 780°C reported by other workers.[4,7]

Apparatus.—A flow diagram of the experimental apparatus is shown in Fig. 1. The column of a GC-1A Shimadzu-type gas chromatograph was replaced by an assembly of a reaction furnace, a water trap, an iodine trap, and an oxygen trap. Impurities in the helium were eliminated by passing it successively through a potassium hydroxide bed, a magnesium perchlorate bed, a copper gauze heated to 300°C, and uranium turnings heated to 800°C.

Purified helium was first made to flow through a standard thermal conductivity cell, and then oxygen was introduced into the helium stream. The two gases were completely mixed by a glass gas-mixing pump.[8] The water vapor in helium-oxygen gases was further eliminated by passing that gas through a water trap, which had been cooled by a liquid nitrogen at −196°C. After they had passed through the reaction furnace, the gases were introduced into the iodine trap in order to remove the iodine produced by the oxidation of uranium iodides in the reaction furnace. Then the gases were made to flow through a reference thermal conductivity cell, a flow meter, and a silica gel bed, and then released into the atmosphere. The flow rate and the partial pressure of oxygen in the carrier gas were controlled by changing the height of mercury in the bubblers.

The reaction furnace is shown in Fig. 2. A silica breakable containing the sample and a breaker (an iron bar sealed in a silica tube) were suspended in a silica tube in the furnace by a supporter (an iron bar sealed in the silica tube). The temperature of the furnace (a nichrome resistance furnace) was controlled by an S-175-type Chino temperature regulator which was able to maintain the temperature within 0.2% of its full scale and also to heat the sample at the desired rate. The temperature of the sample was measured by a copper-constantan thermocouple connected to a P-31-type Yokogawa potentiometer. A thermocouple to measure the reaction temperature was set beneath the sample in the silica tube.

The Heating Curves of Uranium Tetraiodide and Triiodide.—Most of the experiments were performed at the same partial pressure of oxygen (64 mmHg) and total flow rate (60 ml./min.).

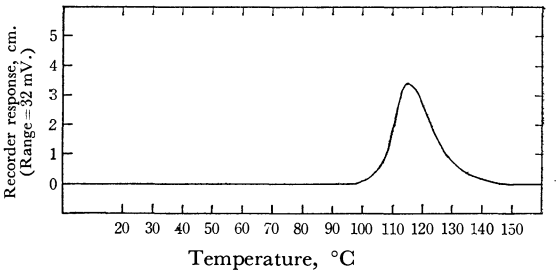

Fig. 4. Heating curve of uranium triiodide.
Sample weight: 0.175 g.
Carrier gas flow rate: 60 ml./min.
Partial pressure of oxygen: 64 mmHg
Rate of temperature increase: 2°C/min.

8) M. Handa, Y. Takahashi and K. Shiba, *Bunseki Kagaku (Japan Analyst)*, **13**, 1262 (1964).

When the base line of the recorder became constant, the breakable containing the sample was broken with a magnet and the sample was dropped into the center of the reaction furnace. Then the temperature of the furnace was raised at a constant rate 2°C/min. The heating curves for uranium tetraiodide and triiodide are shown in Figs. 3 and 4 respectively.

Isotherms for the Oxidation of Uranium Tetraiodide and Triiodide.—The heating curves of uranium tetraiodide and triiodide have peaks at 75 and 115°C respectively. Consequently, the isotherms for the oxidation of uranium tetraiodide and triiodide were determined in the vicinities of each peak.

The experiments were carried out in a similar way to that used for preparing the heating curves, except that the reaction furnace was kept at the given temperature before the sample was introduced into the furnace. Typical isotherm of uranium tetraiodide at 57.0°C is shown in Fig. 5.

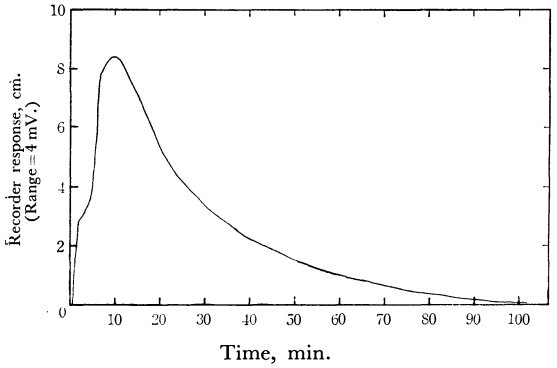

Fig. 5. Rate of oxidation of uranium tetraiodide.
Sample weight: 0.221 g.
Carrier gas flow rate: 60 ml./min.
Partial pressure of oxygen: 64 mmHg
Reaction temperature: 57.0°C

The X-Ray Analysis of the Oxidation Products.—A brown-colored material was obtained by isothermal experiments on both uranium tetraiodide and triiodide. The color turned yellow, however, when the material was taken out into the atmosphere. It was not soluble in water. When the brown material was heated in air at 600°C, the color changed from brown to black. The black material was also insoluble in water. An X-ray diffraction analysis indicated the brown material to be uranium trioxide and the black material to be triuranium octoxide.

The Kinetics of the Reaction.—A system of a solid and a gas may be idealized by assuming the solid to consist of a spherical particle of a uniform size, with the reaction starting on all particles. In such a reaction the following relationship can be deduced.[9-12]

$$(1 - F)^{1/3} = 1 - k't \quad (5)$$

$$F = (m_0 - m_t)/m_0 \quad (6)$$

where m_0 is the initial mass of the particle; m_t, the mass of the particle at time t, and k', the reaction rate constant. The amount of uranium iodide consumed by oxidation is directly proportional to the amount of oxygen consumed, because the oxidation reaction of uranium iodides proceeds according to Eq. 1 or 2. The amount of oxygen is directly proportional to the area of the recorder chart of the gas chromatograph, and the area is directly proportional to the weight of the piece cut off from the recorder chart. To simplify the calculation of the reaction kinetics, the amount of uranium iodide consumed by oxidation was replaced by the weight of the recorder chart.

All the isotherms reach a peak several minutes after the beginning of the experiment, as the temperature of the sample cannot reach the given temperature immediately after the sample is introduced in the furnace. Therefore, the data obtained before the peak of isothermal curve was reached has been omitted in the calculation of the reaction rate.

The plots of $(1-F)^{1/3}$ against the reaction time for uranium tetraiodide and triiodide are shown in Figs. 6 and 7 respectiveley. The experimental points lie on a straight line for each temperature, which is in agreement with Eq. 5, so that the reactions between uranium iodides and oxygen

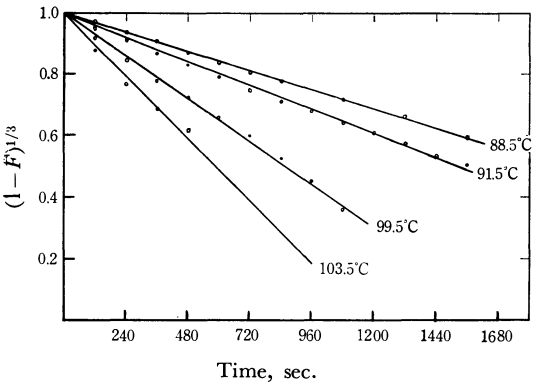

Fig. 7. Reaction of uranium triiodide with oxygen
$(1-F)^{1/3}$ against time at various temperatures.
Sample weight: 0.131 g. (88.5°C), 0.098 g. (91.5°C), 0.064 g. (99.5°C), 0.094 g. (103.5°C)
Carrier gas flow rate: 60 ml./min.
Partial pressure of oxygen: 64 mmHg

are governed by the linear law given by Anderson for a gas-solid reaction.[12]

The Effect of Oxygen Concentration.—Most of the runs were carried out with the same partial pressure of oxygen (64 mmHg) and total flow rate (60 ml./min.). In several runs, however, the partial pressure of oxygen was varied, the total flow rate of the carrier gas being kept approximately constant. Table I summarizes the effect of a variation in the partial pressure of oxygen. There is an approximately linear relationship between the reaction rate and the partial pressure of oxygen, as in the case of the fluorination of uranium tetrafluoride with fluorine.[9]

Table I. The effect of oxygen concentration on the rate constant at 61.5°C for uranium tetraiodide

Oxygen concn. in carrier gas %	Partial pres. (P_{O_2}) of oxygen mmHg	k' sec^{-1}	$k' \times 10^6/P_{O_2}$
8.50	64	3.20×10^{-4}	5.00
5.74	41	2.32×10^{-4}	5.66
4.50	34	1.80×10^{-4}	5.30

The Energy of Activation.—The reaction rate constant, k', was calculated from the slope in Figs. 6 and 7. The logarithm of the reaction rate constant, k', is plotted against the reciprocal of the absolute temperature, which is shown in Fig. 8. The slopes of the straight line in Fig. 8 are -4.6×10^3 and -4.9×10^3 for uranium tetraiodide and triiodide respectively, from which values the activation energies for their reactions with oxygen were estimated to be 21.1 and 22.5 kcal. per mole.

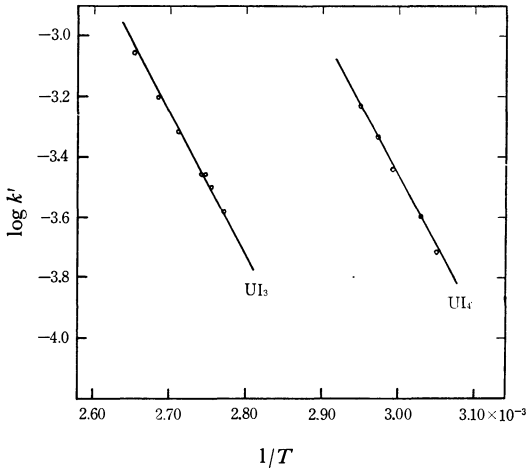

Fig. 8. Arrhenius plot for uranium tetraiodide and triiodide.

The author wishes to thank Professor Seishi Yajima and Mr. Koreyuki Shiba for their valuable discussions and suggestions, and Professor Takanobu Shiokawa for his continuing interest and encouragement during this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1874—1877 (1966)

The π-Electronic Excitation Energies of Anthraquinone

By Akira KUBOYAMA and Kōichi WADA*

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received January 10, 1966)

Following our previous work on *o*-benzoquinone, the calculation of the π-electronic excitation energies of anthraquinone has been carried out with the Pariser-Parr-Pople method. The calculated excitation energies which correspond to the five distinct $\pi\rightarrow\pi^*$ bands have been obtained, though the agreement of the calculated excitation energies and the transition dipole-strengths with the observed energies and strengths are unsatisfactory. The π-electronic charge distribution in carbonyl groups of anthraquinone is almost the same as that of *p*-benzoquinone.

In our previous work,[1] the π-electronic excitation energies of *o*-benzoquinone were calculated using the Pariser-Parr-Popl method,[2,3] and from these results the $\pi\rightarrow\pi^*$ absorption bands of *o*-benzoquinone have been studied. In this paper, similar work on anthraquinone will be reported.

The Method of Calculation

The method of calculation was the same as that used in our previous work.[1] The integral values used have all been shown in our previous paper except for the core resonance integrals for carbon-carbon bonds.

The geometry of anthraquinone has been studied by Sen[4] by means of X-ray analysis. According to Sen's results, anthraquinone is planar, and its bond distances are as shown in Fig. 1.

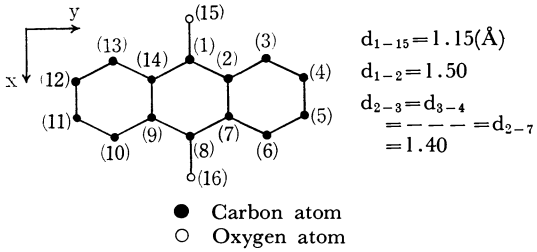

Fig. 1. Interatomic distances

In this work, these bond distances were used, and all the valence angles were assumed to be 120°. It was also assumed that anthraquinone is planar and that its symmetry group is D_{2h}.

As for the core resonance integral (β), the values of 1.45 eV. and 2.39 eV. were used for that over the atoms 1 and 2 and those of the benzene nuclei respectively, according to the method of Pariser and Parr.[2]

In the calculations, an electronic computor NEAC 2101 was used. The calculations were carried out in the same manner as in the previous work.[1]

Results

The molecular orbitals (ϕ_i) and their orbital energies (ε_i) are shown in Table I.[5] The excitation energies of the excited singlet and triplet configurations[6] less than 8 eV. are shown in Table II, along with the corresponding Coulomb and exchange integrals. Those of the orbitally-allowed and orbitally-forbidden transitions are shown in Table II (i) and II (ii) respectively.

The configuration interactions among the configurations in Table II were calculated. The obtained excited-state wave functions ($^{1,3}\Phi_i$), their excitation energies ($^{1,3}E_i-E_0$), the transition dipole-strengths from the ground state, and the interconfigurational matrix elements ($\Phi_{i\rightarrow j}|\mathbf{H}|\Phi_{k\rightarrow l}$) are shown in Table III.

In Table IV, the excitation energies, the transition dipole-strengths and the symmetry species of the excited states, experimentally determined,[7-9]

5) χ_i denotes the $2p\pi$ atomic orbital of *i*-atom.
6) Φ_0 and E_0 denote the wave function and the energy of the ground state respectively. $^1\Phi_{i\rightarrow j}$, $^1E_{i\rightarrow j}$ and $^3\Phi_{i\rightarrow j}$, $^3E_{i\rightarrow j}$ denote the wave functions and the energies of the singlet and triplet configurations, respectively, in which one electron is excited from an occupied orbital χ_i to an unoccupied orbital χ_j. The excitation energy of each excited configuration is given by the following formula.

$$\left.\begin{matrix}{}^1E_{i\rightarrow j}\\ {}^3E_{i\rightarrow j}\end{matrix}\right\}-E_0=(E_j-E_i)-(J_{ij}-K_{ij})\begin{cases}+K_{ij}\\ -K_{ij}\end{cases}$$

J_{ij} and K_{ij} denote Coulomb and exchange integrals over ϕ_i and ϕ_j respectively.

TABLE IV. THE OBSERVED ABSORPTION BANDS OF ANTHRAQUINONE

	Excitation energy, eV.	μ^2, Å^2	Symmetry
Band I	3.8	∼0.3	$^1B_{3u}$
Band II	4.5	∼0.7	$^1B_{2u}$
Band III	4.9	∼1.8	$^1B_{3u}$
Band IV	6.1	∼0.7	?
Band V	∼6.7	>0.7	?

of the observed $\pi\to\pi^*$ absorption bands (I-V) of anthraquinone are shown.[10] The direction of the polarization of the transitions ($^1A_g\to{}^1B_{3u}$, $^1A_g\to{}^1B_{2u}$) are along the x and y axes in Fig. 1 respectively.

In Fig. 2(a) the π-electronic charge densities and π-bond orders of anthraquinone obtained are

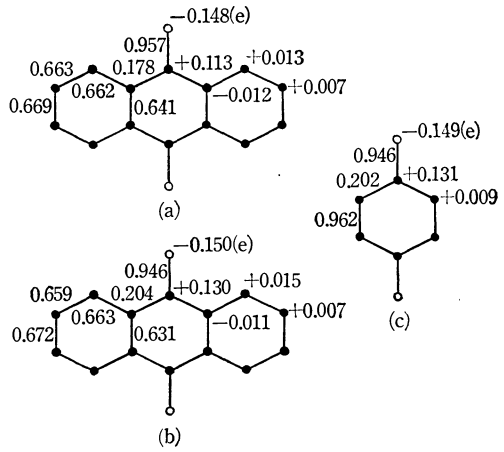

Fig. 2. Molecular diagrams.

10) Anthraquinone has an $n\to\pi^*$ band near 400 mμ.

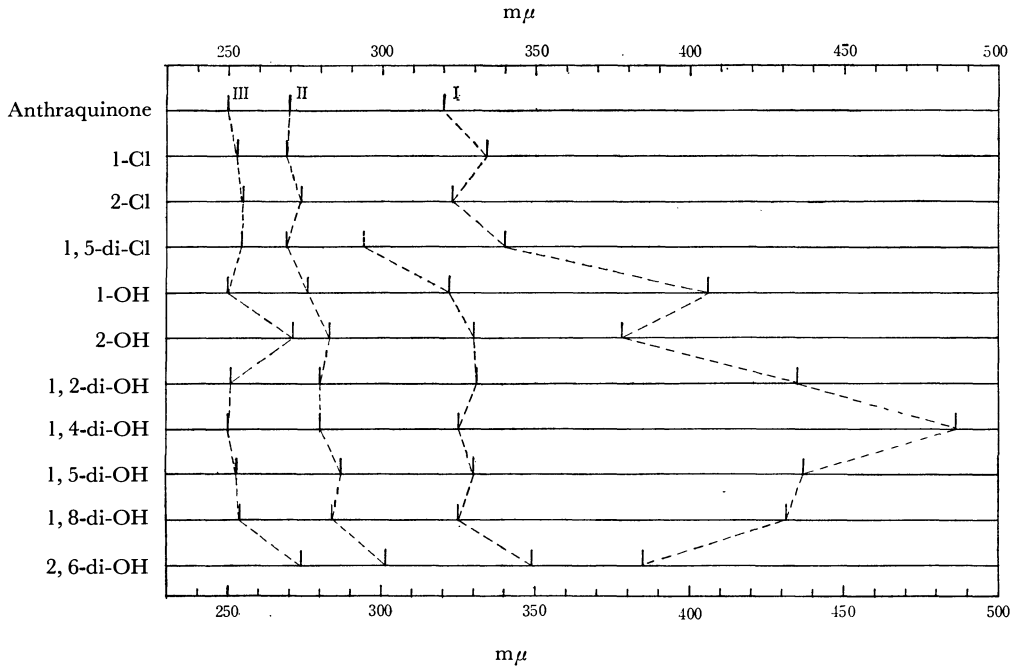

Fig. 3. Correspondence among $\pi \rightarrow \pi^*$ bands of anthraquinone and its chlorine or hydroxyl substitutes.

shown, while Fig. 2(b) shows those obtained using as the core resonance integral over the atoms 1 and 2 the value (1.68 eV.) which corresponds to the bond distance (1.47 Å). In Fig. 2(c) those of *p*-bnezoquinone calculated using the wave functions obtained by Sidman[11] are shown.

Discussion

Since all the intensities of Bands II—V in Table IV are strong, these absorption bands may reasonably be assigned to $\pi \rightarrow \pi^*$ allowed transitions. As for Band I, its intensity is not weak and it has a sharp peak at the longest wavelength edge in saturated hydrocarbons. Therefore, Band I may also reasonably be assigned to an allowed transition. From a comparison of Tables III and IV, Bands II and III may reasonably be assigned to the $E_0 \rightarrow {}^1E_3$ ($^1A_g \rightarrow {}^1B_{2u}$) and $E_0 \rightarrow {}^1E_4$ ($^1A_g \rightarrow {}^1B_{3u}$) transitions respectively. Bands IV and V may also reasonably be assigned to either one of the two transitions ($E_0 \rightarrow {}^1E_5$ ($^1A_g \rightarrow {}^1B_{2u}$) and $E_0 \rightarrow {}^1E_6$ ($^1A_g \rightarrow {}^1B_{3u}$)). Band I may be assigned to the $E_0 \rightarrow {}^1E_1$ ($^1A_g \rightarrow {}^1B_{3u}$), transition though the calculated dipole-strength of this transition is too small in comparison with that of Band I. The absorption band due to the $E_0 \rightarrow {}^1E_2$ ($^1A_g \rightarrow {}^1B_{2u}$) transition may be hidden in Band I. α- or β-Hydroxy-anthraquinone[12] has an absorption band between Bands I and II the intensity of which is nearly equal to that of Band I. This absorption band may be assigned to the $E_0 \rightarrow {}^1E_2$ transition. $\pi \rightarrow \pi^*$ bands of anthraquinone and its various chlorine[13] or hydroxyl[12] substitutes at the wavelengths longer than 240 mμ reasonably correspond to each other, as shown in Fig. 3. Those of various amino-anthraquinones[14] also correspond to those of the corresponding hydroxy-anthraquinones in Fig. 3 respectively.

The calculated singlet excitation energies of anthraquinone are much greater than the observed ones. A similar trend was observed in the *o*-[1] and *p*-benzoquinone[11] studied previously. In anthraquinone the agreement between the transition dipole-strengths calculated and those observed is also unsatisfactory. The alternate use of 1.68 eV. in place of 1.45 eV. as the core resonance integral over the atoms 1 and 2, or the use of −14.00 eV. in place of −13.00 eV. as U_{oo},[1] does not bring about any essential improvement in these points.

In Fig. 2 the charge distribution in carbonyl groups of anthraquinone is similar to those in *p*-benzoquinone and o-benzoquinone shown in our previous paper.[1] Especially it almost agrees with that in *p*-benzoquinone.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1878—1886 (1966)

Correlations of the Structural Unit of Organic Compounds with the *G* Values of Thier Radiolytic Products

By Toshiro Isoya,* Kozo Hirota and Motoyoshi Hatada

Osaka Laboratories, Japanese Association for Radiation Research on Polymers, Neyagawa, Osaka (T. I., K. H., M. H.)
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka (K. H.)

(Received January 11, 1966)

Two correlations have been found between the *G* values of the radiolytic products and the number of the structural unit, *n*, in an organic molecule; (i) The *G* value from the homologous compounds has a linear relation to $1/n$ in the $n \leqq m$ region and is independent of *n* in the $n \geqq m$ region, where *m* is the number of the C–C bond through which the energy can be transferred, and (ii) the $G(CH_4)$ value from paraffin hydrocarbons, where the "terminal effect" is remarkable, has a linear relation to $1/n$ in both the $n \geqq m$ and $n \leqq m$ regions. These relations may be explained in terms of the energy transfer through C–C bonds.

Many studies have been carried out of radiation effects on chemical substances, but fewer investigations into correlations of the radiation effect on substances with their chemical structures have been made.[1-4]

In a previous paper,[5] the radiolysis of ethylene glycol diacetate was studied in order to investigate the effect of the number of ester groups in a molecule; it was found that the yields of gaseous products from ethylene glycol diacetate range from a half to one-third of those from methyl acetate. In the present paper, a similar method of research has been extended to other series of compounds in order to obtain a general rule which can predict the radiation effect for related compounds. Such research may also be useful for a better understanding of the mechanisms of the radiation effect on chemical substances in general.

Experimental

Commercially-available triacetin, glycerol, erythritol, and acetonylacetone were used without further purification.

In each run, each sample (2 ml., or 2 g. in the case of erythritol) was degassed by a conventional vacuum technique in a glass ampoule equipped with a breakable seal. Then the ampoule was sealed off and subjected to irradiation at room temperature with cobalt-60 gamma rays. The dose rate, which was determined by the use of a Fricke ferrous sulfate dosimeter, was 3.1×10^{15} eV. g^{-1} sec^{-1}.

The gaseous products were collected with a Toepler pump through traps at −196°C and −78°C; after their

amounts had been determined, they were subjected to mass spectrometry.

Results and Discussion

This general formula of the compounds can be presented: -(-CHR-)-$_n$; that is, n=1: CH_3R, n=2: CH_2RCH_2R, n=3: $CH_2RCHRCH_2R$,..... Tables I—IV show the G values of products from a series of esters (R=CH_3COO), alcohols (R=HO), ketones (R=CH_3CO), and paraffin hydrocarbons (R=H) respectively. In the tables, the G values of products from four irradiated compounds (tri-

acetin, glycerol, erythritol and acetonylacetone) were obtained, as usual, from the straight lines shown in Figs. 1, 2, 3 and 4. The G values of the others were obtained from the literature.

The G values for gaseous products from various series of compounds are plotted against the reciprocal of the number of the structural unit, $1/n$, in Figs. 5, 6 and 7. When the G values obtained from various authors are used for the sake of comparison, the differences in the experimental conditions, such as the types of radiation, the irradiation temperature, the dose rate, the dose, and the density of the samples, should be taken into consideration. Therefore, for the paraffin series, the G values which were obtained under the most similar experimental conditions are plotted in Figs. 8 and 9. The G values from gaseous substances are plotted in Figs. 8a and 9a, while those from liquid or solid substances are plotted in Figs. 8b and 9b. The G values obtained by different authors are

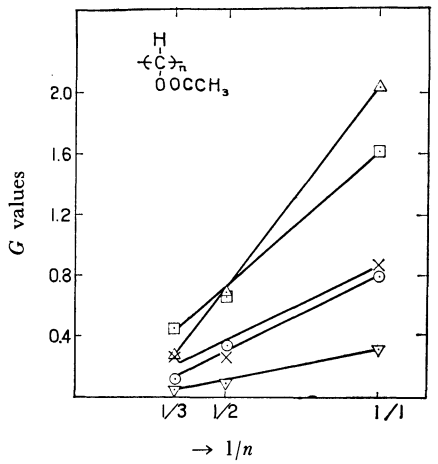

Fig. 5. G values vs. reciprocal of the number of the structural unit.

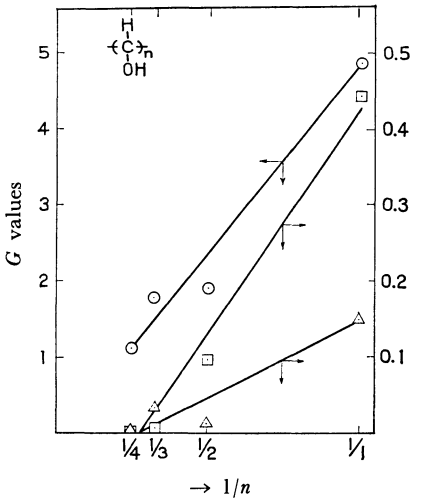

Fig. 6. G values vs. reciprocal of the number of the structural unit.

⊙ H_2, △ CH_4, ▣ CO

also plotted by the use of different symbols in Figs. 8c and 9c. The mean values were adopted as representative when different G values have been reported for a compound.

The G values have linear relations to the reciprocal of the number of the structural unit, $1/n$, in the R=CH_3COO, R=HO and R=CH_3CO series. In the series of paraffin hydrocarbons, R=H, $G(H_2)$ is independent of the structural unit in the $n \geqq$ ca. 6 region and has a linear relation to $1/n$ in the $n \leqq$ ca. 6 region as well as G values from the other series, while $G(CH_4)$ has an almost linear relation to $1/n$ in the two regions.

A schematic process of this radiation-chemical reaction may be presented as follows. The mole-

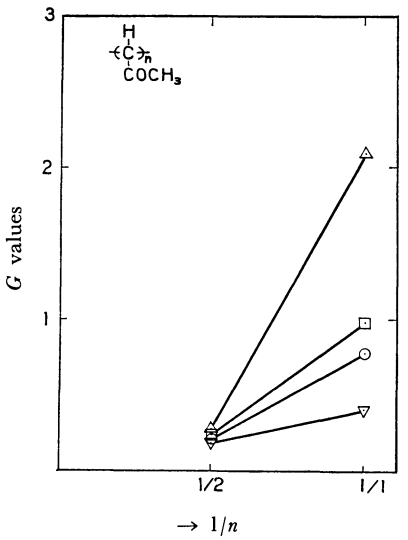

Fig. 7. G values vs. reciprocal of the number of the structural unit.

cule which absorbs energy from ionizing radiations is excited or ionized:

$$A \rightsquigarrow \begin{bmatrix} A^+ + e^- \\ A^* \end{bmatrix} \quad (1)$$

Some produced ions turn finally into excited molecules by means of electron capture;

$$A^+ + e^- \longrightarrow A^* \quad (2)$$

Therefore the primary species correspond to excited molecules or molecular ions, which decompose into radicals and/or produce stable molecules through recombination, abstraction, disproportionation, and other reactions:

$$A^+, A^* \longrightarrow B + C \quad (3)$$

In short, a molecule which absorbs energy of radiation is excited or ionized, and these species decompose to radicals and/or stable products by the bond-rupture of the main or side chain. On the other hand, the overall yield of the product thus formed is generally expressed by the G value. The above relations between the structural units of the compounds and the G values of the products can be explained if the mechanism of the unimolecular decomposition of the excited molecule or molecular ion and the successive reactions are available.

It was proposed by Alexander and Charlesby[59] that the energy absorbed may be transferred over a comparatively far distance along the C–C chain; they based their proposal on their experimental findings that a copolymer of 20 per cent styrene

and 80 per cent isobutylene is more resistant than the pure isobutylene, and that dose required to render a straight-chain hydrocarbon infusible is greatly increased by the presence of an aromatic ring.

It is interesting to compare the results of the following two systems; in one, (A) is a monomer, M, while in the other (B) is a polymer composed of such a monomer, the monomeric unit being assumed to have a similar chemical structure in both systems:

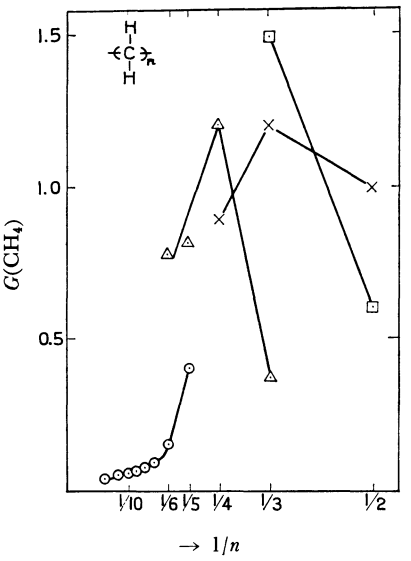

Fig. 9c. G values vs. reciprocal of the number of the structural unit.
⊙ Ref. 42, △ Ref. 25, ▣ Ref. 35, × Ref. 24

(A) M M M M* M M M M

(B) — M — M — M — M*— M — — M — M — M —

In the A system, the energy absorbed is localized on the excited molecule, M*, and enhances the probability of the decomposition of M*, although some part of the energy may be transferred to other molecules. On the other hand, in the B system, the energy absorbed is transferred away by an intramolecular process through the chemical bonds in addition to the intermolecular process. Therefore, the G values of decomposition may be expected to be larger in the A system than in the B system, and if homologous compounds are compared, their G values will decrease with an increase in the number of the monomeric unit, n, in a molecule. However, as the transfer of energy through chemical bonds may be restricted within several bonds, m, the G values of decomposition will be independent of n which is larger than m. This expectation is realized by Figs. 5, 6, 7 and 8, with the exception of $G(CH_4)$ from paraffins. The "m" number is evaluated in each series of -(-CHR-)-$_n$ to be as follows:

R	H	HO	CH_3CO	CH_3COO
m	ca. 6	>4	>2	>3

When R is H, that is, for hydrocarbons, m is given as ca. 6, while is not very different from the $m=12$ stated by Alexander and Charlesby.[59] The same reasoning may be applicable to the other series, in which the G values from monomeric compounds

Table V. A comparison of $G(H_2)$ values from monomers and polymers

Ethylbenzene[60]	$G(H_2)=0.18$
Polystyrene[61,62]	$G(H_2)=0.03$—0.04
Ethanol[63-72]	$G(H_2)=3.5$—5.53
Polyvinylalcohol[62]	$G(H_2)=1.6$
Polyethylene[73-75]	$G(H_2)=3.75$—6.0
Polymethylene[58]	$G(H_2)=5.4$

should be several times larger than those from the corresponding polymers. $G(H_2)$ from polyethylene is nearly equal to that obtained from polymethylene, as was to be expected. Table V compares the $G(H_2)$ values from monomers and polymers.

The curve of $G(CH_4)$ vs. $1/n$ for paraffins shows a different tendency from the curves of the others. This result may be explained similarly as far as the energy transfer is concerned, but the terminal effect must also be introduced. Methane is assumed to come from the rupture of the terminal C–C bonds, and it results only from the excitation of the $m/2$ carbon atoms from the terminal carbon atoms of both ends. Since the carbon atoms in the hydrocarbon molecule are assumed to be excited with an equal probability, the probability of the excitation of carbon atoms within $m/2$ from the terminals is m/n. If the G value of methane formation from hydrocarbons containing i carbon atoms is denoted by $G_i(CH_4)$, $G_n(CH_4)$ is expressed by the equation, $G_n(CH_4)=(m/n)G_m(CH_4)$, in the $n \geqq m$, region, and it decreases with an increase of n in the $n \leqq m$ region as well as the G values of the other products.

The authors are very grateful to Dr. Meiseki Katayama for his suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1886—1893 (1966)

The Effects of Polyamines on the Melting of Polyriboadenylic Acid Plus Polyribouridylic Acid Complexes in a Solution

By Shigesada HIGUCHI and Masamichi TSUBOI

Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received January 17, 1966)

Ultraviolet absorptions of aqueous systems of polyriboadenylic acid (poly A) plus polyribouridylic acid (poly U) have been examined with various Na^+ and Mg^{2+} concentrations and at various temperatures. The transition temperatures (T_m) among the two-stranded conformation, poly(A+U), the three-stranded conformation, poly(A+2U), and the two single-stranded conformations, poly A and poly U, were determined. The effects upon the T_m of adding NH_3^+-$(CH_2)_nNH_3^+$-type diamines (n=2, 3, 4, 5, 6, and 8), spermine, and actinomycin D to the solutions were observed. It was found that these amines stabilize three-stranded poly(A+2U) more than they stabilize the two-stranded (poly(A+U)) and the single-stranded (poly A and poly U) conformations. Among the diamines examined, those with n=2 and 3 values show a greater effect than those with n=4, 5, 6, and 8 values.

This is our second paper on the effects of polyamines on the melting of synthetic nucleic acids. In our first paper[1] we dealt with an aqueous-solution system containing polyriboinosinic acid (poly I) and polyribocytidylic acid (poly C).

1) K. Matsuo and M. Tsuboi, This Bulletin, **39**, 347 (1966).

The word "melting" means a transition in the solution from the double-helical conformation of a 1 : 1 complex, poly(I+C), of these two polymers into random coils of poly I and poly C, i. e.:

$$\text{Poly(I+C)} \rightarrow \text{Poly I} + \text{poly C.} \quad (1)$$

In the present paper we will deal with a system containing polyriboadenylic acid (poly A) and polyribouridylic acid (poly U). Both of these two acids, like poly I and poly C, are synthetic polymers which have the same ribose-phosphate backbone as natural ribonucleic acid (RNA).[2] The system of poly A and poly U is, however, somewhat more complicated than the system of poly I and poly C. In the former, not only a double-helical complex[3] poly(A+U), but also a triple-helical complex[4] poly(A+2U), is formed. Not only a helix-to-random-coil transition, but also transitions of double-to-triple and triple-to-double helices, take place.[5,6] The transition temperatures are affected by the salt concentration in the system, and also by the polyamines added to the solution. The effects of these polyamines are the main subject of this paper.

Experimental

Two samples of polyriboadenylic acid (poly A) were used in the present study. One was purchased from the California Biochemicals Corporation, it showed 4S in an ultracentrifugal sedimentation experiment (Cal. Bio. poly A). The other, purchased from the Miles Chemical Company, showed 8.3S in an ultracentrifugal sedimentation experiment (Miles poly A). Polyribouridylic acid (poly U) was prepared by the use of polynucleotide phosphorylase obtained from *Azotobacter vinelandii*. The product was purified as follows: first it was precipitated by cold ethanol; then it was dissolved in water, deproteinized by chloroform, dialysed against an aqueous solution of 0.01 M ethylene diamine tetraacetate (pH 8), a 1.0 M sodium chloride solution, and distilled water successively, and finally lyophilized. Seven different samples were obtained: Nos. 24, 27, 38, 40, 47, 49, and 50. The sedimentation constants of these samples were, respectively, 8S, 6S, 3.6S, 5.0S, 4.1S, 3.5S, and 1.2S. The polynucleotide concentration in each standard solution was determined by measuring the phosphorous content.[7]

The samples of ethylenediamine dihydrochloride ($NH_3^+(CH_2)_2NH_3^+\cdot 2Cl^-$), 1, 3-diaminopropane dihydrochloride ($NH_3^+(CH_2)_3NH_3^+\cdot 2Cl^-$), 1, 4-diaminobutane dihydrochloride ($NH_3^+(CH_2)_4NH_3^+\cdot 2Cl^-$), 1, 5-diaminopentane dihydrochloride ($NH_3^+(CH_2)_5NH_3^+\cdot 2Cl^-$), 1, 6-diaminohexane dihydrochloride ($NH_3^+(CH_2)_6NH_3^+\cdot 2Cl^-$), 1, 8-diaminooctane dihydrochloride ($NH_3^+(CH_2)_8NH_3^+\cdot 2Cl^-$), and spermine tetrahydrochloride ($NH_3^+(CH_2)_3NH_2^+(CH_2)_4NH_2^+(CH_2)_3NH_3^+\cdot 4Cl^-$) used in this work are all the same as those used in the previous work.[1]

For tracing the conformational changes of the polymers, the ultraviolet absorptions were observed by the use of an Ito Spectrophotometer, Model QU-3. The temperature of the sample solution was controlled as described in our previous paper.[1]

Results and Discussion

1. Evidence of the Formation of a Two-stranded Complex and a Three-stranded Complex.—First, the following three preliminary examinations were made to ascertain whether our samples of poly A and poly U show evidence of forming a multi-stranded complex in solution, as previous investigators[3-6] have reported.

(*i*) *Ultracentrifugal Sedimentation.*—It has been shown that a 1 mole-to-1 mole mixture solution (in a 0.1 M sodium chloride + 0.01 M sodium citrate buffer, pH 7.0) of our poly A and poly U shows only one peak in an untracentrifugal sedimentation pattern (with Schlielen optics). This indicates that a 1 : 1 complex is formed. The sedimentation constant of the complex is found to be appreciably greater than those of the components. For example, the complex of poly A from the California Biochemicals Corp. with 4S and No. 38 poly U with 3.6S gives a sedimentation constant of 6.8S. The complex of Miles poly A with 8.3S and No. 49 poly U with 3.5S gives a sedimentation constant of 11.6S.

(*ii*) *Ultraviolet Absorptions.*—Poly A in a 0.15 M sodium chloride + 0.015 M sodium citrate buffer of pH 7.0 gives a spectrum with an absorption maximum at 257 mμ, and poly U in the same solvent gives a spectrum with an absorption maximum at 261 mμ, while a 1 : 1 mixture shows a spectrum with a maximum at 257 mμ. This spectrum was exactly the same as that reported by Warner.[8] On alkali hydrolysis a gerat hyperchromicity is observed in this absorption band.

(*iii*) *Mixing Curve.*—The absorbance was measured at 259 mμ for several mixtures (at 18±2°C) containing varying proportions of poly A and poly U, while the total nucleotide concentration was kept constant. The solvents examined were as follows:

a) 0.15 M NaCl plus a 0.015 M Na-citrate buffer (pH 7.0).

b) 0.025 M NaCl plus a 0.0005 M Na-citrate buffer (pH 7).

c) 0.015 M NaCl plus a 0.045 M glycylglycine buffer (pH 7.0).

d) 0.1 M NaCl plus a 0.01 M glycylglycine buffer (pH 7.1).

Table I. A summary of what Stevens and Felsenfeld[6] found of the melting process in mixted solutions of poly A and poly U.

A : U mole ratio in the solution	Salt concn.		Melting process	At 259 mμ	At 280 mμ
1 : 1	Low	(A)	Poly(A + U) → poly A + poly U	hyper	no change
	High or + Mg^{2+}	(B)	2 poly(A + U) → poly(A + 2U) + poly A	no change	hypo
			→ 2 poly A + 2 poly U	hyper	hyper
1 : 2	Low	(C)	Poly(A + 2U) → poly(A + U) + poly U	hyper	hyper
			→ poly A + 2 poly U	hyper	no change
	High or + Mg^{2+}	(D)	Poly(A + 2U) → poly A + 2 poly U	hyper	hyper

(This is what Felsenfeld, Davies, and Rich[4] used.)

e) d) plus 0.00025 M ethylenediaminetetraacetic acid (EDTA).

f) d) plus 0.0016 M EDTA.

g) 3 ml. of d) plus 1 ml. of a 0.04 M EDTA solution.

h) d) plus 0.01 M EDTA.

In most cases the absorbance was observed immediately after the mixing of poly A and poly U. In the solvent d) however, the absorbance was observed not only immediately after the mixing, but also 25 min., 2 hr. and 54 hr. after the mixing. In the solvent g) the absorbance was observed 15 min. and 40 min. after the mixing, and also after the mixed solution had been kept overnight. The resulting mixing curve was always similar to what Felsenfeld, Davies, and Rich[4] observed in a solvent with 1.2×10^{-2} M magnesium chloride. It is composed of two straight lines which intersect sharply at a poly A : poly U mole ratio of 1 : 2, as is illustrated in Fig. 1. This indicates that,

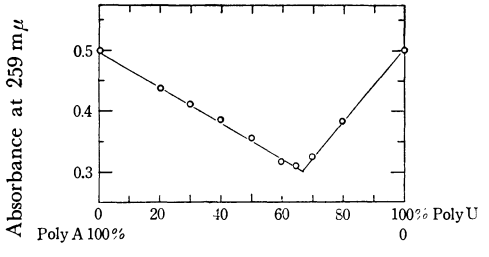

Fig. 1. A mixing curve for poly A and poly U. Solvent: 0.1 M NaCl plus 0.01 M glycylglycine buffer, pH 7.1. Temperature : 18±2°C. The absorbance at 259 mμ was observed at 54 hr. after every mixing of poly A and poly U.

in a mixture of 1 mole of poly A and 2 moles of poly U, a three-stranded complex, poly(A+2U), is formed under any of the above sets of conditions. What we observed in solvent d) is, however, different from what Felsenfeld, Davies, and Rich[4] observed. In this solvent, they observed a mixing curve composed of two straight lines which intersect at a mole ratio of 1 : 1. As will be shown below, this difference may be partly due to the difference in the temperature of the solution. They observed the mixing curve at 25°C, while we observed it at 18°C. On the basis of our rather detailed examination (see above), we may conclude that, at 18°C, a 1 mole-to-2 mole mixture of our poly A and poly U forms a three-stranded complex, poly(A+2U), even in a solvent with a low salt concentration.

2. The Melting Process of Poly(A+U) and Poly(A+2U).—A series of examinations were made to find out the conditions under which poly(A+U) and poly(A+2U) are stable and the process through which these complexes melt into random coils of poly A and poly U. As we were conducting our examinations, a paper of Stevens and Felsenfeld[6] reporting a similar attemt appeared. They showed that the melting process can be followed by tracing the absorbance at 260 mμ and that at 280 mμ. What they found is summarized in Table I. We found, as is illustrated in Fig. 2, that our samples of poly A and poly U show the same behavior as they found (compare Fig. 2 with Table I). On the basis of the results of other similar experiments of ours, as well as of a few previous works by others,[5,6] we have constructed diagrams shown in Figs. 3 and 4. These diagrams illustrate how the melting process in question depends upon the Na^+ concentration in the solvent. Because of an unknown factor, different batches of samples show some small but appreciable differences in melting temperatures. For example, poly(A+U) with No. 49 poly U shows a slightly but still appreciably higher T_m value than poly(A+U) with No. 47 poly U. The sedimentation constants of these two poly U's (No. 49 and 47) are 3.5S and 4.1S respectively, almost equal to each other. The transition temperatures of poly(A+2U) to poly(A+U) in the 1 mole-to-2 moles mixture of our samples are appreciably higher than those observed by Fresco[5] in a region with a lower salt concentration (see Fig. 4). As has been described in the preceding section, our sample does not form poly(A+U) at 18°C, even in a very low-salt environment. In general, the equilibrium of poly(A+U) and poly(A+2U) is a rather delicate one, as will be illustrated in the next section.

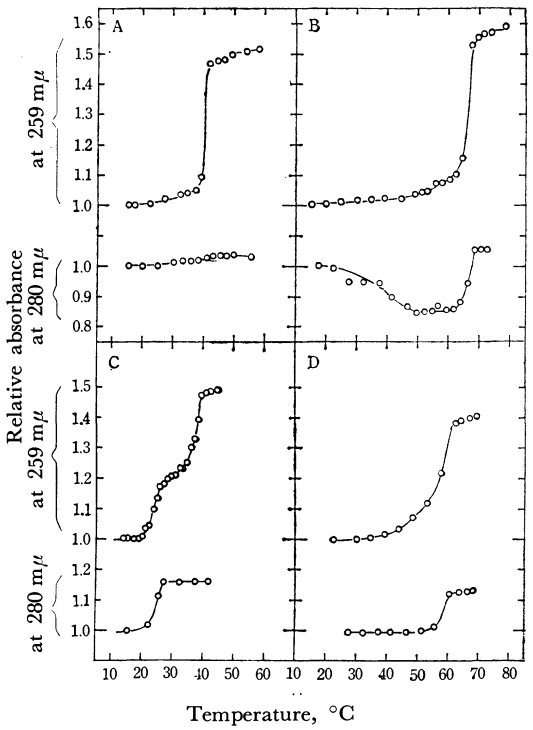

Fig. 2. Four types of melting process A, B, C, and D (See Table I) of helical complexes in mixed solution of poly A and poly U, as followed by observing the absorbance at 259 mμ and 280 mμ.

A: 1 mol. to 1 mol. mixture of Miles poly A and No. 49 poly U in 0.01 M NaCl+0.001 M Na-citrate buffer, pH 7

B: The same with A except +0.001 M $MgCl_2$

C: 1 mol. to 2 mol. mixture of Miles poly A and No. 50 poly U in 0.01 M NaCl+0.001 M Na-citrate buffer, pH 7

D: 1 mol. to 2 mol. mixture of Miles poly A and No. 50 poly U in 0.001 M $MgCl_2$+0.001 M Na-citrate buffer, pH 7

3. A Metastable Poly(A+2U).—In connection with the equilibrium between the two- and three-stranded complexes, we also noticed the following phenomenon.

Miles poly A plus No. 50 (or No. 47) poly U were dissolved, in a 1 : 1 mole ratio, into 0.01 M sodium chloride plus a 0.001 M sodium citrate buffer (pH 7), the solution was then heated. The absorbance at 259 mμ shows one-step melting at 39°C, while the absorbance at 280 mμ shows almost no change throughout the temperature range (15—45°C) examined. The solution of the melted polynucleotides was slowly cooled to 15°C (2 hr. for 45→15°C) and was then examined again as to its melting profile. The absorbance at 259 mμ shows two-step transitions at 26°C and 39°C, while the absorbance at 280 mμ shows a transition at 26°C. This melting profile is similar to

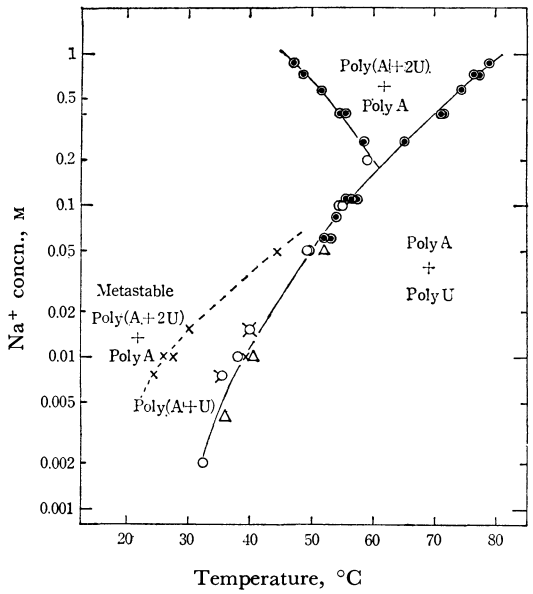

Fig. 3. Melting temperatures of poly(A+U) and poly(A+2U) in solutions with poly A and poly U in 1 : 1 mole ratio and with various Na^+ concentrations.

○: Miles poly A+No. 47 poly U
△: Miles poly A+No. 49 poly U
⊙: Observed by Stevens and Felsenfeld[6]
×: Observed for metastable poly(A+2U) (See section 3)

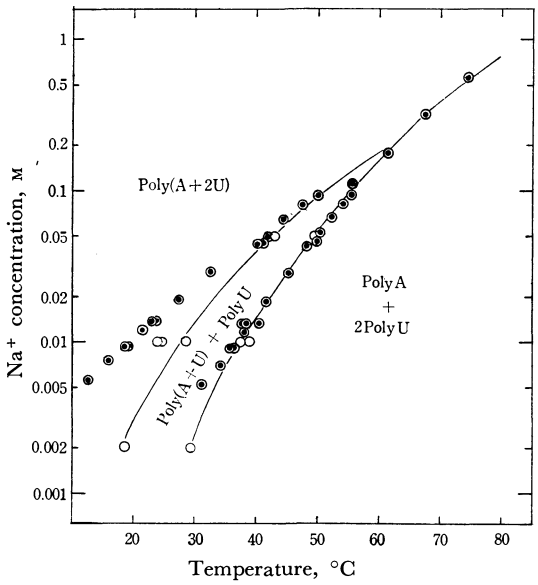

Fig. 4. Melting temperatures of poly(A+2U) and poly(A+U) in solutions with poly A and poly U in 1 : 2 mole ratio and with various Na^+ concentrations.

○: Miles poly A+No. 50 poly U
⊙: Observed by Fresco[5]

that of poly(A+2U) (the type C profile given in Table I or in Fig. 2).

This fact may be interpreted as indicating that the mixing of poly A and poly U (1 : 1) at room temperature causes this reaction:

$$\text{poly A} + \text{poly U} \rightarrow \text{poly(A + U)}, \quad (2)$$

However, the cooling of the melted poly A and poly U (1 : 1) mixture causes another reaction:

$$\text{poly A} + \text{poly U} \rightarrow {}^1/_2\,\text{poly(A + 2U)} + {}^1/_2\,\text{poly A}. \quad (3)$$

Support for this interpretations was obtained by another experiment. First, the three-stranded complex poly(A+2U) was formed in a solution, and then poly A was added to the solution so that the resulting total amounts of poly A and poly U became equivalent to each other (1 : 1 mole ratio). The resultant solution shows a melting profile similar to that of poly(A+2U) in a solution with a 1 : 2 mole ratio. Thus, the added poly A does not react with poly(A+2U); in other words, the reaction:

$${}^1/_2\,\text{poly(A + 2U)} + {}^1/_2\,\text{poly A} \rightarrow \text{poly(A + U)} \quad (4)$$

does not proceed in a low-salt-content environment.

Poly A does not form any highly-ordered conformation by itself at a neutral pH value. Therefore, at lower temperatures, poly(A+U) may be considered to be more stable than the partiallymelted form, 1/2 poly(A+2U) + 1/2 poly A. Thus, the poly(A+2U) resulting from reaction (3) may be considered to be in a metastable state.

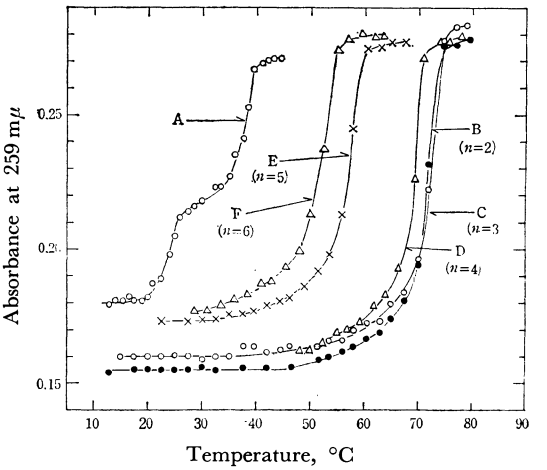

Fig. 6. The variation of the absorbance of Miles poly A plus No. 50 poly U (1 : 2) plus diamine ($NH_3^+(CH_2)_nNH_3^+$) solutions at 259 mμ with temperature.
Solvent: 0.01 M NaCl plus 0.001 M Na-citrate buffer, pH 7
A: No amine, B: 0.001 M $NH_3^+(CH_2)_2NH_3^+$, C: 0.001 M $NH_3^+(CH_2)_3NH_3^+$, D: 0.001 M $NH_3^+(CH_2)_4NH_3^+$, E: 0.001 M $NH_3^+(CH_2)_5NH_3^+$, F: 0.001 M $NH_3^+(CH_2)_6NH_3^+$

4. The Effects of Diamines.—When a $NH_3^+(CH_2)_nNH_3^+$-type diamine is added to a solution of poly(A+U) or poly(A+2U), an effect on the melting profile similar to that of an elevation of the salt concentration of a solution

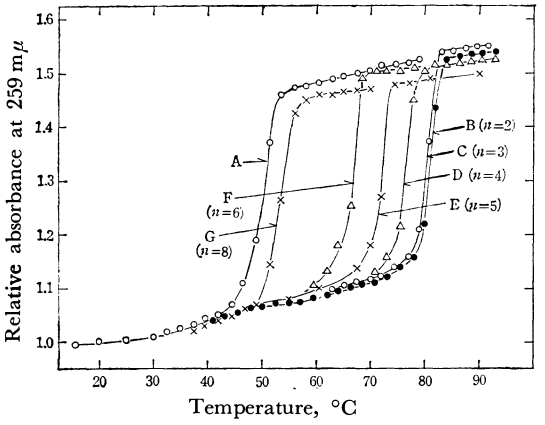

Fig. 5. The variation of the absorbance of Miles poly A plus No. 47 poly U (1 : 1) plus diamine ($NH_3^+(CH_2)_nNH_3^+$) solutions at 259 mμ with temperature.
Solvent: 0.05 M NaCl plus 0.001 M Na-citrate buffer, pH 6.5—7.0

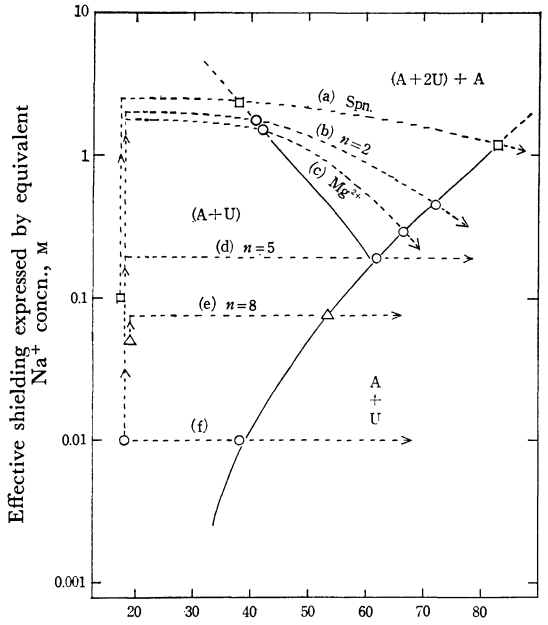

Fig. 8. Route of melting of poly(A+U) drawn on a phase diagram similar to Fig. 3, in a solution (a) with 0.001 M $NH_3^+(CH_2)_3NH_2^+(CH_2)_4NH_2^+(CH_2)_3NH_3^+$, (b) with 0.001 M $NH_3^+(CH_2)_2NH_3^+$, (c) with 0.001 M $MgCl_2$, (d) with 0.001 M $NH_3^+(CH_2)_5NH_3^+$, (e) with 0.005 M $NH_3^+(CH_2)_8NH_3^+$, or (f) without any divalent cation. The vertical dotted lines indicate the effect of the addition of divalent cations. The starting points of these lines indicate the Na^+ concentration of the solution before the addition of the divalent cations.

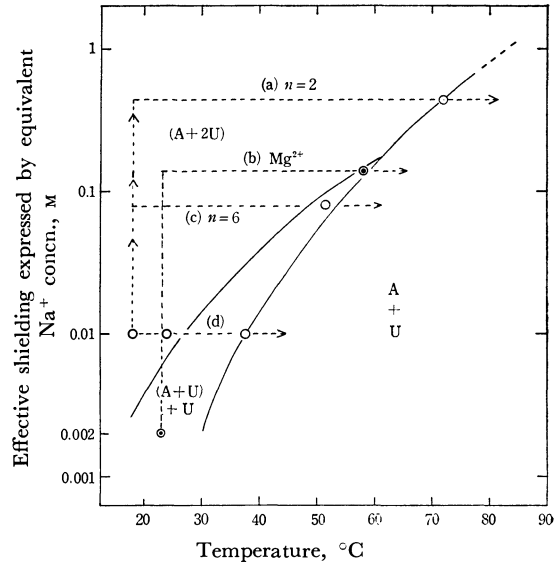

Fig. 9. Route of melting of poly(A+2U) drawn on a phase diagram similar to Fig. 4.
In a solution (a) with 0.001 M $NH_3^+(CH_2)_2NH_3^+$, (b) with 0.001 M $MgCl_2$, (c) with 0.001 M $NH_3^+(CH_2)_6NH_3^+$, or (d) without any divalent cation

is observed (Figs. 5 and 6). The melting temperature of poly(A+U) observed by the absorbance at 259 mμ is elevated (Fig. 5). The melting profile is changed from Type A into Type B (see Table I, Fig. 2, and Fig. 7, A). For poly(A+2U), the two-step melting profile traced by the absorbance at 259 mμ disappears; D-type melting profile is now observed (Fig. 6 and Fig. 7, B). This fact may be interpreted by considering that the effect of the diamine cation is essentially the same as the effect of Na^+, except that the former is much greater than the latter. In general, cations in the solution are considered to be bound by the PO_2^- group of the polynucleotide molecules and to shield the negative charge, so that the inter-strand repulsion is reduced in the two- or three-stranded complex. Therefore, it is probable that phase diagrams similar to those given in Figs. 3 and 4 are valid for every $NH_3^+(CH_2)_nNH_3^+$-type cation, if the ordinate, instead of the actual Na^+ concentration, is assumed to be a measure of the effectiveness of a certain amount of each cation in shielding the negative charge of the polynucleotide chains. On the basis of this interpretation, the effects of a few diamines are shown in Figs. 8 and 9, where the same phase diagrams as are given in Figs. 3 and 4 are used.

As may be seen in Fig. 8, the shielding effect of the $NH_3^+(CH_2)_2NH_3^+$ cation is slightly greater than that of Mg^{2+} for poly(A+U). For poly (A+2U), the shielding effect of $NH_3^+(CH_2)_2 \cdot NH_3^+$ is also somewhat greater than that of Mg^{2+} (see Fig. 9). These facts may be explained by considering that, while the shielding effect of the Mg^{2+} bound to the PO_2^- group may be greater than that of the $NH_3^+(CH_2)_2NH_3^+$, the binding constant of the $NH_3^+(CH_2)_2NH_3^+$ bound to polynucleotide is greater than that of the Mg^{2+}. The binding constant of a $NH_3^+(CH_2)_nNH_3^+$-type cation can be great if the distance of the two amino groups in the cation is nearly equal to the distance between two PO_2^- groups (or between two O^- atoms) in the secondary structure of the polynucleotide molecule in question. In a comparison of diamines with n values of 2, 3, 4, 5, 6, and 8 (cf. Fig. 5), the melting temperatures observed with the $n=2$ and $n=3$ diamines are almost equal to each other and are much higher than the melting temperatures observed with other diamines (see also Fig. 10, (b)). The melting temperature higher than 61°C observed in the system where poly A: poly U=1 : 1 (see Fig. 8) should correspond to the melting reaction:

$$\text{poly(A + 2U) + poly A} \rightarrow \text{2 poly A + 2 poly U} \quad (5)$$

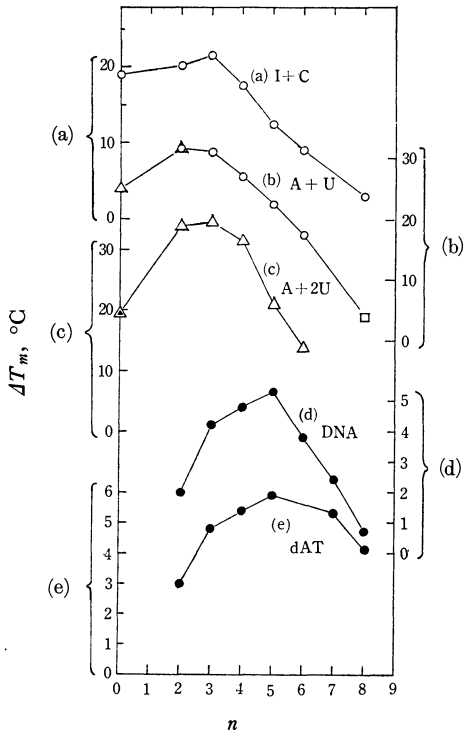

Fig. 10. A relative efficiency of diamines NH_3^+-$(CH_2)_nNH_3^+$ in stabilizing helical nucleic acids plotted against n, the number of the methylene groups placed between the two NH_3^+ groups. The stabilizing efficiency is expressed by an increment in the melting temperature, ΔT_m, of the nucleic acid solution caused by adding a certain amount of the diamine. For $n=0$, ΔT_m caused by Mg^{2+} was plotted. (a) poly(I+C),[1] (b) poly(A+U), (c) poly(A+2U), (d) calf thymus deoxyribonucleic acid,[9] and (e) alternating copolymer of deoxyadenylic acid and deoxythymidylic acid.[9]

○: ΔT_m observed with 0.01 M diamine or Mg^{2+} in 0.05 M NaCl plus 0.01 M Na-citrate buffer, pH 7.0.

△: ΔT_m observed with 0.001 M diamine or Mg^{2+} in 0.01 M NaCl plus 0.001 M Na-citrate buffer, pH 7.

▲: ΔT_m observed with 0.001 M Mg^{2+} plus 0.001 M Na-citrate buffer, pH 7.

□: ΔT_m observed with 0.005 M diamine in 0.05 M NaCl plus 0.001 M Na-citrate buffer, pH 7.

●: ΔT_m observed with 0.04 M diamine in 0.15 M NaCl plus 0.015 M Na-citrate buffer, pH 7.

Therefore, the $NH_3^+\cdots NH_3^+$ distance in the $n=2$ or $n=3$ diamine is considered to reflect a $PO_2^-\cdots PO_2^-$ distance (or $O^-\cdots O^-$ distance) in the three-stranded poly(A+2U) molecule. In the system where poly A : poly U=1 : 2, a melting temperature higher than 61°C should correspond to the melting reaction:

$$\text{poly (A + 2U)} \rightarrow \text{poly A + 2 poly U} \qquad (6)$$

In the comparison regarding this melting temperature shown in Fig. 6, the maximum is also observed around $n=2$ and $n=3$ (see Fig. 10, (c)). As has been described in a previous paper,[1] the maximum ΔT_m value was observed at $n=3$ for poly(I+C) (Fig. 10, (a)). For double-stranded deoxyribonucleic acids, on the other hand, the maximum ΔT_m value was observed at $n=5$[9] (Fig. 10, (d) and (e)). On the basis of what has been described above, these facts may be interpreted as indicating that the nearest $PO_2^-\cdots PO_2^-$ distance (or $O^-\cdots O^-$ distance) in two- or three-stranded-polyribonucleotide is smaller than that in double-stranded polydeoxyribonucleotide.

5. The Effect of Spermine.—The change in the melting profile of poly(A+U) caused by spermine is illustrated in Fig. 11. The melting profile observed with 0.001 M spermine belongs to the Type B in Table I; it is similar to the melting profile observed with 0.001 M Mg^{2+}. The first transition, however, takes place at a lower temperature (at 38°C) with spermine than with Mg^{2+}, while the second transition takes place at a higher temperature (at 83°C) with spermine than with Mg^{2+}. These facts indicate: (1) that spermine (like other cations) stabilizes the three-stranded poly(A+2U) more than it stabilizes the two-stranded poly(A+U) or single-chain poly A and poly U, and (2) that this function of spermine is stronger than that of Mg^{2+}. As may be seen

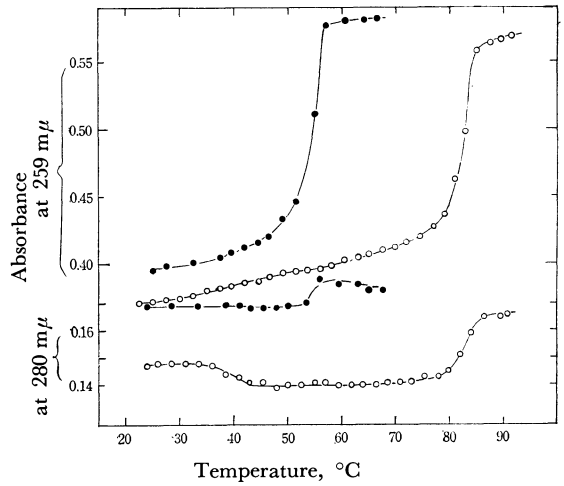

Fig. 11. The variation of the absorbance at 259 mμ and at 280 mμ of Miles poly A plus No. 48 poly U (1 : 1 mol. ratio) solutions with (○) and without (●) spermine (0.001 M).
Solvent: 0.1 M NaCl plus 0.001 M Na-citrate buffer, pH 7

9) H. R. Mahler and B. D. Mehrotra, *Biochim. Biophys. Acta*, **68**, 211 (1963).

in Fig. 8, the effect of spermine (0.001 M) is not only greater than that of Mg^{2+}, but also greater than that of ethylenediamine (0.001 M). This is understandable, because the spermine cation is tetra-valent and so its binding constant to the polynucleotide would be greater and its shielding effect would be greater than those of Mg^{2+} and $NH_3^+(CH_2)_2NH_3^+$. The effect of spermine on the poly A + poly U system may thus be explained qualitatively by considering only the ordinary effect of a cation. So far, it is not necessary to assume a so-called clamping function,[1,10] although it is still probable that spermine has this function also.

6. The Effect of Actinomycin D.—It has been found that 7γ/ml. of actinomycin D has no effect on the melting profile of a 1 : 1 mixture of poly A and poly U.

This work was supported by a grant from the United States Public Health Service (No. GM 10024-02) and a grant from the Ministry of Education of Japan.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1893—1897 (1966)

The Solvent Effect on the Interaction between Perylene and Antimony Pentachloride

By Haruo KURODA, Takako SAKURAI and Hideo AKAMATU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received January 25, 1966)

The electronic spectrum of the mono-positive ions of perylene formed by the interaction of antimony pentachloride was examined in various solvents. The observed spectra may be classified into two types. The one is the spectrum observed when the solvent is of a high dielectric constant, a spectrum which almost coincides with the spectrum of perylene in sulfuric acid. The other is the spectrum observed for a solution in a solvent of a low dielectric constant, a spectrum consisting of broad absorption bands accompanied by an extra band at about 1200 mμ. The former type of spectrum may be attributed to the perylene ions in a free state stabilized by the solvation, and the latter to an associated state involving perylene and antimony pentachloride ions. It is suggested that, in the association of both kinds of ions, two or more perylene ions are in contact with each other, and that the interaction between them is responsible for the shift and broadening of the absorption bands of perylene ions, as well as for the appearance of the extra band.

Polycyclic aromatic hydrocarbons exhibit characteristic deep colors upon interaction with antimony pentachloride in a polar solvent. Aalbersberg, Hoijtink, Mackor and Weijland[1] have shown that this phenomenon is associated with the formation of positive ions of the hydrocarbons as a result of an electron transfer from the hydrocarbons to antimony pentachloride, which is known as a strong electron acceptor. The interaction between perylene and antimony pentachloride is a typical example of such electron transfer. In effect, as antimony pentachloride is added to a nitrobenzene solution of perylene, the absorption bands of the neutral perylene molecule are replaced with new absorption bands which coincide well with the spectrum of perylene in sulfuric acid. Apparently this change in the spectrum indicates the formation of perylene ions, since the spectrum of a sulfuric acid solution of perylene is known to be due to the mono-positive ions of perylene.[2-4] The electron transfer from perylene to antimony pentachloride also occurs in other solvents. We have noticed, however, that the absorption bands are shifted more or less depending on the solvent. This shift is quite remarkable in some cases, too large for the ordinary solvent effect, so that it seems questionable to regard the perylene ions formed by the interaction of antimony pentachloride as always in a free state

in any kind of solvent. The present investigation was undertaken in order to elucidate the effect of solvents on the interaction between perylene and antimony pentachloride.

Experimental

Perylene obtained from the K & K Laboratory was purified by alumina column chromatography, and then by sublimation in vacuo. The following solvents were used: (1) *n*-heptane, (2) cyclohexane, (3) carbon tetrachloride, (4) benzene, (5) toluene, (6) carbon disulfide, (7) trichloroethylene, (8) chloroform, (9) *α*-chloronaphthalene, (10) bromobenzene, (11) chlorobenzene, (12) tetrachloroethane, (13) *cis*-dichloroethylene, (14) *o*-dichlorobenzene, (15) nitrobenzene, and (16) acetonitrile. A solution of perylene, about 10^{-5} mol./l., was prepared with each solvent after it had been well dried by using calcium chloride. Antimony pentachloride was added to the solutions until the absorption spectrum of the neutral perylene molecule was replaced almost completely with the spectrum of the perylene ion. This was usually made with an excess amount of antimony pentachloride. The solutions were not very stable since antimony pentachloride decomposes slowly in most solvents. Therefore, the spectrum was observed immediately after the preparation of each solution. The absorption spectrum in the visible and near-infrared region was measured by means of a Hitachi EPS-2U recording spectrophotometer.

Results and Discussion

The absorption spectra observed in the presence of an excess amount of antimony pentachloride can be classified into two types. The one type of the spectra, which we shall call "type A," has a weak band at about 740 mμ and a strong and sharp band in the 540—560 mμ region. An example of the type A spectrum is given in Fig. 1. This coincides very well with the spectrum of perylene in sulfuric acid (Fig. 2), except for the small red-

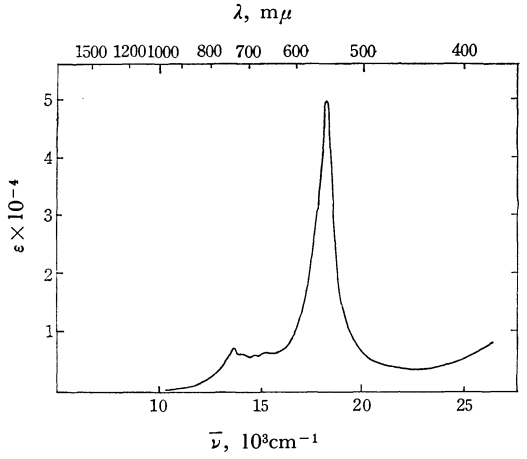

Fig. 1. Absorption spectrum of perylene-$SbCl_5$ in chlorobenzene.

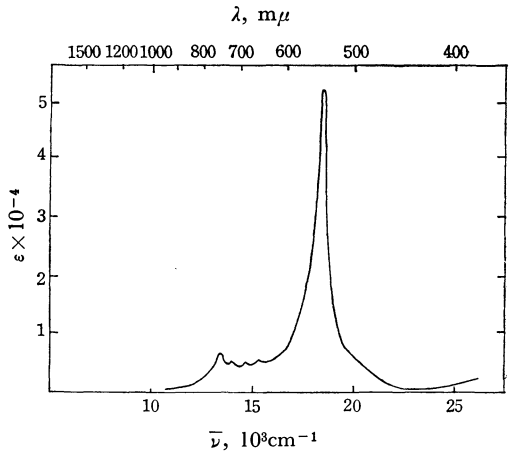

Fig. 2. Absorption spectrum of a sulfuric acid solution of perylene.

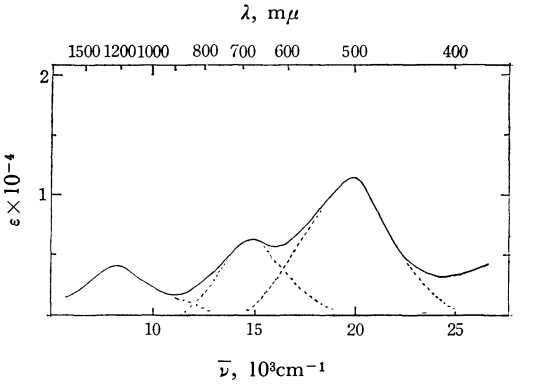

Fig. 3. Absorption spectrum of perylene-$SbCl_5$ in trichloroethylene.

shift of the strong band. The other type of spectrum, "type B", is shown in Fig. 3; this is observed for a trichloroethylene solution. A spectrum of this type is observed when the solvent is of a low dielectric constant. In this case, the absorption bands are appreciably broadened and, at the same time, the strong band of perylene ions at about 550 mμ is considerably blue-shifted. Interestingly, a broad absorption band appears at about 1200 mμ in the spectra of type B, a band which can never be found in the spectra of type A. The origin of this band will be discussed later. The observed wavelengths of the absorption bands are summarized in Table I.

Accoring to Bayliss' theory on the solvent effect,[5] the frequency difference in an absorption band between the gaseous state and the solution is approximately expressed by the following equation:

$$\Delta\nu = b(n^2 - 1)/(2n^2 + 1) \qquad (1)$$

where n is the refractive index of the solvent for the sodium-D line, and b is a constant dependent

** The spectrum of perylene ion in sulfuric acid.

on the oscillator strength of the transition. In the more refined theories given by McRae[6] and Ooshika,[7] it is shown that the solvent shift depends not only on the refractive index, but also on the dielectric constant and other properties of the solvent. However, the Bayliss' relation would be approximately satisfied in the case of an absorption band of a non-polar molecule in a non-polar solvent. This relation can be extended even to the absorption band of a non-polar molecule in a polar solvent, but not to the band of a polar molecule.

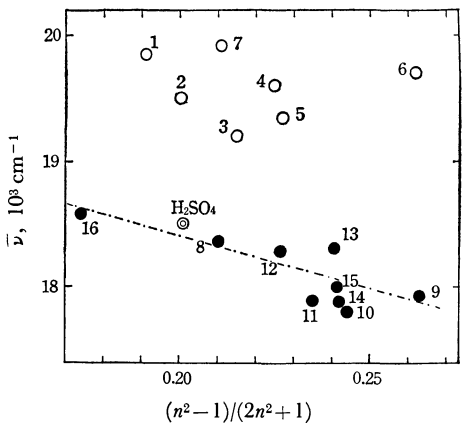

Fig. 4. Solvent shift of a strong absorption band of perylene ion at about 540 mμ. The number of each point indicates the solvent (see Table I).

In Fig. 4, the wave number of the strong band in the 500—560 mμ region is plotted against the value of $(n^2-1)/(2n^2+1)$. The points for the spectra of type A are shown by solid circles, and those for the spectra of type B, by open circles. The solid circles fall on a straight line, as is to be expected from Bayliss' relation. Clearly the solvent shift in the spectra of type A is one that can be understood without the consideration of any specific interaction of perylene ions with solvent molecules or with antimony pentachloride ions. In other words, we can assign the spectra of type A to monopositive ions of perylene in a relatively free state.

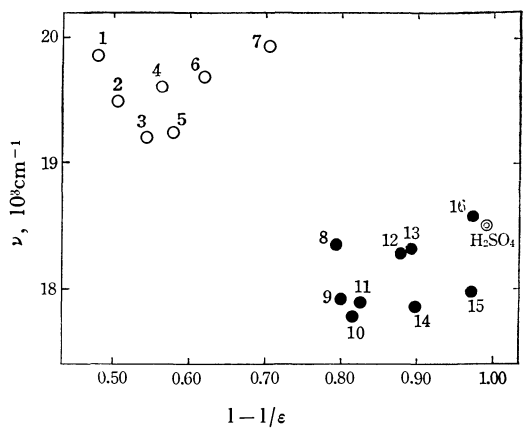

Fig. 5. Relation between the wave number of an absorption band of perylene ion and the dielectric constant of solvent.

6) E. G. McRae, *J. Phys. Chem.*, **61**, 562 (1957).
7) Y. Ooshika, *J. Phys. Soc. Japan*, **9**, 594 (1954).

On the other hand, in Fig. 4, the points for the spectra of type B deviate markedly from the regularity found for the spectra of type A. Apparently the shift of the peak is too large for a usual solvent shift. Hardly any simple relation can be found between the shift and the refractive index of the solvent in this case. These facts, as well as the broadness of the absorption band, suggest the presence of some specific interaction between a perylene ion and its surroundings in a case that exhibits a spectrum of type B.*

It should be noticed that the solvents which give spectra of type B are of a wide variety with respect to the electronic states. It is hard to expect that carbon tetrachloride, *n*-heptane and benzene will exhibit the same specific interaction with perylene ions. Therefore, we can exclude the possibility that the spectrum of type B is caused by a strong interaction between perylene ions and solvent molecules.

In a solution, perylene ions are stabilized by the solvation. The solvation energy which is associated with an electrostatic interaction of the electronic charge on a molecular ion with solvent molecules can be approximately expressed as follows:[9]

$$\Delta E \simeq \sum_i (q_i/2r)(1 - 1/\varepsilon) \qquad (2)$$

where q_i is the charge on the ith atom in the molecular ion; r is the effective interaction radius for the atomic centers, and ε is the dielectric constant of the solvent. Thus ΔE can be regarded as being proportional to $(1-1/\varepsilon)$. The wave number of the strong absorption band is plotted against $(1-1/\varepsilon)$ in Fig. 5. It can be seen that the spectra of type A and those of type B appear in different regions, the boundary between which is at the $(1-1/\varepsilon)$ value of about 0.75. The results described above suggest that, in a solvent with a high dielectric constant, a perylene ion is in a relatively free state as it is fully stabilized by the solvation, whereas in a solvent with a low dielectric constant the solvation energy is not large enough to free a perylene ion from an antimony pentachloride ion; this results in keeping them in an associated state involving the two kinds of ions. One may expect the presence of an equilibrium between the free ion state and the associated state when the dielectric constant of the solvent is a value intermediate between the two regions. In effect, such an equilibrium can be demonstrated by the spectra observed in the case of a mixed solvent consisting of benzene and chlorobenzene. The chlorobenzene solution gives a typical spectrum of type A, while the benzene solution gives a spectrum of type B. The spectra observed for the mixed solvent are shown in Fig. 6. The equilibrium of the two states appears when the volume ratio of chlorobenzene to benzene is 0.6—1.0. As we have already mentioned, the spectra of type B have an extra absorption band at about 1200 mμ which can not be found in the spectra of type A. Seemingly, this absorption band is due to the associated state, and it might be a charge-transfer band.

It is known that a solid complex can be obtained from the interaction between perylene and antimony pentachloride. Unfortunately, the crystal structure of this solid complex has not yet been determined. One could suppose, however, that the positive ions of perylene and the negative ions of antimony pentachloride are arranged alternately in the crystal. The minute crystals of the solid complex are formed when a chloroform solution of antimony pentachloride is sprayed onto the surface of a thin flake of perylene crystal. The difference between the absorption spectra of the crystal before and after the formation of a complex on its surface

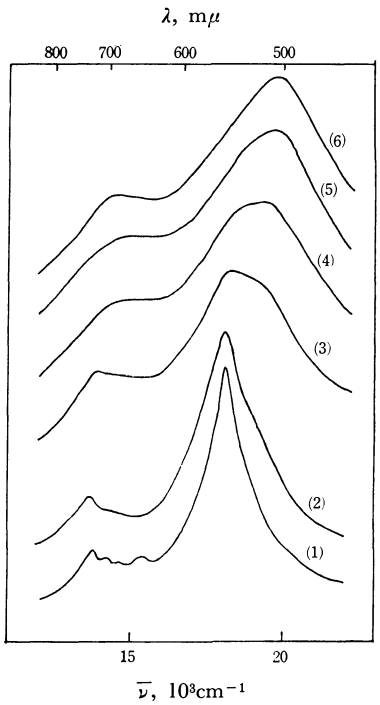

Fig. 6. Absorption spectrum of perylene-$SbCl_5$ in a mixed solvent, benzene-chlorobenzene. The volume ratio of chlorobenzene to benzene is: (1) 2.0, (2) 1.0, (3) 0.9, (4) 0.75, (5) 0.65 and (6) 0.5.

* The possibility of the formation of a covalent complex between perylene and antimony pentachloride can not be excluded, but it is not likely that the spectrum of type B is associated with the covalent complex, as it is quite different from the spectrum known for the proton complex.[8] The spectrum of type B is also different from the spectrum of a colloidal suspension of the solid complex reported by Blomgren and Kommandeur.[10]

can be taken as the spectrum of the solid complex. The spectrum obtained in this way is shown in Fig. 7. The absorption spectrum of the solid complex has also been observed by Blomgren and Kommandeur[10] by using the KBr-pellet method; their spectrum is similar to the spectrum we show in Fig. 7.

The spectrum of the solid complex seems to correspond to the spectrum of type A rather than to that of type B, because: (i) the red-shift of the absorption peak from its position in a spectrum of type A is of the order that can be expected for the solid state, (ii) the band at 760 mμ is relatively sharp, while it is very broad in the spectra of type B, and (iii) the band at 1200 mμ is absent, or very weak. If we assume that the appearance of the spectrum of type B is due to the charge-transfer interaction between a perylene ion and an antimony pentachloride ion, the same type of spectrum could be expected for the solid complex. This is not the case, however, and the charge-transfer band due to the interaction between perylene and antimony pentachloride can not be observed for the solid complex. This leads to the conclusion that the spectrum of type B is caused by some specific interaction of perylene ions which does not take place in the free state nor in the crystal. Probably the large blue-shift and the marked broadening of the absorption bands in the spectrum of type B are due to the effect of interaction between perylene ions; the new band at 1200 mμ could be a charge-transfer band also caused by the interaction between perylene ions, not by the interaction between a perylene ion and an antimony pentachloride ion. This interpretation is possible if we suppose that the associated state formed in the solvents with low dielectric constants does not correspond to the pair of a perylene ion and an antimony pentachloride ion, but to an aggregate of two or more pairs, in which the arrangement of ions is quite different from that in the crystal, and in which perylene ions are in direct contact with each other. Thus the situation that gives the spectrum of type B seems similar to the dimer of radical ions as that has been presented by Hauser and Murrell[11] in the case of Wurster's blue perchlorate. Further evidence for the interaction between perylene ions might be obtained from a study of the electron spin resonance absorption.

Analytical Studies Using the Convection Electrode. XI. Cathodic Stripping Voltammetry of Chloride Ions with the Pushed-out Mercury Drop Convection Electrode

By Junsuke SUZUKI

Faculty of Education, Shizuoka University, Ooiwa, Shizuoka

(Received January 5, 1965)

The cathodic stripping voltammetry of chloride ions in a potassium nitrate or a nitric acid solution was studied by using the Pushed-out Mercury Drop Convection Electrode (PMDCE) (J. Suzuki and T. Ozaki, This Bulletin, **37**, 230 (1964)). The cathodic stripping peak current, i_p, depended upon the rotating rate of the disk, ω (600—1000 r. p. m.); the rate of voltage scan, v(100—300 mV./min.); the pre-electrolysis time, t (~3 min.), and the bulk concentration of chloride ions, C. It was concluded that the corresponding cathodic peak current, i_p, can be given by the equation:

$$i_p = kv\omega^{1/2}Ct^{2/3}$$

where k is the constant. In a 0.1 M nitric acid solution, it was possible to determine the chloride ions in so dilute a solution as 3×10^{-5} M with a good reproducibility.

A series of investigations of the stripping voltammetric analytical technique have shown that the method has a very high sensitivity in the determination of trace amounts of electroactive materials.

The anodic stripping analysis has been applied to the determination of those metal ions which can be deposited on the cathode as metals, and the cathodic stripping analysis, to the determination of those ions which can be precipitated on the surface of the anode as oxides or halides.

Recently, several applications of the mercury or silver electrode to the cathodic stripping analysis have been investigated for the determination of halide ions.[1-7] Ball et al.[1] and Shain and Perone.[5] reported that it was possible to determine chloride ions in solutions as dilute as 0.2 to 2γ/ml. with mercury electrode and iodide ions as dilute as 4×10^{-8} M by using the silver electrode. However, the reproducibilities obtained in these investigations were found not to be satisfactory. These unsatisfactory reproducibilities are considered to be caused by the irregularity of the flowing conditions of the solution during the electrolysis.

On the other hand, at the pushed-out mercury drop convection electrode (PMDCE), when a pulley-shaped disk was rotated near by, the reproducible flowing conditions of solution at the electrode surface were found to be achieved, as has been reported in the previous papers.[8]

In the present work, the PMDCE is applied to the cathodic stripping voltammetry in order to improve its reproducibility. The influences of the various factors upon the cathodic stripping peak current and the quantity of electricity involved in the reduction of the mercurous chloride produced on the surface of the electrode are investigated thoroughly. Also, the experimental equations of the peak current and the quantity of electricity at the PMDCE are derived. These results are described in detail below.

Experimental

Electrolytic Cell and Electrode.—The electrolytic cell used in the present experiment is the same as that described in the previous papers.[8] The electrode used is shown in Fig. 1.

The renewal of the mercury drop surface of the electrode is carried out after each stripping analysis by pushing out one drop (volume: 0.0021 ± 0.0001 cc.) of mercury using a microsyringe. The peak height is found gradually to decrease when the same electrode surface is used repeatedly.

The cell and the saturated calomel reference electrode are connected through a salt bridge containing saturated potassium nitrate. Hence, cross-contaminations of the reference electrode and the sample can be prevented effectively.

The supporting electrolyte solution has a tendency to penetrate into the glass tube of the electrode. Therefore, the inside wall of the tube is coated with silicone film.

Apparatus.—The Shimadzu model RP-2 polarograph is employed for the measurements of stripping curves. The apparatus used for rotating the disk is the same as that used in the previous work.[8]

Reagents.—A nitric acid solution of an extra pure grade is used without further purification, and a potassium nitrate of an extra pure grade is purified by three recrystallizations. Also, a chloride solution is prepared from sodium chloride of an analytical reagent grade (99.99%). All the solutions are prepared with redistilled water.

Procedure.—About a 30-ml. portion of 0.1 M nitric acid or a 0.1 M potassium nitrate solution containing 3×10^{-5} M to 10×10^{-5} M of chloride ions is poured into the electrolytic cell.

The mercury surface of the electrode is renewed, and then mercurous chloride is deposited on the electrode surface by applying a potential of +0.4 V. vs. SCE for 1 min., while rotating the disk at 600 r. p. m. After this pre-electrolysis process, the disk is stopped and the electrolytic solution is allowed to stand for 15 sec.; then the deposited mercurous chloride is stripped polarographically by scanning the potential from +0.4 to 0 V. vs. SCE at a scanning rate of 200 mV./min., i. e., by a linearly-varying potential stripping method. A recorder sensitivity of 0.250 μamp./mm. is selected for recording the stripping curves. All the measurements are carried out at 25 ± 0.5°C.

The peak current, i_p, is measured as is illustrated in Fig. 2, and the quantity of electricity is obtained by measuring the area of the peak with a planimeter.

Results

The Reproducibility of the Peak Current.—A curve typical of those obtained is shown in Fig. 2. On the basis of the curve, the reproducibility of the peak current was investigated. A good reproducibility can always be obtained, with a mean error of $\pm 2\%$.

The Effect of the Pre-electrolysis Time.—By using a 0.1 M nitric acid solution containing 4×10^{-5} M chloride and a 0.1 M potassium nitrate solution containing 10×10^{-5} M chloride, the dependency of the peak current and the quantity of electricity on the pre-electrolysis time was investigated; the results are shown in Fig. 3 and Table I respectively. As can be seen from Fig. 3, the peak current gives a saturation curve with an increase in the pre-electrolysis time. As the pre-electrolysis time is longer than 5 min., the peak current is almost constant. However, in this case, it is necessary to remove the dissolved oxygen before the

stripping, because the reduction of oxygen takes place before all the deposited mercurous chloride have been reduced.

The Influence of the Rotating Rate of the Disk during the Pre-electrolysis on the Peak Current and on the Quantity of Electricity.—The variations in the peak current and the quantity of electricity with the rotating rate (600—1000 r. p. m.) were investigated. The gradual increases in the peak current and in the quantity of electricity with the increase in the rotating rate were found to be as shown in Table II.

Table II. Effects of the rotating rate (ω) on the peak current (i_p) and on the quantity of electricity (Q) involved in the reduction of mercurous chloride (scanning rate: 200 mV./min.)

The Effects of the Voltage Scanning Rate on the Peak Current and on the Quantity of Electricity.—Three scanning rates, of 100 mV./min., 200 mV./min., and 300 mV./min., were investigated; the results are shown in Fig. 4. The figure shows that, as the rate of voltage scan was increased, the peak current increased linearly, but the quantity of electricity was almost constant at every scanning rate.

Discussion

Pre-electrolysis Potential.—At any point on the anodic dissolution wave of mercury, the potential of mercury electrode can be expressed by:

$$E = E^0_{Hg} + 0.059/2 \log C^0_{Hg_2^{2+}} \quad \text{(at 25°C)} \quad (1)$$

where E^0_{Hg} is the standard potential of mercury-mercurous mercury couple (+0.553 V. vs. SCE) and $C^0_{Hg_2^{2+}}$ is the concentration of mercurous ions at the electrode surface. In the presence of chloride ions, however, the anodic wave of mercury shifts to more negative potentials. The anodic reaction can be expressed as follows:

$$2Hg + 2Cl^- = Hg_2Cl_2 + 2e \quad (2)$$

From the Nernst equation for the equilibrium potential[9] the following equation for the half-wave potential is obtained:

$$E_{1/2} = \text{const.} - 0.059 \log C_{Cl^-} \quad \text{(at 25°C)} \quad (3)$$

where C_{Cl^-} is the bulk concentration of chloride.

From Eq. 3, it follows that the $E_{1/2}$ value shifts to values more positive by about 60 mV. for each 10-fold decrease in the chloride concentration, until the chloride wave merges with the wave corresponding to the oxidation of mercury to mercurous

9) I. M. Kolthoff and J. J. Lingane, "Polarography," Vol. 2, Interscience, New York (1952), pp. 577—581.

ions. Therefore, the lower limit of the determination of chloride with the mercury electrode is found to be about 10^{-6} M.

As the solubility product of mercurous chloride is 6×10^{-19} at 25°C, the critical concentration of mercurous ions in a 1×10^{-6} M chloride solution becomes 6×10^{-7} M. By substituting this value into Eq. 1, the potential of the mercury electrode at this concentration is calculated to be:

$$E=0.553+0.030\log 6\times10^{-7}=+0.36 \text{ V. vs. SCE}$$

Consequently, in low concentrations of chloride it is necessary to apply a pre-electrolysis potential of about +0.4 V. vs. SCE. In the present investigation, a pre-electrolysis potential of +0.4 V. vs. SCE was applied.

Peak Current and Voltage Scanning Rate.—Randles[10] and Sevcik[11] independently derived an equation for the cathodic peak height in oscillographic polarography:

$$i_{max} = kAn^{3/2}v^{1/2}D^{1/2}C \qquad (4)$$

where k is the constant; A, the electrode area; n, the number of electrons involved in the reduction; v, the rate of voltage scan; D, the diffusion coefficient, and C, the bulk concentration.

The application of the Randles and Sevcik relationship to the anodic peak current obtained by the stripping method was studied by Nikelly and Cooke.[12] They found that the relation between the anodic peak current and the scanning rate was the same as in the above Eq. 4. Namely, the anodic peak current obtained by the stripping method is proportional to one-half the power of the scanning rate.

Therefore, in the stripping analysis, the selection of a voltage scanning rate is important. In general, the more rapid the rate of voltage scan, the sharper the peak. It is preferable that the scanning rate should be as rapid as possible.

As can be seen from Fig. 4, in contrast with the above finding of Nikelly and Cooke, the present result indicates the linear relation between the peak current and the scanning rate. Further studies are, however, necessary before any definite conclusion recording the disagreement between the Nikelly and Cooke result and the present author's can be drawn.

The Rotating Rate of the Disk.—One of the most important factors affecting the magnitude of the peak current and the quantity of electricity is the amount of mercurous chloride deposited on the electrode during the pre-electrolysis process. The amount of mercurous chloride deposited is governed by the rate of the diffusion of chloride ions toward the electrode surface, that is, the rate of convection caused by stirring the solution. Therefore, the stirring rate should carefully be kept constant; a rapid stirring of the electrolytic solution gives a high sensitivity. However, the effects of the rotating rate on the peak current and on the quantity of electricity have never been investigated.

Using the data in Table II, the relations between the logarithm of the rotating rate and that of the peak current, and that of the quantity of electricity were investigated. It can be seen that both the peak current and the quantity of electricity are proportional to the square root of the rotating rate.

The Pre-electrolysis Time.—The amounts of mercurous chloride deposited are governed by the pre-electrolysis time. Therefore, the peak current and the quantity of electricity depend on the pre-electrolysis time. As Table I shows, the quantity of electricity changes linearly with the increase in the pre-electrolysis time. This indicates that the amounts of mercurous chloride deposited increase linearly with the increase in the pre-electrolysis time. On the other hand, the peak current increases, not linearly, but gradually with the increase in the pre-electrolysis time. This slight deviation from linearity can be explained as follows. The longer the pre-electrolysis time, the larger the amounts of mercurous chloride deposited on the electrode surface. Therefore, at a long pre-electrolysis time, the larger amounts of chloride ions released at the electrode surface during the stripping change the equilibrium potential,[5] and then the dissolution curve obtained becomes broader.

This explanation is supported by the fact that the

larger peak current was obtained on rotating the disk during the stripping in order to remove the chloride ions released and eliminate the effect on equilibrium potential.

Experimental Equations of the Cathodic Peak Current and the Quantity of Electricity at the PMDCE.—As is shown in Fig. 3, the peak current obtained by the PMDCE increases gradually with the increase in the pre-electrolysis time. When the peak current is plotted against two-thirds the power of the pre-electrolysis time, the plots are found to be straight lines, as Fig. 6 shows.

Consequently, considering the effects on the peak current mentioned above, the cathodic peak current, i_p, at the PMDCE may be expressed by the following equation:

$$i_p = k'v\omega^{1/2}Ct^{2/3} \quad (5)$$

Similarly, the quantity of electricity, Q, at the PMDCE may be expressed by:

$$Q = k''\omega^{1/2}Ct \quad (6)$$

where k' and k'' are the constants; v, the rate of the voltage scan; ω, the rotating rate of the disk; t, the pre-electrolysis time, and C, the bulk concentration.

The author is grateful to Professor Tokuro Ozaki of Shizuoka University for his valuable discussions and suggestions, and to Mr. Yoshiya Suganuma for his earnest assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1902—1909 (1966)

The Polarographic Behavior of the Condensation Product of Glyoxal with *o*-Phenylenediamine, and Its Application to the Determination of Glyoxal

By Sôichirô MUSHA, Tamotsu WASA and Tameo NAITO*

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai

(Received December 25, 1965)

In buffer solutions containing excess *o*-phenylene-diamine (OPD), glyoxal is condensed with OPD and the condensation product produces two diffusion-controlled reduction waves ($E_{1/2}=-0.211$ and -0.358 V. vs. SCE, pH=1.6) at pH values below 2.5 and a single well-defined reduction wave ($E_{1/2}=-0.782$ V., pH=8.5) at pH values above 2.5. In the pH range between 2 and 8, an ill-defined reduction wave, which seems to be a catalytic hydrogen wave brought about by the reduction product, is also observed at a more positive potential than a normal hydrogen wave. A linear relationship between the limiting current and the concentration of glyoxal has been obtained under the following conditions, which are recommended for the practical determination of glyoxal; $(1—2)\times10^{-2}$ M for the concentration of OPD, 7—10 for pH, 25°C for the temperature, and 30—60 min. for the condensation time. The application was made to the determination of the purity of a commercial glyoxal aqueous solution, and also to the determination of the glyoxal which is present in ethylene glycol as an impurity. A mechanism for the electrode reactions of the condensation product (i. e., quinoxaline) of glyoxal with OPD was postulated.

It was first reported by Winkel and Proske[1] that glyoxal shows an unstable reduction wave at -1.50 V. in an ammonium chloride solution. The half-wave potential was found by Mackinney and Temmer[2] to be -1.41 V. vs. SCE in a biphthalate buffer at pH 3.4. However, no remarks on the current were made in either paper. More detailed results on the polarographic behavior of glyoxal in various buffer solutions and the mechanisms of its electrolytic reduction have been reported by Elving and Bennett[3]; the reduction wave is typically kinetic-controlled in its character, and hence the limiting current varies with the temperature and with the pH of electrolytic solution, and also decreases with time in the alkaline region because of the instability of glyoxal. Therefore, strict experimental conditions seem to be required if this reduction wave is to be used in the polarographic determination of glyoxal.

One of the present authors has previously reported that the condensation products of dehydro-L-ascorbic acid (DAA) and its related compounds with *o*-phenylenediamine (OPD) show diffusion-controlled reduction waves at a dropping mercury electrode, and that these reduction waves can be applied to the determination of DAA and its related compounds.[4]

An analogous study of glyoxal was made for the present work, and it was found that the condensation product of glyoxal with OPD gives a diffusion controlled reduction wave characteristic of glyoxal.

The present paper will describe the polarographic behavior of the condensation product and a method of analyzing glyoxal by using this reduction wave. Furthermore, some consideration will be given to the mechanism of the electrode reactions of the condensation product (i. e., quinoxaline) of glyoxal with OPD.

Experimental

Materials and Reagents.—The glyoxal was a commercial product (about a 40% aqueous solution) from Wako Pure Chemical Industries, Ltd.; it was used without further purification. Glyoxal-sodium bisulfite monohydrate was prepared according to the method of Ronzio and Waugh.[5] Quinoxaline was prepared by Jones and McLaughlin's method.[6]

Stock solutions of glyoxal and quinoxaline were prepared by using redistilled water or 99% ethanol as the solvent. As the standard solution of glyoxal, 1×10^{-2} M aqueous solution of the pure crystalline monohydrate of glyoxal-sodium bisulfite was used[7]; it was prepared by dissolving the specimen directly into redistilled water.

OPD was a commercial product; it was checked to give no reduction wave in the absence of glyoxal under the present experimental conditions. The stock solution (about 0.1 M) of OPD was prepared fresh daily by dissolving OPD directly in redistilled water. No maximum suppressor was used, since the condensation product showed no maximum under the present polarographic conditions. All the other chemicals were of the reagent grade or better.

Buffer Solutions.—Walpole's buffer for pH values from 1 to 2.5, an acetate buffer for pH 4.3, McIlvanie's buffer for pH 2.2 to 8.0, mixtures of disodium hydrogen phosphate with sodium hydroxide for pH above 8, and Britton-Robinson's buffer (BR buffer) for pH 1.8 to 12.0 were used for examining the effect of pH and, at the same time, for checking the effects of the components of the buffer solution.

Apparatus and Procedure.—The polarographic measurements were carried out with a Yanagimoto Automatic Recording Polarograph (Type PA 101). The characteristics of the capillary used were $m=1.14$ mg./sec. and $t=4.00$ sec./drop in the buffer solution (pH=4.0) when the height of the mercury reservoir was 71.0 cm. and when the applied potential was 0 V. vs. SCE at 25°C.

From the necessity of employing a thermostat for temperature control, a modified H-type electrolytic cell with a potasium nitrate-saturated agar bridge and a sintered glass disk was used. The accuracy of the temperature control was ±0.2°C. A saturated calomel electrode was used as the reference electrode. The cell resistance was less than 240 Ω. To check the potential at the dropping mercury electrode, a Shimadzu Potentiometer (Type 3P) was used, while the final pH of the polarographic solutions was measured with a Yanagimoto pH-meter (Type 42) after the polarographic measurements had been made, when necessary. For the experiments of controlled-potential electrolysis, a Yanagimoto Controlled-Potential Electrolyser (MFG. No. 258) was used.

The experimental procedure was as follows: a given volume (usually 1 to 4 ml.) of the glyoxal stock solution was placed in a 20-ml. volumetric flask; a given volume (usually 1 to 4 ml.) of a 0.1 M aqueous solution of OPD and 10 ml. of an appropriate buffer solution were added, and then the flask was filled up to the mark with redistilled water. A part of the mixture was transferred to an electrolytic cell, and the cell was kept in the thermostat for a given time to allow the condensation reaction to take place. At the same time the dissolved oxygen was removed by bubbling nitrogen gas. After this period of time, the polarograms are recorded.

Controlled-potential Electrolysis.—In order to get information concerning the reversibility of the electrode reaction and to ascertain the number of electrons

participating in the electrode reaction, controlled-potential electrolysis[8-10] was carried out by using the cell shown in Fig. 1.

The experimental procedure was as follows: about 45 ml. of a buffer solution (pH 8.9) was placed in the cathode compartment of the electrolytic cell, and the cell was placed in the thermostat. The solution and the mercury pool cathode (area, about 15 cm^2) were stirred vigorously with a glass propellor stirrer immersed in the mercury-solution interface, and the dissolving oxygen was removed by bubbling nitrogen gas. After the dissolved oxygen had been removed, electrolysis was carried on at a fixed cathode potential (e. g., −1.20 V. vs. SCE) until the current became negligibly small. The circuit was then connected to the polarograph, and 5 ml. of a quinoxaline solution of known concentration, which had been deaerated, was pipetted into the cell. After mixing, the inlet tube of nitrogen gas was pulled up and nitrogen gas was passed over the solution. The stirrer was stopped, and a polarogram was taken. The inlet tube of nitrogen gas was then pushed down again into the solution and the stirring was re-commenced; then the electrolysis was carried out at −1.20 V. vs. SCE, with automatic control, while nitrogen gas was being bubbled through the solution. After a given period, electrolysis was stopped, the electricity required for the electrolysis was measured by a gas coulometer,[10] and a polarogram was recorded according to the procedures described above. These procedures were repeated several times during the course of the electrolysis.

Results and Discussion

Reduction Waves of the Condensation Product of Glyoxal with OPD.—A well-defined reduction wave was obtained when glyoxal was treated with OPD in appropriate buffer solutions by the procedure described above, as may be seen in Fig. 2 (a, b and c). The reduction wave showed all the typical characteristics of a diffusion-controlled current: proportionality between the wave height and the square root of the height of the mercury reservoir (Fig. 3), and a small temperature

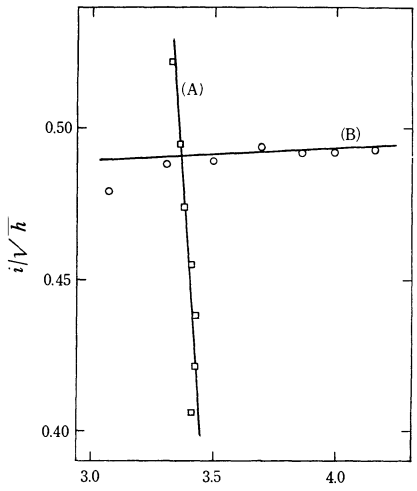

Fig. 3. Relationships between the limiting current (i) and the height (h) of mercury reservoir.
Glyoxal: (A) 3.2×10^{-2} M without OPD at pH 7.0, (B) 8×10^{-4} M with 1×10^{-2} M OPD at pH 8.0. Condensation: 60 min. at 25°C.

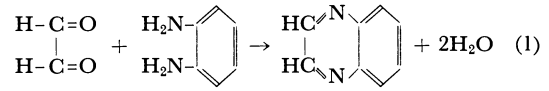
coefficient of 1.9%/deg. Figure 3 also includes the results obtained with glyoxal only.

The shape and the half-wave potential of this reduction wave were practically identical with those of the quinoxaline prepared by Jones and McLaughlin's method.[6] Therefore, the condensation product of glyoxal with OPD under the present experimental conditions is probably quinoxaline, as has been reported by Hinsberg[11] and Liebigs[12], and the reaction may be written as:



glyoxal OPD quinoxaline

The Stability of the Stock Solution of Glyoxal.— Figure 4 shows the change in the limiting currents of the condensation products with the time elapsed (at a room temperature of about 15°C) after the preparation of the stock solutions of glyoxal using 0.1 N sulfuric acid, 0.01 N sulfuric acid, water, or 99% ethanol. Figure 4 indicates that glyoxal in the ethanolic stock solution is the most stable; therefore, the ethanolic stock solution was used for the fundamental experiment. However, for analytical purposes the aqueous stock solution was also used, because the limiting current remained almost constant for a month or more when the condensation was carried out in an alkaline buffered solution.

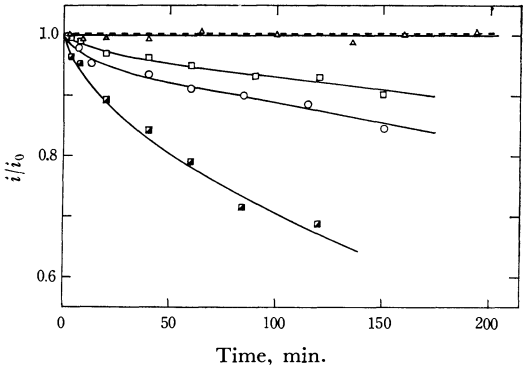


Fig. 4. Stability of the stock solution of glyoxal. Solvent of stock solution: △ 99% ethanol, ○ water, □ 0.01 N H_2SO_4, ◪ 0.1 N H_2SO_4. Condensation: 1×10^{-2} M OPD, 30 min. at 25°C in BR buffer. —— Condensation was carried out at pH 3.80, ---- at pH 8.90 with aqueous stock solution. i_0: initial wave height.

The Effect of pH.—In order to examine the effect of pH on the polarographic behavior of the condensation product of glyoxal with OPD, the concentrations of glyoxal and OPD were kept constant and only the pH of the mixture was changed (Fig. 5). The limiting currents of the condensation products were measured 60 min. after the addition of OPD at 25°C, since they increase with time during the first 40 min., attaining maximum values which remain almost constant for a further 24 hr. over all the pH range studied. Figure 5 shows that the limiting current of the condensation product shows its

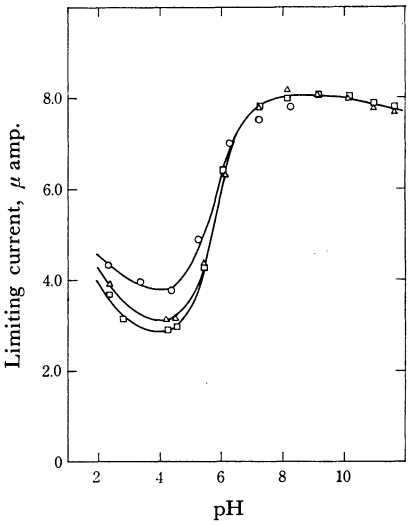

Fig. 5. pH-dependence of the limiting current of the condensation product at 25°C.
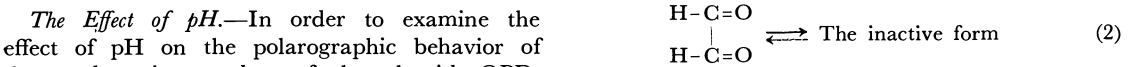
Condensation: 1.6×10^{-3} M glyoxal, 1×10^{-2} M OPD, 60 min. ○ one day after the preparation of ethanolic stock solution of glyoxal, △ 16 days, □ 21 days.

minimum value at pH about 4, and that it increases remarkably at pH above 5, reaching a maximum value in the pH of 7 to 10. The same behavior was not observed in the polarographic investigation of quinoxaline.[13] Also, Fig. 5 shows that the limiting current decreases slowly, at the rate of about 2%/day, in the pH range between 2 and 6 with the time elapsed after the preparation of the stock solution of glyoxal. These results seem to indicate that glyoxal in the stock solution changes into a form inactive (dimer or hydrate form) in the reaction with OPD and that this change is almost irreversible at a pH value of about 4, but that it becomes reversible and the rate of producing glyoxal from the inactive form increases upon either an increase or a decrease in pH from about 4.



At pH values lower than 2.5 the splitting of the reduction wave into two waves which have almost equal heights was observed (Fig. 2). At the pH

between 2 and 8, an ill-defined and irreversible reduction wave was also observed at a more positive potential than the reduction wave of the hydrogen ion; it showed its maximum value at a pH value of about 4 and disappeared at pH values above 8. Further, when the condensation took place at a pH value of about 4, a small oxidation wave ($E_{1/2}=-0.07$ V. vs. SCE), which seems to be due to the condensation product of an aldehyde group of glyoxal with OPD, was observed (Fig. 2, b).

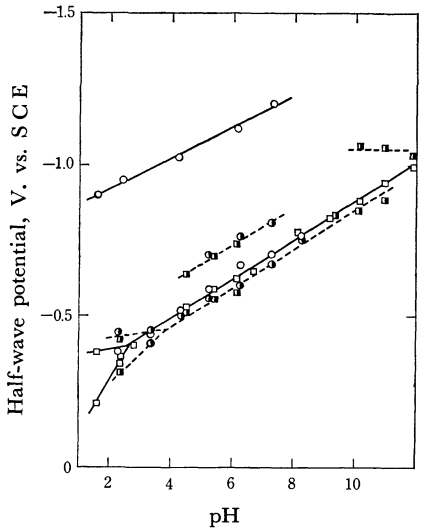

Fig. 6. pH-dependence of the half-wave (summit) potential.
○, ◑: McIlvaine buffer, □, ◧: BR buffer, -○-□-: half-wave potential, --◑--◧--: summit potential, 25°C.

The changes in the half-wave potentials of the condensation product with the pH value are presented in Fig. 6, in which the summit potentials ascertained by a. c. polarography are also shown. As may be seen in Fig. 6, a linear relationship has been obtained; its inclination was about 60 mV./pH at pH values above 2.5. Though no further experiments on the condensation product have been made by a. c. polarography, the changes in the summit potentials, the peak height and the shape of the peak with the pH value are obviously somewhat complicated. A typical a. c. polarogram was observed in the 8—10 pH range.

The influence of the components of buffer solutions on the half-wave potential, the wave height and the shape of the wave was examined, but no appreciable change has been observed.

The Effect of the Concentration of OPD.—Figure 7 shows the relationship at 25°C between the limiting current and the time elapsed after the addition of OPD to an electrolytic solution containing glyoxal and BR buffer with a pH value of 8.90, when the concentration of glyoxal was kept constant approximately at 8×10^{-4} M and the concentration of OPD was changed. With the increase in the concentration of OPD, the growing velocity of the wave increased, so the time required for the condensation was shortened.

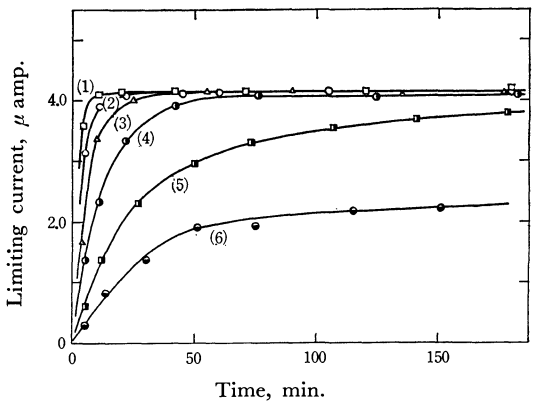

Fig. 7. Effect of the concentration of OPD.
OPD: (1) 2×10^{-2}, (2) 1×10^{-2}, (3) 5×10^{-3}, (4) 2×10^{-3}, (5) 1×10^{-3}, (6) 5×10^{-4} M.
Glyoxal: 8×10^{-4} M.
Condensation was carried out at pH 8.90 at 25°C.

The Effect of the Temperature.—Figure 8 shows the effect of the temperature on the reaction time. When the concentrations of glyoxal and OPD were kept constant and the experimental temperature was raised, the time required for condensation was shortened over all the pH range studied, while it was observed that the limiting current of the condensation product, after its maximum value was attained, decreased slightly with time at temperatures above 45°C.

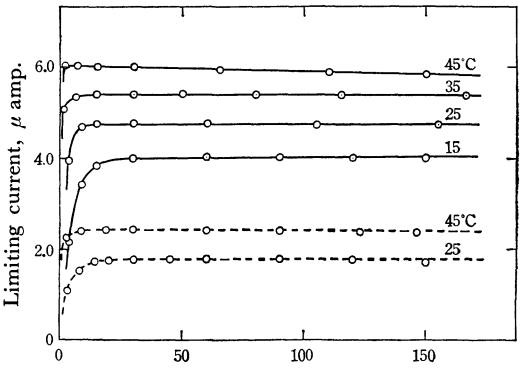

Fig. 8. Effect of the temperature.
Glyoxal: 9.3×10^{-4} M, OPD: 1×10^{-2} M
—— at pH 8.90, ---- at pH 3.80

Electrolysis and Coulometry at a Constant Potential.—Figure 9 shows the change in the polarograms of quinoxaline, the condensation product of glyoxal with OPD, during the course of electrolysis. In the early stages of electrolysis,

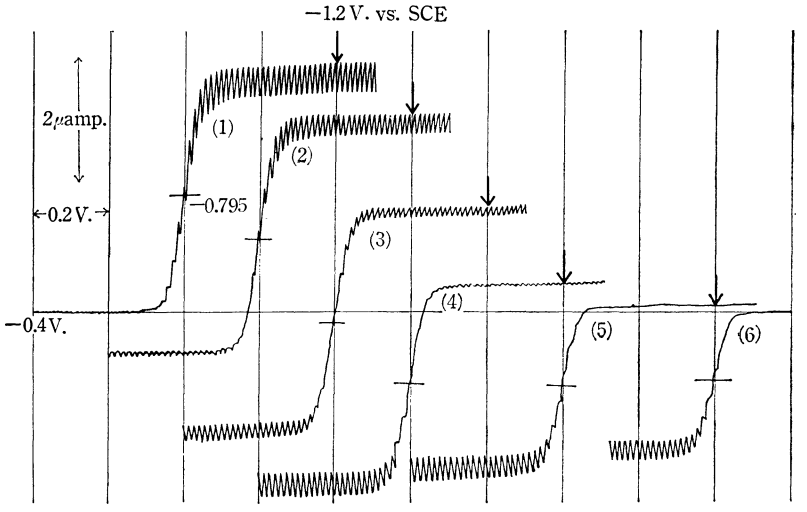

Fig. 9. Controlled-potential electrolysis of quinoxaline at −1.2 V. in BR buffer (pH 8.70) containing 10% ethanol.
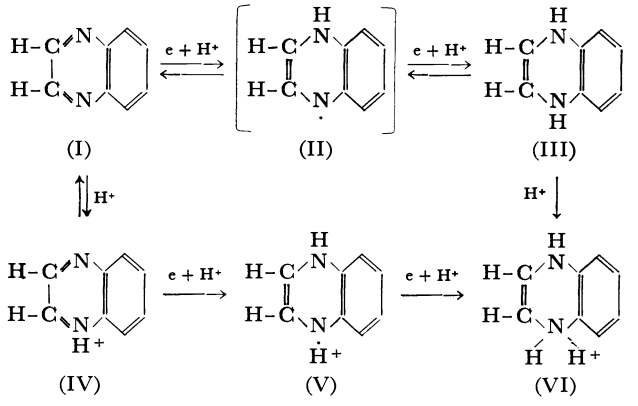
Quinoxaline: 7.2×10^{-4} M. (1) before electrolysis, (2) after 5, (3) 15, (4) 25, (5) 35, and (6) 55 min. at 20°C.



the anodic wave which is due to the oxidation of the electrolytic reduction product grows at the expense of the reduction wave of quinoxaline. On further electrolysis, the height of the anodic wave decreases slowly with time, and at the same time it is observed that the electrolytic solution becomes muddy; this is probably caused by the low solubility of the reduction product in an aqueous solution. However, the electrode reaction is reversible because the half-wave potential of the anodic wave is identical with that of the reduction wave of the condensation product (quinoxaline).

The results of the coulometric study are summarized in Table I. From this study one can conclude that the electrode reaction requires two electrons at pH 9.15.

The mechanism of the electrolytic reduction of quinoxaline is analogous to that of phenazine.[14,15] In strongly acidic solutions, the reduction of quinoxaline occurs in two well-separated steps

Table I. Estimation of the number of electrons required for the reduction of quinoxaline

(see Fig. 2, a), each corresponding to the taking-up of one electron, since the two wave heights almost coincide with each other and the sum of the two wave heights is equal to that of the single wave in the neutral and alkaline ranges. As the pH increases, these waves move closer together, unitl at pH values higher than 2.5 they coalesce into a single two-electron step (see Fig. 2, b, c).

From the observation described above, it may be assumed that in acidic solutions of pH values lower than 2.5 a stable semiquinone (V) is formed in the first reduction step, and that its stability rapidly decreases as the pH value increases. The mechanisms of the electrolytic reductions may be expressed as follows:

$$\begin{array}{ccccc} O & \rightleftarrows & [O] & \rightleftarrows & O \\ \downarrow\uparrow & & & & \downarrow \\ O & \rightarrow & O & - & O \end{array}$$

The third wave (see Fig. 2), though no particular experiments have been made with this reduction wave, is considered to be a catalytic hydrogen wave of the protonated reduction product as in the case of the nitrogen-containing heterocyclic compounds.[16]

Application to the Determination of Glyoxal in Commercial Products.—On the basis of the above results, the following conditions may be recommended as the most practical conditions for the determination of glyoxal by utilizing the wave of the condensation product of glyoxal with OPD: $(1-2)\times10^{-2}$ M for the concentration of OPD, 7—10 for the pH range, 25°C for the temperature, and 30—60 min. for the condensation time. Under these conditions a linear relation was obtained between the concentration of glyoxal and the limiting current of the condensation product in the range of $(0.2—20)\times10^{-4}$ M, as is shown in Fig. 10.

For applying the present polarographic method to the determination of glyoxal in commercial products, the following procedure was employed: 1—5 g. of a commercial reagent (about 40% aqueous solution) was transferred to the 1 l. volumetric flask and diluted to the mark with distilled water. Then, in a run, 2 ml. of the diluted sample was placed in a 20-ml. volumetric flask, 10 ml. of a BR buffer with a pH value of 9.0 and 2 ml. of the aqueous solution of OPD (0.1 M) were added, and then the volume was made up to the mark with distilled water. A part of the mixture was taken in an electrolytic cell and immersed in a thermostat at 25°C for 45 min., during which time dissolved oxygen was removed by the bubbling nitrogen gas. After that, a ploarogram was taken in the usual way (A). In another run,

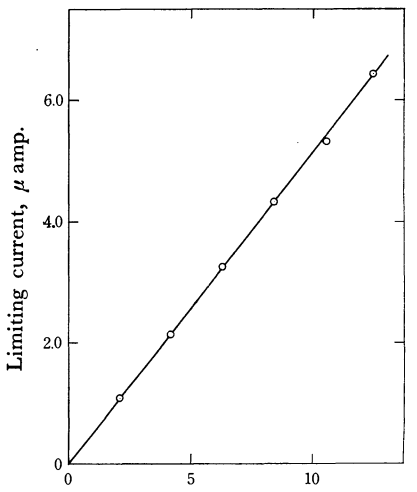

Fig. 10. Linear relationship between the limiting current of the condensation product and the concentration of glyoxal.

2 ml. of the diluted sample was placed in a 20 ml. volumetric flask, and 1 ml. of a standard solution containing glyoxal sodium bisulfite of 1×10^{-3} M, 10 ml. of a BR buffer of pH 9.0, and 2 ml. of the solution of OPD were added. After that, the same procedure as in the former run was followed, and a polarogram was recorded (B). By comparing the two polarograms, (A) and (B), the glyoxal content in the original sample was calculated. Some of the analytical results obtained are listed in Table II, together with those obtained by the titrimetric method[17] based on Cannizaro's reaction. The results obtained by the two methods are in good agreement with each other.

As another application, the determination of glyoxal in commercial products of ethylene glycol containing glyoxal and glycolaldehyde as impurities

17) J. G. Baldinus and I. Rothberg, *Anal. Chem.*, **32**, 1176 (1960).

was carried out. In this determination, the polarographic procedure described above was followed after the following pretreatment of the ethylene glycol sample: the sample was diluted to 2 to 5 times with distilled water, and the resulting diluted solution was allowed to stand overnight to effect hydrolysis, because glyoxal in concentrated ethylene glycol is considered to exist as acetal, which is inactive for OPD. The results obtained by the present polarographic method are given in Table III, together with those obtained by the titration method[18] using hydroxylamine hydrochloride. Though glycolaldehyde shows an anodic wave which is characteristic of monoaldehyde in the buffer solution containing OPD,* the presence of glycolaldehyde does not seriously interfere with the determination of glyoxal by the polarographic OPD method, because it does not give the waves in the potential range used for the determination of glyoxal. On the other hand, when the determination of glyoxal was carried out by the titration method, the presence of glycolaldehyde interfered seriously with the determination of glyoxal.

When such substances as methanol, ethanol, ethylene glycol, glycolic acid and acetone exist in the sample, the limiting current of the condensation product decreases slightly with an increase in the concentration of these substances. However, as long as the determination of the glyoxal is carried out by the standard addition method described above, these substances do not cause any interference, since the substances are not polarographically reducible under the present conditions.

Table III. The results of the determination of glyoxal in commercial ethylene glycol

Exp. No.	Content of glyoxal, %	
	Polarographic	Titrimetric*
1	0.0122	0.1979
2	0.0120	0.1975
3	0.0121	0.1983

* Hydroxylamine titration method (glyoxal + glycolaldehyde).

Aldehydes such as formaldehyde, acetaldehyde, propylaldehyde, butylaldehyde and glycolaldehyde give the anodic waves which have been described in the case of glycolaldehyde under the present experimental conditions, but they do not give reduction waves, whereas glyoxal does. Therefore, the presence of the aldehydes does not cause any interference with the determination of glyoxal. Furthermore, the presence of sulfite ion does not interfere, because electrolytic solutions are alkaline when they have pH values of 8—10.

Methylglyoxal, biacetyl and glyoxylic acid easily react with OPD under the present conditions and give reduction waves the half-wave potentials of which are −0.802, −0.851 and −0.830 V. respectively at pH 8.5. Therefore, the presence of these substances interferes with the determination of glyoxal.

The authors wish to express their thanks to Professor Sôzaburo Ono and Dr. Masanosuke Takagi of the College of Agriculture, University of Osaka Prefecture, for their kind advice and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1910—1915 (1966)

The Synthesis of 2-Alkyl-8-hydroxyquinolines and Their Chelating Behavior with Metal Ions[1,2]

By Hisamitsu KANEKO and Keihei UENO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka

(Received December 27, 1965)

2-Ethyl-, 2-*n*-propyl- and 2-*n*-butyl-8-hydroxyquinolines have been synthesized by the reactions of 8-hydroxyquinoline with alkyl-lithium. The dissociation constants and the chelate stability constants of these ligands with copper(II), zinc(II), nickel(II) and cadmium(II) have been measured in 50% v/v aqueous dioxane at 25.0±0.1°C with no additional electrolyte. Factors affecting the acid dissociation constants and the chelate stability constants will be discussed in this paper.

As a part of our investigations into the relationship between the chemical structure of a chelating agent and the metal chelate stability, a number of 8-hydroxyquinoline derivatives have been brought under investigation. 2-Methyl and 2-phenyl derivatives have been reported in the literature, and the selectivities of their metal chelate formation for certain metal ions have been discussed from theoretical and analytical standpoints.[3]

In this connection, our interest has been focused on the derivatives of 8-hydroxyquinoline with an alkyl group at the C-2 position. For this purpose, a general method for introducing an alkyl group to the C-2 position of 8-hydroxyquinoline has been developed. After investigating several reactions which seem to give the desired products,[4,5] we have finally chosen a method which is similar to the method used for the preparation of 2-phenyl-8-hydroxyquinoline; it consists of the reaction of 8-hydroxyquinoline with alkyl lithium in ether, followed by hydrolysis.[6,7] 2-Alkyl-8-hydroxyquinolines were isolated as hydrochloride because the free bases were difficult to purify because of their low melting points. The results of the syntheses are summarized in Table I. The attempted syntheses of isopropyl and *t*-butyl derivatives were not successful, as the reaction did not give enough yield for our purposes.

It is known that 2-methyl-8-hydroxyquinoline can not form a stable chelate with aluminum, and the selectivity of this reagent is understood to be caused by the steric hindrance of the 2-methyl group of this ligand around the aluminum ion, which has a relatively small ionic radius. Similarly, it may be expected that the introduction of a higher alkyl group to the C-2 position of 8-hydroxyquinoline would result in a different selectivity for metal ions. Thus, the chelate stability constants of 2-alkyl-8-hydroxyquinoline with copper(II), zinc(II), nickel(II) and cadmium(II) have been measured. As these ligands, as well as the metal chelate compounds, were not soluble in water, the acid dissociation constants and the chelate stability constants were measured in 50% v/v aqueous dioxane by the pH titration method.

Experimental

The Synthesis of Ligands.—As an example, the synthesis of 2-*n*-butyl-8-hydroxyquinoline will be described.

All the procedures until the hydrolysis step were conducted under dry nitrogen protected from atmospheric moisture. A solution of 13.6 g. (0.099 mol.) of *n*-butyl-bromide in 30 ml. of ether was dropped into a reaction flask containing 1.7 g. (0.245 mol.) of lithium covered with 50 ml. of ether. The bromide was then added over a 40 min. period, while the temperature was kept below −10°C. After this mixture had been stirred another 1.5 hr., a solution of 2.7 g. (0.019 mol.) of 8-hydroxyquinoline in 100 ml. of ether was dropped into the reaction flask over a 20 min. period. After the stirring had been continued for an additional 2 hr. at −10°C, the reaction product was hydrolyzed by pouring it onto ice chips. The ether layer was separated, and the ether was evaporated to obtain a yellow oil. The oil was taken into hydrochloric acid, and the resulting crystalline mass was repeatedly recrystallized from ethanol. Pale yellow crystals melting at 165.8—167.3°C were thus obtained. Yield: 2.0 g. (45%).

A similar procedure was followed for the synthesis

of 2-ethyl and 2-*n*-propyl derivatives using the corresponding alkyl bromide. The yields, melting points and analytical data for the products are summarized in Table I.

Although tetrahydrofurane was used as a solvent in place of ether in the hope of improving the yield, the reaction did not proceed; only the starting material was recovered.

Chelate Stability Measurements.—*Materials.*—All the ligands were used as hydrochloride. Dioxane, of an analytical grade, was purified by refluxing it with 20% sulfuric acid, followed by repeated distillations.

An 0.1 N sodium hydroxide solution and 0.01 M metal ion solutions (nitrates) were prepared using 50% v/v aqueous dioxane as a solvent. The concentrations of metal ion solutions were determined by EDTA titration.

Apparatus and Procedure.—Potentiometric titration was carried out in a jacketed beaker equipped with a burett for the delivery of a sodium hydroxide solution, a glass electrode and a calomel electrode for pH measurement, and nitrogen inlet and outlet tubes.

The pH was measured with a Horiba-Hitachi Model P pH meter which had been standardized against the pK_a value[8,9] of acetic acid by titrating acetic acid in 50% v/v aqueous dioxane.

The titration was carried out on a solution with a ligand-to-metal ratio of 1 : 1 or 2 : 1, at 25.0±0.1°C and with no additional electrolyte. The titration curves for 2-*n*-butyl-8-hydroxyquinoline are shown in Figs. 1 and 2. The curves for the other ligands were found to be similar to those shown in Fig. 1.

Calculations

The Calculation of the Acid Dissociation Constants.—The acid dissociation constants were calculated from the titration curves of the ligands. The equilibrium constants may be expressed as follows:

$$H_2A^+ \rightleftarrows HA + H^+ \quad K_{NH} = \frac{[H^+][HA]}{[H_2A^+]} \tag{1}$$

$$HA \rightleftarrows H^+ + A^- \quad K_{OH} = \frac{[H^+][A^-]}{[HA]} \tag{2}$$

where H_2A^+ represents the protonated ligand (hydrochlolide).

As is shown in Fig. 1, the two buffer regions are so clearly separated that each dissociation stage can be treated independently. Thus, K_{NH} and K_{OH} can be expressed as follows, according to the standard treatment:

$$K_{NH} = \frac{[H^+](aT_A + [H^+])}{T_A - (aT_A + [H^+])} \tag{3}$$

$$K_{OH} = \frac{[H^+]\{(a-1)T_A - K_W/[H^+]\}}{T_A - \{(a-1)T_A - K_W/[H^+]\}} \tag{4}$$

where T_A and a represent, respectively, the total concentration of the ligand and the number of moles of the base added per mole of ligand, and where $K_W=[H^+]\cdot[OH^-]$.

Calculation of Chelate Stability Constants.—The step-by-step chelate formation constants of the reactions, may be expressed as:

$$M^{2+} + A^- \rightleftarrows MA^+ \quad K_{MA} = \frac{[MA^+]}{[M^{2+}][A^-]} \tag{5}$$

$$MA^+ + A^- \rightleftarrows MA_2 \quad K_{MA_2} = \frac{[MA_2]}{[MA^+][A^-]} \tag{6}$$

The stability constants were calculated by the least-squares method, using the data from 1 : 2 titrations.[10,11] The equation employed for this method was as follows:

$$\frac{\bar{n}}{(\bar{n}-1)[A^-]} = \frac{(2-\bar{n})[A^-]}{(\bar{n}-1)} K_{MA}\cdot K_{MA_2} - K_{MA} \tag{7}$$

where $\bar{n}$ is the average number of ligands bound per metal ion.

If, by replacing each term, one simplifies the above equation as:

$$Y = \frac{\bar{n}}{(\bar{n}-1)[A^-]} \tag{8}$$

$$X = \frac{(2-\bar{n})[A^-]}{(\bar{n}-1)} \tag{9}$$

$$a = -K_{MA} \tag{10}$$

TABLE II. ACID DISSOCIATION CONSTANTS AND STABILITY CONSTANTS OF 2-ALKYL-8-HYDROXYQUINOLINE AT 25.0±0.1°C, $\mu \simeq 0$, $-\log K_W = 16.1$[9]

Ligand 2-R-8-HQ	Acid dissociation constant		Stability constant Ni(II)	Cu(II)	Zn(II)	Cd(II)
R=H	pK_{NH} (3.97)[a]	$\log K_{MA}$	(11.44)	(13.49)	(9.96)	(9.43)
	pK_{OH} (11.54)	$\log K_{MA_2}$	(9.94)	(12.73)	(8.90)	(7.68)
R=CH_3	pK_{NH} 4.63	$\log K_{MA}$	9.3_5	12.4_3	9.8_9	9.1_8
	pK_{OH} 11.83	$\log K_{MA_2}$	8.9_1	11.4_6	9.2_2	8.2_1
R=C_2H_5	pK_{NH} 4.47	$\log K_{MA}$	8.6_9	12.0_5	9.6_6	8.6_6
	pK_{OH} 11.86	$\log K_{MA_2}$	9.0_5	11.2_8	9.3_0	8.3_1
R=n-C_3H_7	pK_{NH} 4.44	$\log K_{MA}$	9.0_1	12.0_6	8.9_6	8.8_4
	pK_{OH} 11.95	$\log K_{MA_2}$	9.4_6	11.8_1	10.4_9	8.7_0
R=n-C_4H_9	pK_{NH} 4.41	$\log K_{MA}$	9.1_8	12.0_5	9.7_5	9.2_8
	pK_{OH} 12.07	$\log K_{MA_2}$	9.8_9	12.2_3	10.2_4	8.9_8

a) The values in parentheses have been taken from Ref. 13.

$$b = K_{MA} \cdot K_{MA_2} = \beta_2 \quad (11)$$

then the equations for the least-squares method can be written as follows:

$$\sum Y = na + b\sum X \quad (12)$$

$$\sum XY = a\sum X + b\sum X^2 \quad (13)$$

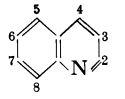
where n represents the number of observed points employed for each set of calculations. The experimental data corresponding to the $\bar{n}$ values of 0.95—1.05 were omitted in the calculations, because these values are very critical to the results. The results of the calculations[12] are summarized in Table II.

Results and Discussion

The Structural Proof for the Ligand.—In order to confirm the proposed structure for 2-alkyl-8-hydroxyquinoline, the NMR spectra were observed on the hydrochlorides in a deuterium oxide solution.

The spectra were measured at 60 Mc./sec., using tetramethylsilane as an internal standard. The results are summarized in Table III, along with their assignments. The table also includes the data for quinoline hydrochloride, 8-hydroxyquinoline hydrochloride and 2-methyl-8-hydroxyquinoline hydrochloride. The peaks at 1.43 τ of 8-hydroxyquinoline hydrochloride are assigned to the protons on C-2 and C-4; the decrease in the intensities of the corresponding peaks in the 1.4—1.6 τ region for the 2-alkyl derivatives indicates the elimination of a proton on either C-2 or C-4 by alkyl substitution. However, the spin-spin coupling constant of these peaks (8.5 c. p. s.) is closer to a J_{34} coupling constant of 7.3 c. p. s. than to the J_{23} coupling constant of quinoline[14]

TABLE III. ASSIGNMENTS OF NMR SPECTRA OF 2-ALKYL-HYDROXYQUINOLINE



Compound	Peaks (τ)*	Intensity	Assignments of proton
Quinoline HCl	0.90	2	C-2, C-4
	1.95	5	C-3, C-5, C-6 C-7, C-8
8-Hydroxy-, HCl	1.43	2	C-2, C-4
	2.03	1	C-5
	2.93	2	C-6, C-7
	3.25	1	C-7
2-Methyl-	1.63	1	C-4
8-hydroxy-, HCl	2.50	1	C-3
	2.80	2	C-6, C-7
	3.07	1	C-3
	7.23	3	$-CH_3$
2-Ethyl-8-hydroxy-,	1.63	1	C-4
HCl	2.37	1	C-5
	2.88	2	C-6, C-7
	3.10	1	C-3
	6.97	2	$-CH_2-$
	8.65	3	$-CH_3$
2-n-Propyl-	1.50	1	C-4
8-hydroxy-, HCl	2.40	1	C-5
	2.73	2	C-6, C-7
	2.93	1	C-3
	6.95	2	$-CH_2-$ (α)
	8.27	2	$-CH_2-$ (β)
	9.00	3	$-CH_3$
2-n-Butyl-	1.47	1	C-4
8-hydroxy-, HCl	2.35	1	C-5
	2.68	2	C-6, C-7
	2.88	1	C-3
	6.93	2	$-CH_2-$ (α)
	8.50	4	$-CH_2-CH_2-$(β,γ)
	9.07	3	$-CH_3$

* The values listed in the table show the center of multiplet peaks.

12) Such calculations were carried out at the Computing Center of Kyushu University.

13) W. D. Johnston and H. Freiser, *J. Am. Chem. Soc.*, **74**, 5239 (1952).

of 5.0 c. p. s., which was chosen as a model compound. Therefore, it is quite likely that the proton on C-2 is eliminated by the alkyl substitution, while the proton on C-4 remains unaltered.

Titration Curves.—The corrected potentiometric titration curves for 2-*n*-butyl-8-hydroxyquinoline, with or without an equivalent amount of metal ions, are given in Fig. 1.

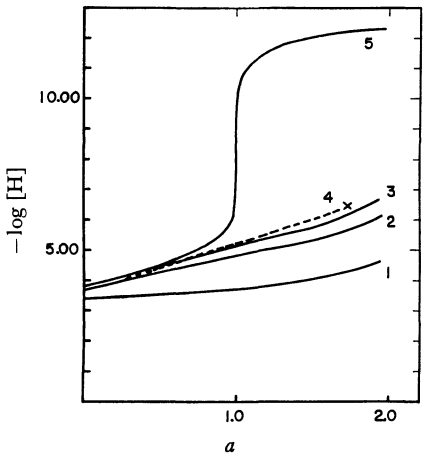

Fig. 1. Titration curves for 1:1 solution.
Concn. of ligand and metal ions: 1×10^{-3} M
1: Cu(II), 2: Zn(II), 3: Ni(II), 4: Cd(II), 5: ligand

The titration curves for the solutions with a 1 : 2 metal ligand ratio are illustrated in Fig. 2. It was noticed that some chelates began to precipitate at the point indicated by "X".

The curves of the other ligands are very similar to those of 2-*n*-butyl-8-hydroxyquinoline. The pK_{NH} and pK_{OH} values were calculated from the data of the titration curves of the ligands, in the ranges of $a=0.3$—0.7 and $a=1.3$—1.7 respectively.

Formation Functions and Equilibrium Constants.—The acid dissociation constants for 2-alkyl-8-hydroxyquinoline are shown in Table II. The pK_{NH} and pK_{OH} values stand for the dissociation of protons from the quinoline nitrogen and the phenolic oxygen respectively.

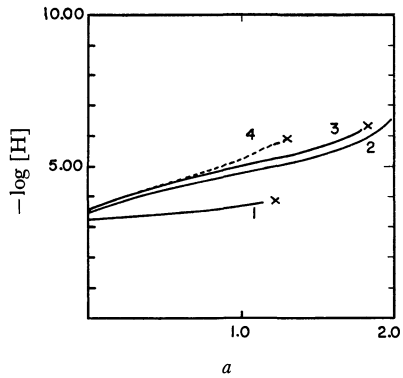

Fig. 2. Titration curves for 1:2 solution.
Concn. of ligand: 2×10^{-3} M
1: Cu(II), 2: Zn(II), 3: Ni(II), 4: Cd(II)

The chelate stability constants of these ligands with various metal ions are also shown in Table II. The reported values for 8-hydroxyquinoline, as well as those for 2-methyl-8-hydroxyquinoline,[13] are also included in the table for the sake of comparison. The chelate stability constants were computed by the least-squares method on the basis of the data on 1 : 2 titration described above. A typical example of calculations, those on the copper(II)-2-*n*-butyl-8-hydroxyquinoline system, is shown in Table IV. It may be seen from the table that fairly consistent stability constants are obtained over a wide range of $\bar{n}$ values, and that one could use the values of three significant figures in a meaningful discussion. These results are satisfactory if one considers the experimental conditions under which the titration was conducted in a non-aqueous solvent without an added electrolyte.

Table IV. Calculations of chelates stability constants on the system copper(II)-2-*n*-butyl-8-hydroxyquinoline (1:2 titration)

	[A]	$\bar{n}$	$X=\frac{(2-\bar{n})[A]}{(\bar{n}-1)}$	$Y=\frac{\bar{n}}{(\bar{n}-1)[A]}$	log K_{MA}	log β_2

3	0.29789×10^{-12}	0.4446	-0.83422×10^{-12}	-0.26870×10^{13}	12.04	24.27
4	0.34875×10^{-12}	0.5272	-0.10863×10^{-11}	-0.31967×10^{13}	12.05	24.28
5	0.40366×10^{-12}	0.6127	-0.14460×10^{-11}	-0.39195×10^{13}	12.07	24.29
6	0.46969×10^{-12}	0.6998	-0.20345×10^{-11}	-0.49639×10^{13}	12.04	24.28
7	0.52703×10^{-12}	0.7919	-0.30600×10^{-11}	-0.72217×10^{13}	12.14	24.30
8	0.61205×10^{-12}	0.8827	-0.58285×10^{-11}	-0.12291×10^{14}	12.07	24.28

$\sum X=-0.15407\times10^{-10}$ $\sum Y=-0.38729\times10^{14}$ log $K_{MA}=12.05$
$\sum X^2=0.52078\times10^{-22}$ $\sum XY=0.11772\times10^{3}$ log $\beta_2=24.28$

log $K_{MA}=12.09\pm0.05$
log $K_{MA_2}=12.20\pm0.07$
log $\beta_2=24.29\pm0.02$

and the early onset of precipitation. Therefore, the following discussion is based mainly on those values of three significant figures.

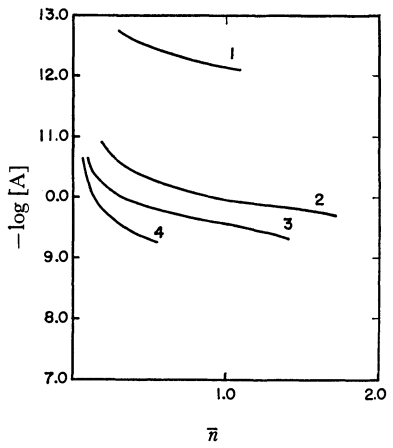

Fig. 3. Formation functions of some divalent metal chelates of 2-*n*-butyl-8-hydroxyquinoline.
Concn. of ligand: 2×10^{-3} M
Metal ions: 1×10^{-3} M
1: Cu(II), 2: Zn(II), 3: Ni(II), 4: Cd(II)

The Bjerrum's formation functions for the metal chelates of 2-*n*-butyl-8-hydroxyquinoline are shown in Fig. 3. Because of the early appearance of the precipitation, the formation curves only extended to $\bar{n}\approx0.6$ for cadmium(II) and $\bar{n}\approx1.0$ for copper(II). Only in the case of zinc(II) was a curve extending over almost the entire range found. Although the formation curve for a 1 : 1 or 1 : 2 chelate ratio has been shown to be symmetrical about $\bar{n}=1$, it does not seem likely in this case. The deviation from symmetry may be due to the easy precipitation.

The Effect of the Alkyl Group on the Chelate Stability.—As is shown in Table II, the pK_{NH} value is almost constant, regardless of the kind of alkyl groups, with the exception of the 2-methyl derivative, which shows a slightly higher pK_{NH} value than the rest of the ligands. On the other hand, the pK_{OH} value increases slightly with the increasing carbon number of the alkyl group.

Irving and Rossotti investigated the effect of alkyl substitution on the acid dissociation constant of 8-hydroxyquinoline; they found that pK_{OH} value increased and the pK_{NH} value decreased when the position of the methyl substitution moved from the C-2 to the C-7 position of the quinoline ring.[15] This effect is understood to be due to the *I*-effect of the methyl group. Similarly, one can expect an *I*-effect of the 2-alkyl group for the 2-alkyl-8-hydroxyquinolines, which have higher pK_{NH} values than 8-hydroxyquinoline, as is shown in Table II. However, the contribution of the *I*-effect of the 2-alkyl group to the pK_{NH} value may be partly cancelled by the steric effect of higher alkyl groups, which will interfere with the access of protonium ions to the quinoline nitrogen. Thus, the pK_{NH} value is highest for the 2-methyl derivative, while 2-ethyl, 2-*n*-propyl and 2-*n*-butyl derivatives have lower pK_{NH} values than the 2-methyl derivative. Regarding the pK_{OH} values, the access of protonium ions to the phenolate oxygen will not be interfered with by a 2-alkyl group. Therefore, pK_{OH} may be influenced only by the *I*-effect of the 2-alkyl group, although this influence may be fairly weak. The increase in the pK_{OH} value with the increase in the carbon number of the alkyl group supports this theory.

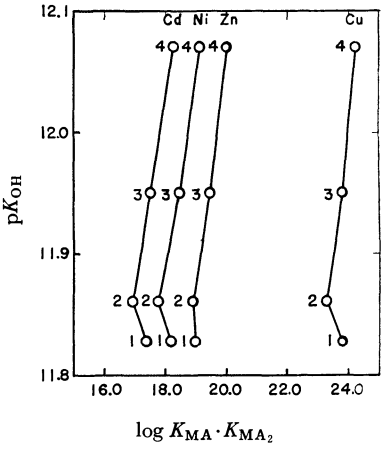

Fig. 4. Correlation between pK_{OH} and $\log K_{MA}\cdot K_{MA_2}$.
1: Me, 2: Et, 3: *n*-Pr, 4: *n*-Bu

As to the chelate stability constants, the values change rather slightly with the variation in alkyl group, as is shown in Table II. However, their differences seem to be large enough to allow us to make a meaningful interpretation of the results.

The order for the decreasing stability constants of 8-hydroxyquinoline was found to obey the Mellor-Maley order. However, the order of nickel and zinc was inverted in the case of 2-alkyl derivatives; thus: 8-hydroxyquinoline: Cu>Ni>Zn>Cd
2-alkyl derivative: Cu>Zn>Ni>Cd

The relationship between the overall stability constants and the acidity of the ligands is shown in Fig. 4. The $\log K_{MA}\cdot K_{MA_2}$ values are plotted against the pK_{OH} values, since the pK_{NH} values are almost contant for all the ligands except the 2-methyl derivatives. As expected, the overall stability constants increase linearly with the increase in the pK_{OH} values. However, in the case of the 2-methyl derivative, the relatively higher pK_{NH} value contributes to the overall stability constants, so that the values for the 2-methyl derivative deviate from linearity.

15) H. Irving and H. S. Rossotti, *J. Chem. Soc.*, **1954**, 2910.

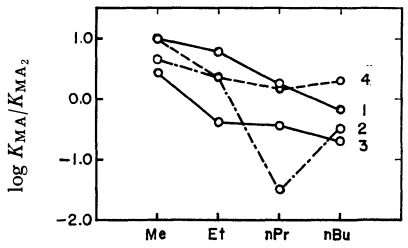

Fig. 5. Correlation for substituents.
1: Cu(II), 2: Zn(II), 3: Ni(II), 4: Cd(II)

The plots of log K_{MA}/K_{MA_2} against the carbon number of the alkyl group are shown in Fig. 5. It may be seen from this figure that the relative stability of 1 : 1 chelate to 1 : 2 chelate decreases with an increase in the carbon number of the alkyl group, with the exceptions of zinc and cadmium chelates of the 2-butyl derivative. This result is quite surprising, because it indicates that the formation of 1 : 2 chelate becomes more favorable when the higher alkyl group is introduced at the C-2 position of 8-hydroxyquinoline. The irregular behavior of zinc and cadmium may be partly explained in terms of the steric hindrance to the tetrahedral coordination structure; however, more experimental data will be needed before we can make a clear-cut explanation of the results obtained in this investigation.

The authors are greatful to the Ministry of Education, Japanese Government, for a grant in support of this work. They also thank to Dr. Kenji Motojima of Japan Atomic Energy Institute for his advice of the initiation of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1915—1922 (1966)

The Constitution, Reactivity and Thermal Change of Phosphate Ores

By Jumpei ANDO and Seiichi MATSUNO

Department of Industrial Chemistry, Faculty of Science and Engineering, Chuo University, Bunkyo-ku, Tokyo

(Received January 12, 1966)

Tests were made on twenty-five samples of phosphate ores from all over the world deposits. All of the samples consisted of apatite, plus small amounts of calcite and other minerals. The apatite crystals of the sedimentary ores ranged in size from around 0.05 μ (Gafsa, North Carolina, etc.) to around 0.5 μ (Taiba), while those of igneous ores reached 100 μ. The difference between the ores in their reactivity with citric, hydrochloric and nitric acid was mainly due to the difference in crystal size. The decomposition of the ores by a mixture of sulfuric and phosphoric acids was seriously affected by the coating of calcium sulfate crystals on the surface of the ores, and also by the aluminum and iron present in the acids and ores. The lattice constant, a_0, of the apatite of the ores ranged from 9.340 to 9.422 Å; it was generally smaller for the ores which had larger F_2/P_2O_5 ratios. Upon calcination above 500°C, the a_0 value of the apatite which had an excess of fluorine increased and approached that of true fluorapatite. The reactivity of the ores with the acids generally decreased upon calcination due to the sintering of the grains and the crystal growth. For ease of decomposition by a mixture of sulfuric and phosphoric acids, the calcined ore should contain a small amount of carbon dioxide. Tests also were made on the amount of organic matter and its decrease upon calcination.

Phosphate ores mined from various fields differ much in their nature. Moreover, it often happens that even ores which have been obtained from the same area and which have essentially the same chemical composition are significantly different in their behavior when treated with acids; this results in trouble for phosphate fertilizer plants. The reason for such differences is not clear.

Moreover, the calcination of ores which has recently been carried out in commercial-scale plants in order to increase the grade of the ores results in a further variation in the nature of the ores. Although many investigators[1-4] have reported on the phosphate ores, there is still much to study about the constitution and the nature of the ores.

*Hydroxyapatite, **Fluorhydroxyapatite, ***Fluorapatite

The present authors[5-7] have recently studied many samples of ores by electron microscopy, X-ray diffraction, surface area measurement, differential thermal analysis and chemical analysis. In the present paper, the results of these studies will be summarized.

Samples

The chemical compositions of the samples of the ores and of the synthetic precipitated apatite are shown in Table I. Most of the ores were sedimentary ores; however, Kola, Lao'Cay and Phallabowa, were of igneous origin. Three ores, Christmas, Macatea and Angaur, were from ocean islands, while all of the others were from continents.

The three samples of calcined Florida ores were produced in commercial-scale plants. The reported calcination temperature was about 800°C for the BPL 75 sample and about 950°C for the others.

Three samples, FA, FHA and HA, were prepared by treating solutions of calcium chloride and sodium phosphate with or without sodium fluoride at 70°C at pH values from 8.0 to 8.6.

The principal mineral of all the ores was apatite. The F_2/P_2O_5 mol. ratios of several ores, such as Florida, Morocco and Gafsa, exceeded 0.33, which is the stoichiometric ratio for fluorapatite. As fluorite (CaF_2) was not detected in the ores, it may be considered that the excess fluorine is present in the apatite crystals, possibly in the form of CO_3F, which replaces PO_4. The ratio was smaller than 0.33 for a few ores, Kola, Phallabowa, Angaur and Christmas, this means that the shortage of fluorine ions had been covered by hydroxyl or other ions.

The ores contained more or less carbon dioxide, partly in the form of calcite and partly in the apatite as CO_3OH[8] or CO_3F, replacing PO_4^{3-}. Most of the carbon dioxide of three ores, Togo, Macatea and Taiba, seemed to be contained in the apatite,

*Hydroxyapatite, **Fluorhydroxyapatite, ***Fluorapatite

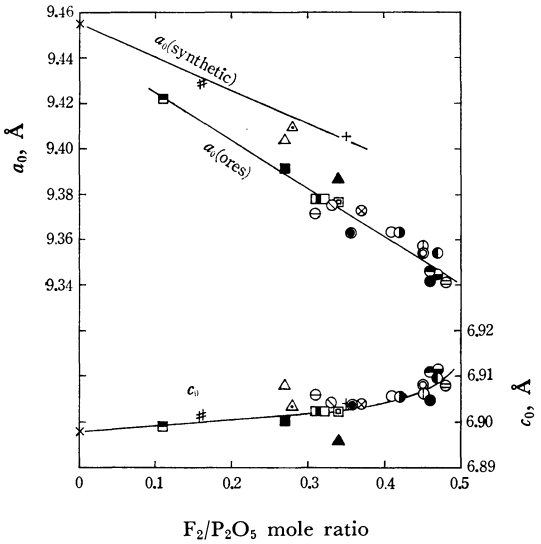

Fig. 1. Relation between the F_2/P_2O_5 ratio and the lattice constants. (The marks indicate the ores as shown in Table II.)

because the amount of calcite was very small in these ores.

The $KMnO_4$ (ml.) notations in Table I show the consumption of a N/10 potassium permanganate solution by 2-g. portions of the ores; this roughly indicates the relative amounts of organic matter, as will be described later.

Results and Discussion

The Relation between the F_2/P_2O_5 Ratio and the Lattice Constants of Apatite.—The lattice constants, a_0 and c_0, determined from (140) and (004) spacings are shown in Table II. The relation between the constants and the F_2/P_2O_5 mole ratio of the samples is shown in Fig. 1.

The a_0 constant was generally smaller when the F_2/P_2O_5 ratio was larger. Fluorapatite has a smaller a_0 value than does hydroxyapatite. An excess of fluorine made the a_0 value even smaller.

Electron microscope photographs

The constant of the ores was smaller than that of the synthetic precipitated apatite with an equal F_2/P_2O_5 ratio, presumably because of the effect of such impurities as CO_2 and R_2O_3 in the apatite. The c_0 constant increased slightly as the ratio increased from 0 to 0.33, and remarkably when the ratio exceeded 0.33, indicating the effect of excessive fluorine.

The Size and Shape of Apatite Crystals.—Apatite crystals of the samples ground to pass through 150 mesh (about 100 μ) were tested by both petrographic and electron microscopes. By the grinding, apatite crystals of the sedimentary ores were hardly destroyed at all because the crystals were generally smaller than 1 μ. The size range of most of the apatite crystals of each smaple is shown in Table II. Electron microscope photographs of typical samples are shown in Photos 1 to 6.

Most crystals of the sedimentary ores obtained from the continents (Florida, Morocco, etc.) were grainy or short-prism in shape, ranging in size from 0.02 to 1 μ. Of this sort of ores, Gafsa and North Carolina had the samllest crystal size, ranging from 0.02 to 0.1 μ, and Taiba had the largest size, ranging from 0.1 to 1 μ.

Most apatite crystals of the ores obtained from the ocean islands (Macatea, Angaur and Christmas) were prisms 0.05 to 0.2 μ in wide and 0.2 to 1 μ long. The igneous ores (Kola, Lao'Cay and Phallabowa) contained much larger crystals, up to 100 μ.

All of the synthetic apatite crystals were prism-shaped. The crystals of hydroxyapatite (HA) were much larger than those of fluorapatite (FA). Of the ores from the islands, the crystals of Christmas 84, which contained a particularly small amount of fluorine, were considerably larger than the others. Of the sedimentary ores from the continents, Gafsa and North Carolina, which had the largest F_2/P_2O_5 ratio, had the smallest crystal size. It seems that the presence of fluorine had depressed the growth of apatite crystals.

The Relation between Citric Solubility, the Height of X-ray Diffraction Peaks and the Specific Surface Area.—It has been reported that citric solubility is a good measure of the agronomic value of powdered phosphate ores.[1] Table II lists the citric solublity of the samples ground to pass through 150 mesh (300 mesh, 50% pass) tested in two ways: (1) 100 ml. of 2% citric acid was added to 1 g. of the sample and shaken for 30 min., and (2) 150 ml. of the acid was added to the sample and shaken for an hour.

The citric solubilities ranged from 5.7 to 45.8% in the 100 ml. method and from 10.7 to 64.4% in the 150 ml. method; they were generally higher for those ores which had smaller crystals and which gave shorter and broader X-ray diffraction peaks.

Figure 2 shows the relation between the height of the (222) peak ($2\theta=46.7°$ by CuKa) and the

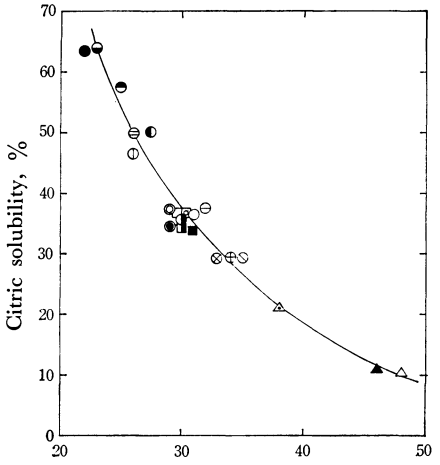

Fig. 2. Relation between the peak height and citric solubility of uncalcined ores. (The marks indicate the ores as shown in Table II.)

citric solubility as determined by the 150 ml. method. A similarly good correlation was found between the height and the solubility by the 100 ml. method, as well as found between the height of the (123) peak ($2\theta=49.5°$) and the solubility by both methods.

The peak height can be measured in several minutes; therefore, it would be useful for the rapid estimation of the nature of the ores. The peak height is related not only to the crystal size but also to the apatite content of the ore, both of which affect the citric solubility. The crystal size can be estimated more precisely by the measurement of the broadening of the diffraction peaks.

The specific surface area of the samples as measured by the nitrogen gas-absorption method is shown in Table II. The surface area was generally higher for the ores with larger citric solubilities; however, the correlation between the solubility and the X-ray peak heights was better than that between the solubility and the specific surface area[5].

Reactivity with Dilute Mineral Acids.—Tests were made on the reactivity of the ores with dilute hydrochloric, nitric, sulfuric and phosphoric acids. Figure 3 shows the relation between the decomposition ratio of the ores and the reaction time when 0.5 g. of the ore, ground to pass through 100 mesh (200 mesh, 70%; 300 mesh, 30% pass), was put into 37 to 40 ml. of N/4 hydrochloric acid (106% of the amount calculated to be needed to convert calcium, iron and aluminum into chlorides) and shaken for 10, 25 and 40 min. at 30°C.

The ease of the decomposition agreed with the fineness of the apatite crystals. The decomposition ratio of Kola was only about 70% when it was shaken for 40 min. Similar results were obtained

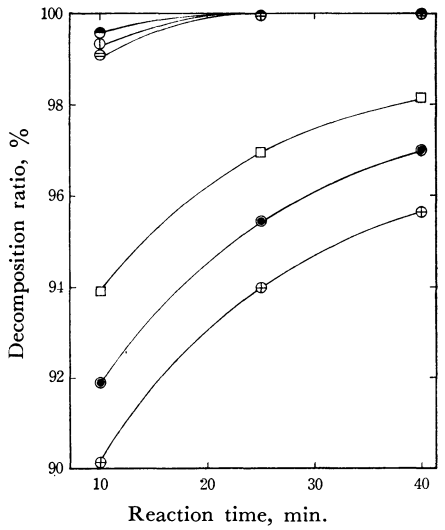

Fig. 3. Decomposition by N/4 hydrochloric acid. (30°C)
◓ Gafsa 64, ⦶ Kossier, ⊜ Morocco 70
□ Macatea 80, ◉ Florida 76, ⊕ Taiba 80

when N/4 nitric acid instead of the hydrochloric acid was used. Tests of the decomposition of Macatea ore by N/4 sulfuric acid showed that the decomposition ratio was close to that by the hydrochloric acid. The decomposition ratio by 1/4 mol. phosphoric acid was much lower.

Decomposition by a Mixture of Sulfuric and Phosphoric Acids.—These decomposition tests were made using a mixture of sulfuric and phosphoric acids at 90°C in a manner similar to that used in the production of wet-process phosphoric acid by the hemihydrate-dihydrate process. For each test, 50 g. of the ore ground to pass through 100 mesh (200 mesh, 70%; 300 mesh, 30% pass) or 150 mesh (200 mesh, 90%; 300 mesh, 50% pass) was used. Reagent-grade sulfuric acid, wet-process phosphoric acid prepared with the respective ore, and water were blended in such a way that, after the decomposition and the hydration of gypsum, the weight ratio of the liquid and the gypsum would be 65 : 35 and the product acid would contain 28% P_2O_5 and 4% SO_3. The decomposition was then carried out at a stirring rate of 120 r. p. m. in a covered glass container equipped with a condenser to prevent the loss o water during the decompostion. The decomposition ratio was mersured in a way similar to that reported by Murata and Noriyama.[9]

The relation between the reaction time and the ratio of the decomposition for several typical ores ground to pass through 100 mesh is shown in Fig. 4. The figure shows that Taiba was decomposed more quickly than was Morocco or

9) A. Murata and T. Noriyama, *Sekko to Sekkai*, No. 68, 9 (1964).

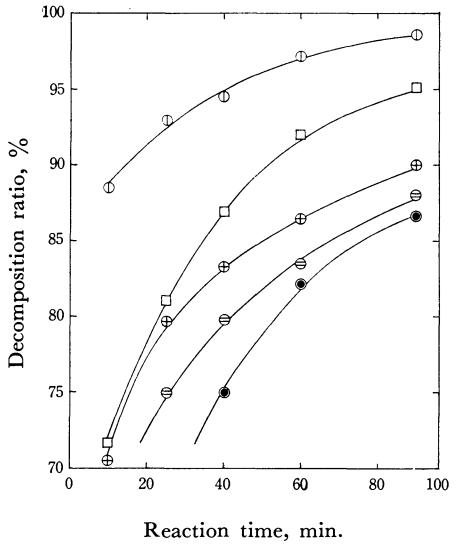

Fig. 4. Decomposition by the mixture of sulfuric and phosphoric acids. (−100 mesh, 90°C)
Ⓘ Kossier, □ Macatea 80, ⊕ Taiba 80, ⊖ Morocco, 70 ◉ Florida 76

Florida. The ease of the decomposition did not agree with the fineness of the apatite crystals of the ores.

Figure 4 also shows that the decomposition of the ores was much slower than when treated with dilute sulfuric or hydrochloric acid. The decomposition became still slower when an increasing amount of sulfuric acid was used. These characteristics of the decomposition by the mixed acid are mainly due to the coating by calcium sulfate hemihydrate crystals on the surface of the ores; this delays the decomposition seriously. The state of the coating differed considerably with different ores.

When the ores ground to pass through 150 mesh were treated in the same manner for 60 min., the decomposition ratio was about 98% for Kossier and Macatea (BPL 80), 95% for Taiba (BPL 80), and 93% for Florida (BPL 68 and 76) and Morocco (BPL 70). Kola was less reactive, and the decomposition ratio was 92% when the sample ground to pass through 150 mesh was reacted for 90 min.

The decomposition tests with the mixed acid were also made at 60°C, in the stable range of calcium sulfate dihydrate. The rate of the decomposition at 60°C was considerably larger than at 90°C for most ores which had been ground to pass through 100 mesh. However, for the ores which had been ground to pass through 150 mesh, the rates of the decomposition at 60°C and at 90°C were nearly equal. Presumably, the true of the reaction between the mixed acid and the ore is larger at 90°C than at 60°C; the effect of the coating by calcium sulfate is also larger at 90°C, and the effect of the coating is more remarkable when the coarser grains of the ore are used.

Carbon dioxide, especially when present in the apatite crystals, seems to promote the decomposition by breaking the calcium sulfate coating as it is released from the ore. The iron and aluminum, especially the latter, present in the ore and the acid delayed the decomposition of the ore.[7] Because of the effects of these many factors, the ease of decomposition can not be predicted on the basis of only the crystal-size measurement of the ores.

The Change in Apatite Crystals by Calcination.—The phosphate ores and synthetic apatite were heated at various temperatures between 500 and 1350°C for an hour. The lattice constant, a_0, of the apatite of most ores changed remarkably upon the heating. The change in typical samples is shown in Fig. 5.

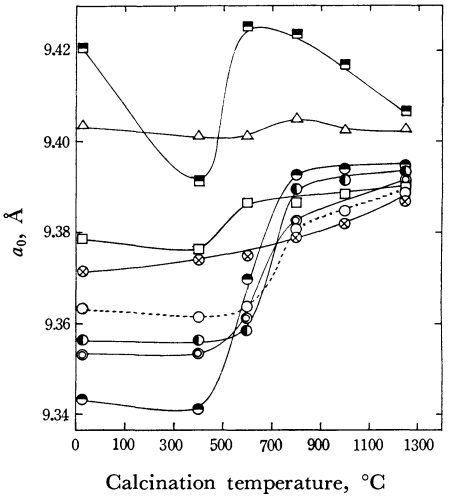

Fig. 5. Change of a_0 on the calcination. (The marks indicate the ores as shown in Table II.)

The a_0 constant of most ores increased when they were heated above 500°C. The increase was more remarkable for such ores as Morocco and Gafsa, which had larger amounts of excess fluorine and which had smaller a_0 values. The a_0 constant of synthetic apatite decreased upon the heating. After they had been heated above 900°C, the a_0 values of most ores, except Christmas 84 and Kola, were close to that of synthetic fluorapatite, 9.39 Å. Kola, which contained about 2% strontium, had larger a a_0, showing that strontium is present in the apatite, replacing calcium. The change of c_0 on the calcination was smaller.

On calcination at 500°C, the X-ray diffraction peak height of the apatite of most ores decreased by about 10%. This is probably caused by some

disorder in apatite crystals which occurred prior to the reorganization and crystal growth of apatite. When the ore was heated above 700°C, a crystal growth of apatite occurred, resulting in an increase in the X-ray diffraction peak height.

Tests with an electron microscope showed that in calcined Florida 81 (Photo. 6) the fine crystals of the initial ore (Photo. 4) began to combine with each other upon calcination at about 950°C, thus forming larger crystals (up to about 10 μ) which resemble those of Kola ore (Photo. 3).

The Change in the Reactivity to Acids on Calcination.—The citric solubility, the reactivity with dilute hydrochloric acid, and that with a mixture of sulfuric and phosphoric acids were tested in ores calcined at various temperatures.

The citric solubility of most ores decreased slightly upon calcination at 500°C, presumably because of the decrease in the porocity of the ores. The decrease in the citric solubility was remarkable upon calcination above 900°C as a result of the crystal growth. After the ores had been heated at 1350°C, the citric solubility of all the ores tested by the 150 ml. method was around 10%.

The decomposition tests by N/4 hydrochloric acid also showed a decrease in the reactivity upon calcination. For example, the decomposition ratios when Florida 76 ore ground to pass through 100 mesh after it had been calcined at 500, 700, 900 and 1100°C was treated for 25 min. were 95.2, 94.5, 93.0 and 91.8% respectively, while that of the uncalcined ore was 96.2%.

The rate of the decomposition by the mixture of sulfuric and phosphoric acids also decreased upon calcination. The decrease was remarkable when the ore had been calcined at above 900°C and had so lost nearly all of its carbon dioxide. Without carbon dioxide, the powdered ore had a tendency to form lumps when mixed with the acid; this caused a further delay in the decomposition. For example, the decomposition ratios of Florida 76 ore ground to pass through 100 mesh after the calcination at 500, 700, 900 and 1100°C were 81.1, 79.8, 71.3 and 69.1% respectively when it was treated with a mixture of reagent-grade sulfuric and phosphoric acids for an hour. The above-mentioned lumps were also formed in large-scale plants.

The decomposition tests with the mixed acid were also made with two samples of calcined Florida ores (79 and 81) produced at commercial-scale plants. In comparison with these, two samples of uncalcined Florida ores (68 and 76) were also tested. In these tests, the ores ground to pass through 150 mesh (200 mesh, 90%; 300 mesh, 50% pass), reagent-grade sulfuric acid and the wet-process phosphoric acid prepared with the respective ores were used. The rate of the decomposition of one of the calcined ores, BPL

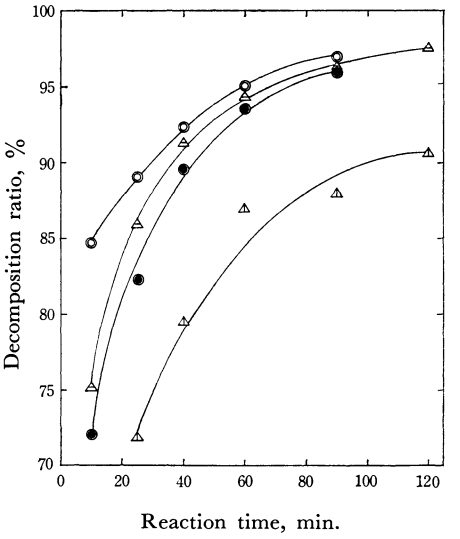

Fig. 6. Decomposition by the mixed acid of the calcined and uncalcined Florida ores.
◎ uncalcined 68, △ calcined 79
◉ uncalcined 76, △ calcined 81

79, was close to that of the uncalcined samples; however, another calcined sample, BPL 81, was decomposed much more slowly, as is shown in Fig. 6. The 81 sample contained no carbon dioxide and formed a considerable amount of lumps when treated with the acid. The 79 sample had a small amount of carbon dioxide (0.4%) and had little tendency to form lumps. The decomposition of this sample was a little quicker than that of the uncalcined ore (76). It is possible that, upon calcinaton at an adequate temperature, the alumina in the ore which usually depresses the rate of the decomposition becomes less reacitve and that in this manner the decomposition is promoted.

The amount of carbon dioxide has much to do with the decomposition. Too much carbon dioxide is not desirable because of too much effervescence. Carbon dioxide present in amounts 0.5 to 1% of the ore would be most desirable for the decomposition.

The Amount of Organic Matter and Its Decrease upon Calcination.—Organic matters contained in the ores are known to affect the nature of gypsum in the production of wet-process phosphoric acid.[10] As an approximate measure of the organic-matter content, the consumption of a potassium permanganate solution was determined on uncalcined and calcined ores in the following way: To 2 g. of a sample, 100 ml. of 3N sulfuric acid was added; they were stirred until the ore had been decomposed. An excess of a 0.1N potassium permanganate solution was then added.

10) K. Murakami and H. Tanaka, *Sekko to Sekkai*, No. 54, 207 (1961).

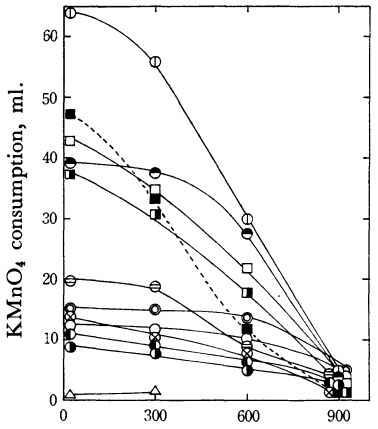

Fig. 7. Decrease of the consumption of $KMnO_4$ on the calcination. (The marks indicate the ores as shown in Table II.)

After the mixture had stood for 24 hr. at room temperature, the slurry was titrated with a 0.1 N sodium oxalate solution. The permanganate consumptions (ml.) by 2 g. portions of the samples are shown in Table I. The permanganate was mainly consumed by organic matter. The consumption by ferrous ions was minor in scale.

The samples of Kossier and Gafsa, the crystal size of which was the smallest, showed the highest consumption. The ores obtained from the ocean islands showed a relatively high consumption. The decrease in the consumption of several typical ores upon calcination is shown in Fig. 7. The manner of the decrease was considerably different for each sample. On heating at 300°C, the decrease was remarkable for Angaur, but it was only slight for the two Florida samples. Such a difference may indicate a difference in the type of organic compound.

Thermal analysis upon heating the ores showed exothermic reactions between 300 and 700°C for most ores. The amount of the exothermic heat was generally larger for those ores which consumed a larger amount of the permanganate, an indication that the exothermic reactions were mainly due to the burning of the organic matters.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1922—1925 (1966)

The Isocyanurates. II. The Syntheses of Several Unsaturated Aliphatic Isocyanurates

By Fumio TANIMOTO, Takatomi TANAKA, Hisao KITANO and Kenichi FUKUI

Department of Fuel Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received August 16, 1965)

Triallyl, trimethallyl and tripropargyl isocyanurates were synthesized in good yields by the reaction of the corresponding halides with potassium cyanate in dimethylformamide or dimethyl sulfoxide. Allyl and ethyl isocyanates were easily trimerized in the presence of alkaline salts in dimethylformamide. Tris(1, 3-pentadienyl) isocyanurate was synthesized by the trimerization of 1, 3-pentadienyl isocyanate in a saturated solution of sodium benzoate in dimethylformamide. 1, 3-Butadienylene-1, 4-diisocyanate was also polymerized in the same solvent; it formed black solid mass, suggesting a polyisocyanurate structure of a low molecular weight.

In the literature considerable attention has been directed to the preparation[1] of and the properties[2] of unsaturated isocyanurates. A method of preparing triallyl isocaynurate from allyl chloride and alkali cyanates had early been patented by Kaiser,[3] but the method consisted of drastic reaction conditions and the yield of the isocyanurate was very poor. Himel and DePree[4] obtained isocyanurates by the reaction of organic halides with alkali cyanates catalyzed by

1) 1 ml. of pyridine was used.
2) Toluene

tertiary amines.

The reaction of organic halides with alkal cyanates was systematically investigated in our laboratory[5]; it was found that the reaction could successfully be carried out in several aprotic solvents. In our previous paper[6] the physico-chemical properties of triallyl isocyanurate and its related compounds were partially discussed.

For the present paper, the preparation of several unsaturated isocyanurates was executed in detail. Triallyl, trimethallyl and tripropargyl isocyanurate were synthesized by the reaction of their corresponding halides with potassium cyanate in dimethylformamide or dimethyl sulfoxide. Tris-(1, 3-pentadienyl) isocyanurate and a polymer of 1, 3-butadienylene-1, 4-diisocyanate were prepared by the trimerization of their corresponding isocyanate in dimethylformamide.

In the reaction of the alkenyl halides with potassium cyanate, the nucleophilic substitution of the halide for the isocyanate was generally fast, while the trimerization of the isocyanate to the isocyanurate might be delayed, because of the reaction conditions. Various alkaline salts, such as potassium cyanate, potassium carbonate, sodium acetate, and sodium benzoate, were found to facilitate the trimerization in the aprotic solvent under anhydrous conditions, in spite of thier low solubility in the solvent (for example, the solubility of potassium cyanate in dimethylformamide was about 0.6 wt.% at 100°C). Potassium cyanate and potassium carbonate accelerated the trimerization of allyl isocyanate in dimethylformamide,[7] even at room temperature, as is shown in Table I; the effect of the same catalysts on ethyl isocyanate trimerization was also studied (cf. Table II). The isocyanurate formation from the isocyanate was deeply favored by the presence of the aprotic solvent and the alkaline salt, but the best-known solvents for isocyanates, toluene and pyridine, were not effective for the trimerization of the

6) K. Fukui, H. Kato, T. Yonezawa, F. Tanimoto and H. Kitano, This Bulletin, **34**, 851 (1961).

7) W. J. Balon, Abst. Papers, 130th Meeting, Am. Chem. Soc., Atlantic City, N. J., Sept. 1956, p. 15; U. S. Pat. 2683144 (1954); I. C. Kogon, *J. Am. Chem. Soc.*, **73**, 4911 (1957); U. S. Pat. 2838511 (1958); Bolon demonstrated that the trimerization of aromatic diisocyanates was effectively catalyzed by sodium benzoate in dimethylformamide; Kogon also reported, with respect to the trimerization of aromatic isocyanates in ethyl alcohol, that the reaction was affected by the use of *N*-methylmorpholine as the catalyst. Aromatic or vinyl isocyanates are known to have a greater tendency to trimerize than allyl isocyanate.[1c]

isocyanate in the presence of the alkaline salt.

When a mixture of allyl, methallyl or propargyl halide and potassium cyanate was kept at 100—145°C in dimethylformamide or dimethyl sulfoxide, the reaction took place in a few minutes and was completed in 2—4 hr., giving the corresponding trialkenyl or trialkynyl isocyanurate in a good yield.

Some unsaturated aliphatic isocyanurates with carbon-carbon multiple bonds directly adjacent to the nitrogen atoms of the triazine ring were difficult to prepare by means of the reaction of corresponding halides with alkali cyanates. For this reason 1, 3-pentadienyl isocyanate and 1, 3-butadienylene-1, 4-diisoycanate were prepared by the Curtius rearrangement of the corresponding acid azide.[8,9]

1, 3-Pentadienyl isocyanate was treated with sodium benzoate in dimethylformamide to give tris(1,3-pentadienyl) isocyanurate. 1,3-Butadienylene-1, 4-diisocyanate was also treated with sodium benzoate in dimethylformamide. The product was a black solid mass which could be dissolved in dimethylformamide to form a black or a deep-colored solution. The analysis of the product suggested the formation of the low-molecular-weight isocyanurate polymer by the trimerization of the diisocyanate.

Experimental[10]

Triallyl Isocyanurate.—In a 1-l. flask 300 g. (4.1 mol.) of dimethylformamide and 200 g. (2.5 mol.) of potassium cyanate were placed. The mixture was then heated to 135°C while being stirred; 190 g. (1.5 mol.) of allyl bromide was then added through the dropping funnel over a period of 2 hr. After the bromide had been added, the reaction mixtute was kept between 135—140°C for an additonal hour. The mixture was then cooled to room temperature, mixed with about 200 ml. of anhydrous acetone, and left to stand overnight. The mixture was filtered, and the precipitate of inorganic salts was washed with acetone. The combined solution of the filterate and acetone was concentrated under reduced pressure. After the solvents had been removed, crude triallyl isocyanurate boiling at 130—145°C/4 mmHg was obtained in a 90% yield (based on the allyl bromide). This crude triallyl isocyanurate was then mixed with about 100 ml. of ligroin and left to stand overnight at 0—10°C. A small amount of white needles (1, 3-diallylurea) was filtered off, and the ligroin was evaporated from the filtrate. The residue was mixed with 50 ml. of petroleum ether, and the mixture was placed in an ice box for a day. Colorless hexagonal plates of pure triallyl isocyanurate were thus obtained in an 80% yield. M. p. 25.0—26.0°C; b. p. 144—146°C/4 mmHg; n_D^{25} 1.5110.

Found: N, 16.82. Calcd. for $C_{12}H_{15}O_3N_3$: N, 16.86%.

Trimethallyl Isocyanurate.—A mixture of 50 g. (0.6 mol.) of potassium cyanate and 110 g. (1.5 mol.) of dimethylformamide was heated to 140°C. Then 45 g. (0.5 mol.) of methallyl chloride was added in about a 1 hr. period. After the chloride had been added, the reaction was continued for 3 hr. at about 140°C. The reaction mexture was then cooled, diluted with 150 ml. of dry benzene, and poured into brine, and the benzene layer was separated. After the solvent had been removed, 47 g. of crude trimethallyl isocyanurate was obtained as a crystalline cake in a 97% yield. The recrystallization of the cake from methanol gave pure trimethallyl isocyanurate, m. p. 85—86°C.

Found: N, 14.38. Calcd. for $C_{15}H_{21}O_3N_3$: N, 14.42%.

Tripropargyl Isocyanurate.—Into a mixture of 27 g. (0.3 mol.) of potassium cyanate and 76 g. (1 mol.) of dimethyl sulfoxide, 24 g. of propargyl bromide (0.2 mol.) was stirred at room temperature. The exothermic reaction took place, and the mixture turned dark. The flask was then immersed in a water bath for 1 hr. to cool the mixture, and then it was warmed to 100°C. After the temperature had been maintained at about 100°C for an additional 3 hr. the mixture was treated as in the case of trimethallyl isocyanurate. The yield of crude tripropargyl isocyanurate was 34% (5.5 g.); the pure isocyanurate had a melting point of 160.5—161.0°C. The yield was increased to as high as 83% when dimethylformamide was used as the solvent.

Found: N, 17.10. Calcd. for $C_{12}H_9O_3N_3$: N, 17.28%.

The Trimerization of Isocyanates to Isocyanurates.—*Trimerization under High Pressure.*—In a 100 ml. autoclave, 10 g. (0.12 mol.) of allyl isocyanate and 50 ml. of anhydrous pyridine were charged and heated at 180—190°C for 10 hr. while being stirred. After it had cooled, the reaction mixture was distilled under reduced pressure in order to collect the fraction boiling at 139—144°C/3 mmHg. The distillate was triallyl isocyanurate, and the yield was about 15%. This material was characterized by infrared analysis, which showed the carbonyl peak at 5.9 μ and the isocyanurate peak at 13.04 μ.

Trimerization under Atmospheric Pressure.—The trimerization of allyl or ethyl isocyanate was carried out in a round-bottomed flask under suitable conditions, as is shown in Tables I and II. After the reaction had been completed, the reaction mixture was filtered. The unchanged isocyanate and the solvent were removed from the filtrate by evaporation under reduced pressure. The residual product was dissolved in benzene and washed with brine. The distillation of the solution under reduced pressure gave a product which was identified as the isocyanurate by infrared analysis.

Sorboyl Azide.—To a suspension of 19.5 g. (0.30 mol.) of activated sodium azide in 120 ml. of pure 1, 4-dioxane, there was added, drop by drop, 30 g. (0.28 mol.) of sorboyl chloride[11] (b. p. 55.5°C/6.5

8) E. W. Barret and C. W. Portar, *J. Am. Chem. Soc.*, **63**, 3434 (1941).

9) H. M. Singleton and W. R. Edwards, Jr., ibid., **60**, 540 (1938).

10) The boiling points and the melting points are uncorrected.

11) R. Adams and L. H. Ulich, *J. Am. Chem. Soc.*, **42**, 599 (1920); K. Taufel, Cl. Franzke and P. Dietze, *Fette, Seifen, Anstrichmittel*, **62**, 592 (1960).

mmHg, n_D^{19} 1.5771) at 10—14°C over a period of 1 hr. After the addition of the chloride had been completed, the mixture was stirred for 24 hr. at 10—14°C, with the subsequent addition of a further 6 g. (0.09 mol.) of sodium azide, and then it was stirred for an additional 24 hr. at that temperature. The reaction mixture was filtered to remove inorganic salt, and sorboyl azide was used without being separated from the dioxane solution.

1, 3-Pentadienyl Isocyanate.—The dioxane solution of sorboyl azide was warmed to 52°C under a slightly reduced pressure. The Curtius rearrangement took place gradually, and the temperature of the reaction mixture was slowly raised to 76°C so as to complete the rearrangement in the period of 4 hr. When the mixture was cooled, there precipitated a yellowish solid material, which was filtered off; the filtrate was distilled to give 1, 3-pentadienyl isocyanate boiling at 27—30°C/8—9 mmHg. The redistillation of the product afforded the pure isocyanate (b. p. 27—28°C/8 mmHg, in a 20% yield based on sorboyl chloride), which was highly reactive and so was converted into stable 1-benzyl-3-(1, 3-pentadienyl) urea, m. p. 157°C, by treatment with benzyl amine and then analyzed.

Found: C, 71.82; H, 7.20; N, 13.30. Calcd. for $C_{13}H_{16}ON_2$: C, 72.19; H, 7.39; N, 12.95%.

Tris(1, 3-pentadienyl) Isocyanurate.—A mixture of 5 g. (0.045 mol.) of 1, 3-pentadienyl isocyanate and 50 ml. of dimethylformamide was added carefully to 100 ml. of a saturated solution of sodium benzoate in dimethylformamide which had been chilled in an ice bath. An exothermic reaction took place immediately, and the solution turned pale yellow. The reaction mixture was then allowed to stand at 60—70°C for 5 hr. After the solvent had been evaporated under reduced nitrogen pressure, the residual mass was washed with water, alcohol, and ether, and then recrystallized from dimethylformamide to give pure tris(1, 3-pentadienyl) isocyanurate (m. p. 235—236°C, in a 90% yield). The isocyanurate was confirmed by infrared analysis.

Found: C, 65.77; H, 6.35; N, 13.14%. Calcd. for $C_{18}H_{21}O_3N_3$: C, 66.04; H, 6.47; N, 12.83%.

Muconyl Diazide.—Muconyl diazide was prepared from the reaction of sodium azide with muconyl dichloride[12] (m. p. 96°C) in a manner similar to that described for sorboyl azide. The dioxane solution of muconyl diazide without purification was used for the preparation of the isocyanate.[13]

1,3-Butadienylene-1,4-diisocyanate.—The Curtius rearrangement of muconyl diazide to the diisocyanate was carried out first at 40°C and then at 58°C and a 3 hr. period under slightly reduced pressure. Although the solution was considerably darkened during the reaction, no precipitation of a solid substance was observed. After two-thirds of the solvent had been removed, however, a yellow solid material was precipitated; this material was removed by filtration. The dioxane solution of the diisocyanate was submitted to isocyanate-group determination.[14] It was thus confirmed that 50 ml. of the solution contained 2 g. of the isocyanate. A small portion of the solution was treated with about two equivalent mol. of benzyl amine to afford 1,4-bis(3-benzylureido)-butadiene-1,3, which was then recrystallized from benzene to give colorless crystals melting at 278—279°C.

Found: C, 69.54; H, 6.53; N, 15.60. Calcd. for $C_{20}H_{22}O_2N_4$: C, 68.55; H, 6.33; N, 15.99%.

The Polymerization of 1, 3-Butadienylene-1, 4-diisocyanate.—To 100 ml. of a saturated solution of sodium benzoate in dimethylformamide, 50 ml. of a dioxane solution containing about 2 g. of the diisocyanate was added. The mixture soon darkened, and it turned almost black in a minute. After the solvents had been removed from the reaction mixture under reduced pressure, a small amount of ether was added to the residue and the black solid mass was triturated in the ether. The black powder was collected by filtration, dried over phosphorus pentoxide, and pulverized in a mortar. The powder was dissolved in dimethylformamide to afford a dark solution. The solution could not be decolorized with Norit Extra or other decolorizing agents. The black solution was then painted on a glass plate, and the solvent was evaporated under reduced pressure to give a dark brown film, which was insoluble in methanol, ethanol, gasoline and benzene. If the black polymer had isocyanuric rings connected with each other by conjugated double bonds, the polymer might have electrically-interesting characteristics.[15]

12) D. S. Bailey, *J. Am. Chem. Soc.*, **71**, 2370 (1949); **78**, 5905 (1956).

13) After the solvent had been removed, the pale yellow residue was recrystallized from methanol and ether to afford white leaflets of pure muconyl diazide, which decomposed explosively when heated to 80°C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1926—1931 (1966)

Photochemical Reactions of Ethyl Chloroglyoxylate with Cyclohexane, Cyclohexene, and Toluene

By Chyongjin PAC and Shigeru TSUTSUMI

Department of Chemical Technology, Faculty of Engineering, Osaka University, Miyakojima-ku, Osaka

(Received September 30, 1965)

The photochemical reactions of ethyl chloroglyoxylate with cyclohexane, *cyclohexene,* and toluene have been carried out, and the reactivity of an alkyl radical towards ethyl chloroglyoxylate has been qualitatively discussed. A cyclohexyl radical attacks the carbonyl group of the acid chloride function in ethyl chloroglyoxylate to cause a chain reaction; cyclohexanecarbonyl chloride (51%) and ethyl cyclohexylglyoxylate (2—3%) are thus obtained, along with other minor products. On the other hand, a cyclohexen-3-yl or a benzyl radical might be unable to attack ethyl chloroglyoxylate under the conditions investigated.

In a previous paper,[1] it has been reported that the photolysis of ethyl chloroformate affords an ethoxycarbonyl radical in a selective manner, accompanied by the direct introduction of the radical into various hydrocarbons; carboxylated products are thus obtained. In such a photolysis, however, the carboxylated products do not form via any chain reactions.

The direct introduction of various carboxyl groups into hydrocarbons by means of radical reactions has received much attention recently.[2-7] Therefore, the photo- and peroxide-induced reactions of oxalyl chloride with a saturated hydrocarbons, such as cyclohexane, are of interest, since a characteristic chain reaction is operative in the formation of cyclohexanecarbonyl chloride.[8,9] To the related chain reactions, however, little attention has been paid.

In our preliminary report concerning the photochemical reactions of ethyl chloroglyoxylate (ECG) with olefins,[10] it has been suggested that the 1 : 1-adduct of ECG and an olefin might be formed via a chain reaction as follows;

$$\mathrm{ClCOCOOEt} \xrightarrow{h\nu} \cdot\mathrm{COCl} + \cdot\mathrm{COOEt}$$

$$>\mathrm{C{=}C}< + \cdot\mathrm{COOEt} \rightarrow -\overset{\cdot}{\underset{|}{\mathrm{C}}}-\underset{|}{\overset{|}{\mathrm{C}}}-\quad (\mathrm{COOEt})$$

$$-\overset{\cdot}{\underset{|}{\mathrm{C}}}-\underset{|}{\overset{|}{\mathrm{C}}}- + \mathrm{ClCOCOOEt} \rightarrow \quad (\mathrm{COOEt})$$

$$-\underset{|}{\overset{|}{\mathrm{C}}}-\underset{|}{\overset{|}{\mathrm{C}}}- + \cdot\mathrm{COOEt} \quad (\mathrm{COCl},\ \mathrm{COOEt})$$

The present paper will discuss whether or not an in situ-generated alkyl radical can attack ECG, and which site of ECG, if it is attacked, is reactive to the alkyl radical.

Results and Discussion

A mixture of ECG and a hydrocarbon placed in a quartz tube was irradiated with a high pressure-mercury arc without a filter. During the course of the irradiation, hydrogen chloride, carbon dioxide, carbon monoxide, ethane, and ethylene were evolved. Traces of ethyl chloride and acetaldehyde were trapped at −60°C at the end of the irradiation. In an attempt to obtain some information on the present photochemical reactions, the benzoyl peroxide-induced reaction of ECG with cyclohexane was carried out; it gave carbon dioxide and ethane, along with a trace of carbon monoxide as the gaseous products. The results concerning the gaseous products are summarized in Table I.

From the photochemical reaction of ECG with cyclohexane, a 51% yield of cyclohexanecarbonyl chloride was obtained; small amounts of the other products (ethyl cyclohexylglyoxylate, ethyl cyclohexanecarboxylate, and diethyl oxalate) were also detected (Table II).

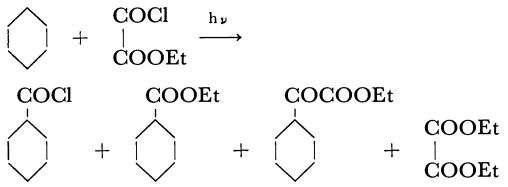
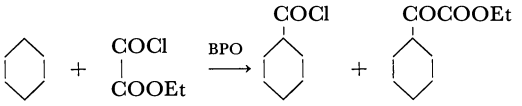
				Diethyl oxalate	d)
				3,3'-Bicyclohexenyl	d)
					ca. 10
27	Toluene 62	41	20	$C_6H_5CH_2COOEt$	ca. 10
				Diethyl oxalate	ca. 10

a) Yields were based on ECG not recovered.
b) The amounts were too small to be measured.
c) Dibenzoyl peroxide-induced reaction.
d) The amounts were not measured.
e) The final product after hydrolysis of the reaction-product.



In contrast to the photochemical reaction, the benzoyl peroxide-induced reaction of ECG with cyclohexane gave no detectable amounts of ethyl cyclohexanecarboxylate and diethyl oxalate. The liquid products were cyclohexanecarbonyl chloride (49%), ethyl cyclohexylglyoxylate (—6%), and a trace of benzoyl chloride.



In both cases, the amount of bicyclohexyl formed was negligible. The liquid products are listed in Table II.

On the basis of the above results, the following scheme can be proposed:

a) Primary processes:

$$\mathrm{ClCOCOOEt} \longrightarrow \begin{cases} \longrightarrow \cdot\mathrm{COCl}\ (\mathrm{I}) + \cdot\mathrm{COOEt}\ (\mathrm{II}) & (1) \\ \longrightarrow \cdot\mathrm{Cl} + \cdot\mathrm{COCOOEt}\ (\mathrm{III}) & (2) \\ \longrightarrow \cdot\mathrm{COCOCl}\ (\mathrm{IV}) + \cdot\mathrm{OEt} & (3) \end{cases}$$

or

$$\mathrm{C_6H_5\overset{O}{\overset{\|}{C}}O\text{-}O\overset{O}{\overset{\|}{C}}C_6H_5} \longrightarrow 2\mathrm{C_6H_5CO_2}\cdot \quad (4)$$

b) The decomposition of radicals:

$$\mathrm{I} \longrightarrow \mathrm{CO} + \cdot\mathrm{Cl} \quad (5)$$

$$\mathrm{II} \longrightarrow \mathrm{CO_2} + \cdot\mathrm{C_2H_5} \quad (6)$$

$$\mathrm{III} \longrightarrow \mathrm{CO} + \mathrm{CO_2} + \cdot\mathrm{C_2H_5} \quad (7)$$

$$\mathrm{IV} \longrightarrow 2\mathrm{CO} + \cdot\mathrm{Cl} \quad (8)$$

$$2\ \mathrm{EtO}\cdot \longrightarrow \mathrm{EtOH} + \mathrm{CH_3CHO} \quad (9)$$

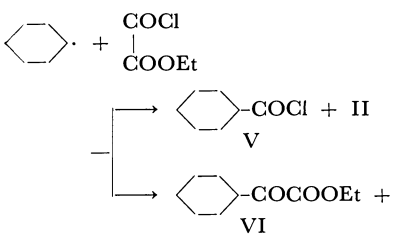
$$\mathrm{C_6H_5CO_2}\cdot \longrightarrow \cdot\mathrm{C_6H_5} + \mathrm{CO_2} \quad (10)$$

c) Chain initiation processes:

(11)

(R=Cl, $\mathrm{C_2H_5}$, EtO, $\mathrm{C_6H_5CO_2}$, and $\mathrm{C_6H_5}$)

d) Chain propagation processes:



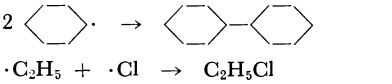
(12)

(13)

e) Chain termination processes:

(14)

(R'=Cl, $\mathrm{C_2H_5}$, COOEt, COCl, and COCOOEt)



(15)

$$\cdot\mathrm{C_2H_5} + \cdot\mathrm{Cl} \rightarrow \mathrm{C_2H_5Cl} \quad (16)$$

f) Other reaction:

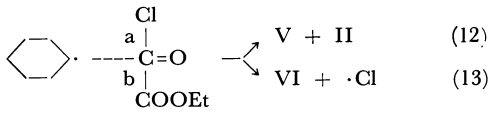
$$\mathrm{EtOH} + \mathrm{ClCOCOOEt} \rightarrow \mathrm{HCl} + \mathrm{C(COOEt)_2H} \quad (17)$$

It has been suggested that oxalyl chloride is photolyzed by the light in the 2537 Å region to cause a homolysis of the carbon-carbon bond, while the light in the 3650 Å region breaks down the chlorine-carbon bond.[11] In the present work, a high pressure-mercury arc was used without any filters; hence the primary processes 4 and 5 probably occur in a manner analogous to the photolysis of oxalyl chloride, though no efforts were made to clarify the primary processes of the photodecomposition of ECG. The formation of acetaldehyde suggests that an ethoxy radical might be generated; namely, the process 3 might take place.

The thermochemical data on the radicals I[12] and II[13] are known; the radicals will decompose as is shown in the processes 5 and 6 respectively. The radicals III and IV are likely to decompose as in the processes 7 and 8 respectively, though little is known of thier stability and their reactivity.

The irradiation in cyclohexane proceeds by a radical chain reaction. The gaseous products continuosly evolved for some time after the light source was shut off. In addition, the molar ratio of the cyclohexanecarbonyl chloride formed to the benzoyl peroxide used showed values of about six in the peroxide-induced reaction.

In the chain transfer process, however, three possible sites of ECG may be attacked; namely, the chlorine atom; the carbonyl group of the acid chloride function, and that of the ester function. The chlorine atom might be resistive to an attack by an alkyl radical, since no significant amounts of ethyl chloride and cyclohexyl chloride were produced. The liquid products from the photo- and the peroxide-induced reactions clearly show that the carbonyl group of the acid chloride function is attacked by a cyclohexyl radical, and that the ratio of the formation of the acid chloride V to the keto-ester VI may be controlled by the relative bond strength of the carbon-carbon, b, and the carbon-chlorine, a, bonds. Unfortunately, the



(12)

(13)

dissociation energies of the respective bonds in ECG have not appeared in any of the literature. Carson and Skinner have estimated the bond energy of the carbon-chlorine bond in acetyl chloride to be 76.7 kcal./mol.[14] Concerning the bond energy of the carbonyl-carbonyl bond in biacetyl, two values have been presented, 60 kcal./mol.[15] and 72 kcal./mol.[16] If the values for the dissociation energies of the C–Cl bond in acetyl chloride and of the C–C bond in biacetyl are used instead of those for the dissociation energies of the bonds a and b in ECG, the carbon-carbon fission 12 might be expected to be preferred over the carbon-chlorine fission 13 in the chain transfer process. This interpretation might be qualitatively consistent with the product-distribution.

There is, however, a difference in the VI/V ratio between the photo- and the peroxide-induced reactions. In the photochemical reaction, the ratio was about one-third of that obtained from the peroxide-induced reaction. It has been reported that esters of α-keto acids, such as pyruvic and phenylglyoxylic acids, are rapidly photolyzed by light promising n–π^* excitation.[17] Since a high pressure-mercury arc was used as the light source, the α-keto ester VI is probable to decompose with ease. Thus, the decrease in the ratio might be ascribed to the photo-decomposition of VI during the irradiation. In fact, a prolonged irradiation causes a great decrease in VI.

The question, however arises as to whether the formation of ethyl cyclohexanecarboxylate from the photochemical reaction is caused by the attack of a cyclohexyl radical on the ester function in ECG, or by the radical coupling of a cyclohexyl radical with an ethoxycarbonyl radical. If the ester function is attacked, diethyl oxalate, an analogue of ECG, can react with a cyclohexyl radical; if so, ethyl cyclohexanecarboxylate and/or ethyl cyclohexylglyoxylate must be formed. Therefore, the benzoyl peroxide-induced reaction of diethyl oxalate with cyclohexane was carried out. Ethyl cyclohexanecarboxylate and the keto ester VI, however, were not detected in the products, whereas bicyclohexyl was obtained. Thus, it was established that the carbonyl group of the ester function in ECG was not attacked by a cyclohexyl radical. As has been suggested in a previous report,[1] the ethoxycarbonyl radical from the photolysis of ethyl chloroformate has a life long enough to associate with a cyclohexyl radical in a solvent cage at room temperature; hence, the formation of ethyl cyclohexanecarboxylate in the present photochemical reaction might be explained in terms of a radical coupling:

(18)

Diethyl oxalate was produced in the photochemical reaction, but not in the peroxide-induced reaction. Dimerization of ethoxycarbonyl radicals can not account for the formation of diethyl oxalate, since we have shown that the radical has not a life long enough to dimerize.[1] It is most reasonable that diethyl oxalate is produced by the reaction of ECG with ethanol as is shown in the process 17. The ethanol might be generated by the disproportionation between ethoxy radicals and/or the hydrogen abstraction of an ethoxy radical from a hydrogen donor. Therefore, it is comprehensible that diethyl oxalate is not produced by the peroxide-induced reaction, which might not involve the generation of ethoxy radicals.

The irradiation of ECG in an excess of *cyclohexene* gave no detectable amounts of an acid chloride. The liquid products obtained showed strong infrared absorption bands assignable to an ester, while no bands corresponding to an acid chloride were observed. As has been shown in Table II, the products mainly consisted of ethyl cyclohexanecarboxylate and 3, 3′-bicyclohexenyl; the amount of cyclohexene-3-carboxylate was small. From these results, it may be concluded that a cyclohexen-3-yl radical has no ability to attack ECG under the present conditions. The results may be interpreted as follows:

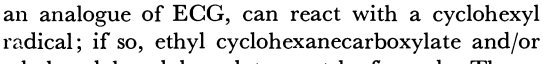
(19)

VII

(20)

(21)

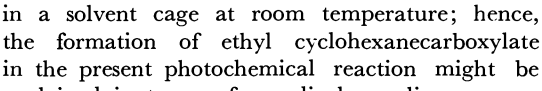
$R''=Cl$ and C_2H_5



(22)

(23)

When an excess of *cyclohexene* was used, VII might predominantly abstract an allylic hydrogen atom of cyclohexene and might have less chance to attack ECG. When a smaller amount of cyclohexene was used than that of ECG, some of the derivative of cyclohexane-1, 2-dicarboxylic acid, VIII, were obtained. It might, therefore, be considered that VII attacks ECG to yield the product VIII.



(24)

In the case of *toluene*, no significant amount of phenylacetyl chloride was formed. The liquid products from the photochemical reaction of ECG with toluene revealed strong bands of an ester in the infrared absorption spectra, whereas the absorption band at 1800 cm^{-1} was observed as the shoulder of the ester bands. Therefore, the amount of the acid chloride, if produced at all, was negligible. The above results suggest that a benzyl radical does not attack ECG, and the ethyl phenylacetate is formed via a radical-association reaction between a benzyl radical and an ethoxycarbonyl radical.

Experimental

Materials.—Cyclohexane, toluene, and diethyl oxalate were obtained commercially and purified in usual ways. Cyclohexene was prepared by the dehydration of cyclohexanol.[18] ECG was prepared by

18) G. H. Coleman and H. F. Johnstone, "Organic Syntheses," Coll. Vol. 1, 183 (1956).

the action of thionyl chloride on ethyl potassium oxalate according to the directions of Southwick.[19] The hydrocarbons were stored over sodium wire. All of the materials were distilled before use.

The Analysis of Gaseous Products and the Apparatus Used.—All of the photochemical reactions were carried out in a quartz tube (50 cm. long, 2 cm. in diameter) immersed in a water bath maintained at room temperature, and with a high pressure mercury arc (600 W.) mounted 1 cm. from the tube. The general procedures used for the analysis of gaseous and condensable products were identical with those described previously.[1] The ratios of the gaseous products were determined by gas chromatographic measurements under two sets of conditions (molecular-sieve 5A column: 2.5 m. at 63°C, and silica-gel column: 2.5 m. at 65°C). Under the former set of conditions, the ratio of carbon monoxide to ethane was determined, while that of carbon dioxide to C_2-hydrocarbons was measured under the latter set.

The gas-liquid chromatographic (g. l. c.) measurements of liquid products were carried out using a 5 mm. × 1 m. column packed with 5% of silicone DC 550 on Chromosorb (A) and a 5 mm. × 2 m. column packed with 5% of dioctyl sebatate on Chromosorb (B).

The Irradiation of ECG in Cyclohexane.—A mixture of ECG (18 g., 0.18 mol.) and cyclohexane (40 g., 0.5 mol.) was irradiated for 5 hr. in an atmosphere of nitrogen. During the course of the irradiation, 2500 cc. of neutral gases was evolved. After the irradiation, the evolution of gases had slowed sufficiently. After the unreacted cyclohexane (ca. 30 g.) had been removed from the irradiated mixture, the remaining oil was distilled under reduced pressure to yield the following fractions:

Fraction 1 (3 g.), b. p. 38—50°C/15 mmHg, which consisted largely of ECG, along with traces of ethylcyclohexane and cyclohexyl chloride, as determined by g. l. c. assay (A).

Fraction 2 (8 g.), b. p. 69—72°C/13 mmHg, which showed infrared absorption bands at 1790 (-COCl), 1770, 1750, and 1180 (-C(=O)-O-) cm^{-1}, and which was treated with aniline to give hexahydrobenzanilide, m. p. 143.5°C (Found: C, 76.52; H, 8.45. Calcd. for $C_{13}H_{17}ON$: C, 76.81; H, 8.43%).

After treatment with absolute methanol, the ratios of methyl cyclohexanecarboxylate to diethyl oxalate and to ethyl cyclohexanecarboxylate were determined by g. l. c. assay (A). Diethyl oxalate and ethyl cyclohexanecarboxylate were each contaminated less than 2%. It was confirmed that diethyl oxalate and ethyl cyclohexanecarboxylate in methanol were not cahnged significantly under the g. l. c. conditions.

Fraction 3 (1 g.), b. p. 103—113°C/13 mmHg, which showed infrared absorption bands assignable to an acid chloride (1790 cm^{-1}) and an ester (1730 and 1180 cm^{-1}). G. l. c. measurements (A) showed that this fraction consisted of ethyl cyclohexylglyoxylate, (ca. 0.7 g.), cyclohexanecarbonyl chloride (ca. 0.3 g.), and a trace of bicyclohexyl. The α-keto ester was identified by mixed melting point tests of its 2, 4-dinitrophenylhydrazone (2, 4-DNP), m. p. 159—159.5°C, which was recrystallized from ethanol (Found: C, 52.92; H, 5.53. Calcd. for $C_{16}H_{20}N_4O_6$: C, 52.74; H, 5.53%).

When the period of the irradiation described above was prolonged for 19 hr., a lower yield of the acid chloride (45%) was obtained, and the α-keto ester could not be isolated as its 2, 4-DNP, although its presence was confirmed by g. l. c. assay (A).

An authentic 2, 4-DNP of ethyl cyclohexylglyoxylate was prepared in the following way. The hydrogenation of mandelic acid on Adam's catalyst gave hexahydromandelic acid;[20] esterification with ethanol followed. A solution of ethyl hexahydromandelate (500 mg.) in acetic acid (50 ml.) was stirred with ice cooling, into which a solution of chromic acid (350 mg.) in acetic acid (50 ml.) was added drop by drop. After 5 hr. of stirring at room temperature, the evaporation of acetic acid in vacuo left a residue. To the residue there was added 100 ml. of water, and the aqueous solution was extracted three times with 100 ml. of ether. The etheral layer was washed with water, and dried over magnesium sulfate, and the solvent was evaporated in vacuo. The remainig, slightly yellow oil was treated with an aqueous solution of 2, 4-dinitrophenylhydrazine in 2 N hydrochloric acid, and then the resultant 2, 4-DNP was recrystallized from ethanol, m. p. 159.5°C (Found: C, 52.90; H, 5.55. Calcd. for $C_{16}H_{20}N_4O_6$: C, 52.74; H, 5.53%).

The Peroxide-induced Reaction of ECG with Cyclohexane.—A mixture of ECG (25 g., ca. 0.18 mol.) and cyclohexane (50 g., 0.6 mol.) containing benzoyl peroxide (2 g., 0.0083 mol.) was refluxed for 19 hr. at 84—85°C under an atmosphere of nitrogen. During the course of the reaction, 2000 cc. of neutral gases was evolved. After the unreacted cyclohexane (47 g.) and ECG (5 g.) had been removed, the remaining oil was distilled under reduced pressure to yield 8 g. of cyclohexanecarbonyl chloride, b. p. 68—72°C/15 mmHg, and 1.5 g. of ethyl cyclohexylglyoxylate, b. p. 112—115°C/15 mmHg. The former fraction showed no infrared absorption bands of esters. The fraction was converted to hexahydrobenzanilide, which was identified by a mixed melting point determination. The latter fraction showed strong bands of an ester and a moderate band of an acid chloride, and was found, by using a g. l. c. assay (A), to consist of ethyl cyclohexylglyoxylate (ca. 1.4 g.), cyclohexanecarbonyl chloride (ca. 0.1 g.) and a trace of bicyclohexyl.

The Peroxide-induced Reaction of Diethyl Oxalate with Cyclohexane.—A mixture of diethyl oxalate (17 g., ca. 0.12 mol.), cyclohexane (42 g., 0.5 mol.), and 2 g. of benzoyl peroxide was refluxed at 84—86°C for 26 hr. under an atmosphere of nitrogen. During the reaction, carbon dioxide was evolved. After the unreacted cyclohexane (38 g.) had removed, the remaining oil was distilled under reduced pressure to yield 15 g. of diethyl oxalate, b. p. 88—90°C/25 mmHg, and 2 g. of a fraction, b. p. 90—100°C/25 mmHg. The latter fraction was found, by g. l. c. assay (A), to consist largely of diethyl oxalate, plus a small amount of bicyclohexyl. No ethyl cyclohexanecarboxylate and ethyl cyclohexylglyoxylate could not be detected by g. l. c. assay (A).

20) H. A. Smith, D. M. Alderman, Jr., C. D. Schacklett and C. M. Welch, ibid., **71**, 3772 (1949).

The Irradiation of ECG in Cyclohexene.—The irradiation of a mixture of ECG (40 g., 0.3 mol.) and cyclohexene (60 g., 0.8 mol.) for 25 hr. gave 80 cc. of neutral gases, unreacted cyclohexene (55 g.) and ECG (30 g.), plus the liquid fractions described below:

Fraction 1 (2.5 g.), b. p. 85—88°C/15 mmHg, which showed infrared absorption bands at 1770 (shoulder), 1740, and 1180 cm^{-1}, but no bands at 1790—1800 (COCl), 3100 (=C-H), and 1670 (C=C) cm^{-1}. The g. l. c. analysis (B) indicated that this fraction consisted of ethyl cyclohexanecarboxylate (1.6 g.), diethyl oxalate (0.7 g.), and ethyl cyclohexene-3-carboxylate[21] (0.2 g.).

Fraction 2 (3 g.), b. p. 100—108°C/15 mmHg, which showed infrared absorption bands assignable to a double bond at 3100 and 1670 cm^{-1}, in addition to the bands of an ester. The g. l. c. analysis (A) showed that this fraction consisted of ethyl cyclohexanecarboxylate (0.5 g.) and 3, 3'-bicyclohexeneyl (2.5 g.).

The remaining brownish oil was refluxed with absolute ethanol, and then distilled to give two fractions. One fraction (0.3 g.), b. p. 120—140°C/15 mmHg, showed six peaks in the gas chromatogram (B). The other (0.7 g.), b. p. 140—155°C/15 mmHg, showed five peaks in the gas chromatogram (B); one of these peaks had the same retention time as that of diethyl hexahydrophthalate, but it was very small. Further investigations were not carried out.

A mixture of ECG (38 g., 0.31 mol.) and cyclohexene (4 g., 0.05 mol.) was irradiated for 2.5 hr., and then another 2 g. of cyclohexene was added into the irradiated mixture. The irradiation was continued for an additional 3.5 hr., and then 4 g. of cyclohexene was added. The mixture was further irradiated for 7 hr. After the unreacted ECG (30 g.) and cyclohexene had removed, the remaining oil was distilled under reduced pressure to yield the following fractions:

Fraction 1 (0.2 g.), b. p. 50—60°C/0.9 mmHg, was found to be a mixture of ethyl cyclohexanecarboxylate, diethyl oxalate, and 3, 3'-bicyclohexenyl.

Fraction 2, (2.5 g.), b. p. 80—110°C/0.9 mmHg, was hydrolyzed with ethanolic potassium hydroxyde, and then acidified to give ca. 1 g. of a solid, which, when recrystallized from water, was found to have a m. p. of 223—224°C. This solid showed no melting point depression upon admixture with authentic *trans*-hexahydrophthalic acid prepared according to the method of Price and Szwarc.[22] (Found: C, 55.44; H, 7.36. Calcd. for $C_8H_{12}O_4$: C, 55.80; H, 7.03%).

The Irradiation of ECG in Toluene.—The irradiation of a mixture of ECG (27 g., 0.2 mol.) and toluene (62 g., 0.67 mol.) for 41 hr. gave 50 cc. of neutral gases. After the unreacted ECG (22 g.) and toluene (55 g.) had been removed, the distillation of the remaining oil afforded 1.5 g. of a fraction, b. p. 110—130°C/17 mmHg, which showed infrared absorption bands at 1770, 1750, and 1180 cm^{-1}, while the band at 1800 cm^{-1} (COCl) was observed on the shoulder of the 1750—1770 cm^{-1} region. Aromatic absorption bands at 3030, 1610, 1010, and 710 cm^{-1} were also observed. When this fraction was analyzed by g. l. c. (A), it was shown to consist of diethyl oxalate (0.5 g.) and ethyl phenylacetate (1 g.). This fraction was hydrolyzed with aqueous sodium hydroxide, and the resultant acid was identified as phenylacetic acid by a mixed melting point determination, m. p. and mixed m. p. 76—77.5°C (Found: C, 70.76; H, 5.88. Calcd. for $C_8H_8O_2$: C, 70.57; H, 5.92%).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1931—1936 (1966)

Aminocyclitols. X. A Synthesis of Deoxyinosamine and Deoxyinosadiamine and Their Nuclear Magnetic Resonance Spectra

By Tetsuo SUAMI and Kenji YABE

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received November 9, 1965)

(±)-1-Deoxy-*muco*-inosamine-4, (±)-1-deoxy-*scyllo*-inosamine-2 and (±)-2-deoxy-*allo*-inosadiamine-3, 5 pentaacetates have been synthesized from 1-deoxy-*myo*-inositol (I). The hydroxyl groups of I are mesylated, and the mesyloxy groups are replaced by azido groups. The reduction of the azido compounds, followed by acetylation, gives the pentaacetyl-deoxyinosamines and deoxyinosadiamine. Their structures have been established by means of a study of the proton magnetic resonance spectra.

Although six deoxyinosamines have been described[1,6] recently, only one deoxyinosadiamine

1) M. Nakajima, A. Hasegawa and F. W. Lichtenthaler, *Ann.*, **680**, 21 (1964).

(deoxystreptamine) has been isolated from a biological origin (neomycin,[2] kanamycin,[3] paromomycin[4] and hygromycin B[5]).

In connection with previous papers of this series,[7] new deoxyinosamines and the deoxyinosadiamine have been synthesized, and their structures have been established by means of a study of the proton magnetic resonance spectra. In the present paper, (±)-1-deoxy-*myo*-inositol [(±)-*vibo*-quercitol] (I) is prepared by the method of McCasland et al.,[8] and then used as a starting material.

(±)-1-Deoxy-*muco*-inosamine-4.—I is heated in acetone in the presence of anhydrous zinc chloride and glacial acetic acid, and the product is subsequently acetylated to give (±)-4, 5, 6-tri-*O*-acetyl-1-deoxy-2, 3-isopropylidene-*myo*-inositol (II) in a 66% yield. Since the *O*-isopropylidene derivative of a vicinal glycol group on a six-membered ring is formed much more easily when the relationship between the hydroxyl group is cis than when trans,[9] the structure of II is assigned as described above; this assignment is confirmed by the further synthesis of the present study.

The *O*-isopropylidene group is easily removed by heating II in 80% aqueous acetic acid thus giving (±)-4, 5, 6-tri-*O*-acetyl-1-deoxy-*myo*-inositol (III) in a 55% yield. When III is reacted with one mole of methanesulfonyl chloride, (±)-4, 5, 6-tri-*O*-acetyl-1-deoxy-3-*O*-mesyl-*myo*-inositol (IV) is obtained in a 51% yield. IV is acetylated to give the tetra-*O*-acetyl derivative (V).

In a previous paper,[10] it has been described that methanesulfonyl chloride attacks an equatorial hydroxyl group selectively, rather than an axial one, in the *myo*-inositol derivative. Therefore, in the *vibo*-quercitol derivative, methanesulfonyl chloride is expected to behave in the same manner. This can be proved by establishing a structure of V, and the NMR spectrum gives an unequivocal confirmation of the structure. The NMR spectrum of V in deuteriochloroform, as Table I shows, exhibits a sharp signal at 6.99 τ which is ascribed to an equatorial mesyloxy group.[10] At 7.83, 7.93 and 7.97 τ, three sharp signals with a 1 : 1 : 2 intensity ratio appear; these signals are expected from one axial acetoxy group and three equatorial acetoxy ones.[11]

When V is treated with sodium azide in boiling aqueous 2-methoxyethanol for 51 hr., and subsequently acetylated with acetic anhydride in pyridine, (±)-4-azido-1, 4-dideoxy-*muco*-inositol tetraacetate (VI) is obtained in a 28% yield. The reduction of VI with Raney nickel in a hydrogen stream and subsequent acetylation give (±)-pentaacetyl-1-deoxy-*muco*-inosamine-4 (VII) in a 58% yield.

The structure of VII is substantiated by its NMR spectrum. The NMR spectrum in deuteriochloroform, as is given in Table I, exhibits three sharp signals, with a 2 : 1 : 1 intensity ratio, at 7.85, 7.96 and 7.98 τ; these signals correspond to two axial acetoxy groups (7.85 τ) and two equatorial ones (7.96 and 7.98 τ). There is also a sharp signal

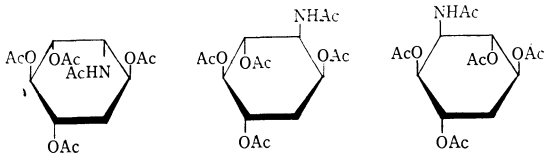
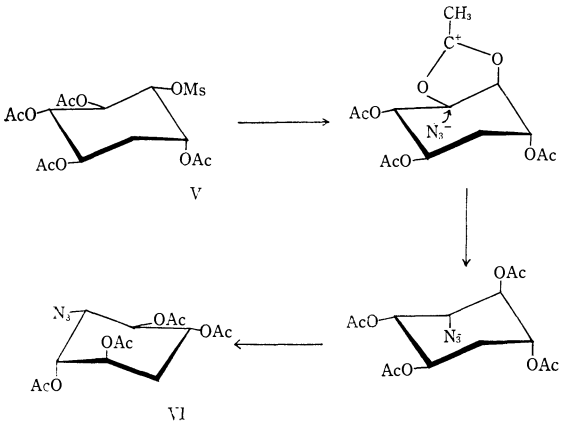
at 8.09 τ which is expected to be from an equatorial acetamido group. Considering the reaction process employed, there are three possible structures for VII: a, b, and c.



a b c

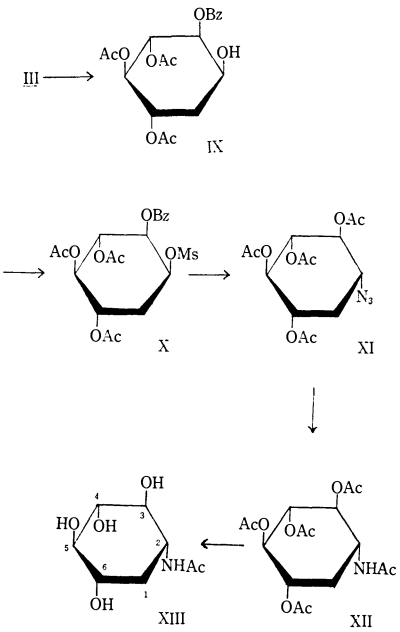
If the demesylation took place via a direct S_N2 mechanism, a would be obtained. b and c are anticipated only from an anchimeric mechanism, a neighboring-group participation. Since there is only one axial acetoxy group in both a and b, however a and b can be eliminated, and only c is compatible with the NMR spectrum. The possible mechanism of the reaction from V to VI is shown in the following scheme:



V VI

The elimination of the mesyloxy group takes place with a neighboring-group participation to form an intermediate acetoxonium ion, and then it is cleaved by an azide ion in a diaxial opening, as has been already observed in the replacement of the mesyloxy group in *myo*-inositol derivatives.[7]

(±)-1-Deoxy-*scyllo*-inosamine-2.—In analogy to the monomesylation of triacetyl deoxyinositol (III→IV), a selective monobenzoylation to the 3-*O*-benzoyl derivative should be possible under conditions analogous to those described in a previous paper.[7] When III is treated with one mole of benzoyl chloride in pyridine under ice cooling, the tri-*O*-acetyl-3-*O*-benzoyl derivative (IX) is obtained in a 58% yield. The mesylation of IX by an ordinary method gives (±)-4, 5, 6-tri-*O*-acetyl-3-*O*-benzoyl-1-deoxy-2-*O*-mesyl-*myo*-inositol (X) in a 87% yield. X is quite different in its physical properties from the (±)-4, 5, 6-tri-*O*-acetyl-2-*O*-benzoyl-1-deoxy-3-*O*-mesyl-*myo*-inositol (XIV) prepared by the benzoylation of IV. The NMR



IX X XI XIII XII

spectrum of X (Table I) reveals a sharp signal at 6.97 τ corresponding to an axial mesyloxy group, while that of XIV (Table I) exhibits a sharp signal shifted to a slightly higher field (6.99 τ), as is to be expected from an equatorial mesyloxy group. Therefore, this presents another example of how benzoyl chloride attacks an equatorial hydroxyl group preferentially.[7]

Then X is treated with sodium azide as described above to give an azido compound (XI), which is hydrogenated and subsequently acetylated to yield (±)-pentaacetyl-1-deoxy-*scyllo*-inosamine-2 (XII). The NMR spectrum of XII, as is shown in Table I, exhibits two sharp signals, with a 2 : 2 relative intensity, at 8.02 and 8.06 τ; these signals correspond to four equatorial acetoxy groups. There is also a sharp signal at 8.22 τ which is to be ascribed to an equatorial acetamido group.

Peak positions are given in τ values, and numbers in parentheses are relative intensities of the signals.

(±)-2-Deoxy-*allo*-inosadiamine-3, 5.— While III is treated with an excess amount of methanesulfonyl chloride in pyridine, the di-*O*-mesyl derivative (XV) is obtained in a 85% yield. The NMR spectrum of XV in deuteriochloroform, as is shown in Table I, exhibits two sharp signals, with equal intensities, at 6.82 and 6.89 τ for the protons of an axial and an equatorial mesyloxy group respectively.[10] Two sharp signals with a 1 : 2 relative intensity at 7.92 and 7.97 τ correspond to three equatorial acetoxy groups.[11]

When XV is heated with sodium azide in boiling aqueous 2-methoxyethanol for 41 hr. and subsequently acetylated by an ordinary method, diazido acetate (XVI) is obtained in a 17% yield. XVI is then hydrogenated in the presence of a catalyst in a hydrogen stream, and the reduction product is acetylated to afford pentaacetyl-deoxyinosadiamine (XVII) in a 68% yield. A selective de-*O*-acylation of XVII with ammonia in methanol yields the diacetamido derivative (XVIII). The structure of XVII is

substantiated by the NMR spectra of XVII in deuteriodimethyl sulfoxide and of XVIII in deuterium oxide. The NMR spectrum of XVIII, as is shown in Table I, shows two sharp signals, with equal intensities, at 7.92 and 7.98 τ, corresponding to an axial and an equatorial acetamido group respectively. The NMR spectrum of XVII, as may be seen in Table I, exhibits four sharp signals, at 7.90, 8.02, 8.13 and 8.23 τ (1 : 1 : 2 : 1), for the protons in an axial and an equatorial acetoxy group, another equatorial acetoxy group overlapped with an axial acetamido group, and an equatorial acetamido group respectively. Therefore, it might be reasonable to identify the structure of XVII as (±)-2-deoxy-*allo*-inosadiamine-3, 5. Considering the product obtained, the following reaction mechanism might be assumed: a mesyloxy group on C-3 is replaced by the participation of the neighboring acetoxy group in a trans position, thus forming an intermediate acetoxonium ion, and then the dioxolane-ring is attacked by a nucleophilic azide ion. The manner in which the ring is cleaved is considered to be the same diaxial opening described above and also observed in previous papers.[7,12] On the other hand, another mesyloxy group on C-2 might be replaced by an azide ion through a direct S_N2 mechanism. The behavior of the latter mesyloxy group is different from that of the mesyloxy group in an inositol derivative in an analogous situation;[7] this point must be studied further.

Experimental

The melting points were determined on a Mitamura Riken hot stage. The melting points marked with asterisks were measured in a liquid bath and are uncorrected. The NMR spectra of the samples were determined at a frequency of 60 Mc. p. s. with a Japan Electron Optics JNM-C-60 spectrometer in deuterium oxide, deuteriochloroform and deuteriodimethyl sulfoxide, using sodium trimethylsilylpropane-sulfonate or tetramethylsilane as an internal standard.

(±)-1-Deoxy-*myo*-inositol (I).—This substance was prepared from *myo*-inositol in a 30.4% yield by the method developed by McCasland et al.[8]

(±)-4, 5, 6-Tri-*O*-acetyl-1-deoxy-2 : 3-isopropylidene-*myo*-inositol (II).—A mixture of 10 g. of I, 50 g. of anhydrous zinc chloride, 50 ml. of glacial acetic acid and 400 ml. of acetone was heated to reflux for 36 hr. After the mixture had then cooled, 100 ml. of pyridine was added to the mixture and the precipitate was removed by filtration. The filtrate was evaporated under reduced pressure and the residue was acetylated overnight in a mixture of 60 ml. of acetic anhydride and 40 ml. of pyridine. After the precipitate had been removed, 150 ml. of chloroform was added to the filtrate. Then the solvent layer was washed with cold water, a 5% sodium carbonate solution and cold water successively. The solvent was evaporated, after drying over anhydrous sodium sulfate, to give 22 g. of an oily residue. The resiude was added to 300 ml. of ligroin and kept in a refrigerator overnight, thus yielding 14.7 g. of the crude product. The crude product was recrystallized from petroleum ether to give 12.8 g. (66.4%) of needles. m. p. *80—82°C. An analytical sample was obtained by a further recrystallization from petroleum ether. m. p. *82—83°C.

Found: C, 54.31; H, 6.62. Calcd. for $C_{15}H_{22}O_8$: C, 54.54; H, 6.71%.

(±)-4, 5, 6-Tri-*O*-acetyl-1-deoxy-*myo*-inositol (III).—A mixture of 2.3 g. of II and 100 ml. of 80% acetic acid was heated on a boiling water bath for two hours, and then evaporated under reduced pressure. The solid residue was recrystallized from ethanol to yield 1.3 g. of a crude product. The product was recrystallized from 5 ml. of ethanol, thus affording 1.1 g. (54.5%) of an analytically-pure product melting at 170—171°C.

Found: C, 49.70; H, 6.21. Calcd. for $C_{12}H_{18}O_8$: C, 49.65; H, 6.25%.

(±)-4, 5, 6-Tri-*O*-acetyl-1-deoxy-3-*O*-mesyl-*myo*-inositol (IV).—To a solution of 5.1 g. of III in 50 ml. of pyridine, 2.0 g. of methanesulfonyl chloride was added drop by drop under agitation at 0—5°C. After the solution had been stirred for two hours, it was left to settle in a refrigerator overnight. The crystals were then collected by filtration, 3.3 g. (50.9%) of the crude product, m. p. 131—131.5°C were thus obtained. An analytical sample was obtained by recrystallization from ethanol. m. p. 131—132°C.

Found: C, 42.54; H, 5.55; S, 8.31. Calcd. for $C_{13}H_{20}O_{10}S$: C, 42.39; H, 5.47; S, 8.70%.

(±)-2, 4, 5, 6-Tetra-*O*-acetyl-1-deoxy-3-*O*-mesyl-*myo*-inositol (V).—A 1.6 g. portion of IV was acetylated with acetic anhydride and pyridine. The crude product was recrystallized from ethanol to give 1.7 g. (95.4%) of crystals melting at *171—172°C.

Found: C, 43.97; H, 5.33; S, 7.78. Calcd. for $C_{15}H_{22}O_{11}S$: C, 43.90; H, 5.40; S, 7.81%.

(±)-2, 3, 5, 6-Tetra-*O*-acetyl-4-azido-1, 4-dideoxy-*muco*-inositol (VI).—A mixture of 0.5 g. of V, 0.25 g. of sodium azide and 30 ml. of 80% aqueous 2-methoxyethanol was heated to reflux for 51 hr. After the solvent had then been removed, a residue was acetylated with acetic anhydride and pyridine. The excess of the reagent was removed, and the residue was dissolved in 2 ml. of ethanol to yield 0.21 g. of the crude product. The crude product was recrystallized from ethanol to give 0.12 g. (27.6%) of crystals melting at 143—144°C.

Found: C, 47.28; H, 5.38; N, 11.63. Calcd. for $C_{14}H_{19}N_3O_8$: C, 47.06; H, 5.36; N, 11.76%.

(±)-Pentaacetyl-1-deoxy-*muco*-inosamine-4 (VII).—A 0.30 g. portion of VI was hydrogenated in 50 ml. of ethanol with Raney nickel T4[13] under a stream of hydrogen (50 p. s. i. g.). After the catalyst had then been removed, the solution was evaporated under reduced pressure. The residue was acetylated to yield 0.22 g. of the product. The crude product was recrystallized from ethanol to give 0.18 g. (57.5%) of plates melting at *215—216°C.

Found: C, 51.63; H, 6.38; N, 3.80. Calcd. for $C_{16}H_{23}NO_9$: C, 51.47; H, 6.21; N, 3.75%.

The hydrolysis of VII with 6 N hydrochloric acid for 6 hr. at 100°C gave the hydrochloride, which showed

12) T. Suami and S. Ogawa, This Bulletin, **38**, 2026 (1965).

13) S. Nishimura, This Bulletin, **32**, 61 (1959).

a single spot of R_f 0.25 (R_f of D-glucosamine hydrochloride: 0.27) in ascending paper chromatography in an acetic acid - ethyl acetate - pyridine - water (1 : 5 : 5 : 3) system[14] at 18—20°C. R_f/R_f glucosamine: 0.94.

(±)-*N*-Acetyl-1-deoxy-*muco*-inosamine-4 (VIII).—The selective de-*O*-acetylation of 0.63 g. of VII in methanol saturated with ammonia gave 0.17 g. of a crude product. The product was recrystallized from ethanol to yield 0.11 g. (32.6%) of crystals melting at 192—193°C.

Found: C, 46.61; H, 7.54; N, 6.69. Calcd. for $C_8H_{15}NO_5$: C, 46.82; H, 7.37; N, 6.83%.

(±)-4, 5, 6-Tri-*O*-acetyl - 3 - *O* -benzoyl - 1 - deoxy-*myo*-inositol (IX).—To a solution of 6.3 g. of III in 40 ml. of pyridine, 3.3 g. of benzoyl chloride was added drop by drop under ice cooling with agitation. After the mixture had settled at room temperature overnight, it was poured into 300 ml. of ice-cold water to give a precipitate which was then collected by filtration. The crude product was recrystallized from 100 ml. of ethanol to give 5.0 g. (58.2%) of crystals melting at *185—187°C.

Found: C, 57.85; H, 5.54. Calcd. for $C_{19}H_{22}O_9$: C, 57.86; H, 5.62%.

(±)-4, 5, 6-Tri-*O*-acetyl-3-*O*-benzoyl - 1 - deoxy-2-*O*-mesyl-*myo*-inositol (X).—A 3.1 g. portion of methanesulfonyl chloride was added to a solution of 7.1 g. of IX in 50 ml. of pyridine under ice cooling with agitation. Then the mixture was poured into ice-cold water to give 7.8 g. of a precipitate. The crude product was recrystallized from ethanol to give 7.4 g. (87.0%) of plates melting at 175—176°C.

Found: C, 50.65; H, 5.19; S, 6.83. Calcd. for $C_{20}H_{24}O_{11}S$: C, 50.84; H, 5.12; S, 6.79%.

(±)- 3, 4, 5, 6-Tetra-*O*-acetyl-2-azido-1, 2-dideoxy-*scyllo*-inositol (IX).—A mixture of 2.2 g. of X, 0.6 g. of sodium azide and 60 ml. of 80% aqueous 2-methoxyethanol was heated to reflux for 64 hr. Then the mixture was treated as has been described in the preparation of VI to give 1.0 g. of the crude product, which was then recrystallized from ethanol, giving 0.9 g. (55.1%) of needles melting at 137—138°C.

Found: C, 47.28; H, 5.35; N, 11.89. Calcd. for $C_{14}H_{19}N_3O_8$: C, 47.06; H, 5.36; N, 11.76%.

(±) - Pentaacetyl - 1 - deoxy - *scyllo*- inosamine-2 (XII).—A 0.95 g. portion of XI was hydrogenated in 30 ml. of ethanol with Raney nickel T4,[13] and then the reduction product was treated as has been described in the preparation of VII to give 0.51 g. of the crude product melting at 226—227°C. The crude product was recrystallized from ethanol to give 0.32 g. (32.7%) of crystals melting at 226—227°C.

Found: C, 51.57; H, 6.03; N, 3.61. Calcd. for $C_{16}H_{23}NO_9$: C, 51.47; H, 6.21; N, 3.71%.

Paper Chromatography.—The hydrochloride of XII was prepared and developed in paper chromatography using the procedure described above. It showed a single spot of R_f 0.14. R_f/R_f glucosamine: 0.52.

(±)-*N*-Acetyl-1-deoxy-*scyllo*-inosamine-2 (XIII).—The selective de-*O*-acetylation of 0.22 g. of XII by ammonia in methanol yielded 0.10 g. of the crude product, which was then recrystallized from a mixture of benzene and methanol to give 0.08 g. (72.7%) of crystals melting at 205—206°C.

Found: C, 47.31; H, 7.43; N, 6.63. Calcd. for $C_8H_{15}NO_5$: C, 46.82; H, 7.37; N, 6.83%.

(±)-4, 5, 6-Tri-*O*-acetyl-2-*O*-benzoyl - 1 - deoxy - 3-*O*-mesyl-*myo*-inositol (XIV).—A 0.6 g. portion of benzoyl chloride was added to a solution of 0.78 g. of IV in 20 ml. of pyridine; the mixture was then warmed for 30 min. and left to stand overnight at room temperature. Then the mixture was poured into ice-cold water to give 0.29 g. of needles melting at 151—152°C. For analysis the product was recrystallized twice from ethanol; yield, 0.17 g. (17.0%); m. p. 159—160°C.

Found: C, 50.97; H, 4.95; S, 6.39. Calcd. for $C_{20}H_{24}O_{11}S$: C, 50.84; H, 5.12; S, 6.79%.

(±)-4, 5, 6-Tri-*O*-acetyl-1-deoxy-2, 3-di-*O*-mesyl-*myo*-inositol (XV).—To a solution of 5.7 g. of III in 50 ml. of pyridine, 5.7 g. of methanesulfonyl chloride was added drop by drop with agitation at 0—5°C. After settling overnight in a refrigerator, the solution was poured into one liter of ice-cold water to obtain crystals, which were then collected by filtration. Yield, 7.4 g. (84.6%); m. p. 179—182°C. An analytical sample was obtained by recrystallizations from ethyl acetate. m. p. 181—182°C.

Found: C, 37.86; H, 4.80; S, 14.53. Calcd. for $C_{14}H_{22}O_{12}S_2$: C, 37.66; H, 4.97; S, 14.36%.

(±)-1, 4, 6 - Tri-*O*-acetyl-3, 5 - diazido - 2, 3, 5 - trideoxy-*allo*-inositol (XVI).—A mixture of 1.35 g. of XV, 1.2 g. of sodium azide and 40 ml. of 80% aqueous 2-methoxyethanol was heated to reflux for 41 hr. Then the mixture was treated as has been described in the preparation of VI to give 0.17 g. (16.5%) of crystals melting at 133—133.5°C.

Found: C, 42.61; H, 4.80; N, 24.45. Calcd. for $C_{12}H_{16}N_6O_6$: C, 42.35; H, 4.74; N, 24.70%.

(±)-Pentaacetyl-2-deoxy-*allo*- inosadiamine - 3, 5 (XVII).—A 1.03 g. portion of XVI was hydrogenated much as has been described in the preparation of VII to give 0.70 g. (67.6%) of crystals melting at *290—291°C.

Found: C, 51.40; H, 6.49; N, 7.43. Calcd. for $C_{16}H_{24}N_2O_8$: C, 51.60; H, 6.50; N, 7.52%.

XVII was hydrolyzed with 6 N hydrochloric acid, and the hydrochloride was developed by paper chromatography. The hydrochloride showed a single spot of R_f 0.14 at 18—20°C. R_f/R_f glucosamine: 0.52.

(±)-*N*, *N'*-Diacetyl - 2 - deoxy-*allo*-inosadiamine-3, 5 (XVIII).—The selective deacetylation of 0.53 g. of XVII as has been described in the preparation of VIII gave 0.16 g. (45.3%)of needles melting at 251—252°C.

Found: C, 49.00; H, 7.12; N, 11.25. Calcd. for $C_{10}H_{18}N_2O_5$: C, 48.77; H, 7.37; N, 11.38%.

The authors wish to thank Professor Sumio Umezawa for his helpful advice; Mr. Saburo Nakada and Miss Sumiko Uchida for their elemental analyses; Mr. Tatsuo Ishikawa for his technical assistance, and the Japan Electron Optics Co., Ltd., and the Research Laboratories of the Tanabe Seiyaku Co. for their measurements of the NMR spectra. This research has been supported in part by a grant of the Ministry of Education, to which the authors' thanks are also due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1937—1941 (1966)

Solvent and Steric Effects on the Solvolysis of Polyvinylsulfonic Acid Esters[1]

By Sadao Yoshikawa, Oh-Kil Kim and Takeshi Hori

Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received November 16, 1965)

The solvolysis of ethanesulfonic acid esters followed closely first-order kinetics, while the case of polyvinylsulfonic acid esters gave strongly-curved first-order plots according to the solvent composition. With a high acetone content, the solvolysis rates of polymeric sulfonic esters decreased gradually with the lapse of time, while in a high water content, the solvolysis was suppressed at the beginning of the reaction but was accelerated remarkably with the reaction time. The former finding indicates the release from the steric congestion which contributed to the initial rate enhancement, while the latter indicates the aggregation of the polymer molecules owing to their strong hydrophobic character. The solvolysis rates, k_p, for polymeric sulfonic esters were much greater than those, k_m, for monomeric analogs in all cases except isopropyl and *n*-butyl esters in 20% aqueous acetone. The relative rate (k_p/k_m) increased with an increase in the acetone content and was apparently greater with the methyl ester than with the other esters, and the value of (k_p/k_m) in relation to the methyl ester in 80% acetone content reached 15. Furthermore, it was found that the proton catalysis by the neighboring sulfonic acid formed on the lapse of reaction time was absent, and also that the salt effect was negligibly small.

In previous papers[2] we have discussed the specific catalytic effects of polymeric sulfonic acids in the hydrolysis of esters in regard to the expansion of the polymer in solutions and to the geometrical distances between the nearest neighboring sulfonic acid groups on the polymer chain. It is the aim of the present paper to study the solvolysis of polyvinylsulfonic acid esters in various compositions of acetone-water mixtures in order to verify the previous assumption. Four kinds of polyvinylsulfonic esters were used: methyl, ethyl, isopropyl and *n*-butyl esters, the respective alkyl ethanesulfonates as the monomeric analog were also employed for the sake of comparison. While there has been no systematic study of the solvolytic reaction of the sulfonic esters comparable to the work on the organic halides, it has generally been accepted that the mechanism of the displacement involves the scission of the C–O bond, except for the special case of the phenyl ester,[3] which is known to be an S_N1-S_N2 borderline mechanism.[4]

Alkyl esters of sulfonic acids are much more reactive than alkyl bromide towards water, as a result of the greater strength of the sulfonic acid group.[5] Changes in the ester alkyl group, the solvent and the nucleophilic reagent alter the conditions, for example, from those favoring an S_N2 mechanism to those favoring the S_N1 mechanism; the substitution of α-alkyl groups increases the ionization tendency, so that in solvents of a high water content, the solvolytic reaction of the isopropyl ester of sulfonic acid is unaffected by hydroxide ions.[6]

The rates of the solvolysis of sulfonic esters as well as of alkyl halides are also dependent on the nature of the leaving group.[7] The case where the leaving group has a polymer chain has, however, hardly ever been studied.[8] A peculiar polymeric effect was found in this solvolytic reaction of polymeric sulfonic esters.

Experimental

Monomers.—A series of alkyl esters of vinylsulfonic acid was prepared by the method of Whitmore and Landau.[9] From 125 g. (1.0 mol.) of sodium sulfite and 285 ml. (3.30 mol.) of ethylene dibromide, there was obtained 275 g. of crude sodium β-bromoethanesulfonate, which, with 150 g. (0.73 mol.) of phosphorus pentachloride, yield 130.3 g. (65%) of β-bromoethanesulfonyl chloride (n_D^{20} 1.5242; b. p. 85°C/3 mmHg).

9) W. F. Whitmore and E. F. Landau, ibid., **68**, 1797 (1946).

Methyl, ethyl, isopropyl and *n*-butyl vinylsulfonates were prepared from 0.11 mol. of β-bromoethanesulfonyl chloride and 0.1 mol. of the corresponding alcohol in the presence of pyridine. The sulfonic esters were redistilled immediately before use.

Polymers.—All the polyvinylsulfonic acid esters were prepared by the bulk polymerization of their respective monomers with γ-irradiation: ten grams of the monomer were poured into an ampoule and evacuated to 1 mmHg; the evacuation and pressuring with nitrogen repeated, and then it was sealed. The polymerization was carried out by exposing it to a ^{60}Co source yielding about 2×10^5 r./hr. for 72 hours at 0°C. The degree of polymerization was determined by the saponification of the polymers with sodium hydroxide into the respective poly-(sodium vinylsulfonate), which was precipitated from 70% methanol and dried in vacuo over phosphorus pentoxide; the value of the intrinsic viscosity[10] of respective poly-(sodium vinylsulfonate) in 0.5 N sodium chloride at 20°C was 10.0 ($\overline{M}_n=13000$) for the methyl ester, 8.2 ($\overline{M}_n=9400$) for the ethyl ester, 9.2 ($\overline{M}_n=11000$) for the isopropyl ester and 2.8 ($\overline{M}_n=1800$) for the *n*-butyl ester.

Other Materials.—Four alkyl (methyl, ethyl, isopropyl and *n*-butyl) ethanesulfonates were prepared from ethanesulfonyl chloride,[11] made from sodium ethanesulfonate[12] and phosphorus pentachloride, and the corresponding sodium alkoxide by modifying the method of Carius.[13] The esters so prepared were colorless liquids having the following boiling points: the methyl ester, 70—72°C/7 mmHg; the ethyl ester, 70—72°C/5 mmHg; the isopropyl ester, 71—73°C/5 mmHg; the *n*-butyl ester, 88—91°C/6 mmHg. The purity of the esters were ascertained by the value of saponification.

Solvolysis Procedure.—The concentrations of all the esters of sulfonic acids were initially adjusted to 7.5×10^{-3}, 1.2×10^{-2} and 3.0×10^{-2} mol./l. in acetone. The reaction mixture was prepared from 8 ml. of the adjusted 7.5×10^{-3} mol./l. ester and 2 ml. of water added from a microburette to make up an 80% acetone solution (v/v); from 5 ml. of the 1.2×10^{-2} mol./l. ester and 5 ml. of water to make up a 50% acetone solution, and from 2 ml. of the 3.0×10^{-2} mol./l. ester and 8 ml. of water to make up a 20% acetone solution. Five or six samples were employed in each run, and each sample, made up from 10 ml. of the mixture, was placed in a glass-stoppered tube placed in a thermostat regulated to 45±0.01°C. The reaction was followed by withdrawing samples from the bath at suitable intervals, and by titrating the liberated sulfonic acid with 0.02 N standard sodium hydroxide using a phenolphthalein indicator. The rate constants, *k*, for hydrolysis were calculated from the simple first-order equation and the individual rate constants in each run were averaged over the range of approximately 40—50% of the reaction.

Results and Discussion

The solvolysis of ethanesulfonic esters followed first-order kinetics closely as is exemplified in Table I, while those of polyvinylsulfonic acid esters obviously deviated from first-order kinetics depending upon the compositions of the acetone-water mixtures, as is illustrated in Figs. 1, 2, 3 and 4. A common tendency is seen in these figures; polyvinylsulfonic acid esters were solvolyzed more slowly with an increase in the acetone content of the mixed solvents as well as in the cases of monomeric sulfonic ester. The effect of adding water to acetone

is to increase the ionizing ability of the solvent and, thereby, to accelerate the solvolytic reaction, which depends on the stabilization of partial charges in the transition state.

However, in 20% acetone, an unusual phase was found in the solvolysis of polymeric esters. At the beginning of the reaction, the solvolysis rate was suppressed, but it was gradually accelerated remarkably with the lapse of time. Thus different aspects of the solvolytic behavior of polymeric sulfonic esters in a high water content are of interest when discussing the reactivity of the polymer in relation to the expansion in solutions rather than to the change in the reaction mechanism.

The solvolysis rates of polymeric sulfonic esters were much greater than that of the monomeric analog in all cases except those of isopropyl and *n*-butyl esters in 20% aqueous acetone. The relative rate between the polymeric ester and the monomeric analog (k_p/k_m) increased in proportion to an increase in the acetone content. It is also important to note that the ratios of the solvolytic rates between the methyl ester and other esters, $(k_R/k_{Me})_m$ for the monomeric analog and $(k_R/k_{Me})_p$ for the polymeric ester (Table II), decrease with the magnitude of ester alkyl except in the case of the isopropyl ester (because of its well-known high polar causes). The decrease in $(k_R/k_{Me})_m$ may be due mainly to the different polarity on the C–O bond which includes a alkyl group, while the decrease in $(k_R/k_{Me})_p$ may be due mainly to the differences in the polar and hydrophobic characters of the alkyl group on the polymer chain, since the steric factors of ethyl and *n*-butyl groups are considered to be of nearly the same magnitude.

Therefore, the relative value $(k_R/k_{Me})_p/(k_R/k_{Me})_m$ indicates the relative hydrophobic factor of the alkyl group of each polymeric ester in a

certain solvent composition. The values decrease with the number of alkyl carbon atoms and gradually increase with an increase in the acetone content of mixed solvents. Such changes in the relative values suggest the major importance of the expansion of polymers in solutions. This undoubtedly suggests that, in a solution of a high water content, the random-coiled molecules of the polymeric ester, especially isopropyl and *n*-butyl esters, are greatly aggregated, where the solvent ratio in the immediate neighborhood of the macromolecule may differ considerably from the bulk-average composition of the medium compared to their corresponding differences in other compositions of the solvent; that the conformational movements of the polymer are restricted by their strong hydrophobic character, and that, hence, the reaction probably occurs mainly on the outer layer of the random-coiled molecule.

This interpretation is clearly supported by the illustrations given in Figs. 5, 6, 7 and 8, where the

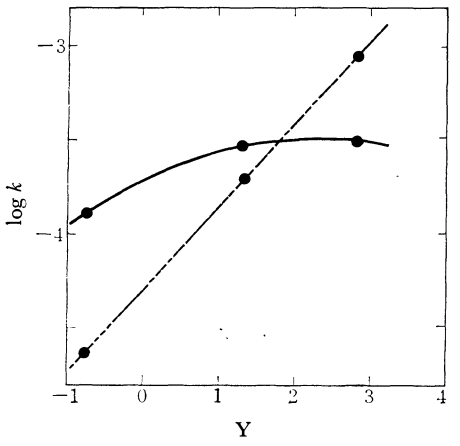

Fig. 8. Solvolysis rates of *n*-butyl ethanesulfonate (dotted line) and *n*-butyl polyvinylsulfonate (solid line) as a function of ionizing power Y.

Grunwald-Winstein correlation[14] is given:

$$\log k = mY + \log k_0$$

where Y is the measure of the ionizing power[15] of the solvent; k_0 is the rate of solvolysis in the standard solvent, and the slope m measures the susceptibility of the substrate to the ionizing power of the solvent. While the solvolysis of ethanesulfonic acid esters gives a linear correlation in Y, that of polymeric sulfonic esters deviates from linearity much more remarkably with the number of alkyl carbon atoms. The reaction rates were, however, accelerated by increasing the hydrophilic character of the polymer because of the sulfonic acid groups formed during the lapse of the reaction time.

On the other hand, the initial rate enhancement in the solvolysis of the polymeric ester in solvents of higher acetone contents may account for the major importance of the steric acceleration arising from the steric congestion by hydrophobic solvation on the polymer chain. This interpretation is also supported by the fact that solvolysis rates of polymer in 50% and 80% aqueous acetone (with the exception of 20% aqueous acetone, for the reason mentioned before) gradually became lower as a result of the release from the congestion between the immediate-neighboring alkyl groups with the lapse of reaction time. Steric assistance has been called[16] upon to explain the abnormally fast rate of the solvolysis of highly-branched tertiary alkyl halides. Such a phenomenon was also found in the solvolysis of cycloalkyl tosylate[17]; the solvolysis is accelerated by the steric interference of γ-opposed hydrogen with the tosylate group called non-bonding repulsion.

Furthermore, the ratio of the solvolysis rates between the series of alkyl polyvinylsulfonate and the corresponding ethanesulfonate (k_p/k_m), which indicates a positive polymeric effect, was much greater with the methyl ester than with the other esters and increased upon an increase in the acetone content of the mixed solvents in each run; the value of (k_p/k_m) towards the methyl ester in 80% acetone content attained 15, as is shown in Table II. These observations can be interpreted to suggest that the change in (k_p/k_m), which is dependent upon the alkyl structures of the polymer and the solvent compositions, involves a difference in the affinity of a substrate to a solvent. This may, in turn, cause the difference in the expansion or conformational movements of the polymer molecule.

A supplementary experiment was carried out with a partially-hydrolyzed polymeric ester to assure the absence of proton catalysis by the neighboring sulfonic acid present on the polymer chain. For example, initially 34% hydrolyzed *n*-butyl polyvinylsulfonate was hydrolyzed under the same conditions except that the solvent composition was 45% aqueous acetone; the rate constant was 3.09×10^{-4} (min^{-1}), which demonstrates that there is no intramolecular proton effect. Furthermore, the effect of added common and uncommon ions with both the polymeric ester and the monomeric analog in various systems showed the salt effect to be negligibly small for the noted concentration. The lack of sensitivity in the solvolyzing arylsulfonic esters (even in esters reacting by an apparent S_N1 mechanism) to the salt effect has also been noted by others.[4,18] In addition, solvolytic reactions of vinylsulfonic acid esters were also carried out in order to compare them with those of ethanesulfonic esters. The hydrolysis rates of the former were almost twice as much as the latter; the rate constants of methyl, isopropyl and *n*-butyl vinylsulfonates in 50% aqueous acetone at 45°C were 1.34×10^{-3}, 9.88×10^{-3} and 3.79×10^{-3} respectively. This magnitude in rates can be expected to result from the inductive electron withdrawal of the vinyl group.

Molecular Rearrangement in Polyphosphoric Acid. II. The Conversion of 1, 2-Dihydro-2-phenylimino-4*H*-3, 1-benzoxazin-4-one to 3-phenyl-2, 4(1*H*, 3*H*)-quinazolinedione[1,2]

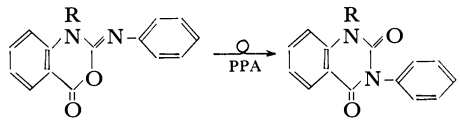
By Masaru KURIHARA and Naoya YODA

Basic Research Laboratories, Toyo Rayon Co., Ltd., Tebiro, Kamakura

(Received November 18, 1965)

The treatment in polyphosphoric acid of the *N*-(phenylcarbamoyl)-anthranilic acid prepared by the reaction of anthranilic acid with phenyl isocyanate has been shown to yield 1, 2-dihydro-2-phenylimino-4*H*-3, 1-benzoxazin-4-one or 3-phenyl-2, 4(1*H*, 3*H*)-quinazolinedione, depending on the reaction temperature. An intramolecular rearrangement has been found to occur by the treatment of exocyclic iminobenzoxazinone with polyphosphoric acid to afford quinazolinedione. The mechanisms of conversion in polyphosphoric acid have been proposed to account for the experimental results, and the structure of 2-phenylimino-4*H*-3, 1-benzoxazin-4-one has been presumed by means of infrared and ultraviolet spectroscopies and elemental analyses. The products of the reaction of *N*-methylanthranilic acid with phenyl isocyanate have been shown to be 1-methyl-3-phenyl-2, 4(1*H*, 3*H*)-quinazolinedione, 1-methyl isatoic anhydride and *N*-methyl-2-(phenylcarbamoyl)-carbanilide. Furthermore, the formation of the mixed anhydride of carboxylic acid and phosphoric acid as a reaction intermediate has been postulated.

The most frequently reported use of polyphosphoric acid is cyclodehydration, or more specifically, intramolecular acylation.[3,4] To our knowledge no studies have been carried out in polyphosphoric acid on the conversion of compound I to quinazolone derivatives II. In connection with the solution polymerization, in polyphosphoric acid, of 4, 4'-diamino-biphenyl-3, 3'-dicarboxylic acid with diisocyanate by cyclopolycondensation reactions,[5] the cyclodehydration of *N*-(phenylcarbamoyl)-anthranilic acid in polyphosphoric acid[6] was studied; two condensation products, 1, 2-dihydro-2-phenylimino-4*H*-3, 1-benzoxazin-4-one (Ia) and 3-phenyl-2, 4(1*H*, 3*H*)-quinazolinedione (IIa) have been isolated, depending upon the reaction temperature. The authors also found that the intramolecular rearrangement in PPA of Ia to IIa occurs by heating Ia at 150°C through a phosphorylated reaction intermediate.



I II

(Ia R=H) (IIa R=H)
(Ib R=CH_3) (IIb R=CH_3)

In a previous paper[2] it has been shown that the reaction of anthranilic acid with aromatic isocyanate in the presence of PPA proceeded to the formation iminobenzoxazinone and quinazolinedione by way of phosphorylated intermediates. This type of rearrangement in PPA is especially notable because a possible mechanism for the cyclodehydration in PPA of *N*-(phenylcarbamoyl)-anthranilic acid involves phosphorylated reaction intermediates,[4] while the reaction in PPA afforded I and II, the former product arising from the presumed intermediate, V, via kinetic control, while the latter product was formed from V via thermodynamic control. The method of the synthesis of benzoxazinone (I), quinazolinedione (II) and related compounds is outlined in Scheme 1.

When *N*-(phenylcarbamoyl)-anthranilic acid (m. p. 186°C; from ethanol) is treated with PPA at 80—100°C for 1 hr., cyclodehydration occurs, thus yielding quantitatively 1, 2-dihydro-2-phenylimino-4*H*-3, 1-benzoxazin-4-one (Ia) (m. p. 193°C;

from chloroform), possibly through a phosphorylated reaction intermediate V. The OPO_3 fragment represents the phosphoric acid moiety, which is of an indefinite composition. A similar compound of phosphoric-carboxylic mixed anhydride was recently prepared by the reaction of silver dibenzyl phosphate with an alkyl chloroformate.[7] Conversion is effected by the treatment of Ia with PPA at 150°C for 1 hr.; this results in the formation of 3-phenyl-2, 4(1*H*, 3*H*)-quinazolinedione (IIa) (m. p. 281°C from ethanol) in an 80% yield.[8] The presumed reaction intermediate VIa is formed by the phosphorylation of the carbonyl group of benzoxazinone (Ia) in PPA, followed by ring opening to Va and recyclization, thus yielding quinazolinedione (IIa) by losing the polyphosphoric acid species. The direct cyclodehydration of *N*-(phenylcarbamoyl)-anthranilic acid is also effected by treatment with PPA at 150°C for 5 hr., thus affording quinazolinedione (IIa). When anthranilic acid was treated with an excess amount of phenyl isocyanate in bulk, 2-(phenylcarbamoyl)-carbanilide (IVa) was obtained quantitatively.[2,8d] The phosphorylation mechanism is supported by the experimental evidence of the polymerization reaction of 4, 4'-diamino-biphenyl-3, 3'-dicarboxylic acid with phenyl diisocyanate in PPA and by the successful isolation of the corresponding *phosphoric-carboxylic anhydride of polyurea acid.* The structure was determined by analyses of the phosphorus content by means of both colorimetry and emission X-ray measurements.

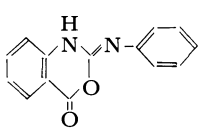
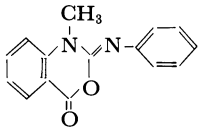
carbonyl absorption of Ia shows a bathochromic shift of 13 cm^{-1} as compared with the carbonyl absorption of the endocyclic C=N structure (IX); it is presumed that the exocyclic C=N structure is resonance stabilized because of the hybridization of π-electron orbitals of the C=N double bond with the phenyl group. The apparent stability of *N*-phenyliminobenzoxazinone (Ia) by resonance stabilization is supported by the fact that *N*-phenyliminobenzoxazinone (Ia) was isolated as a crystalline solid, whereas *N*-methyl imino and *N*-ethylimino derivatives are not stable enough to be isolated at 40—80°C; their presence was detected by thin-layer chromatography and by a study of the infrared spectrum at lower temperatures. The infrared data of these compounds will be compared elsewhere.

The absorption characteristics and the intensities of the ultraviolet spectra of benzoxazinone (Ia) and related compounds are summarized in Table I. The C=N double bond exhibits two characteristic absorption maxima in the 275—295 mμ range. The endocyclic C=N double bond of the VIII structure shows characteristic peaks at 285 and 298 mμ, and the Schiff base, *N*-benzylmethylene-2-phenylenediamine (X) has two characteristic C=N absorptions, at 275 and 282 mμ.[15] In the spectrum of benzoxazinone (Ia), characteristic maxima of the C=N bond are found at 282 mμ (9200) and 292 mμ (8600). Although the model compounds described in Table I, Fig. 1 and Fig. 2 may not represent exactly the fine structure of Ia, conclusive evidence was obtained by the direct comparison of the characteristic absorption bands of the infrared and ultraviolet spectra of Ia with those of Ib; these peaks of the C=N bond may be assigned to the exocyclic C=N bond on the basis of both the spectral comparison and the chemical reactivity of the compound Ia towards phenyl isocyanate.



(Ia)



(Ib)

They show a bathochromic effect in the following increasing order (as is shown in Table I, the hyperchromic effect was observed in the same order):

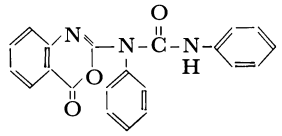
noncyclic C=N < exocyclic C=N < endocyclic C=N

These effects are in good agreement with the results on the infrared spectral characteristics, and a tautomeric structure Ia was assigned to iminobenzoxazinone. In the exocyclic iminobenzoxazinone (Ia), the C=N double bond is conjugated not only with the benzene ring but also with the benzoxazinone ring through unshared electrons of ester oxygen and the carbonyl group; this may explain the apparent stability of Ia relative to the other tautomeric structure Ia'.

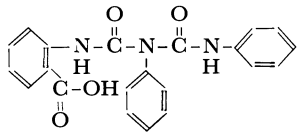
13) P. Grammaticakis, *Compt. rend.*, **247**, 2013 (1958).
14) P. Grammaticakis, *Bull. soc. chim. France*, **1962**, 487.
15) R. C. Elderfield and V. B. Meyer, *J. Am. Chem. Soc.*, **76**, 1887 (1954).

When *N*-methylanthranilic acid is treated with an equimolar amount of phenyl isocyanate, exocyclic iminobenzoxazinone (Ib) is the only possible product. It was found that it undergoes molecular rearrangement to form a thermodynamically-controlled product, 1-methyl-3-phenyl-2, 4(1*H*, 3*H*)-quinazolinedione (IIb), together with 1-methylisatoic anhydride (XIIIb) (m. p. 164—166°C) and *N*-methyl-2(phenylcarbamoyl)-carbanilide (IVb) (m. p. 252—253°C).

The treatment of exocyclic iminobenzoxazinone (I) with phenyl isocyanate failed to produce either 2-(phenylcarbamoyl)-phenylamino-4*H*-3, 1-benzoxazin-4-one (XI) or the other possible product (XII).

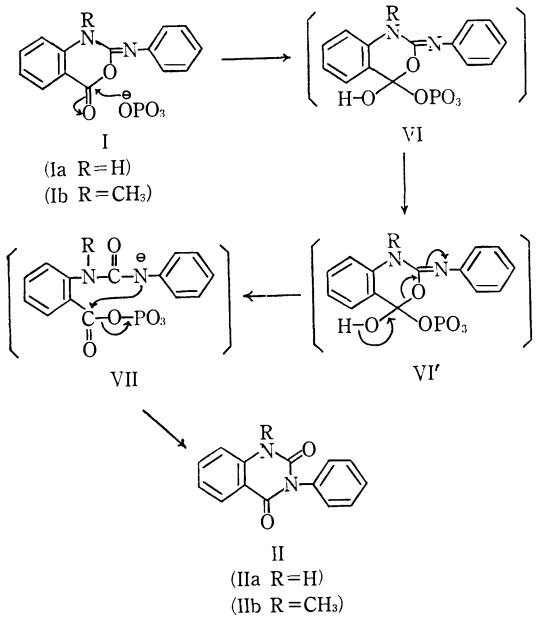


(XI)



(XII)

A possible mechanism for the molecular rearrangement of iminobenzoxazinone (I) to quinazolinedione (II) in PPA involves the phosphorylated intermediates VI and VII; it is shown in the following scheme (2), which is based on the experimental evidence of the phosphoric-carboxylic mixed anhydride of polyurea acid.[1,4]



I
(Ia R=H)
(Ib R=CH_3)

VI

VII

VI'

II
(IIa R=H)
(IIb R=CH_3)

When I is treated with PPA at 150°C, the carbonyl group of benzoxazinone I is phosphorylated to form the reaction intermediate VI, followed by ring opening to form the mixed anhydride of carboxylic acid and phosphoric acid VII. The anion of ureido nitrogen attacks the carbonyl group of the mixed anhydride to cleave the phosphoric acid species. Recyclization is completed by quinazolinedione ring fromation II. A similar mechanism has been suggested for the hydrolysis of salicylphosphate, which involves the formation of a cyclic transition state.[16]

Experimental[17]

The Preparation of *N*-(Phenylcarbamoyl)-anthranilic Acid.—A 3.5 g. portion (0.03 mol.) of phenyl isocyanate was dissolved in 20 ml. of benzene. The solution was then gradually added into 40 mol. of a benzene solution containing 2.74 g. (0.01 mol.) of anthranilic acid at 50°C. After the mixture had been heated under reflux at 80°C for 1 hr., the precipitate was filtered and washed several times with benzene. Recrystallization from ethanol yielded needles which melted at 185—186°C (lit.[10] m. p. 183°C). The yield was 4.97 g. (97%). The infrared spectrum (KBr) shows a band at 3320 cm^{-1} (N-H stretching). The carbonyl stretching bands fall at 1675 cm^{-1} (carboxyl) and at 1663 cm^{-1} (ureido carbonyl).

Ultraviolet spectrum: λ_{max} 265 mμ (ε, 37500); 306 mμ (ε, 9149).

Found: C, 65.70; H, 4.72; N, 10.93. Calcd. for $C_{14}H_{12}O_3N_2$: C, 65.62; H, 4.72; N, 10.93%.

The Preparation of 3-Phenyl-2, 4(1*H*, 3*H*)-quinazolinedione (IIa). — A mixture of 3.00 g. (0.0117 mol.) of *N*-(phenylcarbamoyl)-anthranilic acid and 200 g. of PPA was placed in a three-necked flask fitted with a mechanical stirrer. The mixture was heated at 150°C for 5 hr., and the resulting solution was poured into 300 ml. of distilled water. The precipitate was filtered off and washed twice with a dilute aqueous sodium carbonate solution. Then it was washed thoroughly with water and dried. The yield was 2.38 g. (100%). It was recrystallized from ethanol to obtain needles, m. p. 280°C (lit.[10] 280°C). The infrared spectrum (KBr) showed bands at 3200 cm^{-1} (bonded N-H), 1725 cm^{-1} (4-carbonyl), 1650 cm^{-1} (2-carbonyl) and 1600 cm^{-1} (phenyl). The ultraviolet spectrum exhibited absorption maxima at λ_{max} 243 mμ (ε, 11200) and 312 mμ (ε, 3490).

Found: C, 70.33; H, 4.38; N, 11.76; mol. wt.,

16) J. D. Chanley, E. M. Gindler and H. Sobotka, *J. Am. Chem. Soc.*, **74**, 4347 (1952).

17) All the melting points were taken on a Büchi Melting Point Apparatus and are uncorrected. The microanalyses were carried out by the Microanalytical Section of these laboratories. The infrared spectal were recorded with Perkin-Elmer (Model 125) and Hitachi (Model EPI-S) recording spectrophotometers, using a potassium bromide disk or Nujol. The ultraviolet spectra were recorded with a Cary Model 14 recording spectrophotometer in ethanol. The molecular weights were determined with a Mechrolab Model 310A vapor pressure osmometer in benzene and ethyl methyl ketone.

241. Calcd. for $C_{14}H_{10}O_2N_2$: C, 70.58; H, 4.23; N, 11.48%; mol. wt., 238.

The Preparation of 1, 2-Dihydro-2-phenylimino-4*H*-3, 1-benzoxazin-4-one (Ia).—A 0.300 g. portion (0.00117 mol.) of *N*-(phenylcarbamoyl)-anthranilic acid was added to 20 g. of PPA, and then the mixture was heated at 80—100°C for 1 hr., and after the reaction, poured into 100 ml. of distilled water. It was then filtered, and washed with a 10% aqueous sodium caraonate solution and distilled water successively. Several recrystallizations from chloroform yielded needles, m. p. 193°C (lit.[8a,d,e] 192—193°C), in a 95% yield. The infrared spectrum (Nujol) shows absorption bands at 3300 cm^{-1} (N-H), 1747 cm^{-1} (lactone carbonyl), 1650 cm^{-1} (>C=N-) and 1240 cm^{-1} and 1060 cm^{-1} (C-O-C). The ultraviolet spectrum had absorption maxima at λ_{max} 244 mμ (ε, 8160), 282 mμ (ε, 9200), 292 mμ (ε, 8600) and 332 mμ (ε, 2665).

Found: C, 70.28; H, 4.25; N, 11.25; mol. wt., 237. Calcd. for $C_{14}H_{10}O_2N_2$: C, 70.58; H, 4.28; N, 11.48%; mol. wt., 238.

The Intramolecular Rearrangement of 1, 2-Dihydro-2-phenylimino-4*H*-3, 1-benzoxazin-4-one (Ia) to 3-Phenyl-2, 4(1*H*, 3*H*)-quinazolinedione (IIa).—A mixture of 0.200 g. (0.0084 mol.) of I and 20.0 g. of PPA was heated at 150°C for 5 hr. It was then poured into 100 ml. of distilled water, and the resulting precipitate was filtered and washed with a 10% aqueous sodium carbonate solution. It was then washed thoroughly with distilled water and dried. The yield was 0.140 g. (70%). It was recrystallized from ethanol to obtain colorless needles, m. p. 282°C. It was identified by a comparison of its infrared spectrum (KBr) with that of II prepared directly from *N*-(phenylcarbamoyl)-anthranilic acid in PPA. The infrared bands at 1240 cm^{-1} (-N=C-O-C-) and 1060 cm^{-1} (-C-O-C-) disappeared.

The Preparation of 2-Phenyl-4*H*-3, 1-benzoxazin-4-one (VIII).—A mixture of 3.40 g. (0.025 mol.) of anthranilic acid and 3.5 g. (0.025 mol.) of benzoyl chloride was dissolved into 115 g. of PPA; the solution was heated at 120 to 140°C for 12 hr., and then heated for 0.5 hr. It was then poured directly into 300 ml. of distilled water; the precipitate was filtered and washed thoroughly with distilled water to afford the product in a 99% yield. The product was recrystallized from ethanol to obtain colorless needles. It has a m. p. of 130.0—130.5°C. The infrared spectrum (KBr) shows carbonyl bands at 1760 cm^{-1} and 1060 cm^{-1} (C-O-C). The ultraviolet spectrum has bands at λ_{max} 241 mμ (ε, 22220), 275 mμ (ε, 16400) (shoulder), 285 mμ (ε, 21430), 298 mμ (ε, 19740) and 321 mμ (ε, 11600).

Found: C, 75.15; H, 4.03; N, 6.21; mol. wt., 230. Calcd. for $C_{14}H_9O_2N$: C, 75.32; H, 4.06; N, 6.28%; mol. wt., 223.

The Phosphorylated Intermediate of 4, 4'-Diamino-biphenyl-3, 3'-dicarboxylic Acid (BDC) with Phenyl Diisocyanate in PPA.—A 2.72 g. portion of purified BDC (0.01 mol.) and a 1.60 g. portion of phenyl diisocyanate (0.01 mol.) were dissolved in a 86 g. portion of PPA with vigorous mechanical stirring; the polymerization vessel was then heated at 90—100°C for 1 hr. After the completion of the reaction, the resulting polymer solution was poured into 300 g. of ice water and the precipitated polymer was filtered. It was washed several times with 50 ml. each of distilled water, and dried under a vacuum at 60°C. The phosphoric-carbonic anhydride of polyurea acid was obtained in 92% yield. The m. p. was above 350°C; the inherent viscosity measured in a 0.5% concentration at 25°C in concentrated sulfuric acid was found to be $\eta_{inh}=1.01$.

Found: C, 45.11; H, 2.82; N, 9.45; P*, 10.86. Calcd. for $(C_{22}H_{16}O_{12}N_4P_2)_n$: C, 44.79; H, 2.74; N, 9.50; P, 10.50%.

The Preparation of 2-Methyl-4*H*-3, 1-benzoxazin-4-one (IX).—A mixture of 2.74 g. (0.01 mol.) of anthranilic acid and 60 ml. of acetic anhydride was heated at 120°C under reflux for 5 hr. The solvent was then removed under reduced pressure, and the residue was recrystallized from petroleum ether to obtain colorless needles, m. p. 86—88°C (lit.[9] 80—81°C), in a 90% yield (3.45 g.).

The infrared spectrum (KBr) shows absorption band at 1757 cm^{-1} (carbonyl), 1647 (>C=N-), 1268 cm^{-1}, and 1054 cm^{-1} (=C-O-C).

The ultraviolet spectrum exhibits absorption maxima at λ_{max} 249 mμ (ε, 7160), 306 mμ (ε, 2900), and 315 mμ (ε, 2660).

Found: C, 67.15; H, 4.45; N, 8.70; mol. wt., 168. Calcd. for $C_9H_7O_2N$: C, 67.07; H, 4.38; N, 8.09%; mol. wt., 168.

The Reaction of *N*-Methylanthranilic Acid with Phenyl Isocyanate A).—A 3.02 g. (0.02 mol.) portion of *N*-methyl anthranilic acid (m. p. 186—187°C, recrystallized from aqueous ethanol) was dissolved into 100 ml. of benzene at 60°C for 20 min. To this solution there was they added a 2.38 g. (0.02 mol.) portion of phenyl isocyanate (b. p. 46—47°C/7 mmHg) in 10 ml. of benzene, and the mixture was refluxed at 80°C for 2.5 hr. After the mixture had been allowed to cool at room temperature, the precipitate was filtered, washed several times with distilled water, and dried. It was then recrystallized twice from ethyl acetate to obtain colorless needles in a 43% yield. M. p. 252—253°C. It was identified as *N*-methyl-2-(phenylcarbamoyl)carbanilide by a study of its infrared spectrum and by elemental analysis.

The infrared spectrum (KBr) shows absrotpion bands at 3300 cm^{-1} (N-H), and 1650 cm^{-1} (amide carbonyl). Ultraviolet spectrum: λ_{max} 210 mμ (ε, 29200), 257 mμ (ε, 33600).

Found: C, 73.49; H, 5.71; N, 12.60. Calcd. for $C_{21}H_{19}O_2N_3$: C, 73.02; H, 5.55; N, 12.17%.

The filtrate of the benzene solution was refluxed further at 80°C for 5 hr., and the benzene was removed under a vacuum to afford a cyclized reaction product. After recrystallization from a chloroform/cyclohexene (1 : 1) solution, colorless needles were obtained in 41% yield. M. p. 164—166°C. The product was found to be 1-methylisatoic anhydride by elemental analysis and by a study of its infrared spectrum. The infrared spectrum (KBr) shows absorption bands at 1770 cm^{-1} (carbonyl), 1720 cm^{-1} (carbonyl) and 1605 cm^{-1}.

The ultraviolet spectrum has bands at λ_{max} 223 mμ (ε, 49400), 248 mμ (ε, 17800), 252 mμ (ε, 17900), and 315 mμ (ε, 2730).

Found: C, 61.44; H, 4.40; N, 8.10; mol. wt., 177.

* The phosphorus was determined by colorimetry analysis with ammonium metavanadate and ammonium molybdate, and by emission X-ray analysis.

Calcd. for $C_9H_7O_3N$: C, 61.01; H. 3.98; N, 7.91%; mol. wt., 181.

B)—The reaction was carried out in tetrahydrofuran instead of benzene at −2°C for 1 hr., at 10°C for 1 hr., and at 20°C for 1 hr. successively. The solvent was then removed under a vacuum at 60°C, and the residue was extracted with 200 ml. of a 10% aqueous sodium carbonate solution. The product was precipitated by acidifying the solution with 12% hydrochloric acid. When the product was recrystallized from a chloroform/cyclohexane (1:1) solution, colorless needles were obtained in a 59.5% yield. M. p. 231—322°C. It was identified as 1-methyl-3-phenyl-2, 4(1*H*, 3*H*)-quinazolinedione (lit.[18] 229—230°C).

The infrared spectrum (KBr) shows characteristic carbonyl absorption bands of quinazoline-dione at 1706 cm^{-1}, 1680 cm^{-1}, 1658 cm^{-1} and 1610 cm^{-1}. The ultraviolet spectrum has absorption maxima at λ_{max} 245 mμ (ε, 5540) and 270 mμ (ε, 756).

Found: C, 71.08; H, 4.87; N, 10.80. Calcd. for $C_{15}H_{12}O_2N_2$: C, 71.41; H, 4.80; N, 11.11%.

The neutral fraction of the tetrahydrofuran solution was extracted with benzene, and a crystalline solid was obtained in a 14.5% yield; this was indentified as *N*-phenyl-2-(phenylcarbamoyl)carbanilide (m. p. 252—253°C) by a comparison of its infrared spectrum with that of an authentic sample and it was found to have no melting point depression on admixture.

The Attempted Cyclization of *N*-Phenyl-2-(phenylcarbamoyl)carbanilide with Polyphosphoric Acid.—A 1.0 g. portion of *N*-phenyl-2-(phenylcarbamoyl)carbanilide was added to 60 g. of polyphosphoric acid, and the mixture was heated at 140—150°C for 5 hr. After the reaction, the mixture was poured into 100 ml. of distilled water, washed with 50 ml. of 5% aqueous sodium carbonate, and filtered. The starting material was thus recovered almost quantitatively, m. p. 249—250°C.

Found: C, 73.44; H, 5.15; N, 12.50. Calcd. for $C_{21}H_{19}O_2N_3$: C, 73.02; H, 5.55; N, 12.17%.

The authors gratefully acknowledge the interest and encouragement of Drs. Toshio Hoshino and Ryoji Nakanishi of the Basic Research Laboratories, Toyo Rayon Company, Ltd. The authors are also indebted to Mr. Yasuyuki Ebata and his staff for their microanalyses, and Mr. Toshio Mizushima for his emission X-ray analysis.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1948—1951 (1966)

The Synthesis of 5- and 6-Aminoazulene Derivatives from 5- and 6-Acetylazulene Derivatives

By Tetsuo Nozoe and Kahei Takase

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

and Masao Tada

The Research Institute for Tuberculosis, Leprosy and Cancer, Tohoku University, Kitayoban-cho, Sendai

(Received November 19, 1965)

The Schmidt reactions on diethyl 5-acetyl-2-aminoazulene-1, 3-dicarboxylate and diethyl 6-acetyl-2-aminoazulene-1, 3-dicarboxylate afforded diethyl 2, 5-diaminoazulene-1, 3-dicarboxylate (I) and diethyl 2, 6-diaminoazulene-1, 3-dicarboxylate respectively. A preferential formation of the 5-acetamido-2-amino compound upon the mild acetylation of I, which contrasted with the preferential diazotization of the 2-amino group, was observed.

In a previous paper,[1] it was reported that 5- and 6-aminoazulene derivatives were synthesized by the reaction of 5-acetamidotropolone derivatives and ethyl cyanoacetate. 6-Aminoazulene derivatives were also synthesized from 6-bromoazulene derivatives by nucleophilic displacement with ammonia or amines.[2,3] In the present paper, the authors will described a third route of synthesizing aminoazulene derivatives, in which the aminoazulenes are synthesized from 5- and 6-acetylazulene derivatives[4] by the Schmidt reaction.

The treatment of diethyl 5-acetyl-2-aminoazulene-1, 3-dicarboxylate (I)[4] or its ethylene ketal (II)[4] with sodium azide in concentrated sulfuric acid gave two compounds, III and IV. One of these, III, was identical with the diethyl 5-acetamido-2-aminoazulene-1, 3-dicarboxylate which had already been obtained.[1] The other one, IV, was confirmed

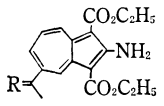
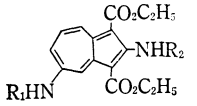
to be diethyl 2, 5-diaminoazulene-1, 3-dicarboxylate from the facts that the acetylation of IV gave III and the mild alkaline hydrolysis of III gave IV. The further acetylation of III afforded a diacetamido compound V.





I: R=O

II: R=

III: R_1=$COCH_3$; R_2=H

IV: R_1=R_2=H

V: R_1=R_2=$COCH_3$

The same treatment of diethyl 5-acetylazulene-1, 3-dicarboxylate (VI)[4] with sodium azide and concentrated sulfuric acid afforded diethyl 5-aminoazulene-1, 3-dicarboxylate (VII). The acetylation of VII gave an acetamido compound VIII, which was also derived from III by deamination with isoamyl nitrite and sulfuric acid. When treated with isoamyl nitrite and sulfuric acid, the diamino compound IV gave the amino compound VII, in which the amino group at Position 2 was only deaminated. This fact shows that the basicity of the 2-amino group of IV is greater than that of the 5-amino group. The ultraviolet absorption spectra of the compounds, IV, V, VII and VIII, are shown in Fig. 1.

In an attempt to synthesize 2, 5-diaminoazulene

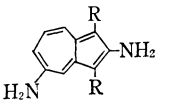
(IX), the corresponding dicarboxylic acid X obtained by the alkaline hydrolysis of III or IV was submitted to thermal decarboxylation, thus forming a dark tarry material from which none of the desired product was isolated.



IX: R=H

X: R=COOH

The preferential formation of 5-acetamido-2-amino compound III on the mild acetylation of 2, 5-diamino compound IV, which contrasts with the preferential diazotization of the 2-amino group, can be explained by the operation of a steric hindrance caused by the presence of the two ethoxycarbonyl groups adjacent to the 2-amino group. Similar phenomena are also observed in the case of diethyl 2, 6 - diaminoazulene - 1, 3 - dicarboxylate (XI).[1] The Schmidt reactions on diethyl 6-acetyl-2-aminoazulene-1, 3-dicarboxylate (XII)[4] and its ethylene ketal (XIII)[4] afforded 2, 6-diaminoazulene derivative (XI). The reaction of diethyl 6-acetylazulene-1, 3-dicarboxylate (XIV)[4] gave both the 6-amino compound (XV) and the 6-acetamido compound (XVI).[1]

Experimental[5]

The Schmidt Reaction of Diethyl 5-Acetyl-2-aminoazulene-1, 3-dicarboxylate (I). — Into a solution of I (1.0 g.) in concentrated sulfuric acid (4 ml.), sodium azide (240 mg.) was added in small portions with stirring at room temperature. After having been stirred for 2 hr., the mixture was diluted with water (30 ml.), made slightly alkaline with 2 N sodium hydroxide, and allowed to stand in a cold place. The solid

5) All melting points are uncorrected. Shoulders in the UV spectral data are designated by "sh."

(600 mg.) which precipitated out was collected by filtration, washed with water, and recrystallized from ethanol to give yellow needles (300 mg.; m. p. 184—185°C), which showed no depression of melting point on admixture with diethyl 5-acetamido-2-aminoazulene-1, 3-dicarboxylate (III).[1)]

The residue obtained by the evaporation of the filtrate was dissolved in benzene, and the benzene solution was passed through a column of alumina. The column was eluted with benzene. The crude crystals (50 mg.) obtained from the effluent, were recrystallized from ethanol to give diethyl 2, 5-diaminoazulene-1, 3-dicarboxylate (IV) (40 mg.; m. p. 145—146.5°C) as dull orange micro-prisms.

Found: N, 9.32. Calcd. for $C_{16}H_{18}O_4N_2$: N, 9.27%.

λ_{max}^{MeOH} mμ (log ε): 220.5 (4.11), 235 (3.99) sh, 289 (4.43), 335 (4.88), 389 (4.07), 476 (3.28).

IR (Nujol): 3535, 3365, 3255, 1667, 1626 cm^{-1}.

The Dipicrate of IV.—Dark yellowish green micro-prisms (from ethanol); m. p. 147—148°C.

Found: C, 44.47; H, 3.17; N, 14.69. Calcd. for $C_{16}H_{18}O_4N_2$-$C_{12}H_6O_{14}N_6$: C, 44.22; H, 3.18; N, 14.74%.

When it was refluxed in acetic anhydride for 30 min., IV was acetylated to give III. This III (100 mg.) was then heated under reflux with potassium hydroxide (100 mg.) in 80% aqueous ethanol (5 ml.) for 3 hr.; by this procedure IV (20 mg.) was obtained.

The Schmidt Reaction of Diethyl 2-Amino-5-(1, 1-ethylenedioxyethyl)azulene-1, 3-dicarboxylate (II).—Into a solution of II (100 mg.) in concentrated sulfuric acid (1 ml.), sodium azide (25 mg.) was added in small portions with stirring at room temperature; the reaction mixture was then treated as in the above-mentioned method to give both III (35 mg.) and IV (4 mg.).

Diethyl 2, 5-Diacetamidoazulene-1, 3-dicarboxylate (V).—A solution of III (30 mg.) in acetic anhydride (1 ml.) was refluxed for 1 hr. The residue obtained by the evaporation of the solvent was recrystallized from aqueous ethanol to give V (20 mg.; m. p. 132—133°C) as brown micro-needles.

Found: C, 62.20; H, 5.71; N, 7.31. Calcd. for $C_{20}H_{20}O_6N_2$: C, 62.16; H, 5.74; N, 7.25%.

λ_{max}^{MeOH} mμ (log ε): 247.5 (4.47), 319 (4.70), 329 (4.82), 378 (3.86), 394 (3.86), 465 (3.46).

IR (Nujol): 3470, 3345, 1712, 1704, 1672 cm^{-1}.

By the same treatment, IV was acetylated to give V.

Diethyl 5-Aminoazulene-1, 3-dicarboxylate (VII).—*a) From Diethyl 5-Acetamido-2-aminoazulene-1, 3-dicarboxylate (III).*—A solution of III (200 mg.) in dioxane (12 ml.) and concentrated sulfuric acid (0.8 ml.) was warmed on a water bath for 10 min. and chilled. Into the solution, a solution of sodium nitrite (100 mg.) in water (4 ml.) was added with stirring without cooling. After the mixture had been stirred for 3 hr., a solution of sodium hypophosphite (1.6 g.) in water (10 ml.) was added. The mixture was stirred for a further 2 hr. and then allowed to stand overnight at room temperature. The reaction mixture was diluted with water and extracted with benzene. The extract was washed with water, dried over anhydrous sodium sulfate, and passed through a column of alumina. The column was eluted with benzene. From the effluent, the crude crystals (30 mg.) were obtained. Recrystallization from ethanol afforded VII (m. p. 157—158°C) as purple scales.

Found: C, 66.66; H, 5.69; N, 4.78. Calcd. for $C_{16}H_{17}O_4N$: C, 66.88; H, 5.96; N, 4.88%.

λ_{max}^{MeOH} mμ (log ε): 240 (4.24), 282 (4.47), 305 (4.40), 395 (4.32), 565 (3.20).

IR (Nujol): 3390, 3320, 3215, 1684, 1647 cm^{-1}.

b) From Diethyl 2, 5-Diaminoazulene-1, 3-dicarboxylate (IV).—To the diazotized solution of IV (200 mg.) with sodium nitrite (100 mg.), sodium hypophosphite (1.6 g.) was added, and the reaction mixture was treated as in a); VII (45 mg.) was thus obtained.

c) From Diethyl 5-Acetylazulene-1, 3-dicarboxylate (VI).—Into a mixture of VI (150 mg.) in chloroform (3 ml.) and concentrated sulfuric acid (2 ml.), sodium azide (70 mg.) was stirred in small portions without cooling. After the mixture had been stirred for 20 min., the acid layer was diluted with water and extracted with benzene. The extract was then washed with water, dried over anhydrous sodium sulfate, and passed through a column of alumina. The crystals obtained from the effluent were recrystallized from ethanol to give VII (8 mg.).

Diethyl 5-Acetamidoazulene-1, 3-dicarboxylate (VIII).—*a) From Diethyl 5-Acetamido-2-aminoazulene-1, 3-dicarboxylate (III).*—Into a solution of III (200 mg.) in dioxane (12 ml.) and concentrated sulfuric acid (1.2 ml.), a solution of sodium nitrite (100 mg.) in water (4 ml.) was gradually dropped with stirring under ice-water cooling. After the mixture had been stirred for 40 min. at room temperature, a solution of sodium hypophosphite (1.6 g.) in water (10 ml.) was added. The mixture was treated as in the case of VII-a) and gave reddish violet crystals (30 mg.). Recrystallization from a mixture of benzene and cyclohexane afforded VIII (20 mg.; m. p. 191—192°C) as pale purple scales.

Found: C, 65.58; H, 5.79; N, 4.30. Calcd. for $C_{18}H_{19}O_5N$: C, 65.64; H, 5.82; N, 4.25%.

λ_{max}^{MeOH} mμ (log ε): 235 (4.22) sh, 242 (4.23), 277 (4.53), 306 (4.59), 380 (4.24), 391 (4.23), 522 (2.96).

IR (Nujol): 3185, 1686, 1639 cm^{-1}.

b) From Diethyl 5-Aminoazulene-1, 3-dicarboxylate (VII).—A solution of VII (20 mg.) in acetic anhydride was warmed on a water bath for 5 min. The residue produced by the evaporation of the solvent was then recrystallized from aqueous methanol to give VIII (15 mg.).

2, 5-Diaminoazulene-1, 3-dicarboxylic Acid (X).—To a solution of III (200 mg.) in ethanol (6 ml.), a 10% potassium hydroxide aqueous solution (2 ml.) was added. The mixture was refluxed for 4 hr., concentrated to 2/3 volume under reduced pressure, diluted with water (20 ml.), and extracted with ethyl acetate. The extract was washed with water and dried over anhydrous sodium sulfate. The brownish black residue (45 mg.) obtained by the evaporation of the solvent was recrystallized from a mixture of benzene and cyclohexane to give X (30 mg.; m. p. above 285°C) as fine black crystals.

Found: N, 11.07. Calcd. for $C_{12}H_{10}O_4N_2$: N, 11.38%.

IR (Nujol): 3470, 3355, 3225, 1650, 1621 cm^{-1}.

IV was hydrolyzed to give X by the same treatment.

Diethyl 2, 6-Diaminoazulene-1, 3-dicarboxylate (XI).—Into a solution of diethyl 6-acetyl-2-aminoazulene-1, 3-dicarboxylate (XII) (1.0 g.) in concentrated sulfuric acid (4 ml.), sodium azide (240 mg.) was added in small portions with stirring without cooling; the reaction mixture was then treated as in the case of I to give the crude crystals (400 mg.). Recrystallization from benzene gave dull brown plates (290 mg.; m. p. 207—208°C), which showed no depression of melting point on admixture with XI[1]; the infrared spectrum was identical with that of XI.

XI (30 mg.) was also derived from diethyl 2-amino-6-(1, 1-ethylenedioxyethyl)azulene-1, 3-dicarboxylate (XIII) (100 mg.) by the same treatment.

The Schmidt Reaction of Diethyl 6-Acetylazulene-1, 3-dicarboxylate (XIV).—Into a mixture of XIV (70 mg.) in chloroform (3 ml.) and concentrated sulfuric acid (1.5 ml.), sodium azide (30 mg.) was added in small portions with stirring without cooling. After the mixture has been stirred for 30 min., the acid layer was diluted with ice-water and extracted with ethyl acetate. The extract was washed with water, dried over anhydrous sodium sulfate, and passed through a column of alumina. The column was eluted with ethyl acetate, and from the first effluent, XIV (3 mg.) was recovered. Orange leaflets (15 mg.; m. p. 220—221°C) from the second and orange scales (20 mg.; m. p. 235—236°C) from the third were obtained. The former showed no depression of melting point on admixture with diethyl 6-acetamidoazulene-1, 3-dicarboxylate (XVI),[1] and the latter showed no depression of melting point on admixture with diethyl 6-aminoazulene-1, 3-dicarboxylate (XV).[1]

Expenses for the present series of experiments were defrayed by grants-in-aid for Scientific Research from the Ministry of Education and from the Up. John Co., Ltd. The infrared spectra in this paper were measured by using a infrared spectrophotometer purchased by a grant-in-aid for Scientific Research from the Toyo Rayon Co., Ltd. The authors wish to express their deep gratitude for these contributions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1951—1953 (1966)

The Reaction of Methylchlorodisilanes with *t*-Butyl Hydroperoxide

By Kazuhisa KAWAZUMI and Bunjiro MURAI

Department of Material Technology and Technical Services, Central Research Laboratory
Tokyo Shibaura Electric Co., Ltd., Toshiba-cho, Kawasaki

(Received November 20, 1965)

The authors wished to get two new organosilyl peroxides with a silicon-silicon linkage, *t*-butylperoxypentamethyldisilane [$(CH_3)_3SiSi(CH_3)_2(OOC(CH_3)_3)$] and 1, 2-di-*t*-butylperoxytetramethyldisilane [$((CH_3)_3COO)(CH_3)_2SiSi(CH_3)_2(OOC(CH_3)_3)$], by the reaction of the corresponding chlorodisilanes with *t*-butyl hydroperoxide. The reaction, however, did not give the desired product; rather, it led to the formation of *t*-butoxypentamethyldisiloxane [$(CH_3)_3SiOSi(CH_3)_2(OC(CH_3)_3)$] and 1-*t*-butoxy-3-*t*-butylperoxytetramethyldisiloxane [$((CH_3)_3CO)(CH_3)_2SiOSi(CH_3)_2(OOC(CH_3)_3)$] respectively, substances which are believed to have resulted from the intramolecular rearrangement of the desired peroxydisilanes.

Chlorosilanes react readily with alkyl hydroperoxides to form fairly stable alkylperoxysilanes with the Si–O–O–C group. The literature on organosilicon compounds contains no example of a disilane with peroxy substituents. The present investigation was undertaken to prepare two derivatives of this class of compounds, *t*-butylperoxypentamethyldisilane (I) and 1, 2-di-*t*-butylperoxytetramethyldisilane (II), by treating the corresponding chlorodisilanes[1] with *t*-butyl hydroperoxide in the presence of pyridine:

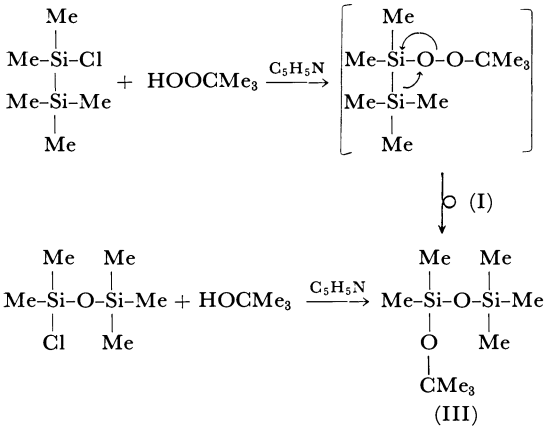
$$Me_3SiSiMe_2Cl + HOOCMe_3 \xrightarrow{C_5H_5N} Me_3SiSiMe_2(OOCMe_3)$$
(I)

$$ClMe_2SiSiMe_2Cl + 2\,HOOCMe_3 \xrightarrow{C_5H_5N} (Me_3COO)Me_2SiSiMe_2(OOCMe_3)$$
(II)

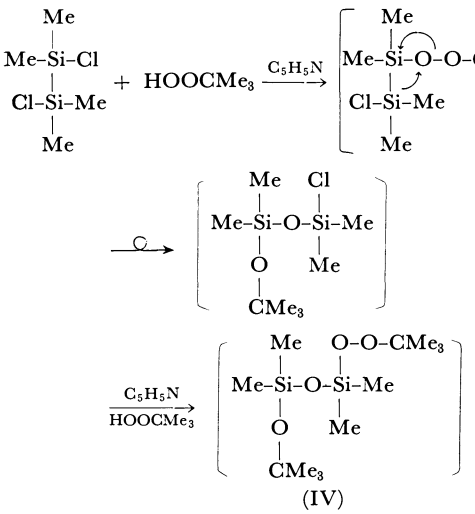
However, these products were not obtained. The reaction between *t*-butyl hydroperoxide and pentamethylchlorodisilane gave a non-peroxidic compound, *t*-butoxypentamethyldisiloxane (III), the formation of which may well be ascribed to the intramolecular rearrangement of the unstable peroxide intermediate. Proof for the structure of

1) M. Kumada, M. Yamaguchi, Y. Yamamoto, J. Nakajima and K. Shiina, *J. Org. Chem.*, **21**, 1264 (1956).

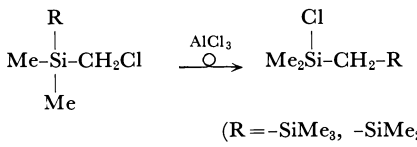
III was afforded by its unambiguous synthesis from pentamethylchlorodisiloxane and *t*-butyl alcohol:



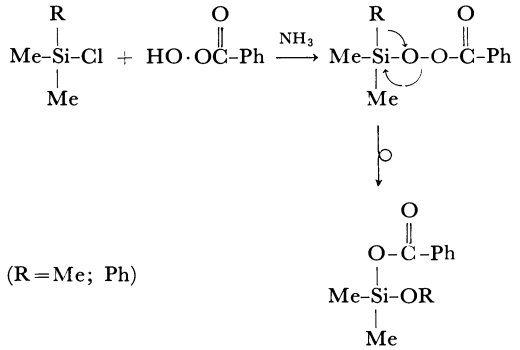
Similarly, from the reaction between 1, 2-dichlorotetramethyldisilane and *t*-butyl hydroperoxide, 1-*t*-butoxy-3-*t*-butylperoxytetramethyldisiloxane (IV) was obtained instead of the corresponding peroxidic compound (II). Apparently, the reaction proceeded as follows:



These results indicate that both silyl groups, Me_3Si and $ClMe_2Si$, have much greater migratory aptitudes than the methyl group, as was observed previously by Kumada and his collaborators[2] in the case of the intramolecular rearrangement of chloromethyldisilanes with anhydrous aluminum chloride:



Intramolecular rearrangements of organosilyl peroxides have been reported by Buncel and Davies.[3] They observed the rearrangement only when they attempted to prepare acylperoxysilanes from the reaction between peroxybenzoic acid and trimethylchlorosilane or dimethylphenylchlorosilane:



Similar nucleophilic 1, 2-rearrangements have been reported with other organometallic and organometalloidal compounds.[4,5]

Experimental

Starting Materials.—*Pentamethylchlorodisilane and 1, 2-Dichlorotetramethyldisilane.*—These were obtained by the method reported in detail by Kumada and his collaborators.[1]

t-Butyl Hydroperoxide.—The authors used *t*-butyl hydroperoxide-90, produced by Wallace & Tiernan, Inc., the purity of which is 90%.

Pentamethylchlorodisiloxane.—This was prepared from 1, 3-dichlorotetramethyldisiloxane ($ClMe_2SiOSiMe_2Cl$)[6,7] by methylation with the Grignard reagent.

The Reaction between Pentamethylchlorodisilane and *t*-Butyl Hydroperoxide.—A 500-ml. four-necked flask was fitted with an air-tight stirrer, a thermometer, a dropping-funnel and a reflux condenser with a calcium chloride tube. In the flask these were then placed 27 g. (0.27 mol.) of *t*-butyl hydroperoxide, 20 g. (0.253 mol.) of pyridine, and 200 ml. of petroleum ether. Into this mixture, a mixture of 41.7 g. (0.25 mol.) of pentamethylchlorodisilane and 50 ml. of petroleum ether was stirred over a 75-minute period. At once pyridine hydrochloride was precipitated. During the addition, the mixture was cooled with an ice-bath below 10°C. After the addition, the mixture was stirred over 5 hr. at room temperature. When the mixture was filtered, the organic layer was obtained. The ether was removed, and the residual oil was then distilled under reduced pressure to give 39 g. of a liquid boiling over the range from

t-Butoxypentamethyldisiloxane (III).—In a three-necked flask equipped with a stirrer, a dropping funnel and an efficient reflux condenser with a calcium chloride tube, 14.8 g. (0.2 mol.) of *t*-butyl alcohol was added to a mixture of 30 g. (0.164 mol.) of pentamethylchlorodisiloxane (Found: Cl, 19.3. Calcd. for $C_5H_{15}OSi_2$·Cl: 19.0%), 15.6 g. (0.197 mol.) of pyridine, and 200 ml. of dry ether. During the reaction, the mixture was cooled with an ice-bath below 10°C. After the addition of the *t*-butyl alchol, the reaction mixture was refluxed over a period of one hour with stirring. The pyridine hydrochloride was then removed by filtration. The evaporation of ether from the filtrate, followed by fractional distillation, gave 13.9 g. of a liquid, b. p. 47—49°C/14.5 mmHg. Redistillation under ordinary pressure gave a colorless liquid (B), b. p. 155°C. The physical properties and analytical data for this product B also are shown in Table I.

The Reaction between 1, 2-Dichlorotetramethyldisilane and *t*-Butyl Hydroperoxide.—This reaction was carried out in essentially the manner described above, except that 28.1 g. (0.15 mol.) of 1, 2-dichlorotetramethyldisilane was added to a mixture of 32.4 g. (0.324 mol.) of *t*-butyl hydroperoxide, 24 g. (0.3 mol.) of pyridine in 300 ml. of dry petroleum ether. We thus obtained 11.9 g. of a colorless liquid (C), b. p. 89—89.5°C/13 mmHg; its physical properties and analytical data are listed in Table II.

Results and Discussion

From the two reactions of *t*-butyl hydroperoxide with pentamethylchlorodisilane and with 1, 2-dichlorotetramethyldisilane, two new compounds, III and IV, were isolated, but no organosilyl peroxide that contains both silicon-silicon and one or two peroxy groups was obtained.

Evidence for this conclusion was afforded by determinations of the active oxygen contents, the molecular refractions, and the retention times by means of gas chromatography and a study of the infrared spectra. The infrared spectrum of A agreed with that of B in all ranges. The retention time of A in the gas chromatogram agreed with that of B. The other physical properties (cf. Tables I and II) also supported these results.

Summary

Pentamethylchlorodisilane and 1, 2-dichlorotetramethyldisilane easily react with *t*-butyl hydroperoxide; they give not the corresponding peroxides with the silicon-silicon linkage, but *t*-butoxypentamethyldisiloxane and 1-*t*-butoxy-3-*t*-butylperoxytetramethyldisiloxane respectively. The formation of these two products through the intramolecular rearrangement of the unstable peroxy intermediates has been discussed.

The authors wish to express their hearty thanks to Professor Makoto Kumada and Dr. Mitsuo Ishikawa of Kyoto University for their valuable advice and discussions throughout this work.

The Anionoid Substitution Reaction of Diethyl 2-Acetamido-6-bromoazulene-1, 3-dicarboxylate

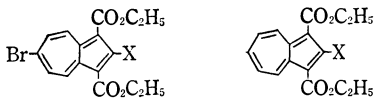
By Masao TADA

The Research Institute for Tuberculosis, Leprosy and Cancer, Tohoku University, Kitayoban-cho, Sendai

(Received November 24, 1965)

The bromine atom in diethyl 2-acetamido-6-bromoazulene-1, 3-dicarboxylate (I) is as reactive toward the anionoid reagents as in diethyl 6-bromoazulene-1, 3-dicarboxylate. Twenty-seven 6-substituted azulene derivatives have been synthesized from I by the nucleophilic substitution reaction. On one of them, diethyl 2-acetamido-6-diethylaminoazulene-1, 3-dicarboxylate, the removal of the 2-acetamido group has been carried out, giving diethyl 6-diethylaminoazulene-1, 3-dicarboxylate.

In a previous paper[1] dealing with anionoid substitution reactions on diethyl 6-bromoazulene-1, 3-dicarboxylate (I), it was shown that the bromine atom of I was easily displaced with various anionoid reagents, such as amines, alkoxide and mercaptide. In more recent work,[2] it was found that the bromine atom of diethyl 2-amino-6-bromoazulene-1, 3-dicarboxylate (II)[3,4a,b] was also displaced with alkoxide or mercaptide, but this reaction required much more severe conditions than those with I, and II did not react with amines. Such differences between the reactivities of I and II toward anionoid reagents may be attributed to the existence or nonexistence of the electron-releasing amino group which enhances the electron density at Position 6. The author's interest in the activity of the bromine atom in I and II has led to the suggestion that the bromine atom of diethyl 2-acetamido-6-bromoazulene-1, 3-dicarboxylate (III) will be reactive toward the anionoid reagents. The present paper will deal with reactions of III with various anionoid reagents.



I: X=H
II: X=NH_2
III: X=$NHCOCH_3$
VII: X=$N(COCH_3)_2$

IV: X=NH_2
V: X=$NHCOCH_3$
VI: X=$N(COCH_3)_2$

It has been reported that the acetylation of diethyl 2-aminoazulene-1, 3-dicarboxylate (IV) was not achieved by heating IV in acetic anhydride for 3 hr.[4a] However, the heating of IV in acetic anhydride for 7—10 hr. gave a monoacetyl derivative V and a diacetyl derivative VI. When it was treated with acetic anhydride under the same conditions, the amino compound II gave a mixture of a monoacetyl derivative III and a diacetyl derivative (VII). The further acetylation of III afforded VII, while the alkaline or the acidic hydrolysis of VII gave a mixture of III and II. The relation among IV, V and VI was similar to that among 6-bromoazulene derivatives, II, III and VII. The ultraviolet spectra of these acetates are shown in Fig. 1.

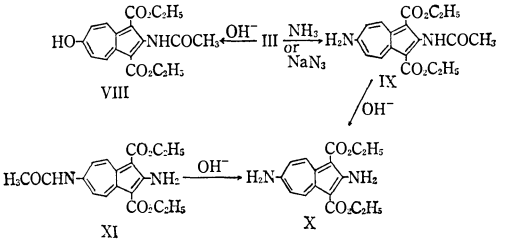
The treatment of III with aqueous ethanolic alkali afforded II and a hydroxyazulene derivative VIII, which in turn gave an acetoxy derivative ($\nu_{C=O}$ 1770 cm^{-1}) when heated with acetic anhydride. The treatment of III with ammonia or sodium azide (in the presence of dimethyl sulfoxide)[5] afforded diethyl 2-acetamido-6-aminoazulene-1, 3-dicarboxylate (IX). The alkaline hydrolysis of IX yielded diethyl 2, 6-diaminoazulene-1, 3-dicarboxylate (X), which had also been derived from diethyl 6-acetamido-2-aminoazulene-1, 3-dicarboxylate (XI).[6] The reaction of III



with sodium ethoxide in ethanol afforded diethyl 2-acetamido-6-ethoxyazulene-1,3-dicarboxylate (XII), and the treatment of III in ethanol with an aqueous solution of sodium hydrosulfide afforded the 6-mercapto derivative (XIII). The ultraviolet spectra of these derivatives are shown in Fig. 2.

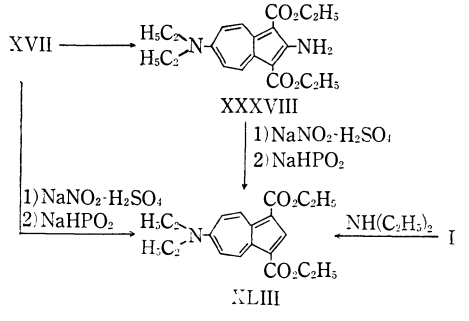
-6-(3-methoxypropylamino)- (XXIX), -6-(3-morpholinopropylamino)- (XXX), -6-anilino- (XXXI), -6-(2-pyridylamino)- (XXXII), -6-(3-methylpyridin-2-yl)amino- (XXXIII), -6-(4-pyridylamino)- (XXXIV), -6-(2-quinolylamino)- (XXXV), and -6-(4-antipyrinylamino)azulene-1, 3-dicarboxylate (XXXVI).

It was mentioned in the previous report[1] that the reaction of 2-acetamido-6-bromoazulene (XXXVII)[4b] with amines did not afford any 6-aminoazulene derivatives. Therefore, it can be understood that the activity of the bromo group at Position 6 of III is enhanced by the presence of two ethoxycarbonyl groups at Positions 1 and 3, by which III is invested with reactivity towards anionoid reagents, thus giving some 6-substituted azulene derivatives.

XXXVII

The acidic or the alkaline hydrolysis of XVII, XIX, XX, XXIV and XXVIII afforded 2-amino compounds XXXVIII, XXXIX, XL, XLI and XLII respectively; these deacetylations were more difficult than the deacetylation of the 6-acetamido-2-aminoazulene derivative XI.[6] The substituents were removed in XVII and XXXVIII; the diazotization reaction of XXXVIII was realized by sodium nitrite and an excess of sulfuric acid, while the decomposition of the diazonium salt formed was achieved on letting it stand in the presence of sodium hypophosphite. The reaction carried out in



dioxane gave diethyl 6-diethylaminoazulene-1, 3-dicarboxylate (XLIII), which had also been derived from I.[1] An acetamido group in XVII, upon being hydrolyzed with the sulfuric acid, XLIII, was directly obtained from XVII. An attempt to derive 2-amino-6-diethylaminoazulene did not succeed. The ultraviolet spectra of XVII and XXXVIII are shown in Fig. 3.

Some compounds of these anionoid reaction products have been investigated in terms of the growth-inhibitory activity in relation to Crocker Sarcoma 180 and Bashford Carcinoma 63.[7]

3. Diethyl 2-acetamido-6-anilinoazulene-1,3-dicarboxylate (XXXI)
4. Diethyl 2-amino-6-diethylaminoazulene-1,3-dicarboxylate (XXXVIII)

Experimental[8]

The Reaction of Diethyl 2-Amino-6-bromoazulene-1, 3-dicarboxylate (II) and Acetic Anhydride.—A solution of II (5.0 g.) in acetic anhydride (8 ml.) was refluxed for 8 hr., and the residue produced by the evaporation of the excess of acetic anhydride under reduced pressure was dissolved in hot ethanol (60 ml.). The insoluble compound was recrystallized from ethyl acetate to give diethyl 2-acetamido-6-bromoazulene-1, 3-dicarboxylate (III) (m. p. 212—213°C; 4.0 g.) as pale red needles.

Found: C, 53.09; H, 4.37; N, 3.42. Calcd. for $C_{15}H_{18}O_5NBr$: C, 52.95; H, 4.44; N, 3.43%.

λ_{max}^{MeOH} mμ (log ε): 234 (4.23), 245 (4.22)sh, 272 (4.13), 314 (4.69)sh, 324 (4.78), 360 (3.87)sh, 379 (3.89), 496 (2.39).

IR (Nujol): 3270, 1718, 1658 cm^{-1}.

From the ethanol solution, brilliant red needles were obtained; these were recrystallized from ethanol to afford diethyl 2-diacetylamino-6-bromoazulene-1, 3-dicarboxylate (VII) (m. p. 141—142°C; 0.5 g.).

Found: C, 53.34; H, 4.42; N, 3.10. Calcd. for $C_{20}H_{20}O_6NBr$: C, 53.34; H, 4.48; N, 3.11%.

λ_{max}^{MeOH} mμ (log ε): 233 (4.39), 274 (4.28), 316 (4.83), 350 (4.03), 373 (3.75), 509 (2.69).

IR (Nujol): 1704, 1686 cm^{-1}.

Refluxing II (5.0 g.) in acetic anhydride for 12 hr. gave III (0.6 g.) and VII (4.1 g.), while refluxing III (50 mg.) in acetic anhydride for 1.5 hr. afforded VII (45 mg.).

The Hydrolysis of III.—a) A mixture of III (50

7) H. Endo and M. Tada, *Sci. Rep. Res. Inst. Tohoku Univ.(C)*, **11**, 377 (1964).

8) All melting points are uncorrected. Shoulders in the UV spectral data are designated by "sh."

mg.) in ethanol (8 ml.) and 6 N sulfuric acid (2 ml.) was refluxed for 1.5 hr. After the mixture had been cooled, the crystals precipitated gave II (20 mg.).

b) A mixture of III (100 mg.) in ethanol (6 ml.) and a 10% potassium hydroxide alcohol solution (6 ml.) was stirred for 2 hr. at room temperature; by this procedure II (20 mg.) was obtained.

The Hydrolysis of VII.—a) A mixture of VII (150 mg.) in ethanol (5 ml.) and 6 N sulfuric acid (1.5 ml.) was refluxed for 30 min. After it had cooled, III (130 mg.) precipitated out.

b) To a suspension of VII (1.0 g.) in ethanol (30 ml.) concentrated ammonia water (10 ml.) was added, and the mixture was warmed on a water bath for 5 min. At once III (850 mg.) was precipitated.

c) A mixture of VII (50 mg.) in ethanol (5 ml.) and 6 N sulfuric acid (3 ml.) was refluxed for 2 hr.; by this procedure II (15 mg.) was obtained.

Diethyl 2-Acetamidoazulene-1, 3-dicarboxylate (V).—A solution of IV (0.6 g.) in acetic anhydride (2 ml.) was refluxed for 7 hr., and the residue produced by the evaporation of the solvent was dissolved in benzene. The solution was then passed through a column of alumina and eluted with benzene. From the effluent, IV (50 mg.) was recovered; when the column was then further eluted with ethyl acetate, crude crystals were obtained. Recrystallization from methanol afforded V (m. p. 141—142°C; 0.4 g.) as red prisms.

Found: C, 65.94; H, 5.69; N, 4.28. Calcd. for $C_{18}H_{19}O_5N$: C, 65.64; H, 5.82; N, 4.25%.

λ_{max}^{MeOH} mμ (log ε): 243 (4.37), 268 (4.32), 306 (4.80)sh, 315 (4.88), 351 (3.95), 366 (3.98), 480 (2.77).

IR (Nujol): 3330, 1706, 1664 cm^{-1}.

Diethyl 2-Diacetylaminoazulene-1, 3-dicarboxylate (VI).—A solution of IV (0.6 g.) in acetic anhydride (3 ml.) was refluxed for 10 hr. The residue produced by the evaporation of the solvent was recrystallized from methanol to give VI (550 mg.; m. p. 138—138.5°C) as red needles.

Found: C, 64.85; H, 5.70; N, 3.63. Calcd. for $C_{20}H_{21}O_6N$: C, 64.68; H, 5.70; N, 3.77%.

λ_{max}^{MeOH} mμ (log ε): 234 (4.51), 275 (4.46), 304 (4.70), 337 (3.87), 366 (3.92), 505 (2.93).

IR (Nujol): 1727, 1689 cm^{-1}.

Diethyl 2-Acetamido-6-hydroxyazulene-1, 3-dicarboxylate (VIII).—A solution of III (0.2 g.) in ethanol (30 ml.) was added to a 10% potassium hydroxide aqueous solution (5 ml.), and the mixture was stirred for 1 hr. at room temperature. After the mixture had been allowed to stand overnight, the II (20 mg.) which precipitated was filtered off. The filtrate was diluted with water (20 ml.) and acidified with 6 N sulfuric acid. The crystals which separated were recrystallized from aqueous ethanol to give VIII (m. p. 217—218°C (decomp.); 0.1 g.) as dull yellow crystals.

Found: N, 4.14. Calcd. for $C_{18}H_{19}O_6N$: N, 4.06%.

λ_{max}^{MeOH} mμ (log ε); 234 (4.51), 275 (4.46), 304 (4.70), 337 (3.87), 366 (3.92), 505 (2.93).

IR (Nujol): 3410, 3155, 1706, 1647 cm^{-1}.

The Acetate of VIII: Obtained as reddish brown crystals by refluxing VIII in acetic anhydride for 15 min. (from aqueous ethanol); m. p. 137—138°C.

Found: N, 3.89. Calcd. for $C_{20}H_{21}O_7N$: N, 3.62%.

λ_{max}^{MeOH} mμ (log ε): 244 (4.18), 268 (4.20), 312 (4.72)sh, 318 (4.77), 368 (3.94), 465 (2.85).

IR (Nujol): 3270, 1770, 1715, 1664 cm^{-1}.

Diethyl 2-Acetamido-6-aminoazulene-1, 3-dicarboxylate (IX).—*a) From Liquid Ammonia.*—III (500 mg.) was added to an excess of liquid ammonia. After the mixture had stood for one week at room temperature, the residue obtained by the evaporation of the ammonia was dissolved in ethyl acetate. The solution was then passed through a column of alumina and eluted with ethyl acetate. From the first effluent, II (30 mg.) was obtained. From the second effluent, yellow crystals (310 mg.) were obtained; these were recrystallized from ethanol to give IX (m. p. 225—225.5°C) as yellow scales.

Found: C, 62.82; H, 5.54; N, 8.07. Calcd. for $C_{18}H_{20}O_5N_2$: C, 62.78; H, 5.85; N, 8.14%.

λ_{max}^{MeOH} mμ (log ε): 267 (4.20), 288 (4.27), 337 (4.85), 393 (4.23).

IR (Nujol): 3410, 3360, 3270, 1672, 1647 cm^{-1}.

The Picrate of IX: M. p. 155°C (decomp.); dull brown micro-prisms (from ethanol).

Found: N, 11.95. Calcd. for $C_{24}H_{23}O_{12}N_5$: N, 12.21%.

b) From Sodium Azide.—III (300 mg.) and sodium azide (1.0 g.) were added to dimethyl sulfoxide (10 ml.). The mixture was then heated on a water bath for 15 hr. After dilution with water (250 ml.), it was extracted with ethyl acetate. The extract was washed with 2 N acetic acid and water, and dried over anhydrous sodium sulfate. The extract was then passed through a column of alumina and eluted with ethyl acetate. From the effluent, IX (100 mg.) was obtained.

Diethyl 2, 6-Diaminoazulene-1, 3-dicarboxylate (X).—A mixture of IX (25 mg.) in ethanol (6 ml.) and 6 N sulfuric acid (1.5 ml.) was refluxed for 40 min., and the mixture was concentrated to half volume under reduced pressure. After the addition of water (6 ml.), the solution was neutralized with sodium hydrogen carbonate and the crystals thereby formed were recrystallized from benzene to give dull brown plates (m. p. 206—207°C; 10 mg.), which showed no depression of melting point on admixture with an authentic specimen[6] of X and which were identified with X by a comparison of their infrared spectra.

Diethyl 2-Acetamido-6-ethoxyazulene-1, 3-dicarboxylate (XII).—To a solution prepared from metallic sodium (20 mg.) and absolute ethanol (6 ml.), finely powdered III (200 mg.) was added. The mixture was then stirred for 5 hr. at room temperature. After it had stood overnight, it was diluted with water and the crystals thereby formed were recrystallized from aqueous ethanol to give XII (m. p. 116—117°C; 150 mg.) as yellow needles.

Found: C, 64.70; H, 6.58; N, 3.71. Calcd. for $C_{20}H_{23}O_6N$: C, 64.33; H, 6.21; N, 3.75%.

λ_{max}^{MeOH} mμ (log ε): 245 (4.34), 278 (4.24), 327 (4.79), 372 (3.97), 408 (3.77)sh.

IR (KBr): 3530, 3380, 1718, 1701, 1681, 1667 cm^{-1}.

Diethyl 2-Acetamido-6-mercaptoazulene-1, 3-dicarboxylate (XIII).—Into a suspension of III (50 mg.) in ethanol (10 ml.), a 27% sodium hydrosulfide aqueous solution (3 ml.) was added. The mixture was then stirred for 3 hr. at room temperature. After it had stood overnight, this mixture was diluted with water (40 ml.) and acidified with 6 N sulfuric acid. The

acidic solution was extracted with ethyl acetate. The extract was washed with water and dried over anhydrous sodium sulfate. The residue obtained by the evaporation of the solvent was recrystallized from benzene to yield XIII (m. p. 220—221°C; 20 mg.) as red micro-prisms.

Found: C, 61.05; H, 4.96; N, 3.68. Calcd. for $C_{18}H_{19}O_5NS$: C, 59.82; H, 5.30; N, 3.88%.

IR (Nujol): 3400, 3280, 1709, 1684, 1650 cm^{-1}.

Diethyl 2-Acetamido-6-hydrazinoazulene-1, 3-dicarboxylate (XIV).—Eighty per cent hydrazine hydrate (5 ml.) was added to a suspension of II (100 mg.) in methanol (10 ml.), and the mixture was stirred for 3 hr. at room temperature. After it had stood overnight, the reaction mixture was concentrated to half volume and added with water. The crystals thereby formed were recrystallized from ethanol to afford XIV (m. p. 203—204°C (decomp.); 60 mg.) as yellow micro-needles.

Found: C, 60.16; H, 5.63; N, 11.48. Calcd. for $C_{18}H_{21}O_5N_3$: C, 60.16; H, 5.89; N, 11.69%.

λ_{max}^{MeOH} mμ (log ε): 222 (4.27), 271 (4.26), 288 (4.19)sh, 341 (4.77), 399 (4.26).

IR (Nujol): 3340, 3320, 1667, 1645 cm^{-1}.

The Acetate of XIV: M. p. 234.5—235°C, pale brown micro-needles (from ethanol).

Found: N, 10.58. Calcd. for $C_{20}H_{23}O_6N_3$: N, 10.47%.

Diethyl 2-Acetamido-6-phenylhydrazinoazulene-1, 3-dicarboxylate (XV).—Into a solution of phenylhydrazine (3 ml.) in ethanol (10 ml.), III (300 mg.) was added. The mixture was then refluxed for 1 hr. and concentrated to 1/4 volume. After the addition of water (50 ml.) and 2 N acetic acid (5 ml.), the crystals thereby formed were recrystallized from ethanol to give XV (m. p. 218—219°C; 190 mg.) as brownish yellow micro-prisms.

Found: C, 66.00; H, 5.71; N, 9.54. Calcd. for $C_{24}H_{25}O_5N_3$: C, 66.19; H, 5.79; N, 9.65%.

λ_{max}^{MeOH} mμ (log ε): 270 (4.21)sh, 285 (4.22), 342 (4.75), 402 (4.31).

IR (KBr): 3380, 3330, 3290, 1701, 1647 cm^{-1}.

Diethyl 2-Acetamido-6-dimethylaminoazulene-1, 3-dicarboxylate (XVI).—To a mixture of a 40% dimethylamine aqueous solution (10 ml.) in methanol (20 ml.), III (500 mg.) was added, and the mixture was refluxed for 30 min. After the addition of water (40 ml.), the crystals thereby separated were recrystallized from methanol to give XVI (m. p. 179—180°C; 300 mg.) as yellow silky needles.

Found: C, 64.77; H, 6.19; N, 7.42. Calcd. for $C_{20}H_{24}O_5N_2$: C, 64.50; H, 6.50; N, 7.52%.

λ_{max}^{MeOH} mμ (log ε): 223 (4.27), 270 (4.28), 344 (4.82), 402 (4.37).

IR (Nujol): 3260, 1695, 1637 cm^{-1}.

Diethyl 2-Acetamido-6-diethylaminoazulene-1, 3-dicarboxylate (XVII).—III (500 mg.) was added to a mixture of diethylamine (5 ml.) and ethanol (6 ml.), and the mixture was refluxed for 1 hr. After the addition of water (30 ml.), the crystals which separated were recrystallized from ethanol to give XVII (m. p. 165—166°C; 320 mg.) as yellow micro-prisms.

Found: N, 6.85. Calcd. for $C_{22}H_{28}O_5N_2$: N, 7.00%.

λ_{max}^{MeOH} mμ (log ε): 271 (4.28), 290 (4.11)sh, 345.5 (4.82), 403 (4.41).

IR (Nujol): 3260, 1701, 1669, 1642 cm^{-1}.

Diethyl 2-Acetamido-6-(2-phenylethylamino)-azulene-1, 3-dicarboxylate (XVIII).—To a mixture of β-phenylethylamine (300 mg.) in ethanol (20 ml.), III (300 mg.) was added. The mixture was refluxed for 1 hr. and then concentrated to 1/3 volume. After the addition of water (30 ml.) and 2 N hydrochloric acid (3 ml.), the crystals thereby formed were recrystallized from aqueous ethanol to afford XVIII (m. p. 163—164°C; 210 mg.) as yellow leaflets.

Found: C, 69.39; H, 6.33; N, 5.95. Calcd. for $C_{26}H_{28}O_5N_2$: C, 69.62; H, 6.29; N, 6.25%.

λ_{max}^{MeOH} mμ (log ε): 270 (4.22), 290 (4.15), 343 (4.83), 399 (4.32).

IR (KBr): 3340, 3300, 1701, 1684, 1650 cm^{-1}.

Diethyl 2-Acetamido-6-(2-hydroxyethylamino)-azulene-1, 3-dicarboxylate (XIX).—III (80 mg.) was added to a solution of ethanolamine (2 ml.) in ethanol (5 ml.). The mixture was then refluxed for 30 min. and concentrated to 1/3 volume. After the addition of water (20 ml.), the crystals thereby obtained were recrystallized from aqueous ethanol to afford XIX (m. p. 207—208°C; 45 mg.) as yellow needles.

Found: N, 7.01. Calcd. for $C_{20}H_{24}O_6N_2$: N, 7.21%.

λ_{max}^{MeOH} mμ (log ε): 220 (3.99), 269 (4.17), 290 (4.13), 342 (4.78), 399 (4.27).

IR (Nujol): 3330, 3270, 1695, 1664 cm^{-1}.

Diethyl 2-Acetamido-6-[di(2-hydroxyethyl)-amino]azulene-1, 3-dicarboxylate (XX).—III (0.8 g.) was added to a solution of diethanolamine (5 ml.) in ethanol (10 ml.). The mixture was then refluxed for 1 hr. and concentrated to half volume. After the addition of water, the crystals which separated were recrystallized from aqueous methanol to XX (m. p. 210—211°C; 500 mg.) in the form of brownish yellow needles.

Found: C, 60.98; H, 6.49; N, 6.97. Calcd. for $C_{22}H_{28}O_7N_2$: C, 61.10; H, 6.53; N, 6.48%.

λ_{max}^{MeOH} mμ (log ε): 225 (3.97), 270 (4.25), 347 (4.77), 404 (4.38).

IR (Nujol): 3300, 1704, 1658 cm^{-1}.

Diethyl 2-Acetamido-6-(2-cyanoethylamino)-azulene-1, 3-dicarboxylate (XXI). — III (200 mg.) was added to a mixture of β-aminopropionitrile (2 ml.) and triethylamine (2 ml.) in ethanol (15 ml.). The mixture was then refluxed for 2 hr. and concentrated to 1/4 volume. After the addition of water, the reaction solution was neutralized with 2 N hydrochloric acid. The crystals thereby formed were recrystallized from aqueous ethanol to afford XXI (m. p. 105—106°C; 110 mg.) as yellowish orange leaflets.

Found: N, 10.39. Calcd. for $C_{21}H_{23}O_5N_3$: N, 10.58%.

λ_{max}^{MeOH} mμ (log ε): 268 (4.20), 289 (4.13), 342 (4.74), 398 (4.24).

IR (KBr): 3530, 3410, 3280, 2257, 1695, 1661 cm^{-1}.

Diethyl 2-Acetamido-6-[di(2-cyanoethyl)amino]-azulene-1, 3-dicarboxylate (XXII).—III (300 mg.) was added to a mixture of 3, 3′-iminodipropionitrile (3 ml.) and triethylamine (3 ml.) in ethanol (10 ml.). The mixture was then refluxed for 2.5 hr. and concentrated to 1/4 volume. After the addition of water (50 ml.),

the reaction mixture was extracted with benzene, and the extract was washed with 2 N hydrochloric acid and water. After being dried over anhydrous sodium sulfate, the benzene extract was passed through a column of alumina and eluted with benzene. From the effluent, III (80 mg.) was recovered; the column was then further eluted with a mixture of benzene and ethyl acetate. From the effluent, dull orange crystals were obtained; these were recrystallized from aqueous ethanol to give XXII (m. p. 136—138°C; 135 mg.) as brownish yellow micro-prisms.

Found: N, 12.60. Calcd. for $C_{24}H_{26}O_5N_4$: N, 12.44%.

λ_{max}^{MeOH} mμ (log ε): 270 (4.25), 288 (4.16)sh, 341 (4.83), 400 (4.32).

IR (KBr): 3510, 3360, 2247, 1689, 1656 cm^{-1}.

Diethyl 2-Acetamido-6-allylaminoazulene-1, 3-dicarboxylate (XXIII).—A mixture of III (200 mg.) and allylamine (2 ml.) in ethanol (10 ml.) was treated as in the case of XVII; by this procedure XXIII (m. p. 144—145°C; 110 mg.) was obtained as orangish yellow prisms (from ethanol).

Found: C, 65.47; H, 6.44; N, 7.19. Calcd. for $C_{21}H_{24}O_5N_2$: C, 65.61; H, 6.29; N, 7.29%.

λ_{max}^{MeOH} mμ (log ε): 270 (4.23), 289 (4.17), 342 (4.80), 399 (4.29).

IR (KBr): 3360, 1706, 1689 cm^{-1}.

Diethyl 2-Acetamido-6-diallylaminoazulene-1, 3-dicarboxylate (XXIV).—A mixture of III (200 mg.) and diallylamine (3 ml.) in ethanol (10 ml.) was treated as in the case of XVI; by this procedure XXIV (m. p. 158—159°C; 120 mg.) was obtained as orange needles (from methanol).

Found: N, 6.77. Calcd. for $C_{24}H_{28}O_5N_2$: N, 6.60%.

λ_{max}^{MeOH} mμ (log ε): 234 (3.99)sh, 248 (4.15), 257 (4.15), 275 (4.11), 324 (4.68), 342 (4.55), 389 (4.25).

IR (Nujol): 3250, 1721, 1701, 1678 cm^{-1}.

Diethyl 2-Acetamido-6-ethyleneiminoazulene-1, 3-dicarboxylate (XXV).—A mixture of III (60 mg.) and ethyleneimine (4 ml.) in methanol (4 ml.) was refluxed for 10 min. After the addition of water (40 ml.), the crystals thereby formed were recrystallized from methanol to give XXV (m. p. 164.5—165.5°C; 20 mg.) as orange micro-prisms.

Found: C, 64.68; H, 5.95; N, 7.43. Calcd. for $C_{20}H_{22}O_5N_2$: C, 64.85; H, 5.99; N, 7.56%.

λ_{max}^{MeOH} mμ (log ε): 238 (3.95), 268 (4.10), 334 (4.77), 367 (4.13)sh, 399 (4.21), 445 (3.17)sh.

IR (Nujol): 3175, 1701, 1692, 1642 cm^{-1}.

Diethyl 2-Acetamido-6-pyrrolidinoazulene-1, 3-dicarboxylate (XXVI).—A mixture of III (200 mg.) and pyrrolidine (2 ml.) in ethanol (10 ml.) was treated as in the case of XVIII to form XXVI (m. p. 182—183°C (decomp.); 100 mg.) as brilliant yellow micro-scales (from aqueous ethanol).

Found: C, 66.19; H, 6.72; N, 6.70. Calcd. for $C_{22}H_{26}O_5N_2$: C, 66.31; H, 6.58; N, 7.03%.

λ_{max}^{MeOH} mμ (log ε): 272 (4.26), 292 (4.10)sh, 347 (4.78), 402 (4.40).

IR (KBr): 3410, 1709, 1669 cm^{-1}.

Diethyl 2-Acetamido-6-piperidinoazulene-1, 3-dicarboxylate (XXVII).—A mixture of III (200 mg.) and piperidine (10 ml.) in methanol (20 ml.) was treated as in the case of XIV to form XXVII (m. p. 141—142°C; 130 mg.) as yellow needles (from ethanol).

Found: C, 66.85; H, 6.43; N, 6.82. Calcd. for $C_{23}H_{28}O_5N_2$: C, 66.97; H, 6.84; N, 6.79%.

λ_{max}^{MeOH} mμ (log ε): 270.5 (4.32), 274 (4.32), 347.5 (4.77), 410 (4.42).

IR (Nujol): 3250, 1706, 1639 cm^{-1}.

Diethyl 2-Acetamido-6-morpholinoazulene-1, 3-dicarboxylate (XXVIII).—A mixture of III (200 mg.) and morpholine (4 ml.) in ethanol (10 ml.) was treated as in the case of XVI, thus forming XXVIII (m. p. 205.5—206°C; 135 mg.) as yellow needles (from methanol).

Found: C, 63.65; H, 6.56; N, 6.60. Calcd. for $C_{22}H_{26}O_6N_2$: C, 63.75; H, 6.32; N, 6.76%.

λ_{max}^{MeOH} mμ (log ε): 233 (4.01), 271 (4.25), 347 (4.74), 409 (4.40).

IR (Nujol): 3280, 1718, 1701, 1647 cm^{-1}.

Diethyl 2-Acetamido-6-(3-methoxypropylamino)-azulene-1, 3-dicarboxylate (XXIX).—A mixture of III (200 mg.) and 3-aminopropyl methyl ether (2 ml.) in ethanol (10 ml.) was treated as in the case of XVIII to give XXIX (m. p. 157—158°C; 90 mg.) as brownish yellow prisms (from aqueous ethanol).

Found: C, 63.56; H, 6.73; N, 6.62. Calcd. for $C_{22}H_{28}O_6N_2$: C, 63.44; H, 6.78; N, 6.73%.

λ_{max}^{MeOH} mμ (log ε): 269 (4.25), 290 (4.28), 342 (4.81), 397 (4.32).

IR (KBr): 3290, 1706, 1678, 1647 cm^{-1}.

Diethyl 2-Acetamido-6-(3-morpholinopropylamino)azulene-1, 3-dicarboxylate (XXX).—A mixture of III (200 mg.) and 3-aminopropylmorpholine (2 ml.) in ethanol (12 ml.) was refluxed for 2 hr. and then concentrated to 1/4 volume under reduced pressure. After the addition of water, the solution was extracted with ethyl acetate. The extract was washed with 2 N acetic acid and water, and dried over anhydrous sodium sulfate. The residue obtained by the evaporation of the solvent was recrystallized from aqueous ethanol to afford XXX (m. p. 67—68°C; 60 mg.) as yellow micro-needles.

Found: N, 8.68. Calcd. for $C_{25}H_{33}O_6N_3$: N, 8.91%.

λ_{max}^{MeOH} mμ (log ε): 269 (4.10), 286 (4.03)sh, 343 (4.69), 399 (4.19).

IR (KBr): 3400, 3330, 1695, 1684, 1653 cm^{-1}.

Diethyl 2-Acetamido-6-anilinoazulene-1, 3-dicarboxylate (XXXI).—A mixture of III (500 mg.) and aniline (5 ml.) in ethanol (10 ml.) was treated as in the case of XXX to give XXXI (m. p. 233—234°C; 380 mg.) as yellow leaflets (from aqueous ethanol).

Found: C, 68.82; H, 5.84; N, 6.48. Calcd. for $C_{24}H_{24}O_5N_2$: C, 68.56; H, 5.75; N, 6.66%.

λ_{max}^{MeOH} mμ (log ε): 270 (4.21), 274 (4.20)sh, 348 (4.58), 417 (4.30).

IR (KBr): 3250, 3215, 1701, 1669, 1642 cm^{-1}.

Diethyl 2-Acetamido-6-(2-pyridylamino)azulene-1, 3-dicarboxylate (XXXII).—A mixture of III (200 mg.), 2-aminopyridine (1 g.), and triethylamine (2 ml.) in ethanol (10 ml.) was refluxed for 7 hr. and then concentrated to half volume. After the reaction mixture had been cooled, the III (80 mg.) which had precipitated was filtered off. The filtrate was acidified with 2 N hydrochloric acid and extracted with benzene. After being washed with water and dried over anhydrous sodium sulfate, the extract was passed through a column

of alumina and eluted with benzene. From the first effluent, III (30 mg.) was recovered, while from the second effluent, the crystals obtained were recrystallized from ethanol to give XXXII (m. p. 185—186°C; 15 mg.) as orange needles.

Found: 9.75. Calcd. for $C_{23}H_{23}O_5N_3$: N, 9.97%.

λ_{max}^{MeOH} mμ (log ε): 228 (4.27)sh, 271 (4.29), 303 (4.14)sh, 354 (4.69), 422 (4.57).

IR (KBr): 3360, 3230, 1701, 1669, 1647 cm^{-1}.

Diethyl 2-Acetamido-6-(3-methylpyridin-2-ylamino)azulene-1, 3-dicarboxylate (XXXIII). — A mixture of III (200 mg.), 2-amino-3-methylpyridine (2 ml.) and triethylamine (2 ml.) in ethanol (10 ml.) was treated as in the above experiment to form XXXIII (m. p. 110—112°C; 15 mg.) as yellow micro-prisms (from aqueous ethanol); III (20 mg.) was also recovered.

Found: N, 9.35. Calcd. for $C_{24}H_{25}O_5N_3$: N, 9.65%.

λ_{max}^{MeOH} mμ (log ε): 270 (4.23), 297 (4.16)sh, 344 (4.75), 400 (4.29).

IR (KBr): 3340, 3310, 1706, 1689, 1658, 1647 cm^{-1}.

Diethyl 2-Acetamido-6-(4-pyridylamino)azulene-1, 3-dicarboxylate (XXXIV).—A mixture of III (200 mg.), 4-aminopyridine (400 mg.) and triethylamine (2 ml.) in ethanol (10 ml.) was treated as in the case of XXXII to form XXXIV (m. p. 145—146°C; 35 mg.) as yellow needles (from ethanol); III (70 mg.) was also recovered.

Found: C, 65.56; H, 5.25; N, 9.69. Calcd. for $C_{23}H_{23}O_5N_3$: C, 65.54; H, 5.50; N, 9.97%.

λ_{max}^{MeOH} mμ (log ε): 232 (4.26), 278 (4.31), 324 (4.85), 369 (4.09), 439 (3.13).

IR (KBr): 3300, 1718, 1704, 1645 cm^{-1}.

Diethyl 2-Acetamido-6-(2-quinolylamino)-azulene-1, 3-dicarboxylate (XXXV). — A mixture of III (300 mg.), 2-aminoquinoline (300 mg.) and triethylamine (3 ml.) in ethanol (15 ml.) was treated as in the case of XXXII to form XXXV (m. p. 220—221°C; 20 mg.) as reddish yellow prisms (from ethanol); III (180 mg.) was also recovered.

Found: C, 68.53; H, 5.32; N, 8.66. Calcd. for $C_{27}H_{25}O_5N_3$: C, 68.78; H, 5.34; N, 8.91%.

Diethyl 2-Acetamido-6-(4-antipyrinylamino)-azulene-1, 3-dicarboxylate (XXXVI).—A mixture of III (300 mg.), 4-aminoantipyrine (300 mg.) and triethylamine (3 ml.) in ethanol (15 ml.) was treated as in the case of XXXII to form XXXVI (m. p. 234—235°C; 80 mg.) as deep yellow micro-prisms (from ethanol).

Found: C, 65.55; H, 5.57; N, 10.38. Calcd. for $C_{29}H_{30}O_6N_4$: C, 65.65; H, 5.70; N, 10.56%.

λ_{max}^{MeOH} mμ (log ε): 277 (4.35), 282 (4.34)sh, 343 (4.69), 390 (4.36).

IR (KBr): 3230, 3165, 1709, 1689, 1672, 1661 cm^{-1}.

Diethyl 2-Amino-6-diethylaminoazulene-1, 3-dicarboxylate (XXXVIII).—A mixture of XVII (200 mg.) and 12 N sulfuric acid (1 ml.) in ethanol (5 ml.) was refluxed for 50 min. and then concentrated to half volume under reduced pressure. After the addition of water (40 ml.), the crystals thereby formed were dissolved in benzene. The benzene solution was passed through a column of alumina and eluted with benzene. From the effluent, crystals (80 mg.) were obtained; these crystals were recrystallized from ethanol to give XXXVIII (m. p. 153—154°C; 65 mg.) as brownish yellow prisms.

Found: C, 67.27; H, 7.00; N, 7.65. Calcd. for $C_{20}H_{26}O_4N_2$: C, 67.02; H, 7.31; N, 7.82%.

λ_{max}^{MeOH} mμ (log ε): 227 (4.33), 265.5 (4.49), 303 (4.16), 354.5 (4.74), 419 (4.28), 444 (4.32), 480 (4.05)sh.

IR (Nujol): 3530, 3370, 1715, 1678 cm^{-1}.

The Picrate of XXXVIII: M. p. 155—157°C, reddish brown prisms (from ethanol).

Found: C, 53.27; H, 4.56; N, 11.98. Calcd. for $C_{26}H_{29}O_{11}N_5$: C, 53.15; H, 4.98; N, 11.92%.

Diethyl 2-Amino-6-(2-hydroxyethylamino)azulene-1, 3-dicarboxylate (XXXIX). — A mixture of XIX (40 mg.) in ethanol (5 ml.) and 6 N sulfuric acid (1 ml.) was refluxed for 1 hr. After the addition of water, the crystals thereby precipitated were recrystallized from ethanol to yield XXXIX (m. p. 184—185°C; 15 mg.) as yellowish brown prisms.

Found: C, 62.17; H, 6.01; N, 7.84. Calcd. for $C_{18}H_{22}O_5N_2$: C, 62.41; H, 6.40; N, 8.09%.

λ_{max}^{MeOH} mμ (log ε): 252 (4.09), 297 (3.91)sh, 343 (4.76), 409 (4.24).

IR (Nujol): 3530, 3370, 3300, 1706, 1684, 1667, 1603 cm^{-1}.

Diethyl 2-Amino-6-[di(2-hydroxyethyl)amino]-azulene-1, 3-dicarboxylate (XL).—A 10% potassium hydroxide aqueous solution (1 ml.) was added to a solution of XX (100 mg.) in ethanol (5 ml.). The mixture was then refluxed for 10 min. and concentrated to half volume under reduced pressure. After the addition of water (30 ml.), the reaction solution was extracted with benzene. The benzene extract was washed with water and dried over anhydrous sodium sulfate. After the removal of the solvent, the crystals which remained were recrystallized from aqueous methanol to form XL (m. p. 146—147°C; 30 mg.) as orangish yellow prisms.

Found: N, 6.89. Calcd. for $C_{20}H_{26}O_6N_2$: N, 7.18%.

IR (Nujol): 3530, 3340, 1667, 1634 cm^{-1}.

Diethyl 2-Amino-6-diallylaminoazulene-1, 3-dicarboxylate (XLI).—A mixture of XXIV (150 mg.) in ethanol (6 ml.) and 6 N sulfuric acid (1 ml.) was treated as in the case of XXXVIII to give XLI (m. p. 123—124°C; 20 mg.) as brownish yellow micro-prisms (from a mixture of benzene and cyclohexane).

Found: N, 7.16. Calcd. for $C_{22}H_{26}O_4N_2$: N, 7.33%.

λ_{max}^{MeOH} mμ (log ε): 228 (4.31), 263 (4.47), 300 (4.13), 354 (4.72), 419 (4.22), 444 (4.24), 480 (3.98)sh.

IR (KBr): 3480, 3360, 1667, 1634 cm^{-1}.

Diethyl 2-Amino-6-morpholinoazulene-1, 3-dicarboxylate (XLII).—A solution of XXVIII (50 mg.) in ethanol (4 ml.) and 6 N sulfuric acid (1.5 ml.) was treated as in the case of XXXVIII to give XLII (m. p. 134—134.5°C; 10 mg.) as yellow needles (from methanol); then XXVIII (15 mg.) was also recovered.

Found: N, 7.13. Calcd. for $C_{20}H_{24}O_5N_2$: N, 7.52%.

λ_{max}^{MeOH} mμ (log ε): 260 (4.42), 293 (4.00), 349 (4.69), 428 (4.21), 480 (3.95)sh.

IR (Nujol): 3460, 3340, 1675, 1667, 1634 cm^{-1}.

The Picrate of XLII: M. p. 156—157°C, brownish black crystals (from ethanol).

Found: C, 52.12; H, 4.66; N, 11.50. Calcd. for $C_{26}H_{27}O_{12}N_5$: C, 51.91; H, 4.52; N, 11.64%.

Diethyl 6-Diethylaminoazulene-1, 3-dicarboxylate (XLIII).—*a) From XXXVIII.* — Into a solution of XXXVIII (180 mg.) and concentrated sulfuric acid (0.6 ml.) in dioxane (10 ml.), sodium nitrite (50 mg.) in water (2 ml.) was stirred at room temperature. After the mixture had been stirred for a further 30 min., sodium hypophosphite (1.5 g.) was added. The mixture was then stirred for a further 3 hr. and then allowed to stand overnight at room temperature. The reaction mixture was diluted with water and extracted with ethyl acetate. The extract was washed with water and dried over anhydrous sodium sulfate. It was then passed through a column of alumina and eluted with benzene. From the effluent, the crystals were obtained; they were then recrystallized from ethanol to give yellow needles (25 mg.), which showed no depression of melting point on admixture with an authentic specimen[1] of XLIII.

The water-layer was adjusted to a slightly alkaline state with a 10% potassium hydroxide aqueous solution and extracted with ethyl acetate. By the same purification, XLIII (5 mg.) was obtained.

b) From XVII.—A solution of XVII (200 mg.) and concentrated sulfuric acid (1 ml.) in dioxane (10 ml.) was warmed on a water bath for 15 min. and then treated as in a) to yield XLIII (35 mg.).

The author wishes to express his thanks to Professor Tetsuo Nozoe and Professor Kahei Takase, Faculty of Science, Tohoku University, for their kind guidance throughout the course of the present work. Thanks are also due to Professor Hideo Endo of the Institute for his interest and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1961—1967 (1966)

The Oxygen Exchange Reaction of Phenol in Acidic Media[1)]

By Shigeru OAE,† Reiko KIRITANI†† and Waichiro TAGAKI†

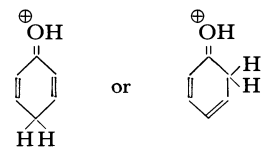
† *Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka*

†† *Department of Chemistry, Radiation Center of Osaka Prefecture, Sakai, Osaka*

(Received December 15, 1965)

The acid-catalyzed oxygen exchange reaction to a number of phenolic compounds that is, phenol, *o*- *m*- and *p*-hydroxy phenols, α- and β-naphthols, *o*- *m*- and *p*-nitrophenols, *o*- *m*- and *p*-aminophenols, *o*- and *p*-bromophenols, 2, 4, 6-tribromophenol, *o*- *m*- and *p*-cresols and 2, 4, 6-trimethylphenol, plus quinone for comparison with ^{18}O-enriched water was carried out under various conditions. A plot of the log k_x/k_h line against Hammett σ-constants in the substituted phenols gave a fairly good correlation line ($\rho=0.47$) except in the cases of *p*-bromophenol and *p*-aminophenol. The mechanism of these reactions has been discussed.

During the course of our study of the acid-catalyzed hydrolysis of phenyl benzenesulfonate with concentrated hydrochloric acid in ^{18}O-enriched water, we found that the phenol recovered was always incorporated with an excess of ^{18}O and that the amount of ^{18}O incorporation increased with prolonged heating.[2)] We have suggested that, in a strong acidic medium and at a high temperature, such as 180°C, phenol readily accepts a proton at either the *p*- or *o*- position to form a quasi-stable incipient carbonium ion intermediate (A) in which the original hydroxyl function acquires more of a carbonyl character, and hence the oxygen exchange is facilitated.



(A)

Gold and Satchell have proposed that phenolic compounds usually accept one proton at either the *o*- and *p*-position in a strong acidic medium to form the σ-complexes of the corresponding conjugate acids.[3)] Such a σ-complex has been shown by NMR and ultraviolet spectroscopic studies[4)] to exist in an appreciable concentration in the cases of phloroglucinol and its alkyl ethers. However,

the ultraviolet spectra of phenol itself in concentrated sulfuric acid indicates that the major species is the oxygen-protonated phenol, while the so-called σ-complex is of only minor importance.[5]

Although the equilibrium concentration of such a σ-complex of phenol would be quite low around room temperature, it would definitely be increased at an elevated temperature. Moreover, even though its concentration would be low, the ring protonation is undoubtedly a very facile equilibrium reaction in view of the rapid hydrogen exchange reaction of phenol in strong acidic media; it would also be very important in the present oxygen exchange reaction. The ring protonation at the *o*- and *p*-positions to form the σ-complex causes the hydroxy group to acquire something of a carbonyl character, thus making the subsequent acid-catalyzed oxygen-isotopic exchange with ^{18}O-enriched water very facile. Incidentally, the carbonyl group of ketone or aldehyde is known to undergo very facile oxygen isotopic exchange with that of water in both acidic and alkaline media.[6] The overall picture of the reaction process is quite analogous to that of Bucherer-type reaction of naphthols. Naphthols, known to have something of a carbonyl character, undergo facile nucleophilic replacement reactions. Namely, β-naphthol is known to react with such nucleophilic reagents as sulfurous acid[7] and thioglycolic acid.[8] Here again these reactions are believed to proceed by the attack of the nucleophile at the carbonyl carbon of the quasi keto-form intermediate, formed by the ring protonation at either the *o*- or the *p*-position.

Therefore, the oxygen exchange reaction of phenol can best be understood when one assumes a mechanism involving a prior ring protonation and the subsequent nucleophilic attack of water at the carbonyl carbon. However, this somewhat unfamiliar idea has to be tested with more investigations in view of the fact that, although the hydroxylic proton of phenol has been shown to undergo a very facile D–H exchange in both acidic and alkaline aqueous media,[9] the oxygen exchange of the hydroxyl group with solvent water itself has been believed not to occur, even in a strong acidic medium.

This work was undertaken in order to determine the most suitable reaction conditions of oxygen exchange and in order to clarify the mechanism by examining the effect of the substituent on the rate of oxygen exchange.

Results and Discussion

The oxygen exchange reaction was tested at first under conditions similar to those used for the acid-catalyzed hydrolyses of phenyl benzenesulfonate[2] and *p*-nitrophenyl benzenesulfonate.[10] Phenol and 10 N hydrochloric acid, prepared by dissolving hydrogen chloride gas in ^{18}O-enriched water, were sealed in a glass tube, and the tube was heated under the conditions listed in Table I. The same procedure was also used for the solution 4.8 N hydrochloric acid. In a separate experiment, a mixture containing the same reactants was refluxed. The products, labeled phenols, were then recovered and subjected to ^{18}O analysis by the usual method.[11] The reaction conditions and the results are shown in Table I.

The phenols recovered were always incorporated with an excess of ^{18}O when the exchange reactions were carried out at 180°C in a sealed tube, the amount of ^{18}O incorporation increasing with an increase in the duration of heating. Since the reaction conditions used in this work were rather drastic, one might expect some possible rearrangement products from the phenols used. However, it was found that all the phenols used in this work, except for the isomeric nitrophenols, were recovered in almost quantitative yields. The purities of these recovered phenols were checked by infrared, ultraviolet and gas chromatographic analyses, and by the fractional recrystallization of the ester derived from the phenols, no rearranged phenol was detected from any of the phenols applied. Even in the case of the isomeric nitrophenols, where some severe decompositions were observed, the recovered phenols were identical to the starting phenols, although the yields of the recovered phenols were low. The change in the concentration of hydrochloric acid from 10 N to 4.8 N did not affect the extent of ^{18}O incorporation. However, both at 110°C in a sealed tube and under a reflux, no oxygen exchange was observed, even after 24 hr. These results can be explained by assuming either an increased concentration of the intermediate (A) at high temperatures, or an increased rate of the nucleophilic attack of water, or both.

The contribution of the quinoid structure A would be greater for the oxygen exchange of β-naphthol and related compounds than for that of phenol. Therefore, the oxygen exchange reactions of catechol, resorcinol, hydroquinone, quinone and both α- and β-naphthols were next investigated. The procedures for the preparation of the reaction mixtures and the reaction conditions were similar

to those described in connection with the oxygen exchange of phenol (Table I). The results are shown in Table II.

Unlike the cases of monobasic phenols, the oxygen exchange of dibasic phenol listed in Table II took place not only at 180°C, but also at 110°C, except for the case of *o*-hydroxyphenol (catechol). The very facile oxygen exchange of both α- and β-naphthols is evident from their higher amounts of oxygen exchange, about 40%, even at 110°C. Here, the mechanism involving the quasi-quinoid intermediates appears to fit the experimental observations. It is interesting to note that the amount of ^{18}O incorporation was higher with resorcinol than those of the other *o*- and *p*-isomers. The same trend was observed in the cases of isomeric aminophenols.

We next carried out a series of experiments in the hope of obtaining more concrete information on the nature of this exchange reaction through comparing the substituent effects on the oxygen exchanges. This exchange reaction is considered to fall in the category of aromatic nucleophilic displacement reactions; it is also considered generally that the rate-determining step would be the addition of solvent water to the phenolic carbon. An important question is whether or not the quinoid structure A described before is well developed before the rate-determining step. If the hydroxyl group acquires a distinct carbonyl character before the actual oxygen-exchange reaction, the substituent effect represented by Hammett σ-values should nicely fit, just as in the cases of nucleophilic attack on a carbonyl carbon.

A similar substituent effect would be expected when the quinoid structure makes no contribution, with little assistance of ring protonation, and when the reaction proceeds directly through the nucleophilic attack on the aromatic carbon. However, in the latter case a strong electron-withdrawing substituent, such as the nitro group, would facilitate the exchange, especially by resonance, more than what may be expected from the σ- constant, and the substituent effect would be better expressed by σ^--constants. Furthermore, an important difference would be expected between the effects of *m*- and either the *o*- or *p*-OH and the NH_2 group. Ring protonation to form the quinoid structures would be favored for *m*-OH and *m*-NH_2 phenols because of the contribution of the following

TABLE III. OXYGEN EXCHANGE REACTION OF SUBSTITUTED PHENOLS

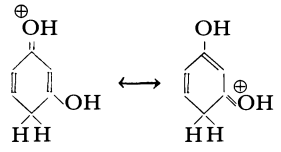
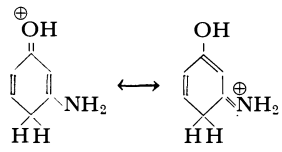
Numerical values in parentheses represent the ^{18}O concentration of phenolic oxygen calculated from the concentration of whole molecule by neglecting the ^{18}O exchange of nitro group.



IIa IIb



IIIa IIIb

resonance structures (IIa, IIb, IIIa, IIIb). Such a stabilization of quinoid structure is not expected for the corresponding *o*- and *p*-isomers. On the other hand, amino phenol is considered to be equilibrating with its *N*-protonated conjugate acid, and the *p*-ammonio group would strongly hinder the protonation at the same *p*-position, while the *m*-ammonio group would not much obstruct the protonation to the hydroxyl group at either the *o*- or the *p*-position. Both free amino and ammonio groups which are equilibrating thus favor the quinoid structure for the *m*-isomer much more than for the *p*-isomer. The same conclusions may be drawn for the hydroxyl group.

The results of the oxygen exchange reactions of isomeric nitrophenols, aminophenols, bromophenols and cresols are shown in Table III. The oxygen exchanges for cresol and bromophenol were the same or slightly less than that for unsubstituted phenol. Marked differences were observed for isomeric amino and nitro phenols. *p*-Nitrophenol showed an unusually high extent of oxygen exchange as compared to its *o*- and *m*-isomers, whereas the oxygen exchange of *m*-aminophenol was far greater than those of the *o*- and *p*-isomers. The same trend as in aminophenols, although less marked was observed for hydroxyphenols (Table II). Another remarkable observation is that practically no oxygen exchange takes place for *o*-isomers of amino-, hydroxy- and nitrophenol. Steric hindrance alone cannot explain such results, since the oxygen exchange was observed for *o*-cresol and *o*-bromophenols, although such exchange was smaller

than in the corresponding *m*- and *p*-isomers. Another responsible factor for the remarkable retardation of the ^{18}O exchange would be the intramolecular hydrogen bondings, which are expected for the former three phenols and which would stabilize the ground states much more than the transition states of the former three phenols.

Competitive Reaction—As is indicated in the runs of *p*-nitrophenol in Table III, the percentage of oxygen exchange was greater here despite the shorter reaction time. Since the reaction temperature was high and since the reactions were carried out in a sealed tube in an electric furnace, it was difficult to maintain the same reaction conditions. Therefore, we have carried out competitive reactions in order to eliminate other complicating factors and obtain at least a semi-quantitative measure of the relative reactivities of the isomeric phenols.

The reaction conditions and the procedures were essentially the same as those described above. A mixture of equimolar amounts of the unsubstituted reference phenol and a substituted phenol was sealed with a large excess of ^{18}O-enriched 10 N hydrochloric acid. The reaction products were then separated into phenol and substituted phenol by a combination of distillation, recrystallization and gas chromatography. The relative reactivity, k_x/k_h, was calculated using Eq. 3:

$$\frac{dX_t}{dt} k_x(X_\infty - X_t) \quad [H_2{}^{18}O] \tag{1}$$

$$\frac{dh_t}{dt} k_h(X_\infty - h_t) \quad [H_2{}^{18}O] \tag{2}$$

$$k_x/k_h = \log \frac{(X_\infty - X_0)}{(X_\infty - X_t)} \Big/ \log \frac{(X_\infty - h_0)}{(X_\infty - h_t)} \tag{3}$$

X_∞ : Calculated ^{18}O-atom% of the reaction mixture at equilibrium

X_t : Observed ^{18}O-atom% of the substituted phenol at the time *t*.

h_t : Observed ^{18}O-atom% of the unsubstituted phenol at the time *t*.

X_0 : Initial ^{18}O-atom% of substituted phenol ($t=0$).

h_0 : Initial ^{18}O-atom% of unsubstituted phenol ($t=0$).

Since Eq. 3 is derived from Eqs. 1 and 2, neglecting the reverse reaction, the k_x/k_h value depends on the extent of oxygen exchange; for more precise values, extrapolation to zero-time values is desirable. For a more precise ^{18}O-analysis, it is desirable that the atom % of the ^{18}O-enriched water be as high as possible. However, we had access to ^{18}O-enriched water of only 1.5% ^{18}O enrichment in the present work. Therefore, the values of k_x/k_h are unavoidably crude. In spite of these limitations, the two values of k_x/k_h for each isomer at different times were close to each other and, hence, may be used as reactivity measures of the isomeric phenols. The trends in Table IV are similar to those found in Table III. *m*-Aminophenol and *p*-nitrophenol are about three times more reactive than unsubstituted phenol. Methyl and bromo-substituents slightly decrease the reactivity, while *p*-aminophenol again shows an unusually low reactivity.

A plot of log k_x/k_h against Hammett σ-constants did not give a good correlation curve for isomeric methyl, bromo and *p*-nitro groups. Since aminophenol is considered to be an equilibrium mixture of free amino and ammonio species, it is difficult to assign any substituent constant to this group.

Table IV. Competitive reaction of phenol with related phenols

X_∞: ^{18}O Atom % of each compound when exchange reaction was taken place completely.

However, if the substituent constant of the trimethyl ammonio group, 0.904 for m-$\overset{\oplus}{N}(CH_3)_3$, is taken as the constant for m-$\overset{\oplus}{N}H_3$, and if $\sigma_p^-(=1.27)$ is used for p-nitrophenol, a fairly good correlation line ($\rho=0.47$) is obtained, as is shown in Fig. 1, although p-nitrophenol, p-bromophenol and, especially, p-aminophenol still greatly deviate from this line.

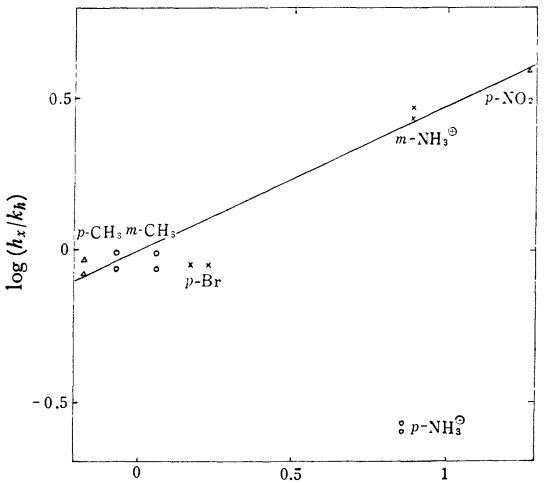

Fig. 1

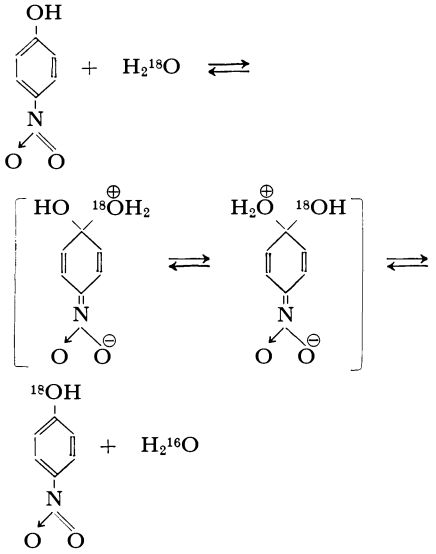
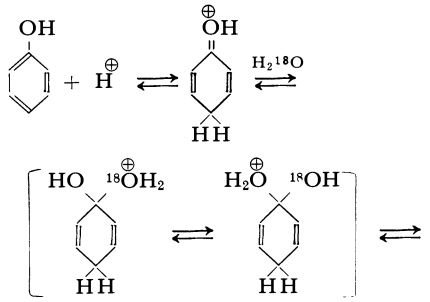
A self-consistent explanation of all the above results is not easy. However, there are a few points of interest worthy of attention. The ρ value was found to be substantially smaller than that expected from ordinary aromatic nucleophilic substitutions. We believe that it is by no means a ρ value for a simple aromatic nucleophilic substitution, but a value that results from two succesive reactions with two different ρ values opposite in sign, i. e., the prior equilibrium reaction of protonation and the subsequent aromatic nucleophilic reaction. The small ρ value with a positive sign may indicate that the electronic effect of the substituent operates more at the second step, namely, the aromatic nucleophilic substitution, than at the prior protonation equilibrium reaction. The correlation of the reactivity of p-nitrophenol by the σ^--constant seems to indicate that the mechanism of the oxygen exchange of this phenol is different from those of the other phenols, as has been discussed before, the ring protonation to form the intermediate of the quinoid structure is not necessary, and the reaction may well proceed through direct nucleophilic displacement due to the strong electron-withdrawing ability of the p-nitro group (Eq. 4). This is consistent with our previous observations that the acid-catalyzed hydrolysis of p-nitrophenyl benzenesulfonate under strong acidic conditions proceeds partly through the fission of the phenolic C–O bond, while the hydrolysis of the unsubstituted phenyl benzenesulfonate proceeds by the fission of the S–O bond and practically no phenolic C–O bond fission was detected. The mechanism of the oxygen exchange of the other isomers seems to be better explained by assuming the quinoid structure A as the pre-equilibrium species which participates in the rate-determining step.

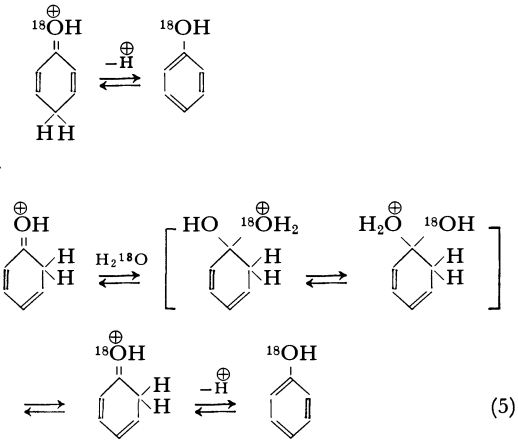


(4)

Only this mechanisms seems capable of explaining the large rate differences between p- and m-aminophenol presented before, irrespective of whether the contributing species is a free amino group or a protonated ammonio group. The usual unreactivity of p-aminophenol is undoubtedly due to the low concentration of the incipient quinoid intermediate A formed in the unfavored equilibrium of protonation, because the electron-withdrawing inductive effect of the ammonium group serves to deactivate the benzene ring for an electrophilic attack. The decreased reactivity of bromophenols is probably also due to the decreased concentration of the incipient intermediate A formed in the pre-equilibrium protonation, since the bromo group is known to deactivate the benzene ring for an electrophilic attack due to its strong electron-withdrawing inductive effect.

In conclusion, the mechanism involving the quinoid intermediate may be summarized as in Eq. 5:





or

Experimental

The Oxygen Exchange Reaction of Substituted Phenols.—a) In a sealed tube, in 10 N hydrochloric acid: A phenol (1 g.) and 5 ml. of ^{18}O-enriched aqueous 10 N hydrochloric acid were sealed in a tube and heated at 110°C or 180°C for a suitable time. Then the sealed tube was broken, and all the contents except resorcinol, quinone and aminophenols were extracted with ether. The ether layer was dried over calcium chloride and concentrated, and the residue was treated in the following manner: Phenol was purified by distillation under reduced pressure or by reaction with bromine to give 2, 4, 6-tribromophenol, m. p. 96°C; catechol was recrystallized from alcohol, m. p. 105°C; hydroquinone was recrystallized from alcohol, m. p. 170—171°C; α-naphthol was purified by sublimation, m. p. 96°C; β-naphthol was purified by sublimation, m. p. 122—123°C; nitrophenols were purified by recrystallization or sublimation—*o*-nitrophenol (m. p. 44—45°C), *m*-nitrophenol (m. p. 97°C) and *p*-nitrophenol (m. p. 113—114°C); bromophenols were purified by distillation—*o*-bromophenol (b. p. 194°C) and *p*-bromophenol (b. p. 238°C, 92°C/24 mmHg); 2, 4, 6-tribromophenol was purified by sublimation, m. p. 96°C; and 2, 4, 6-trimethylphenol was recrystallized from ethanol, m. p. 75°C. Both resorcinol and quinone, after they had been subjected to the ^{18}O exchange experiments, were separated from the sealed tubes and collected by filtration. Resorcinol was purified by sublimation (m. p. 110—111°C), while quinone was recrystallized from alcohol, m. p. 115°C.

The aminophenols which separated as hydrochloride after the evaporation of the water from the reaction mixture were collected and recrystallized from water. The ammonium salts were neutralized with aqueous sodium hydroxide, and the free aminophenols which precipitated were filtered and recrystallized from ethanol—*o*-aminophenol (m. p. 170—174°C), *m*-aminophenol (m. p. 122—123°C) and *p*-aminophenol (m. p. 188°C). The reaction mixtures for isomeric cresols were separated into two layers. The upper, oily layer was distilled under reduced pressure, thus producing *o*-cresol (b. p. 191—192°C), *m*-cresol (b. p. 202°C) and *p*-cresol (b. p. 202°C).

Other Conditions for the ^{18}O Exchange.—b) In 4.8 N hydrochloric acid: The procedures were the same as in a).

c) Under reflux: The same reaction mixture of phenol and 10 N hydrochloric acid as was used in the above experiments was placed in a 20 ml. flask and refluxed for 6 hr. The procedure of the separation of phenol was the same as that described above.

All the results described in above (a), b) and c)) are shown in Tables, I, II and III.

When nitrobenzene was treated by the same procedure as in the reaction of nitrophenols, it was verified that the oxygen exchange of the nitro group did not take place.

Competitive Reactions.—a) Aminophenol: Phenol (0.800 g. (8.5×10^{-3} mol.)), *m*- or *p*-aminophenol (0.800 g. (7.33×10^{-3} mol.)) and 10 N hydrochloric acid containing excess ^{18}O (8.000 g. (0.444 mol.)) were sealed in a tube. The sealed tubes were then heated at 180°C for 4, 7 or 8 hr. The entire contents were extracted with ether and treated as above. Phenol was obtained from the ether layer, and aminophenol, from the aqueous layer.

b) *p*-Nitrophenol: Phenol (0.800 g. (8.5×10^{-3} mol.)), *p*-nitrophenol (0.800 g. (5.75×10^{-3} mol.)) and 10 N hydrochloric acid containing excess ^{18}O (8.000 g. (0.444 mol.)) were sealed in a tube. The sealed tubes were then heated at 180°C for 2 or 4 hr. The entire contents were extracted with ether, and the ether layer was dried over calcium chloride. The ether extract was then put into a sublimation apparatus to which a trap cooled with dry ice - acetone had been joined. When the sublimation apparatus was heated in vacuo, purified *p*-nitrophenol in the sublimation apparatus and phenol in the trap were simultaneously obtained.

c) Cresol: Phenol (0.800 g. (8.5×10^{-3} mol.), *o*-*m*- or *p*-cresol (0.800 g. (7.39×10^{-3} mol.)) and 10 N hydrochloric acid containing excess ^{18}O (8.000 g. (0.444 mol.)) were sealed in a tube. The sealed tubes were then heated at 180°C for 4 or 8 hr. The entire contents were extracted with ether, and the ether extracts were distilled. The distilled mixture was then separated to phenol and cresol by gas chromatography, using a 2 m. column of silicone 550, with nitrogen as the carrier gas (10—13 cc./min.), with a temperature of 160°C, and with a sensibility of 1.

d) Bromophenol: Phenol (0.800 g. (8.5×10^{-3} mol.)), *o*- or *p*-bromophenol (0.800 g. (4.62×10^{-3} mol.)) and 10 N hydrochloric acid containing excess ^{18}O (8.000 g. (0.444 mol.)) were sealed in a tube. The sealed tubes were then heated at 180°C for 8, 24 or 25 hr., and the entire contents were treated by the same procedure as was used for cresol.

All the phenols thus separated were subjected to ^{18}O analysis, and the k_x/k_h value was calculated according to Eqs. 1—3.

The Oxidation of Methyl Sorbate with Monoperphthalic Acid

By Yasuo SUHARA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

and Toshikatsu MINAMI

Chiba Institute of Technology, Narashino-shi, Chiba

(Received December 20, 1965)

The products obtained by treating methyl sorbate with monoperphthalic acid under various conditions were studied by chemical and spectroscopic procedures. From the results of chemical tests and spectroscopic observations in the infrared and ultraviolet regions, it was inferred that the product in all cases is methyl *trans*-4, 5-epoxy-*trans*-2-hexenoate. This inference was confirmed by NMR spectroscopy.

Epoxy compounds are, in general, prepared from non-conjugated fatty acids or their derivatives by treatment with organic peracids. However, some epoxy compounds can be prepared from conjugated unsaturated hydrocarbons by treatment with peracetic acid.[1] On the other hand, our previous study[2] has shown that the substances obtained by treating β-eleostearic acid (*trans*-9-*trans*-11-*trans*-13-octadecatrienoic acid) and its methyl ester with peracetic, perbenzoic, and monoperphthalic acids are not epoxy compounds but hydroxy-acyloxy compounds. Therefore, an investigation has been made to see whether methyl sorbate (*trans*-2-*trans*-4-hexadienoate) can be epoxidized by the action of an organic peracid. The results of this investigation will be described in this paper.

In the present study, methyl sorbate was treated with monoperphthalic acid under the conditions indicated in Table I.

The saponification values and the oxirane oxygen contents of the products were 396.8—401.7 and 10.3—11.0% respectively; these values agree with the theoretical values of methyl monoepoxyhexenoate (saponification value, 394.7; oxirane oxygen content, 11.3%). Although all the products had small peroxide values (10.3—13.3 meq./kg.), such values may be due to the presence of traces of monoperphthalic acid.

However, the oxidation products cannot be identified with methyl monoepoxyhexenoate on the basis of the above data alone. According to Bauer and Bähr,[3] an oxo compound (hexaoxostearic acid) is formed when a conjugated unsaturated fatty acid (eleostearic acid) is treated with perbenzoic acid. Hence, the products obtained in the present study may contain oxo groups.

The carbonyl values of the oxidation products were, therefore, determined by using hydroxylamine hydrochloride. The values obtained were 162.8—179.2. Also, the carbonyl values of methyl sorbate and crotonate, determined for purposes of comparison by the same method, were 175.6 and 101.0 respectively. On the other hand, in the test by Legal reaction with sodium nitroprusside, the oxidation products, methyl sorbate and crotonate, all gave negative results. From these observations it may be considered that the oxidation products do not contain oxo groups and that, in the determination of carbonyl values, hydroxylamine may have interacted with the carbon-carbon double bond presumed to exist in the products.

The fact that hydroxylamine interacts with the carbon-carbon double bond in an α-monoenoic fatty acid has already been reported.[4] This fact supports the above inference; it also suggests that the carbon-carbon double bond in the product of the oxidation of methyl sorbate exists in the position α to the carbonyl group.

This predicted position of the double bond was confirmed by ultraviolet spectroscopic studies. The molar absorbance of the product in a heptane solution at λ_{max} 217.7 mμ was 13700. The intense absorption at this wavelength arises from the conjugation of a double bond with a carbonyl group in hydrocarbon chains.[5]

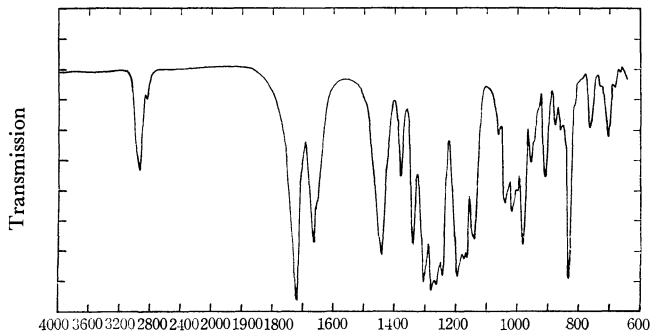

Fig. 1. Infrared absorption spectrum of the oxidation product.

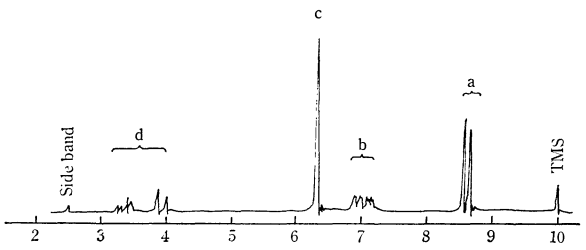


Sweep rate, 3.96 c.p.s./sec.; 100 Mc.; H_1, −70 db

Fig. 2. NMR spectrum of the oxidation product (0.1 g.) in carbon tetrachloride (1 ml.).

The structural characteristics of the oxidation products were further studied by infrared spectroscopy. In this case, the infrared spectra of methyl sorbate, crotonate and levulinate were also determined for purposes of comparison. The infrared spectra of the oxidation products were nearly all the same; one of them is presented in Fig. 1. The band at 980 cm^{-1} is due to the trans double bond existing in the position α to the carbonyl group in unsaturated fatty acids.[6] The absorption band exhibited by the oxidation products at 834 cm^{-1} may correspond to the band at 837 cm^{-1} in the spectrum of methyl crotonate.

The two bands at 1280 and 877 cm^{-1} in the spectrum of the product suggest the presence of *trans*-epoxy groups, because the literature[7] shows that many of the *trans*-epoxy compounds hitherto studied absorb near 1250 and 890 cm^{-1}. This spectroscopic information is in harmony with the results of the oxirane oxygen determination. The slight displacement of the observed bands

6) L. J. Bellamy, "The Infra-red Spectra of Complex Molecules," Methuen & Co. Ltd., London (1958), p. 45.

7) L. J. Bellamy, ibid., p. 115.

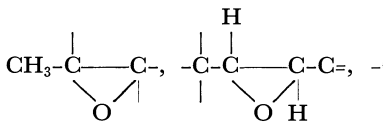
from the normal band positions may be due to the presence of a double bond near the epoxy group in the oxidation product.

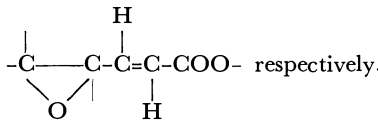
The type of epoxy group suggested by the spectrum can be supported theoretically. From the stereochemical point of view, it is evident that the epoxy groups resulting from the reaction of methyl sorbate with paracids must exist in the trans-form, for methyl sorbate contains two trans-double bonds and, according to Lynch and Pausacker,[8] epoxidation with organic peracids always results in cis-addition.

Moreover, no absorption bands due to the conjugated double bond (1614 and 997 cm^{-1} [9]), the γ-keto carbonyl group (1736 cm^{-1} in the spectrum of methyl levulinate) and the hydroxyl group (near 3500 cm^{-1} [10]) appear in the spectrum of the oxidation products.

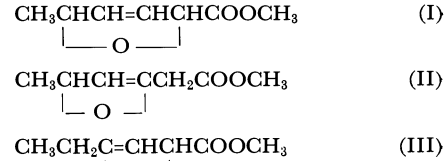
From the results of chemical tests and spectroscopic observations, it follows that the oxidation product obtained in each experiment contains neither a hydroxyl nor a keto carbonyl group, but an epoxy group and a double bond. As the ultraviolet and infrared spectra show, the double bond is in the position α to the ester carbonyl group; hence, the epoxy group is an α-epoxy group.

This conclusion was confirmed by NMR spectroscopy. The spectrum is presented in Fig. 2. As might be expected from the molecular structure suggested above, there appear four signals (mostly multiplets), which are marked a, b, c, and d in the figure. The chemical shift and signal intensity (peak area) measurements indicate that the signals, a, b, c, and d, are due to the groups





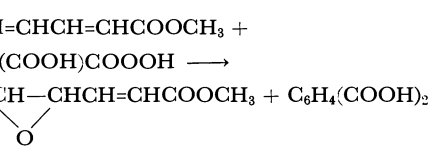
In a study similar to the present one, Smit[11] has stated that the product obtained by treating 9, 11-octadecadienoic acid with perbenzoic acid is a γ- or β-epoxide. Should the reaction of methyl sorbate with monoperphthalic acid proceed in nearly the same manner as the reaction of 9, 11-octadecadienoic acid with perbenzoic acid, one of the three epoxides represented below by formulas I, II, and III would be formed:



Whichever the product may be, the ultraviolet spectrum will show an absorption peak near 183 mμ (due to the isolated double bond[12]) and the infrared spectrum will show an absorption band in the 1070—1140 cm^{-1} range (associated with the larger ring of the cyclic ether group[7]). Moreover, if the product is epoxide II or III, the NMR spectrum will show five signals.

However, none of these characteristics have been observed in the present study. Hence, there is no possibility of the formation of γ- and β-epoxides under the conditions employed.

On the basis of the information obtained, it can be concluded that the product obtained in each of the present experiments is methyl *trans*-4, 5-epoxy-*trans*-2-hexenoate, and that the reaction of methyl sorbate with monoperphthalic acid proceeds as follows:



Even when the mole ratio of monoperphthalic acid to methyl sorbate is 2 to 1 (Exp. No. 4), the reaction does not give the diepoxide at all. (In this case, the yield of the monoepoxide is about twice the yield obtained when the mole ratio is 1 to 1.) This fact indicates that the double bond in the α position is resistant to the action of monoperphthalic acid.

Experimental*

Materials Used.—Monoperphthalic acid was prepared from phthalic anhydride by treatment with hydrogen peroxide in an ether solution according to the procedure of Goryaev et al.[13] Methyl sorbate, crotonate, and levulinate were prepared from the corresponding fatty acids by esterification with methanol in the presence of sulfuric acid as a catalyst.

Methyl sorbate: Purity: 98.2%. n_D^{25}: 1.5001. Acid value: 2.0.

Saponification value: Found, 447.3; Calcd., 444.8. UV ε: 23500 at λ_{max} 253.5 mμ in a heptane solution.

Analysis.—The consumption of monoperphthalic acid was determined by the method of Wheeler.[14]

The oxirane oxygen content was determined with a hydrogen bromide-glacial acetic acid solution by the method described in our previous paper.[15] The carbonyl values were determined by the method of Milewsky and Wentzel.[16]

The purity of the methyl esters noted above, and of the reaction products, was determined by gas-liquid chromatography. The instrument used was a Hitachi Gas-Liquid Chromatograph KGL-2 with a polyester column.

Spectroscopic Observation.—The ultraviolet absorption was measured in a heptane or ethanol solution with a Hitachi ESP-2U spectrophotometer.

The infrared absorption was measured in liquid films with a Shimadzu IR-27 infrared spectrophotometer, using sodium chloride cells.

The nuclear magnetic resonance spectrum was determined with a Varian HR-100 NMR spectrometer.

The Reaction of Methyl Sorbate with Monoperphthalic Acid.—Methyl sorbate (0.15 or 0.30 mol.) was added to a solution of monoperphthalic acid (0.30 mol.) in ether (280 ml.), and the mixture was stirred under the conditions indicated in Table I. After a specified period of time, the reaction mixture containing the precipitate formed by the reaction was filtered, and the ether in the filtrate was distilled off in vacuo. Chloroform was then added to the distillation residue. At this moment, a precipitate was again formed. The chloroform solution containing the precipitate was filtered; and the filtrate was washed with water and dried over anhydrous sodium sulfate. The chloroform was then distilled off in vacuo; the residue was subjected to vacuum distillation to yield a pure oxidation product of methyl sorbate.

Anal. (Purified Product in Table I, Exp. No. 2).—Found: C, 58.91; H, 7.12; O, 33.87. Calcd. for $C_7H_{10}O_3$: C, 59.14; H, 7.09; O, 33.77%; mol. wt., 142.16. Purity: 98.0%. n_D^{25}: 1.4619. B. p. 81—83°C/8 mmHg.

The precipitate separated from the reaction mixture and that separated from the chloroform solution were combined, and the whole was recrystallized from water. The recrystallization gave monoclinic crystals melting at 208—210°C. A mixture of the crystals with *o*-phthalic acid (m. p. 210—211.5°C) melted at 199.5—202°C. The analytical characteristics of the crystallized precipitate are as follows: Acid value: found, 681.6; calcd. for *o*-phthalic acid, 675.4. Saponification value (found): 678.4. UV ε: 1260 at λ_{max} 274 mμ in an ethanol solution. (The λ_{max} in a methanol solution[17] is 272 mμ.) Therefore, the precipitate is *o*-phthalic acid.

We are grateful to Dr. Osamu Yamamoto for determining the NMR spectrum, to Mr. Katsuhiko Higuchi for performing the gas-liquid chromatographic analysis, and to Mr. Heisuke Sugita for performing the elementary analysis.

Studies of Thio Acids. VI.[1] The Electrolysis of Thiostearic Acid*1

By Yoshio HIRABAYASHI and Tetsuro MAZUME*2

Faculty of Engineering, Gifu University, Kagamigahara-shi, Gifu

(Received December 25, 1965)

Potassium thiostearate was electrolyzed in methanol in the presence of an excess of thiostearic acid by the use of platinum electrodes and a direct current. The product obtained by this electrolysis was found to consist of distearoyl disulfide, methyl stearate, stearic acid, and thiostearic acid. The mechanism of the formation of the above components was discussed in contrast with that of the Kolbe reaction of fatty acids.

Many studies of the Kolbe reaction of fatty acids have been made, whereas the studies of the electrolysis of thio acid have been very scanty, Bunge[2] reported that thioacetic acid (CH_3COSH) yielded diacetyl disulfide ($CH_3COSSOCCH_3$) on electrolysis, the reaction of which was different from the Kolbe reaction of fatty acids. However, no study of the electrolysis of higher aliphatic thio acids has yet been reported.

The present investigation was undertaken to

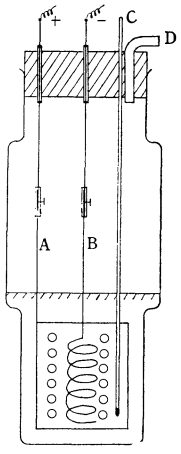
1) Part V of this series: Y. Hirabayashi, M. Mizuta and T. Mazume, This Bulletin, **38**, 1099 (1965).
2) N. Bunge, *Ber.*, **3**, 295, 911 (1870).

*1 Parts of this study were presented at the Symposium of Oils and Fats of the Chemical Society of Japan, Nagoya, November, 1958.
*2 Present address: Shimogamo-kishimotocho, Sakyo-ku, Kyoto.

obtain detailed knowledge of the electrolysis of thio acids. Potassium thiostearate was electrolyzed in methanol in the presence of an excess of thiostearic acid; then the reaction mechanism was discussed and the products investigated. The results will be described in this paper.

Experimental*3 and Results

Experimental Methods and Conditions.—After a solution of thiostearic acid (6 g.)*4 in absolute methanol (60 ml.) had been neutralized with ca. 1 N methanolic potassium hydroxide (21.75 ml.; concentration of methanol: 96 vol.%), thiostearic acid (5 g.) and methanol (40 ml.) were added; then the resulting solution was electrolyzed in an electrolytic cell, as is shown in Fig. 1,



A: Anode
B: Cathode
C: Thermometer
D: Outlet tube of gas

Fig. 1. Electrolytic cell.

in which a platinum spiral wire was used as the cathode and a platinum cylinder with holes (4 cm. in diameter and 5 cm. high.) as the anode.

Conditions of electrolysis:
Direct current
Voltage: 11.0—11.5 V.
Current: 0.5 amp. (at the beginning)
Temperature of electrolyte: 50—55°C

A while after the electrolysis had started, a solid substance was gradually deposited on the anode; this substance disturbed the passage of the current through the solution, and the evolution of the gas (H_2) on the cathode was also gradually decreased. Then, after the electrolysis had occasionally been interrupted, the deposit on the anode was scraped off into the solution with a glass rod in order to expose the anode surface as much as possible and so facilitate continued electrolysis. A current of 0.5 amp. was again passed through the solution after the exposure of the anode surface. After 2 hr., thiostearic acid (5 g.) and methanol (10 ml.) were again added. Furthermore, after 3 hr., thiostearic acid (5 g.) and methanol (20 ml.) were again added in order to make the electrolysis continue for 5 more hours. The total period of the electrolysis was 10 hr.; the interruptions of electrolysis for the removal of the deposit mentioned above corresponded to one-third of the total period, although almost no interruption was required in the last 2 hr.

The Identification of the Products.—After the electrolysis had ended, the contents of the cell were diluted with warm water (600 ml.), acidified with dilute hydrochloric acid, and extracted with ether; then the ether layer was washed with water in order to remove the excess hydrochloric acid. The ether layer was dark yellow and turbid. The suspending ether-insoluble matter was filtered off; then the filtrate was dried over anhydrous sodium sulfate, and the ether was removed. The following parts were obtained: the

d: Fraction A-3 in Table II

*3 All the melting points are uncorrected. The ultraviolet absorption spectra were measured with a Shimadzu quartz-spectrophotometer, model QB-50, and a silica cell (1 cm.).

*4 The characteristics of the thiostearic acid used in this experiments were as follows: m. p. 39.8—40.3°C; neutralization value, 185.8; sulfur content, 10.54 (iodine method), 10.62% (Kitamura's method).

ether-insoluble part, 5.5 g.; the ether-soluble part, 15.5 g.

The ether-insoluble part (5.5 g.) was repeatedly recrystallized from benzene to give, eventually, four fractions. Their characteristics and their absorption spectra are shown in Table I and Fig. 2.

The fractions, 1, 2, and 3, were identified as distearoyl disulfide by means of their characteristics and absorption spectra. Fraction 4 formed 3.3% of the total product. Its principal component was distearoyl disulfide, but it was supposed from its characteristics and absorption spectrum to contain a trace of an impurity. The saponification values of the above fractions were measured in order to determine whether or not hydrocarbons, formed by a reaction similar to the Kolbe reaction of fatty acids, were present. Their saponification values varied depending upon the heating time and the alkali concentration, but they were almost identical with the values determined by measuring an authentic distearoyl disulfide under the same conditions. Consequently, the presence of hydrocarbon in these fractions was unlikely.

The ether-soluble part (15.5 g.) was again dissolved in ether, washed thoroughly with a dilute solution of potassium hydroxide, and divided into neutral (N) and acidic (A) parts by the usual method. The contents of N and A in the total product were 64.8 and 9% respectively. Each part was repeatedly recrystallized from hexane and methanol, thus giving, eventually, four fractions (from N) or three fractions (from A). Their characteristics and ultraviolet absorption spectra are shown in Table II and Fig. 2.

(A-1)	0.6	69.5—70.5	197.2	—
(A-2)	0.2	69 —70	196.3	0.6
(A-3)	0.7	45 —50(60)	102.8	1.8[b]

A.V.: acid value, S(J): sulfur content determined by the iodine method, a): saponification value 188.2, b): S(K) 6.9%

These fractions were identified as follows:

N-1 was distearoyl disulfide which could not be separated out by the ether-extraction.

N-2, N-3, and N-4 were methyl stearate, judging from their characteristics; above all, N-2 was identified by a mixed melting point determination with an authentic sample, while it was known by their ultraviolet absorption spectra that they contained a trace of an impurity; above all, its content was highest in N-4.

A-1 was stearic acid.

A-3 was thiostearic acid, containing 30—40% of an unidentified substance.

As a result of the above investigations, the components and composition of the product were found to be approximately as follows:

Distearoyl disulfide+	31%
Methyl stearate	37
The part in which methyl stearate is the principal component+	24
Stearic acid	4
The part in which thiostearic acid is the principal component+	4

(+: Supposed to contain traces of unidentified substances).

Discussion

The electrolysis of potassium thiostearate in methanol (above 96 vol.%) in the presence of an excess of thiostearic acid at 50—55°C gave a product consisting of large amounts of distearoyl disulfide and methyl stearate, small amounts of stearic acid and thiostearic acid, and a trace of an unidentified substance. However, since hydrocarbons were not present in the product, the reaction mechanism of electrolysis of thio acids is considered to be different from that of the Kolbe reaction of fatty acids. Accordingly, more consideration will now be given to this subject.

The mechanism of the Kolbe reaction of fatty acids has been established to be as follows[3]: in the initial step, acyloxy radicals are formed by the discharge of a carboxylate anion on an anode; they decompose into alkyl radicals and carbon dioxide, and then the alkyl radicals yield saturated hydrocarbons, olefin, alcohol, and ester.

On the contrary, in the electrolysis of the potassium salt of thio acid, it may be considered that the acylthio radical ($RCOS\cdot$) is formed on an anode by the discharge of the carbothiolate anion ($RCOS^-$) formed from the potassium salt of thio acid; then the acylthio radical is dimerized to diacyl disulfide without being decomposed into alkyl radicals and carbon oxysulfide (Eq. 1). It is interesting that the electrolysis of thio acid is different from the Kolbe reaction of fatty acids in which various products are formed from acyloxy radicals. However, it is still unknown whether or not the difference between the two reactions is to be attributed to the difference in properties between $RCOO\cdot$ and $RCOS\cdot$. It may be also considered that two dimers, $(RCO)_2O_2$ and $(RCO)_2S_2$, are formed from $RCOO\cdot$ and $RCOS\cdot$ in the respective cases; the different products formed by the two reactions may be attributed to

3) E.g., C. L. Wilson and W. T. Lippincott, *J. Am. Chem. Soc.*, **78**, 4290 (1956).

the difference in stability between the two dimers*5: i. e., $(RCO)_2O_2$ proceeds to decomposition and $(RCO)_2S_2$ remains. In this case, the mechanism of the Kolbe reaction should be reconsidered by considering the results of this study.

On the other hand, it may also be considered that the formation of distearoyl disulfide is caused by the oxidation with oxygen generated at the anode by a trace of mixed water (Eq. 2). However, since it has been recognized that electrolysis in absolute methanol (CH_3OH–$C_{17}H_{35}COSK$–$C_{17}H_{35}COSH$ system) also gives distearoyl disulfide under the same conditions,*6 distearoyl disulfide is not formed by oxidation with the oxygen generated at the anode, but by the dimerization of the acylthio radicals, as has been mentioned above.

The reason for the formation of a large amount of methyl stearate is considered to be as follows: it has been recognized that distearoyl sulfide is formed by the elimination of hydrogen sulfide when thiostearic acid is heated in methanol at about 60°C; thiostearic acid and methyl stearate are then formed from the distearoyl sulfide and the methanol. Furthermore, the latter reaction is accelerated by the presence of a trace of alkali[1] (Eq. 3). On the other hand, it is also considered that methyl stearate is also formed by the direct reaction of thiostearic acid and methanol (Eq. 4). Accordingly, it may be concluded that methyl stearate is formed by the above reactions during a long-continued electrolysis in methanol, and that the formation of methyl stearate has no direct relation with the electrolysis.

A small amount of stearic acid may be formed by the change of thiostearic acid to stearic acid in the presence of a trace of water and alkali (Eq. 5).

The formation mechanism of the principal components was to be concluded as has been described. However, since unidentified substances were found in some fractions of the product, though present only in traces, and since an equilibrium between thiolic and thionic forms of the potassium salt of thio acid may exist in the solution, reactions other than above-mentioned may possibly occur. This situation will be clarified under other conditions by more detailed investigations in the near future.

*5 In a study of the mechanism of the electrolysis of potassium caproate, Fichter et al. have stated that the decomposition of the primary electrolysis product, $(C_5H_{11}CO_2)_2$, is due to the evolution of heat at the cathode. (F. Fichter and R. Zumbrunn, *Helv. Chim. Acta*, **10**, 869 (1927).)

The good parallel between the products of Kolbe reactions and the decomposition of the corresponding diacyl peroxides suggests that the two processes have common paths or that peroxides are intermediates in the former. (S. Goldschmidt and M. Minsinger, *Chem. Ber.*, **87**, 956 (1954).)

Cyclopropene Derivatives. II.* The Reaction of Diazoketone with Triple Bond

By Naruyoshi OBATA and Ichiro MORITANI**

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received December 29, 1965)

The additions of some keto-carbene to a triple bond were studied. Since keto-carbene rearranges easily to a ketene derivative (Wolff rearrangement), the carbenic addition will always be in competition with the rearrangement. In the case of benzoylphenylcabene, the rearrangement is preferred, and no cyclopropene derivative is obtained. However, benzoyl and acetylcarbene, both having hydrogen instead of phenyl as a substituent, could be successfully added to diphenylacetylene and di-*n*-butylacetylene, thus giving 1, 2-disubstituted cyclopropene derivatives. Thus, it was found that the acylcyclopropenes were synthesized in a single step by the utilization of the carbenic addition of keto-carbene to a triple bond.

A very attractive way to synthesize cyclopropenylketone seems to be the addition of keto-carbene to a triple bond. It is well known, however, that the decomposition of diazoketone gives a ketene derivative, which is a product of Wolff rearrangement.[1] Actually, certain ketenes, such as diphenylketene, have already been prepared by this method.[2] Since, however, the intermediate of this Wolff rearrangement will presumably be keto-carbene,[3] the addition of keto-carbene to an olefinic bond will always be in competition with the Wolff rearrangement.

Another possible side reaction of keto-carbene will be the 1, 3-dipolar addition to an unsaturated bond. Huisgen and his co-workers[3,4] investigated this addition extensively. They studied the competition of the 1, 3-dipolar addition with the Wolff rearrangement and concluded that the rearrangement was much faster than the addition. In the presence of copper powder, however, they successfully directed the reaction to the 1, 3-dipolar addition route. Keto-carbene co-ordinated to copper, and its further rearrangement was prevented.

Several workers[5] have successfully investigated the addition of benzoylcarbene and acetylcarbene to an ordinary double bond and to isolated cyclopropane derivatives respectively. In general, however, a triple bond is less reactive toward electrophilic attack than is a double bond.[6] Since carbene is known as an electrophilic reagnet,[7] its addition to a triple bond will be more sluggish than to a double bond. In other words, the Wolff rearrangement will compete more strongly in the addition of keto-carbene to a triple bond.

In the present investigation, the addition of various keto-carbenes, phenylbenzoylcarbene, benzoylcarbene and acetylcarbene, to diphenylacetylene and di-*n*-butylacetylene was studied. The successful one-step synthesis of some acylcyclopropenes will here be reported.

Results and Discussion

The thermal decomposition of azibenzil (I) in diphenylacetylene produced 2, 3, 4-triphenyl-1-naphthyl diphenylacetate (IV) in a 46.2% yield. In the presence of copper powder, the yield of IV was 28.7%. The basic hydrolysis of IV gave 2, 3, 4-triphenyl-1-naphthol (V) and diphenylacetic acid (VI). No cyclopropene derivative (III) was detected among the products in this case. The formation of IV is undoubtedly due to the preferential rearrangement of I to diphenylketene (VII).

Smith and Hoehn studied the reaction of diphenylacetylene with diphenylketene and isolated the

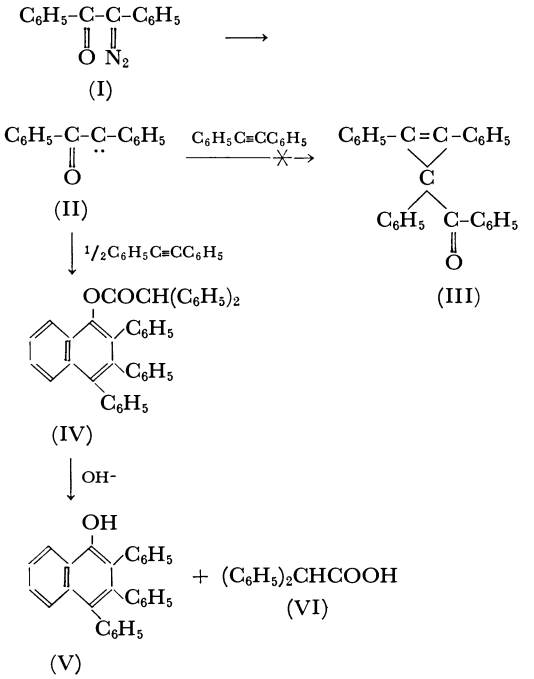
same material.[8] In the present experiment, both materials, IV and V, showed satisfactory results of elemental analysis and molecular weights.

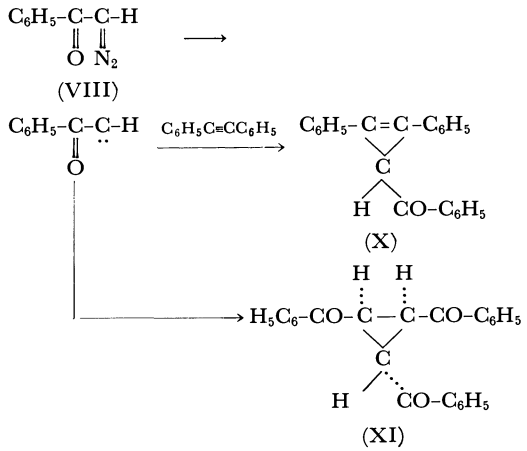


The structure of IV and V was further confirmed by the comparison of thier ultraviolet and proton magnetic resonance spectra with those of authentic 1, 2, 3-triphenyl-naphthalene. An attempt to transform V to a naphthalene derivative failed. *p*-Toluenesulfonate of V was treated with a large excess of Raney-nickel in ethanol,[9] but the tosyl group would not be removed.

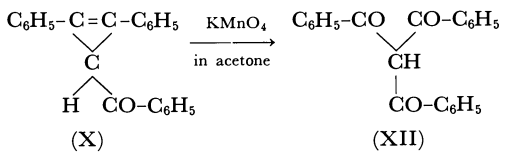
Apparently, phenylbenzoylcarbene (II) rearranged preferentially; no carbenic addition product was detected. One possible reason for this preferential rearrangement could be a steric factor. It may be expected, therefore, that the replacement of the bulky phenyl group by hydrogen might make the carbenic addition to a triple bond possible. Thus, the thermal decomposition of diazoacetophenone, *p*-methoxy-diazoacetophenone and diazoacetone was investigated.

The decomposition of diazoacetophenone (VIII) in a large excess of diphenylacetylene resulted in the formation of two pure materials, X and XI. The infrared and ultraviolet spectra of X exhibited all of the characteristic absorptions of diphenylcyclopropene derivatives.[10] The results of the elemental analysis and the molecular weight determination were also in good agreement with the results for benzoyldiphenylcyclopropene.

Thus, compound X was identified as the desired cyclopropene derivative. Compound XI was found to be *trans*-1, 2, 3-tribenzoylcyclopropane on the basis of its melting point[11] and its infrared spectrum. The proton magnetic resonance spectrum was superimposable upon the reported one.[11c]



The structure of X was confirmed by the following observations. The permanganate oxidation of X produced tribenzoylmethane (XII) in a 57.1% yield. XII was identified by comparing it with an authentic sample.[12]



The reaction of 1, 2-diphenylcyclopropenylcarboxylic acid chloride, prepared via a different route,[13] with phenyl magnesium bromide gave an identical ketone (X).* Finally, the sodium borohydride reduction of X afforded phenyl-1, 2-diphenylcyclopropenyl carbinol in a very high yield.

The yields of X and XI were 1.2% and 7.8% respectively. The presence of copper powder markedly increased the yields, up to 8.1% for X and to 30.8% for XI.

Similarly, diazoacetophenone (VIII) was decomposed in di-*n*-butylacetylene, decyne-5, in the

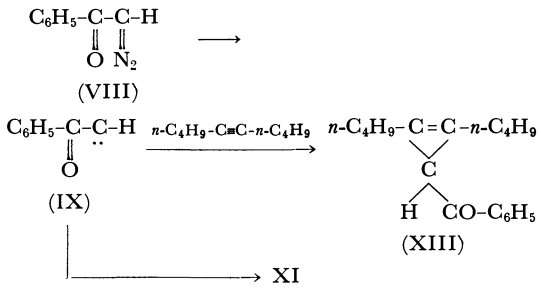
* Breslow reported[13] the synthesis of X utilizing diphenylcadmium instead of phenyl magnesium bromide. The same reaction as the Breslow's was followed, but we could not obtained X.

presence of copper powder; 3-benzoyl-1, 2-di-*n*-butylcyclopropene-1 (XIII) was thus obtained in a 21.1% yield. A small amount of XI, 1.8%, was also formed.



In the infrared region, compound XIII showed characteristic absorptions at 1667 cm^{-1} ($\nu_{C=O}$), and 1900 cm^{-1} ($\nu_{C=C}$). Its proton magnetic resonance spectrum is shown in Fig. 1. Aliphatic protons were separated nicely.

p-Methoxydiazoacetophenone (XIV) was also decomposed in diphenylacetylene in the presence of copper powder. The yield of 3-*p*-methoxybenzoyl-1, 2-diphenylcyclopropene-1 (XV) was 3.2%.

In a similar manner, diazoacetone (XVI) produced cyclopropene derivatives in both diphenyl acetylene and di-*n*-butylacetylene. The yields of XVII and XVIII was found to be 3.3% and 2.5% respectively.

All of the present results are summarized in Table I. The formation of *trans*-tribenzoylcyclopropane in a relatively large amount strongly suggests that the addition of acylcarbene to a triple bond is actually the case. It is known that the photodecomposition of pyrazolenine produces cyclopropene derivatives,[14] while thermally pyrazolenine is simply rearranged to aromatized pyrazol.[15] No example of its thermal decomposition to a cyclopropene derivative has yet been reported. Consequently, the intermediacy of pyrazolenine in the present study is practically out of the question.

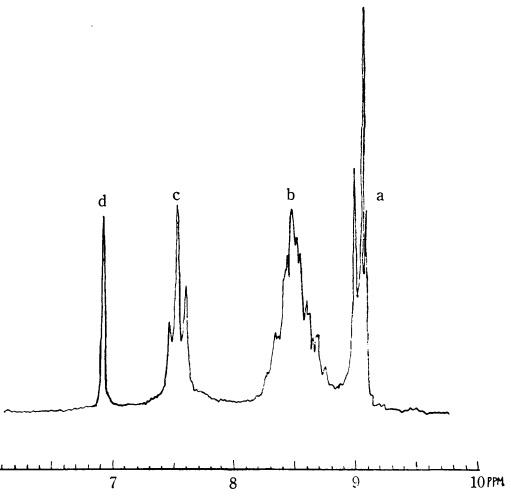


Fig 1. Proton magnetic resonance spectrum of 3-benzoyl-1, 2-di-*n*-butylcyclopropene-1.

In the case of phenylcarbene, no addition to a triple bond occurred, whereas other carbenes IXX ($R^2=H$; $R^1=C_6H_5$, p-$CH_3OC_6H_4$, CH_3) added to a triple bond and produced yield. As is shown in Runs 2 and 3, the change in substituents on acetylene from the phenyl group to the *n*-butyl group resulted in a big increase in the yield of cyclopropene derivatives. This is understandable because of the difference in basicity between these two acetylenes. Substitution on carbene by more electron-releasing substituents, such as *p*-methoxybenzoyl and acetyl, instead of benzoyl reduced the yields of addition products. This is reasonable because of the electrophilic nature of the reacting carbene intermediate.

Experimental*

The Reaction of Azibenzil with Diphenylacetylene, 2, 3, 4-Triphenyl-1-naphthyl Diphenylacetate (IV).—A solution of azibenzil, m. p. 79—80°C with decomposition (reported m. p. 79°C (decomp.)[16]), 7.5 g. (0.034 mol.), in 25 ml. of digylme was added, drop by drop, to a solution of diphenylacetylene, 10.1 g. (0.057 mol.), in 5 ml. of diglyme at 140°C. The addition was completed after one and a half hours. The reaction mixture was then kept at 140°C for an additional 30 min. After it had cooled, the mixture was poured into a large amount of water. The organic material was extracted with ether three times. The combined ethereal solution (ca. 300 ml.) was washed successively with ten 50 ml. portions of water in order to remove the diglyme. After the solution had been dried with anhydrous magnesium sulfate, the ether was removed by evaporation and the residue was subjected to column chromatography. Activated alumina (250 g.) was used for this. Each fraction was analyzed by infrared and ultraviolet spectroscopy. Elution with petroleum ether afforded 8.65 g. (0.049 mol.) of recovered diphenylacetylene. Elution with benzene gave 4.4 g. (46.2%) of 2, 3, 4-triphenyl-1-naphthyl diphenylacetate, m. p. 169—170°C (chloroform) (reported m. p. 168—169°C[8]).

Found: C, 89.02; H, 5.34. Calcd. for $C_{42}H_{30}O_2$: C, 89.01; H, 5.34%. Mol. wt.: Found: 558, by freezing point-depression method in benzene. Calcd. for $C_{42}H_{30}O_2$: 556.7.

The characteristic infrared absorptions were 1760 cm^{-1} ($\nu_{C=O}$) and 1125 cm^{-1} (ν_{C-O}). The ultraviolet maxima in acetonitrile were 235 mμ (log ε 4.76) and 292 mμ (log ε 4.11). The NMR spectrum showed a multiplet (15 hydrogens) at 2.50—3.25τ and a singlet (1 hydrogen) at 5.02 τ.

In the presence of copper powder at 100°C, IV was obtained in a 28.7% yield.

2, 3, 4-Triphenyl-1-naphthol (V).—The hydrolysis of IV with pottasium hydroxide in a 50% water-ethanol mixture gave 2, 3, 4-triphenyl-1-naphthol, m. p. 162—163°C (ethanol) (reported m. p. 163°C[8]), in a 81% yield and diphenylacetic acid, m. p. 147—148°C (water) (reported m. p. 144—145°C[17]), in 74% yield. A mixed-melting-point determination of resultant diphenylacetic acid with an authentic material showed no depression.

The same naphthol derivative was also obtained by the reduction of diphenylacetate with litium aluminum hydride.

Found: C, 90.36; H, 5.42; O, 4.17; mol. wt., 326. Calcd. for $C_{28}H_{20}O$: C, 90.29; H, 5.42; O, 4.29%; mol. wt., 372.4.

The ultraviolet maxima in ethanol were 243 mμ (log ε 4.73), 260 mμ (log ε 4.58) and 310 mμ (log ε 3.95). The NMR spectrum showed a multiplet (19 hydrogens) at 1.65 —3.95τ, and a sharp singlet (1 hydrogen) at 4.61τ.

1, 2, 3-triphenylnaphthalene was prepared by following the known route[18]; m. p. 151.5—152.5°C. (ethanol-benzene) (reported m. p. 151°C[18]). Its UV and NMR spectra were very similar to those of V.

p-Toluenesulfonate of V was prepared by Tipson's method[19]; m. p. 171—172°C (ethanol). The *p*-toluenesulfonate (0.15 g.) thus obtained was treated with Raney nickel (5 g.) in ethanol (20 ml.) at the reflux temperature for 10 hr.[9] After the mixture had been worked up as usual the starting *p*-toluenesulfonate was obtained. Five days' refluxing gave the same results.

Found: C, 79.76; H, 4.91; S, 5.85. Clacd. for $C_{35}H_{26}O_3S$: C, 79.82; H, 4.97; S, 6.08%.

The Reaction of Diazoacetophenone with Diphenylacetylene, 3-Benzoyl-1, 2-diphenylcyclopropene (X).—A solution of diazoacetophenone, m. p. 46.5—47.5°C (reported m. p. 47—48°C[20]); 10.1 g. (0.069 mol.), in dried diglyme (40 ml.) was added, drop by drop, to a solution of diphenylacetylene (20.0 g. (0.11, mol.)) in dried diglyme (10 ml.) over a period of one and a half hours at 140°C. After the mixture had been worked up as in the former case, the reaction products were separated by alumina-column chromatography. After the recovered diphenylacetylene had been completely eluted out by petroleum ether, the eluent was changed to benzene. In relatively later fractions 3-benzoyl-1, 2-diphenylcyclopropene-1, 0.25 g. (1.2%); m. p. 152—153°C (ethanol), was obtained. After the eluent had been changed from benzene to ether, *trans*-1, 2, 3-tribenzoylcyclopropane, 0.55 g. (7.8%); m. p. 216—217°C (reported m. p. 215—217°C[11a,b]), was obtained in later fractions.

In a separate experiment, a mixture of 20.1 g. of diphenylacetylene, 9.95 g. of diazoacetophenone and 4.4 g. of copper powder was brought to reaction at 100°C. The yield of X was 1.62 g. (8.1%) and XI was 2.52 g. (30.8%).

The structure of X was identified on the basis of the following observations.

---

* Melting points are uncorrected. The molecular weights were determined by a vapor pressure osmometer unless otherwise stated. Diglyme (diethyleneglycol dimethyl ether) was dried over lithium aluminum hydride and distilled under reduced pressure.

Found: C, 89.10; H, 5.61; mol. wt., 280. Calcd. for $C_{22}H_{16}O$: C, 89.16; H, 5.44%; mol. wt., 296.3.

The infrared characteristic absorptions as a KBr pellet were 3060 cm^{-1}, 3020 cm^{-1} and 2990 cm^{-1} (ν_{C-H}), 1845 cm^{-1} ($\nu_{C=C}$) and 1668 cm^{-1} ($\nu_{C=O}$). The ultraviolet maxima were 228 mμ (log ε 4.39), 235 mμ (log ε 4.41), 244 mμ (log ε 4.28), 294 mμ(sh) (log ε 4.31), 308 mμ (log ε 4.40) and 321 mμ(sh) (log ε 4.24). NMR showed a multiplet (2 hydrogens) at 1.82τ, a multiplet (13 hydrogens) at 2.50τ, and a singlet (1 hydrogen) at 6.15τ.

2, 4-Dinitrophenylhydrazone of X was also prepared; m. p. 193—194°C (ethanol-benzene), Its infrared and ultraviolet spectra showed the presence of a cyclopropene skeleton.

Found: N, 11.85. Calcd. for $C_{28}H_{20}O_4N_4$: N, 11.76%.

trans-Tribenzoylcyclopropane (XI) gave the following results:

Found: C, 81.34; H, 5.21. Calcd. for $C_{24}H_{18}O_3$: C, 81.34; H, 5.12%.

NMR exhibited a multiplet (15 hydrogens) at 1.75 —2.80τ, a triplet (1 hydrogen) at 5.77τ, and a doublet (2 hydrogens) at 6.28τ.

The Oxidation of 3-Benzoyl-1, 2-diphenylcyclopropene, Tribenzoylmethane (XII).—Ketone X (0.230 g. (0.00077 mol.)) was dissolved in 10 ml. of acetone, and an acetone solution of potassium permanganate was then added to it drop by drop. The addition of permanganate was stopped when the solution did not discolor. After the filtration of manganese(IV) oxide, the reaction mixture was poured into a large amount of water, and the organic material was extracted with benzene three times. The combined benzene solution was then washed with water and dried over anhydrous magnesium sulfate. The evaporation of benzene gave a white solid material, tribenzoylmethane, m. p. 232—233°C (benzene) (reported 224 —226°C[12]); 0.145 g. (57.1%).

Found: C, 80.13; H, 5.01. Calcd. for $C_{22}H_{16}O_3$: C, 80.47; H, 4.91%.

The same material was prepared from dibenzoylmethane and benzoyl chloride.[12] The mixed melting point of two samples showed no depression. The infrared spectra of the two samples were superimposable.

The Reaction of Diphenylcyclopropenecarboxylic Acid Chloride with Phenyl Magnesium Bromide, 3-Benzoyl-1, 2-diphenylcyclopropene (X).—A mixture of 1.20 g. (0.0049 mol.) of 1, 2-diphenylcyclopropenecarboxylic acid, m. p. 208—209°C (reported m. p. 209—211°C),[21] and a large excess of oxalyl chloride was heated under refluxing for 2 hr.[22] The excess oxalyl chloride was removed by distillation. To the residue benzene and petroleum ether were added, and then they were removed under reduced pressure. The residual white solid material was dissolved in 50 ml. of absolute ether. To this solution there was added, drop by drop, a solution of a Grignard reagent, prepared from 1.6 g. of bromobenzene and 0.36 g. of magnesium in 20 ml. of absolute ether, at 0°C. After this mixture had been worked up as usual, there was obtained a white solid, 3-benzoyl-1, 2-diphenylcyclopropene, m. p. 152—153°C (no melting point was reported in the literature[13]); 0.64 g. (44.1%). This sample showed no melting point depression when mixed with the sample obtained above.

An attempt to follow Breslow's procedure,[13] utilizing diphenyl cadmium instead of a Grignard reagent, failed; the material isolated was the original carboxylic acid, m. p. 208—209°C.

The Sodium Borohydride Reduction of X, Phenyl - 1, 2 - diphenylcyclopropenyl Carbinol.—Benzoylcyclopropene (X) (0.327 g. (0.0011 mol.)) was reduced with sodium borohydride (0.053 g.) in ethanol (10 ml.) at reflux temperature for 3 hr. Carbinol, m. p. 84—85°C (petroleum ether); 0.265 g. (81%), was obtained.

Found: C, 88.73; H, 6.41. Calcd. for $C_{22}H_{18}O$: C, 88.56; H, 6.08%.

The infrared characteristic absorptions were 3200 cm^{-1} (ν_{O-H}) and 1810 cm^{-1} ($\nu_{C=C}$). The ultraviolet maxima in ethanol were 224 mμ (log ε 4.39), 230 mμ (log ε 4.44), 237 mμ (log ε 4.35), 310 mμ (log ε 4.30), 320 mμ (log ε 4.39) and 337 mμ (log ε 4.22). The NMR spectrum showed a multiplet (15 hydrogens) at 2.27—2.95τ, a doublet (1 hydrogen) at 5.54τ (J=7 c. p. s.), doublet (1 hydrogen) at 7.57τ (J=7 c. p. s.) and a singlet (broad, 1 hydrogen) at 7.94τ.

3-Benzoyl-1, 2-di-*n*-butylcyclopropene-1 (XIII).—Decyne-5[23] (15.25 g. (0.11 mol.)) and copper powder (7.35 g.) were placed in a reaction flask, and to them there was added 7.35 g. (0.0503 mol.) of diazoacetophenone[20] in 20 ml. of diglyme at 100°C were a period of two hours. After this mixture had been worked up as above, *trans*-tribenzoylcyclopropane (XI) was separated (0.314 g. (1.8%)). A fraction eluted with petroleum ether containing 10% ether was collected and distilled. 3-Benzoyl-1, 2-di-*n*-butylcyclopropene (XIII) boiled at 131—132°C (3×10^{-1} mmHg) (n_D^{20} 1.5202).

Found: C, 83.99; H, 9.59; mol. wt., 268. Calcd. for $C_{18}H_{24}O$: C, 84.32; H, 9.44%; mol. wt., 256.4.

The infrared characteristic absorptions were 1900 cm^{-1} ($\nu_{C=C}$) and 1667 cm^{-1} ($\nu_{C=O}$).

3-*p*-Methoxybenzoyl-1, 2-diphenylcyclopropene-1 (XV).—To a mixture of diphenylacetylene (18.15 g. (0.102 mol.)) and copper powder (3.8 g.) in 10 ml. of diglyme there was added 9.9 g. (0.056 mol.) of *p*-anisyl-diazomethane[24] in 30 ml. of diglyme over a two-hour period at 100°C. After this mixture had been worked up as above, 0.590 g. (3.2%) of 3-*p*-methoxybenzoyl-1,2-diphenylcyclopropene (XV) was obtained, m. p. 137—138°C (ethanol).

Found: C, 84.40; H, 5.54. Calcd. for $C_{23}H_{18}O_2$: C, 84.64; H, 5.56%.

The characteristic infrared peaks were 1840 cm^{-1} ($\nu_{C=C}$) and 1665 cm^{-1} ($\nu_{C=O}$). The ultraviolet maxima in ethanol were 223 mμ (log ε 4.57), 234 mμ (log ε 4.40), 292 mμ (log ε 4.64), 308 mμ (log ε 4.56) and 324 mμ (log ε 4.35). The NMR spectrum showed a doublet (2 hydrogens) at 1.90τ, a multiplet (10 hydrogens) at 2.30—2.80τ, a doublet (1 hydrogen) at 3.12τ, a singlet (3 hydrogen) at 6.18τ, and a singlet (1 hydrogen) at 6.30τ.

3-Acetyl-1, 2-diphenylcyclopropene-1 (XVII).—ω-Diazoacetone[24] (10.59 g. (0.110 mol.)) in 20 ml. of diglyme was added, drop by drop, to a mixture of 23.46 g. (0.132 mol.) of diphenylacetylene and 6.35 g. of copper powder in 10 ml. of diglyme at 100°C over the period of one hour. The reaction mixture was then treated in a manner similar to that described previously. From the fraction eluted out by an ether-benzene mixture, 3-acetyl-1,2-diphenylcyclopropene-1, m. p. 101—102°C (petroleum ether), was obtained in 3.3% yield.

Found: C, 87.12; H, 6.14; mol. wt., 230. Calcd. for $C_{17}H_{14}O$: C, 87.15; H, 6.14%; mol. wt., 234.3.

The infrared characteristic absorptions were 1840 cm^{-1} ($\nu_{C=C}$) and 1685 cm^{-1} ($\nu_{C=O}$). The ultraviolet maxima in ethanol were 226.5 mμ (log ε 4.37), 234 mμ (log ε 4.32), 283 mμ (log ε 4.24), 294 mμ (log ε 4.35), 318 mμ (log ε 4.38) and 330 mμ (log ε 4.34). The NMR spectrum exhibited a singlet (1 hydrogen) at 7.18τ, a singlet (3 hydrogens) at 8.25τ, and a multiplet (10 hydrogens) at 2.25—2.80τ.

2, 4-Dinitrophenylhydrazone of XVII melted at 210—211°C (decomp.) (an ethanol-benzene mixture).

Found: C, 66.96; H, 4.43. Calcd. for $C_{23}H_{18}O_4N_4$: C, 66.60; H, 4.38%.

p-Toluenesulfonylhydrazone of XVII was also prepared; m. p. 180—181°C (benzene).

Found: C, 71.86; H, 5.51. Calcd. for $C_{24}H_{22}O_2N_2S$: C, 71.61; H, 5.51%.

The Sodium Borohydride Reduction of XVII.—Ketone XVII (0.230 g.) was reduced by sodium borohydride (0.096 g.), in ethanol at the reflux temperature. Methyl-1, 2-diphenylcyclopropenyl carbinol, m. p. 78—79°C (petroleum ether), was obtained in a 96.1% yield.

Found: C, 85.99; H, 6.78. Calcd. for $C_{17}H_{16}O$: C, 86.40; H, 6.83%.

The characteristic infrared peaks were 3200 cm^{-1} (ν_{O-H}), 1810 cm^{-1} ($\nu_{C=C}$) and 1075 cm^{-1} (ν_{C-O}). The ultraviolet .maxima were 224 mμ (log ε 4.39), 230 mμ (log ε 4.44), 237 mμ (log ε 4.35), 310 mμ (log ε 4.30), 320 mμ (log ε 4.39), and 337 mμ (log ε 4.22). The NMR spectrum exhibited multiplet (10 hydrogens) at 2.25—2.90τ, a multiplet (1 hydrogen) at 6.12τ, a doublet (1 hydrogen) at 7.75τ, a broad singlet (1 hydrogen) at 8.20τ, and a doublet (3 hydrogens) at 8.80τ.

3-Acetyl-1, 2-di-*n*-butylcyclopropene-1 (XVIII).—A solution of ω-diazoacetone[24] (9.20 g. (0.11 mol.)) in 20 ml. of diglyme was added, drop by drop, to a mixture of 27.35 g. (0.197 mol.) of decyne-5 and 6.38 g. of copper powder at 100°C over a two-hour. After the usual treatment of the reaction mixture, fractions were eluted by a petroleum ether - ether mixture, collected, and distilled. 3-Acetyl-1, 2-di-*n*-butylcyclopropene-1, b. p. 77—78°C/0.3 mmHg; 0.485 g. (2.5%), was thus obtained.

Found: C, 79.91; H, 11.30. Calcd. for $C_{13}H_{22}O$: C, 80.35; H, 11.41%.

The infrared spectrum showed characteristic absorptions at 1895 cm^{-1} ($\nu_{C=C}$) and 1685 cm^{-1} ($\nu_{C=O}$). The NMR spectrum exhibited a triplet (4 hydrogens) at 7.58τ, a singlet (1 hydrogen) at 7.84τ, a singlet (3 hydrogens) at 8.16τ, a multiplet (8 hydrogens) at 8.52τ, and a triplet (6 hydrogens) at 9.06τ.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1980—1988 (1966)

The Synthesis and Reactions of Benzo-1, 4-thiazinotropone Derivatives*[1]

By Tetsuo NOZOE, Toyonobu ASAO and Kazuko TAKAHASHI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received December 29, 1965)

Three isomeric benzo-1, 4-thiazinotropones were obtained. Benzo-1, 4-thiazino[3, 2-b]tropones substituted with the chloro, the bromo, the nitro or the acetamido group at the seven-membered ring were synthesized by the reaction of di- or trihalotropolone, or 3-bromotropolones with the nitro or the acetamido group, with *o*-aminothiophenol. The bromination of benzo-1, 4-thiazino[3, 2-b]tropone (I) and its 8-isopropyl derivative (II) afforded 7- and/or 9-substituted compounds. In the case of nitration, 5-oxide and 5-oxide of 7-nitro derivative were obtained. The reaction of I or II with thionyl chloride unexpectedly gave the 7, 9-dichloro derivative of I, or four kinds of chloro derivatives of II.

The preparation of benzo[b]tropothiazine (cyclohepta[b]benzo[e]-1, 4-thiazine) (I), benzo-1, 4-thiazino[3, 2-b]tropone (cyclohepta[b]benzo-1, 4-thiazine-10(11*H*)-one) (II), and their alkyl and methoxyl derivatives by the reaction of 2-halotropones or 3-halotropolones with *o*-aminothiophenol has been reported.[1] The present paper will deal with the synthesis of the isomeric compounds and the various derivatives of II, and with some electrophilic substitution reactions of these compounds.

The condensation of 2-chloro-3-hydroxytropone[2]

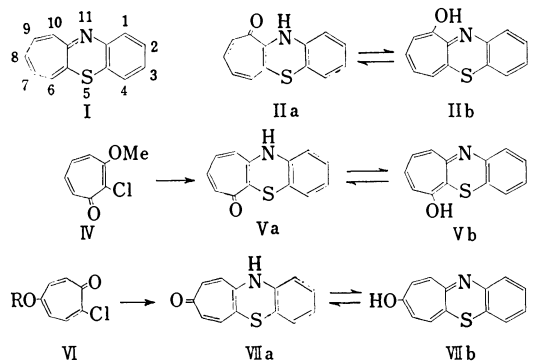
*1 Presented at the 13th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1960.

1) T. Nozoe, T. Asao and K. Takahashi, This Bulletin, **34**, 146 (1961).

2) S. Seto, *Sci. Repts. Tohoku Univ.*, **I, 73**, 275 (1953).

with *o*-aminothiophenol (III) in methanol gave a small amount of a compound which could not be purified. However, when a solution of 2-chloro-3-methoxytropone (IV)[2] and III in methanol was allowed to stand in an ice bath, benzo-1, 4-thiazino[2, 3-b]tropone (V) was obtained as violet needles in a 23% yield. The condensation of 2-chloro-5-methoxytropone (VI; R=Me)[3] with III at 0°C gave an oily substance (VII). The analytical values of VII satisfied the formula, $C_{13}H_9ONS$, and the infrared and ultraviolet spectra of VII were completely in agreement with those of the product obtained from the reaction of 2-chloro-5-hydroxytropone (VI; R=H)[3] and III. These facts indicate that the methoxy group of 2-chloro-5-methoxytropone was hydrolyzed during the reaction with III.

It is known[1] that II exists as the keto form (IIa) rather than the enol form (IIb). The structure of V and VII were also examined for the



presence of any keto-enol tautomerism. The compounds V and VII were slightly soluble in an acidic medium but not in an alkaline medium, and they did not form any molecular compound such as a picrate.

The ultraviolet spectra (Fig. 1) of V in methanol and in an acidic medium are essentially similar to those of II, and the infrared spectrum of V displays

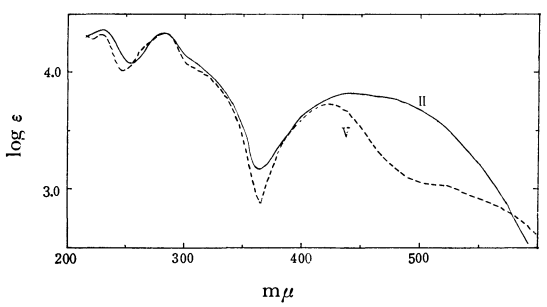


Fig. 1. Ultraviolet absorption spectra of II and V in MeOH.

3) T. Nozoe, T. Asao, E. Takahashi and K. Takahashi, This Bulletin, **39**, 1310 (1966).

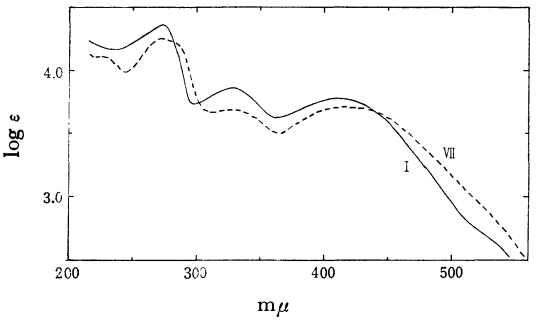

Fig. 2. Ultraviolet absorption spectra of I and VII in MeOH.

peaks at 3280, 3200, 1633 and 1615 cm^{-1} which are not observed in the spectrum of I. From these observations, it may be assumed that V exists as its keto form (Va) rather than as the enol form (Vb). The ultraviolet spectra (Fig. 2) of VII in methanol and in an acidic medium are similar to those of I rather than to those of II; however, the infrared spectrum of VII shows a peak at 1630 cm^{-1} (C=O). From these facts alone, it is difficult to draw any conclusions regarding the tautomerism of VII. A further, detailed investigation of the tautomerism of these isomeric thiazinotropones will, therefore, be carried out.

The reactions of *o*-aminothiophenol (III) with the following halotropolones have been studied. 3, 6-Dibromotropolone,[4] when treated with two molar equivalents of III in methanol, gave three compounds, as deep violet plates (VIII), red crystals (IX) and violet plates (X). From their analysis and absorption spectra, VIII was shown to be a pentacyclic compound formed by the condensation of two molecules of III with one molecule of 3, 7-dibromotropolone, as is shown in the scheme, while IX and X were shown to be the 9-*o*-aminophenylthio- and 9-bromo-derivatives of II respectively.

The application of one molar equivalent of III to 5, 7-dibromohinokitiol (3, 5 - dibromo - 6 -isopropyltropolone)[5] afforded the 7-*o*-aminophenylthio-8-isopropyl derivative of II (XI), plus a small amount of a compound which is assumed to be the 7-bromo-8-isopropyl derivative (XII). The 7-bromo-9-isopropyl derivative of II (XIII) was obtained by refluxing 5, 7-dibromo-α-thujaplicine (3, 5-dibromo-7-isopropyltropolone)[6] and III in methanol for 5 hr. However, 3-*o*-aminophenylthio - 5 - bromo - 7 - isopropyltropolone (XIV) was obtained in addition to XIII when the above mixture was refluxed for 2.5 hr.; XIV was

then converted into XIII by refluxing it in acetic acid. The difficulty in the cyclization of XIV is considered to be due to the steric interference and to the electron releasing effect of the isopropyl group.

On refluxing 3, 5, 7-tribromotropolone[7] and III in methanol, the 7,9-dibromo derivative XV was obtained in a good yield. On the other hand, when the reaction mixture was allowed to stand at room temperature, 3-*o*-aminophenylthio-5, 7-dibromotropolone (XVI) was obtained as the main product, in addition to some XV; XVI, on being heated above its melting point, afforded XV. Similar results were obtained in the reaction of 3, 5, 7-trichlorotropolone[8] and III, which afforded the 7, 9-dichloro derivative XVII as well as 3-*o*-aminophenylthio-5, 7-dichlorotropolone (XVIII). XVIII was converted into XVII on being heated above its melting point. When a mixture of 3-bromo-5-nitrotropolone[9] and III in methanol was allowed to stand at room temperature, the 7-nitro derivative of II (XIX) was obtained as black needles.

The nitration of 7-bromohinokitiol afforded two crystalline substances, m. p. 136°C and 111°C, which were considered to be stereoisomers of 7-bromo-5-nitrohinokitiol.[10] However, the latter compound has been shown recently[11] to be a mixture of 7-bromo-5-nitrohinokitiol and a small amount of 7-bromo-3-nitrohinokitiol. The application of III to each of these two substances afforded the same compound, the 7-nitro-8-isopropoyl derivative XX, but the isomeric 9-nitro-8-isopropyl derivative could not be isolated.

When 5-amino-3-bromotropolone[4,12] was allowed to react with III, only 5-amino-3-*o*-aminophenylthiotropolone (XXI) was obtained, even when the reaction mixture was refluxed. The compound XXI did not cyclize when heated above its melting point, and the starting material was recovered, while the *N, N'*-diacetyl derivative was formed when XXI was heated with acetic anhydride. This resistance to cyclization may be attributed to the electron-releasing resonance effect of the amino group in the tropolone nucleus. If this is so, cyclization may be expected to occur when 5-acetamido-3-bromotropolone is used instead of 5-amino-3-bromotropolone. Indeed, both the *N*-acetyl and *N, O*-diacetyl derivatives[4] of 5-amino-3-bromotropolone afforded the 7-acetamido derivative of II (XXII) when they were refluxed with *o*-aminothiophenol (III).

The reactions of 2, 3-, 2, 5- and 2, 7-dibromotropones with III gave no definite compound; only

resinous products were obtained. The reactions of 7-amino-, 7-acetamido- and 7-diethylamino-2-bromotropone with III resulted in the complete recovery of the starting materials, whereas 7-benzamido-2-bromotropone yielded 7-benzamido-2-*o*-aminophenylthiotropone (XXIII), which did not afford any cyclization product, even when heated.

The general method utilized for the synthesis of phenothiazines, i. e., the reaction of diphenylamines and sulfur, was applied to 2-toluidinotropone, but the desired product was not obtained; only resinous products were formed.

The bromination of I in acetic acid in the presence of sodium acetate gave a poor yield of compound XXIV, assumed to be the tribromo derivative, in addition to a considerable amount of the recovered starting material. The ultraviolet spectrum*2 of XXIV shows a considerable hypsochromic shift. Furthermore, the 743 cm^{-1} band, due to the out-of-plane deformation of a 1, 2-disubstituted benzene, is present in the infrared spectrum of compound I, but not in the spectrum of XXIV. Therefore, it appears that some substitution must have occurred not only in the seven-membered ring but also in the benzene ring. However, the structure of XXIV could not be established.

The bromination of II afforded a monobromo derivative identical with the 9-bromo derivative X. The bromination of 8-isopropylbenzo-1, 4-thiazino[3, 2-b]tropone (XXV) afforded two products. One of the products was shown to be the 7-bromo derivative XII which had been obtained previously by the reaction of 5, 7-dibromohinokitiol and *o*-aminothiophenol. The structure of the second product, the analyses of which are in accord with those of a dibromo derivative of XXV, was deduced from the facts that its infrared spectrum shows absorption at 750 cm^{-1}, due to an out-of-plane deformation of a 1, 2-disubstituted benzene nucleus, and that its ultraviolet spectrum is similar to those of the 7, 9-dichloro- and the 7, 9-dibromo derivatives of II. This indicates that the compound is the 7, 9-dibromo derivative XXVI.

The nitration of I with fuming nitric acid did not give any definite product except the starting material. However, when II was treated with fuming nitric acid in acetic acid, three compounds were isolated. One of the compounds was found to be identical with the 7-nitro derivative XIX. The other two compounds (XXVII and XXVIII) have molecular formulae of $C_{13}H_9O_2NS$ and $C_{13}H_8O_4N_2S$ respectively, and they exhibit infrared absorption at 1026 and 1027 cm^{-1} respectively, due to a sulfoxide group[13]; therefore, they are considered to be the sulfoxide of II and its mononitro derivative respectively. Actually, XXVIII has also been obtained by the oxidation of II with hydrogen peroxide in acetic acid; this will be described in the following paper. The nitro group in XXVII must be located at the 7-position, since XXVII was also obtained by the oxidation of XIX. The nitration of XXV afforded two products XXIX and XXX. From their analyses and their infrared spectra, it was found that XXIX is the mononitro derivative of the simple sulfoxide XXX. In order to determine the position of the nitro group in XXIX, the authentic 7-nitro compound XX was oxidized with hydrogen peroxide. However, the product was not XXIX, but the sulfone XXXI, which shows absorptions due to a sulfone group[13] at 1295, 1284, 1151 and 1135 cm^{-1} in its infrared spectrum. However, the oxidation of XXIX in the same manner also gave XXXI, thus confirming that XXIX is the 7-nitro derivative of XXX. Similar examples of the oxidation of sulfide by nitric acid have often been observed with the phenothiazines. The oxidation of benzo-1, 4-thiazino[3, 2-b]tropones will be reported in the following paper.

From the results of the above electrophilic substitution reactions, it may be concluded that the ionic structure IIc of II contributes greately to these reactions.

Tropones condensed with some five-membered heterocycles, such as 3-phenylpyrrolo[2, 3-b]-tropone (XXXII)[14] and 2-hydroxyimidazolo-[5, 4-b]tropone (XXXIII)[15] which in part have a structural similarity to benzo-1, 4-thiazino-[3, 2-b]tropones, afforded their chloro derivatives, 8-chloro-3-phenyl-1-azaazulene and 2, 4-dichloro-1, 3-diazaazulene respectively, on treatment with phosphorus oxychloride or thionyl chloride. These reactions are considered to proceed through the enol forms. Although II is considered to exist as its keto form,[1] if II is able to assume the enol form, it may be expected that the 10-chloro derivative of I might be obtained by the reaction of II with some chlorinating reagents. The reaction of II with phosphorus oxychloride in pyridine resulted in the complete recovery of the starting material. However, on being treated with 1.25 molar equivalents of thionyl chloride in dry benzene, II afforded, as violet needles, a product which was not the expected 10-chloro derivative of I, but the 7, 9-dichloro derivative of II (XVII) obtained already by the reaction of 3, 5, 7-trichlorotropolone and *o*-aminothiophenol.

The reaction of XXV and thionyl chloride was carried out, and four products were obtained as

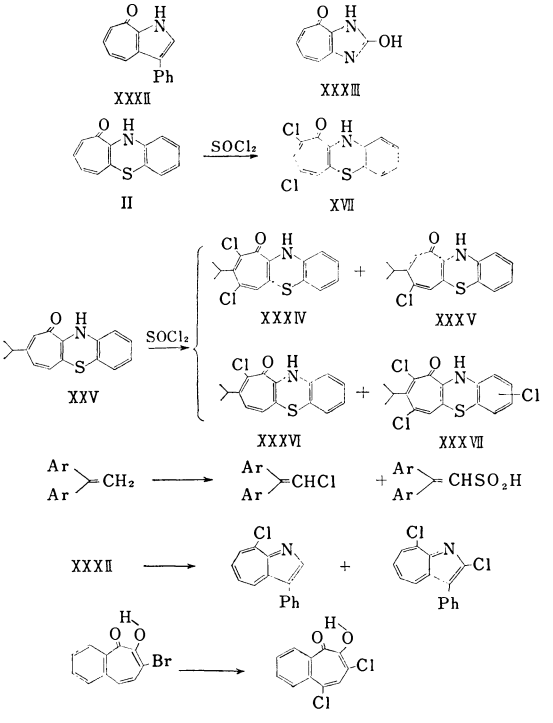
13) L. J. Bellamy, "The Infrared Spectra of Complex Molecules," Methuen and Co., London (1958), p. 350.

14) T. Nozoe, Y. Kitahara and J. Shin, to be published.

15) T. Nozoe, T. Mukai and K. Matsumoto, to be published.

follows. By heating XXV with 1.25 molar equivalents of thionyl chloride in dry benzene, red violet prisms (XXXIV), m. p. 156°C, and violet needles (XXXV), m. p. 156°C, were obtained, while from another run of the reaction, red violet plates (XXXVI), m. p. 149°C, were obtained in addition to the compound XXXV. Each of these products showed a depression in its melting point when mixed with any of the others. When XXV was treated with 2.5 molar equivalents of thionyl chloride, it yielded violet needles (XXXVII), m. p. 210°C. The yields of these four products in the crude state were moderate, but their purification proved difficult; consequently, the yields of the pure compounds were fairly low.

The structures of these four products were not determined chemically, but from a consideration of the results of their analyses and their ultraviolet and infrared spectra; the following conclusions were reached. The ultraviolet spectra of these four products show that they have not undergone any skeletal change. The infrared spectra of XXXIV, XXXV and XXXVI show peaks between 741—745 cm^{-1}, due to the out-of-plane deformations of a 1, 2-disubstituted benzene; therefore, it is considered that no substitution has taken place in the benzene rings of these three products. Analyses showed the molecular formulae of XXXIV—XXXVII to be $C_{16}H_{13}ONSCl_2$, $C_{16}H_{14}ONSCl$, $C_{16}H_{14}ONSCl$ and $C_{16}H_{12}ONSCl_3$, respectively. Since the ultraviolet spectrum of XXXIV is similar to those of the 7, 9-dihalo derivatives XV, XVII and XXVI, XXXIV is



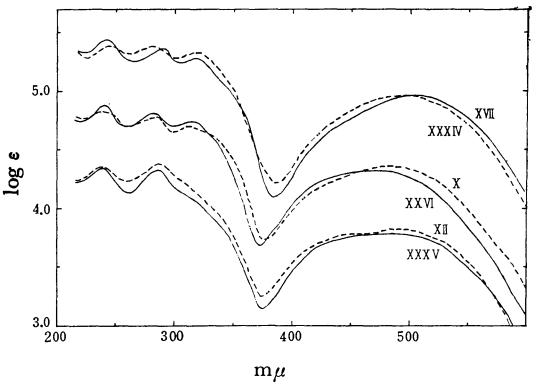


Fig. 3. Ultraviolet absorption spectra of X, XII, XVII, XXXIV, XXXV and XXXVI in MeOH.

assumed to be the 7, 9-dichloro derivative of XXV. The ultraviolet spectra of XXXV and XXXVI are similar to those of XII and X respectively; therefore, it is assumed that they are the 7-chloro and the 9-chloro derivatives of XXV respectively. Two of the three chlorine atoms in XXXVII are considered to be located at the 7- and 9- positions; since its infrared spectrum shows no absorption attributable to a 1, 2-disubstituted benzene, the remaining chlorine atom might be substituted in the benzene ring. However, its position could not be defined.

It is clear from the above that the reactions of benzo-1, 4-thiazino[3, 2-b]tropones with thionyl chloride result in the formation of products chlorinated at the 7- and/or the 9-positions. However, when the compound I was treated with thionly chloride, the reaction resulted in the recovery of the starting material and the formation of a small amount of an undefined, amorphous product.

Such substitutions involving the replacement of a hydrogen atom by the chlorine atom of thionly chloride, without the use of a catalyst, have also been observed in other cases. Patai and Bergmann[16] reported that the reaction of 1, 1-diarylethylene and thionyl chloride afforded mainly 1, 1-diaryl-2-chloroethylene and a small amount of 1, 1-diarylethylenesulfinic acid. Nozoe et al.[14] found that 2, 8-dichloro-3-phenyl-1-azaazulene and 8-chloro-3-phenyl-1-azaazulene were obtained from the reaction of XXXII with thionyl chloride, while Ebine[17] reported that the reaction of 7-bromo-3, 4-benzotropone with thionyl chloride gave an adduct which was converted into 5,7-dichloro-3, 4-benzotropone by recrystallization from ethanol.

Patai et al. has explained the mechanism of the above reaction by assuming that the reaction proceeds through the attack of an SOCl cation at

16) S. Patai and F. Bergmann, *J. Am. Chem. Soc.*, **72**, 1034 (1950).
17) S. Ebine, This Bulletin, **34**, 881 (1961).

a highly negative position, followed by the elimination of SO. Our results are inconsistent with the above mechanistic consideration, since, as has been mentioned previously, the position which undergoes chlorination with thionyl chloride is the same as that which is attacked by electrophilic reagents.

Experimental*3

Benzo-1, 4-thiazino[2, 3-b]tropone (V).—To a solution of 2-chloro-3-methoxytropone (IV) (100 mg.) in methanol (5 ml.), *o*-aminothiophenol (III) (80 mg.) was added; the mixture was then allowed to stand for 6 hr. in an ice box. The crystals which precipitated out were collected by filtration and recrystallized from a large amount of methanol, thus affording 30 mg. of V as black needles, m. p. 286°C (decomp.).

Found: C, 68.89; H, 4.03; N, 6.20. Calcd. for $C_{13}H_9ONS$: C, 68.72; H, 3.99; N, 6.17%.

λ_{max}^{MeOH} mμ (log ε): 230 (4.32), 285 (4.35), 320sh (3.96), 425 (3.71).

$\lambda_{max}^{0.1N\ HCl}$ mμ (log ε): 235 (4.28), 292 (4.41), 334 (3.90), 440 (3.74).

Benzo-1, 4-thiazino[4, 5-b]tropone (VII).—a) To a solution of 2-chloro-5-methoxytropone (VI; R=Me) (200 mg.) in methanol (8 ml.), III (167 mg.) was added; the mixture was then allowed to stand for 48 hr. in an ice box. The solvent was removed, the residue was dissolved in benzene, and the solution was washed with 2 N hydrochloric acid, followed with a 2 N sodium hydroxide solution and water, each three times, dried, and passed through an alumina column. Removing the solvent from the effluent gave 70 mg. of VII as a reddish oil.

Found: C, 68.91; H, 4.38; N, 5.68. Calcd. for $C_{13}H_9ONS$: C, 68.72; H, 3.99; N, 6.17%.

λ_{max}^{MeOH} mμ (log ε): 225 (4.24), 275 (4.25), 330 (3.69), 418 (3.70).

$\lambda_{max}^{0.1N\ HCl}$ mμ (log ε): 238 (4.20), 288 (4.13), 358 (3.95), 460—470 (3.46).

b) A solution of 2-chloro-5-hydroxytropone (VI; R=H) (110 mg.) and III (91.5 mg.) in methanol (15 ml.) was refluxed for one hour. The black resinous substance obtained by removing the solvent was dissolved in chloroform and passed through an alumina column; a reddish oily substance was thus obtained. Its infrared and ultraviolet spectra were superimposable upon those of VII obtained by procedure a).

The Reaction of 3, 7-Dibromotropolone with *o*-Aminothiophenol (III).—When a solution of 3, 7-dibromotropolone (280 mg.) and III (260 mg.) in methanol (8 ml.) was refluxed for 2.5 hr., 240 mg. of crude crystals were obtained. The crystals were separated into a soluble part A and an insoluble part B in benzene, and B was recrystallized from pyridine-ethanol, thus yielding VIII as deep violet plates, m. p. 175—176°C.

Found: C, 68.33; H, 3.42; N, 8.52. Calcd. for $C_{19}H_{12}N_2S_2$: C, 68.67; H, 3.64; N, 8.43%.

λ_{max}^{MeOH} mμ (log ε): 282 (4.51), 490—500 (4.00). In A, an insoluble part in methanol was recrystallized from pyridine, thus affording IX as reddish prisms, m. p. 251—252°C.

Found: C, 64.98; H, 3.80; N, 7.76. Calcd. for $C_{19}H_{14}ON_2S_2$: C, 65.15; H, 4.03; N, 8.00%.

λ_{max}^{MeOH} mμ (log ε): 245 (4.26), 280 (4.16), 355 (4.34), 470 (3.76). The part in A soluble in methanol was recrystallized from pyridine-methanol to give X as violet plates, m. p. 221—222°C.

Found: C, 50.93; H, 2.51; N, 4.62. Calcd. for $C_{13}H_8ONSBr$: C, 51.16; H, 2.31; N, 4.59%.

λ_{max}^{MeOH} mμ (log ε): 242 (4.32), 287 (4.28), 313 (4.19), 485 (3.86).

The Reaction of 5, 7-Dibromohinokitiol with III.—A solution of 5, 7-dibromohinokitiol (300 mg.) and III (124 mg.) in methanol (5 ml.) was refluxed for 2 hr. The solvent was removed, and the residue was dissolved in benzene, washed with water, and evaporated to leave a dark reddish oily substance. The crystals which were precipitated out by adding ether to the oil were filtered and recrystallized from ethanol to give 80 mg. of XI as reddish needles, m. p. 205°C.

Found: C, 66.99; H, 5.09; N, 7.12. Calcd. for $C_{22}H_{20}ON_2S_2$: C, 67.33; H, 5.14; N, 7.14%.

λ_{max}^{MeOH} mμ (log ε): 239 (4.64), 290 (4.34), 323 (4.22), 490 (3.86). The solvent of the filtrate was removed, and the residue was dissolved in benzene, washed with 6 N hydrochloric acid and a 10% sodium carbonate solution, and passed through an alumina column. From the effluent, XII was obtained as violet needles, m. p. 198—199°C.

Found: N, 4.46. Calcd. for $C_{16}H_{14}ONSBr$: N, 4.02%.

λ_{max}^{MeOH} mμ (log ε): 240 (4.26), 287 (4.27), 486—492 (3.73).

The Reaction of 5, 7-Dibromo-α-thujaplicine with III.—a) To a solution of 5, 7-dibromo-α-thujaplicine (1.66 g.) in methanol (20 ml.), III (1.33 g.) was added and the mixture was refluxed for 5 hr. The solvent was removed, leaving a reddish residue which was then dissolved in benzene. The solution was washed with a 2 N sodium hydroxide solution, followed by 2 N hydrochloric acid and water. The benzene solution was passed through an alumina column and eluted with benzene. 700 mg. of a reddish oil was obtained, it was then crystallized with ether. Recrystallization from methanol afforded XIII as reddish plates, m. p. 84—85°C.

Found: C, 55.44; H, 3.97; N, 3.98. Calcd. for $C_{16}H_{14}ONSBr$: C, 55.18; H, 4.05; N, 4.02%.

λ_{max}^{MeOH} mμ (log ε): 238 (4.38), 286 (4.28), 470—480 (3.86).

b) A solution of 5, 7-dibromo-α-thujaplicine (500 mg.) and III (404 mg.) in methanol (6 ml.) was refluxed for 2 hr. The crystals which separated out on cooling were filtered and recrystallized from methanol, yielding 230 mg. of XIV as pale yellow needles, m. p. 165°C. An ethanolic solution of XIV turned green when treated with ferric chloride.

Found: C, 52.48; H, 4.29; N, 4.24. Calcd. for $C_{16}H_{16}O_2NSBr$: C, 52.46; H, 4.40; N, 3.83%.

From the mother liquor, 264 mg. of hydrobromide of III and 80 mg. of XIII were obtained.

The Cyclization of XIV to XIII.—A solution of XIV (20 mg.) in acetic acid (3 ml.) was refluxed for 2.5 hr. The solvent was then distilled off in vacuo,

*3 All melting points are uncorrected.

the residue was dissolved in benzene, and the solution was washed with a 2 N sodium hydroxide solution, 2 N hydrochloric acid and water. By removing the solvent, 15 mg. of a reddish, oily substance was obtained. The ultraviolet and infrared spectra of this oil were superimposable upon those of XIII.

The Reaction of 3, 5, 7-Tribromotropolone with III.—To a solution of 3, 5, 7-tribromotropolone (360 mg.) in methanol (15 ml.), III (140 mg.) was added; when the solution was then allowed to stand for 2 hr. at room temperature, 170 mg. of crystals (A) were obtained. By letting the filtrate stand, 200 mg. of violet crystals (B), m. p. 228—230°C, were obtained. These crystals A were dissolved in chloroform and shaken with a 10% sodium carbonate solution; yellow sodium salt was thus obtained. From the chloroform layer, 50 mg. of violet crystals (C) were obtained. When the sodium salt was dissolved in water and acidified with 2 N hydrochloric acid, 85 mg. of yellow crystals were obtained. Recrystallization from chloroform-methanol afforded XVI as yellow prisms, m. p. 176°C.

Found: C, 38.44; H, 2.58; N, 3.29. Calcd. for $C_{13}H_9O_2NSBr_2$: C, 38.73; H, 2.25; N, 3.48%.

The combined crystals of B and C were recrystallized from chloroform, giving XV as reddish violet needles, m. p. 237—238°C.

Found: C, 40.62; H, 1.56; N, 3.29. Calcd. for $C_{13}H_7ONSBr_2$: C, 40.53; H, 1.83; N, 3.64%.

λ_{max}^{MeOH} mμ (log ε): 252 (4.30), 275 (4.31), 320 (4.18), 510—520(3.92). The heating of XVI over its melting point gave XV quantitatively.

The Reaction of 3, 5, 7-Trichlorotropolone with III.—To a solution of 3, 5, 7-trichlorotropolone (240 mg.) in methanol (4.5 ml.), III (150 mg.) was added; the solution was then allowed to stand at room temperature. After 2 hr. 110 mg. of yellow crystals were obtained by filtration. Recrystallization from chloroform-ethanol gave XVIII as orange yellow prisms, m. p. 178—179°C.

Found: C, 49.24; H, 2.84; N, 4.49. Calcd. for $C_{13}H_9O_2NSCl_2$: C, 49.99; H, 2.90; N, 4.48%.

From the filtrate obtained from the reaction mixture, 120 mg. of violet crystals were obtained. Recrystallization from chloroform gave XVII as violet needles, m. p. 237—238°C.

Found: C, 53.34; H, 2.09; N, 4.46. Calcd. for $C_{13}H_7ONSCl_2$: C, 53.06; H, 2.40; N, 4.76%.

λ_{max}^{MeOH} mμ (log ε): 242 (4.43), 290 (4.35), 315 (4.25), 500—510 (3.95). The heating of XVIII over its melting point gave XVII quantitatively.

7-Nitrobenzo-1, 4-thiazino[3, 2-b]tropone (XIX).—By allowing a solution of 3-bromo-5-nitrotropolone (322 mg.) and III (170 mg.) in methanol (8 ml.) to stand, 132 mg. of crystals were obtained. Recrystallization from acetone afforded XIX as black needles, m. p. 260°C (decomp.).

Found: C, 56.98; H, 3.11. Calcd. for $C_{13}H_8O_3N_2S$: C, 57.36; H, 2.96%.

λ_{max}^{MeOH} mμ (log ε): 232 (3.14), 295 (4.11), 366 (4.00), 553 (3.78).

8-Isopropyl-7-nitrobenzo-1, 4-thiazino [3, 2-b] tropone (XX).—*a) From 7-Bromo-5-nitrohinokitiol with a m. p. of 135°C.*—By allowing a solution of 7-bromo-5-nitrohinokitiol (410 mg.) and III (185 mg.) in methanol (9 ml.) to stand at room temperature for 10 hr., 150 mg. of crystals were obtained. Recrystallization from acetone gave 90 mg. of XX as black needles, m. p. 230°C.

Found: C, 61.00; H, 4.56; N, 8.79. Calcd. for $C_{16}H_{14}O_3N_2S$: C, 61.14; H, 4.49; N, 8.91%.

λ_{max}^{MeOH} mμ (log ε): 238 (4.36), 290 (4.32), 438—450 (3.74), 515 (3.79).

b) From 7-Bromo-5-nitrohinokitiol with a m. p. of 111°C.—The reaction of 7-bromo-5-nitrohinokitiol (170 mg.) and III (95 mg.) according to a method similar to that described above resulted in 54 mg. of XX, m. p. 230°C, which showed no depression of melting point on admixture with the sample obtained from the procedure a); moreover, the ultraviolet and infrared spectra of these two samples were superimposable upon one another.

5-Amino-3-(*o*-aminophenylthio)tropolone (XXI).—A solution of 5-amino-3-bromotropolone (300 mg.) and III (190 mg.) in ethanol (25 ml.) was refluxed for 2 hr. The reddish oil obtained by removing the solvent was dissolved in water, neutralized with sodium hydrogen carbonate, and extracted with ethyl acetate. From the extract, 320 mg. of crystals, m. p. 215—218°C, were obtained. Recrystallization from ethanol gave XXI as brown prisms, m. p. 218—219°C.

Found: C, 59.92; H, 4.56; N, 10.73. Calcd. for $C_{13}H_{12}O_2N_2S$: C, 59.99; H, 4.65; N, 10.77%.

Diacetate: pale brown crystals, m. p. 253—254°C.

Found: C, 59.20; H, 5.02; N, 8.00. Calcd. for $C_{17}H_{16}O_4N_2S$: C, 59.30; H, 4.68; N, 8.14%.

7-Acetamidobenzo-1, 4-thiazino[3, 2-b]tropone (XXII).—The reaction of 5-acetamido-3-bromotropolone (44 mg.) and III (27 mg.) in methanol gave 40 mg. of XXII, m. p. 251°C (from ethanol).

Found: C, 63.10; H, 4.39; N, 9.48. Calcd. for $C_{15}H_{12}O_2N_2S$: C, 63.38; H, 4.26; N, 9.86%.

λ_{max}^{MeOH} mμ (log ε): 235 (4.31), 286 (4.23), 318 (4.19), 477 (3.84). The compound XXII was also obtained from 5-acetamido-2-acetoxy-7-bromotropone and III by the method described above.

2-Benzamido-7-(*o*-aminophenylthio) tropone (XXIII).—A solution of 2-bromo-7-benzamidotropone (150 mg.) and III (70 mg.) in methanol (5 ml.) and benzene (1 ml.) was refluxed for 5 hr. The crystals which precipitated out were recrystallized from methanol, thus yielding XXIII as pale yellow crystals, m. p. 185—186°C.

Found: C, 68.78; H, 4.73; N, 7.86. Calcd. for $C_{20}H_{16}O_2N_2S$: C, 68.96; H, 4.63; N, 8.04%.

The Bromination of Benzo[b]tropothiazine (I).—To a solution of I (500 mg.) and sodium acetate (214 mg.) in acetic acid (25 ml.), bromine (470 mg.) in acetic acid (1 ml.) was added drop by drop at room temperature, and then the mixture was stirred for 1 hr. The precipitate was removed by filtration, the filtrate was concentrated, water was added, and the precipitate formed was filtered. A solution of the crude product in benzene was chromatographed on alumina and eluted with benzene. The crystals were recrystallized from ethanol to afford 60 mg. of XXIV as orange needles, m. p. 156.5°C.

Found: C, 35.17; H, 1.47; N, 2.88. Calcd. for $C_{13}H_6NSBr_3$: C, 34.81; H, 1.35; N, 3.12%.

λ_{max}^{MeOH} mμ (log ε): 225 (4.34), 255 (4.41), 355 (3.88).

The Bromination of Benzo-1, 4-thiazino[3, 2-b]-tropone (II).—To a stirred solution of II (500 mg.)

and sodium acetate (180 mg.) in acetic acid (25 ml.), these was added a solution of bromine (353 mg.) in acetic acid (0.5 ml.) under cooling with ice. The mixture was then stirred for a further 30 min. and allowed to stand overnight in an ice box. The crystals which separated out were filtered and purified by alumina chromatography, followed by recrystallization from pyridine, to give 190 mg. of reddish violet needles, m. p. 226—227°C; undepressed on admixture with a compound X prepared by the reaction of 3, 7-dibromotropolone with *o*-aminothiophenol.

The Bromination of 8-Isopropylbenzo-1, 4-thiazino[3, 2-b]tropone (XXV).—To a stirred solution of XXV (500 mg.) and sodium acetate (169 mg.) in acetic acid (30 ml.), these was added, drop by drop, a solution of bromine (365 mg.) in acetic acid (1 ml.) under cooling with ice. After this addition, the solution was stirred for 2 hr., and the solid thus precipitated was filtered and washed with methanol. Repeated recrystallizations of the more insoluble part of the solid from chloroform-methanol afforded 140 mg. of XXVI as reddish needles, m. p. 205—207°C.

Found: C, 45.28; H, 3.07; N, 3.22. Calcd. for $C_{16}H_{13}ONSBr_2$: C, 45.00; H, 3.07; N, 3.28%.

λ_{max}^{MeOH} mμ (log ε): 246 (4.31), 279 (4.27), 295 (4.27), 315(4.23), 470(3.80). The mother liquor of the recrystallization was evaporated to a small volume, water was added, and the solution was extracted with benzene. The dried benzene solution was then passed through an alumina column and eluted with benzene. The crystals (80 mg.) obtained from the effluent were recrystallized from methanol to give violet needles, m. p. 198°C. The ultraviolet and infrared spectra of these crystals were identical with those of XII, the 7-bromo derivative of XXV, obtained by the reaction of 5, 7-dibromohinokitiol with *o*-aminothiophenol.

The Nitration of Benzo-1, 4-thiazino[3, 2-b]tropone (II).—To a stirred solution of II (2.0 g.) in acetic acid (20 ml.), a solution of fuming nitric acid (0.6 ml.) in acetic acid (2 ml.) was added dropwise at 5—7°C over a period of 1.5 hr. After this addition, the reaction mixture was allowed to stand at room temperature for 4 hr. and then in an ice box overnight. Black crystals (720 mg.) were obtained by filtration. The crystals were chromatographed on an alumina column using chloroform and recrystallized from chloroform to give black needles, m. p. 262°C (decomp.). The ultraviolet and infrared spectra of these crystals are superimposable upon those of 7-nitrobenzo-1, 4-thiazino[3, 2-b]-tropone (XIX). The filtrate from the reaction mixture was diluted with water and extracted with chloroform, the solvent was removed, and the residue was washed with ether and then crystallized by the addition of chloroform. The crystals were filtered and recrystallized from acetic acid to give XXVII as yellow prisms (210 mg.), m. p. 273°C.

Found: C, 53.53; H, 2.93; N, 9.22. Calcd. for $C_{13}H_8O_4N_2S$: C, 54.17; H, 2.80; N, 9.72%.

λ_{max}^{MeOH} mμ (log ε): 234 (4.29), 435 (4.28). The above filtrate from the chloroform solution was then concentrated and passed through an alumina column. The crystals obtained from the first effluent by chloroform were recrystallized from benzene and then from dilute ethanol to afford 240 mg. of XXVIII as yellow prisms, m. p. 207°C.

Found: C, 64.27; H, 3.60; N, 5.65. Calcd. for $C_{13}H_9O_2NS$: C, 64.20; H, 3.73; N, 5.76%.

λ_{max}^{MeOH} mμ (log ε): 234 (4.42), 365 (4.22), 380 (4.22).

The Nitration of 8-Isopropylbenzo-1, 4-thiazino-[3, 2-b]tropone (XXV).—To a stirred solution of XXV (600 mg.) in acetic acid (6 ml.), a solution of nitric acid (144 mg.) in acetic acid (1 ml.) was added drop by drop under cooling with ice. After being allowed to stand at room temperature for 4 hr., the reaction mixture was diluted with water and extracted with chloroform. The extract was concentrated to a small volume, passed through an alumina column, and eluted with chloroform. The crystals obtained from the first effluent were recrystallized from methanol to afford 210 mg. of XXX as yellow prisms, m. p. 174°C.

Found: C, 67.21; H, 4.89; N, 4.89. Calcd. for $C_{16}H_{15}O_2NS$: C, 67.36; H, 5.30; N, 4.91%.

λ_{max}^{MeOH} mμ (log ε): 237 (4.43), 363 (4.20), 382 (4.23). The crystals obtained from the later effluent were recrystallized from methanol to give 32 mg. of XXIX as yellow prisms, m. p. 263°C.

Found: C, 58.21; H, 4.00; N, 8.26. Calcd. for $C_{16}H_{14}O_4N_2S$: C, 58.18; H, 4.27; N, 8.48%.

λ_{max}^{MeOH} mμ (log ε): 240 (4.40), 400 (4.26).

The Oxidation of 7-Nitrobenzo-1, 4-thiazino-[3, 2-b]tropone (XIX).—To a suspended solution of XIX (80 mg.) in acetic acid (1 ml.) 35% hydrogen peroxide (0.04 ml.) was added; the mixture was then allowed to stand at room temperature for a week, during which time it was occasionally stirred. Yellow brown crystals were filtered out, treated with charcoal in acetic acid, and recrystallized from the same solvent to give 50 mg. of yellow prisms, m. p. 273°C (decomp.). The ultraviolet and infrared spectra of this crystals were superimposable upon those of XXVII.

8-Isopropyl-7-nitrobenzo-1, 4-thiazino[3, 2-b]tropone 5, 5-Dioxide (XXXI).—a) A mixture of XX (80 mg.) and 35% hydrogen peroxide (0.1 ml.) in acetic acid (1 ml.) was allowed to stand at room temperature for 2 weeks. The crystals which precipitated out were then filtered and recrystallized from acetic acid affording XXXI as yellow needles, m. p. 295°C (decomp.).

Found: C, 56.90; H, 4.18; N, 7.15. Calcd. for $C_{16}H_{14}O_5N_2S$: C, 55.49; H, 4.08; N, 8.09%.

b) A mixture of XXIX (34 mg.) and 35% hydrogen peroxide (0.05 ml.) in acetic acid (1 ml.) was allowed to stand at room temperature for a week. The crystals which separated out were recrystallized from acetic acid to give yellow needles, m. p. 295°C (decomp.) which were identical with the XXXI obtained from XX.

The Reaction of Benzo-1, 4-thiazino[3, 2-b]tropone (II) with Thionyl Chloride.—After a solution of II (200 mg.) and thionyl chloride (130 mg.) in dry benzene (25 ml.) had been allowed to stand at room temperature for 30 min., the solution was refluxed for 3 hr.; then the solvent and excess of thionyl chloride were distilled off. The residue was washed with 2 N sodium hydroxide and water each three times, the benzene solution was dried over sodium sulfate, and the solvent was removed to give 150 mg. of a crude product. A benzene solution of the product was then passed through an alumina column, and the crystals obtained from the elute were recrystallized from benzene to yield violet needles, m. p. 223°C. This product was

identified as 7, 9-dichlorobenzo-1, 4-thiazino[3, 2-b]-tropone (XVII) by a mixed melting point determination and by a comparison of the ultraviolet and infrared spectra.

The Reaction of 8-Isopropylbenzo-1, 4-thiazino-[3, 2-b]tropone (XXV) with Thionyl Chloride.—a) A solution of XXV (500 mg.) and thionyl chloride (270 mg.) in dry benzene (30 ml.) was refluxed for 3 hr. After the evaporation of the solvent, the residue was dissolved in benzene, washed with water, dried, and passed through an alumina column. The crystals obtained from the first effluent were recrystallized from acetone, thus affording 20 mg. of XXXIV as violet prisms, m. p. 154—156°C.

Found: C, 55.55; H, 3.45; N, 4.11. Calcd. for $C_{16}H_{13}ONSCl_2$: C, 56.82; H, 3.87; N, 4.14%.

λ_{max}^{MeOH} mμ (log ε): 245 (4.35), 278 (4.35), 320 (4.32), 495 (3.90). The crystals obtained from the second effluent were recrystallized from acetone to give 60 mg. of XXXV as violet needles, m. p. 155—156°C, which showed a marked depression of melting point on admixture with another compound XXXIV.

Found: C, 62.84; H, 4.42; N, 4.89. Calcd. for $C_{16}H_{14}ONSCl$: C, 63.28; H, 4.65; N, 4.61%.

λ_{max}^{MeOH} mμ (log ε): 240 (4.38), 287 (4.36), 495 (3.81).

b) A solution of XXV (500 mg.) and thionyl chloride (270 mg.) in dry benzene (40 ml.) was allowed to stand for 4 hr. at room temperature, and then it was refluxed for 5 hr. After a work-up such as that described above, 30 mg. of XXXVI as reddish violet plates, m. p. 149°C (from acetone) were obtained from the first fraction of the chromatograph.

Found: C, 62.31; H, 4.18; N, 4.69. Calcd. for $C_{16}H_{14}ONSCl$: C, 63.21; H, 4.65; N, 4.61%.

λ_{max}^{MeOH} mμ (log ε): 240 (4.39), 280 (4.30), 313 (4.25), 470 (3.83). The crystals obtained from the second fraction were recrystallized from acetone to give 80 mg. of violet needles, m. p. 156°C; undepressed on admixture with XXXV.

c) A solution of XXV (2.0 g.) and thionyl chloride (2.2 g.) in dry benzene (20 ml.) was refluxed for 10 hr. The solvent was then distilled off, and the residue was recrystallized from benzene, thus yielding 410 mg. of XXXVII as violet needles, m. p. 208—210°C.

Found: C, 51.36; H, 3.31; N, 3.85. Calcd. for $C_{16}H_{12}ONSCl_3$: C, 51.60; H, 3.25; N, 3.78%.

λ_{max}^{MeOH} mμ (log ε): 250 (4.29), 265 (4.88), 320 (4.25), 490—500 (3.84).

The authors wish to express their gratitude to the Sankyo Co. for its donation of a research fund which covered a part of the expenses for this work. The infrared and ultraviolet spectrophotometers used in this study were purchased with a grant-in-aid for Fundamental and Technical Research from the Toyo Rayon Co., Ltd., to whom the authors are grateful.

Benzo-1, 4-thiazino[3, 2-b]tropone 5-Oxides and 5, 5-Dioxides*1

By Tetsuo NOZOE, Toyonobu ASAO and Kazuko TAKAHASHI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received December 29, 1965)

The oxidation of benzo-1, 4-thiazino[3, 2-b]tropone and its 8-isopropyl derivative with hydrogen peroxide afforded the corresponding 5-oxides or 5, 5-dioxides. The stability of these oxides to heating, acid and alkali was examined. The bromination or nitration of these oxides gave mainly 9-bromo or 9-nitro derivatives. 7- or 9-Aminobenzo-1, 4-thiazino[3, 2-b]tropones were obtained by the reduction of the corresponding nitro compounds.

In their previous papers,[1,2] the present authors reported on the synthesis and some electrophilic substitution reactions of benzo-1, 4-thiazino-[3, 2-b]tropones (cyclohepta[b]benzo-1, 4-thiazin-10(11*H*)-ones). This study has now been extended to the oxidation of benzothiazinotropones; the present paper will deal with the formation and with the reactions of sulfoxides and sulfones of benzothiazinotropones.

The hydrogen peroxide oxidation of benzo[b]-tropothiazine (cyclohepta[b]benzo-1, 4-thiazine)[1] (I) yielded an amorphous, unidentified product, whereas the oxidation of benzo-1, 4-thiazino[3, 2-b]tropone (II)[1] with one molar equivalent of hydrogen peroxide in acetic acid easily afforded the corresponding sulfoxide (5-oxide) (III), as has been reported previously.[2] The treatment of III with a further mole of the reagent, or that of II with two molar equivalents of the reagent, gave the corresponding sulfone (5, 5-dioxide) (IV).

*1 Presented at the Local Meeting of the Chemical Society of Japan, Sendai, September, 1960.

II R=H V R=isoPr III R=H VI R=isoPr IV R=H VII R=isoPr

The structure of IV is evident from the presence of bands characteristic of the sulfone group[3] at 1130 and 1189 cm^{-1} in its infrared spectrum. A similar oxidation of 8-isopropylbenzo-1, 4-thiazino-[3, 2-b]tropone (V) gave the corresponding sulfoxide (VI) and sulfone (VII).

The reduction of these oxidation products with zinc in acetic acid regenerated the corresponding thiazinotropones, II or V. These four oxidation products have higher melting points, lower solubilities in organic solvents, and shorter wavelength absorption maxima in the ultraviolet (Fig. 1) region, than do the corresponding starting materials, II or V.

Although II and V are weak bases, their sulfoxides and sulfones have an acidic character, as is shown

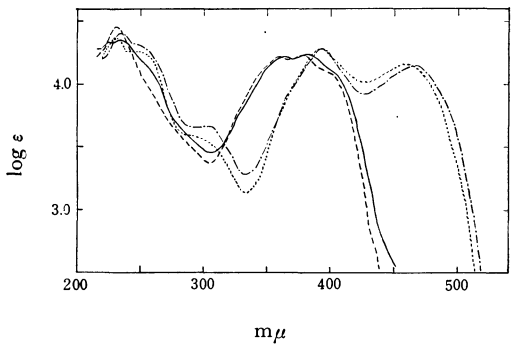

Fig. 1. Ultraviolet absorption spectra of III (—— in MeOH, —·— in 0.1 N NaOH) and IV (---- in MeOH, ····· in 0.1 N NaOH).

by their ultraviolet absorption spectra in an alkaline medium, which exhibit considerable bathochromic shifts as compared with those in methanol. Furthermore, III gave a sodium salt, as orange needles, which can be recrystallized from a 2 N sodium hydroxide solution, but which reverts to the parent acid, III, in water or in polar organic solvents. VI also gave a sodium salt, but it could not be successfully crystallized. Such an acidic character can obviously be attributed to the strong electronegativity of the sulfoxide or the sulfone groups.

In spite of their great stability to alkali, the sulfoxides, III and VI, are unstable to acids or to heating: when III or VI was heated at a temperature near its melting point for 10—15 min., its color changed from yellow to a reddish brown, decomposition occurred, and II or V was formed in about a 20% yield. Also, the attempted acetylation of III or VI with acetic anhydride at 140°C for one hour resulted in the formation of II or V respectively. The treatment of III or VI with 6 N sulfuric acid resulted in a dark brown coloration and in the formation of small amounts of II or V respectively, together with amorphous, unidentified substances. When heated with 10% hydrobromic acid for 2 hr., III gave II and reddish violet crystals of a halogenated compound (VIII) which has been shown to be the 9-bromo derivative of II.[2] Examples of the reduction and reductive halogenation of sulfoxides by acid have previously been observed with phenothiazine 5-oxide[4] and thianthrene 5-oxide.[5] The fact that VIII was also obtained[2] by the bromination of II is consistent with the mechanism proposed[6] for the reductive halogenation, which involves the initial reduction of the sulfoxide to the sulfide by acid, with the liberation of a mole of free halogen which subsequently attacks the heterocycle. In contrast to the sulfoxides, III and VI, the sulfones, IV and VII, were very stable to heat or to acids. This difference in the stability of sulfoxides and sulfones can be attributed to the difference in their S–O bond energies.[7]

As has already been reported,[1] the attempted alkylation of II or V with alkyl halide was unsuccessful. Since these oxidation products have an acidic character, one would expect alkylations or acylations of the OH or the NH group to be feasible. However, the attempted methylation of III or VI with methyl iodide, or the benzoylation with benzoyl chloride in pyridine, resulted

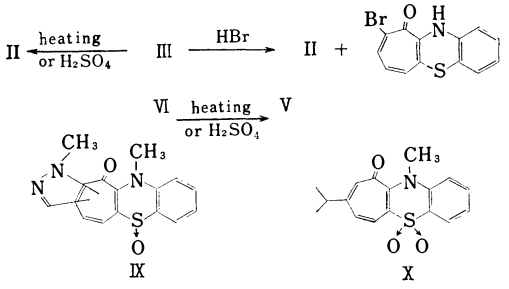
in the recovery of the starting materials, while the attempted acetylation with acetic anhydride resulted in the recovery of the starting materials or in the formation of decomposition products, II or V.



The reaction of the sodium salt of III with methyl iodide also did not afford any methylated product. However, the treatment of III with a large excess of diazomethane gave a small amount of yellow prisms (IX). From its analysis ($C_{16}H_{13}O_2N_3S$), and from the absence of an N–H stretching vibration band in its infrared spectrum, structure IX with a condensed pyrazole ring may be proposed for the compound. This is also supported by the fact that the reaction of tropones with diazomethane is known to give *N*-methylpyrazolotropones.[8] From the reaction of IV with diazomethane, a small amount of yellow crystals were obtained, but an attempt to purify them was not successful. When treated with diazomethane, VII yielded a small amount of a neutral yellow crystaline compound (X). From its analysis and from its infrared spectrum (no N–H band), X may be thought to be the simple *N*-methyl derivative, 8-isopropyl-11-methylbenzo-1, 4-thiazino[3, 2-b]tropone 5, 5-dioxide.

Sulfoxides or sulfones in the phenothiazine series undergo electrophilic substitution at the same position as does phenothiazine itself[9]; it is also known[2] that the bromination of II or V occurs at the 7- and/or the 9-positions, and that nitration occurs at the 7-position. Some electrophilic substitution reactions of the sulfoxides, III and VI, and the sulfones, IV and VII, were investigated for the sake of comparison with the above results.

The action of one molar equivalent of bromine

on III in acetic acid in the presence of sodium acetate gave the dibromide XI, which was also obtained by the oxidation of 7, 9-dibromobenzo-1, 4-thiazino-[3, 2-b]tropone (XII).[2] The reaction of bromine and IV under the same conditions as in III gave monobromosulfone XIII, which was also obtained by the oxidation of 9-bromobenzo-1, 4-thiazino-[3, 2-b]tropone (VIII). Similarly, VI and VII yielded the monobromo compounds, XIV and XV, respectively. The fact that the location of the bromine atoms introduced into both compounds is the same as was established by the hydrogen peroxide oxidation of XIV, which afforded XV in a good yield. In order to determine the position of the bromine atoms, XIV was heated with zinc in acetic acid, thus obtaining two products, one of which was proved to be V. The ultraviolet absorption spectrum of the other product, red violet crystals (XVI), was different from that of 7-bromo-8-isopropylbenzo-1, 4-thiazino[3, 2-b]tropone, but it was similar to that of the 9-chloro derivative reported previously.[2] It is, therefore, clear from the above, and from the elemental analyses, that XVI is 9-bromo-8-isopropylbenzo-1, 4-thiazino-[3, 2-b]tropone; accordingly, XIV and XV are the sulfoxide and the sulfone, respectively, of XVI. When the bromination of VI was carried out without sodium acetate, a small amount of 7, 9-dibromo-8-isopropylbenzo-1, 4-thiazino[3, 2-b]tropone (XVIII) was obtained, together with unidentified products which were presumably formed by the decomposition of the sulfoxide with the hydrogen bromide liberated during the reaction of VI with bromine.

With the expectation that the bromine would be replaced by an ethoxy group, the sulfoxide XIV was heated with sodium ethoxide in a sealed tube; unexpectedly, however, VI was obtained, besides the recovery of the starting material.

The treatment of III in acetic acid with 1.5 molar equivalents of fuming nitric acid afforded a mononitro derivative XIX different from the 7-nitro derivative of III.[2] From the fact that no substitution had occurred in the benzene nucleus (the infrared spectrum of XIX exhibited a band at 770 cm^{-1} which is assigned to the out-of-plane deformation of a 1, 2-disubstituted benzene), and since the bromination of the sulfoxide occurs mainly at the 9-position, XIX is likely to be 9-nitrobenzo-1, 4-thiazino[3, 2 - b]tropone 5-oxide. The nitration of IV yielded a yellow mononitro compound XX, which was also obtained by the oxidation of XIX. It therefore, follows that the nitro group of XX is located at the 9-position.

Similarly, the nitration of VI and VII afforded the sulfoxide XXI and the sulfone XXII of 8-isopropyl-9-nitrobenzo-1, 4-thiazino[3,2-b]tropone respectively; the latter was also obtained by the oxidation of XXI. As a result of the effect of the nitro group, the ultraviolet spectra of XIX and

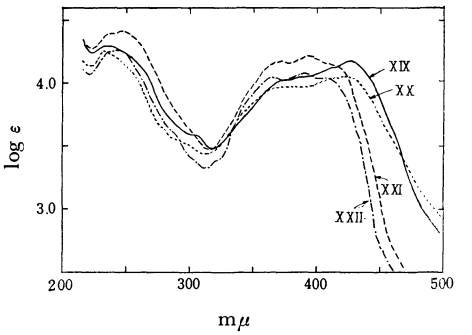

Fig. 2. Ultraviolet absorption spectra of XIX, XX, XXI and XXII in MeOH.

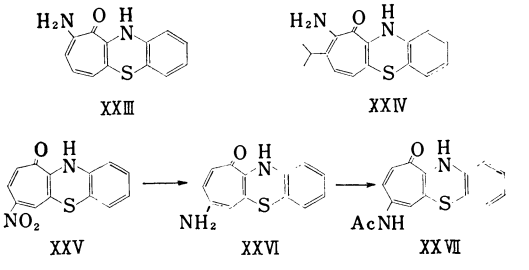
XX (Fig. 2) show considerable bathochromic shifts in comparison with those of III and IV. However, the spectra of the 8-isopropyl homologs (XXI and XXII) show only a small shift in comparison with those of VI and VII. This difference may be attributed to the decrease in the coplanarity of the nitro group and the benzothiazinotropone ring due to steric interference by the isopropyl groups at the position adjacent to the nitro groups in XXI and XXII.

The apparent reactivities of these sulfoxides and sulfones to the electrophilic reagents are greater than those of the benzothiazinotropones. It is considered that this is due to the greater electron density on the rings of the benzothiazinotropone 5-oxides or 5, 5-dioxides because of the easier deprotonation from N–H than on those of benzothiazinotropones.

It has been demonstrated[2] that the nitration of II or V introduces a nitro group at the 7-position, and that it simultaneously causes the oxidation of the sulfur atoms. In view of the nitration experiments described above, it is clear that, in the former cases, the nitration of the benzothiazinotropone rings occurs initially, and that this is followed by the oxidation of the nitrated products.

It has become clear from the above experiments that the bromination of sulfoxides and sulfones of benzothiazinotropone gives 7, 9-dibromo or 9-bromo derivatives, while their nitration produces 9-nitro derivatives exclusively.

When XIX and XXI were heated with zinc in acetic acid, 9-aminobenzo-1, 4-thiazino[3, 2-b]tropone (XXIII) and its 8-isopropyl homolog XXIV,



respectively, were obtained in good yields. The attempted reduction of 7-nitrobenzo-1, 4-thiazino-[3, 2-b]tropone (XXV)[2] by a similar method furnished a resinous product. However, the catalytic reduction of XXV in the presence of Pd-C gave an unstable 7-amino derivative (XXIV), the acetylation of which yielded 7-acetamidobenzo-1, 4-thiazino[3, 2-b]tropone (XXVII).[2]

Experimental*2

Benzo-1, 4-thiazino[3, 2-b]tropone 5-Oxide (III).—A solution of benzo-1, 4-thiazino[3, 2-b]tropone (II) (500 mg.) and hydrogen peroxide*3 (0.24 ml.) in acetic acid was allowed to stand at room temperature for a week. When water was then added to the solution, 490 mg. of yellow needles, m. p. 202°C, were obtained by filtration. Recrystallization from ethanol gave III as yellow needles, m. p. 207°C; a mixed m. p. determination with authentic III[2] showed no depression.

λ_{max}^{MeOH} mμ (log ε): 234 (4.42), 365 (4.22), 380 (4.22).

$\lambda_{max}^{0.1\ N\ NaOH}$ mμ (log ε): 233 (4.38), 393 (4.29), 466 (4.15).

Sodium salt: orange needles; m. p. 223—225°C (decomp.).

Found: C, 55.12; H, 3.19; N, 4.51. Calcd. for $C_{13}H_8O_2NSNa \cdot H_2O$: C, 55.12; H, 3.56; N, 4.95%.

Benzo-1, 4-thiazino[3, 2-b]tropone 5, 5-Dioxide (IV).—a) A solution of II (500 mg.) and hydrogen peroxide (0.7 ml.) in acetic acid (3 ml.) was allowed to stand for a week at room temperature. The crystals (490 mg.) which separated out were collected by filtration. Recrystallization from chloroform-methanol afforded yellow crystals (IV), m. p. 266°C.

Found: C, 60.30; H, 3.35; N, 5.48. Calcd. for $C_{14}H_9O_3NS$: C, 60.23; H, 3.50; N, 5.40%.

λ_{max}^{MeOH} mμ (log ε): 232 (4.44), 358 (4.20), 380 (4.21).

$\lambda_{max}^{0.1\ N\ NaOH}$ mμ (log ε): 232(4.35), 394(4.28), 459 (4.15).

b) A solution of III (500 mg.) and hydrogen peroxide (0.5 ml.) in acetic acid (3 ml.) was allowed to stand for 5 days at room temperature. The precipitated crystals were then recrystallized from chloroform-methanol, thus affording 450 mg. of IV, m. p. 266°C.

8-Isopropylbenzo-1, 4-thiazino[3, 2-b]tropone 5-Oxide (VI).—A solution of V (243 mg.) and hydrogen peroxide (0.11 ml.) in acetic acid (5 ml.) was allowed to stand at room temperature for 3 days. The solution was then diluted with water and extracted with chloroform. When the solvent was removed from the extract, and the residue was recrystallized from dilute methanol, VI (200 mg.) was afforded as yellow prisms, m. p. 174°C. This showed no depression of melting point on admixture with an authentic sample,[2] and their ultraviolet and infrared spectra are identical.

λ_{max}^{MeOH} mμ (log ε): 237(4.43), 363(4.20), 382(4.23).

$\lambda_{max}^{0.1\ N\ NaOH}$ mμ (log ε): 235(4.34), 250(4.30), 393 (4.21), 460 (4.06).

8-Isopropylbenzo-1, 4-thiazino[3, 2-b]tropone 5, 5-Dioxide (VII).—a) A solution of V (100 mg.) and hydrogen peroxide (0.1 ml.) in acetic acid (1 ml.) was allowed to stand at room temperature for a week. The precipitated crystals (86 mg.) were then recrystallized from methanol to give yellow crystals (VII), m. p. 195°C.

Found: C, 63.74; H, 5.10; N, 4.53. Calcd. for $C_{16}H_{15}O_3NS$: C, 63.78; H, 5.02; N, 4.65%.

λ_{max}^{MeOH} mμ (log ε): 234 (4.56); 360 (4.23), 377 (4.25).

b) A solution of VI (100 mg.) and hydrogen peroxide (0.1 ml.) in acetic acid (1 ml.) was allowed to stand for 5 days at room temperature. The precipitated crystals were then recrystallized from methanol to yield 80 mg. of VII, m. p. 195°C.

The Reductions of III, IV, VI and VII.—a) A mixture of III (65 mg.), acetic acid (3 ml.) and zinc (194 mg.) was heated at about 90°C for one hour. The excess of zinc was then filtered off, and the filtrate was diluted with water (20 ml.) and extracted three times with benzene. The solvent was removed, and the residue was recrystallized from methanol, thus affording 27 mg. of red needles, m. p. 158—160°C. This showed no depression of melting point on admixture with II.

b) A mixture of IV (100 mg.), acetic acid (5 ml.) and zinc (250 mg.) was heated at about 90°C for 2 hr. The excess of zinc was then filtered off, water was added, and the solution was extracted with benzene. The extract was chromatographed on alumina and then recrystallized from methanol to afford 20 mg. of II.

c) A mixture of VI (100 mg.), acetic acid (2.5 ml.) and zinc (100 mg.) was heated at about 90°C for one hour. When the mixture was then worked up as has been described above, 30 mg. of V, m. p. 94°C, were obtained.

The Thermal Decompositions of III and VI.—a) 5-Oxide (III) (25 mg.) was heated at around its melting point in a test tube for 10 min. The yellow color then gradually turned red. The resulting oil was dissolved in benzene and passed through an alumina column. From the effluent, 10 mg. of red crystals, m. p. 158°C, were obtained. The melting point of these crystals was not depressed by their admixture with II.

b) After VI (25 mg.) had been heated at around its melting point for about 10 min., the resultant red oil was distilled at 120°C/2 mmHg; 5 mg. of red crystals, m. p. 92°C, were thus obtained which showed no depression of melting point on admixture with V.

The Action of Acetic Anhydride to VI.—A solution of VI (150 mg.) in acetic anhydride (5 ml.) was heated at 140°C for one hour. Water was then added to the solution was extracted with benzene, and the extract was dried and passed through an alumina column. Red crystals (30 mg.), m. p. 92°C, were obtained, which showed no depression of melting point on admixture with V.

The Effect of 6 N Sulfuric Acid on III and VI.—a) By adding 6 N sulfuric acid to 5-oxide (III) (50 mg.), the compound was dissolved at once, and the color of the solution turned from brown to dark red. After being allowed to stand overnight, the solution was diluted with water, extracted with benzene, and purified by passing it through an alumina column; this gave 10 mg. of II.

b) After a solution of VI dissolved in 6 N sulfuric acid had been allowed to stand overnight, water was added, it was extracted with benzene, and the extract was passed through an alumina column; thus a small amount of V was afforded.

The Reaction of III with Hydrobromic Acid.—

*2 All melting points are uncorrected.

*3 The concentration of hydrogen peroxide used in all these experiments was 35%.

A solution of III (200 mg.) in 48% hydrobromic acid (2 ml.) was heated at about 90°C for 30 min. Water (30 ml.) was then added, the solution was extracted with chloroform, and the extract was washed with water and submitted to alumina chromatography. The first elution gave 40 mg. of red crystals, m. p. 158°C, after being recrystallized from methanol; undepressed on admixture with benzo-1, 4-thiazino[3, 2-b]tropone (II). The latter elution afforded 35 mg. of violet plates, m. p. 221°C; undepressed by admixture with 9-bromobenzo-1, 4-thiazino[3, 2-b]tropone (VIII).

The Reaction of III with Diazomethane.—To a solution of III (50 mg.) in methanol (30 ml.), 50 ml. of an ethereal solution of diazomethane prepared from 5 g. of *N*-nitrosomethylurea was added under cooling with ice; the mixture was then allowed to stand for 36 hr. in an ice box. After the insoluble starting material had been collected by filtration, the filtrate was evaporated to leave a red oil; this oil was dissolved in benzene and passed through an alumina column. From the effluent, 46 mg. of yellow prisms (IX), m. p. 194°C, were obtained after recrystallization from methanol.

Found: C, 61.56; H, 4.18; N, 12.95. Calcd. for $C_{16}H_{13}O_2N_3S$: C, 61,73; H, 4.21; N, 13.50%.

λ_{max}^{MeOH} mμ (log ε): 267 (4.26), 354 (4.03), 420 (3.84).

A considerable amount of a yellowish oily product was obtained besides IX, but it could not be purified.

The Reaction of VII with Diazomethane.—To a suspension of VII (100 mg.) in methanol (6 ml.), 10 ml. of an ethereal solution of diazomethane prepared from 1 g. of *N*-nitrosomethylurea was added under cooling by ice; the mixture was then kept in an ice box for 40 hr. The undissolved starting material was filtered off, and the residue obtained by removing the solvent from the filtrate was dissolved in chloroform and passed through an alumina column. From the effluent, 45 mg. of yellow crystals (X), m. p. 159—160°C, were obtained after recrystallization from methanol.

Found: C, 64.63; H, 5.37; N, 3.83. Calcd. for $C_{17}H_{17}O_3NS$: C, 64.75; H, 5.43; N, 4.44%.

λ_{max}^{MeOH} mμ (log ε): 236 (4.44), 368 (4.18).

7, 9-Dibromobenzo-1, 4-thiazino[3, 2-b]tropone 5-Oxide (XI).—a) To a stirred solution of III (200 mg.) and sodium acetate (74 mg.) in acetic acid (2 ml.) a solution of bromine (144 mg.) in acetic acid (1 ml.) was added under cooling by ice; the solution was then kept overnight in an ice box. The crystals (137 mg.) which separated out were collected, and recrystallized from chloroform-ethanol to afford orange plates (XI), m. p. 249°C (decomp.).

Found: C, 39.20; H, 1.96; N, 3.24. Calcd. for $C_{13}H_7O_2NSBr_2$: C, 38.94; H, 1.76; N, 3.49%.

λ_{max}^{MeOH} mμ (log ε): 236 (4.27), 268 (4.30), 380 (4.29).

b) A solution of 7, 9-dibromobenzo-1, 4-thiazino-[3, 2-b]tropone (XII) (60 mg.) and hydrogen peroxide (0.04 ml.) in acetic acid (4 ml.) was allowed to stand for 62 hr. at about 30°C. The crystals which separated out were filtered off and recrystallized from chloroform-ethanol to afford XI, m. p. 246°C (decomp.). The ultraviolet and infrared spectra of this compound are identical with those of the compound obtained in procedure a).

9-Bromobenzo-1, 4-thiazino[3, 2-b]tropone 5, 5-Dioxide (XIII).—a) To a stirred solution of IV (209 mg.) and sodium acetate (70 mg.) in a mixture of acetic acid (2 ml.) and chloroform (1.5 ml.), a solution of bromine (138 mg.) in acetic acid (1 ml.) was added under cooling by ice; the solution was then kept overnight in an ice box. The crystals which separated out were filtered and recrystallized from a large amount of acetic acid to give 150 mg. of yellow crystals (XIII), m. p. over 300°C.

Found: C, 46.31; H, 2.37; N, 4.16. Calcd. for $C_{13}H_8O_3NSBr$: C, 46.19; H, 2.39; N, 4.14%.

λ_{max}^{MeOH} mμ (log ε): 233 (4.28), 366 (4.18).

b) A solution of VIII (72 mg.) and hydrogen peroxide (0.2 ml.) in acetic acid (3 ml.) was allowed to stand for 5 days at about 30°C. Crystals (71 mg.), m. p. over 300°C, were obtained by filtration, followed by recrystallization from acetic acid. The ultraviolet and infrared spectra of this compound are identical with those of the compound obtained in a).

9-Bromo-8-isopropylbenzo-1, 4-thiazino[3, 2-b]-tropone 5-Oxide (XIV).—To a stirred solution of VI (200 mg.) and sodium acetate (65 mg.) in acetic acid (2 ml.), a solution of bromine (123 mg.) in acetic acid (1 ml.) was added. After it had been stirred for 2 hr., the solution was diluted with water and extracted with chloroform. The residue left by removing the solvent from the extract was crystallized by the addition of methanol. Recrystallization from acetone gave 126 mg. of yellow crystals (XIV), m. p. 224°C (decomp.).

Found: C, 52.83; H, 3.74; N, 3.58. Calcd. for $C_{16}H_{14}O_2NSBr$: C, 52.77; H, 3.87; N, 3.85%.

λ_{max}^{MeOH} mμ (log ε): 255 (4.33), 368 (4.13), 391 (4.11).

9-Bromo-8-isopropylbenzo-1, 4-thiazino[3, 2-b]-tropone 5, 5-Dioxide (XV).—a) To a stirred solution of VII (210 mg.) and sodium acetate (63 mg.) in a mixture of acetic acid (2 ml.) and chloroform (1.5 ml.), a solution of bromine (123 mg.) in acetic acid (1 ml.) was added. When the solution was left standing in an ice box for a day, 224 mg. of crystals were obtained. Recrystallization from a mixture of chloroform and methanol afforded yellow needles (XV), m. p. 272°C (decomp.).

Found: C, 50.40; H, 3.65; N, 3.86. Calcd. for $C_{16}H_{14}O_3NSBr$: C, 50.55; H, 3.71; N, 3.69%.

λ_{max}^{MeOH} mμ (log ε): 252 (4.30), 363 (4.25).

b) A solution of XIV (137 mg.) and hydrogen peroxide (0.1 ml.) in acetic acid (3 ml.) was allowed to stand for 4 days at about 30°C. The crystals which were precipitated were filtered and recrystallized from chloroform-methanol to give yellow needles, m. p. 270°C. The ultraviolet and infrared spectra of this crystals are superimposable upon those of the compound (XIV) obtained in a).

The Reduction of XIV.—A mixture of XIV (200 mg.), zinc (400 mg.) and acetic acid (4 ml.) was heated for 3 hr. at about 90°C. A solid was filtered off, and the filtrate was diluted with water and extracted with chloroform. The residue left by removing the solvent from the extract was dissolved in benzene and passed through an alumina column. From the first effluent, red violet crystals (XVI), m. p. 159—162°C, were obtained; the ultraviolet spectrum of these crystals (λ_{max}^{MeOH} mμ (log ε): 240 (4.38), 277 (4.30), 313 (4.25), 470 (3.83)) closely resembles that of 9-chloro-8-isopropylbenzo-1, 4-thiazino[3, 2-b]tropone.[2] From the latter effluent, red crystals, m. p. 95°C, were obtained; these crystals showed no depression of melting

point on admixture with 8-isopropyl-1,4-thiazino[3,2-b]-tropone (V).

9-Nitrobenzo-1, 4-thiazino[3, 2-b]tropone 5-Oxide (XIX).—To a stirred solution of III (200 mg.) in acetic acid (3 ml.), a solution of fuming nitric acid (80 mg.) in acetic acid (1 ml.) was added drop by drop. After the mixture had been allowed to stand overnight, 83 mg. of crystals were obtained; the recrystallization of these from acetic acid gave yellow crystals (XIX), m. p. 255°C (decomp.).

Found: C, 54.16; H, 2.82; N, 9.55. Calcd. for $C_{13}H_8O_4N_2S$: C, 54.17; H, 2.80; N, 9.72%.

λ_{max}^{MeOH} mμ (log ε): 235 (4.31), 370 (4.03), 427 (4.18).

$\lambda_{max}^{0.1\ N\ NaOH}$ mμ (log ε): 227 (4.29), 400 (3.81), 497 (4.27).

9-Nitrobenzo-1, 4-thiazino[3, 2-b]tropone 5, 5-Dioxide (XX). — a) To a stirred solution of IV (200 mg.) in a mixture of chloroform (1 ml.) and acetic acid (3 ml.), a solution of fuming nitric acid (100 mg.) in acetic acid (1 ml.) was added drop by drop at room temperature. After the mixture had stood for 36 hr. in an ice box, 130 mg. of crystals were obtained. Recrystallization from acetic acid afforded yellow crystals (XX), m. p. over 320°C.

Found: C, 51.20; H, 2.56; N, 9.33. Calcd. for $C_{13}H_8O_5N_2S$: C, 51.32; H, 2.65; N, 9.21%.

λ_{max}^{MeOH} mμ (log ε): 232 (4.25), 380 (3.98), 420 (4.05).

From the filtration of the products of the recrystallization, 97 mg. of the starting material were recovered.

b) A solution of XIX (100 mg.) and hydrogen peroxide (0.1 ml.) in acetic aicd (2 ml.) was allowed to stand for a week at room temperature. The crystals which separated out were then collected and recrystallized from acetic acid, thus affording yellow crystals (43 mg.), m. p. over 320°C. The ultraviolet and infrared spectra of these crystals are superimposable upon those of XX obtained in a).

8-Isopropyl-9-nitrobenzo-1, 4-thiazino[3, 2-b]tropone 5-Oxide (XXI). — To a stirred solution of VI (570 mg.) in acetic acid (6 ml.) a solution of fuming nitric acid (140 mg.) in acetic acid (1 ml.) was added; the mixture was then allowed to stand in an ice box overnight. When the crystals which separated out were collected and recrystallized from acetic acid, they gave 428 mg. of yellow crystals (XXI), m. p. 263°C (decomp.).

Found: C, 58.23; H, 4.12; N, 8.73. Calcd. for $C_{16}H_{14}O_4N_2S$: C, 58.18; H, 4.27; N, 8.48%.

λ_{max}^{MeOH} mμ (log ε): 223 (4.37), 247 (4.39), 370 (4.15), 395 (4.21).

8-Isopropyl-9-nitrobenzo-1, 4-thiazino[3, 2-b]tropone 5, 5-Dioxide (XXII).—a) To a stirred solution of VII (202 mg.) in a mixture of acetic acid (3 ml.) and chloroform (1 ml.), a solution of fuming nitric acid (90 mg.) in acetic acid (1 ml.) was added; the mixture was then allowed to stand in an ice box for 40 hr. The precipitated crystals (133 mg.) were collected and recrystallized from a large amount of acetic acid to give yellow crystals (XXII), m. p. 320°C (decomp.).

Found: C, 55.22; H, 4.04; N, 7.75. Calcd. for $C_{16}H_{14}O_5N_2S$: C, 55.49; H, 4.08; N, 8.09%.

λ_{max}^{MeOH} mμ (log ε): 243 (4.27), 365 (4.05), 390 (4.07).

b) A mixture of XXI (15 mg.), and hydrogen peroxide (0.05 ml.) in acetic acid (1 ml.) was allowed to stand at room temperature for 4 days. The crystals which separated out were recrystallized from acetic acid to give yellow crystals, m. p. 320°C (decomp.). The ultraviolet and infrared spectra of the crystals are superimposable upon those of XXII obtained in a).

9-Aminobenzo-1, 4-thiazino[3, 2-b]tropone (XXIII).—A mixture of XIX (200 mg.), and zinc (900 mg.) in acetic acid (6 ml.) was heated for 2 hr. at about 90°C. The excess of zinc was then filtered off, and the filtrate was diluted with water and extracted with chloroform. The extract was dried, passed through an alumina column, and eluted with chloroform. From the effluent, orange needles (XXIII) (27 mg.); m. p. 165°C, were obtained after recrystallization from benzene.

Found: C, 64.65; H, 4.37; N, 11.36. Calcd. for $C_{13}H_{10}ON_2S$: C, 64.46; H, 4.16; N, 11.57%.

λ_{max}^{MeOH} mμ (log ε): 238 (4.36), 349 (4.58), 440 (3.79).

9-Amino-8-isopropylbenzo-1, 4-thiazino[3, 2-b]-tropone (XXIV).—Orange needles (XXIV) (27 mg.); m. p. 136°C (from methanol), were obtained by the reduction of XXI (162 mg.) with zinc in acetic acid according to the procedure described above.

Found: C, 67.81; H, 5.77; N, 10.63. Calcd. for $C_{16}H_{16}ON_2S$: C, 67.59; H, 5.67; N, 9.85%.

λ_{max}^{MeOH} mμ (log ε): 239 (4.35), 348 (4.60), 435 (3.77).

The Reduction of 7-Nitrobenzo-1, 4-thiazino[3, 2-b]tropone (XXV).—A mixture of XXV (100 mg.), and 5% Pd-C (10 mg.) in acetic acid (10 mg.) was submitted to catalytic hydrogenation. After 27 ml. of hydrogen had been taken up, the catalyst was filtered off, and the filtrate was diluted with water and extracted with benzene and then with chloroform. The combined extracts gave reddish crystals (XXVI), m. p. 208°C, but they could not be purified. Acetic anhydride was added to the crystals, and the solution was heated gently. The violet needles (50 mg.) which separated out were recrystallized from methanol to afford deep reddish prisms, m. p. 251°C, which were identified with 7-acetamidobenzo-1, 4-thiazino[3, 2-b]tropone[2] (XXVII) by a mixed melting point determination and by a comparison of their ultraviolet and infrared spectra.

The authors wish to express their gratitude to the Sankyo Co. for its donation of a research fund which covered a part of the expenses for this work. The infrared and ultraviolet spectrophotometers used in this study were purchased with a grant-in-aid for Fundamental and Technical Research from the Toyo Rayon Co., Ltd., to whom the authors are grateful.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 1995—1998 (1966)

Vinylacetic Acid Ester Formation in the Reaction of Crotonoyl Chloride with Alcohol in the Presence of *t*-Amine

By Toshitsugu OZEKI and Masakatsu KUSAKA

Yokkaichi Laboratory, Daikyowa Petrochemical Co., Ltd., Daikyo-cho, Yokkaichi, Mie

(Received January 5, 1966)

In the esterification of crotonoyl chloride, vinylacetic acid ester was obtained predominantly, with an unusual double bond shift from the α, β- to the β, γ-position in the presence of a strong basic amine. In the case of ethyl alcohol, for example, the yields of ethyl vinylacetate were as follows (%): triethylamine (96.1), tributylamine (86.1), *N*-ethyl morpholine (74.6), *N*, *N*-diethyl aniline (0.1) and pyridine (0.9). The rest were *cis*- and *trans*-crotonic acid esters.

The interesting facts were found by the authors that, in the reaction of crotonoyl chloride with alcohol in the presence of a strong basic amine (the Einhorn reaction),[1] an unusual shifts of the double bond from the α, β- to the β, γ-position occurred and that vinylacetic acid ester was obtained predominantly (Eq. 1):

$$CH_3CH{=}CHCOCl + ROH + R_3'N \longrightarrow CH_2{=}CHCH_2COOR + CH_3CH{=}CHCOOR + R_3'N^+HCl^- \quad (1)$$

major product minor product

Although the double bond shift from the α, β- to the β, γ-position has been reported in the hydroformylation of ethyl crotonate and crotonamide,[2-4] such a double bond shift has not ever been reported in relation to the Einhorn reaction; the occurrence of a double bond shift from a conjugated to an unconjugated system in such a reaction is very interesting.

Experimental

Reagents.—All the reagents used except crytonoyl chloride were obtained commercially. The alcohols, amines and benzene were purified by fractional distillation after they had been treated with a drying agent. Crotonic acid, sodium hydroxide and sulfuric acid (98%), each available in a G. R. grade, were used without further purification. Crotonoyl chloride (b. p. 120—123°C, n_D^{18} 1.4598), prepared from crotonic acid and thionyl chloride, was identified by means of its NMR[5] and IR (960 cm^{-1}, $^{H}\rangle C{=}C\langle_{H}$ and 1768 cm^{-1}, C=CCOCl) spectra. The spectra are shown in Figs. 1 and 2.

0.2 mm.

Procedure.—The alcohol, amine and solvent were placed in a flask fitted with a thermometer, a mechanical stirrer, a condenser, and a dropping funnel. Through the dropping funnel, crotonoyl chloride was then added slowly into the mixture with stirring at room temperature; after 15 min. the supernatant liquid of the reaction

mixture was analyzed by gas chromatography in order to determine the product ratio. As amine hydrochlorides were soluble in benzene in Exp. 8, 9 and 12, an equal volume of *n*-hexane was added to the reaction mixture to precipitate them; thereafter an aliquot was withdrawn from the upper layer. In the Schotten-Baumann (Exp. 14) and Fisher (Exp. 15) methods, the benzene layer was submitted to analysis. A typical gas chromatogram for Exp. 2 is shown in Fig. 3. The results obtained are shown in Table I.

Identification

The products always consisted of three isomeric esters (denoted as I, II and III); they were isolated by fractional gas chromatography in some reactions (Shimadzu GC-11A; Tricresyl phosphate (20%) 4.5 m.; He; 100°C).

Characteristic infrared bands for methyl and ethyl esters are shown in Table II. These characteristic bands indicate the presence of the following functional groups[6];

in I	nonconjugated carbonyl group nonconjugated terminal vinyl group,
in II	conjugated carbonyl group conjugated cis-double bond,
and in III	conjugated carbonyl group conjugated trans-double bond.

NMR measurements for methyl and ethyl esters

6) L. J. Bellamy, "The Infrared Spectra of Complex Molecules," John Wiley & Sons, New York (1958), Chap. 3 and Chap. 11.

were carried out at 100 Mc.[7] The data are listed in Table III.

The spectra for II and III were analyzed and found to be of the ABX_3 type; their chemical shifts and coupling constants were consistent with the values given to *cis*- and *trans*-methyl crotonates in the literature.[5,8,9] It was reasonable to identify the spectra for I as the $ABCX_2$ type.[10] This result agreed well with the values for methyl vinylacetate.[11] These assignments were also supported by the proton ratios obtained by the integration of each signal.

The refractive index, the retention time in gas chromatography, and the infrared and ultraviolet spectra for I_{Me} were completely identical with those values for authentic methyl vinylacetate as prepared by Vogel's method.[12] Furthermore, the results of ozone oxidation, followed by the formaldehyde test using chromotropic acid, were positive, indicating the presence of a terminal vinyl group.

The physical and chemical constants for the isolated methyl and ethyl esters are shown in Table IV. Their iodine and saponification values were in agreement with the calculated values. The refractive indices were identical with the values in the literature.[12,13]

As to the other esters shown in Table I, analogous behavior in chemical and physical analysis was observed. Therefore, in all cases I, II and III were identified as the vinylacetic acid ester, the *cis*-crotonic acid ester and the *trans*-crotonic acid ester respectively.

Discussion

The absence of vinylacetyl chloride in crotonoyl chloride was confirmed by the absence of peaks at 1800 cm^{-1} (unconjugated acyl halide), 910 and 990 cm^{-1} (terminal vinyl) in IR, and by the near 6.5 τ-value (substituted methylene, $C{=}CCH_2{-}COX$) in NMR.

Regarding gas chromatography, the same results were obtained with both tricresyl phosphate and diethyleneglycol succinate columns; no isomerization was observed in either column. Therefore, the composition of the products must be correct.

It may be understood from Table I that the vinylacetic acid ester was formed predominantly in the presence of a strong basic amine (Exp. 1—10), with little dependence on the sort of alcohol, but that the crotonic acid ester was predominant in the presence of a weak basic amine (Exp. 11—12). In the reaction without amine or in Schotten-Baumann and Fisher reactions, however, the crotonic acid ester was formed predominantly. These facts suggest that the amine plays an important role in the formation of the vinylacetic acid ester.

The occurrence of an unusual double bond shift from a conjugated to an unconjugated system is very interesting. Hickmott has reported the following reaction (Eq. 2)[14]:

$$\begin{aligned} &RCH{=}CHCOCl + R'OH + R_3''N \longrightarrow \\ &\quad Cl^-R_3''N^+CHCH_2COOR' + \\ &\qquad\quad \underset{R}{|} \\ &\quad \text{main product} \\ &RCH{=}CHCOOR' + R_3''N^+HCl^- \qquad (2) \\ &\qquad\qquad (R{=}H,\ CH_3) \end{aligned}$$

This reaction may participate in the reaction mechanism of vinylacetic acid ester formation. Further investigation is now in progress and will be reported on at a later data.

The authors thank Dr. Shizuyoshi Sakai, Dr. Kenji Yokota and Dr. Ken Kanematsu of Nagoya University for their useful advices and Miss Kikuko Hayamizu of The Government Chemical Industrial Research Institute, Tokyo and Mr. Makoto Takeuchi of Japan Electron Optics Laboratory Co., Ltd. for NMR measurement and analysis.

7) NMR spectra at 100 Mc. were measured in The Government Chemical Industrial Research Institute, Tokyo. The NMR spectra at 60 Mc. were measured with a JNM 3H-60 (room temp.; bulk; stand. $(CH_3)_4$-Si) apparatus in the Japan Electron Optics Laboratory Co., Ltd.; the same results were obtained.

The Synthesis of γ-Alkylamides of L-Glutamic Acid. The Reactions of Metallic Salts of L-Pyrrolidonecarboxylic Acid with Primary Alkylamines

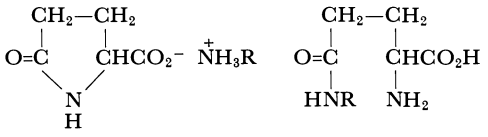
By Yoshitaka YAMADA, Moritaro SAKURAI and Yoshio TSUCHIYA

Central Research Laboratories, Ajinomoto Co., Inc., Kawasaki

(Received January 5, 1566)

L-Theanine, a principal component of flavors contained in green teas, and its homologs have been synthesized by the reactions of several metallic salts of L-pyrrolidonecarboxylic acid with primary alkylamines. Hitherto, γ-alkylamides of L-glutamic acid had been prepared in low yields by the reactions of L-pyrrolidonecarboxylic acid with anhydrous alkylamines. The use of metallic salts, especially cupric, zinc, and manganese salts, increased the yields of the γ-amides remarkably.

L-Theanine is a form of *N*-(γ-L-glutamyl)ethylamine known to be a principal component of the flavors contained in green teas, especially those of a higher grade.[1] Several procedures are available for the synthesis of L-theanine, e. g., the treatment of γ-ethyl *N*-benzyloxycarbonyl-L-glutamate with anhydrous ethylamine,[2] and that of L-pyrrolidonecarboxylic acid with aqueous[3] or anhydrous[4] ethylamine. The ring-opening reactions of pyrrolidonecarboxylic acid with primary alkylamines are equilibrium reactions and are remarkably affected by the solubilities of the products, γ-alkylamides of glutamic acid, in the reactant alkylamines.



The yield of optically active L-theanine from L-pyrrolidonecarboxylic acid is compared with that of DL-theanine from DL-pyrrolidonecarboxylic acid in Fig. 1.

As a rule, the γ-alkylamides of racemic glutamic acid are less soluble in alkylamine than those of the optically active isomer. Consequently, if the L-amides produced could be made insoluble in the corresponding alkylamines by some means, the yields of the γ-amides might be increased. The present studies were initiated in search of a method which could displace the equilibrium and which would lead to complete conversion.

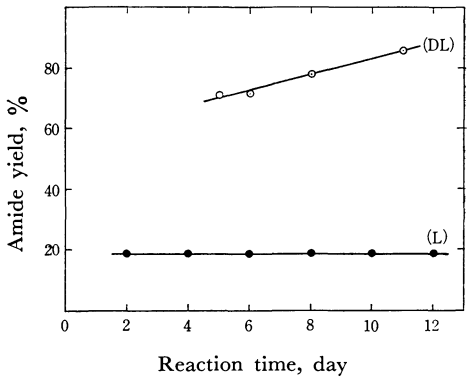


Fig. 1. The comparison of the yields of L- and DL-theanines. (Ethylamine and the respective acids were heated at 60°C in the molar ratio of 4 : 1.)

Experimental

Cupric L-Pyrrolidonecarboxylate.—Into a solution of 12.9 g. (0.1 mol.) of L-pyrrolidonecarboxylic acid in 100 ml. of water, basic cupric carbonate was added with stirring under a slight warming until the evolution of carbon dioxide ceased. After the mixture had then been filtered, the filtrate was concentrated under reduced pressure. The crystalline mass was filtered and then dried over sulfuric acid under reduced pressure. The yield of the cupric salt was 35.6 g. (91%); m. p. 190—210°C (decomp.).

Found: C, 30.50; H, 5.37; N, 7.42; Cu, 15.88. Calcd. for $C_{10}H_{12}O_6N_2Cu\cdot 4H_2O$: C, 30.65; H, 5.14; N, 7.15; Cu, 16.21%.

Zinc L-Pyrrolidonecarboxylate.—The zinc salt was prepared according to the procedure for the cupric salt described above.

Found: C, 33.62; H, 4.77; N, 7.61. Calcd. for $C_{10}H_{12}O_6N_2Zn\cdot 2H_2O$: C, 33.58; H, 4.51; N, 7.84%.

Manganese L-Pyrrolidonecarboxylate.—This was prepared in a similar manner, but attempts to crystallize the resultant syrup were unsuccessful.

4) Y. Tuchiya, Japanese Pat. 197059.

L-Theanine, *N*-(γ-L-Glutamyl)ethylamine.— Thirty-two grams of anhydrous cupric L-pyrrolidonecarboxylate dried at 100°C under reduced pressure were treated with 51 ml. of anhydrous ethylamine for seven days at 70°C in a sealed glass tube. At the end of this time, the solution was concentrated to dryness under reduced pressure to yield the violet crystalline mass. The residue was suspended in 300 ml. of water, and then the cupric ions were removed by the usual method using hydrogen sulfide. The solution, now free from cupric ions, was decolorized with activated charcoal, concentrated under reduced pressure, and cooled. The colorless crystalline precipitate was collected and dried over concentrated sulfuric acid under reduced pressure.

Yield: 30.3 g. (87%); m. p. 214—215°C (decomp.).

Found: C, 48.06; H, 8.11; N, 16.05.

Calcd. for $C_7H_{14}O_3N_2$: C, 48.26; H, 8.10; N, 16.08%.

Cupric complexes of L-theanine prepared by the method described above were recrystallized from hot water before analysis.

Found: C, 40.79; H, 6.54; N, 13.31; Cu, 15.61. Calcd. for $C_{14}H_{26}O_6N_4Cu$: C, 41.01; H, 6.39; N, 13.66; Cu, 15.50%.

e) A syrup was obtained from this run.
f) Metallic mercury was isolated from this run.

Results

The preliminary experiments have revealed that cupric, zinc and manganese salts of L-pyrrolidonecarboxylic acid are soluble in alkylamines, but the corresponding salts of the γ-alkylamides are insoluble. Thus, the use of these salts provides the best method for preparing γ-alkylamides of L-glutamic acid.

The experimental results of the reactions of various salts of L-pyrrolidonecarboxylic acid with anhydrous ethylamine are summarized in Table I. Similarly, the results of the reactions of zinc L-pyrrolidonecarboxylate with several primary alkylamines are given in Table II. The physical properties of the γ-alkylamides prepared are shown in Table III.

TABLE III. PHYSICAL PROPERTIES OF THE γ-ALKYLAMIDES OF L-GLUTAMIC ACID

a) Specific rotation was measured in a neutral aqueous solution. (c 2, H_2O)

The L-Theanine thus prepared was identified by a comparison of its melting point, paper chromatographic behavior and infrared spectrum with those of an authentic sample prepared by the aminolysis of γ-ethyl *N*-benzyloxycarbonyl-L-glutamate with ethylamine, followed by hydrogenolysis.[2] Accordingly, it is evident that the alkylamino group is located in the γ-position of the L-glutamic acid residue.

We wish to express our deep thanks to Dr. Haruomi Oeda for his kind encouragement and valuable suggestions.

The Reaction of Butadiene with Ethylene. I.* A New Synthesis of 3-Methyl-1, 4-pentadiene

By Masao IWAMOTO and Sadao YUGUCHI

Central Research Laboratories, Toyo Rayon Company, Ltd., Sonoyama, Otsu

(Received January 20, 1966)

3-Methyl-1, 4-pentadiene, 1, 4-hexadiene, and 1, 3-hexadiene were obtained, in the weight ratio of 2 : 1 : 2, by the use of a ternary catalyst consisting of a combination of ferric chloride and triethylaluminum, with triphenylphosphine as the third component. The products were identified by means of gas chromatography, infrared spectroscopy, mass spectroscopy, NMR, and hydrogenation. The effects of the catalyst compositions and the reaction conditions on the yield and the product composition were also studied. In order to obtain the C_6-dienes in the weight ratio described above, the following conditions are desirable; temperature 20—30°C, P/Fe mole ratio 1—2, Al/Fe mole ratio 3—5, and a high ethylene pressure. Although the use of several phosphorus compounds as the third component in the catalyst instead of triphenyl phosphine was investigated, these compounds were ineffective in the selective formation of C_6-dienes. It was suggested that the compound which serves as the third component in the catalyst plays an important role.

A linear dimerization of butadiene has been made by means of catalytic actions of cobalt complex catalysts[1-4] and a ternary catalyst consisting of a combination of ferric chloride and alkylaluminum compounds, with triphenyl phosphine as the third component.[5]

In the course of our study of the preparation of 1, 4-hexadiene from butadiene and ethylene, we have found that the ternary catalyst mentioned above catalyzed the formation of a mixture of C_6-dienes, i. e., 3-methyl-1, 4-pentadiene, 1, 4-hexadiene, and 1, 3-hexadiene. This paper will describe the identification of the reaction products and will study the factors affecting the reaction.

3-Methyl-1, 4-pentadiene was recently obtained by the thermally-initiated reaction of acetylene with 2-butene.[6] The preparation procedure described in this paper is also a convenient method to obtain the compound.

Experimental

Reagents.—Butadiene (purity: 98%) was purified by passing it through a series of columns filled with a ethyleneglycol-metallic sodium solution, potassium hydroxide pellets, activated alumina, and a triethylaluminum-liquid paraffin solution (about 10%) successively; it was then condensed in a measuring vessel kept in a dry ice - methanol bath. Ethylene (Nihon Petrochemical Co.) was used without further purification. Toluene (Udex grade) was purified by distillation under nitrogen. Anhydrous ferric chloride was sublimated in vacuo before use. The triphenyl phosphine and other compounds used as the third component in the catalysts were obtained commercially. Triethylaluminum (Ethyl Corp.) was uesd without purification.

Reaction Procedure.—A 200 ml. stainless steel autoclave equipped with a magnetic stirrer was used as the reactor. Calculated amounts of anhydrous ferric chloride, toluene, triphenyl phoshine, butadiene, and triethylaluminum were introduced, in that order, into the reactor, which had been flushed with nitrogen in advance. During the procedure, the reactor was kept at below −20°C to prevent the evaporation of butadiene. Then the reactor was closed and kept at reaction temperatures. The reaction was carried out under a constant ethylene pressure while the mixture was continuously being stirred. After a proper reaction time the catalyst was quenched by adding a small amount of methanol, and then the reaction mixture was washed with water containing a small amount of dilute hydrochloric acid.

The organic layer was thoroughly washed with water, dried with anhydrous sodium sulfate, and disitlled. A fraction which was distilled at bath temperature of up to 200°C was collected and analyzed by gas chromatography. The compositions of the products were calculated by the area ratios of the gas chromatogram. Higher boiling materials were recorded as a residue.

Analysis.—For the gas chromatographic analysis of the reaction products, copper tubing (4 mm. in diameter and 3 m. long) packed with Apiezon Grease L was used. For the hydrogenated product, a Golay column (45 m. long) coated with Apiezon Grease L was used. The purifications of 3-methyl-1, 4-pentadiene

and 1, 3-hexadiene in order to identify them were carried out after a preparative gas chromatography (Yanagimoto model GCS-1003). All analyses were carried out at 100°C, using helium as the carrier gas.

The infrared spectra of samples were determined by a Hitachi infrared spectrometer, model EPI-S. The NMR spectrum of 3-methyl-1, 4-pentadiene was obtained by a Varian A60 apparatus at 60Mc. Mass spectra were taken, in order to determine the molecular weight and in order to identify the skeletal structures of the hydrogenated products, by a Hitachi mass spectrometer, RMU-6.

Results and Discussion

The Identification of the Reaction Products. —The gas chromatogram (Fig. 1) of the reaction mixture indicates that it includes several components. The peaks 1, 2, 4, 6, 7, 8, and 9 in Fig. 1 were identified as air, unreacted butadiene, 1, 4-hexadiene, cyclohexene, 3-methyl-1, 4, 6-heptatriene, toluene, and 1, 3, 6-octatriene respectively by comparing their retention times with those of authentic samples. For the identification of the unknown products, each of the components of peaks 3 and 5 was collected by preparative gas chromatography. The infrared spectrum of the component of peak 3 showed the presence of a terminal double bond (910 and 992 cm^{-1}) and a methyl group (1377 cm^{-1}). The spectrum of the component of peak 5 showed the presence of a conjugated double bond (1600 and 1640 cm^{-1}), a trans-double bond (960 cm^{-1}), a terminal double bond (898 and 1002 cm^{-1}), and a methyl group (1374 cm^{-1}). Since both components had the same molecular peak, at *m/e* 82, in their mass spectra, these compounds must be hydrocarbons with the same six carbon atoms. The distillate, b. p. 45—60°C, was collected by distillation at atmospheric pressure and was hydrogenated at room temperature with hydrogen, using palladium black as the catalyst. Before the hydrogenation, the distillate contained three components and peaks 1′, 2′, and 3′ in Fig. 2A corresponded to the peaks 3, 4, and 5 respectively in Fig. 1. However, the hydrogenated product contained only two components (Fig. 2B). The area ratio of the peak 1′ to the two other peaks combined in Fig. 2A was about 1 to 2, and the ratio of the two peaks in Fig. 2B was about 1 to 1.8. It may be considered, therefore, that the components of the peaks 2′ and 3′ were hydrogenated to the same saturated hydrocarbon. Both components in the hydrogenated product had the same molecular peak, at m/e 86. This suggests that each of the components of peaks 3 and 5 in Fig. 1 has two double bonds, those of the component of peak 3 being of the vinyl type and those of the component of peak 5 being conjugated. The pattern coefficients of 3-methylpentane and *n*-hexane in API data agreed entirely with the mass spectral data of the two components of the hydrogenated product. In the NMR spectrum of the component of peak 3, the doublet at 8.9 τ indicates the presence of a secondary methyl group, while the multiplet at 7.14 τ indicates the presence of the following partial structure: $=CH-CH(CH_3)-CH=$.

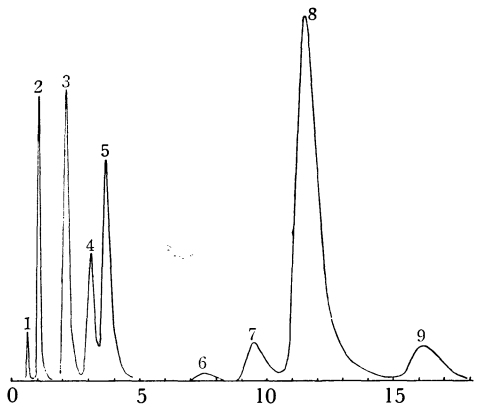

Fig. 1. Gas chromatogram of the reaction mixture of Exp. 5 in Table II.

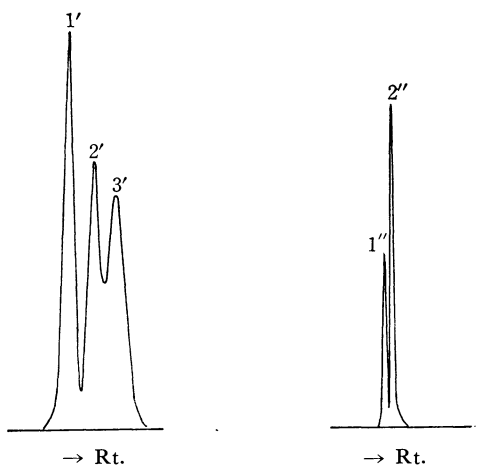

Fig. 2. Gas chromatograms, A: Before hydrogenation, B: After hydrogenation.

It is quite reasonable to conclude, from the evidence described above, that the component of peak 3 is 3-methyl-1, 4-pentadiene and that the component of peak 5 is 1, 3-hexadiene.

The Reaction of Butadiene with Ethylene. —The reaction of butadiene with ethylene can form the following four compounds as a 1 : 1 addition product; 3-methyl-1, 4-pentadiene, 1, 4-hexadiene, 1, 3-hexadiene, and cyclohexene.

The reaction conditions were examined using a catalyst consisting of a combination ferric chloride, triphenyl phosphine, and triethylaluminum. The catalyst containing no triphenyl phosphine was inactive in the reaction of butadiene with

ethylene. The effects of the catalyst composition are shown in Table I. In all the runs, considerable side reactions of butadiene (the dienylation of butadiene) occurred, giving linear dimers as a by-product. The dienylation of ethylene gave 1, 3-hexadiene, which amounted to about 40 wt.% of the C_6-dienes obtained. The formation rate of 1, 3-hexadiene decreased slightly at higher Al/Fe mole ratios. A proper Al/Fe mole ratio of high activity probably exists in the range from two to five. The reaction temperature affected the yield of C_6-dienes and their composition (Table II). The reactions proceeded smoothly even at 20°C. More 3-methyl-1, 4-pentadiene than 1, 4-hexadiene was formed at lower reaction temperatures. The weight ratio of three C_6-dienes, i. e.,

3-methyl-1, 4-pentadiene, 1, 4-hexadiene, and 1, 3-hexadiene, in the products obtained at 20—30°C was about 2 : 1 : 2. The average formation ratio of C_6-dienes to butadiene dimers in ten runs under the same conditions was 4.5 to 1. Therefore, the average yield of 3-methyl-1, 4-pentadiene was about 25—30%. The condition of high ethylene pressure was advantageous to the formation of C_6-dienes. As the butadiene initially-charged increased, the yield of C_6-dienes decreased because more butadiene dimers and higher boiling materials were formed. As is shown in Table III, the butadiene dimers were predominantly formed by the catalysts containing phosphorus oxychloride, triphenyl phoshine oxide, tributyl phosphite or triethyl phosphite rather than triphenyl phoshine. Both triphenyl arsine and triphenyl stibine were ineffective. It may be considered that phosphorus compounds as the third component in the catalyst played an important role, one which might characterize the nature of the active site. These experimental results suggest that the variations in the reaction conditions affect the composition of the reaction products only slightly but that the third component affects it intensely. According to this suggestion, a search for the proper third component has been carried out and a new catalyst for the exclusive formation of 1, 4-hexadiene has been found. The details will be reported shortly.

In order to form the linear 1 : 1 addition products, a hydrogen atom transfer from either butadiene or ethylene is indispensable. The catalyst, consisting of cobalt compound and metal alkyl, studied by Wittenberg[4] promoted exclusively the hydrogen transfer from butadinene to give 1, 3-hexadiene; however, the catalyst, consisting of $Fe(C_5H_7O_2)_3$ and triethylaluminum, studied by Hata[7] promoted the transfer from ethylene to give 1, 4-hexadiene. In contrast, the ternary catalyst in this study can promote both reactions; further, the hydrogen which is transferred from ethylene adds to butadiene in two ways, that is, by 1, 2-addition to give 3-methyl-1, 4-pentadiene and by 1, 4-addition to give 1, 4-hexadiene. These ways are analogous to the linear dimerization of butadiene to give 3-methyl-1, 4, 6-heptatriene and 1, 3, 6-octatriene. The direction of the addition of hydrogen in all cases obeyed Markownikov's rule. Which monomers release a hydrogen atom is probably governed by the nature of the active site that is characterized by the combined effects of the catalyst components. Hydrogen transfer may occur in the same way as in the dimerzation of butadiene, through an intermediate with a hydrogen-metal bond.[8] However, it is not clear whether the hydrogen in the intermediate is a protonic or a hydride ion. Since a more detailed study of the mechanism of the hydrogen transfer reaction is required, this will be the subject of a future report.

The authors wish to express their thanks to Dr. H. Kobayashi for permission to publish this work. They wish also to thank Mr. I. Shionoya for his kindness in measuring the mass spectra.

The Reactions of *N, N*-Dimethylbenzamide Diethylmercaptole

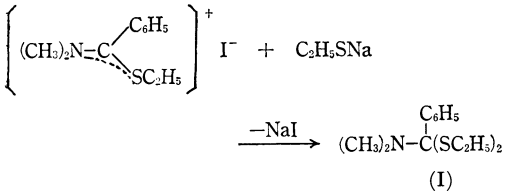
By Teruaki MUKAIYAMA and Tatsuaki YAMAGUCHI

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received January 26, 1966)

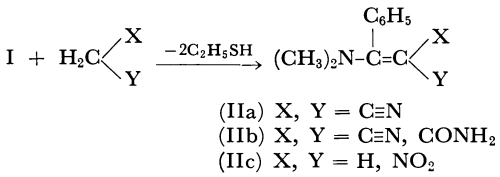
The reactions of *N, N*-dimethylbenzamide diethylmercaptole with active methylene compounds, amines, hydrazines, benzaldoxime, benzhydroxamic acid and heavy metal salts have been studied. Active methylene compounds, hydroxylamine, hydrazine and phenylhydrazine were found to react with *N, N*-dimethylbenzamide diethylmercaptole to give the corresponding α-dimethylaminobenzylidene derivatives by eliminating ethyl mercaptan. In addition, such heterocyclic compounds as 2-phenylimidazoline, 2-phenyloxazoline and 2, 5-diphenyl-1, 3, 4-oxadiazole were derived from *N, N*-dimethylbenzamide diethylmercaptole by cyclization reactions with ethylenediamine, 2-aminoethanol and benzoylhydrazine respectively. Further, it was found that *N, N*-dimethylbenzamide diethylmercaptole reacted with benzaldoxime and benzhydroxamic acid to give the dehydrated products benzonitrile and phenyl isocyanate respectively. Finally, it was established that heavy metal salts, such as mercuric oxide, mercuric cyanide and silver cyanide, reacted with *N, N*-dimethylbenzamide diethylmercaptole to liberate heavy metal mercaptides, thus giving *N, N*-dimethylbenzamide, *N, N*-dimethylbenzamide dicyanide and *N, N*-dimethylbenzamide ethylmercaptocyanide respectively.

It was reported in a preceding paper[1] that *N, N*-dimethylbenzamide methylethylmercaptole had been derived from *N, N*-dimethyl-*S*-methylthiobenzamide iodide and sodium ethylmercaptide. In the present experiment, the reactions of *N, N*-dimethylbenzamide diethylmercaptole (I) with active methylene compounds, amines, hydrazines, benzaldoxime, benzhydroxamic acid and heavy metal salts were investigated.



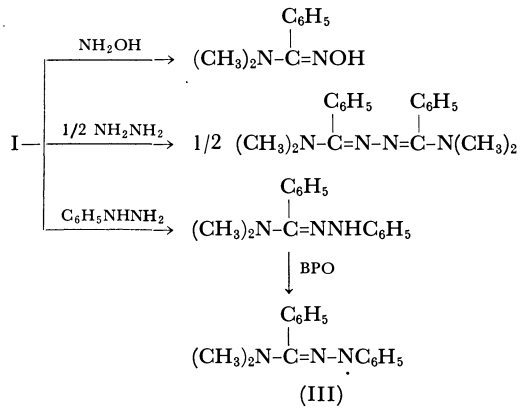
(I)

In the first place, it was found that the amide mercaptole (I) reacted with active methylene compounds to give the condensation products, i. e., α-dimethylaminobenzylidene derivatives (II) of the active methylene compounds, in fairly good yields, along with ethyl mercaptan. For example, malonitrile easily reacted with the amide mercaptole (I) at room temperature, with the evolution of ethyl mercaptan, and gave α-dimethylaminobenzylidene malonitrile (IIa) in a 71% yield; on the other hand, this compound could not be obtained from *N, N*-dimethyl-*S*-methylthiobenzamide iodide by the method mentioned in the previous paper.[1]



(IIa) X, Y = C≡N
(IIb) X, Y = C≡N, $CONH_2$
(IIc) X, Y = H, NO_2

Next, it was established that hydroxylamine, hydrazine and phenylhydrazine easily reacted with the amide mercaptole (I), resulting in the formation of the corresponding condensation products, i. e., *N, N*-dimethylbenzamidoxime, *N, N*-dimethylbenzamidazine and *N, N*-dimethylbenzamide phenylhydrazone respectively, in good yields. The *N, N*-dimethylbenzamide phenylhydrazone thus obtained was a red-brown oil which gradually turned dark-violet when it was exposed to the air. The electron-spin-resonance spectrum of the deep green oil which resulted from the treatment of *N, N*-dimethylbenzamide phenylhydrazone with

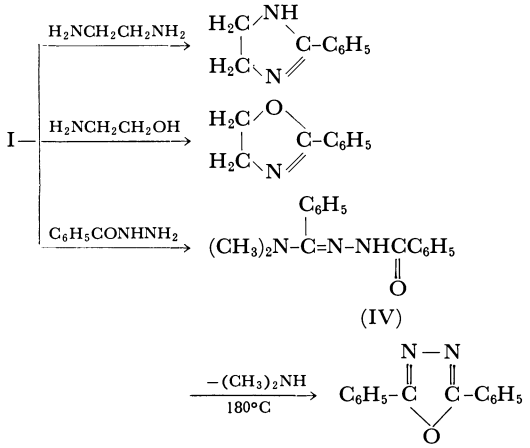


(III)

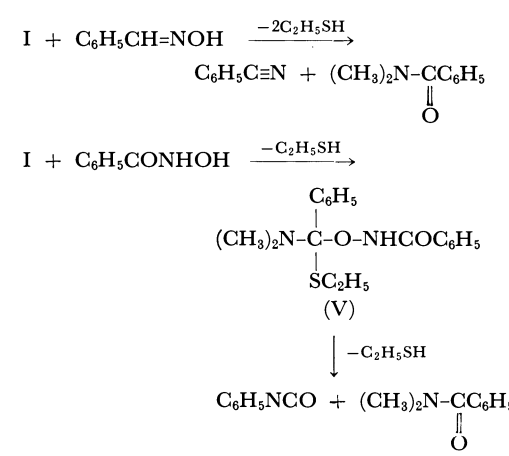
1) T. Mukaiyama, T. Yamaguchi and H. Nohira, This Bulletin, **38**, 2107 (1965).

benzoyl peroxide in benzene showed seven equally-spaced lines. This result would indicate that a stable free radical with a hydrazyl structure (III) exists in the above-mentioned oily substance.

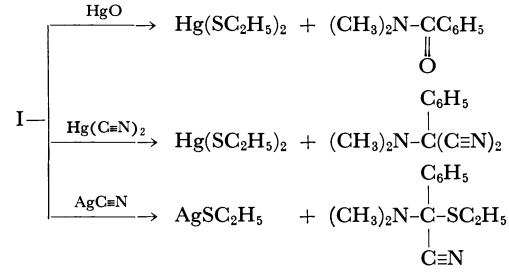
When *N, N*-dimethylbenzamide diethylmercaptole (I) was treated with bifunctional active hydrogen compounds, such as ethylenediamine and 2-aminoethanol, heterocyclic compounds, i. e., 2-phenylimidazoline and 2-phenyloxazoline respectively, were given in good yields by means of the elimination of ethyl mercaptan and dimethylamine. In addition, the treatment of the amide mercaptole (I) with benzoylhydrazine in refluxing ethyl acetate gave an oily product which, on heating at 180°C, readily solidified to give 2, 5-diphenyl-1, 3, 4-oxadiazole in a 77.5% yield. The initially-obtained oily substance may be identified as *N, N*-dimethylbenzamide benzoylhydrazone (IV) because its infrared spectrum shows absorption bands at 3265 (NH), 2940 (CH_3), 1665 (C=O) and, 1640 cm^{-1} (C=N).



In the next place, since the amide mercaptole (I) is very easily hydrolyzed to *N, N*-dimethylbenzamide and ethyl mercaptan, intramolecular dehydration reactions of benzaldoxime and benzhydroxamic acid by means of the amide mercaptole (I) were attempted. Benzaldoxime reacted with the amide mercaptole (I) to give, as expected, benzonitrile in a good yield, together with *N, N*-dimethylbenzamide and ethyl mercaptan. On the other hand, when benzhydroxamic acid was mixed with the amide mercaptole (I), a vigorous evolution of ethyl mercaptan was observed; after this gas evolution had been ceased, a red-brown oil was obtained. This oily substance decomposed, upon being heated at 140—150°C, to yield phenyl isocyanate and *N, N*-dimethylbenzamide, while ethyl mercaptan was eliminated. The structure of the intermediate oil seems to be V; its infrared spectrum shows main absorption bands at 3250 (NH), 2915 (CH), 1620 (C=O) and 1510 cm^{-1} (CH).



Since some of heavy metal salts can easily be converted to heavy metal mercaptides by treating them with mercaptans, reactions of the amide mercaptole (I) with heavy metal salts, such as mercuric oxide, mercuric cyanide and silver cyanide, were attempted. When mercuric oxide and mercuric cyanide were treated with the amide mercaptole (I), *N, N*-dimethylbenzamide and *N, N*-dimethylbenzamide dicyanide respectively resulted in good yields, while mercury ethylmercaptide was eliminated. In a similar fashion, the reaction of silver cyanide with the amide mercaptole (I) gave silver ethyl mercaptide and *N, N*-dimethylbenzamide ethylmercaptocyanide in fairly good yields.



Further, it was established that the amide mercaptole (I) reacted with lead tetraacetate to give lead acetate, diethyl disulfide, acetic anhydride and *N, N*-dimethylbenzamide in good yields.

$$I + Pb(OCOCH_3)_4 \rightarrow Pb(OCOCH_3)_2 + CH_3COOCOCH_3 + C_2H_5SSC_2H_5 + (CH_3)_2NCOC_6H_5$$

These results showed that the amide mercaptole (I) was oxidized to *N, N*-dimethylbenzamide and diethyl disulfide, while lead tetraacetate was reduced to lead acetate. In the course of this oxidation-reduction reaction, acetic anhydride was produced in a good yield. The oxidation reactions of amide mercaptoles by means of other oxidizing reagents are now being investigated.

Experimental[2]

N, N-Dimethylbenzamide Diethylmercaptole (I).—A suspension of 64 g. (0.2 mol.) of *N*, *N*-dimethylbenzamide-*S*-ethylthiobenzamide iodide, prepared from *N*, *N*-dimethylthiobenzamide and ethyl iodide, and 17 g. (0.2 mol.) of sodium ethylmercaptide in dry ether (300 ml.) was stirred at room temperature for 3 hr. After the white precipitate of sodium iodide had been filtered off, the filtrate was concentrated; the distillation of the residual liquid gave 31 g. (63.5%) of *N*, *N*-dimethylbenzamide diethylmercaptole (I). B. p. 105—109°C/0.2 mmHg, n_D^{16} 1.5732; IR; 2950(s), 2850(s), 2760(m), 1480(m), 1445(s), 1260(m), 1010(s), 790(s), 730(s) and 700 cm^{-1}(s).

Found: C, 63.27; H, 8.20; N, 5.96. Calcd. for $C_{13}H_{21}NS_2$: C, 63.15; H, 8.19; N, 5.45%.

N, *N*-Dimethylbenzamide diethylmercaptole (I) is a pale yellow oil with a mercaptan odor; it turns red-brown after standing for a few days.

The Reaction of the Amide Mercaptole (I) with Malonitrile.—A solution of 2.50 g. (0.01 mol.) of the amide mercaptole (I) and 0.66 g. (0.01 mol.) of malonitrile in dry ether (30 ml.) was stirred at room temperature. The reaction soon started, with the evolution of ethyl mercaptan, and a white precipitate was separated from the solution. After the stirring had been continued for 2 hr., the white precipitate was filtered and recrystallized from 95% ethanol. Yield IIa, 1.40 g. (71%); m. p. 120—121°C.

Found: C, 73.14; H, 5.51; N, 21.28. Calcd. for $C_{12}H_{11}N_3$: C, 73.07; H, 5.62; N, 21.38%.

The infrared spectrum of this compound showed the absorption band at 2180 cm^{-1} assigned to the C≡N bond.

The Reaction of the Amide Mercaptole (I) with Cyanoacetamide.—When a mixture of 2.50 g. (0.01 mol.) of the amide mercaptole (I) and 0.85 g. (0.01 mol.) of cyanoacetamide was heated at 115°C, the evolution of ethyl mercaptan was observed. After 5 minutes' heating, the reaction mixture was cooled and triturated with dry ether. Then the ether was evaporated and the resulting solid was recrystallized from 95% ethanol. Yield (IIb), 0.7 g. (32.5%); m. p. 163—164°C.

Found: C, 67.06; H, 5.99; N, 19.45. Calcd. for $C_{12}H_{13}N_3O$: C, 66.95; H, 6.09; N, 19.52%.

The infrared spectrum of this compound showed absorption bands at 3370, 2160 and 1640 cm^{-1}.

The Reaction of the Amide Mercaptole (I) with Nitromethane.—A solution of 2.50 g. (0.01 mol.) of the amide mercaptole (I) and 0.65 g. (0.01 mol.) of nitromethane in benzene (10 ml.) was refluxed for an hour. After the benzene had been removed in vacuo, the resulting solid was recrystallized from benzene (or ethanol). Yield IIc, 1.00 g. (52%); m. p. 128°C. This material showed no depression in a mixed melting point determination with an authentic sample prepared by the previously reported method.[1]

The Reaction of the Amide Mercaptole (I) with Hydroxylamine.—Hydroxylamine was prepared from hydroxylamine hydrochloride by the method described in the literature.[3] M. p. 31—33°C. A benzene solution of 1.20 g. (0.005 mol.) of the amide mercaptole (I) and 0.175 g. (0.005 mol.) of hydroxylamine was refluxed for 2 hr. After this mixture had cooled, the solvent was removed in vacuo and the resulting *N*, *N*-dimethylbenzamidoxime was recrystallized from benzene. Yield, 0.82 g. (92%); m. p. 123—124°C.

Found: C, 65.76; H, 7.42; N, 16.89. Calcd. for $C_9H_{12}N_2O$: C, 65.83; H, 7.37; N, 17.06%.

The Reaction of the Amide Mercaptole (I) with Hydrazine.—Anhydrous hydrazine was prepared by the dehydration of hydrazine hydrate with sodium hydroxide. B. p. 114°C. A solution of 2.45 g. (0.01 mol.) of the amide mercaptole (I) and 0.16 g. (0.005 mol.) of hydrazine in dry benzene (20 ml.) was refluxed for 2 hr. After the benzene had been removed in vacuo, the resulting white solid was recrystallized from ethanol. Yield, 1.00 g. (68%); m. p. 137—138°C.

Found: C, 73.54; H, 7.47; N, 18.85. Calcd. for $C_{18}H_{22}N_4$: C, 73.43; H, 7.53; N, 19.03%.

The Reaction of the Amide Mercaptole (I) with Phenylhydrazine.—To a solution of the amide mercaptole (I) (2.50 g., 0.01 mol.) in dry benzene (20 ml.), there was added a solution of phenylhydrazine (1.08 g., 0.01 mol.) in dry benzene (10 ml.) under a nitrogen atmosphere. After it had been refluxed for 2 hr., the reaction mixture was concentrated and distilled in vacuo under nitrogen. Yield, 1.71 g. (71.5%); b. p. 127—129°C/0.03 mmHg.

Found: C, 73.83; H, 7.06; N, 17.36. Calcd. for $C_{15}H_{17}N_3$: C, 75.28; H, 7.16; N, 17.56%.

To a solution of 0.50 g. of *N*, *N*-dimethylbenzamide phenylhydrazone in dry benzene (15 ml.) there was added, drop by drop, a solution of 0.25 g. of benzoyl peroxide in dry benzene (10 ml.) under a nitrogen atmosphere. The dark-colored reaction mixture was stirred for an additional 30 min., and then the benzene was removed in vacuo at room temperature. The electron-spin-resonance spectrum of the resulting deep-green oil was recorded in the benzene solution.

The Preparation of 2-Phenylimidazoline and of 2-Phenyloxazoline.—A solution of 1.25 g. (0.005 mol.) of the amide mercaptole (I) and 0.30 g. (0.005 mol.) of anhydrous ethylenediamine in dry benzene (20 ml.) was refluxed for 3 hr. Then the benzene was removed under reduced pressure, and the resulting 2-phenylimidazoline was recrystallized from ethanol (or benzene). Yield, 0.70 g. (96%); m. p. 100—101°C (lit.[4] 101°C). A mixed melting point determination with an authentic sample showed no depression.

In a similar way, 2-phenyloxazoline was obtained in a 67% yield (b. p. 125—127°C/17 mmHg) when the amide mercaptole (I) and 2-aminoethanol were reacted in refluxing chloroform for 3 hr.

Found.: C, 73.00; H, 6.76; N, 9.47. Calcd. for C_9H_9NO: C, 73.45; H, 6.61; N, 9.52%.

The Reaction of the Amide Mercaptole (I) with Benzoylhydrazine.—A solution of 2.60 g. (0.01 mol.) of the amide mercaptole (I) and 1.36 g. (0.01 mol.) of benzoylhydrazine in 40 ml. of ethyl acetate was refluxed for 3 hr., and then the solvent was removed under reduced pressure. The resulting yellow oil was, in situ, heated to 180°C for a while; after it had cooled, it solidified to give 2, 5-diphenyl-1, 3, 4-oxadiazole (1.72 g.;

2) All melting points and boiling points are uncorrected.

4) G. Forrsel, *Ber.*, **25**, 2135 (1892).

77.5%), which was then recrystallized from absolute ethanol. M. p. 136—137°C)lit.[5] 135—136°C).

Found: C, 75.61; H, 5.02; N, 12.41. Calcd. for $C_{14}H_{10}N_2O$: C, 75.65; H, 4.54; N, 12.61%.

The Reaction of the Amide Mercaptole (I) with Benzaldoxime.—A solution of 2.60 g. (0.01 mol.) of the amide mercaptole (I) and 1.21 g. (0.01 mol.) of *syn*-benzaldoxime in dry benzene (25 ml.) was refluxed for an hour. After the benzene had been removed, the residual liquid was distilled in vacuo to give 0.66 g. (67.5%) of benzonitrile (b. p. 88—93°C/22 mmHg), together with *N, N*-dimethylbenzamide (1.19 g., 80%; b. p. 93—98°C/1.0 mmHg). They were identified by comparing their infrared spectra with those of authentic samples.

The Reaction of the Amide Mercaptole (I) with Benzhydroxamic Acid.—When 2.60 g. (0.01 mol.) of the amide mercaptole (I) was mixed with 1.37 g. (0.01 mol.) of benzhydroxamic acid, an exothermic reaction soon took place and ethyl mercaptan was evolved violently. After the gas evolution had ceased, the resulting red-brown oil was, in situ, heated at 140—155°C; then it was distilled under reduced pressure to give 0.68 g. (57.5%) of phenyl isocyanate and 1.23 g. (82%) of *N, N*-dimethylbenzamide.

The Reaction of the Amide Mercaptole (I) with Mercuric Oxide.—Into a suspension of 2.16 g. (0.01 mol.) of meruric oxide in acetonitrile (25 ml.), there was added a solution of 2.60 g. (0.01 mol.) of the amide mercaptole (I) in acetonitrile (10 ml.). After the reaction mixture had then been stirred at room temperature for 30 min., it was heated at 50°C for an additional 30 min., cooled, and filtered to remove a white percipitate. After the filtrate had been concentrated, the resulting solid part was filtered, washed, and combined with the initial precipitate; this gave 1.20 g. (46%) of mercury ethylmercaptide (recrystallized from ethanol; m. p. 76—78°C; lit.[6] 76.5°C). The filtrate was concentrated and distilled to give 0.90 g. (60%) of *N, N*-dimethylbenzamide, b. p. 145—147°C/34 mmHg.

The Reactions of the Amide Mercaptole (I) with Mercuric Cyanide and Silver Cyanide.—A solution of 2.60 g. (0.01 mol.) of the amide mercaptole (I) in dry tetrahydrofuran (10 ml.) was added to a suspension of 2.52 g. (0.01 mol.) of mercuric cyanide in dry tetrahydrofuran (15 ml.); the mixture was then stirred at room temperature for an hour. After the solvent had been removed in vacuo, the resulting solid was recrystallized from acetonitrile (ca. 10 ml.); filtration gave 0.95 g. (72%) of mercury ethylmercaptide. The filtrate was concentrated and distilled to give 1.18 g. (64%) of *N, N*-dimethylbenzamide dicyanide, b. p. 100—103°C/5 mmHg.

Found: C, 71.44; H, 5.99. Calcd. for $C_{11}H_{11}N_3$: C, 71.33; H, 5.99%.

In a similar way, when silver cyanide was treated with the amide mercaptole (I) in refluxing tetrahydrofuran, pale yellow silver mercaptide was precipitated; this was then filtered off. The distillation of the filtrate gave a 46% yield of *N, N*-dimethylbenzamide ethylmercaptocyanide (b. p. 103—107°C/1.0 mmHg), which showed an infrared spectrum identical with that of the authentic sample derived by the previously-reported method.[1]

The Reaction of the Amide Mercaptole (I) with Lead Tetraacetate.—When a solution of 2.60 g. (0.01 mol.) of the amide mercaptole (I) and 4.43 g. (0.01 mol.) of lead tetraacetate in dry benzene (50 ml.) was heated at 60°C, a white precipitate was separated from the solution. After stirring had been continued for 2.5 hr., the white precipitate of lead acetate was filtered and dried. It weighed 2.28 g. (70%). The filtrate was then concentrated and fractionated, giving 0.80 g. (81%) of acetic anhydride (b. p. 65—67°C/57 mmHg), 0.43 g. (70%) of diethyl disulfide (b. p. 74—75°C/45 mmHg) and 1.07 g. (71%) of *N, N*-dimethylbenzamide (b. p. 130—133°C/17 mm Hg). They were identified by means of their infrared spectra.

The authors wish to thank Dr. Kazuo Shimogoshi for his analysis of the ESR spectrum.

Studies on D-Glucosamine Derivatives. XIII.*1 The Synthesis of *N*-Acetyl-1-*O*-aminoacyl-D-glucosamines

By Juji YOSHIMURA and Masuo FUNABASHI

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received February 5, 1966)

For the purpose of examining the properties of the glycosidic ester linkage of sugars to amino acids, *N*-acetyl-1-*O*-aminoacyl-D-glucosamines were synthesized. *N*-Acetyl-4, 6-*O*-benzylidene-D-glucosamine was condensed with an equimolar amount of *N*-benzyloxycarbonyl amino acids by the dicyclohexylcarbodiimide method, followed by the hydrolytic and hydrogenolytic removal of the protecting groups. *N*-Acetyl-3-*O*-acetyl-D-glucosamine was also newly prepared as a contrast compound.

Though the presence of glycosidic ester lingkage between *N*-acetyl-D-galactosamine and L-glutamic acid in ovine submaxillary gland mucoprotein, reported by Gottschalk et al.,[1] is at present doubted by several workers,[2] it seems to be of interest to examine the properties of such a possible linkage.

The homologues, in which amino acids are linked to C-6, C-4, or C-3 positions of *N*-acetyl-D-glucosamine, were synthesized in previous experiments[3,4]; the present paper will describe the selective synthesis of *N*-acetyl-1-*O*-aminoacyl-D-glucosamines.

Results and Discussion

The glycosidic hydroxyl group in a sugar moiety is generally accepted to be much more reactive than the other groups, but few examples of the selective acylation of this hydroxyl group are known. Zervas[5] has reported the selective synthesis of 1-*O*-benzoyl-β-D-glucose by condensing sodium salt of 4, 6-*O*-benzylidene-D-glucose with an equimolar amount of benzoyl chloride, followed by hydrogenolysis.

In a similiar manner 1-*O*-glycyl-D-glucose sulfate[6] has been obtained from the sugar and *N*-benzyloxycarbonyl-glycyl chloride. On the other hand, it is known that the primary hydroxyl group of unprotected D-glucose or *N*-acetyl-D-glucosamine is directly acylated with an equimolar amount of *N*-Z*2-amino acids by the dicyclohexylcarbodiimide (DCC) method.[3,7]

In view of the facts mentioned above, *N*-acetyl-4, 6-*O*-benzylidene-D-glucosamine (I) was used as the starting material, in which the primary hydroxyl group is protected. The compound I was condensed with an equimolar amount of *N*-Z-amino acids (a, *N*-Z-glycine; b, *N*-Z-L-alanine; c, β-benzyl *N*-Z-L-aspartate) by DCC in pyridine or in a mixture of pyridine and dimethylformamide (DMF) to give *N*-acetyl-1-*O*-(*N*-Z-aminoacyl)-4,6-*O*-benzylidene-D-glucosamines (II) in a 40—50% yield. In order to remove the benzylidene group, II was then hydrolyzed with 70% acetic acid at 100°C for half an hour; *N*-acetyl-1-*O*-(*N*-Z-aminoacyl)-D-glucosamines (IIIa and IIIb) were isolated in ca. a 20% yield. Although the complete hydrolysis of *N*-Z-aminoacyl group was observed in the case of IIc, the catalytic hydrogenolysis of IIc in glacial acetic acid with palladium-charcoal (10%) could be directly carried out to give *N*-acetyl-1-*O*-(L-α-aspartyl)-D-glucosamine (IVc) in a 46% yield. The removal of the benzyloxycarbonyl group from IIIa and IIIb was also performed by palladium-catalyzed hydrogenolysis in the presence of oxalic acid, and *N*-acetyl-1-*O*-aminoacyl-D-glucosamines (IVa and were isolated as labile oxalates.

The infrared spectra of II and III showed the absorption band of ester carbonyl at 1730—1750 cm^{-1} and that of urethane carbonyl at 1690—1710 cm^{-1}. These compounds gave one spot in paper chromatography and showed no mutarotation, which indicates that the position of the ester linkage is at C-1. The anomeric structure of these compounds, which seems likely to depend on the solvent in the first condensation reaction, as will

(Z=-$COOCH_2Ph$)

be described in the Experimental Section, was deduced from the rotational values and the infrared spectra.

In order to compare the properties with III, *N*-acetyl-3-*O*-acetyl-D-glucosamine (V) was newly prepared by the hydrolytic and hydrogenolytic removal of benzylidene and benzyl groups from benzyl *N*-acetyl-3-*O*-acetyl-4, 6-*O*-benzylidene-β-D-glucosaminide.[4] In contrast with III, V showed mutarotation in water ($[\alpha]_{578}^{14}$ +89°—+44°). In the periodate oxidation of these compounds in an acetate buffer (pH 5.0) for 20 hr., overoxidation was observed in each case; for example, β-IIIa and V consumed, respectively, 5.0 and 3.4 mol. of periodates, as is shown in Fig. 1. Therefore, the periodate oxidation would not be adopted for determining the structure of *O*-acyl derivatives of *N*-acetyl-D-glucosamine as it is known in other amino sugar derivatives.[8]

However, the position of the ester linkage in II-IV is concluded to be at C-1 from the facts that the compounds do not show mutarotation

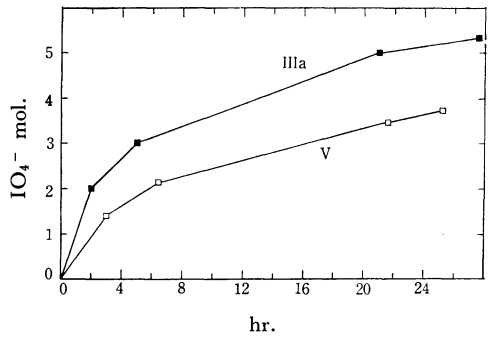

Fig. 1. Periodate Oxidation of *N*-acetyl-1-*O*-(*N*-benzyloxyloxycarbonylglycyl)-β-D-glucosamine (IIIa) and *N*-acetyl-3-*O*-acetyl-α-D-glucosamine (V).

and that 1-*O*-(*N*-Z-glycycl)-D-glucose, prepared by the procedure mentioned above, also showed no mutarotation and consumed 2 mol. of periodate, an amount consistent with the supposed structure.[9]

Experimental

All melting points are uncorrected. The optical rotations were measured at 578 mμ using a Carl-Zeiss polarimeter. Paper chromatography was carried out on Toyo Roshi No. 50 filter paper using the following solvent systems: A) isobutanol saturated with water, and B) *n*-butanol, acetic acid and water (4 : 1 : 5). An aqueous solution of 1% potassium iodide — 1% starch,[10] and a 0.1% ninhydrin solution in *n*-butanol were used as the spray reagents.

***N*-Acetyl-1-*O*-(*N*-benzyloxycarbonyl-glycyl)-4, 6-*O*-benzylidene-β-D-glucosamine (IIa).**—A solution of *N*-acetyl-4, 6-*O*-benzylidene-D-glucosamine (9.3 g.; 0.03 mol.) dissolved in a mixture of hot dry pyridine (80 ml.) and DMF (30 ml.) was cooled to room temperature. *N*-Z-Glycine (6.3 g.; 0.03 ml.) and DCC (8.0 g.; 0.039 mol.) were then added, and the mixture was allowed to stand overnight in a refrigerator. The precipitate of dicyclohexylurea was filtered off and washed with toluene. The filtrate and the washings were then concentrated to half their volume under reduced pressure and poured into ice water (300 ml.). The precipitate was filtered and washed several times with water.

The fractional recrystallization of the dry crude product was repeated several times from methanol in order to remove the unchanged starting material, I, which was recovered in ca. 30% yield. The final recrystallization from a mixture of methanol and pyridine (10 : 1) gave 4.1 g. (40%) of IIa, m. p. 180—182°C (decomp.), $[\alpha]_{578}^{20}$ −36° (*c* 0.49, pyridine).

Found: C, 60.04; H, 5.81; N, 5.36, Calcd. for $C_{25}H_{28}O_9N_2$ (500): C, 59.99; H, 5.64; N, 5.60%.

In another experiment, only dry pyridine (150 ml.)

8) A. B. Foster and D. Horton, "*Advances in Carbohydrate Chemistry*," XIV, Academic Press, New York (1959) p. 258.

9) Private communication from N. Muramatsu (Central Research Laboratory of Ajinomoto Co. Ltd.).

10) H. N. Rydon and P. W. Smith, *Nature*, **169**, 922 (1952).

was used as the solvent, and the filtrate was concentrated under reduced pressure to a gelatinous residue, which was then washed with ether or ethyl acetate.

After fractional recrystallization, 5.1 g. (49%) of the product was obtained. M. p. 178—181°C (decomp.); $[\alpha]_{578}^{15}$ −20° (*c* 0.51, pyridine).

Found: C, 59.93; H, 5.36; N, 5.48%.

The rotational value and the infrared spectrum indicate the product to be contaminated with the α-anomer.

N-Acetyl-1-O-(N-benzyloxycarbonyl-L-alanyl)-4, 6-O-benzylidene-α, β-D-glucosamine (IIb). — *N*-Benzyloxycarbonyl-L-alanine (6.1 g.) was condensed with I (4.5 g.) by DCC (4.8 g.) in dry pyridine (120 ml.). It was subsequently treated in the manner described above. Yield, 3.1 g.; m. p. 172—175°C (decomp.); $[\alpha]_{578}^{17}$ +23° (*c* 0.59, pyridine).

Found: C, 60.13; H, 6.29; N, 5.51. Calcd. for $C_{26}H_{30}O_9N_2$ (514): C, 60.69; H, 5.88; N, 5.45%.

N-Acetyl-1-O-(β-benzyl N-benzyloxycarbonyl-L-aspartyl)-4, 6-O-benzylidene-α, β-D-glucosamine (IIc).—The compound I (9.3 g.; 0.03 mol.) was condensed with β-benzyl *N*-benzyloxycarbonyl-L-aspartate (10.6 g.; 0.03 mol.) by DCC (8.0 g.; 0.039 mol.) in pyridine (150 ml.). Yield, 4.9 g.; m. p. 183—185°C (decomp.); $[\alpha]_{578}^{29}$ −9.8° (*c* 0.05, pyridine).

Found: C, 62.78; H, 5.49; N, 4.52. Calcd. for $C_{34}H_{36}O_{11}N_2$(648): C, 62.95; H, 5.59; N, 4.33%.

N-Acetyl-1-O-(N-benzyloxycarbonyl-glycyl)-β-D-glucosamine (IIIa).—A suspension of IIa (2.5 g.) in 70% acetic acid (60 ml.) was heated on a boiling water bath for 30 min. while being stirred. The solution was then concentrated under reduced pressure to a gelatinous residue, which was redissolved in water and extracted twice with ether. The aqueous layer was then extracted five times with *n*-butanol (10 ml.). The *n*-butanol extract was evaporated in vacuo to a crystalline residue. The recrystallization from ethanol and ether gave a compound IIIa with a m. p. of 178—180°C (decomp.). R_f 0.65 (Solvent A) and $[\alpha]_{578}^{16}$ −20° (*c* 0.2, water).

Found: C, 52.15; H, 5.92; N, 7.02. Calcd. for $C_{18}H_{24}O_9N_2$ (412): C, 52.42; H, 5.87; N, 6.79%.

The compound IIa which was condensed in pyridine was treated in the same manner to give a product with a m. p. of 153—155°C (decomp.) and a $[\alpha]_{578}^{23}$ −11° (*c* 0.41, water).

N-Acetyl-1-O-(N-benzyloxycarbonyl-L-alanyl)-α-D-glucosamine (IIIb).—A suspension of the crude IIb (4.2 g.) in 70% acetic acid (70 ml.) was heated on a boiling water bath for 30 min. while being stirred. The solution was diluted with water to 500 ml. and neutralized with sodium bicarbonate. The precipitate was filtered off, and the filtrate was extracted with ether (10 ml.×3). The aqueous layer was then extracetd with *n*-butanol (20 ml.×5), and the extract was concentrated in vacuo to a crystailline residue. Recrystallization from ethanol gave 0.43 g. of white needles with a m. p. of 165—167°C (decomp.). R_f 0.71 (Solvent A), $[\alpha]_{578}^{13}$ +80° (*c* 0.23, water).

Found: C, 53.75; H, 6.28; N, 6.53. Calcd. for $C_{19}H_{26}O_9N_2$ (426): C, 53.51; H, 6.15; N, 6.57%.

N-Acetyl-1-O-glycyl-β-D-glucosamine Oxalate (IVa).—A mixture of IIIa (620 mg.), oxalic acid dihydrate (190 mg.) and 0.6 g. of Pd-C (10%) in 70% methanol (10 ml.) was shaken with hydrogen until the absorption had substantially ceased.

After the catalyst had then been removed, ether was added to the filtrate and centrifugation was performed to collect a precipitate. For the purification the precipitated solid was dissolved in a few drops of water, reprecipitated with ethanol, centrifugated, and dried in vacuo. The amorphous hygroscopic powder, which is gradually decomposed with browning in moist air, gave a single ninhydrin positive spot on paper chromatography (R_f 0.19, solvent B). Yield, 310 mg. (60%); it gradually melts at ca. 82°C with decomposition. $[\alpha]_{578}^{15}$ −7.6° (*c* 0.53, water).

Found: C, 38.93; H, 7.08; N, 7.45. Calcd. for $C_{10}H_{18}O_7N_2 \cdot 1/2(COOH)_2 \cdot H_2O$: C, 38.71; H, 6.20; N, 8.21%.

N-Acetyl-1-O-(L-alanyl)-α-D-glucosamine Oxalate (IVb).—The compound IIIb (170mg.) was hydrogenated in 70% methanol (10 ml.) with 0.2 g. of Pb-C (10%) in the presence of oxalic acid dihydrate (40 mg.). The subsequent operations were performed in the same manner as with IVa. Yield, 52 mg. (37%); R_f 0.25 (solvent B). It melted gradually at ca. 70°C with decomposition; $[\alpha]_{578}^{15}$ +96° (*c* 0.25, water).

Found: C, 37.62; H, 6.53; N, 8.05. Calcd. for $C_{11}H_{18}O_6N_2 \cdot 1/2(COOH)_2 \cdot 2H_2O$; C, 38.58; H, 7.02; N, 7.88%.

N-Acetyl-1-O-(L-α-aspartyl)-α, β-D-glucosamine (IVc).—A mixture of IIc (1 g.) and 1 g. of Pd-C (10%) in glacial acetic acid (30 ml.) was shaken with hydrogen for 15 hr. After the catalyst had been removed, acetone (220 ml.) and ether (300 ml.) were added to the filtrate and centrifugation was performed to collect a precipitate. This was subsequently treated in the same manner as IVa. Yield, 240 mg. (46%); m. p. 149°C (decomp.); R_f 0.15 (Solvent B), $[\alpha]_{578}^{14}$ +9.4° (*c* 0.53, water).

Found: C, 40.62; H, 7.18; N, 8.03. Calcd. for $C_{12}H_{20}O_9N_2 \cdot H_2O$: C, 40.67; H, 6.21; N, 7.90%.

Benzyl N-Acetyl-3-O-acetyl-β-D-glucosaminide.—A suspension of benzyl *N*-acetyl-3-*O*-acetyl-4, 6-*O*-benzylidene-β-D-glucosaminide[4] (1.0 g.) in 70% acetic acid (40 ml.) was heated on a boiling water bath for half an hour. The solution was then concentrated in vacuo to dryness. The preduct was recrystallized from ethanol (17 ml.). Yield, 0.57 g. (72%); m. p. 201—203°C; R_f 0.72 (Solvent A) and $[\alpha]_{578}^{15}$ −66° (*c* 0.36, methanol).

Found: C, 57.98; H, 6.58; N, 3.85. Calcd. for $C_{17}H_{23}O_7N$(353): C, 57.78; H, 6.56; N, 3.96%.

N-Acetyl-3-O-acetyl-β-D-glucosamine (V). — A mixture of benzyl *N*-acetyl-3-*O*-acetyl-β-D-glucosaminide (0.71 g.), oxalic acid dihydrate (0.15 g.) and 0.7 g. of Pd-C (10%) in 60% methanol (20 ml.) was shaken with hydrogen at room temperature for 5 hr. After the catalyst had been removed, the filtrate was concentrated under reduced pressure to dryness. The paper chromatography of the product gave 3 spots (R_f 0.12, 0.35 and 0.71, solvent A), which correspond to *N*-acetyl-D-glucosamine, V and the starting material respectively. V was then separated with a column of magenesol-cerite (1 : 3) by eluting it with water-saturated isobutanol.

The recrystallization of the crude product from ethanol gave colorless needles with a m. p. of 159—161°C (decomp.). Yield, 0.21 g. (40%); R_f 0.35 (Solvent A); $[\alpha]_{578}^{14}$ +89° (after 5 min.)→ +44° (after 50 hr.) (*c* 0.48, water).

Periodate Oxidation.—The oxidation of *N*-acetyl-1-*O*-(*N*-benzyloxycarbonyl - glycyl) - β - D - glucosamine (IIIa), shown in Fig. 1, will be described as an example.

A solution of IIIa (41.5 mg.) in 20 ml. of an acetate buffer (pH 5.0) and 20 ml. of a sodium periodate solution (445.2 mg./40 ml.) were placed in a measuring flask. The flask was then allowed to stand in a refrigerator at 5°C and the solution was subjected to titration four times during a 30 hr. period. To 10 ml. of the sample there was added a 10 ml. portion of a 5% solution of borax and 0.5 g. of potassium iodide. Titration was performed with a 0.05 N sodium arsenite solution (F=1.050). A blank solution was used for correction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2012—2014 (1966)

The Synthesis of *dl*-α-Dihydrocaranone and γ-Lycorane

By Nasuo UEDA, Takashi TOKUYAMA and Takeo SAKAN

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received February 11, 1966)

dl-α-Dihydrocaranone (XII) has been synthesized stereoselectively, using the ring-closure reaction via benzyne intermediate of *N*-(2-bromo-4, 5-methylenedioxybenzyl)octahydroindole-6-one (X) with lithium piperidide in tetrahydrofuran. *dl*-γ-Lycorane (III) has been obtained by the Hauptmann reduction of XII.

The stereoisomers of lycorane derived from lycorine have been studied by Takeda and Kotera.[1] They established the stereochemistry of all of the possible isomers, α-, β-, γ- and δ-lycorane (I, II, III and IV). Recently, the stereoselective synthesis of *dl*-α- and β-lycorane has been reported by Hill,[2] but γ- and δ-lycorane have not yet been synthesized. The present investigation was undertaken in order to synthesize γ-lycorane stereoselectively, considering the biosynthesis[3] of the Amaryllidaceae alkaloids.

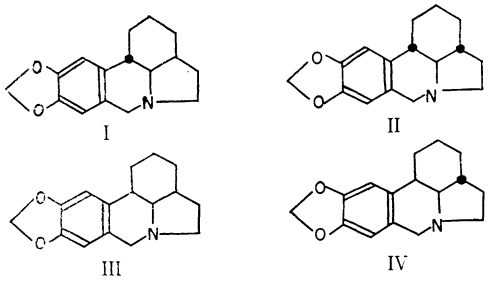

Fig. 1. The four stereoisomers of lycorane.

2-Bromo-4, 5-methylenedioxybenzyl bromide (V) was treated with 2, 5-dihydro-4-methoxyphenethylamine (VI) to give monobenzyl (VII) and di-benzyl (VIII) derivatives, which were then separated and purified by chromatography on silica gel. The ratio of VII to VIII was 3 : 1.

The monobenzyl derivative, VII, was hydrolyzed with 2 N hydrochloric acid into a 3-cyclohexenone

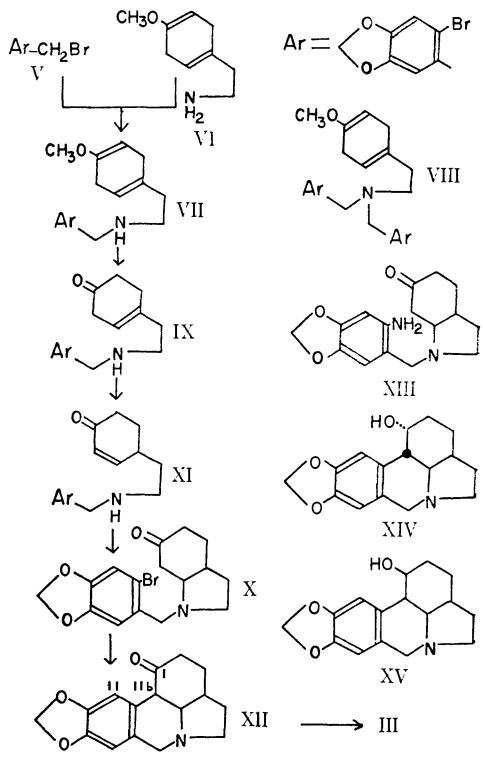

Fig. 2.

(IX) hydrochloride, $C_{16}H_{18}NO_3 \cdot HCl$, m.p. 163°C. The NMR spectrum ($CDCl_3$) of the free base showed a vinyl proton multiplet at 4.35τ (1H) and a NH proton singlet at 5.2 τ (Fig. 3). The 3-cyclohexenone, IX, was refluxed in an 8 N hydrochloric acid - ethanol solution to yield *N*-(2-bromo-4, 5-methylenedioxybenzyl)-octahydroindole-6-one (X), which was then purified by chromatography on silica gel.

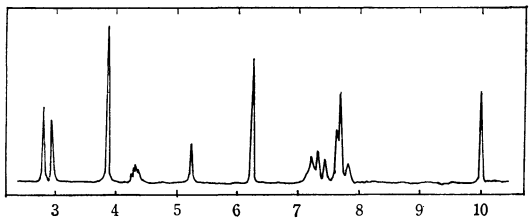

Fig. 3. NMR spectrum of XI (60 Mc.).

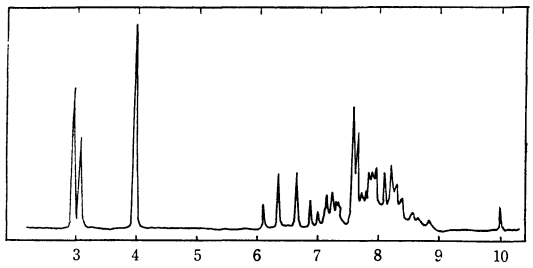

Fig. 4. NMR spectrum of X (60 Mc.).

The formation of the octahydroindole ring was deduced from the following facts. The NMR spectrum of this base showed a benzyl proton quartet at 6.4 τ (2H, AB type) (Fig. 4). The observed nonequivalence of the benzyl protons may arise from different magnetic shielding due to a molecular asymmetry resulting from the formation of the octahydroindole ring[4]. This base was then converted to its hydrochloride, $C_{16}H_{18}BrNO_3 \cdot HCl \cdot H_2O$, m.p. 123—125°C. The infrared spectrum of the hydrochloride exhibited the characteristic bands of an ammonium salt of the tertiary amine in the 2500—2700 cm^{-1} region. The more stable cis-fused octahydroindole ring may be obtained in this case.

The product obtained from α-dihydrocaranine (XIV) by Oppennauer oxidation was reported by Kotera[1] to be homogeneous α-dihydrocaranone (XII), which was isomeric at C_{11b} as compared with XIV. He suggested that another isomeric dihydrocaranone, the C_{11b} epimer of XII, might be unavailable due to non-bonded interaction between the C_{11}-aromatic proton and C_1-carbonyl-oxygen. Therefore, we considered the benzyl-octahydroindole, X, which has a cis-fused ring, would give XII upon treatment with strong bases.

Recently, Bunnett and his coworkers[5] reported many experiments on ring-closure reactions via benzyne intermediates. They mainly used potassium amide as the basic reagent.

The reaction of X with sodium or potassium amide in liquid ammonia did not give XII, but an amino-substituted derivative (XIII) solely. On the other hand, the treatment of X with lithium piperidide in tetrahydrofuran gave XII as the main product. This product was purified with chromatography over silica gel (35—40% yield) and recrystallized from methanol to give prisms, m.p. 147.5—149.5°C. The infrared spectrum in a chloroform solution was identical with that of the authentic *l*-α-dihydrocaranone.

dl-α-Dihydrocaranone, XII, was converted into its thioketal, m.p. 113.5—115°C, which was then desulfurized to *dl*-γ-lycorane, m.p. 101—102°C, by the method of Kotera.[1c]

The infrared spectrum of this compound was identical with that of the authentic *dl*-γ-lycorane. The reduction of XII with lithium aluminium hydride gave a mixture of two isomeric dihydrocaranines. The isomers were separated efficiently by silica gel chromatography into *dl*-1-epi-γ-dihydrocaranine, (XV), m.p. 135.5—136.5°C and *dl*-γ-dihydrocaranine, (C_1-epimer of XV), m.p. 180—181°C. The ratio of the isomers was 6 : 1. The infrared spectrum of the main product in a chloroform solution was identical with that of the authentic *l*-1-epi-γ-dihydrocaranine.

Experimental*1

2-Bromo - 4, 5 - methylenedioxybenzyl Bromide (V).*2—This was prepared by the method of Naik.[6]

2, 5-Dihydro-4-methoxyphenethylamine (VI).—This compound was prepared by a method similar to that described by Clarke.[7]

2-Bromo-4, 5 - methylenedioxybenzyl - (2, 5-dihydro-4-methoxyphenethyl)amine (VII).—A solution of 7 g. of V and 7.5 g. of VI in 500 ml. of absolute ethyl ether was kept at room temperature for one week. After the filtration of the deposited hydrobromide of VI, the solvent was removed under reduced pressure. The oily residue was then chromatographed over 130 g. of silica gel. Elution with a chloroform - ethyl ether solution (95 : 5 — 90 : 10) gave 2 g. of a dibenzyl derivative, VIII, as the first fraction. The product

7) C. B. Clark and A. R. Pinder, ibid., **1958**, 1967.

was then recrystallized from benzene - petroleum ether to give prisms, m. p. 88—89°C.

Found: C, 51.93; H, 4.48; N, 2.44. Calcd. for $C_{25}H_{25}O_5NBr_2$: C, 51.83; H, 4.35; N, 2.42%.

As a second fraction, 6 g. of a monobenzyl derivative (VII) were eluted.

4-[*N*-(2-Bromo-4, 5-methylenedioxybenzyl)-2'-aminoethyl]-3-cyclohexene-1-one (IX).—To a solution of 6.6 g. of the monobenzyl derivative (VII) in 150 ml. of ethanol, 300 ml. of a 2 N hydrochloric acid solution was added; the mixture was then allowed to stand at room temperature for 24 hr. The needles which thus formed were filtered (4.4 g.) and recrystallized from 1-propanol to give the 3-cyclohexenone (IX) hydrochloride, m. p. 163°C; infrared spectrum: ν_{max}^{Nujol} 1705 cm^{-1} (C=O), 2740 cm^{-1} (NH_2^+).

Found: C, 49.63; H, 4.95; N, 3.57. Calcd. for $C_{16}H_{19}NO_3BrCl$: C, 49.44; H, 4.93; N, 3.60%.

***N*-(2-Bromo-4, 5-methylenedioxybenzyl)octahydroindole-6-one (X).**—A solution of 4.5 g. of 3-cyclohexenone IX, or its hydrochloride in 200 ml. of ethanol and 200 ml. of 8 N hydrochloric acid was refluxed for 6—7 hr. The solvent was then evaporated under reduced pressure. The residue was dissolved in 100 ml. of water, and the solution was basified with a 10% sodium hydroxide solution and extracted with chloroform. The chloroform extract was washed with water, dried over sodium sulfate, and evaporated to dryness. The residue was chromatographed over silica gel. Elution with a chloroform-methanol-triethylamine solution (98.5 : 1 : 0.5) gave 3.7 g. of oily octahydroindolone, X. Its hydrochloride shows a m. p. of 123—125°C (infrared spectrum: ν_{max}^{Nujol} 1705 cm^{-1} (C=O), 2650 cm^{-1} (NH^+)).

Found: C, 46.97; H, 5.35; N, 3.44. Calcd. for $C_{16}H_{18}BrNO_3 \cdot HCl \cdot H_2O$: C, 47.25; 5.21; N, 3.20%.

The Reaction of Octahydroindolone (X) with Sodium Amide.—A solution of 360 mg. of the octahydroindolone, X, in 20 ml. of absolute ethyl ether was treated with a solution of sodium amide, prepared from 0.2 g. of sodium metal in 200 ml. of liquid ammonia, for 2.5 hr. After the addition of 0.3 g. of ammonium chloride and 30 ml. of ethyl ether, the ammonia was evaporated. Cold water was added to the mixture, and it was extracted with ether. The ethereal extracts were washed with water, dried, and evaporated to dryness. The residue was then chromatographed over a silica gel column. Elution with a chloroform-methanol-triethylamine solution (98.5 : 1.0 : 0.5) gave 250 mg. of an oily amino-substituted derivative, XIII, which was then derived to its acetate, prisms, m. p. 143—144°C.

Found: C, 65.62; H, 6.62; N, 8.53. Calcd. for $C_{18}H_{22}N_2O_4$: C, 65.44; H, 6.71; N, 8.48%.

The Reaction of Octahydroindolone (X) with Lithium Piperidide.—Into 580 mg. of octahydroindolone, X, in 120 ml. of tetrahydrofuran, a tetrahydrofuran solution of lithium piperidide, which had been prepared from 1 ml. of piperidine and 2 ml. of 4 N *n*-butyllithium in hexane, was added at 40—45°C with stirring under a nitrogen stream over about a one-hour period. After the mixture had then been stirred for a further 10—12 hr., the orange-yellow reaction mixture was cooled to 10°C, neutralized with ammonium chloride. After the addition of water, the resulting two layers were separated and the aqueous layer was extracted with ether. The tetrahydrofuran layer and the extracts were combined, and washed with a saturated aqueous solution of sodium chloride. The solvent was removed under reduced pressure, and the residue was chromatographed over 10 g. of silica gel. Elution with a chloroform - ethyl ether - methanol solution (94 : 5 : 1) gave 180 mg. of XII, which was then recrystallized from methanol to give prisms, m. p. 147.5—149.5°C.

Found: C, 70.94; H, 6.35; N, 5.34. Calcd. for $C_{16}H_{17}NO_3$: C, 70.83; H, 6.32; N, 5.16%.

The authers express their thanks to Dr. Kenichi Takeda and Dr. Katsumi Kotera for their helpful advice and for infrared identification.

Studies of Aminosugars. XIII. The Synthesis of Paromamine*

By Sumio UMEZAWA and Shinkiti KOTO

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei, Tokyo

(Received December 25, 1965)

Paromamine has been synthesized by condensing the *N*, *N'*-dinitrophenyl derivative of deoxystreptamine with the *N*-dinitrophenyl derivative of acetobromoglucosamine in nitromethane in the presence of mercuric salts, and by then removing the protecting groups by treatment with methanolic ammonia and hydrolysis with Dowex 1X2. The synthetic sample was shown to be identical with natural paromamine by a comparison of their infrared spectra and by microbiological assay. The identity was also proved by the determination of the $\Delta[M]_{CuAm}$ values of the tri-*N*-acetate of the synthetic and natural specimens by the copper-complex methods.

Paromamine,[1] an aminoglucoside, has received wide attention in recent years in the field of chem-

* Part XXVI of "Studies on Antibiotics and Related Substances," by S. Umezawa.

1) T. H. Haskell, J. C. French and Q. R. Bartz, *J. Am. Chem. Soc.*, **81**, 3480 (1959).

istry of antibiotics, since it shows antibacterial activity[2] and is a common moiety of such useful antibiotics as paromomycin I, II and kanamycin C.[3] We now know three examples of aminoglucosides, composed of two carbohydrate moieties, which exert antibiotic action on bacteria, i. e., paromamine, neamine[4] and 4-*O*-(6-amino-6-deoxy-α-D-glucopyranosyl)-deoxystreptamine[5]; however, they have never been synthesized.

The present paper will present the details of our work on the synthesis of paromamine, work which was announced previously in a preliminary communication,[6] as well as details of some additional related studies.

The acetohalogeno derivatives of glucosamine, hitherto successfully used to synthesize α-glucosaminides of bulky alcohols, are 3, 4, 6-tri-*O*-acetyl-2-(2, 4-dinitroanilino)-2-deoxy-α-D-glucopyranosyl bromide[7] (I) and 3, 4, 6-tri-*O*-acetyl-2-(*p*-methoxybenzylidenamino)-2-deoxy-α-D-glucopyranosyl bromide[8]; however, to our knowledge, no α-glucosaminide of any kind of cyclic secondary alcohol has ever been synthesized with these acetobromo derivatives of glucosamine. Since deoxystreptamine is lacking in reactivity, and since, consequently, the conditions of glucosidation inevitably become drastic, a preliminary condensation of the more stable bromide (I) with cyclohexanol by Helferich's method[9] has been tested: Cyclohexyl 3, 4, 6-tri-*O*-acetyl-2-(2, 4-dinitroanilino)-2-deoxy-α-D-glucopyranoside (II) and its β-isomer (III) have been successfully obtained. An analogous reaction was then applied to the synthesis of paromamine.

The condensation of bis-*N*, *N'*-(2, 4-dinitrophenyl)-deoxystreptamine[10] with I in nitromethane in the presence of mercuric cyanide and bromide, gave a mixture of glucosides. The acetylation of the mixture and separation by TLC gave 4-*O*-[3, 4, 6-tri-*O*-acetyl-2-(2, 4-dinitroanilino)-2-deoxy-α-D-glucopyranosyl]-5, 6-di-*O*-acetyl-*N*, *N'*-bis-(2, 4-dinitrophenyl)-deoxystreptamine (IV).

On the other hand, paromamine was converted into tris-*N*-(2, 4-dinitrophenyl)-paromamine; when further acetylated, it gave penta-*O*-acetyl-tris-*N*-(2, 4-dinitrophenyl)-paromamine.

The infrared spectrum of IV could be completely superimposed on that of the above mentioned derivative of natural paromamine. The melting point of IV was not depressed by admixture with the derivative of natural paromamine.

The hydrolysis of IV with methanolic ammonia, followed by treatment with Dowex 1 X2 (OH^-), gave a crude base, which was then chromatographed on a column of cellulose powder. Finally, the ninhydrin-positive fraction was rechromatographed on Dowex 1 X2 (OH^-) to give a crystalline free base of 4-*O*-(2-amino-2-deoxy-α-D-glucopyranosyl)-deoxystreptamine (V).

Paper chromatography of the synthetic product V illustrated that its R_f value corresponds to that of paromamine. A paper chromatographic study of the synthetic product hydrolyzed by refluxing it with 3 N hydrochloric acid showed just three spots, those of D-glucosamine, deoxystreptamine and the unchanged material.

Finally, the absolute configuration of the synthetic product and its identity with the natural paromamine were confirmed by a modified method[11] using cuprammonium-glucoside complexes.[12] Tri-*N*-acetylparomamine includes two pairs of adjacent hydroxyl groups which make projected angles of about +60° and −60°, one in the glucosamine moiety and other in the deoxystreptamine moiety. Accordingly, the $\Delta[M]_{CuAm}$ of tri-*N*-acetyl paromamine may be expected to be nearly zero as a result of internal compensation. The free base V was acetylated and de-*O*-acetylated to afford 4-*O*-(2-acetamido-2-deoxy-α-D-glucopyranosyl)-*N*, *N'*-diacetyl-deoxystreptamine (VI).

The determination of the $\Delta[M]_{CuAm}$ values of the synthetic product and the corresponding tri-*N*-acetyl derivative of natural paromamine gave values of +191 and +13 respectively. If VI were a 5-*O*- or 6-*O*-linked derivative of deoxystreptamine, instead of the 4-*O*-linked derivative mentioned above, the $\Delta[M]_{CuAm}$ values would be +2000 or +4000 respectively. The observed values for $\Delta[M]$'s of VI and tri-*N*-acetyl paromamine agree within the range of experimental error. Thus, the synthetic product, VI, was proved to be identical with the *N*-acetyl derivative of natural paromamine.

In the above-mentioned synthesis, the DNP group appears to have played an important role in the α-glucoside formation, for the dinitrophenylamino group would not be expected to exert a considerable anchimeric affect on the anomeric center. It is also conceivable that the plane of the phenyl group occupies a position almost perpendicular to the sugar body in the transition state; therefore, it is not so much of a steric hindrance, while the anchimeric effect of the 6-*O*-acetyl group[13] has a favorable influence on the formation of α-linkage in the polar solvent, nitromethane.

The synthetic product V behaved in conformity with natural paromamine in antibiotic spectra and minimal inhibitory concentrations (MIC) as is shown in Table I.

Table I. The MIC's of the synthetic (V) and natural paromamine as determined by the dilution method in bouillon

Test organisms		MIC μg./ml. V	MIC μg./ml. Paromamine
Bacillus subtilis PCI 219	(24 hr.)	125	125
Mycobacterium tuberculosis 607	(96 hr.)	>1000	>1000

In view of the established method of synthesis of deoxystreptamine by Nakajima et al.,[14] the above synthesis may be regarded as a total synthesis of paromamine.

It has been reported[15] that a kind of diastereoisomer of paromamine can be obtained from a crude product by acid reversion or, alternatively, by the reaction mentioned above, but no definite configurational assignment could be made at that time. Subsequently, the diastereoisomer was proved to be 5-*O*-(2-amino-2-deoxy-α-D-glucopyranosyl)-deoxystreptamine.[16]

Experimental

General Procedures.—TLC was performed on "Silica-Rider for TLC" (Dai-ich Pure Chemicals Co.) using three solvent systems, (a) benzene: MEK=4 : 1, (b) benzene : MEK=10 : 3, and (c) ethyl acetate : methanol=1 : 1, as the mobile phase. The DNP derivatives were visualized directly on an air-dried plate as yellow spots or bands, while others were detected by spraying a dried chromatogram with 50% sulfuric acid and heating it at 90—100°C. The extraction from Silica Rider was carried out with excess acetone. Paper chromatography was performed on Toyo filter paper No. 51, using the (d) solvent system (*n*-butanol : pyridine : water : acetic acid=6 : 4 : 3 : 1); ninhydrin (0.25%) in pyridine was sprayed on.

Cyclohexyl 3, 4, 6-Tri-*O*-acetyl-2-(2, 4-dinitroanilino)-2-deoxy-α-D-glucopyranoside (II). — To a solution of I (534 mg., 1 mmol.) and cyclohexanol (0.31 ml., 3 mmol.) in nitromethane (21 ml.), there was added mercury(II) cyanide (130 mg., 0.5 mmol.) and mercury(II) bromide (180 mg., 0.5 mmol.); the mixture was then stirred at 27—29°C for 6 days. The reaction mixture was evaporated, and the dark residue (1.19 g.) was treated with chloroform. The filtrate was washed with 10% aqueous potassium bromide (10 ml.×4) and distilled water (10 ml.×3), dried over sodium sulfate, and evaporated to give a reddish brown sirup (709 mg.). This was extracted with boiling ethanol (20 ml.), and then the solution was allowed to stand at room temperature overnight, thus precipitating a yellow crystalline solid (375 mg.). Two recrystallizations from ethanol gave crystals of cyclohexyl 3, 4, 6-tri-*O*-acetyl-2-(2, 4-dinitroanilino)-2-deoxy-α-D-glucopyranoside (II), m. p. 201.5°C, $[\alpha]_D^{17}$ +43° (*c* 0.81, chloroform). IR spectrum (KBr): 3320, 3100, 1620, 1590, 1530, 1332 (NH–DNP); 2910, 2840 (cyclohexyl); 1750, 1225 (O–Ac), 850 cm^{-1} (type 2a of the pyranose ring).

Found: C, 51.77; H, 5.21; N, 7.49. Calcd. for $C_{24}H_{31}N_3O_{12}$ (553): C, 52.07; H, 5.65; N, 7.59%.

The mother liquor separated from II further deposited yellow needles (200 mg.), m. p. 179—179.5°C, $[\alpha]_D^{26}$ −53° (*c* 1.0, chloroform). The optical rotation and the infrared spectrum of the product showed that it is cyclohexyl 3, 4, 6-tri-*O*-acetyl-2-(2, 4-dinitroanilino)-2-deoxy-β-D-glucopyranoside (III).

Found: C, 52.10; H, 5.68; N, 7.49. Calcd. for $C_{24}H_{31}N_3O_{12}$ (553): C, 52.07; H, 5.65; N, 7.59%.

4-*O*-[3, 4, 6-Tri-*O*-acetyl-2-(2, 4-dinitroanilino)-2-deoxy-α-D-glucopyranosyl]-5, 6-di-*O*-acetyl-*N*, *N'*-bis-(2, 4-dinitrophenyl)-deoxystreptamine (IV).—A suspension of I (5.0 g., 9.4 mmol.), bis-*N*, *N'*-(2, 4-dinitrophenyl)-deoxystreptamine[12] (3.1 g., 6.3 mmol.), mercury(II) cyanide (1.2 g., 4.8 mmol.) and mercury-(II) bromide (1.7 g., 4.8 mmol.) in nitromethane (15 ml.) was heated at about 95°C for 50 hr. while occasionally being stirred. The reaction mixture was then diluted with chloroform (100 ml.), and the dark brown filtrate was dried up in vacuo to give a residue (8.0 g.) which left a hard gummy substance (fraction A) (3.1 g.) when extracted with hot chloroform (50 ml.). The evaporation of the chloroform solution gave a dark residue (fraction B) (4.0 g.). Fraction B was chromatographed on silicon dioxide (170 g., 3.8×24 cm.) with benzene-ethanol (10 : 1, v/v) to give a yellow solid

(fraction B') (0.91 g.). Fraction A was again dissolved in ethyl acetate, filtered and evaporated to afford a brown residue (fraction A') (2.9 g.). Fractions A' and B' were combined and chromatographed on thin layer plates (20×20×0.05 cm; 160 sheets) with the a a solvent system; the distance of development was 10 cm. Three fractions, C, D and E (0.93 g., 0.83 g., and 1.58 g.), were obtained; the rate of flow of C was the largest. The fraction C was then further separated into two nearly equal fractions by preparative TLC using the b solventsystem. A yellow homogeneous substance (270 mg.) was obtained from the fraction with the smaller R_f value. The product was then acetylated with acetic anhydride (4 ml.) and pyridine (4 ml.) overnight at room temperature. The crude acetate was subjected to preparative TLC using the b solvent system; the distance of development was 17 cm. Extraction with acetone from the main band gave a yellow solid. This solid was taken up in acetone and filtered, and an excess of ethanol was added to afford fine yellow needles of the title compound (IV), m. p. 275—280°C (decomp.; sintered at about 200°C). $[\alpha]_D^{24}$ +250° (*c* 0.9, acetone). IR spectrum (KBr): 3345, 3100, 1628, 1593, 1525, 1336, 745 (NH–DNP); 1758, 1220 cm^{-1} (O–Ac).

Found: C, 46.47; H, 4.21; N, 12.37. Calcd. for $C_{40}H_{41}N_9O_{24}$ (1031): C, 46.56; H, 4.01; N, 12.22%.

4-*O*-(2-Amino-2-deoxy-α-D-glucopyranosyl)-deoxystreptamine (V).—A sample (30 mg.) of IV was dissolved by gently stirring into methanolic ammonia (40 g.) saturated at 0°C and then kept standing at room temperature overnight. Evaporation in vacuo was followed by letting the mixture stand under reduced pressure for several hours in order to remove the acetamide. The red residue was then dissolved in an acetone-water mixture (1 : 1), and an excess of Dowex 1X2 (OH^-) was added to the yellow solution. The mixture was shaken at room temperature overnight, and filtered, and the colorless filtrate was evaporated in vacuo. The product (10 mg.) was mixed with cellulose powder (200 mg.), placed on a column of cellulose powder (4.0 g.; 18×1.05 cm.), and eluted with the d solvent mixture, the fractions being cut into 20-ml. portions. The appearance of the product was examined by means of ninhydrin coloration. After the evaporation of the solvent at about 25°C, the fractions of tube Nos. 3—4 afforded a colorless sirup (8 mg.); this sirup was deionized with Dowex 1X2 (OH^-) and distilled water. The evaporation of drop Nos. 15—45 gave the pure free base (V), 7.0 mg. (74% from IV), $[\alpha]_D^{24}$ +111° (*c* 0.75, water).

Found: C, 44.15; H, 7.64; N, 12.67. Calcd. for $C_{12}H_{25}N_3O_7$ (323.5): C, 44.57; H, 7.79; N, 13.00%.

Descending paper chromatography of the synthetic product illustrated that its R_f value corresponded well with that of paromamine as ascertained by ninhydrin coloration.

4-*O*-(2-Acetamido-2-deoxy-α-D-glucopyranosyl)-*N*, *N'*-diacetyl-deoxystreptamine (VI).—A sample (11 mg.) of V was acetylated with acetic anhydride (1 ml.) and pyridine (1 ml.) at about 30°C for one week; then, after the evaporation of the excess reagent, the crude product was de-*O*-acetylated with methanolic sodium methylate (4 ml., 0.02%) at room temperature overnight. Neutralization with Amberlite IR 120 (H^+), followed by evaporation, gave a colorless residue which was then deionised by the use of Dowex 1X2 (0.8×8 cm.) and Dowex 50WX8 (0.3×4 cm.) successively, and developed with water. The elute was evaporated to yield a crystalline solid (4.7 mg.); $[\alpha]_D^{15}$ +110° (*c* 0.34, water), $[\alpha]_{436}^{15}$ +200° (*c* 0.34, water), $[\alpha]_{436}^{15}$ +243° (*c* 0.33, CuAm), $\Delta[M]_{CuAm}$ +191. The R_f value of the product, as ascertained using the c solvent system, corresponded well with that of tri-*N*-acetyl paromamine obtained by the same procedure of acetylation and de-*O*-acetylation.

Found: C, 47.87; H, 6.92; N, 9.41. Calcd. for $C_{18}H_{31}N_3O_{10}$ (449.5): C, 48.10; H, 6.95; N, 9.35%.

Penta-*O*-acetyl-tris-*N*-(2, 4-dinitrophenyl)-paromamine.—A suspension of paromomycin sulfate (Sankyo Co.) (1.0 g.) in methanol (25 ml.) containing concentrated hydrochloric acid (1 ml.) was refluxed gently for 8 hr. The resulting colorless crystals were then collected and washed with methanol; yield, 356 mg. The crude product (340 mg.) was dissolved in distilled water (1.0 ml.), put on the Dowex 1×2 (OH^-) column (1×13 cm.), and developed with distilled water, the fractions being cut into 5-ml. portions. The evaporation of the fraction of tube Nos. 2—4, which was detected by ninhydrin coloration, followed by crystallization from methanol, gave a sample of chromatographically-pure paromamine (190 mg.).

Found: C, 44.36; H, 7.59; N, 12.86. Calcd. for $C_{12}H_{25}N_3O_7$ (323.5): C, 44.57; H, 7.79; N, 13.00%.

A mixture of the paromamine (163 mg.) and sodium bicarbonate (193 mg.) in water (6 ml.) was stirred for a while. To the solution there were then added 2, 4-dinitrofluorobenzene (308 mg.) and ethanol (3.5 ml.), after which the mixture was stirred for about 6 hr. at 29—30°C, until the yellow gummy product initially formed became powdery; yield, 350 mg. (85%). The crude product of tris-*N*-(2, 4-dinitrophenyl)-paromamine was acetylated with acetic anhydride (5 ml.) and py-pyridine (5 ml.). The resulting yellow glass was crystallized from acetone as fine needles by the gradual addition of ethanol. Two recrystallizations from an acetone-ethanol mixture gave a chromatographically-pure product, m. p. 275—280°C (decomp.; sintered at about 200°C); $[\alpha]_D^{24}$ +262° (*c* 0.9, acetone).

Found: C, 46.23; H, 3.98; N, 12.24. Calcd. for $C_{40}H_{41}N_9O_{24}$ (1031): C, 46.56; H, 4.01; N, 12.22%.

The infrared spectra of the product and of IV were identical.

The authors wish to thank Mr. Saburo Nakada for his microanalyses, Mrs. Michiko Ishizawa for her infrared analyses, and Mr. Hiroyuki Odawara and Miss Mizuko Handa for their technical assistances.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2018—2020 (1966)

Organoboron Compounds. XI.* The Polymerization of Vinylboronic Acid

By Seiji KATO,** Keiko KIMURA, Katsuhisa NAGATA and Yojiro TSUZUKI

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received February 22, 1966)

It has been found that potassium persulfate is a good initiator for the polymerization of vinylboronic acid. With this initiator the polymerization has been studied in acidic as well as in basic medium, and the best conditions for the polymerization have been established with the help of molecular weight determination of the products. The highest molecular weight has been observed in basic medium to be about 7000. A mixed solvent (1 : 1) of ether and acetone has been used as the precipitant. The variation in the rate of polymerization and the boron content has been investigated in a narrow range of pH, from 6 to 8.

In the course of our investigation of some boronic acids we observed that boronic acids with an alkyl or an aryl group attached to the boron atom can be converted, on oxidation and hydrolysis, into the corresponding alcohol and boric acid. In the case of vinylboronic acid, where a vinyl group is linked with the boron atom, it is to be expected that polyvinyl alcohol may eventually be produced by its polymerization, oxidation and hydrolysis, as is formulated below:

$$RX \longrightarrow RB(OH)_2 \xrightarrow[\text{Hydrolysis}]{\text{Oxidation}} ROH + B(OH)_3$$

$$CH_2{=}CH \longrightarrow \underset{\displaystyle X}{\overset{\displaystyle |}{CH_2{-}CH}} \longrightarrow -\left[\underset{\displaystyle B(OH)_2}{\overset{\displaystyle |}{CH_2{-}CH}}\right]_n-$$

$$\xrightarrow[\text{Hydrolysis}]{\text{Oxidation}} -\left[\underset{\displaystyle OH}{\overset{\displaystyle |}{CH_2{-}CH}}\right]_n- + B(OH)_3$$

Ritter et al.[1,2] and Matteson[3] have, however, pointed out that a resonance stabilization of the intermediate radical would result from the carbon-boron π-bonding when the vinyl group is one of the three groups bonded to the boron atom:

$$\underset{\displaystyle B}{\overset{\displaystyle |}{>C{=}C-}} \longleftrightarrow \underset{\displaystyle B^-}{\overset{\displaystyle \|}{>C^+{-}C-}}$$

In general, there are two processes in the vinyl-type polymerization, namely, ionic and radical polymerization. As a result of the mesomeric effect described above, and as a result of the great difficulty encountered in removing the free water from vinylboronic acid, it is probable that no ionic initiator has any influence on opening the vinyl group. In fact, no polymerization was effected when a solution of vinylboronic acid was treated with ionic initiators, but radical polymerization really occurred when potassium persulfate was used as an initiator.

Vinylboronic acid and its butyl ester were prepared by Normant[4] and by Matteson[5], who reported that polymerization readily set in during the synthesis. The present paper will deal with more detailed experiments carried out on the polymerizing factor of vinylboronic acid; the results of these experiments are shown in Tables I—IV.

As regards the polymerization in an aqueous solution, some instances have been known, such as those of itaconic acid[6] and acrylic acid, both of which use potassium persulfate as the initiator. On the other hand, *p*-vinylbenzeneboronic acid has been found to enter into polymerization by the same initiator in *t*-butyl alcohol.[7] Vinylboronic acid can be polymerized to higher-molecular substances in a dilute solution of sodium hydroxide rather than in a dilute solution of hydrochloric acid.

The polyvinylboronic acids of higher degrees of polymerization are soluble in water, and the lower polymers are soluble in an extremely dilute alkaline solution. All of them are insoluble in common organic solvents with the exception of tetrahydrofuran.

It has been established experimentally that the best conditions for polymerization are when the concentration of the medium is 0.11 N alkali, the concentration of the initiator is 4% (weight percent based on the monomer), and the temperature is 50°C. The rate of polymerization and the boron content were investigated in a narrow pH range, from 6 to 8, with the specimens of polyvinylboronic acids obtained under the conditions described above. The results are shown in Fig. 1.

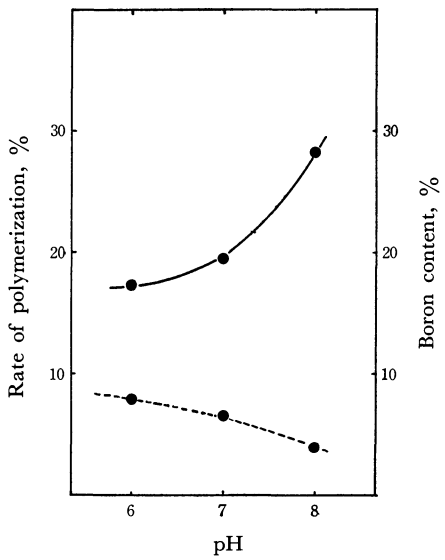

Fig. 1. The rate of polymerization and the boron content of the products in the range of pH 6—8.
—— rate of polymerization, ---- born content

The rate of polymerization becomes higher with an increase in the pH value, but the boron content decreases. This may show that the cleavage of the carbon-boron bond has really occurred.

The infrared spectra of the products obtained in an acidic medium show absorptions of 3500 cm^{-1} (O–H), 1300—1400 cm^{-1} (B–O), 1000—1100 cm^{-1} (B–C) and 2900 cm^{-1} (CH, CH_2), while those of the products obtained in a basic medium resemble the spectra of polyvinyl alcohol.

Since their structure is similar to that of polyvinyl alcohol, the average molecular weight was roughly estimated from the following equation (I), using the constants of polyvinyl alcohol ($K=8.5\times10^{-4}$ and $\alpha=0.62$ at 20°C),[8] the molecular weight being about 7000 (maximum) in a basic medium and from 500 to 1000 in an acidic medium:

$$[\eta] = KM^{\alpha} \qquad (I)$$

The intrinsic viscosity was measured in water and found to be in the range from 0.04 to 0.2 at 20°C, so the products should be called "oligomers" rather than "polymers."

Experimental Results

The Preparation of Vinylboronic Acid.—The method used here was practically identical with that of Matteson,[4] who prepared vinylboronic acid from vinylmagnesium bromide and trimethyl borate, but the procedure of crystallization was somewhat modified. After acidifing the solution of vinylboronic acid sodium salt with phosphoric acid, and extracting it with ether, the ethereal solution was concentrated. The vinylboronic acid was then precipitated by pouring a concentrated ethereal solution of it into a large quantity of *n*-hexane before using it; it was dried in a vacuum oven within five minutes, m. p. 83°C. Yield 35%.

Selection of Initiator.—The initiators used in the experiments are listed in Table I. A solution of 2 g. of the monomer in 10 ml. of the solvent was prepared. This solution was then introduced in seven 20-ml. sealed tubes, each containing 0.05 g. of the initiator. All the tubes were deaerated and sealed under reduced presure. Samples 1—3 were kept at a constant temperature of 80°C for 24 hr., and samples 4—7, at −70°C in a dry ice - acetone bath for 48 hr. From sample 3 a polymer was isolated by adding a mixed ether-acetone solvent (1 : 1 by volume), while no polymer was obtained from the others with any kind of precipitating reagent.

Table I. Initiators and solvents of polymerization

No.	Initiator	Solvent	Type of polymerization
1	Benzoic peroxide	*t*-Butylalcohol	Radical
2	Azobisisobutylonitrile	*t*-Butylalcohol	Radical
3	Potassium persulfate	Water	Radical
4	Sodium naphthalene	Glycoldimethyl ether	Ionic
5	Ethyllithium	Ethyl ether	Ionic
6	Sodium cyanide	Dimethylformamide	Ionic
7	Sodium triphenylmethane	Ethyl ether	Ionic

Polymerization of Vinylboronic Acid.—Further polymerization experiments employing potassium persulfate initiation were carried out both in basic medium of an aqueous solution of sodium hydroxide and in acidic medium of an aqueous solution of hydrochloric acid.

Table II. Rate of polymerization and normality of medium[a]

Acidic medium[b]			Basic medium[c]			
No.	Normality of HCl	Pr %	No.	Normality of NaOH	Pr %	Pd %
1	0.25	3.2	1	0.065	62.5	14
2	0.05	4.5	2	0.11	64.5	77
3	0.0025	8.5	3	0.55	—*	—
4	0.0005	16.0	4	1.11	—	—

a) All sealed tubes were kept at 50°C in a bath for 48 hr.
b) Monomer (1.25 g.) was introduced each in four sealed tubes each with 10 ml. of water containing hydrochloric acid of the specified normal concentration and with 0.05 g. of initiator.
c) Monomer concentration was 0.8 g. per 10 ml. of water containing sodium hydroxide of the specified normal concentration. Initiator (0.016 g.) was added.
* Not precipitated in a mixture of ether-acetone (1 : 1 by volume).

8) H. Staudinger and H. Warth, *J. prakt. Chem.*, **155**, 261 (1940).

TABLE III. RATE OF POLYMERIZATION AND CONCENTRATION OF INITIATOR[a]

Acidic medium[b]			Basic medium[c]			
No.	Quantity of initiator[d] %	Pr %	No.	Quantity of initiator[d] %	Pr %	Pd %
1	0.5	5.0	1	1.0	64.0	93
2	1.0	6.5	2	2.0	64.5	77
3	2.0	10.5	3	4.0	65.8	54
4	4.0	16.0	4	8.0	53.3	40

a) All sealed tubes were kept at 50°C in a bath for 48 hr.
b) A stock solution of the monomer was prepared, which contained 1.25 g. of the sample in 10 ml. of hydrochloric acid of concentration 5×10^{-4} N.
c) Solvent was a sodium hydroxide solution of 0.11 N. A solution of the monomer was of the concentration corresponding to the acidic medium.
d) Expressed by the number of grams per 100 g. of vinylboronic acid taken.

The relations of the rate of polymerization to the normality of the medium, the concentration of the initiator, and the temperature of polymerization were investigated. The experimental methods employed were described below each of Tables II—IV. All the tubes used in the experiments were dearated and sealed under a vaccum. A tetrahydrofuran solution of the polymer was precipitated and purified in a mixed solvent of ether and acetone (1 : 1 by volume). The rate of polymerization was determined by weight percent based on the monomer. The polymerization degree was measured at 20°C using a dilute-type Ubbelohde viscosimeter. The symbols used in Tables II—IV are as follows: (Pr)—the rate of polymerization, and (Pd)—the degree of polymerization.

Determination of Boron.—Although a number of methods have been proposed for the analysis of boron, they are for the most part troublesome. Our modification of the method of Martin[9] has been proved to be easier and more practical.

TABLE IV. RATE OF POLYMERIZATION AT VARIOUS TEMPERATURES

Acidic medium[a]			Basic medium[b]			
No.	Temp. °C	Pr %	No.	Temp. °C	Pr %	Pd %
1	0	10.0	1	0	10.0	—*
2	15	12.0	2	20	35.0	78
3	30	16.0	3	30	62.0	77
4	50	16.5	4	50	69.0	99

a) Monomer (1.25 g.) was placed in each tube with 10 ml. of 5×10^{-4} N of hydrochloric acid and with 0.05 g. of potassium persulfate.
b) Monomer solution consists of 0.8 g. per 10 ml. of water containing 0.11 N of sodium hydroxide. Concentration of initiator was fixed at 2%, namely 2 g. per 100 g. vinylboronic acid taken.
* Not precipitated in a mixture of ether-acetone (1: 1 by volume).

The sample is refluxed with a sodium peroxide solution for several hours until it is dissolved. The solution is then exactly neutralized to pH 6.9 with hydrochloric acid by the help of a pH-meter; when mannitol is added, the solution is titrated back with a standard solution of sodium hydroxide until the pH-meter indicates 6.9 exactly. The boron content (%) is given by the following equation (II):

$$B\% = \frac{10.8}{W} \times \frac{NV}{V_t} \qquad \text{(II)}$$

where N and V are the normality and the used volume of a standard solution of sodium hydroxide respectively, where V_t is the final volume of the solution of the sample, and where W is the number of grams of the weighed sample.

The Dimerization of Ethylene Using Palladous Chloride as the Catalyst

By Yasuo KUSUNOKI*, Ryokei KATSUNO, Noboru HASEGAWA, Susumu KUREMATSU, Yoshio NAGAO, Kanzi ISHII and Shigeru TSUTSUMI

Department of Chemical Engineering, Faculty of Engineering, Osaka University, Miyakojima-ku, Osaka

(Received September 21, 1965)

The dimerization of ethylene was carried out using palladous chloride as the catalyst. Acetic acid, ethylene dichloride, ethylene tetrachloride, benzene, chlorobenzene, triethyleneglycol, acetic acid esters, chloroform, cyclohexane and ethanol were employed as the reaction solvents, and the effects of these solvents on the reaction were investigated. The best yield of butylene (about 1500 mol.% to palladous chloride) was obtained, when acetic acid was used as the solvent; the yield decreased gradually following the above order of solvents until, when ethanol was used as the solvent, it yielded only 96 mol.%. However, in all solvents dimerization was carried out predominantly, and only a few higher polymers were obtained. It is very interesting that the solvent effect mentioned above was different from the effect of solvents in the isomerization of olefin when metal carbonyl was used as the catalyst. To explain these results, a hydride ion-shift mechanism has been proposed.

Recently, many reports have been published on the polymerization or isomerization of olefins, using Ziegler-Natta catalysts or metal carbonyls.[1] In these reactions the intermediate formation of a π-complex between olefin and catalyst was assumed. The present study will deal with the dimerization of ethylene using palladous chloride, which easily forms a complex with ethylene and which gives butylenes in a fairly good yield. Although the dimerization proceeded with few side reactions, the effects of solvents on this reaction were comparatively great. Some solvents, e. g., acetic acid or halogenated hydrocarbons, led to excellent yields of the dimerization products, whereas others, e. g., ethanol, led to lower yields. The maximum yield of butylenes (about 1500 mol.% to the palladous chloride based on the ethylene) was obtained in the case of the acetic acid solvent.

From these results it may be considered that this dimerization reaction is similar to a Friedel-Crafts-type reaction.

Results and Discussion

The experimental conditions are shown in Table I, while the results are summarized in Table II; it is clear from Table II that the highest yield of butylenes is obtained when acetic acid is used as a solvent, and that the yield decreases in the order of the solvents as they are listed in this table, from dichloroethane to ethanol. It may generally be said that the ratio of butylene-2 to butylene-1 decreases with the decrease in the yield of butylenes.

As a by-product, a small amount of hexene was detected in every case; octene or isobutyl chloride was also detected in some cases. However, when an acetic acid ester was used as a solvent, the formation of isobutyl chloride was remarkable. The fact that, in an ethanol solvent, small amounts of ethyl vinyl ether and acetal were detected by gas chromatography, agrees with the observations by Stern and Spector,[2] and Moiseef et. al.[3]

As has been described above, the dimerization of ethylene proceeds predominantly with a palladous chloride catalyst; the formation of higher olefins is negligible. The relation between the yield of butylenes and the kind of solvent is quite contradictory to Mannel's results[4] on the isomerization of olefin with a metal carbonyl catalyst; Mannel obtained good results by using methanol, ethanol, acetone and benzene solvents, while he regarded acetic acid, carbon tetrachloride and acid chlorides as unsuitable solvents. As the mechanism of these isomerizations, the formation of the so-called π-en-yl-type complex by way of a proton shift from a π-complex may be described. Huettel[5] has already pointed out that the hydrogen

Cyclohexane	3.4	244	12	88	Hexene
Ethanol	1.4	96	38	62	Ethyl vinyl ether, Acetal

a) Calculated as follows: $\frac{\text{mol. of butylene produced} \times 2}{\text{mol. of } PdCl_2 \text{ used}} \times 100$

b) Given as percentage of respective peak area in gas chromatography.

c) The amounts of by-products are generally too small to be determined quantitatively.

chloride from Zeise's salt was eliminated and that a complex of another type was formed as:

$$(C_nH_{2n}\cdot PdCl_2)_2 \rightarrow (C_nH_{2n-1}\cdot PdCl)_2 + 2HCl$$

In our experiments the formation of hydrogen chloride was clearly detected. Therefore, considering the Friedel-Crafts-type reaction caused by a palladous chloride - hydrogen chloride system, as in the case of aluminum chloride, these dimerization reactions may be explained as:

$$CH_2{=}CH_2 \xrightarrow[HCl]{PdCl_2} [CH_3{-}\overset{\oplus}{C}H_2][\overset{\ominus}{PdCl_3}] \xrightarrow{CH_2=CH_2} [CH_3{-}CH_2{-}CH_2{-}\overset{\oplus}{C}H_2][\overset{\ominus}{PdCl_3}] \xrightarrow{H^-\text{-shift}} CH_3{-}CH_2{-}\overset{\oplus}{C}H{-}CH_3$$

$$\longrightarrow \begin{cases} \xrightarrow{-H^+} \begin{cases} CH_3{-}CH{=}CH{-}CH_3 \\ CH_3{-}CH_2{-}CH{=}CH_2 \end{cases} \\ \xrightarrow{CH_3\text{-shift}} CH_2{-}\underset{CH_3}{\underset{|}{CH}}{-}CH_3 \xrightarrow{Cl^-} ClCH_2CH\begin{matrix} CH_3 \\ CH_3 \end{matrix} \end{cases}$$

Although the reaction may be explained by the proton - shift mechanism in the case of a metal carbonyl catalyst, the hydride-ion-shift mechanism seems adequate for a palladous chloride catalyst, considering that the effects of solvents on the reaction are quite opposite. Moreover, the fact that the yield of butylene decreases upon a decrease in the dielectric constant of solvents agrees with Pepper's work.[6] However, such polar solvents as acetic acid or ethanol, which have a cocatalytic character in themselves showed either an exceptionally large or an exceptionally small yield of butylene. On the other hand, esters would have a peculiar solvent effect, resulting in a remarkable yield of isobutyl chloride.

Experimental

Apparatus.—A stainless-steel autoclave equipped with a magnetic stirrer was used.

6) D. C. Pepper, *Trans. Faraday Soc.*, **45**, 397 (1949).

Reagents.—Palladous chloride: A commercial product of an extra pure grade was used.

Ethylene: Commercial ethylene in a cylinder was used.

Solvents: Commercial solvents were purified and dried as usual before use.

Palladous chloride (8.8 g.; 0.05 mol.) and 40 ml. of solvent were charged into the autoclave and compressed to 60 kg./cm^2 (at room temperature) with ethylene. The autoclave was stirred at room temperature for about half an hour to dissolve the ethylene in the solvent sufficiently, heated to a desired temperature, and again stirred during the reaction. Table I summarizes the reaction conditions for each solvent.

In these cases where a violent absorption of ethylene was observed, additional ethylene was charged in. After the reaction had ended, the autoclave was cooled to room temperature, the pressure read, and the autoclave was again heated to about 50°C while being stirred in order to expel the gaseous products. The gas was passed through cold a trap cooled with dry ice - methanol and a washing bottle containing distilled water to absorb the hydrogen chloride, and then collected in a gas holder. The liquid condensed in the cold trap was vaporized at room temperature after it had been weighed and they collected in another gas holder. The gases were analyzed by gas chromatography (T. C. P. column, 3 m.; temperature, 40°C.; H_2 flow rate, 17.5 cc./min.).

The liquid product was separated from the catalytic residue by filtration and distilled. The distillates were analyzed by gas chromatography, using such proper column packing materials as tricresyl phosphate, polyethylene glycol, and dinonyl phthalate.

The Cyclisation of Anthrimides to Carbazoles. III.* The Structure of Indanthrene Gray A

By K. S. NAIR and K. H. SHAH

Department of Chemical Technology, University of Bombay, Matunga, Bombay 19, India

(Received September 24, 1965)

The anthraquinonyl amino group of the 1, 2'-dianthrimide type, when included in the complex structure of vat dyes, does not cyclise to yield a carbazole structure, with alkali, under the conditions of isoviolanthrone formation; rather, it cleaves to yield an alizarin-type derivative under the conditions of violanthrone formation. The constitution assigned to Indanthrene Gray A (Colour Index No. 60020) has thus been confirmed.

An anthraquinonyl amino group of the 1, 2'-dianthrimide type, when included in the complex structure of such vat dyes as Indanthrene Gray M and Indanthrene Olive T, has been proved to be present as such and not as carbazole (a cyclised structure) during their formation by means of mild treatment with alcoholic alkali.[1] The action of alkali on the 1, 2'-dianthrimide type under conditions of isoviolanthrone and violanthrone fusion needs to be studied further, for 1, 1'-dianthrimide is known to cyclise to a carbazole at 180—230°C.[2]

The Action of Alkali under Conditions of Isoviolanthrone Fusion.—Indanthrene Gray A (Colour Index No. 60020) is manufactured by the condensation of bis (9-bromo-3-benzanthronyl) sulphide (Ib) with two moles of 1-aminoanthraquinone to yield (Ic), and by subsequent fusion with alkali. The dye is assigned the IIIc structure, which contains an isoviolanthrone nucleus and 1, 2'-dianthrimide-type groups.

Isoviolanthrone is formed from bis (3-benzanthronyl) sulphide (Ia) by treatment with isobutanolic alkali at 140°C.[3] Therefore, the assumption of the formation of isoviolanthrone in this case is justified. The dye is obsolete, however, and no manufacturing details are available. The following process was standardised in order to obtain an authentic specimen of the dye. 9-Bromo-3-nitrobenzanthrone, upon being heated with sulphur in trichlorobenzene, gave bis (9-bromo-3-benzanthronyl) disulphide (IIb)[4], which was converted to sulphide (Ib) upon being heated with phenol.[5] The sulphide was condensed with 1-amino-anthraquinone to yield (Ic). The authentic

4) P. Nawiasky, E. Holzapfeb and O. Braunsdorf, D. R. Pat. 443021 (To I. G. Farbenindustrie AKT-GES), March 31, 1927: *Friedlaender*, **15**, 727 (1927).

5) P. Nawiasky, E. Holzappel and O. Braunsdorf, D. R. Pat. 441465 (To I. G. Farbenindustrie AKT-GES), Feb. 17, 1927; *Friedlaender*, **15**, 730 (1927).

dye was obtained by treating (Ic) with isobutanolic potassium hydroxide at 140°C for two hours. It was a dark blue powder which dissolved in concentrated sulphuric acid with a deep olive green colour and dyed cotton from an alkaline dithionite vat a grayish blue. It did not contain sulphur. It was analysed as $C_{62}H_{30}N_2O_6$ and exhibited λ_{max} at 250, 275, 310, 360, 410, 660, 730 mμ in sulphuric acid and two bands at 1675 and 1645 cm^{-1} in its infrared spectrum.

Bradley[6] has recorded the spectral characteristics of violanthrone (λ_{max} at 223, 385, 573, 760, and 845 mμ) and isoviolanthrone (λ_{max} at 220, 270, 390, 668, 732 mμ) in sulphuric acid. The spectra of the dye indicated the presence of an isoviolanthrone nucleus in the dye.

Venkataraman[7] has observed that anthrimides exhibit an λ_{max} in the 360 mμ region and two bands at 1670—1664 and 1665—1630 cm^{-1} in their infrared spectra, and carbazoles, a broad band in the 508 mμ region and one band at 1666 cm^{-1} in their infrared spectra. On this basis the spectrum of the dye indicated the presence of uncyclised anthrimide groups.

An unambiguous synthesis of the structure IIIc was carried out by condensing 2, 11-diamino isoviolanthrone with 1-chloroanthraquinone in naphthalene in the presence of copper oxide. The product exhibited chemical and spectral properties identical with those of the above product. The compound IIIc was cyclised with aluminium chloride in nitrobenzene. Crystallisation from nitrobenzene gave blue black needles which dissolved in concentrated sulphuric acid with a bluish green colour and which had no affinity for cotton from an alkaline dithionite vat. It exhibited λ_{max} at 270, 310, 380, 410, 500, 665, and 735 mμ and a band at 1670 cm^{-1} in the infrared spectrum and so can be assigned the structure IV.

The Action of Alkali under Conditions of Violanthrone Fusion.—Fierz-David[8] has suggested the structure V for the product obtained by the alkali fusion of 9-(1-anthraquinonyl amino) benzanthrone (VIc). The structure assumes the formation of a carbazole ring and a violanthrone nucleus. Fierz-David assumes cyclisation to take place at the 2, 13-positions of the violanthrone nucleus. However, 1, 2'-dianthrimide cyclises at 1', 2-positions with titanium tetrachloride.[9] Therefore, the cyclisation probably takes place at 4, 11-positions, as in VII.

Bradley[2] has observed that the action of fused alkali on 1, 2'-dianthrimide yields alizarin as the main product. 1, 2'-Dianthrimide type structures, unlike 1, 1'-dianthrimide, do not cyclise under the conditions of alkali fusion to yield carbazole, but they cleave to yield alizarin-type derivatives. Therefore, confirmation is essential for the structure V.

The fusion of VIc with potassium hydroxide at 220°C gave a violet substance which did not contain nitrogen; it was analysed as $C_{34}H_{16}O_6$, and its infrared spectra indicated the presence of the

hydroxyl group. It showed λ_{max} in sulphuric acid at 385, 500, 580, 630, 765, 845 mμ, indicating the presence of a violanthrone nucleus, and gave a tetrachloroacetoxy derivative. This substance can be assigned the structure VIIId. It dyed cotton a greenish violet from an alkaline dithionite vat and dissolved in concentrated sulphuric acid with a greenish blue colour.

Similarly, the fusion of Ic with caustic potash at 220°C gave a product which did not contain nitrogen. It was analysed for $C_{34}H_{16}O_6$ and gave a tetrachloroacetoxy derivative. It exhibited λ_{max} in sulphuric acid at 380, 490, 635, 670 and 740 mμ, showing the presence of isoviolanthrone, and its infrared spectrum indicated the presence of a hydroxyl group. It dissolved in concentrated sulphuric acid with a bluish green colour and dyed cotton from an alkaline dithionite vat a greenish violet. It can be assigned the structure IIId.

An authentic specimen of VII was obtained as follows: 3, 12-Diamino violanthrone was condensed with 1-chloroanthraquinone. The product exhibited two bands at 1675 and 1650 cm^{-1} in its infrared spectrum and λ_{max} at 315, 365, 385, 405, 570, 765 and 845 mμ. It dyed cotton a grayish blue and dissolved in concentrated sulphuric acid with a dark bluish green colour: it was analysed as $C_{62}H_{30}N_2O_6$(VIIIc). Treatment with aluminium chloride gave a product exhibiting a band at 1660 cm^{-1} in the infrared spectrum and λ_{max} in sulphuric acid at 310, 395, 405, 510, 570, 765 and 840 mμ. It gave a greenish blue colour in concentrated sulphuric acid and had no dyeing property. This shows that the cyclisation has taken place as in VII.

Experimental

Bis(9-bromo-3-benzanthronyl) Sulphide (Ib).—9-Bromo-3-nitrobenzanthrone (5 g.) was stirred under reflux with sulphur (15 g.) in trichlorobenzene (120 g.) for three hours. The trichlorobenzene was then steam-distilled, and the product IIb was collected. Crystallisation from *o*-dichlorobenzene gave yellow plates, m. p. 320° (3 g.). The above product (3 g.) was then stirred with phenol (15 g.) for 8 hr. at 180°C. The yellow product (2 g.) obtained after dilution with alcohol (30 ml.) was crystallised from *o*-dichlorobenzene in the form of yellow needles, m. p. above 300°C.

Found: S, 4.5. Calcd. for $C_{34}H_{16}Br_2O_2S$: S, 4.9%.

Bis- 9, 9'-di(1-anthraquinonylamino) - 3 - benzanthronyl Sulphide (Ic).—Ib (1.7 g.), 1-aminoanthraquinone (1.2 g.), anhydrous sodium carbonate (0.60 g.), and a trace of copper oxide were stirred under reflux in naphthalene (12 g.) for 24 hr. The product (2.5 g.) was collected after the naphthalene had been removed by steam distillation and the copper oxide had been removed by washing it with dilute hydrochloric acid. Crystallisation from nitrobenzene gave deep brown needles.

Found: N, 3.4; S, 3.3. Calcd. for $C_{62}H_{32}N_2O_6S$: N, 3.0; S, 3.4%.

Indanthrene Gray A.—One gram of Ic was added to a mixture of caustic potash (2 g.) in isobutanol (4 g.) at 70°C and the mixture was then stirred at 140°C for 2 hr. After dilution with water and air oxidation, a blue black residue was collected. Crystallisation from nitrobenzene gave blue black needles. They dissolved in concentrated sulphuric acid with a deep olive green colour and dyed cotton from an alkaline dithionite vat a grayish blue. λ_{max} in concentrated sulfuric acid: 250, 275, 310, 360, 410, 660, 730 mμ. IR: 1675 and 1645 cm^{-1}.

Found: C, 82.7; H, 3.0; N, 2.7. Calcd. for $C_{62}H_{30}N_2O_6$: C, 82.9; H, 3.3; N, 3.1%.

2, 11-Bis(1-anthraquinonylamino)isoviolanthrone (IIIc).—2, 11-Diamino isoviolanthrone (2 g.), 1-chloroanthraquinone (2 g.), anhydrous sodium carbonate (0.8 g.) and traces of copper oxide were stirred under reflux in naphthalene (25 g.) for 48 hr. The product, collected after steam distillation, was washed free of copper. It crystallised from nitrobenzene in the form of blue-black needles. It showed spectral properties and colour reactions identical to those of the above product.

Found: C, 82.5; H, 3.5; N, 3.4. Calcd. for $C_{62}H_{30}N_2O_6$: C, 82.9; H, 3.3; N, 3.1%.

The Cyclisation of IIIc.—One gram of IIIc was stirred with anhydrous aluminum chloride (4 g.) and nitrobenzene (25 ml.) at 140°C for six hours. The resulting mixture was steam-distilled to remove the nitrobenzene. The product gave blue-black needles on crystallisation from nitrobenzene. It dissolved in concentrated sulphuric acid with a bluish green colour and had no affinity for cotton from an alkaline dithionite vat. λ_{max} in concentrated sulphuric acid at 270, 310, 380, 410, 500, 665 and 735 mμ. IR.; 1670 cm^{-1}.

Found: N, 2.9. Calcd. for $C_{62}H_{26}N_2O_6$: N, 3.1%.

3, 4, 11, 12-Tetrahydroxy Violanthrone (VIIId).—9-(1-Anthraquinonyl amino) benzanthrone (1 g.) was added to molten caustic potash (8 g.) at 220°C, and then the mixture was stirred for 30 min. at the same temperature. The product was collected after dilution with water and aerial oxidation for one hour. Repeated crystallisations from nitrobenzene gave bluish-violet needles (0.35 g.). The product dissolved in concentrated sulphuric acid with a blue colour and dyed cotton from an alkaline dithionite vat a greenish violet. λ_{max} in sulphuric acid at 385, 500, 580, 630, 765, and 845 mμ, and IR: 3350 cm^{-1}.

Found: C, 78.6; H, 4.0. Calcd. for $C_{34}H_{16}O_6$: C, 78.5; H, 3.1%.

The Chloroacetoxy Derivative of VIIId. — The above compound (1 g.) and chloroacetyl chloride (6 ml.) were stirred under reflux for 8 hr. The resulting product (1.2 g.) was collected after dilution with water. Crystallisation from nitrobenzene gave brownish-black needles which dissolved in concentrated sulphuric acid with a greenish blue colour and which dyed cotton from an alkaline dithionite vat a greenish violet.

Found: Cl, 17.6. Calcd. for $C_{42}H_{20}Cl_4O_{10}$: Cl, 17.2%.

1, 2, 10, 11-Tetrahydroxy Isoviolanthrone (IIId).—One gram of Ic was added to molten caustic potash at 220°C and the mixture was stirred for 30 min. The residue was collected after dilution with water and air oxidation. Crystallisation from nitrobenzene gave

blue-black needles (0.30 g.). They dissolved in concentrated sulphuric acid with a bluish green colour and dyed cotton from alkaline dithionite vat a greenish violet. The product did not contain nitrogen; λ_{max} in sulphuric acid at 380, 490, 635, 670 and 740 mμ, and IR: 3350 cm^{-1}.

Found: C, 78.2; H, 3.8. Calcd. for $C_{34}H_{16}O_6$: C, 78.5; H, 3.1%.

The Chloroacetoxy Derivative of IIId.—The above product, IIId (1 g.), was refluxed with chloroacetyl chloride (6 ml.) for 8 hr. The resulting product (1.1 g.) was collected after dilution with water. It crystallized from nitrobenzene in brownish-blue needles which dissolved in sulphuric acid with a greenish blue colour and which dyed cotton from an alkaline dithionite vat a greenish violet.

Found: Cl, 16.8%. Calcd. for $C_{42}H_{20}Cl_4O_{10}$: Cl, 17.2%.

3, 12 - Bis(1 - anthraquinonylamino)violanthrone (VIIIc).—3, 12-Diaminoviolanthrone (2 g.), 1-chloroanthraquinone (2 g.), anhydrous sodium carbonate (0.80 g.), and a trace of copper oxide were stirred under reflux in naphthalene for 48 hr. The product was collected after steam distillation.

It crystallised from nitrobenzene in the form of grayish blue needles which dissolved in concentrated sulphuric acid with a greenish blue colour. It dyed cotton from an alkaline dithionite vat a grayish blue. λ_{max} in sulphuric acid: 315, 365, 385, 405, 570, 765, and 845 mμ. IR: 1675, 1650 cm^{-1}.

Found: C, 82.6; H, 3.2; N, 2.8. Calcd. for $C_{62}H_{30}N_2O_6$: C, 82.9; H, 3.3; N, 3.1%.

The Cyclisation of VIIIc.—The substance VIIIc (2 g.) and anhydrous aluminum chloride (8 g.) and nitrobenzene (40 ml.) were stirred at 140°C for 6 hr. The product obtained after steam distillation gave a blue-black powder from nitrobenzene. It dissolved in concentrated sulphuric acid with a greensish blue colour and had no dyeing property. λ_{max} in sulphuric acid at 310, 395, 405, 510, 570, 765 and 845 mμ IR: 1660 cm^{-1}.

Found: N, 2.8. Calcd. for $C_{68}H_{26}N_2O_6$: N, 3.1%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2026—2040 (1966)

The Effects of Magnesium Fluoride on the Thermal Behavior of Serpentine*

By Hanzo MASE and Tomoyuki FUKUDA

Department of Applied Chemistry, Faculty of Industry, Iwate University, Ueda, Morioka

(Received October 7, 1965)

By means of thermogravimetric, differential thermal, and X-ray diffraction techniques, the thermal behavior of a mixture of serpentine (heated at 730°C for 1 hr.) with 31 per cent magnesium fluoride and or mixtures of serpentine with 10, 15.5, 20, 31, 40, and 62 per cent magnesium fluoride were examined at various temperatures up to 1450°C and for various heating periods. The presence of magnesium fluoride affects the shapes of serpentine thermogravimetric and differential thermal curves, but it hardly affects the starting temperatures of the dehydroxylation of the serpentine (730°C) at all. The thermogravimetric curves showed a gradual weight loss above the dehydroxylation temperature of serpentine. In the differential thermal curves, the height reduction of two serpentine exothermic peaks (830°C and 1100°C), and the appearance of two or three endothermic peaks above 1000°C were observed; moreover, a mixture of the preheated serpentine with 31 per cent magnesium fluoride showed a new exothermic peak at 775°C. These effects of magnesium fluoride were discussed. The main heating products of serpentine in the presence of magnesium fluoride were fluorine norbergite, forsterite, magnesioferrite, and magnesium oxide, whereas those of serpentine alone were forsterite and enstatite.

It is well known that the formation of mullite from kaolinite occurs above 1000°C. Recently Bien and Keyser[1] have shown that mullite can be formed at a temperature as low as 600°C (i. e., immediately after the dehydroxylation of kaolinite) through the action of aluminum fluoride. Locsci[2,3] has also elucidated that aluminum fluoride reacts with kaolinite via an intermediate, topaz $Al_2(F, OH)_2SiO_4$, below 575°C to form $Al_6F_6Si_2O_9$ (veszpremite, metakaolinite fluoride), which decomposes rapidly at 800°C to 900°C to form mullite.

Crystallographically speaking, serpentine is composed of magnesium hydroxylphyllosilicate and is very similar to kaolinite, which is composed of

aluminum hydroxylphyllosilicate. Therefore, it seems reasonable to assume that magnesium fluoride might contribute to the formation of forsterite and enstatite, which are the stable high-temperature phases of the silica-magnesia system, at a relative lower temperature on the thermal decomposition of serpentine.

Experimental

Materials.—The serpentine used was rock from Kuroishimori (Iwate Prefecture) crushed to powder passable through a 200 mesh sieve with the composition: SiO_2 39.29, Fe_2O_3 7.09, Al_2O_3 2.54, CaO 1.10, MgO 38.02 (ignition loss 12.51, moisture 1.20 per cent). Its thermal behavior was determined by following the thermogravimetric analysis (TGA) and differential thermal analysis (DTA) (Figs. 1 and 2 respectively).

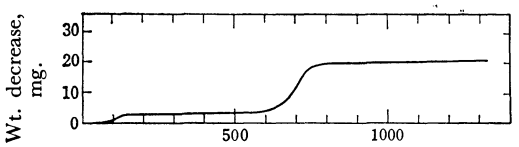

Fig. 1. TGA curve of serpentine.
Sample: 0.3 g.

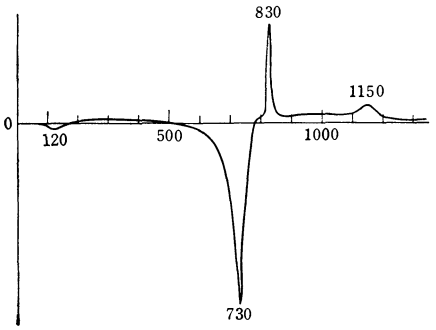

Fig. 2. DTA curve of serpentine.
Sample: 0.890 g.

Figures 1 and 2 indicate that serpentine was endothermally dehydroxylated between 500 and 700°C, and that its original structure was destroyed with a loss in weight and changed exothermally to forsterite and silica at about 800°C without a weight loss.[4-6]

The magnesium fluoride employed was of a G. R. grade of commercial origin (Morita Chemicals Co., Ltd.). Its thermal behavior was shown by TGA and DTA curves (Figs. 3 and 4 respectively), which indicated that the magnesium fluoride hardly changes in weight

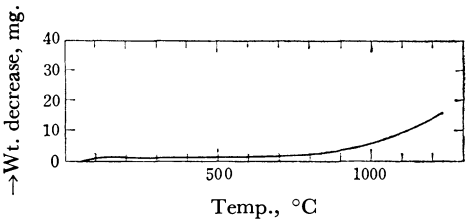

Fig. 3. TGA curve of magnesium fluoride.
Sample: 0.4137 g.

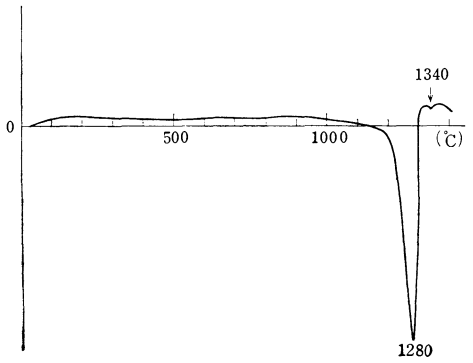

Fig. 4. DTA curve of magnesium fluoride.
Sample: 0.850 g.

up to about 790°C, but that it gradually decreases in weight above 790°C and begins to melt at about 1180°C.

Six mixtures of serpentine were prepared, with 10, 15.5, 20, 31, 40, and 62 per cent mangesium fluoride respectively. Moreover, a mixture of the serpentine (heated at 730°C for 1 hr.) was prepared with 31 per cent magnesium fluoride (hereafter referred to as the preheated mixture (31 per cent). These powdered mixtures were homogenized in a dry state. Of these mixtures, those containing 15.5, 31, and 62 per cent magnesium fluoride (hereafter referred to as the 15.5, 31, and 62 per cent mixtures respectively) give materials with the following compositions if it is assumed that serpentine reacts stoichiometrically with magnesium fluoride:

(15.5 per cent) $2\,Mg_3Si_2O_5(OH)_4 + 2\,MgF_2 \rightarrow 3\,Mg_2SiO_4 + 2\,MgO + SiF_4 + 4\,H_2O$

(31 per cent) $Mg_3Si_2O_5(OH)_4 + 2\,MgF_2 \rightarrow Mg_2SiO_4 + 3\,MgO + SiF_4 + 2\,H_2O$

(62 per cent) $Mg_3Si_2O_5(OH)_4 + 4\,MgF_2 \rightarrow 7\,MgO + 2\,SiF_4 + 2\,H_2O$

The ignition losses calculated from these idealized chemical equations are 25.94, 34.87, and 46.38 per cent respectively.

Methods.—A Shimadzu X-ray Diffractometer (GX-A type) with a Geiger Counter was used with Cu$K\alpha$ radiation. The operating conditions were as follows:

Target, Cu; Scatter slit, Not placed;
Filter, Ni; Full scale count, 500 or 1000 c. p. s.;
Voltage, 35 kV.; Scanning speed, 2deg./min.;

4) H. Heraldsen, *C. Min. A.*, **1928**, 311; S. Caillire, *Compt. rend.*, **196**, 628 (1933).
5) R. Kiyoura and Y. Ito, *J. Ceram. Assoc. Japan (Yogyo Kyokai Shi)*, **16**, 525 (1953).
6) H. Mase, *J. Chem. Soc. Japan, Ind. Chem. Sect. (Kogyo Kagaku Zasshi)*, **60**, 1502 (1957); **62**, 793, 895 (1959).

Current, 15 m amp.; Time constant, 5 sec.;
Divergence slit, 1 mm.;
2θ range measured, 16—70°;
Receiving slit, 0.25 mm.; Chart speed, 20 mm./min.

The TGA and DTA measurements of the mixtures (15.5 and 31 per cent) were carried out at the Shimadzu Analytical Centre. The operating conditions were as follows:

	TGA	DTA
Neutral material	—	α-Al_2O_3
Atmosphere	Air	Air
Sensitivity	200 mg./full scale	100 μV.
Chart speed	2 min./div.	2 min./div.
Heating velocity	12°C/min.	12°C/min.
Sample holder	TB-2S	BHL-2IV.

However, the sample with 62 per cent magnesium fluoride was measured with a Shimadzu Recording Differential Thermal Analysis Apparatus and its attached Thermobalance (DT-2A and TB-2 types, respectively) in our laboratory. The operating conditions were the same as the above except for the following factors:

	TGA	DTA
Sensitivity	100 mg./full scale	—
Chart speed	4 min./div.	4 min./div.
Heating velocity	10°C/min.	10°C/min.

Results and Discussion

Weight Losses During Heating.—Three mixtures (15.5, 31, and 62 per cent) were examined by TGA. The results obtained are shown in Fig. 5, together with that for a preheated mixture (31 per cent). Figure 5 shows that both the mixtures (15.5 and 31 per cent) have two weight losses in the region up to about 800°C—namely, the dehydration of serpentine and magnesium fluoride between 30 and 130°C, and the dehydroxylation of serpentine starting at about 580°C. When these mixtures are heated above 750°C, gradual weight losses are observed up to about 1450°C, whereas pure serpentine shows no weight loss in this temperature region (Fig. 1). These results suggest that magnesium fluoride may affect the starting temperature of the dehydroxylation of serpentine hardly at all, and that a weight loss above 750°C may be closely related to the thermal changes of magnesium fluoride.

Differential Thermal Analysis and X-Ray Diffraction Analysis.—The presence of magnesium fluoride markedly affects the height of the serpentine endothermic and exothermic peaks. This is well shown by the DTA curves in Fig. 6 obtained for the mixtures with magnesium fluoride. These curves and that for serpentine alone (Fig. 2) resemble one another very closely up to 750°C; in this region, endothermic effects due to the dehydration of serpentine and magnesium fluoride and to the dehydroxylation of serpentine were observed. An increase in the amount of magnesium

fluoride markedly reduced the height of the endothermic peak at about 730°C.

With the 15.5 and 31 per cent mixtures, three endothermic peaks appear above 1000°C. Each of these 15.5 per cent mixture peaks was situated at higher temperatures than those of the 31 per cent mixture. On the other hand, the 62 per cent mixture shows a sharp and large endothermic peak near 1250°C and a weak and small endothermic one at 1290°C.

The preheated mixture (31 per cent) shows no endothermic peak below 1000°C, because the serpentine has been completely dehydroxylated, but it does show an exothermic peak at 775°C and two endothermic peaks above 1000°C, which are situated at lower temperatures than those of the 31 per cent mixture. In order to make clear the crystallographic significance of these peaks, each of the

* In this table, the very weak diffraction lines were omitted except when the special need was not seen. Moreover, the figures prefixed in small prints stand for the order in intensity for the main ones. For each specimen:
ffrst column: 2 (°),
second column: intensity of diffraction
(abbr.) s, strong; m, middle; w, weak; vw, very weak
third column: identifiication
(abbr.) S, serpentine; M, magnesium fluoride; F, forsterite;
MF, magnesioferrite; N, fluorine norbergite; O, magnesium oxide
X-ray diffraction data for the raw sample with 62 per cent magnesium fluoride were omitted because those were almost identical with the raw sample with 40 per cent magnesium fluoride.

mixtures was heated at various temperatures and for various heating periods, and then quenched in air. These were then examined by X-ray diffraction analysis. The results are illustrated in Table I.

An Endothermic Effect between 600 and 800°C.—As has been mentioned above, no changes occur below about 600°C except for the dehydration of mixtures occurring below about 200°C. In the case of the 62 per cent mixture, no changes occurred even when it was heated at 600°C for 5 hr. (Table I).

As is generally known, the principal reaction occurring between 600 and 800°C is the dehydroxylation of serpentine; however, in the presence of magnesium fluoride, the following reactions appear to occur successively.

The Formation of Fluorine Norbergite ($Mg_2SiO_4 \cdot MgF_2$).[7]—All the mixtures always gave the characteristic diffraction peaks of fluorine norbergite

* The figures and abbreviations are all the same as those in Table I.

when heated at 700°C or 800°C for 1 hr. The mixtures with higher contents of magnesium fluoride (e. g., 40 or 62 per cent) formed fluorine norbergite at 700°C for 1 hr., while, on the contrary, those with lower contents of magnesium fluoride (10, 15.5, 20, or 31 per cent) formed fluorine norbergite at 800°C for 1 hr. However, even in the latter cases, the serpentine has been dehydroxylated by heating at 700°C and above for 2 hr. Therefore, it is evident that a larger amount of magnesium fluoride facilitates the formation of fluorine norbergite at lower temperatures. As is shown in Table I, the number and intensity of the characteristic peaks of fluorine norbergite decrease with the amount of magnesium fluoride and with the rise in the heating temperatures; namely, its diffraction peaks were intensified as the heating temperature was elevated, showing maximum values at about 1000°C, but being generally reduced above 1070°C. However, the 62 per cent mixture formed a product chiefly consisting of fluorine norbergite when treated even at 1250°C for 1 hr., although the 10 per cent mixture gave a product mainly consisting of forsterite when treated at 800°C for 1 hr.

The preheated mixture (31 per cent) displayed an exothermic peak at 775°C, without any endothermic effect below 1000°C on its DTA curve. The product heated at 775°C for 1 hr. clearly showed the presence of fluorine norbergite; furthermore, the product heated immediately beyond the exothermic peak temperature (850°C) showed the absence of fluorine norbergite (Table II). Therefore, the formation of fluorine norbergite appears to be exothermic.

As has been mentioned above, the endothermic peak due to the dehydroxylation of serpentine at about 730°C was reduced with an increase in the amount of magnesium fluoride. This seems to be due not only to the decreased amount of serpentine, but also, at the same time, to the overlapping of the exothermic effect of the formation of fluorine norbergite. In other words, the forsterite formed endothermally on the dehydroxylation of serpentine probably immediately combines with magnesium fluoride under the evolution of heat. The forsterite which is then formed, at the moment of the birth (in statu nascendi), appears to be in a specially active state. From this point of view, the mixtures of serpentine with magnesium fluoride appear to form fluorine norbergite at a temperature lower than 775°C—immediately after the dehydroxylation of serpentine.

$$2\ Mg_3Si_2O_5(OH)_4 \rightarrow 3\ Mg_2SiO_4 + SiO_2 + 4\ H_2O \quad (1)$$

$$Mg_2SiO_4 + MgF_2 \rightarrow Mg_2SiO_4 \cdot MgF_2 \quad (2)$$

The Formation of Magnesioferrite ($MgFe_2O_4$).— Magnesioferrite was formed from all the mixtures of serpentine with magnesium fluoride at about 700°C or 800°C for 1 hr., and from serpentine alone at 730°C for 1 hr. The formation temperature of magnesioferrite agreed approximately with those of forsterite and fluorine norbergite. In general, the characteristic X-ray diffraction peaks of magnesioferrite were observed more clearly and more sharply in the presence of magnesium fluoride than those of serpentine alone. It seems likely that magnesium fluoride may accelerate the crystal growth of magnesioferrite.

Magnesioferrite is formed principally according to the following reaction:

$$MgO + Fe_2O_3 \rightarrow MgFe_2O_4 \quad (3)$$

where magnesium oxide is a component of the intermediate, unstable phase ($Mg_3Si_2O_7$) which had resulted from the dehydroxylation of serpentine,[4,6] and where ferric oxide is one of the impurities of serpentine.

Various Reactions between 800 and 1100°C.—As is generally known, serpentine shows two exothermic peaks in this temperature region; the first one, at about 830°C, is attributed to the crystal growth of forsterite, and the second, at about 1100°C, to the formation of enstatite. In the presence of magnesium fluoride, both these exothermic peaks exhibit a tendency to be reduced or to disappear with an increase in the amount of magnesium fluoride.

The disappearance of the first peak is due to Reaction 2—the conversion of forsterite into fluorine norbergite—at about 775°C.

The Hydrolysis of Magnesium Fluoride and Related Phenomena.—A plausible explanation for the disappearance of the second peak is as follows.

The water vapor evolved on the dehydroxylation of serpentine—Reaction 1—appears to react with a part of the magnesium fluoride to produce magnesium oxide, together with hydrogen fluoride, which perhaps successively attacks the serpentine

* The figures and abbreviations used in X-ray diffraction data are all the same as those in Table I.

or amorphous silica and forsterite resulting from Reaction 1:

$$MgF_2+H_2O \rightarrow MgO+2\ HF \quad (4)$$

$$SiO_2+4\ HF \rightarrow SiF_4+2\ H_2O \quad (5)$$

$$Mg_2SiO_4+8\ HF \rightarrow 2\ MgF_2+SiF_4+4\ H_2O \quad (6)$$

$$Mg_3Si_2O_5(OH)_4+14\ HF \rightarrow 3\ MgF_2+2\ SiF_4+4\ H_2O \quad (7)$$

The following reaction also appears to occur at that time:

$$2\ MgO+SiO_2 \rightarrow Mg_2SiO_4 \quad (8)$$

This reaction is a combination of magnesium oxide and silica in the amorphous state, and it appears to be accelerated by the hydrogen fluoride and silicon tetrafluoride resulting from Reactions 4—7.[8] The product, forsterite, successively reacts with magnesium fluoride to form fluorine norbergite —Reaction 2, or with hydrogen fluoride—Reaction 6.

According to Sychev,[8] pure magnesium fluoride does not show any volatilization between 800 and 1300°C, but water vapor present in the furnace atmosphere hydrolyzes it rapidly, forming magnesium oxide. Therefore, Reaction 4—the hydrolysis of magnesium fluoride—was expected to progress rapidly, but magnesium fluoride remained in the free state when heated up to 1070°C for 1 hr. In addition, the preheated mixture (31 per cent) also contained the free magnesium fluoride, even when heated at 1075°C for 1 hr., because the constitutional water of serpentine had almost all been lost.

The X-ray diffraction data of the heated mixtures (Table I) showed that magnesium fluoride exists partly in the form of fluorine norbergite and partly in the free state. However, the free magnesium fluoride disappeared entirely at about 1070°C, except for the 62 per cent mixture. It is worth noticing that the X-ray diffraction peaks of magnesium oxide distinctly appeared immediately after the magnesium fluoride had disappeared. This indicates that the hydrolysis of magnesium fluoride—Reaction 4—progresses completely in practice at 1070°C for 1 hr., and that the thermal change of magnesium fluoride is very closely related to the formation of magnesium oxide. However, this reaction seems to progress gradually to a slight degree in the region between about 730 and 1070°C, as is shown by the gradual weight decrease above 730°C on the TGA curves (Fig. 5).

The Formation of Magnesium Oxide and Forsterite. —The mixtures with comparatively large amounts of magnesium fluoride formed magnesium oxide above about 1070°C. The X-ray diffraction peaks of magnesium oxide were especially clearly confirmed in the mixtures with 31 per cent and more magnesium fluoride; on the contrary, its formation was not clear in the mixtures with 20 per cent and less magnesium fluoride. In the case of serpentine alone, no formation of magnesium oxide was observed in this temperature region. Thus magnesium oxide results from the hydrolysis of magnesium fluoride according to Reaction 4, and a part of it successively reacts with the amorphous silica formed on the dehydroxylation of serpentine —Reaction 1 — to produce forsterite according to Reaction 8.

The disappearance of the second exothermic peak of serpentine at 1100°C seems to be caused by the interaction of amorphous silica with magnesium oxide or hydrogen fluoride—Reaction 8 or 5, because the amorphous silica plays an important role in the formation of enstatite ($SiO_2+Mg_2SiO_4 \rightarrow 2\ MgSiO_3$).

Two or Three Endothermic Effects above 1000°C.—In order to elucidate these effects, the 15.5, 31, and 62 per cent mixture and the preheated mixture (31 per cent) were heated just below and beyond these peak temperatures. They were then examined in term of their weight losses (and fluorine contents in the case of the 31 per cent mixture only), and by X-ray diffraction. The results are summarized in Table III.

Table III shows that the first endothermic peak in the temperature region above 1000°C is most closely related to the remarkable decrease in weight (and the fluorine contents*). Moreover, just beyond these peak temperatures, none of the mixtures contained magnesium fluoride except for the 62 per cent mixture, and none formed magnesium oxide except for the 15.5 per cent mixture.** Therefore, it can be concluded that these first endothermic effects are to be attributed to the hydrolysis of magnesium fluoride by the water vapor according to Reaction 4, which leads to the evolution of hydrogen fluoride and silicon tetrafluoride. It should be noted that, besides the constitutional water of serpentine and the moisture of the furnace atmosphere, the water vapor resulting from Reactions 5—7 participates in Reaction 4.

The second endothermic effect may perhaps be attributed to the melting of magnesium fluoride (m. p. 1265°C). This is deduced from the fact

8) M. M. Sychev, *Trudy Leningrad Tekhnol. Inst. im Lensoveta,* **1955**, No. 34, 29—31; *Chem. Abstr.*, **50**, 12434d.

* When the 31 per cent mixture was heated for 1 hr. at the following temperatures, the fluorine contents of the products were as follows:

	1075°C	1210°C	1280°C	1320°C	1350°C
F, %	7.84	5.59	0.65	0.46	0.33

were 1210°C and 1320°C correspond to the first and second peaks respectively.

** In the 15.5 per cent mixture, the characteristic peaks of magnesium oxide were too weak for its presence to be concluded.

that the product heated immediately beyond the peak temperature was sintered. However, at about 1250°C (its first peak) and above, the 62 per cent mixture gave the sintered mass, which was shrunked and cracked. Furthermore, the intensities of the first and second peaks of both the 15.5 and 31 per cent mixtures exhibit a tendency to increase and to approach nearer toward each other with an increase in the amount of magnesium fluoride. These appear to indicate that its first endothermic peak between 1060 and 1280°C is to be attributed to the melting of magnesium fluoride in addition to its hydrolysis; namely, in this temperature region, the melting of magnesium fluoride occurs simultaneously with its hydrolysis. From this point of view, the second endothermic peak of a mixture (62 per cent) probably corresponds to the third ones for both the mixtures (15.5 and 31 per cent). Moreover, in this mixture, the existence of the free magnesium fluoride in the temperature region above the first endothermic peak is also probably caused by the melting of magnesium fluoride, which results from a decrease in the contact area between the magnesium fluoride and the water vapor.

The third endothermic peak of the preheated mixture (31 per cent) was not found in the region above the second one. Moreover, the intensity of the third endothermic peak decreases with an increase in the amount of magnesium fluoride. The reason for these results is not yet evident. Further work is required to explain fully the second and third effects.

Furthermore, the weight losses during heating were by far smaller than the calculated values (Table III). This is probably due to the formation of fluorine norbergite, which is more thermally stable than magnesium fluoride.

The Mineral Composition of the Heated Products.—The color of the heated products of all the mixtures generally vary from brownish white to dark brown as the temperature is raised. This is mainly caused by the formation and the crystal growth of magnesioferrite, and of the ferric oxide resulting from the oxidation of ferrous oxide, which is one of the impurities of serpentine.

Independent of the amount of magnesium fluoride, the products heated above the first endothermic peak temperature mainly consist of similar components—forsterite, magnesioferrite, fluorine norbergite, and magnesium oxide. The amount of the latter two increases with an increase in the amount of magnesium fluoride; especially in the case of the mixture with 62 per cent magnesium fluoride, its product when it is heated at 1250°C for 1 hr. is composed chiefly of magnesium oxide and fluorine norbergite, accompanied by a small amount of magnesioferrite—it contains almost no forsterite (Table I). On the other hand, forsterite is the principal component of the heated products with a decrease in the amount of magnesium fluoride. Moreover, among these components, the amount of fluorine norbergite tends to decrease in the temperature region above 1070°C; on the contrary, the three others are thermally stable.

The authors wish to express their gratitude to Mr. Shiro Saito for his help with the X-ray diffraction, the differential thermal, and the thermogravimetric analyses.

NOTES

The Cyclisation of Anthrimides to Carbazoles. IV.* The Cyclisation of 4, 4'-Dibenzamido Dianthrimides

By K. H. SHAH and K. M. SHAH

Department of Chemical Technology, University of Bombay, Matunga, Bombay 19, India

(Received September 24, 1965)

Indanthrene Corinth RK (C. I. No. 65020), containing only one benzamido group in the 4th position, does not cyclise to a carbazole, but hydrolyses with sulphuric acid at 100°C.[1] The cyclisation of a dianthrimide to a carbazole with sulphuric acid is successful only when two benzamido groups are present in 4, 4'- or 4, 5'- or 5, 5'-positions. E.g., Indanthrene Gray K, 4, 4'-dibenzamido-1, 1'-dianthrimide, cyclises to the corresponding carbazole, Indanthrene Olive R.

In order to confirm this observation and to compare the reactivity of 1, 1'- and 1, 2'-dianthrimides, 4, 4'-dibenzamido-1, 2'-dianthrimide was prepared by the condensation of 1-benzamido-3-bromoanthraquinone with 1-amino-4-benzamido anthraquinone. The product exhibited λ_{max} values at 290, 325—330 and 455 mμ. When treated with sulphuric acid at 26—30°C for about three hours while being stirred, it changed to another compound which exhibited λ_{max} values at 280, 360—380, 570 mμ. Indanthrene Gray K exhibits λ_{max} values at 250—260, 335—340 and 435 mμ. Indanthrene Olive R exhibits λ_{max} values at 225, 260—270, 360—380, 548, and 580 mμ. From these changes it is evident that 4, 4'-dibenzamido-1, 2'-dianthrimide cyclises to a carbazole under this treatment.

The spectral study of the rates of cyclisation with sulphuric acid (see attached graphs) of 4, 4'-dibenzamido-1, 1'-dianthrimide and 4, 4'-dibenzamido-1, 2'-dianthrimide indicated that the former compound cyclised readily in almost 50 min., while the latter compound cyclised very slowly (in about three hours) in an unstirred, 1 cm. long cell on a recording spectrophotometer (C ϕ-C 10). Therefore, 1, 1'-dianthrimide derivative cyclises more readily than the corresponding 1, 2'-dianthrimide derivative.

One point to be noted is that dianthrimides without benzamido groups exhibit λ_{max} values at 360 mμ, those with a benzamido group in the 4-position exhibit λ_{max} values at 390—405 mμ,[1] and those with two benzamido groups in the 4, 4'-positions exhibit λ_{max} values at 435—455 mμ. The corresponding carbazoles containing benzamido group in the 4 or 4, 4'-positions exhibit λ_{max} values at 360—380 mμ.[1] This does not apply to carbazoles containing benzamido groups in 4, 5'- or 5, 5'-positions. Indanthrene Brown FFR or R, obtained by the cyclisation of 4, 5'-dibenzamido-1,1'-dianthrimide, exhibits λ_{max} values at 343, 560 and 605 mμ.[2] Indanthrene Golden Orange 3G, obtained by the cyclisation of 5, 5'-dibenzamido-1, 1'-dianthrimide, exhibits λ_{max} values at 323 and 640 mμ.[2]

Experimental

Ultraviolet and visible spectra were taken on a Carl-Zeiss spectrophotometer, while the rate of cyclisation was studied on a Recording Spectrophotometer (C ϕ-C 10). Analar sulphuric acid was used.

The Purification of Indanthrene Gray K.—The commercial dye (4 g.), after water and alcohol solubles had been removed, crystallised from nitrobenzene as blue needles; these needles gave a green color when dissolved in concentrated sulphuric acid. UV: $\lambda_{max}^{H_2SO_4}$ mμ: 250—260, 335—340, 430—440.

Found: C, 75.5; H, 3.9; N, 6.6. Calcd. for $C_{42}H_{25}N_3O_6$: C, 75.6; H, 3.8; N, 6.8%.

The Cyclisation of Indanthrene Gray K.—The above dye (1.2 g.) was stirred with concentrated sulphuric acid (8 g. of 96%) for two hours at 26—28°C. The olive dye which precipitated when the solution was then poured on ice was collected. It crystallized from nitrobenzene as microcrystals. UV: $\lambda_{max}^{H_2SO_4}$ mμ 262, 360—375, 538—545, and 580. In 50 min. Indanthrene Gray K was cyclised to Indanthrene Olive R by "Analar" sulphuric acid at 23°C; this was indicated by the recording spectrophotometer (see attached graph).

The Purification of Commercial Indanthrene Oilve R.—The commercial dye (2 g.), after water and alcohol solubles had been removed, crystallised from nitrobenzene as microcrystals which gave a red color

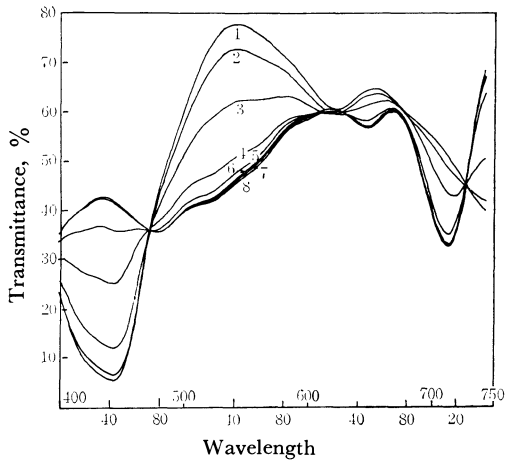
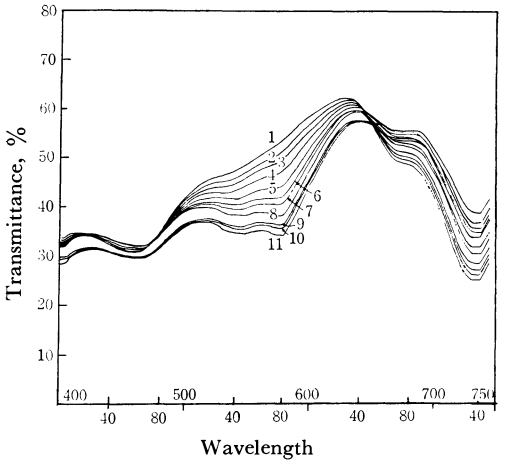
4, 4'-dibenzamido-1, 1'-dianthrimide



4, 4'-dibenzamido-1, 2-dianthrimide



when dissolved in concentrated sulphuric acid. UV: $\lambda_{max}^{H_2SO_4}$ mμ: 225, 260—270, 360—380, 548, 580.

4, 4'-Dibenzamido-1, 2'-dianthrimide. — *1-Benzamido-3-bromoanthraquinone.*—A mixture of crystallised 1-amino-3-bromoanthraquinone[3] (1.5 g.), benzoyl chloride (2 ml.), and *o*-dichlorobenzene (13 ml.) was refluxed while being stirred for two hours. The product was then collected; it crystallised from benzene as yellowish-green needles.

Found: N, 3.9. Calcd. for $C_{21}H_{12}BrNO_3$: N, 3.5%.

4, 4'-Dibenzamido-1, 2'-dianthrimide. — A mixture of crystallised 1-amino-4-benzamido anthraquinone (0.6 g.), 1-benzamido-3-bromoanthraquinone (0.75 g.), sodium acetate (0.2 g.), soda-ash (0.2 g.), copper powder (0.07 g.), copper acetate (0.01 g.) and naphthalene (8.0 g.) was refluxed while being stirred for eight hours. The product (1.1 g.) was collected after steam distillation. It separated from nitrobenzene as blackish-gray microcrystals; these gave a greenish-yellow colour when dissolved in concentrated sulphuric acid. UV: $\lambda_{max}^{H_2SO_4}$ mμ: 290, 325—330, 455.

Found: C, 74.0; H, 3.7; N, 5.6. Calcd. for $C_{42}H_{25}N_3O_6 \cdot 0.5H_2O$: C, 74.5; H, 3.8; N, 6.2%.

The Cyclisation of 4, 4'-dibenzamido-1, 2'-dianthrimide.—The above dye (0.6 g.) was stirred with concentrated sulphuric acid (8 ml.) for 3.5 hr. at 25—30°C. The black compound which precipitated when the solution was then poured on ice crystallised from nitrobenzene as black needles; when dissolved in concentrated sulphuric acid, these needles gave a reddish-violet colour. UV: $\lambda_{max}^{H_2SO_4}$ mμ 280, 360—380, 570.

Found: C, 74.4; H, 3.7. Calcd. for $C_{42}H_{23}N_3O_6 \cdot 0.5H_2O$: C, 74.8; H, 3.6%.

4, 4'-Dibenzamido-1, 2'-dianthrimide was cyclised in three hours by "Analar" sulphuric acid at 23°C, as was indicated by a recording spectrophotometer (see attached graph).

Summary

Cyclisation of a dianthrimide to a carbazole with sulphuric acid is successful only when two benzamido groups are present. The spectral study of rates of cyclisation with sulphuric acid indicates that 4, 4'-dibenzamido-1, 1'-dianthrimide cyclises more readily than 4, 4'-dibenzamido-1, 2'-dianthrimide.

Studies on Reactions of Polypropylene. VII. The Modification of Polypropylene by Making Use of Oxidation and Treatment with Toluylene Diisocyanate

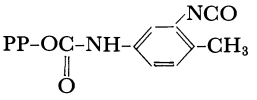
By Yukio MIZUTANI, Keiichi YAMAMOTO and Shigeo HISANO

Tokuyama Soda Co., Ltd., Tokuyama, Yamaguchi

(Received November 29, 1965)

It is well-known that there are a few drawbacks in the practical use of polypropylene, including its poor dyeability and its susceptibility to oxidation. In this work, the latter drawback was utilized in order to improve the former. Namely, polypropylene (PP) was oxidized in order to introduce the hydroperoxide group[1,2] or the carbonyl group,[3] and then these groups were reduced to the hydroxyl group.

$$\text{PP} \xrightarrow{\text{air}} \text{PP-OOH} \xrightarrow{AlEt_3} \text{PP-OH} \xrightarrow{\text{TDI}}$$



(PP-TDI)

When PP–OH prepared is dipped in toluylene diisocyanate (TDI), one of the two isocyanate groups of TDI may react with the hydroxyl group of PP–OH and TDI may be fixed to the polypropylene chain. The other isocyanate group may still be reactive and may react with a dye in the dyeing process. The film of PP–OH was dipped in TDI at room temperature for 8 days; then the film of PP-TDI was washed with dry acetone untill no TDI was detected in acetone. Absorption bands were detected at 4.5 μ and 5.9—6.7 μ in the infrared spectrum of this film (Fig. 1). On the other hand, these bands were not detected in the spectrum of the film of PP similarly treated.

From the fact that the film of PP-TDI was perfectly soluble in hot *p*-xylene and that the isocyanate group was present in the film, as is indicated by the absorption band at 4.5 μ, it is clear that, while one of two isocyanate groups of TDI reacted with the hydroxyl group on the polypropylene chain, the other group remained reactive. The band at 4.5 μ disappeared when the film was treated with dry methanol, but it could survive the dipping of the film in water for two days, although the film then became a cloudy white. It seems likely that the isocyanate group is protected from water by the water-repelling property of polypropylene. As the removal of TDI soaked in the polymer was not needed practically, the TDI content of the PP-TDI film was weighed without any special treatment other than wiping of TDI on the surface of the film with a filter paper. The results are shown in Table I.

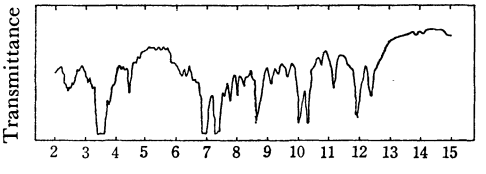


Fig. 1. The infrared spectrum of PP-TDI after acetone-extraction.

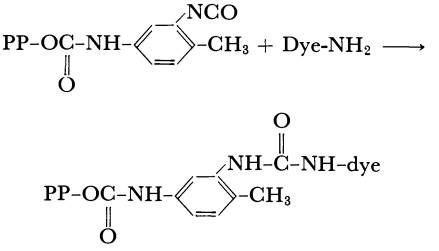
Table I. The TDI content of the film of PP-TDI

Dipping time in TDI, day	2	4	6	8
TDI content, %	1—3	2—4	3—5	4—7

For comparison, the film of PP was dipped in TDI for 8 days. The final TDI content was only about 1% and was less than those listed in Table I, because the film of PP containing no hydroxyl group could not fix the TDI in the film.

The films and fibers of PP–OH were dipped in TDI for 8 days, washed quickly with dry acetone, and dyed by the ordinary method with such dispersed dyes as Duranol Red X3B, Celliton Blue Extra, and Estrol Fast Violet B. They were dyed deeply, clearly, and homogeneously to the inner part (Photo 1).



The dyed fiber was not decolored by extraction with acetone. This was evidence of the perfect fixation of the dye in the fiber, as had been elucidated by

Kubota et al.[4] Since the isocyanate group is protected from water, as has been described above, and since it reacts with amino groups more rapidly than with water,[5] the addition reaction between the isocyanate group and amino groups of the dyes should occur in the dyeing process. When the film of PP-TDI was treated with dry methanol, the isocyanate group in the film was killed. Accordingly, this film was dyeable with the dispersed dye, but it was easily decolored by acetone.

PP-OH could be prepared also by the relatively severe oxidation of polypropylene to introduce the carbonyl group and then by reduction with lithium aluminum hydride. The film thus treated acted in a manner similar to that of the film described above, except that the film became partially insoluble in hot *p*-xylene when dipped in TDI at room temperature for 7 days. This can be explained as resulting from the crosslinking behavior of TDI and the much greater content of the hydroxyl group in the film.

Experimental

Materials.—The powdery polypropylene used contained no stabilizer and its properties were as follows: melt index (at 230°C, load: 2.16 kg./cm.^{2}): 2.5, and specific gravity (at 23°C): 0.912. The film about 0.2 mm. thick was molded under a nitrogen atmosphere, and the fiber was spun at 270°C under a nitrogen atmosphere by the use of a spinneret 0.5 mm. in diameter.

The Preparation of PP-OH.—(1) The powdery sample was oxidized at 70°C for 7 hr. under air in order to introduce the hydroperoxide group. The oxidized sample (4 g.) was dipped in a 2% *n*-heptane solution of aluminum triethyl (70 cc.) at 20°C for 24 hr., then hydrolyzed with a 0.1 N aqueous solution of hydrochloric acid, and washed with water. The hydroxyl group to be introduced was limited to be about 0.3%.[1] (2) The powdery sample was oxidized at 125°C for 2 hr. under air in order to introduce the carbonyl group. The oxidized sample (1 g.) was refluxed for 4 hr. in an ether solution of lithium aluminum hydride (1.9 g./200 cc.) under a nitrogen atmosphere, then washed with methanol, a 15% aqueous solution of sodium hydroxide and water.

The Effect of the Temperature on the Fluidization of Supported Metal Catalysts

By Etsuro ECHIGOYA, Hiroshi HAGIWARA* and Akio SAKURAI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received December 8, 1965)

The fluidization technique has become a widely-used method for solid-gas contact operations in the chemical industry. In general, metal powder shows agglomeration when it is heated in a hydrogen stream.[1,2] In hydrogenation experiments using a fluidized bed appearatus, it is necessary to find a metal powder catalyst which is stable without agglomeration under the reaction conditions. The aim of the present experiments is to find such a catalyst, on which shows stable fluidization characteristics under the operating conditions.

Experimental Method

Metal Powders for the Fluidization Experiments.—Commercial-grade metal powders of silver, copper, nickel, iron and stainless steel were used.

The Preparation of Supported Nickel and Cobalt Catalysts for the Fluidization Experiment.—30% *Nickel-Diatomaceous Earth.*—Powdered diatomaceous earth was added to a solution of a 1 N nickel nitrate solution to the slurry; then these was slowly added, at 20°C, an equivalent quantity of ammonium carbonate dissolved in water. The precipitate, after being filtrated and washed, was dried at 100°C and calcined at 400°C for 2 hr.

TABLE I. THE AGGLOMERATION TEMPERATURES OF VARIOUS KINDS OF METAL POWDERS IN A STREAM OF HYDROGEN OR IN AIR

Metal	Size, mesh	Fluidizing gas	Agglomeration temperature, °C	M. p., °C
Ag	−100+200	Air	85	960.8
Cu	−100+200	H_2	250	1083
Cu	−100+200	Air	>400	
Ni	−150+300	H_2	325	1455
Fe	−100+300	H_2	345	1535
Fe	−100+150	H_2	>420	
Stainless steel	−150+200	H_2	>390	

10% Nickel-Silica Catalyst.[3]—This catalyst was prepared by the super-coprecipitation method from a mixed-solution of nickel nitrate and sodium silicate, using ammonium carbonate at 20°C, and with vigorous stirring. The precipitate was washed with distilled water on the filter, dried at 100°C, and calcined at 550°C for 2 hr.

20% Nickel-Alumina and 20% Cobalt-Alumina.—The powdered alumina was added to a solution of cobalt nitrate. The slurry was stirred for some time, and to it these was then slowly added, at 20°C, a quantity of dissolved ammonium carbonate in a slight excess; the mixture was then heated and kept at 60—70°C for 5 hr. After it had been filtrated and washed, the precipitate was dried at 100°C and calcined at 500°C for 2 hr. The structure and properties of the catalysts were described in a previous report.[4]

The Fluidization Test.—An experimental method reported before[1] was used for the fluidization tests. The bed temperatures were measured with a thermocouple immersed in the bed. Fluidizing difficulties due to agglomerate formation were directly visible through the pyrex tube, but they could also be readily deduced from the pressure-drop readings.

Results and Discussion

(1) Metal powders showed agglomeration when heated in a stream of hydrogen. The experimental results are shown in Table I. The agglomeration temperature was influenced by many factors, such as the particle size and the kinds of gas used. In the case of silver, agglomeration was observed even in air at 85°C.

(2) The nickel-diatomaceous earth catalyst ceased to be fluidized after a few hours. The agglomerates which formed were of a relatively low mechanical strength. Cooling the bed to room temperature, while maintaining the gas flow, was sufficient to bring about fluidization again. If this cycle of heating and cooling was repeated several times, a gradual lowering of the agglomeration temperature, characterized by the cessation of fluidization, was observed, but after a still larger number of cycles this temperature appeared to tend toward a constant value (Table II, B).

TABLE II. INDUCTION PERIOD DATA OF THE AGGLOMERATION PROCESS OF Ni-DIATOMACEOUS EARTH

Catalyst	Run	Reaction temp., °C	Induction period, t, min.
(A)	1	350	20
New	2	350	30
Cat.	3	300	140
	4	325	30
	5	275	155
(B)	6	350	2
Repeated	7	325	6
catalyst	8	275	35
	9	275	24

When a fresh sample of nickel-diatomaceous earth powder was maintained at a constant temperature under the fluidizing conditions, difficulties due to agglomeration did not occur immediately. A time interval which depended on the bed temperature was observed. The "induction period" was, therefore, defined as the time interval between the beginning of fluidization and the first major decrease in pressure drop, a decrease which culminated in complete bed immobility. Such induction periods were not observed with the other catalyst compositions, but the possibility of their occurance after lengths of time greater than those used in our experiments (about 40 hr.) can not be ruled out. The induction-period data of the agglomeration process is given in Table II, A for the nickel-diatomaceous earth. The Arrehenius plot correlated the induction period as a function of the reciprocal bed temperature, so the data may be represented by an empirical equation:

$$\frac{1}{t} = A \exp\left(-\frac{\Delta E}{RT}\right) \qquad (1)$$

Where t is the induction period (min.); T is the bed temperature, °K and A and E are experimental constants. E is regarded as the activation energy for the overall agglomeration process. The activation energy calculated from the slope of these line was about 22 kcal.

4) H. Hagiwara and E. Echigoya, This Bulletin, **38**, 2163 (1965).

(3) At the reaction temperature, cobalt-alumina, nickel-alumina and nickel-silica catalyst powders could be fluidized satisfactorily for 40 hr. of continuous operation.

It was found from the above results that the nickel-diatomaceous earth catalyst in which the nickel is not combined with the carrier forms agglomerates under the reaction conditions, while the cobalt or nickel catalysts in which the metal forms a complex with the carrier resists the formation of agglomerates.

The cobalt-alumina catalyst found in this experiment was used for the experiments on the hydrogenation of aniline with a fluidized bed; good results were thus obtained.[5]

The agglomeration phenomena might be explained by connecting it with the sintering process of the metal.[6-8]

The authors wish to thank Professor Kiyoshi Morikawa for his valuable discussion and constant guidance.

Acetamide as the *N*-Methylaminating Reagent. The Reaction of Halogenonitrobenzenes with Acetamide

By H. L. SHARMA, V. N. SHARMA and R. L. MITAL

Department of Pharmacology, S. M. S. Medical College, Jaipur, India
Department of Chemistry, University of Rajasthan, Jaipur, India

(Received January 20, 1966)

During an attempt to develop a new method for the synthesis of nitrobenzoxazoles, required for pharmacological work, from halogenonitrobenzenes and acetamide, we came across an interesting reaction which indicates the possible use of acetamide as a *N*-methylaminating reagent, a use which has not been reported hitherto. It has been found that when halogenonitrobenzenes are heated under reflux in the presence of copper sulphate, the halogen activated by the nitro groups is replaced by a methylamino group, thus yielding nitro-*N*-methylanilines.

The compound obtained by treating 1-chloro-2, 4-dinitrobenzene (I) with acetamide by this method was found to be homogeneous by thin-layer chromatography (Silica gel G, activated at 110°C for 24 hr.) using a benzene-ethanol mixture (1 : 1, v/v) which had been purified before use by standard methods. Its structure has been identified as 2, 4-dinitro-*N*-methylaniline, as it exhibits bands at 1515 cm^{-1} and 1351 cm^{-1} corresponding to asymmetric and symmetric stretching valence vibrations of the NO_2-group, and bands at 3350 cm^{-1} and 1645 cm^{-1} corresponding to N–H stretching and deformation vibrations of the secondary amino group. Moreover, it has been found to be identical with the product obtained by treating 2, 4-dinitrochlorobenzene with methylamine.[1]

The reaction was further studied with 3-chloro-1-iodo-(II), 3-chloro-1-bromo-2, 6-dinitro-4-methylbenzene (III) and with some other halogenonitrobenzenes (IV—VI).

Both the halogen atoms in compounds II and III are likely to be reactive, as they have two nitro groups, either in both the ortho positions or in the ortho and para positions. Neither of them, however, is replaced in this reaction. The products obtained in both cases are identical and invariably contain chlorine, indicating that in this reaction only halogen at position 1 is substituted.

This preferential replacement of the halogen atom can be explained by considering the spatial details of the halogen atom at position 3. The spatial consideration reveals that the NO_2 group at position 2 in compounds II and III is effectively held out of the plane of the ring by the bulky halogen atoms. Moreover, the "H" atoms of the methyl group are tetrahedrally placed. Therefore, the approach of the attacking reagent at position 3 is inhibited due to the *nonbonded interaction* of the tetrahedrally-placed "H" atoms of the methyl group on the side and the "O" atom of the twisted nitro group on the other side; hence, its replacement by the $NH–CH_3$ group is inhibited.

A detailed investigation of the mechanism of this reaction is in progress; it will be communicated separately in the near future.

* Lit. m. p. 173, 106—107, 128, 160 and 160°C respectively.

Experimental

2, 4-Dinitro-*N*-methylaniline.[2]—A mixture of 1 chloro-2,4-dinitrobenzene (2.0 g., 0.01 mol.), copper sulphate (0.1 g., 0.004 mol.) and acetamide (8.0 g.) was refluxed with stirring for about 10 hr. The melt was then poured into ice cold water (ca. 30 ml.). The solid thus separated was filtered and extracted with ethanol. The residue obtained after evaporating the ethanol was crystallised by water in the form of yellow crystals, m. p. 175°C (Found: C, 42.34; H, 3.51; N, 20.98. Calcd. for $C_7H_7O_4N_3$: C, 42.64; H, 3.55; N, 21.31%). (Lit.[2] m. p. 176°C, undepressed on admixture with the the sample obtained above.)

Following the above procedure, a few halogenonitrobenzenes were successfully converted into the respective *N*-methylanilines[3-6] (Table I). In a few cases the product was isolated by extracting the diluted reaction mixture with benzene.

The authors wish to express their grateful thanks to Dr. R. M. Kasliwal, Principal, S. M. S. Medical College, Jaipur, and to Professor Dr. R. C. Mehrotra, Head of the Chemistry Department, University of Rajasthan, Jaipur, for providing facilities.

The Effect of Thermal Treatment on the Electric Conductivity of Muscovite

By Michio ASHIDA, Teizo WATANABE and Wasaburo JONO

Department of Industrial Chemistry, Faculty of Engineering, Kobe University, Nada-ku, Kobe.

(Received January 25, 1966)

It is well known that large, well-crystallized sheets of muscovite are resistant to thermal decomposition at temperatures above 500°C. According to Grim and Bradley,[1] the differential thermal curves for coarse-grained muscovite showed only a single dehydration reaction, beginning at about 800°C with a peak at about 900°C. On the other hand, Roy[2] reported that the dehydration curve for muscovite showed a slow, relatively gradual loss of water up to about 800°C, without any restricted interval of large water loss, and that its differential thermal curve was characterized by the lack of a definite peak. Gaines and Vedder[3] demonstrated the loss of structual hydroxyl groups

1) R. E. Grim and W. F. Bradley, "X-ray Identification and Structure of the Clay Minerals," Mineralogical Society of Great Britain Monograph, (1951), p. 147.

2) R. Roy, *J. Am. Ceram. Soc.*, **32**, 202 (1949).

3) G. L. Gaines., Jr., and W. Vedder, *Nature*, **201**, 495 (1964).

by infrared spectroscopy when a thin sheet of muscovite was heated for a long enough time at 600°C. Arizumi and Maekawa[4] investigated the mechanism of gas evolution from muscovite in vacuo and suggested that there were two sources of gas evolution, one of which was a surface contamination and the other was the OH^- ion, a component of the crystal network. They reported that the temperature at which muscovite became opaque was between 720°C and 750°C, and that dehydration began to take place at the lower temperature. It is clear, therefore, that the dehydration process occurs in muscovite without a general destruction of the crystal lattice. The primary step in this process is the formation of water molecules from structural OH^- groups. Fripiat and Toussaint[5] investigated the dehydroxylation of kaolinite by conductivity measurements.

As is well known, muscovite is a good electric insulator. However, when muscovite sheets were heated at high temperatures in vacuo, it behaved characteristically in its conductivity. In this paper, the conductivity will be measured in order to explain some behavior associated with the dehydroxylation.

Experimental

A large well-crystallized sheet of muscovite was cut into pieces 20 mm. square. The thickness of the sheet was in the range from 0.05 to 0.1 mm. Aluminum metal was evaporated onto the freshly-cleaved surface as electrodes. For the surface electrical conductivity measurements, the distance between electrodes was 10 mm. in width and 0.5 mm. in length. For the volume conductivity measurements, electrodes were prepared on both planes of the muscovite sheet by the evaporation of metal. The diameter of the electrodes was 10 mm., and the distance from an electrode to the guard ring was 8 mm. The crystallographic principal axes of muscovite were determined in its basal plane by the use of a polarizing microscope. The muscovite sheets thus prepared were placed in a Pyrex glass tube of 30 mm. in diameter. The glass tube was wrapped with a grounded copper foil in order to keep it from the stray electric field and then inserted in an electric furnace. The conductivity was measured at a pressure of about 5×10^{-5} mmHg with a vibration-reed electrometer apparatus. Since the plate of methacrylic resin which was used as an insulator in the conductivity apparatus had a resistivity of about 10^{15} Ω, it was impossible to measure a higher resistivity than 10^{16} Ω·cm. for the specimen.

Results

The muscovite sheets were heated up to temperatures below 450°C, held at that temperature, and then cooled to room temperature in vacuo. The temperature dependencies of the surface and volume conductivities were measured by continuous heating and cooling. Figure 1 shows the change in the volume conductivity observed when the temperature of muscovite is increased and decreased.

4) T. Arizumi and S. Maekawa, *Oyo Butsuri*, **23**, 150 (1954).
5) J. J. Fripiat and F. Toussaint, *J. Phys. Chem.*, **67**, 30 (1963).

A linear increase of the log ρ versus the reciprocal absolute temperature curve was observed in the range from 150°C to 450°C. While the sheet was kept at a temperature lower than 300°C for one hour, the conductivity remained constant. The conductivity in the cooling process decreased in accordance with the same curve as that in the heating process. When the specimen was held at 400°C for one hour, the conductivity increased a little, while on cooling the curve decreased along the curve with a slope similar to that of the heating curve. In this case, the conductivites in the heating and cooling processes were of the same order, and the discrepancy between them was very slight. In contrast to the volume conductivity, the surface conductivity exhibited a characteristic behavior in the same range of temperatures. Figure 2 shows the changes in the surface conductivity along the a- and b-axes of muscovite caused by the thermal treatment. When a specimen was heated to 300°C, held at that temperature for one hour, and then cooled to room temperature, no apparent change was observed between the heating and cooling curves on the surface conductivity. On the contrary, it should be noted that the surface conductivity gradually increased and then became constant after about one hour while the specimen was kept at 400°C, and that the relatively high conductivity still remained after the cooling process. Although no discrepancy between the values obtained along the a-axis and those along the b-axis was observed in the heating curve, the conductivity along the b-axis increased considerably more than that along the a-axis while the specimen was kept at 400°C. The linear relations of the log ρ versus the reciprocal T curve in both cooling curves have similar inclinations, which are different from that in the heating curve. The activation energy was determined from the inclination to be 0.43—0.47 eV. for the former and about 1.08 eV. for the latter. This suggests that the surface conduction mechanism of muscovite was changed by the thermal treatment at 400°C.

Discussion

The crystal lattice of muscovite is characterized by the repetition of so-called subcells about 10 Å thick, with two sheets of oxygentetrahedron with a silicon or aluminum atom at the center, as is shown in Fig. 3. The triangular basal planes of tetrahedral sit on a plane of the cleavage face and are linked to one another to form a hexagonal network as a whole. Above each center of the hexagonal space formed by the six tetrahedra, a K^+ ion is located. On the other side of the layer, the centers of the hexagon defined by the tetrahedron apexes are filled with OH^- ions, forming a dioctahedral layer between two opposite-facing

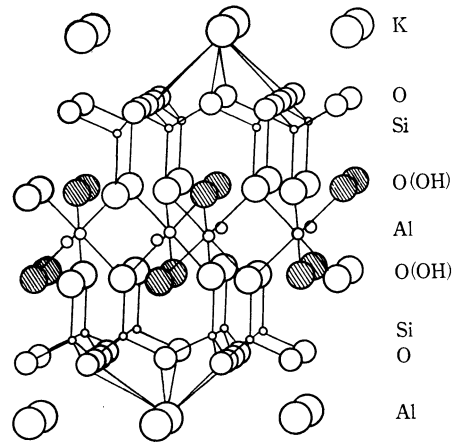

Fig. 3. Muscovite structure.

tetrahedron sheets. Although each layer has its own hexagonal symmetry, a monoclinic configuration is found in the subcell and a plane of symmetry passes through the OH^- ions perpendicularly to the layer. Tsuboi[6] and Vedder et al.[7,8] investigated the behavior of OH^- ions by infrared spectroscopy. Vedder and McDonald[7] concluded from the pleochroism of the OH^- stretching band that the vibrational transition moments are tilted out of the cleavage plane by about 16°. Their projection onto the cleavage plane makes an angle of about 32° with the b-axis. At 400°C, the surface conductivity along the a-axis was different from that along the b-axis. This finding suggested that the compositions included not only in the top layer but also in the subcells contribute to the surface conductivity. It is reasonable to postulate that the variation in muscovite structure occurred only in layers near the surface, since no apparent change was observed in the volume conductivity at this temperature.

Fripiat and Toussaint[5] observed that when kaolinite was heated, the process corresponding to a slow increase in conductivity appeared between 100°C and 360°C. They suggested that this process was due to the delocalization of protons which involve the free hydrid orbitals of octahedral oxygens. Finely-divided muscovite begins to lose its structural water at an appreciable rate at temperatures as low as 450°C (Ref. 2).

By taking these facts into account, the dehydroxylation of muscovite may be explained as follows. The protons in the dioctahedral layer increase the delocalization with a rise in the temperature up to 300°C, thus giving rise to a slow increase in the conductivity. When the temperature of muscovite

reaches about 400°C, a water molecule is formed from the structural hydroxyl group and the dehydroxylation of muscovite begins, without a general destruction of the crystal lattice by the diffusion of the water molecules. In this process, lattice defects which are caused in layers near the surface by dehydroxylation contribute to an increase in the surface conductivity. The anisotropy of the conductivity is assumed to be due to the anisotropic arrangement of hydroxyl ions in the crystal lattice.

The Pyrolysis of Organodisilanes

By Hideki SAKURAI, Ryongsu KOH, Akira HOSOMI and Makoto KUMADA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received February 3, 1966)

It has previously been reported[1] that hexamethyldisilane undergoes rearrangement at 600°C to give trimethyl(dimethylsilylmethyl)silane. The experiments described below will deal with the analysis of the products of this reaction, together with related investigations.

After hexamethyldisilane was passed slowly through a quartz tube heated at 600°C, the reaction products were collected in a trap immersed in a liquid-nitrogen bath. The careful examination of the reaction mixture by gas chromatography revealed that there were two main products, trimethylsilane (I) and trimethyl(dimethylsilylmethyl)-silane (II), along with unchanged hexamethyldisilane. The formation of these compounds is consistent with the reaction scheme we proposed earlier:

$$(CH_3)_3Si\text{–}Si(CH_3)_3 \rightarrow 2(CH_3)_3Si\cdot$$

$$(CH_3)_3Si\cdot + (CH_3)_3SiSi(CH_3)_3 \rightarrow (CH_3)_3SiH + (CH_3)_3SiSi(CH_3)_2CH_2\cdot \quad (2)$$

(I)

$$(CH_3)_3SiSi(CH_3)_2CH_2\cdot \rightarrow \cdot Si(CH_3)_2CH_2Si(CH_3)_3 \quad (3)$$

$$\cdot Si(CH_3)_2CH_2Si(CH_3)_3 + (CH_3)_3SiSi(CH_3)_3 \rightarrow (CH_3)_3SiCH_2Si(CH_3)_2H + (CH_3)_3SiSi(CH_3)_2CH_2\cdot \quad (4)$$

(II)

The ratio of the amount of II to that of I was found to be approximately 4 : 1 by gas chromatographic analysis. Accordingly, this value indicates that the average kinetic chain length of the reaction is about 4.

In this connection, a typical free radical reaction initiated by benzoyl peroxide in hexamethyldisilane was investigated at 80°C. The main products of the reaction between hexamethyldisilane and benzoyl peroxide were benzene, benzoic acid, 1, 2-bis(pentamethyldisilanyl)ethane (III), benzylpentamethyldisilane, and a small amount of an unidentified compound. No rearranged product, II, was formed. Therefore, in a solution at a low temperature, the pentamethyldisilanylmethyl radical does not undergo rearrangement as in the pyrolysis. Only dimerization was the main fate of this free radical.

$$2(CH_3)_3SiSi(CH_3)_2CH_2\cdot \rightarrow (CH_3)_3SiSi(CH_3)_2CH_2CH_2(CH_3)_2SiSi(CH_3)_3$$

(III)

Judging from this fact, the reaction 3 seems to be rate-determining and to require a higher activation energy than the other processes.

Finally, it is interesting to note that 1, 2-diphenyltetramethyldisilane did not undergo rearrangement at 600°C. The recovered material was essentially as pure as the starting material. Apparently, the substitution of phenyl groups increases the dissociation energy of the silicon-silicon bond.

Experimental

Trimethylsilane (I).—This was prepared from trimethylchlorosilane by reduction with lithium aluminum hydride in di-*n*-butyl ether.

Trimethyl(dimethylsilylmethyl)silane (II).—This was prepared from trimethyl(dimethylchlorosilylmethyl)silane by reduction with lithium aluminum hydride in ether. To a stirred suspension of 4.4 g. (0.11 mol.) of lithium aluminum hydride in 200 ml. of dry ether, there was added, drop by drop, 25 g. (0.138 mol.) of trimethyl(dimethylchlorosilylmethyl)-silane dissolved in 100 ml. of ether. During the addition, a gentle reflux of the ether was observed to take place. The reaction mixture was heated to reflux for 7 hr. and then submitted to distillation under reduced pressure. After the solvent had been removed, the mixture was fractionally distilled to give 12 g. (59%)

1) K. Shiina and M. Kumada, *J. Org. Chem.*, **23**, 139 (1958).

of II boiling at 118°C, n_D^{20} 1.4168. Topchiev et al.[2] prepared II from dichloro(trichlorosilylmethyl)silane, b. p. 119—20°C, n_D^{20} 1.4158.

The Pyrolysis of Hexamethyldisilane.—Hexamethyldisilane (40 g., 0.27 mol.) was passed slowly through a 3.7×50 cm. quartz tube mounted in a thermostatted furnace at 600°C. The reaction products, with unchanged hexamethyldisilane, were collected in a trap which was directly linked with the quartz tube and immersed in a liquid-nitrogen bath. The amount of material recovered was 38 g. The mixture was then analyzed on a gas chromatographic column packed with Apiezon L on Celite 545. The components were eluted on this column in the order of I (4.3 mol.%), a trace of an unidentified component, hexamethyldisilane (78.2 mol.%), II (17.5 mol.%), and a trace of another unidentified component.

The Attempted Pyrolysis of 1, 2-Diphenyltetramethyldisilane.—Diphenyltetramethyldisilane (20 g.; 0.074 mol.) was evaporated at reduced pressure (2 mmHg) and then passed slowly through the quartz tube described above at 600°C. The material thus recovered (17 g.) was analyzed on a gas chromatographic column packed with Apiezon L on Celite 545; this disclosed a single peak of the starting material.

The Decomposition of Benzoyl Peroxide in Hexamethyldisilane.—To a 200 ml. four-necked flask equipped with a mechanical stirrer, a reflux condenser, a thermometer, and a gas inlet tube, there were added 15 g. (0.062 mol.) of benzoyl peroxide and 100 g. (0.683 mol.) of hexamethyldisilane. The mixture was then heated at 100°C, stirred for 6 hr. under a slow stream of nitrogen, and cooled. The reaction mixture was washed with a saturated sodium bicarbonate solution and with water. The organic layer was dried and subjected to distillation. The fraction boiling at temperatures up to 110°C and that boiling at 110—113°C were mainly composed of recovered hexamethyldisilane and a small amount of benzene. The fraction boiling over the range from 100 to 120°C at 18 mmHg was found to consist mainly of 1, 2-bis(pentamethyldisilanylmethyl)ethane,[3] plus a small amount of benzylpentamethyldisilane. Both compounds were separated by gas chromatography (Silicone DC 550 on Celite 545) and identified by comparing their infrared spectra and retention times with those of authentic samples.

The research was supported in part by a grant-in-aid of the Ministry of Education and by the Kawakami Memorial Foundation, to both of which institutions the authors' thanks are due.

The Electron Spin Resonance of Irradiated Single Crystals of Dichloroacetamide

By Michio KASHIWAGI

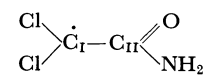
Basic Research Laboratories, Toyo Rayon Company, Ltd., Kamakura

(Received March 5, 1966)

Although there have been many ESR studies of irradiated single crystals, only Pooley and Whiffen[1] have reported the chlorine coupling constant in organic radicals. We will here report the chlorine coupling found in X-irradiated single crystals of dichloroacetamide. Simultaneously we will report on the hyperfine couplings for N and H nuclei of the amide group, which have not been investigated so far.

Single crystals of dichloroacetamide were prepared from methanol solutions by slow evaporation. The crystals were prismatic, with a well-developed face. An orthogonal axis system, xyz, was defined for the sake of convenience. The x and the y axes were selected in the developed face, with the x axis parallel to the elongated direction of the crystal. The y axis was found by ESR measurements to be along the monoclinic unique axis.[2] The crystals were X-irradiated at room temperature to 1 Mrad. The ESR spectra of the irradiated crystals were measured at 9.5 kMc./sec.

Figure 1 shows a typical ESR spectrum of the irradiated single crystals of dichloroacetamide. The spectrum is a septet with an ill-resolved substructure and with an intensity ratio of approximately 1 : 2 : 3 : 4 : 3 : 2 : 1. The septet is to be expected for a radical with two equally coupling chlorine (spin 3/2) nuclei; this indicates that the radicals produced in dichloroacetamide are of the form;



A similar radical, $F_2C_IC_{II}ONH_2$, was found in

TABLE I. PRINCIPAL VALUES AND DIRECTION COSINES FOR A^{Cl} OF THE RADICAL Cl_2CCONH_2

Principal values		Direction cosines with respect to the xyz axis system		
A_1^{Cl}	3G	0.96	$\mp$0.20	−0.20
A_2^{Cl}	5G	0.02	$\pm$0.75	−0.66
A_3^{Cl}	14G	0.28	$\pm$0.63	0.72

irradiated trifluoroacetamide,[3] where the radial is planar and where the F_2CCON skeleton is in the nodal plane of a π orbital on C_I. The fluorine coupling constant has a cylindrical symmetry, with the cylindrical axis perpendicular to the radical plane. A similar situation may be anticipated in the case of dichloroacetamide. However, the chlorine quadrapole coupling gives rise to a breakdown in the usual selection rule, $\Delta M_I=0$; this makes it difficult to analyze the ESR spectra. Measurements show that the ESR spectra exhibit a considerably different appearance from the simple septet when the coupling constant of the chlorine is smaller than about 7 *G*.[4] A crude estimation has been made of the principal values of the coupling constant by a least-squares analysis of the angular dependence of coupling constants larger than 7 *G*. The results are shown in Table I; these results can be used in considering the radical orientation, but they are too rough to make it possible to discuss the electronic structure of the radical in detail.

The substructure of the septet is resolved into a quintet for a magnetic field perpendicular to the radical plane. The substructure is different from the superposition of the hyperfine structure due to ^{35}Cl and ^{37}C.[5] This can well be explained by equal couplings of one N and two H nuclei of the amide group, as is shown in Fig. 2. There is some delocalization of the unpaired electron in the π system from the carbon C_I to the nitrogen, and the unpaired electron would couple with N and H nuclei. The calculation of Hückel MO[6] shows that the spin density on the nitrogen of the amide group increases in the order of: F_2CCONH_2[3] < $Cl_2CCONH_2 \approx FHCCONH_2$[7] < R_2CCONH_2 (R:H, CH_2 or CH_3). This indicates that $FHCCONH_2$ should give N and H couplings with the same order of magnitude as those in Cl_2CCONH_2. Moreover, R_2CCONH_2 and F_2CCONH_2 should give couplings with larger and smaller magnitudes respectively. The experimental data[3,6,8] are consistent with the prediction; this supports the preceding mechansim of the N and H couplings. The couplings will be treated in detail in discussing irradiated succinamide.[8]

3) R. J. Lontz and W. Gordy, *J. Chem. Phys.*, **37**, 1357 (1962). According to this paper, the N and H couplings are too small to be detected.

4) The quadrapole effect is very intense when the quadrapole coupling is of a magnitude comparable to that of the hyperfine coupling. From this fact it may be inferred that the quadrapole coupling, $3eqQ/4I(2I-1)$, is$\sim 7G$(20 Mc.) and that, therefore, $eqQ=\sim 80$ Mc. in this radical.

SHORT COMMUNICATIONS

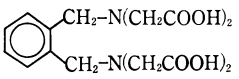
A New Chelating Agent, α, α'-Diamino-*o*-xylene-*N*, *N*, *N'*, *N'*-tetraacetic Acid

By Takeshi ANDO and Keihei UENO*

The Chemical Laboratory, General Education Department, Kyushu University, Otsubo-Machi, Fukuoka

(Received June 15, 1966)

A large number of ethylenediaminetetraacetic acid (EDTA) derivatives have been known in the literatures, and it is therefore, possible to study the influence of electronic and steric variations on their chelating behaviors toward metal ions. However not many informations are available about the EDTA derivatives containing the benzene ring. We are now successful to synthesize α, α'-diamino-*o*-xylene-*N*, *N*, *N'*, *N'*-tetraacetic acid, (*o*-XyDTA) which is a new complexane containing benzene ring.



The tetramethyl ester of this acid was prepared by the condensation of α, α'-dibromo-*o*-xylene (0.01 mol.) with iminodiacetic acid dimethyl ester (0.06 mol.) in dry acetone at 70—80°C, with refluxing for 8 hr. After the reaction, the precipitated iminodiacetic acid dimethyl ester hydrobromide was filtered off and the crude tetra ester was obtained from the filtrate after distilling off acetone under reduced pressure. The ester was hydrolyzed with 10% sodium hydroxide at 70°C for 8 hours. After cooling, the pH of the solution was adjusted to about 1. The precipitated crude acid was recrystallized from hot water: yield about 20%. It decomposed at 226—229°C.

Found: C, 52.27; H, 5.53; N, 7.64%.[1] Calcd. for $C_{16}H_{20}N_2O_8$: C, 52.17; H, 5.53; N, 7.64%.

Pure acid is slightly soluble in water (about 0.4 g./1000 ml. H_2O).

The acid dissociation constants were determined by the potentiometric method at 25°C, in a medium of ionic strength of 0.10, with sodium hydroxide as a titrant. The titration curve is essentially the same as that of EDTA. The constants of this acid were calculated by the method of Schwarzenbach et al.[2] except that an algebraic method of solution was used instead of a graphical one. The results are $pk_1=2.0$: $pk_2=2.71$: $pk_3=5.99$: $pk_4=10.88$. The values of k_1, k_2, k_3 are similar to those of EDTA, but k_4 is fairly less than EDTA.

This acid showed similar chelating behavior to EDTA on the qualitative test using metal indicators such as Erio T (pH 10, Ca, Mg) or xylenol Orange (pH 5—6, Zn).

The chelating behavior toward metal ions in aqueous solution is now under study. The results of the detailed investigation on this ligand will be published later.

On the Hyperfine Structure of the ESR Spectra of Copper(II) Complexes

By Hiroshi Yokoi and Taro Isobe

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received May 17, 1966)

The solvent effects on the ESR spectra of several copper(II) complexes have been investigated in order to examine the theoretical basis of the ESR of copper(II) complexes. When planar 4-coordinated copper(II) complexes are dissolved in basic solvent, one or two of the basic solvent molecules are known to coordinate to the complexes along the axis normal to the molecular plane; spectroscopical studies of these phenomena have been carried out by several authors.[1] For this work the ESR spectra of cupric bis-acetylacetone chelate (I) and cupric bis-acetylacetone-ethylenediimine chelate (II) were measured in various solvents; the ESR spectra of II in all the solvents used show a clearly-resolved extra hyperfine structure due to the two nitrogen nuclei of ligand. The magnetic parameters determined are listed in Table I.

It is shown in Table I that the g values increase and the absolute A values decrease remarkably when the basicity of the solvent used is increased. The odd electron is placed in the antibonding B_{1g} molecular orbital, in which the coefficient of $d_{x^2-y^2}$ is taken as α. The values of α^2 were evaluated from copper hyperfine interaction by the usual procedures;[2] they are listed in the last column of Table I, from which it may be seen that α^2 decreases as the solvent basicity increases. However, it is reasonable to consider that α^2 should increase in basic solvents for the following reasons: First, the covalency of the metal-ligand bonding should decrease upon the coordination of basic solvent molecules because of the repulsion between the 3d electrons and the electrons which come from the solvent molecules, and the increase of α^2 is theoretically consistent with the tendency for $g_{\parallel}$ to increase. Second, the extra hyperfine interaction energy of the ligand nitrogen nuclei in II decreases in basic solvent; this fact definitely indicates that α^2 increases in basic solvents. It may be concluded from the above discussion that there is some uncertainty as to the theoretical basis of the ESR of copper(II) complexes.

The Fermi contact term, k_0, arises from the spin polarization of s-electrons and has been assumed to be constant.[3] In the case of planar copper(II) complexes in basic solvents, the 4s-orbital of the copper atom interacts with the σ-orbitals of solvent molecules; the degree of their mixing depends on the basicity of the solvents. Therefore, the spin polarization of the 4s-electrons contributes to the value of k_0 to a varying extent, and k_0 is not exactly constant. It seems that the above mentioned uncertainty can be ascribed to this property of k_0. Recently, Kivelson and Lee reported k_0 to vary in vanadyl complexes.[4] Some other copper(II) complexes show the same solvent effects as the complexes under discussion. Details will be published elsewhere.

Table I. Magnetic[a] and bonding parameters

Copper complex	Solvent[b]	$g_{\parallel}$	$g_{\perp}$	$A_{\parallel}\times10^4$ (cm^{-1})	$A_{\perp}\times10^4$ (cm^{-1})	$A_N\times10^4$ (cm^{-1})	α^2
I	A[c]	2.256	2.056	197	22		0.86
	B	2.309	2.070	167	14		0.84
	C	2.322	2.071	158	14		0.83
II	A	2.191	2.05	207		12.9	0.83
	B	2.218	2.06	195		12.2	0.82
	C	2.230	2.06	186		12.2	0.81

a) All ESR spectra were measured in ca. 0.01 M solution at 77°K.

b) Solvent A: toluene. Solvent B: 10% pyridine, 90% toluene. Solvent C: 10% piperidine, 90% toluene. Magnetic parameters did not depend on the mixing ratio of two solvents in solvents B and C.

c) Although the solubility of I in toluene is very small, the magnetic parameters of I in toluene could be determired from the ESR spectrum measured in toluene-chloroform solvent. Details will be published elsewhere.

The Novel Transesterification of Quaternary Ammonium Dithiocarbonates and Thiolesters

By Hiroshi YOSHIDA, Saburo INOKAWA and Tsuyoshi OGATA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu

(Received July 6, 1966)

It is well known that transesterification occurs when an ester is heated with an alcohol in the presence of acid or a base.

In the previous papers[1] the present authors have reported that methylxanthates reacted with trimethylamine at room temperature to form quaternary ammonium dithiocarbonates, as in Eq. 1.

$$MeOCS_2R + Me_3N \rightarrow \underset{(I)}{Me_4\overset{+}{N}\overset{-}{S}COSR} \qquad (1)$$

When the ammonium salts were mixed with esters in acetonitrile, transesterification was observed; this reaction will be described in this communication.

Reactions were carried out in acetonitrile homogeneously for about 20 min. at room temperature. After the solvent had been evaporated in vacuo, the residue was separated into an ether-soluble part (A) and an insoluble part (B). A was a mixture of esters, and B was a mixture of quaternary ammonium dithiocarbonates. B was then treated with methyl iodides, as has previously been reported.[1] The products were identified through comparison with authentic samples via their gas chromatographic retention times (silicone grease column, 130—180°C). The results are shown below.

$$\left.\begin{array}{l} I(R=Me) + MeSCOSEt^{1a)} \\ I(R=Et) + MeSCOSMe^{1a)} \\ I(R=Et) + MeSCOSEt \end{array}\right\} \rightarrow$$

$$MeSCOSMe + MeSCOSEt + EtSCOSEt + I(R=Me) + I(R=Et) \qquad (2)$$

$$I(R=Et) + MeSCSSMe^{2)} \rightarrow MeSCSSMe + MeSCSSEt^{3)} + I(R=Me) + I(R=Et) \qquad (3)$$

$$I(R=Et) + C_6H_5COSMe^{4)} \rightarrow C_6H_5COSMe + C_6H_5COSEt^{4)} + I(R=Me) + I(R=Et) \qquad (4)$$

Reactions 2—4 showed that almost all of the ethyl radicals of I(R=Et) were transferred to the esters and that a large amount of I(R=Me) was found in the residual ammonium salts. Although thiolesters reacted easily with I(R=Et), esters such as methyl benzoate, dimethyl carbonate[5] did not react under similar reaction conditions.

These experimental results show that I(R=Me) is more stable than I(R=Et), that carbonyl-SR bond fisson may occur, and that then mercapto groups may exchange with each other.

Rotatory Dispersions and Circular Dichroisms of Platinum(II) Complexes

By Haruko Ito (née Sugi), Junnosuke Fujita and Kazuo Saito

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received July 27, 1966)

For square-planar complexes, various schemes for orbital energies have been proposed (Fig. 1), but they all make the practical assignment of the absorption bands of platinum(II) complexes difficult. Several attempts have been made to overcome this problem,[1] but it still remains unsolved.

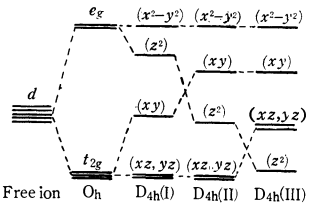

Fig. 1. Probable modes of orbital splitting in square-planar D_{4h} complex.

Table I. The symmetries of the excited states, the magnetic moment and the electric moment brought about by stretching vibrations (D_{4h})

	Excited configuration	Magnetic polarization	Vibronic (stretching) polarization
$d_{xy} \rightarrow d_{x^2-y^2}$	A_{2g}	μ_z	r_x, r_y
$d_{xz}, d_{yz} \rightarrow d_{x^2-y^2}$	E_g	μ_x, μ_y	r_x, r_y, r_z
$d_{z^2} \rightarrow d_{x^2-y^2}$	B_{1g}	—	r_x, r_y

We have measured the R. D. and C. D. spectra of platinum(II) complexes containing *l*-propylenediamine and studied the splitting of the d orbitals on the basis of an analysis of these spectra. Table I shows the symmetries of the excited states, the magnetic moment, and the electric moment brought about by stretching vibrations for a planar complex with D_{4h} symmetry.

It can be seen that only the $d_{xy} \rightarrow d_{x^2-y^2}$ and d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$ transitions have magnetic moments. In the former transition, however, the electric moment and the magnetic moment are perpendicular to each other. This selection rule still holds for symmetries lower than D_{4h}, so far as the stretching vibration alone is considered. Therefore, only the transition to the E_g state should be optically active.

The maxima of the absorption frequencies and the $\varepsilon_l - \varepsilon_r$ values are shown in Table II. The C. D. spectra due to the vicinal effects of propylenediamine have positive signs in all the complexes studied. The fact that only the bands 2 and 4 are optically active supports the idea that both transitions are $A_{1g} \rightarrow E_g$ ($d_{xz}, d_{yz} \rightarrow d_{x^2-y^2}$), the lower frequency band involving the triplet, and the other, the singlet state. The ordering of D_{4h}(III) in Fig. 1 can account for these results. The rotatory strength of [Pt *l*-pn$_2$]Cl$_2$ is just twice that of [Pt *l*-pn en]Cl$_2$. This indicates that the magnitude of the Cotton effect due to the vicinal effect is proportional to the number of optically active ligands; there is no appreciable interaction between the ligands.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2057—2062 (1966)

The Effect of Substituents on the Half-Wave Potential of the Polarographic Reduction of Pyridine *N*-Oxide Derivatives[1]

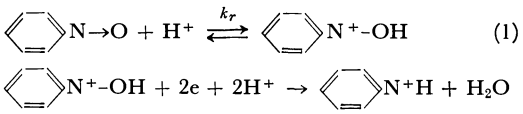
By Tanekazu KUBOTA and Hiroshi MIYAZAKI

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received March 23, 1965)

Polarograms of twenty-three pyridine *N*-oxide derivatives substituted at γ- and β-positions were extensively measured at various pH's. The half-wave reduction potential, $E_{1/2}$, was expressed by the form $-E_{1/2}=a\,[\mathrm{pH}]+b$. The wave height due to the reduction of the $\rangle N\rightarrow O$ group decreased with an increase in the pH in a pH region over ~6. This phenomenon was common to all the compounds studied here; it was thought to be useful in identifying an aromatic *N*-oxide group by the polarographic method. The $E_{1/2}$ plot against Hammett's σ value of the substituent satisfied a linear relation well, and the slope of Hammett's ρ value was positive. This indicates that the reduction process is nucleophilic. The linear relation was explained qualitatively on the basis of the MO theory by applying the second-order perturbation method.

In a previous paper[2] concerning the pH dependence of the polarographic reduction wave of pyridine *N*-oxide, we showed that the reduction wave is actually due to the 2-electron reduction of the protonated *N*-oxide; we also determined the rate constant, k_r; in the proton addition process (1) using the equation derived by Koutecky[3] and by Matsuda[4]:



(1)

In the present study, polarographic measurements will be extended to twenty-two substituted pyridine *N*-oxides, and the relationship between their half-wave potential values ($E_{1/2}$) and Hammett's substituent constants (σ) will be discussed in terms of the lowest vacant MO energy of the substituted pyridine *N*-oxides and their protonated species predicted by the second-order perturbation method.

Experimental

Measurements.—The polarograms were recorded with two Yanagimoto polarographs, Model PA-102 and PB-4. The pH values were determined with a Beckman pH meter, Model G. The capillaries used for the dropping mercury electrode had the following values of m and t at an open circuit: (A) $m=1.23$ mg./sec. and $t=4.35$ sec. at $h=65$ cm., and (B) $m=0.879$ mg./sec. and $t=4.48$ sec. at $h=70$ cm. Capillary A was used in measurements with compounds I, IV, V, VI, and VII, and capillary B, with the other eighteen compounds. All the polarographic measurements were made at 25 ± 0.1°C in a suitable buffer solution after bubbling purified nitrogen in for about 10 min. in order to remove the oxygen dissolved in the solution. The buffer solutions were the same as those employed in the previous report.[2] The ionic strength of the sample solution was adjusted to 0.45 by the addition of an appropriate amount of sodium chloride. A saturated calomel electrode was used as the external reference electrode. Measurements were made with about a 5×10^{-4} mol./l. solution containing an accurately-weighed sample, and the values obtained from three separate measurements were averaged.

Materials.—The compounds investigated in the present study are listed in Table I. Compounds II, VIII, XII, XIV, and XXIII were kindly supplied by Dr. Sadazi Kaziwara of our laboratory, and III, by Professor Yutaka Mori of Osaka Gakugei University. Compounds IV, V, IX, and X were synthesized by respective substitution reactions[5] from γ-nitropyridine *N*-oxide (XIII), which had been prepared by the nitration of pyridine *N*-oxide.[5] Compounds I, VI, VII, XI, XV, XVI, XVII, XVIII, XIX, XX, XXI, and XXII were prepared from the corresponding substituted pyridines by hydrogen peroxide oxidation in acetic acid. β-Fluoro-,[6] β-chloro,[7] and β-bromo[7] pyridines were prepared according to the literature, while β-methoxypyridine was prepared by the decomposition of diazotized β-aminopyridine in the presence of methanol.*1 The other substituted pyridines used for the above-mentioned *N*-oxide preparations were commercial products and were purified by a conventional method. All the compounds used for polarographic measurements were purified by at least three recrystallizations, and their purities were checked

* Two waves were observed: −0.204 V. and −1.436 V. attributed to reduction steps of NO_2 and $\rangle N\rightarrow O$ groups, respectively.

by ultraviolet and infrared spectral methods and by elementary analyses.

Results and Discussion

The Polarographic Behavior of Substituted Pyridine *N*-Oxides.—First let us discuss the polarographic behavior of pyridine *N*-oxides substituted by NH_2, NHOH, OCH_3, OC_2H_5, CH_3, C_2H_5, and $NHCOCH_3$ at the γ-position and by NH_2, OCH_3, CH_3, C_2H_5, $NHCOCH_3$ and F at the β-position. A typical example of their polarograms is shown in Fig. 1 (b). All the compounds of this group showed a one-step reduction wave in the pH region studied (pH > 1.0). The wave height corresponded to a 2-electron reduction in an acidic medium according to the Ilkovic equation, using the same constants as those used in the previous paper,[2] but the wave decreased rapidly with an increase in pH in the pH range over ~6. These phenomena are just the same as those observed in the reduction of pyridine *N*-oxide (I),[2] whose polarogram is also shown in Fig. 1 (a). Thus the wave corresponds to the 2-electron reduction of the protonated N→O group, and the behavior observed in the pH region over ~6 is probably due to the wave including the kinetic current arising from the proton addition to the N→O group in the molecules.[2] This type of pH dependence was also observed with all the other substituted pyridine *N*-oxides studied here and with some nitrone derivatives;[8] hence it may be thought to be characteristic of the reduction of aromatic *N*-oxides, and it would be very useful for the identification of an aromatic *N*→O group by the polarographic method. The variation in the half-wave potential, $E_{1/2}$, with pH can be expressed by Eq. 2 in the pH region from 1 to 8 with all the compounds of this group except for the two amino derivatives.*2 The slopes, *a*, were almost all of the same order, as can be seen from Table II.

$$-E_{1/2} = a[\mathrm{pH}] + b \qquad (2)$$

In the polarograms of γ-chloro- and γ-bromopyridine *N*-oxides, the maximum shown by the

*2 We obtained two straight lines, crossing at pH = 2.60 and 4.50 for II and XIV respectively. It should be noted that these values do not coincide with the pK_a's values (3.65 and 1.47 respectively).[9] At the present time, no satisfactory explanation for this fact can be given.

a : Pyridine *N*-oxide (I) (5.28×10^{-4} mol./l.)
b : β-$NHCOCH_3$ derivative (XVIII) (4.40×10^{-4} mol./l.)
c : β-Cl derivative (XX) (4.78×10^{-4} mol./l.)
d : γ-Br derivative (X) (5.19×10^{-4} mol./l., 0.005% gelatin added)
The dotted line in (d) represents the maximum wave which always appeared in reduction of γ-halogen derivatives in measurements without gelatin.

dotted line in Fig. 1 (d) was always observed over a wide pH range, although this maximum disappeared upon the addition of small amount (0.005%) of gelatin to the electrolytic solution. It should be noted, however, that the wave height of the γ-substituted halogen compounds was a little higher than that for the compounds discussed in the foregoing paragraph. On the other hand, no maximum was found with the β-chloro or the β-bromo derivatives. The polarograms of the former are shown in Fig. 1(c). The pH dependences of $E_{1/2}$ of the four halogen-substituted pyridine *N*-oxides also satisfied Eq. 2.

Cyano and carboethoxy derivatives (XI, XII, XXII and XXIII) exhibited somewhat different polarographic behavior. Thus, the polarograms of these compounds always showed two-step reduction waves.*3 The pH dependence of the first wave height was similar to that for the common

*3 Two waves also appeared in the polarographic reduction of halogen-substituted pyridine *N*-oxides, but the separation of the two was ambiguous.

pyridine *N*-oxides discussed earlier, while the second wave height held almost unchanged over a wide pH range. Therefore, only one wave, which corresponds to the second one in the acidic solution measurements, was observed in measurements at a higher pH value. The situation may be demonstrated well by Fig. 2. It would be reasonable to identify the first wave as the reduction of the protonated cation ($\rangle N^+-OH$) on the basis of its

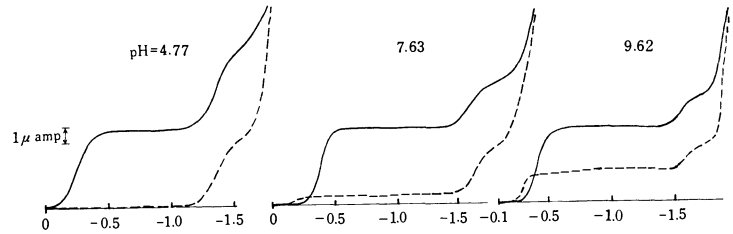

Fig. 3. Polarograms of γ-NO_2 (5.49×10^{-4} mol./l., 0.005% gelatin added, ——) and γ-NHOH (4.73×10^{-4} mol./l., ----) derivatives of pyridine *N*-oxide.

pH dependence and of the relation of its $E_{1/2}$ value to Hammett's σ, which will be discussed below. A plausible assignment of the second wave can not be attained at the present time. It was difficult to establish the relationship between $E_{1/2}$ and pH for XII in the lower pH region because of the ambiguous separation of the two waves, but a good linear plot was obtained in the 4—9 pH region, where the separation was clear.

The polarogram of γ-nitropyridine *N*-oxide (XIII) shown in Fig. 3 is of special interest. It was found that the compound shows two reduction waves, the first of which corresponds to an approximately four-electron reduction on the basis of the Ilkovic equation,[2] and that its wave height is almost independent of the pH value. On the other hand, the second wave height decreased as the pH increased. This two-step reduction can be reasonably explained as follows. At first the nitro group of the compound is reduced to NHOH by the first 4-electron reduction, and then the γ-hydroxyaminopyridine *N*-oxide (III) formed is subjected to $\rangle$N→O-group reduction. This assumption is based on the facts that: (i) the second reduction wave of the nitro derivative (XIII) appeared at nearly the same $E_{1/2}$ value as that of the hydroxyamino derivative (III), and (ii) the pH dependence of its wave height was a typical one associated with the $\rangle$N→O-group reduction discussed before. Moreover the $E_{1/2}$-σ plot falls right on the straight line in Fig. 4 if we plot the $E_{1/2}$ of the second wave of XIII against the σ value for γ-NHOH instead of that for NO_2, a fact suggesting that the second reduction wave of XIII is that of III to γ-hydroxyaminopyridine. However, an alternative possibility for the intermediate cannot be ruled out, for some other chemical evidence on pyridine *N*-oxide[5] would suggest that the intermediate produced by the first 4-electron reduction is 4, 4'-azopyridine 1, 1'-dioxide. However, the polarographic measurement of this azo compound, m. p. 246°C (decomp.); (5.09×10^{-4} mol./l., 0.005% gelatin added) showed two reduction waves. One was a wave of $E_{1/2}=-1.266$ V., and the limiting current was $i_l=3.79$ μamp. at pH=4.80, both $E_{1/2}$ and i_l being pH-dependent, and i_l decreased in the alkaline region. The other was a wave at about −0.01 V. at pH 4.80 continuing from an anodic wave. The former wave may be due to the reduction of an *N*-oxide group, but no further conclusive discussion can be made, since Hammett's σ values of the *p*-azo group are not known.*4

The Relationship between the Reduction Potentials of Substituted Pyridine *N*-Oxides and Hammett's σ Constants.—The plotting of $E_{1/2}$ versus Hemmett's σ constant of substituted pyridine *N*-oxides is of special interest in understanding the effect of substituents on $E_{1/2}$ and in elucidating the reduction mechanism.

As is apparent from Table II, the pH dependence of $E_{1/2}$ is nearly of the same order, and so we would expect straight lines with roughly equal slopes for the above plotting made at different pH's. Table I and Table III show the $E_{1/2}$ values observed at pH=5.0 and the selected σ values, cited mainly from Jaffé's review,[10] repectively. The plots of $E_{1/2}$ at pH=5.0 vs. σ are depicted in Fig. 4, where we can see that a good linear relation holds between them. The linear relation was also obtained for the values at different pH's, as had been expected. The slopes, that is, the ρ's of Hammett's equation, are: +0.457, 0.495 and 0.584 at pH values of 3.0, 4.0 and 5.0 respectively.

The plot for γ-NH_2 using the value of $\sigma=-0.66$ derived by Jaffé[10] deviated largely from the straight line in Fig. 4; the reduction actually took place at a more positive potential than that to be expected from the σ value. Zuman[11] found a similar trend of the *p*-NH_2 value in the polarographic reduction of other systems, and he set σ as −0.13 in order to fit the polarographic reduction potential data. This σ value is better than Jaffé's, −0.66, for the present system, but it is not close enough

*4 In the meanwhile it would be worthwhile to point out that the γ-NHOH derivative (III) showed two waves in the alkaline region (see Fig. 3, the dotted curves). The first wave may be due to an azo-type compound formed from III in an alkaline solution.[5] In fact, the solution of III becomes more yellowish at a higher pH value.

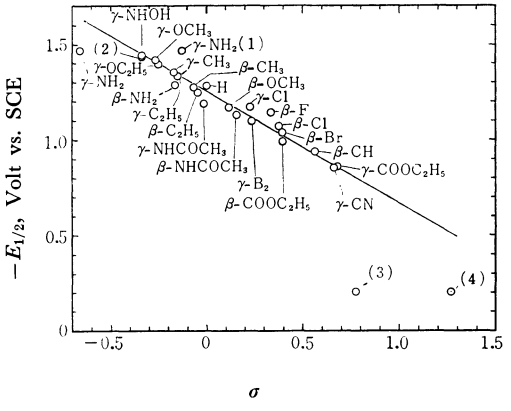

Fig. 4. The plot of $E_{1/2}$ against Hammett's σ. The points indicated by 1, 2, 3 and 4 represent, respectively, the plots of $E_{1/2}$ for II against Zuman's σ of γ-NH_2 (point 1), $E_{1/2}$ for the second wave of XIII against σ of γ-NHOH (point 2), and $E_{1/2}$ for the first wave of XIII against σ (point 3) and σ^- (point 4) of γ-NO_2 group.

to fit straight line, as do the other substituents. Another exceptional case is that of an NO_2 group. We can see from Fig. 4 that the plots of $E_{1/2}$'s corresponding to the first and the second waves of γ-nitropyridine *N*-oxide deviate eminently from the straight line, regardless of the choice of convertional σ or σ^- values for the γ-NO_2 group. This situation has been explained above.

Now it should be noted that the ρ value is positive. This means that the more electron-releasing a substituent is, the more negative is the $E_{1/2}$ value. From this we can say that the first process which occurred on the cathode was an electron transfer from a dropping-mercury electrode to the active center of the molecule to be reduced ($\rangle N^+$-OH), in which process the electron on the dropping mercury electrode acted as a nucleophilic reagent. The same conclusion was also drawn by Zuman for other systems.[11]

A Consideration of the Relationship between $E_{1/2}$ and Hammett's σ in Terms of the Lowest Vacant MO Energy Qualitatively Predicted by the Second-Order Perturbation Method.—It would be noteworthy if we could point out that the MO theory gives some basis for the interpretation of the above-mentioned relationship between $E_{1/2}$ and Hammett's σ, as well as of the well-known relationship between $E_{1/2}$ and the lowest vacant orbital energy.

For the sake of convenience, a substitued pyridine oxide is divided into two composite systems, as is shown in Fig. 5, where R and S represent a pyridine oxide part and a substituent located at the β or γ position*5 respectively. If we pick substituents having only one π-MO, such as CH_3, OCH_3, or NH_2, the lowest vacant orbital energy, E_{iR}, of pyridine oxide will change to E_{iR} according to Eq. 3, which was derived by the second-order perturbation mehtod;[12]

$$E_{iR} = E^{\circ}_{iR} + \frac{(C_{iR})^2\beta^2_{r-s}}{E^{\circ}_{iR} - E^{\circ}_{S}} \qquad (3)$$

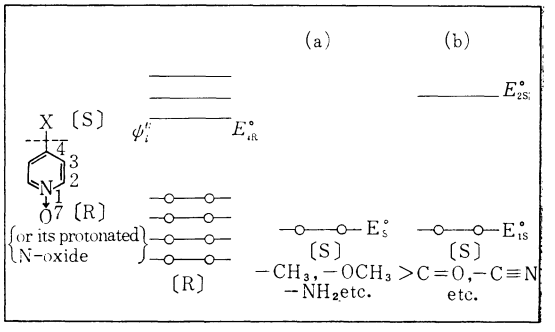

Fig. 5. Schematic diagram of MO for substituted pyridine *N*-oxides.

*5 The atom at which the substituent is attached is designated as r.

12) K. Higashi and H. Baba, "Quantum Organic Chemistry," Asakura Publishing Co., Tokyo (1956), p. 164 (in Japanese).

Here C_{iR}, β_{r-s}, and E_S° represent, respectively, the coefficient on the atom r in MO ϕ_i, the resonance integral between the atom r in a pyridine oxide part and the atom s in a substituent, and the energy of the highest-filled MO of the substituent. As β_{r-s} can be assumed to be a constant as the first approximation, the smaller the $|E_S^\circ|$ value or the larger the $|C_{ir}|$ value is, the smaller is the $|E_{iR}|$.*6 If we use the naive MO's parameter, δ in our discussion,*6 we can say that $E_{1/2}$ should move towards more negative values with a decrease in the δ of the substituent.[13] The order of estimated δ values appearing in the literature[14] is $CH_3>OH—OR>NH_2—NR_2$; therefore, the order of $-E_{1/2}$ should be the reverse. This predicted order of $-E_{1/2}$, $NH_2>OCH_3>CH_3$ agrees with the order predicted from σ values using Fig. 4. However, for the case of halogen substituents, a similar teatment was not successful, probably because of their fairly large σ inductive effects, as well as because of intramolecular charge transfer from MO's of R to, for example, the 3-d atomic orbital of chlorine. These electron-withdrawing effects would be a reason why halogens have positive values of Hammett's σ's and why halogen-substituted pyridine oxides showed an easier reduction.

Let us now consider the term C_{ir}. Our previous MO calculations[15] on pyridine oxide and its proton addition compound always resulted in a larger coefficient on the 4-position than on the 3-position as to the lowest vacant MO (symmetry b_2); $|C_4|>|C_3|$. This suggests that the substituted pyridine oxide at the 4-position should have a larger $-E_{1/2}$ value than that at the 3-position for the same substituent. This prediction agreed with the observed $E_{1/2}$ data.

For a substituent having two or more π-MO's, like $>C=O$, $-C\equiv N$, etc., Eq. 3 is rewritten as:

$$E_{iR} = E_{iR}^\circ + \sum_{j=1}^{n} \frac{(C_{ir}\cdot C_{js})^2\cdot\beta_{rS}^2}{E_{iR}^\circ - E_{jS}} \qquad (4)$$

Generally speaking, however, the orbital (E_{iR}°) interacts more strongly with the vacant orbital of the substituent (E_{2S}° or higher) because of a smaller energy difference, as may be understood from Fig. 5; consequently, the level will be lowered. This stabilization results in an easier reduction (a smaller $-E_{1/2}$) of the substituted pyridine oxide compared with its mother compound. This also coincides with the tendency to be expected from Hammett's σ values.

In the case of nitropyridine *N*-oxide, the $-E_{1/2}$ value due to an NO_2 group reduction is much lower than that due to $\rangle N\rightarrow O$-group reduction. This indicates that the lowest empty orbital of the compound originates from the nitro group.

The authors wish to express their deep thanks to Professor Emeritus Eiji Ochiai of The University of Tokyo and to Professor Shinzi Koide of Mukogawa Women's University in Nishinomiya for their valuable advice. Thanks are also due to Professor Mitsugi Senda of Kyoto University and Professor Saburo Nagakura of the Institute for Solid State Physics, The University of Tokyo, for their helpful discussions, and to Professor Yutaka Mori of Osaka Gakugei University and Dr. Sadazi Kaziwara of our laboratory for supplying some samples and for their discussions.

*6 If we put $E_S^\circ=\alpha+\delta\beta$, δ is the parameter which is now being discussed. In addition, E, α, and β are negative values, and $-E_{iR}^\circ<-E_S^\circ$.

A Phtometric Particle-size Analyzer with a Moving Light Flux

By Yoshihide KOTERA, Kazuo SATO and Akihiro MIYAYAMA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received September 2, 1965)

A recording, photometric, particle-size analyzer has been developed which is useful in measuring the particle-size distributions of powdered materials in the subsieve range. Provision for continuously moving the optical system upwards allows for rapid analysis of the finer particles, while by moving the system downwards accurate analysis of the particles with a larger density is possible. It was ascertained that the movement of the optical system has no effect on the results obtained.

The photo-extinction method of size-frequeny determination offers great possibilities, as has been pointed out by Rose,[1] for the development of a precise and convenient technique applicable to both routine and research investigations. As a matter of fact, however, this method takes a long time for a routine application, just as do the other sedimentation methods of size-frequency determination. Talcite and Paulus[2] constructed a recording, photometric, particle-size analyzer which has a provision for continuously varying the sedimentation depth so that the analysis can be carried out within an hour. However, they did not clarify how the movement of the sedimentation vessel affects the results obtained, and their system may be accompanied by trouble resulting from the movement of the vessel. We have now constructed an analyzer provided with an apparatus for continuously moving the light flux upwards or downwards, in order thus to carry out a rapid analysis of the finer particles or an accurate analysis of the particles with a larger density. The optical system designed to move smoothly allows a complete, accurate analysis to be made within an hour. The comparison of the results obtained by means of an apparatus with a moving light flux with those obtained by the ordinary static method makes it clear that the movement of the optical system has no effect on the analysis.

Principles.—The principles of the photo-extinction method have been published elsewhere.[1] The absorbance of a powder suspension is related to its concentration by an extension of the Lambert-Beer law:

$$\ln (I_0/I) = kcl \sum_{d_0}^{d_1} K_x n d_x^2 \qquad (1)$$

where I_0=the intensity of the incident light; I=the intensity of the transmitted light; k=a factor equal to A_p/d_x^2, where A_p is the projected area of a particle, and d_x, the diameter; c=the concentration of the powder suspension (g./ml.); l=the length of the cell; K_x=the extinction coefficient, that is, the ratio of the light-obscuring power of a particle to that for the same particle if the "square law" of geometrical optics were applicable, and n=the number of particles, whose diameter is d_x, per gram of powder. When we begin with a uniform suspension and a transverse light beam at a fixed depth below the surface, no change in the absorbance of the suspension will occur until the largest particles in the suspension fall from the surface to the level of the measuring beam. At this time the absorbance will decrease by an amount proportional to the concentration of the largest particles. Any point on the absorbance-vs.-time curve represents, then the concentration of particles smaller than the particle which would fall the distance, h, from the surface to the measuring beam during the time, t. When the light flux moves upwards or downwards, two cases may be considered:

a) when the light flux moves upwards with a constant velocity, v_0, from a point whose depth is b below the surface of the suspension, then:

$$h = b - v_0 t$$

and: $$d_x = K\sqrt{v} = K\sqrt{h/t};$$

Then: $$t = K^2 b/(d_x^2 + K^2 v_0);$$

b) when the flux moves downwards with a constant velocity, v_1, from a point whose depth is b below the surface of the suspension and when, after a time, t_1, it moves upwards with the same velocity, then:

$$h = v_1 t + b \quad \text{for} \quad t < t_1$$
$$t = K^2 b/(d_x^2 - K^2 v_1)$$

or: $$h = v_1(2t_1 - t) + b \quad \text{for} \quad t > t_1$$
$$t = K^2(2v_1 t_1 + b)/(d_x^2 + K^2 v_1)$$

where: $K^2 = 18\eta/g(\rho_p - \rho)$,

and η=the viscosity of the medium (poise), ρ_p=the density of the particle (g./ml.), ρ=the density

2) N. A. Talvite and H. J. Paulus, *Rev. Sci. Instr.*, **27**, 763 (1956).

of the medium (g./ml.), and g=the gravitational constant (cm./sec./sec.).

A size-distribution based on the weight is expressed in the form of:

$$F_x = \frac{d_m}{K_m}(\ln I_1 - \ln I_2) \Big/ \sum_0^\infty \frac{d_m}{K_m}(\ln I_1 - \ln I_2),$$

where I_1 or I_2 is the intensity of the transmitted light for the suspension containing the powder whose diameters are in the range from 0 to d_1 or d_2 respectively. d_m is the mean of d_1 and d_2, and the K_m is the K_x value for d_m. I_1 and I_2 are proportional to the photocurrents, M_1 and M_2, from the photomultiplier.

Thus a size-distribution curve is obtained with an absorbance coordinate representing the concentration of particles less than the stated size and a time ordinate representing the particle size in terms of the Stokes diameter.

Design Constructions.—The analyzer is arranged as shown in the schematic diagram of Fig.

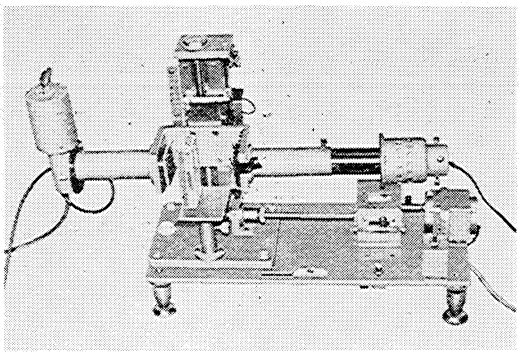

Fig. 2. Picture of the analyzer.

1. The apparatus is pictured in Fig. 2. The light source is a 5-amp., 6-V. bulb with a straight coiled filament and operated at a rated voltage from a 6-V. storage battery, the current being controlled with a rheostat. The collimation of a light beam is required for accurate analysis; therefore, the beam is made parallel by a condenser lens at its focal distance from the light source, while a slit immediately before the sedimentation cell limits the dimensions and angular divergence of the beam. A second slit following the cell cuts off the scattered light. A filter mount is located between the cell and the second slit, and a neutral filter is used for the control of the light intensity, while an interference filter is mounted when monochromatic light is required. The distance from the light source to the sedimentation cell is 33 cm., and that from the cell to the surface of the photomultiplier is 22 cm. The sedimentation cell must have parallel sides; its usual size is $40 \times 15 \times 100$ mm. The applied voltage for the photomultiplier, RCA-931A, is 700 V. to 770 V. The photocurrent is recorded by a Honeywell recorder.

The slit width is fixed at 25 mm., while its height may be varied in two fixed steps; 1 mm. and 2 mm. The optical system, including the light source, the lens, the slits and the photomultiplier, is mounted on a steel base arm and is fastened to a vertical brass slide. It can be raised or lowered by means of a standard micrometer head; this micrometer is coupled, by way of a set-screw clutch and right-angle drive, to a synchronous motor geared to raise or lower the

optical system. The rate may be varied in three fixed steps; 0.033 cm./sec., 0.011 cm./sec., and 0.0037 cm./sec. A reverse microswitch automatically changes the movement of the optical system from downwards to upwards when the system reaches the surface of the fixed height in the sedimentation cell, while a second microswitch shuts off the motor at the end of the run and may also shut off the paper drive of the recorder.

A 50 cm. × 26 cm. × 1 cm. structural, channel-steel plate forms the base of the analyzer; a rigid mounting surface for the sedimentation cell is fixed upon this base.

Operation.—Silica sand (density: 2.66) and tungsten carbide powder (density: 14.0) were used as the two samples for the test of the analyzer. The mixing of the suspension, whose concentration of solids was varied in several steps, was accompanied by quick inversions and agitations of the cell and by returning it to the cell component without delay. Sodium hexametaphosphate (0.2% of the total volume) was added to the suspension prior to the mixing in order to obtain a good dispersion. The intensity of the light beam was adjusted and the recorder chart and the mechanism which moves the optical system were actuated beforehand in order for the record to begin to operate at the instant when the cell was returned to its compartment. The chart speed was 0.0423 cm./sec. When the optical system is lowered in the first period of the experiment, the reverse switch changes the movement at the time of the arrival of the system at the fixed surface, its height from the surface of the suspension being measured before the start of the experiments. On the arrival of the light flux at the suspension surface, the measurement is finished.

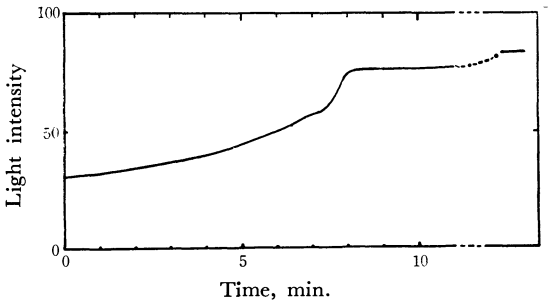

Fig. 3. Example of the chart obtained.

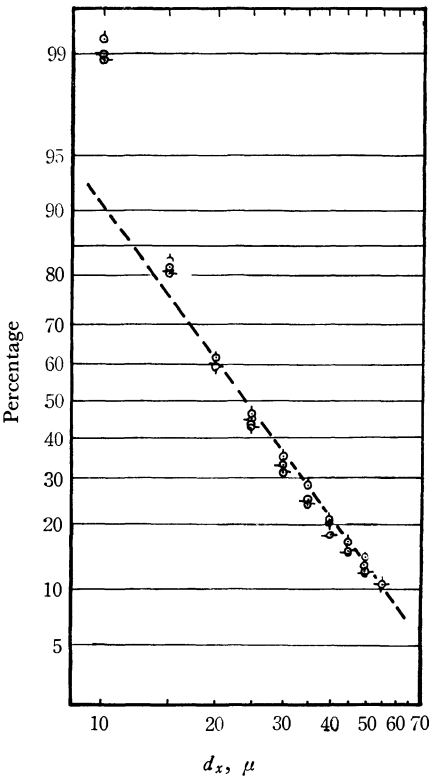

Fig. 4. Typical curves of particle-size distribution.
⊙ : A Fixed light flux.
⊙-: B Moved upwards $b=6$ cm.
⊙ : C Down- and upwards
-⊙ : D Moved upwards $b=10$ cm.

Performance.—The experimental data obtained under the conditions shown in Table I were calibrated in terms of Stokes' diameter. A typical procedure is shown in Table II, which relates the description to the principles. The values of K_m, the extinction coefficient, are those published by Rose, while M_x is the reading of the photocurrent for the suspension of the powder whose diameter is d_x. The summation of the values of $\{1/K_m \cdot d_x \cdot \log(M_{x-1}/M_x)\}$ was carried out from right to left in the table, that is, beginning with the value for the largest particles. The chart obtained in the experiments is shown in Fig. 3. Typical curves of particle-size distribution are shown in Fig. 4. In this figure it may be seen that the movement of the light flux has no effect upon the particle-size distribution curves. The deviation of the measured values with the movement of the light flux against those in the case of a fixed flux was very small and was estimated to be within the range of experimental error. It might be due to the disturbance of the suspension which remains immediately after the mixing of the powder suspension; this may cause the portion with the smaller diameter to increase. Such a deviation may occur when the analysis is carried out without taking the precaution of suppressing the disturbance of the suspension. Experiments are now being carried out in our laboratory in order to clarify this phenomenon. The fluctuations rise from other sources than the movement of the light flux, such as the inhomogeneity of the dispersion and the fluctuation of the cell temperature. The result for tungsten carbide powder seems to be more accurate in the subsieve range when the light flux is moved downwards at the beginning of the measurement than in the case of a fixed flux. In this case it was possible to shorten the measuring time to 9 min. by moving the flux, while the measurement with a fixed flux takes 30 min. All the measurements shown in Table I were carried out in 10 min., and the calculation for one measurement was about 10 min. longer than in the case of a fixed flux. The latter would be shortened by the use of an appropriate calculating chart.

Studies of the Surface Oxide Layer of Platinum Electrode

By Kunio OHASHI, Kazuo SASAKI* and Shigeo NAGAURA

Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received September 29, 1965)

The formation and reduction rates of the oxide layer of the platinum electrode were investigated by triangular-wave voltammetry and chronopotentiometry. A rate equation for the anodic process has been proposed in order to describe the fact that the electrode potential increases linearly with an increase in the surface concentration of oxygen. The cathodic reduction of surface oxide obeys the second-order rate law with respect to the amount of oxide covering the surface.

It has commonly been accepted that, in the electrolysis of an aqueous solution, an oxide layer is formed on the surface of the platinum electrode before any oxygen evolves. The chemical properties of the oxide and the kinetics of this electrode process have been studied by many workers.[1-16]

The present investigation has been carried out by means of chronopotentiometry and triangular wave voltammetry in order to understand the

formation and reduction kinetics of the oxide, in a 1 N sulfuric acid solution. In a previous paper,[14] it was pointed out that the formation rate of the oxide can be elucidated by one of the following assumptions, either (a) or (b): (a) the apparent rate constant, k, of the electron transfer step obeys the equation: $k=k_0\exp(-g\theta)$, where θ is the surface coverage of the oxide layer, and g, a constant, or (b) the reaction involves the rate-determining adsorption step of the discharged species, which obeys Elovich's rate equation.[17] In this paper, the rate equation previously proposed for the anodic process[14] has been re-examined for a wider range of current density. For the cathodic process, a rate equation has been proposed.

Experimental

All the experiments were conducted at 25°C in 1 N aqueous sulfuric acid solutions prepared by mixing distilled water (sepcific resistance $>1\times10^6$ ohm·cm.) and concentrated pure sulfuric acid which had been obtained from the Wako Pure Chemical Ind. Co. (Osaka). For all experiments, the solutions were deaerated by nitrogen gas.

Two kinds of platinum electrode were used. One was a wire electrode of 0.1 cm. in diameter and about 1 cm. long, while the other was the same in platinum, a cross-sectional area of which was exposed. Before each run of measurements, the electrode was cleaned by dipping it in a chromic acid mixture and washed with distilled water. Finally, it was subjected to alternate anodic and cathodic polarizations in the 1 N sulfuric acid solution. A saturated calomel electrode was used as the reference electrode.

Chronopotentiometry.—A series of experiments was carried out by using the chronopotentiometric technique, with a current reversal. An electronic pen-recorder (Model EPR-2TB, Toa Electronics Ltd.; pen speed, 0.5 sec. for the full span; input impedance, 1.8 MΩ) was used to record the potential-time curve at low current densities of about 100 μamp./cm^2 or less, whereas at higher current densities a cathode ray oscilloscope (Model 502-A, Matsushita Communication Ind. Co., Ltd.; input impedance, 1 MΩ) was employed. The electrolytic current passing through the cell was switched by means of a mercury switching device.

Triangular Wave Voltammetry.—An electronic potentiostat (Model N-EP-2, Nichia Keiki, Sapporo) was used in this experiment. The electrolytic current was recorded by means of the electronic pen-recorder. The maximum sweep rate was limited by the response of the pen-recorder; it was about 0.4 V./sec.

Results and Discussion

The Anodic Chronopotentiogram and the Potential-Current Curve.—A typical chronopotentiogram obtained at the current density of 32 μamp./cm^2 is shown in Fig. 1. The oxide layer was formed in the region C and reduced in C'. Since the potential-time curve was almost linear in C, the increment of surface oxide with the electrode potential, dq/dE, was determined in this region. The results are listed in Table I in terms of $n\boldsymbol{F}(dq/dE)$*1.

The transition time in C, τ_a, was always greater than that in C', τ_c. The ratio of τ_a to τ_c was, for instance, about 1 : 0.8 at the current density of 32 μamp./cm^2. The cause of this discrepancy is not certain, but this problem will be referred to again at the end of this article.

A typical current-potential curve obtained at the sweep rate of 0.2 V./sec. is illustrated in Fig. 2. The curve shows two peaks in the region A, where the ionization of chemisorbed hydrogen occurs.[7]

17) S. Yu. Elovich and G. M. Zhabrova, *Zhur. Fiz. Khim.*, **13**, 1761, 1775 (1939).

*1 The value of q is in mol./cm^2. The number of electrons, n, involved in the reaction concerned was assumed to be 2.

The regions denoted by C and C′ correspond to those denoted by the same notations in Fig. 1. The amount of charge (Q_H) required in A was graphically determined to be 4.0×10^2 μcoul./cm.^{2} while that (Q_O) required in C′ was 8.2×10^2 μcoul./cm^2. Thus, the ratio Q_H/Q_O was almost 1/2. This value coincides with that obtained by Will and Knorr,[7] who suggested a one-to-one correspondence between hydrogen and oxygen atoms on the surface of the platinum electrode.

The Rate Equation for the Anodic Process. —The anodic formation rate of the surface oxide obeys the following equation, as was pointed out in a previous paper.[14]

$$i_a = n\boldsymbol{F}k_a \exp(\beta n\boldsymbol{F}E/\boldsymbol{R}T-\lambda_a q) \qquad (1)$$

where i_a is the anodic current density; k_a and λ_a, constants; q, the amount of oxygen deposited to form the oxide layer (in mol./cm^2), and where the other symbols have their usual significance. The electrode potential, E, referred to the normal hydrogen electrode (NHE), was used in Eq. 1 instead of the overpotential.

Since in the experimental conditions $di_a/dt=0$ in the chronopotentiometry, Eq. 1 may be simplified as follows;

$$dq/dt = \frac{\beta n\boldsymbol{F}}{\lambda_a\boldsymbol{R}T}\cdot\frac{dE}{dt} \qquad (2)$$

This equation indicates that dq/dE should be constant, regardless of the current density. In fact, the experimentally-determined values of $n\boldsymbol{F}(dq/dE)$ were approximately constant even though the current densities employed were in a wide range, as may be seen in Table I. The slight decrease in $n\boldsymbol{F}(dq/dE)$ with an increase in the current density may be caused by another reason.*2

In Eq. 1, there is an additional exponential term describing the current dependence upon the amount of surface oxide deposited. Such a form of rate equation has often been found in the chemisorption process,[18,19] in which the activation energy, ε, of chemisorption increases linearly with an increase in the surface coverage, θ, of adsorbed species, as is shown by:

$$\varepsilon = \varepsilon_0 + r\theta$$

Since the surface coverage, θ, can be given by q/q_s, in which q_s is the amount of oxygen at the full coverage, the following equation can be written in analogy to Eq. 1:

$$i_a = n\boldsymbol{F}k_a \exp\{(\beta n\boldsymbol{F}E - r\theta)/\boldsymbol{R}T\} \qquad (3)$$

A rate equation of this form has also been applied to some electrode processes involving the chemisorption of reactant or intermediate product.[20]

Although Eq. 1 is analogous to Eq. 3 in form, it is hard to say whether the process concerned is the chemisorption of oxygen or the surface oxide formation.

For this reason, the term "surface oxide" has been used in the present article without any specification of its physico-chemical nature.

The Rate Equation for the Cathodic Process. —Since no rate equation has been strictly confirmed so far, the following equation will be assumed for the time being;

$$i_c = n\boldsymbol{F}k_c q^m \exp(-\alpha n\boldsymbol{F}E/\boldsymbol{R}T+\lambda_c q) \qquad (4)$$

where i_c is the cathodic current density, and k_c and λ_c are constants. In contrast to Eq. 1, the variable, q, which describes the surface concentration of oxygen is included in both the pre-exponential and the exponential terms in order to see the effect of this variable. In addition, the number of the reaction order, m, was introduced.

The time derivative of Eq. 4 is:

$$\frac{di_c}{dt} = i_c\left\{\left(\frac{m}{q}+\lambda_c\right)\frac{dq}{dt} - \frac{\alpha n\boldsymbol{F}}{\boldsymbol{R}T}\cdot\frac{dE}{dt}\right\} \qquad (5)$$

For the chronopotentiometric experiment, where the current is kept constant, Eq. 5 can be written as:

$$\frac{dE}{dt} = -\frac{\boldsymbol{R}T}{\alpha n\boldsymbol{F}}\left\{\frac{m}{\tau_c-t}+\frac{\lambda_c i_c}{n\boldsymbol{F}}\right\} \qquad (6)$$

by using the relations of $n\boldsymbol{F}q=(\tau_c-t)\cdot i_c$ and $i_c=-n\boldsymbol{F}\,dq/dt$. The slope, dE/dt, at the midpoint of the cathodic transition wave is:

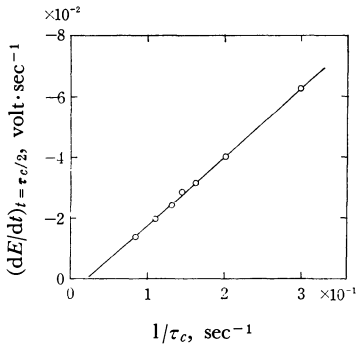

Fig. 3. Slope at the midpoint of the cathodic transition wave plotted against the reciprocal of the transition time (examination Eq. 7). The current density was kept at 1.8×10^2 μamp./cm^2 and the potential at which the anodic current as was reversed to cathodic one was changed.

*2 This behavior may be related to the fact that τ_a was greater than τ_c. If a part of the oxide dissolves chemically from the electrode surface, the value of dq/dE should decrease with an increase in the current density.

20) B. E. Conway and E. Gileadi, *Can. J. Chem.*, **42**, 90 (1964).

$$\left(\frac{dE}{dt}\right)_{\tau_c/2} = -\frac{RT}{\alpha nF}\left\{\frac{2m}{\tau_c} + \frac{\lambda_c i_c}{nF}\right\} \quad (7)$$

Eq. 7 is examined in Fig. 3, where the slope of the potential-time curve determined at $\tau_c/2$ is plotted against the reciprocal of the transition time. The linearity is very good. It must be noted that the straight line crosses an ordinate near the point of origin. This shows a small value of λ_c (about 2% of λ_a). Therefore, the exponential contribution of q in Eq. 4 is negligible, and the term can safely be dropped. The slope of Fig. 3 should give $2mRT/\alpha nF$. Assuming $n=2$,*3 α/m is found to be 0.13.

Since, in the potential sweep experiment, the sweep rate is constant and di_c/dt is zero at the point of the cathodic current peak, the following equation can be obtained from Eq. 5:

$$\frac{1}{i_{max}} = \frac{RT}{\alpha(nF)^2 v}\left\{\frac{m}{q_{max}} + \lambda_c\right\} \quad (8)$$

where v is the sweep rate in V./sec. ($v=-dE/dt$ for the cathodic potential sweep) and where the subscript *max* denotes the values of each quantity observed at the current peak.

It was observed that the peak current value decreases with the decrease in the amount of oxide layer deposited anodically. In Fig. 4, the reciprocal of the peak current, $1/i_{max}$, is plotted against $1/q_{max}$. The value of q_{max} is the amount of oxide yet remaining unreduced until the potential of current peak is reached. Each q_{max} value was obtained by the graphical integration of the current-potential curve. The straight line intersects the ordinate at the point of origin, thus confirming the negligible value of λ_c. From the slope, α/m was found to be 0.13.

The reaction order, m, can be determined from the potential sweep experiment. The results obtained are shown in Fig. 5, where ($\log i_c - m \log q$)

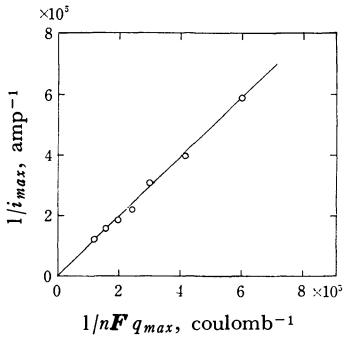

Fig. 4. The reciprocal of the peak current (i_{max}) is plotted against the reciprocal of the amount of oxide yet remained at the potential of current peak (examination of Eq. 8).
Sweep rate: 0.1 V./sec.
Electrode area: 7.8×10^{-3} cm²

*3 Cf. the reaction scheme proposed below.

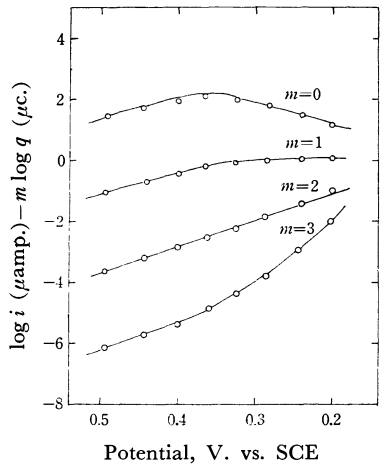

Fig. 5. The determination of the number of reaction order.
Sweep rate: 54 mV./sec.
Electrode area: 0.41 cm²

is plotted against the electrode potential. Four curves correspond to the arbitrary values of $m=$ 0, 1, 2 and 3 respectively. A straight line was obtained over the whole range of the cathodic reduction (C′ in Fig. 2) only when $m=2$. Accordingly, it can be concluded that the cathodic process is a second-order reaction with respect to the surface concentration. Therefore, the proper rate equation for the cathodic process becomes:

$$i_c = nFk_c q^2 \exp(-\alpha nFE/RT) \quad (9)$$

Another indication that the reaction order should be of the second-order was obtained by the following examination.

If the exponent of the amount of the oxide is unity instead of two, the following equation can be written as in Eq. 9, under the conditions of the potential sweep experiment, i. e., $dE/dt=-v=$ constant:

$$i_c = nFk_{c,I}\, q \exp\left\{-\frac{\alpha_I nF}{RT}(E_{t=0} - vt)\right\} \quad (10)$$

where the I subscript refers to the first-order reaction and where $E_{t=0}$ denotes the potential at which the direction of the potential sweep is reversed. By writing Eq. 10 as;

$$i_c = nFk_I q \exp\left(\frac{\alpha_I nF}{RT} vt\right) \quad (10')$$

and by integrating, using the relation $-nFdq/dt = i_c$,

$$i_c = nFk_I q_0 \exp\left(\frac{k_I}{P_I}\right)\exp\left\{x - \frac{k_I}{P_I}\exp(x)\right\} \quad (11)$$

where q_0 is the total amount of oxide to be reduced and where the other notations are:

$$P_I = \frac{\alpha_I nFv}{RT} \quad \text{and} \quad x = P_I t$$

Since $di_c/dt=0$ at the current peak,

$$P_I t_{max} = \ln \frac{P_I}{k_I} \tag{12}$$

By introducing Eq. 12 into Eq. 11, one can obtain an expression of the peak current, i_{max}:

$$i_{max}=nFq_0 P_I \exp\left\{\frac{k_I}{P_I}-1\right\} \tag{13}$$

Assuming $k_I P_I \ll 1$*4

$$i_{max}=\frac{\alpha_I (nF)^2 q_0 v}{eRT} \tag{14}$$

From the last equation, the transfer coefficient, α_I, can be determined by using the peak value of the current as determined experimentally. Once α_I is obtained, k_I is determined using Eq. 12.

If, however, the rate is second-order with respect to the surface concentration, Eq. 9 can be expressed in terms of time, i. e.,;

$$i_c = nFk_{II}q^2 \exp\left(\frac{\alpha_{II} nFvt}{RT}\right)$$

After similar treatment, as has been done with the equations from 11 to 14, the following relation are obtained:

$$i_c = nFk_{II}\left[\frac{P_{II}q_0}{k_{II}q_0\{\exp(x)-1\}+P_{II}}\right]^2 \exp(x) \tag{15}$$

$$P_{II}t_{max} = \ln\left(\frac{P_{II}}{k_{II}q_0}\right) \tag{16}$$*4

and by inserting Eq. 16 into Eq. 15:

$$i_{max} = \frac{\alpha_{II}(nF)^2 q_0 v}{4RT} \tag{17}$$

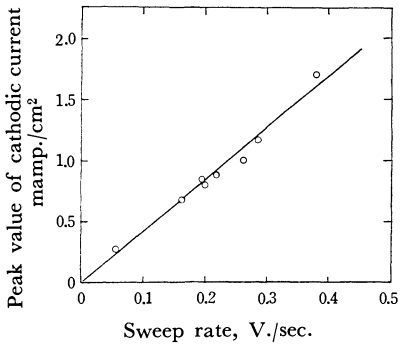

Fig. 6. Plot of cathodic peak current against sweep rate.

The α_{II} and k_{II} parameters can be determined by means of Eqs. 17 and 16. Equation 14 or 17 shows that the peak value of the current should be proportional to the sweep rate. This is confirmed in Fig. 6.

The values of kinetic parameters determined for the first- and second-order reactions are listed in Table II, where α_I and α_{II} were determined from Fig. 6 using either Eq. 14 or 17. The validity of the drived equations, 11 and 15, is examined in Fig. 7. It can easily be seen that the curve drived from Eq. 15 coincides with the experimental curve depicted for the sake of comparison. In the foregoing examination, the value of α/m was found to be 0.13, which is just half as much as the value of $\alpha_{II}=0.26$ determined for the second-order reaction (see Table II). This may, again, give the value of m to be two. The apparent rate constant, k_c, in Eq. 9 was determined as 5×10^{13} cm²/mol. sec. at 0 V. (vs. NHE).

Vetter[5] once suggested that hydrogen peroxide might be produced during the cathodic reduction of the surface oxide of the platinum electrode. According to him, the number of electrons, n, involved in the anodic oxide formation must be two per atom of oxygen deposited, whereas n is unity if the cathodic reduction product is hydrogen peroxide. Hence, in this case the quantity of charge observed in the anodic oxide formation should be twice as much as that in the cathodic reduction. Although Vetter's assumption was not based upon

TABLE II. NUMERICAL VALUES OF PARAMETERS REQUIRED IN THE CALCULATION OF EQS. 11 AND 15
Apparent rate constants, k_I and k_{II}, refer to 1.30 V. (SCE), at which the direction of the potential sweep was reversed. The value of q_0 was found as 5.1×10^{-9} mol./cm².

	m	α	k_I or k_{II}		v
1st order	1	0.18	1.9×10^{-6}	(sec^{-1})	0.054 (V./sec.)
2nd order	2	0.26	1.3	($cm^2 sec^{-1} mol^{-1}$)	0.054 (V./sec.)

*4 The validity of this assumption was confirmed by the derived result, $(k_I/P_I)=1.4\times 10^{-7}/v$. A similar assumption made in deriving Eq. 16 was confirmed by the result, $(k_{II}q_I/P_{II})=3.2\times 10^{-10}/v$.

any direct proof of the formation of hydrogen peroxide, its formation has recently been confirmed by Peters and Mitchell,[21] and also by Bianchi and Mussini.[22] They observed that hydrogen peroxide is produced with a high current efficiency during the cathodic reduction of the dissolved oxygen on the platinum electrode. Although Liang and Juliard[23] reported that no hydrogen peroxide was detected in the same system, this discordant finding, in our opinion, might have arisen from the different surface states of the electrode used.

Since, at the platinum electrode, the cathodic reduction of the dissolved oxygen and the surface oxide take place voltammetrically in one step,[24,25] the mechanism of the cathodic reduction of these two species will be quite similar. Therefore, it is probable that hydrogen peroxide will be produced intermediately during the reduction of surface oxide. If this is the case, the second-order rate law observed by the authors seems to favor the elucidation of the hydrogen peroxide formation. This problem, together with the reactions of dissolved oxygen and hydrogen peroxide, will be discussed elsewhere.[25]

The discrepancy found between τ_a and τ_c can be attributed partly to the intermediate formation of hydrogen peroxide. The reaction scheme may be written, for instance.*5 as:

$$\left.\begin{array}{l} \rightarrow 2PtO + 2H^+ + 2e \rightarrow 2Pt + H_2O_2 \quad (I) \\ \quad Pt + H_2O_2 \rightarrow PtO + H_2O \quad (II) \end{array}\right\}$$

If a part of the hydrogen peroxide formed by the bimolecular step (step I) diffuses away from the platinum surface without oxidative decomposition (step II), τ_c must be less than τ_a.

A New Method of Quantitative Differential Thermal Analysis

By Takeo OZAWA

Electrotechnical Laboratory, Tanashi-machi, Kitatama-gun, Tokyo

(Received October 26, 1965)

This paper presents a rigorous new theory of differential thermal analysis, taking account of the temperature gradient in the sample. From this consideration, a new quantitative method is proposed, where a solid-cell holder of low thermal conductivity is set between a sample cell and a metal block, and a thermocouple is inserted tightly between the outside wall of the cell and the cell holder. By means of this arrangement, the peak area becomes proportional to the heat of transformation, irrespective of the kinds and the states of samples and operational variables. The experimental verification using various samples and the effect of several operational variables, such as the heating rate, the concentration of a diluent, the packing density, and the depth of the packing sample, are also shown; satisfactory results are obtained. Two new concepts, the sensitivity and the response time of the system, are proposed and evaluated. Conventional methods are criticized, and the inherent limitations of differential thermal analysis are discussed.

Differential thermal analysis has been widely used in scientific and engineering fields to study clays, soaps, polymers and various other organic and inorganic materials[1-3] since Le Chaterier's first employment of its prototype in 1887.[4] By this method we can record the temperature difference between a sample and a thermally-inert reference material heated at a constant rate by an external furnace, and thermal transformations occurring in the sample can thus be recognized as deviations from the base line in the record of the temperature difference against the time, which forms a differential thermogram.

Although numerous reports have hitherto been published, there remain problems about the quantitative differential thermal analysis, namely, the method of estimating the heat of transformation by differential thermal analysis. In order to evaluate the heats of transformation from differential thermograms, Vold[5] suggested a theory which requires a knowledge of the heat capacity of the sample. If her theory is further developed, a relation can be derived which corresponds to the theories of Kerr and Kulp;[6] Speil, Swerdlow, Pask and Davices;[7] Evans, Hutton and Mathews,[8] and so on, who all indicate that the area enclosed by the peak and the base line in a differential thermogram is proportional to the heat of transformation. However, in these theories the experimental condition for the constant of the proportionality between the heat and the area is not shown to be independent of the sorts of the samples and other experimental factors, because the effects of the volume and the shape of the sample are neglected in the theories.

On the other hand, considering these effects Soulé[9] and Nagasawa[10] suggested that the proportionality constant contains the apparent density and apparent thermal conductivity of the sample; furthermore, Boersma[11] pointed out, for the same reasons, that quantitative differential thermal analysis by the conventional methods is inherently impossible, because the proportionality constant becomes a function of the apparent thermal conductivity of the sample. Soulé thus suggested a method which makes the proportionality constant independent of the thermal conductivity of the sample and other operational factors, but his method has not yet been developed. Strum[12] extended Boersma's theory and introduced a method of quantitative differential thermal analysis, but it is a rather complicated one. Otsubo and Yamaguchi[13] also published their rigorous treatment of heat conduction within the apparatus of differential thermal analysis and devised an approximate method of estimating the heat; their theory is, however, essentially equivalent to Vold's theory, and also the value of the specific heat of the sample is needed if we are to analyze the data. Naturally, therefore, the theory is limited in application. Strella[14] recently proposed a new method, but it is a complicated one and seems to contain some rough assumptions. Therefore, quantitative differential thermal analysis has not yet been established.

Recently Speros and Woodhouse[15] reported on "quantitative differential thermal analysis," but theirs is essentially a differential enthalpic analysis,[16] one which has different theoretical bases, different advantages, and a limited application, because the temperature difference between the sample and the reference material must be nullified and the error of such operation has a serious effect at a higher temperature; this is also the case in an adiabatic calorimeter.

Although the direct measurement of the specific heat by an adiabatic calorimeter (or differential enthalpic analysis) is an absolute, excellent method, the differential thermal analysis has the following advantages over it: (1) the simplicity and ease of the operation and the analysis of the data; (2) its applicability to cooling processes and to measurements under a high pressure[17] and/or at a higher temperature, and (3) its applicability to chemical reactions and exothermic phenomena such as crystallization.[18] Therefore, it is still important to establish quantitative differential thermal analysis.

In the present paper, the author will report a theory of broad vision from which he has derived a new, simple and convenient method of estimating the heat of transformation by differential thermal analysis; the experimental verification of the method will also be shown. From these considerations we can elucidate the sensitivity of the apparatus, the resolution of the peaks, the influence of some operational factors on the differential thermograms, and the inherent limitations of differential thermal analysis.

Theoretical Considerations

As has been mentioned above, there have been no rigorous treatments of the temperature gradient in the sample in the previous theories of differential thermal analysis. Now, an exact elucidation of the temperature gradient should be attempted. In a conventional apparatus, the sample and the reference material are packed in a pair of cavities of a metal block, and a temperature-detection device is inserted into the center of each cavity. In some cases,[19] the sample and reference cells with the

temperature-detection devices are inserted in the cavities of the metal block without touching the walls at all. In the method described in this paper, the sample and reference cells are put into cell-holders set in the cavities of the metal block, while the temperature-detection devices are located between the cells and the cell holders. These arrangements are illustrated in Fig. 1. The cell holder is made of thermally-inert solid material of a low thermal conductivity in which a temperature gradient develops corresponding to the heat flow into the sample, as will be seen later.

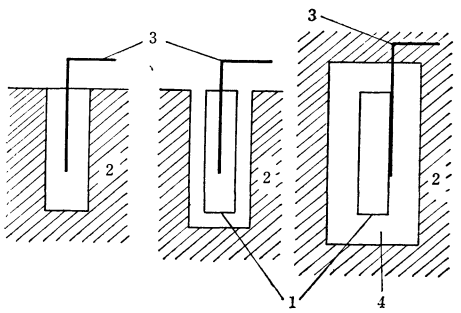

Fig. 1. The three types of the arrangements of the cell (1), the metal block (2), the temperature detection device (3) and the cell holder (4).

Now, let us consider the temperature gradient in the sample, the reference material and the cell holders. We can derive the equations of the heat flow for these materials by assuming that the heat transfers by conduction only, that the heat is not lost at the interface between the cell holder and the cell, and that the temperature of the inner surface of the cell holder is equal to that of the surface of the cell. The metal block is heated at a constant rate, a, of heating (or cooling). It is also assumed that the metal block has so large a heat capacity and thermal conductivity, and/or that it is controlled so strictly in its heating rate, that the heating rate of the metal block is not disturbed by the heat of transformation occurring in the sample. For the sake of simplicity the shape of the cell is cylindrical and it is long enough for us to be able to neglect the heat flow through the ends. The heat loss through the temperature-detection device is also neglected.

Within the sample:

$$\lambda_s \nabla T_s = c_s \rho_s \frac{\partial T_s}{\partial t} + \rho_s \Delta H \frac{\partial m}{\partial t} \tag{1}$$

and within the cell holder:

$$\lambda_h \nabla T_h = c_h \rho_h \frac{\partial T_h}{\partial t} \tag{2}$$

where:

∇ = a Laplacian

λ = the thermal conductivity

T = the temperature

c = the specific heat

ρ = the apparent density

t = the time

ΔH = the heat of the transformation of the sample per unit mass

$\frac{\partial m}{\partial t}$ = the rate of the transformation in mass,

and where the subscripts s and h denote the sample and the cell holder.

The boundary and initial conditions of the above equations are as follows:

$$T = at \qquad \text{at } r = R_o \tag{3}$$

$$\lambda_s \frac{\partial T_s}{\partial r} = \lambda_h \frac{\partial T_h}{\partial r} \qquad \text{at } r = R_i \tag{4}$$

$$T_s = T_h \qquad \text{at } r = R_i \tag{5}$$

and

$$T_s = T_h = 0 \qquad \text{at } t = 0 \tag{6}$$

where

r = the distance from the central axis

R_o = the outer radius of the cell holder

R_i = the inner radius of the cell holder

= the radius of the cell

These equations can be applied to other arrangements of the sample. Namely, if R_o is made equal to R_i, the solution becomes one for a conventional appearatus. In an apparatus such as (b) in Fig. 1, the temperature is measured at the center of the sample, and the solution of the equations can be applied if one neglects the heat transfer by convection and radiation in the air gap between the cell and the metal block.

Assuming a cylindrical symmetry, we have the next solutions of Eqs. 1 and 2, when the transformation does not occur in the sample; i. e., $\partial m/\partial t = 0$ (see in Appendix).

$$T_s = at - \frac{a}{4\lambda_h}\left[c_h\rho_h(R_o^2 - R_i^2) + 2R_i^2(c_s\rho_s - c_h\rho_h)\log\frac{R_o}{R_i}\right] - \frac{ac_s\rho_s}{4\lambda_s}(R_i^2 - r^2) + \sum_{n=0}^{\infty} \boldsymbol{A}_n(r)\exp\left(-\frac{t}{\tau_n}\right) \tag{7}$$

$$T_h = at - \frac{a}{4\lambda_h}\left[c_h\rho_h(R_o^2 - r^2) + 2R_i^2(c_s\rho_s - c_h\rho_h)\log\frac{R_o}{r}\right] + \sum_{n=0}^{\infty} \boldsymbol{B}_n(r)\exp\left(-\frac{t}{\tau_n}\right) \tag{8}$$

where $\boldsymbol{A}_n(r)$'s and $\boldsymbol{B}_n(r)$'s are functions of r only, and where τ_n's are the roots of the equation:

$$\sqrt{\lambda_h c_h \rho_h}\boldsymbol{J}_0\left(R_i\sqrt{\frac{c_s\rho_s}{\lambda_s\tau_n}}\right)\Big[\boldsymbol{J}_1(R_ix)\boldsymbol{Y}_0(R_ox) - \boldsymbol{J}_0(R_ox)\boldsymbol{Y}_1(R_ix) = \sqrt{\lambda_s c_s \rho_s}\boldsymbol{J}_1\left(R_i\sqrt{\frac{c_s\rho_s}{\lambda_s\tau_n}}\right) \times [\boldsymbol{J}_0(R_ix)\boldsymbol{Y}_0(R_ox) - \boldsymbol{J}_0(R_ox)\boldsymbol{Y}_0(R_ix)] \quad (9)$$

where x is equal to $\sqrt{c_h\rho_h/\lambda_h\tau_n}$, where $\boldsymbol{J}_0$ and $\boldsymbol{J}_1$ are Bessel functions of the zero and 1st orders respectively, and where $\boldsymbol{Y}_0$ and $\boldsymbol{Y}_1$ are Neuman functions of the zero and 1st orders respectively.

The following equations are derived analogously for the reference material and its cell holder:

$$T_r = at - \frac{a}{4\lambda_h}\left[c_h\rho_h(R_o^2 - R_i^2) + 2R_i^2(c_r\rho_r - c_h\rho_h)\log\frac{R_o}{R_i}\right] - \frac{ac_r\rho_r}{4\lambda_r}(R_i^2 - r^2) + \sum_{n=0}^{\infty}\boldsymbol{C}_n(r)\exp\left(-\frac{t}{\tau_n'}\right) \quad (10)$$

$$T_{h'} = at - \frac{a}{4\lambda_h}\left[c_h\rho_h(R_o^2 - r^2) + 2R_i^2(c_r\rho_r - c_h\rho_h)\log\frac{R_o}{r}\right] + \sum_{n=0}^{\infty}\boldsymbol{D}_n(r)\exp\left(-\frac{t}{\tau_n'}\right) \quad (11)$$

where the subscripts r and h' denote the reference material and its cell holder respectively, where $\boldsymbol{C}_n(r)$'s and $\boldsymbol{D}_n(r)$'s are functions of r only, and where τ_n''s are the roots of the equation:

$$\sqrt{\lambda_h c_h \rho_h}\boldsymbol{J}_0\left(R_i\sqrt{\frac{c_r\rho_r}{\lambda_r\tau_n'}}\right)[\boldsymbol{J}_1(R_ix')\boldsymbol{Y}_0(R_ox') - \boldsymbol{J}_0(R_ox')\boldsymbol{Y}_1(R_ix')] = \sqrt{\lambda_r c_r \rho_r} \times \boldsymbol{J}_1\left(R_i\sqrt{\frac{c_r\rho_r}{\lambda_r\tau_n'}}\right)[\boldsymbol{J}_0(R_ix')\boldsymbol{Y}_0(R_ox') - \boldsymbol{J}_0(R_ox')\boldsymbol{Y}_0(R_ix')] \quad (12)$$

where x' is equal to $\sqrt{c_h\rho_h/\lambda_h\tau_n'}$.

The last terms of Eqs. 7, 8, 10 and 11 form the Bessell-Fourier series expressing the transient temperature; they are related to the temperature distribution in the steady state.

As the temperatures are measured at the interfaces between the cells and the cell holders in the present method, the temperature difference between the sample and the reference material, ΔT, is given by:

$$\Delta T = T_s - T_r = \Delta T_b + \sum_{n=0}^{\infty}\boldsymbol{A}_n(R_i)\exp\left(-\frac{t}{\tau_n}\right) - \sum_{n=0}^{\infty}\boldsymbol{C}_n(R_i)\exp\left(\frac{t}{\tau_n'}\right) \quad (13)$$

where:

$\Delta T_b = a(C_r - C_s)/K$

$K = 2\pi l\lambda_h/\log(R_o/R_i)$

$C_s = \pi R_i^2 c_s\rho_s l$ = the heat capacity of the sample plus the cell

$C_r = \pi R_i^2 c_r\rho_r l$ = that of the reference material plus the cell

l = the length of the cell.

The height of the base line is ΔT_b, and the other terms give the transient temperature.

From Eq. 13 it is apparent that it is necessary for the heat capacity of the reference material to be equal to that of the sample, as has already been pointed out by Vold[5]; the necessity of this remains in our method derived by the rigorous treatment. The differential method eliminates the error due to the fluctuation of the base line caused by the fluctuating rate of heating, if the above necessity is fulfilled, and it is preferable that τ_n''s be nearly equal to τ_n's; i. e., it is preferable that the reference material have a similar effective thermal conductivity. The role of the reference material is neither more nor less than this elimination.

The values of $\boldsymbol{A}_n(r)$'s, $\boldsymbol{B}_n(r)$'s, $\boldsymbol{C}_n(r)$'s and $\boldsymbol{D}_n(r)$'s do not play an important role in the measurement, and so we need not know their exact values, because these series converge to zero in the intervals of the order of $5\tau_n$ and $5\tau_n'$, which are important ones. It is necessary to know. The largest values of τ_n's and τ_n''s, τ_0 and τ_0' are the response times of the system, and they give the order of the time necessary for the system to attain to a steady state. If the values of τ_0 and τ_0' are large, the measurement of the transformation occurring at a lower temperature becomes obscure, because the system has not attained to the steady state before it reaches the transformation temperature. It should be noted that τ_n and τ_n' do not depend on the point of the temperature measurement and the heating rate, but on the thermal properties and the geometry of the system. It should also be pointed out that τ_n is important to the measurement in yet another way, as will be discussed below.

We should now like to discuss the other transient state after the transformation. Suppose that the transformation in the sample is completed at $t = t_c$ and that the temperature distribution is different from that of the steady state. As the same equations, 1 and 2, and the same boundary conditions, 3, 4 and 5, hold for this case, the transient temperature distribution is given corresponding to different initial conditions, because the temperature distribution at the steady state and the τ_n's are determined irrespective of the initial temperature distribution (see Appendix).

$$T_s = at - \frac{a}{4\lambda_h}\left[c_h\rho_h(R_0^2 - R_i^2) + 2R_i^2(c_s\rho_s - c_h\rho_h)\log\frac{R_0}{R_i}\right] - \frac{ac_s\rho_s}{4\lambda_s}(R_i^2 - r^2) + \sum_{n=0}^{\infty} \boldsymbol{E}_n(r)\exp\left(-\frac{t-t_c}{\tau_n}\right) \quad (14)$$

$$T_h = at - \frac{a}{4\lambda_h}\left[c_h\rho_h(R_0^2 - r^2) + 2R_i^2(c_s\rho_s - c_h\rho_h)\log\frac{R_0}{r}\right] + \sum_{n=0}^{\infty} \boldsymbol{F}_n(r)\exp\left(-\frac{t-t_c}{\tau_n}\right) \quad (15)$$

where the last terms are the Bessell-Fourier series related to the temperature distribution at t_c, and where the τ_n's are, as before, the roots of Eq. 9.

Thus, the transient temperature disappears in the time interval of the order of $5\tau_0$, which determines the resolution of the adjacent peaks and which should be called "the response time" determining the resolving power of the system. It is of interest to note that the response time of the system is not given in the dimension of temperature but in that of time, and that, if the second transformation occurs within the temperature range of the order of $5a\tau_0$, the peaks may overlap. These facts suggest the advantage of a low heating rate. However, there is a possibility of resolving these overlapped peaks in a different way. If τ_0 is large enough compared to the other τ_n's, which may be true in most cases, the transient temperature of the Bessell-Fourier series can be approximated by a single exponential function. Thus, if one plots the logarithm of $(\Delta T - \Delta T_b)$ against the time beginning at the top of the peak, the points lie on a straight line after the completion of the transformation. Such a procedure not only resolves the overlapped peaks, but also gives, though only approximately, the time of the completion of the transformation, the determination of which is important in the measurements of binary mixtures, high polymeric samples, and chemical reactions, because these changes occur over a wide range of temperature. This linearity can also be used to separate the peaks. For example, in order to ascertain the melting behavior of high polymers, one must plot the change in the crystallinity against the temperature. By using differential thermal analysis, this can be done by separating the peaks with these exponentially-decaying curves. Ke[20] divided the peak into components, but his method of division should be revised on the basis of the present facts. The above-mentioned linear relationship was pointed out and shown experimentally by Vold[5] and by Otsubo et al.,[13] but it should be noted that τ_0 determines the resolving power and that it can be estimated by Eq. 9 in designing the apparatus.

20) B. Ke, *J. Polymer Sci.*, **42**, 15 (1960).

Finally we consider the area under the peak, for which the relation (see Appendix) holds:

$$\Delta H \cdot M = K \cdot A \quad (16)$$

where M is the mass of the sample and A is the area of the peak. The proportionality coefficient, K, is given above; it is related to the geometry and thermal conductivity of the cell holder, not to the thermal properties of the sample. Therefore, the coefficient is the constant characteristic of the apparatus. This fact is the basis of this quantitative differential thermal analysis; the cell holder serves as the heat-flow-meter, developing within itself the proportional magnitude of the temperature gradient to be measured. The proportionality coefficient can be evaluated by the measurement of a sample of a known heat of transformation. As it is related to the thermal conductivity, it would be a function of the temperature and one needs to measure the transition of the known latent heat over the workable temperature range in order to evaluate the proportionality coefficient.

As has already been pointed out by Boersma,[11] in the conventional method, the sample plays two quite different parts, parts which conflict with each other: (a) a producer of heat to be measured, and (b) a heat measureing resistance in which the heat flow develops a temperature gradient necessary for the measurement. Thus, in the conventional model, the temperature gradient within the sample is essential. However, in the present method the temperature gradient within the sample can be reduced without sacrificing the sensitivity of the apparatus. If one introduces a certain device to diminish the temperature gradient within the cell, the peaks will be sharpened, and the accuracy of the temperature measurement and the resolution of the peaks may even be increased.

Essentially, this method of quantitative differential thermal analysis is a technique for measuring the heat by the temperature gradient existing in the given inert material, through which the heat flows into the sample cell.

Let us now discuss the optimum design of the

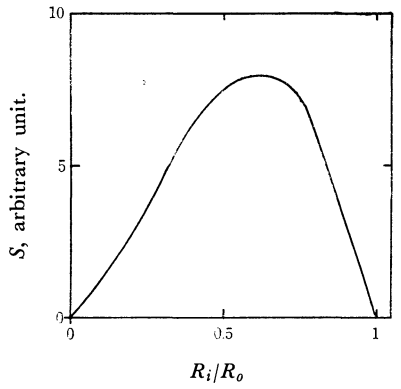

Fig. 2. The sensitivity versus the ratio, R_i/R_0.

cell holder. The "sensitivity" of the apparatus, S, could be defined as the peak area per the unit heat of transformation occurring in the unit volume of the sample:

$$S = A/\rho_s \Delta H = V_s/K \tag{17}$$

Namely,

$$S = R_i^2 \log (R_o/R_i)/2\lambda_h \tag{18}$$

The sensitivity increases with the second power of the radius of the cell. It may easily be seen that, for a given R_o, the optimum ratio of R_i to R_o is $e^{-1/2}$; the sensitivity is plotted against the ratio in Fig. 2. If R_i is fixed, the sensitivity increases logarithmically with an increase in R_o.

For a glass transition[21-24] or a second-order transition, where the specific heat of the sample changes without latent heat, a step-by-step change in the base line is recorded as being due to the change in the heat capacity of the sample. The height of the step-by-step change is derived:

$$\Delta T_{b2} - \Delta T_{b1} = aS\Delta c_s \rho_s \tag{19}$$

where ΔT_{b1} and ΔT_{b2} are the temperature differences in the steady state before and after the transition respectively, and where Δc_s is the change in the specific heat of the sample. In this case, the change in the base line depends on the sensitivity and the heating rate, and thus higher heating rates are preferred. The response time to the new base line would also be of the order of $5\tau_0$.

Thus, we have a theoretical basis for estimating the heat of transformation by differential thermal analysis, and the expressions of the response time and the sensitivity have been given. The inherent limitations of the differential thermal analysis should now be considered. In the derivation given above, the heat capacity of the sample is implicitly assumed to be constant. If the heat capacity changes at the thermal transformation, the base line must change after the peak; the estimation of the peak area should suffer from these changes. The theoretical treatment can be derived considering these changes in the thermal properties of the sample; the corrected area is shown in Fig. 3, where the time interval, τ_c, has the following value (see Appendix):

$$\tau_c = c_h \rho_h \left(R_o^2 - R_i^2 - R_i^2 \log \frac{R_o}{R_i} \right) \Big/ 4\lambda_h \log \frac{R_o}{R_i} + c_s' \rho_s' R_i^2 \log \frac{R_o}{R_i} \Big/ 4\lambda_h \tag{20}$$

where c_s' and ρ_s' are the specific heat and the density of the sample after the transition, and where τ_c contains those unknown values. Therefore,

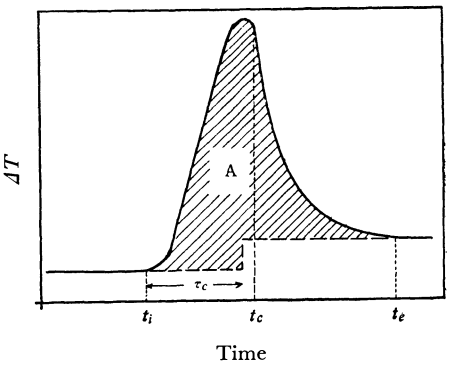

Fig. 3. The corrected peak area.

no accurate correction can be made unless those values are known. Strella[14] suggested a method of correction, but his theory contains rough assumptions and it seems that, using it, the error due to the assumptions would become larger than the correction.

The end effect neglected in the theory should also be considered; this effect would add some terms to the proportionality coefficient and could be decreased if the length of the cell is large enough in comparison with its diameter. The heat flow through the leads of the temperature-detection device is also neglected; it would also add some correction terms to the proportionality coefficient if the leads pass through the metal block and if the heat flows into the cell through the leads not from the outside but from the metal block.

Finally, let us give the proportionality coefficient, the sensitivity and the response time for other types of arrangements and discuss them briefly. For the most conventional type (as is shown in (a) of Fig. 1), because $R_o = R_i = R$ and $r = 0$ (see Appendix):

$$K = 4\pi l \lambda_s \tag{21}$$

$$S = R^2/4\lambda_s \tag{22}$$

and:

$$J_0(R\sqrt{c_s \rho_s/\lambda_s \tau_n}) = 0 \tag{23}$$

For the type shown in (b) of Fig. 1 (see Appendix):

$$K = 4\pi l/[1/\lambda_s + (2/\lambda_a) \log (R_o/R_i)] \tag{24}$$

$$S = R_i^2[1/4\lambda_s + (1/2\lambda_a) \log (R_o/R_i)] \tag{25}$$

Here the τ_n's are the roots of an equation similar to Eq. 9, where λ_h, c_h and ρ_h are replaced with those of air, λ_a, c_a and ρ_a respectively. If λ_s is much larger than λ_a,

$$K \fallingdotseq 2\pi l \lambda_a / \log (R_o/R_i) \tag{26}$$

The proportionality coefficient becomes the coefficient independent of the kind and the state of the sample, but the heat exchange by radiation and convection disturbs the proportionality, especially above 300°C.

Experimental

Apparatus.—In designing the apparatus, the assumptions made in the mathematical derivations must be taken into account, besides the arrangement of the cell, the cell holder and the temperature-detection device; the metal block must have a large enough heat capacity and heat transfer coefficient; it is preferable that the thermal conductivity of the cell holder be low and have a small temperature dependency; the solid cell holder must cover the entire surface of the cell; it should make a good, reproducible thermal contact with the surface of the cell if possible, and the temperature gradient in the system has a cylindrical symmetry (in other words, the length of the cylinder must be long enough compared with its radius). The temperature gradient in the metal block must be negligibly small. The response time and sensitivity must also be taken into account.

The purpose of constructing our apparatus is to study the thermal behavior of high polymeric meterials. Hence, the apparatus is expected to be operated up to 600°C and it must be suitable to a sample with a low thermal conductivity. The following apparatus is constructed for the above purpose, but the principles of the design considered in this research are essentially applicable to other fields of research.

According to the above considerations, the apparatus shown in Figs. 4 and 5 is constructed. The metal block consists of three separable parts, which cover the cell holders, as is shown in Fig. 4; these are made of nickel because of its thermal stability. Although copper and aluminum are preferred because of their higher thermal conductivities, these metals are not stable at high temperatures. In the block are drilled six cylindrical cavities, in which are inserted the cell holders, the cells, and the thermocouples. In two of the six cavities are set reference cells with the same heat capacity as that of the sample; in three of them, a sample cell, and in the sixth and last one a reference cell with a half-amount of the reference material. The temperature difference between the last reference cell and the ordinary reference cell serves as a monitor to indicate the false deflection of the base line due to the fluctuation of the heating rate or other accidential causes. The other three temperature differences between the three sample cells and the two reference

3 Metal block 4 Heater
5 Quartz support 6 Thermocouple

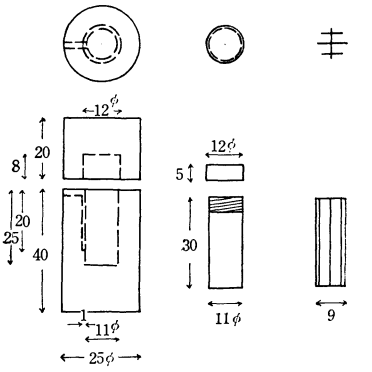

Fig. 5. The cell holder, the cell and the heat distributor.

cells are recorded. This arrangement makes possible the simultaneous measurement of three samples.

The block is inserted into a furnace made of a nickel cylinder. Nichrome wire about 0.3 mm. in diameter is wound on the mica film with which the side and bottom of the furnace are convered. As the heat capacity of the block is several hundreds times as large as that of the sample and the reference materials plus the cells, the linear heating of the block would not be disturbed by the heat of transformation occurring in the sample. Therefore, the control of the temperature of the furnace, not of the block itself, is suitable in this case in order to reduce the fluctuation of the heating rate, because of the faster response to control; furthermore, the narrow air gap between the block and the furnace absorbs the fluctuation of the short period and plays a role analogous to an electrical smoothing circuit.

Fused quartz is chosen as the material of the cell holder for the reasons mentioned above and because of its strength. The transition at 573°C of quartz has had little effect on the thermograms previously obtained, probably because of its small heat effect and its differential use. The shape of the holder is shown in Fig. 5. The thermocouple is inserted through the side groove. In determining the dimensions and the material of the holder, the proportionality coefficient, K, is calculated to be about 6 cal./°C min. at 100°C; the response times, τ_0's are also calculated and tabluated in Table I. These values are satisfactory, because $5a\tau_0$ is about 2°C at the heating rate of 30°C/hr. except for water.

The cell is made of stainless steel, SUS 27, or nickel;

its shape is shown in Fig. 5, which also shows the heat distributor, which is put into the cell to reduce the temperature gradient in the cell, to sharpen the peak, and to increase its accuracy and resolving power.

The whole system mentioned above is covered with a shield case preventing heat loss to the outside, and the apparatus is placed in a vacuum chamber.

As is shown in Fig. 4, the thermocouple leads pass through the metal block and the cell holder and are inserted between the interface and into the groove cut on the inner surface of the cell holder. These passages prevent the heat from flowing directly to the outside through the leads. The heat flows from the metal block into the sample cell through the thermocouple leads, but the proportionality of the peak area to the heat of transformation could be said to hold, taking account of this heat flow, which would add a certain correction term to the proportionality coefficient, because no heat flows into the cell from other parts of the apparatus. If a similar thermocouple and a similar insulating tube are always used, this heat flow occurs reproducibly.

An alumel-chromel thermocouple 0.3 mm. in diameter, manufactured by Hoskins Mfg. Co., is used with an alumina insulating tube 1 mm. in outer diameter. As the electromotive force of the thermocouple increases almost linearly with an increase in the temperature, the thermocouple is preferable for differential thermal analysis.

A cam-driven program controller of the three-position action type, purchased from the Chino Works, Ltd. (model E 142), is used to control the furnace temperature from 0 to 600°C; the power supplied to the furnace is controlled by the three-position action of the controller. Furthermore, the voltage of the supplied power is increased at the heating cycle with a synchronous motor when the temperature is not higher than the set point, and decreased at the cooling cycle when the temperature is not lower. A multipoint recorder with a 250 mm.-wide strip-chart, a d. c. amplifier (model AM101) and a relay-box (Ohkura Electric Co., Ltd.) recorded the four temperature differences and the temperature of the reference material as functions of the time. The full-scale span of the recorder corresponds to 60 μV. of the output of the differential thermocuples when fed through the d. c. amplifier at its highest sensitivity; it also corresponds to a 600°C rise in the temperature of the reference material. The dotting period for each point is 36 sec. Almost all runs are made at a heating rate of 30°C/hr. under an ambient pressure.

Materials.—The materials to be tested are used without purification. The manufacturer and the grade are listed in Table II. The 200—300 mesh powder of α-alumina from Nishio Kogyo Co., Ltd. is used as the reference material. Quartz sand of a 99.8% purity, occurring in Fukushima Prefecture and supplied by Nihon Optical Co., Ltd., is used as the diluent.

Results

To prove the validity of the theory, we should be able to show experimentally that the proportionality coefficient, K, does not depend on the sample and the operational variables, but on the temperature. Two types of experiments are made. (1) The measurements to obtain the proportionality coefficient are done on various kinds of samples of known heats of transition, including organic materials, inorganic salts and metals. The smoothed curve of the coefficients must be drawn against the temperature. (2) The coefficient is obtained for the transition of potassium perchlorate at 299.8°C, changing such operational variables as the heating rate, the packing density, the concentration of the diluent, and the depth of packing the sample. The same value of the coefficient must be obtained irrespective of the values of the variables.

First, the difference in the base line between the beginning and the end of the peak must be considered. As has been pointed out in connection with theoretical considerations, no true correction of the difference can be made unless the specific heat and the density of the sample are known. Therefore, the base line under the peak is taken as a straight line between the base line at the beginning and that at the end. Any error due to the above approximation would be small, because the differences in the base line, even if they exist, are small compared with the peak areas in most of the cases described below.

Next, we must check the reproducibility of the data which are obtained in investigations of the transitions of ammonium nitrate at 84°C and 125°C by the method of an analysis of the variance, where the elements are the cell holder, the cell, and the cylindrical cavity. The results of the analysis shows that the variance in the proportionality coefficient contains the variance of the cell holder because of the poor interchangeability, which is presumably due to the low precision of the machining. The standard deviation due to the experimental error amounts of about 7%; if one uses a given cell holder and measures the heat with this apparauts, the error of a single measurement may be 7%. In the following experiment three cell holders are used; they show middle values of the proportionality coefficient among the twelve and do not differ appreciably from one another.

Three methods of determing the temperature of the transformation have been used: the temperature is obtained at the point where the peak starts to develop, or at the top of the peak, or at the intersection of the line extrapolating the steeply-rising portion of the peak to the initial base line. The choice of method depends on the particular apparatus. The best estimate of the temperature of the transformation with our apparatus is obtained at the intersection. The temperatures obtained by this estimation are included in Table II. The average deviation of the measured temperature from the reported temperature is +2°C. A typical peak is reproduced in Fig. 6.

The results of Experiment (1) are tabulated in

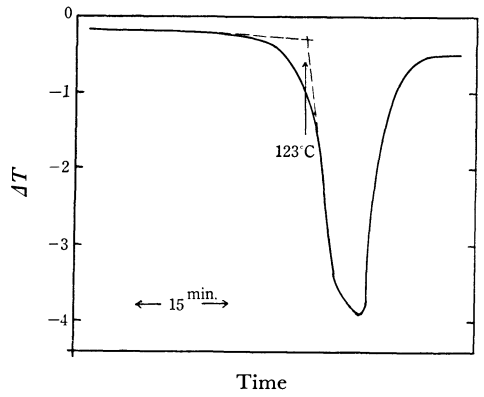

Fig. 6. A typical peak of benzoic acid.

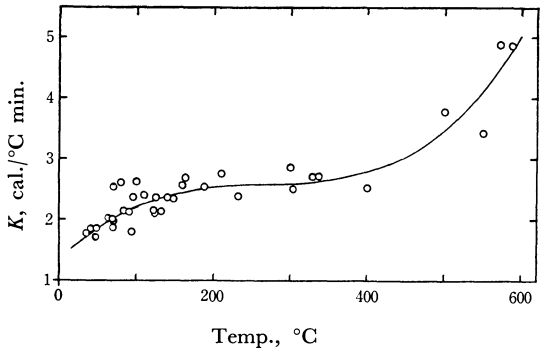

Fig. 7. The proportionality coefficient versus the temperature.

Table II, which also lists the measured temperatures of transformation, their literature values, and the literature heats of transformation, ΔH_{lit}. The proportionality coefficients are plotted in Fig. 7; the best fit was obtained by the method of the least squares, with a confidence limit of 95%. The formula of the smoothed curve is:

$$K = 1.507259 + 8.782709 \times 10^{-3}\, T - 1.808468 \times 10^{-5}\, T^2 + 6.324056 \times 10^{-14}\, T^4 \qquad (27)$$

where T is the temperature in °C. Considering the great variety of samples, their thermal conductivities, and particle sizes, Fig. 7 is sufficient to indicate that the proportionality coefficient is a function of the temperature only and that it is independent of the kinds and states of the samples. The standard deviations of the mean values of the proportionality coefficient of three or more measurements are 2% to 13%, as is shown in Table II; these errors are caused partly by the difference in the cell holders. Large deviations are found in the measurements of organic samples, presumably because of their broad peaks. The scattering of the points about the smoothed curve in Fig. 7 is due to the random error of the measurements, the difference in the cell holders, and the error in the reported values of the heat of transformation. The variance in the points is the sum of the three variances.

Now, we observe the dependency of the proportionality coefficient on the operational variables. The effects of the heating rate, the packing density, the concentration of the diluent and the depth of packing the sample are shown in Figs. 8, 9, 10 and 11 respectively. The packing density is varied as follows: for the most densely packed one, the powder sample is tamped into the cell as tightly as possible; for the second, the sample is poured into the cell, tapping the cell repeatedly; for the third, the sample is poured and tapped slightly, and for the most loosely packed one, the sample is poured lightly. To vary the concentration of the diluent, the weighed amounts of the powder sample and the diluent are mixed in a mortar and packed into the cell with a similar density. Except for the last effect, the operational variables have no effect on the proportionality coefficient.

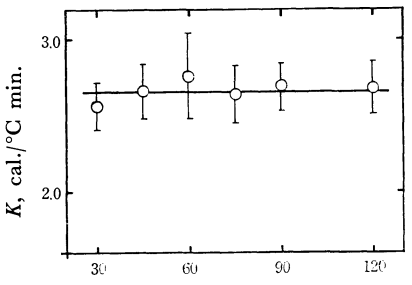

Fig. 8. The effect of heating rate. The range shown is the standard deviation.

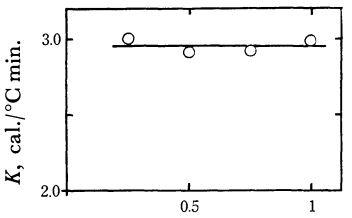

Fig. 9. The effect of packing density.

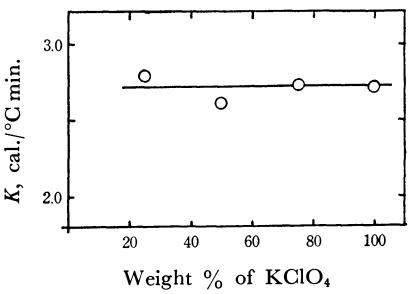

Fig. 10. The effect of diluent.

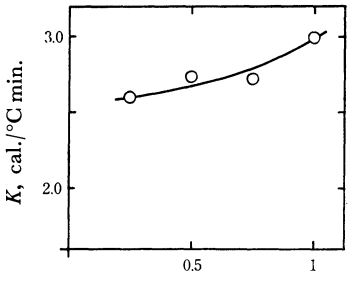

Fig. 11. The effect of the depth of packing the sample. The ratio of the depth of packing the sample to the depth of the cell is abscissa.

as has been expected in the theoretical considerations. The last effect would disturb the heat flow of the cylindrical symmetry and the consequent temperature gradient along the cylindrical axis would change the value of the proportionality coefficient. This finding suggests that the sample must be filled up to the top of the cell, even though loosely.

Besides these experiments, the effect of the diluent is tested by using the reference material of alumina as the diluent; the proportionality coefficient varies in this case. Alumina does not seem suitable as a diluent, probably because of the intereaction between the sample and the diluent.

These results shown above give an assurance of validity of the theory. We may conclude that the proportionality coefficient does not depend on the kind and state of the sample, but that it depends on the temperature only, as has been expected in the theoretical considerations, and that the estimation of the heat of transformation occurring in the sample is possible by this type of quantitative differential thermal analysis.

It would be explained by loose thermal contact due to a little air gap between the cell and the cell holder that the value of the proportionality coefficient obtained is smaller than the expected one of 6 cal./°C min. The linear relation of $\log(\Delta T - \Delta T_b)$ against the time after the completion of the transformation is verified experimentally; it is shown in Fig. 12. The response times, τ_0's, are also examined on some organic and inorganic samples and found to be about 1.5 min. for most samples. A reasoning similar to the above explanation of the proportionality coefficient applies to the discrepancy between the obtained response time and the calculated ones in Table I. It should also be noted that the effect of the heat distributor in the cell is neglected in the calculation of the response times.

To show an effect of the metal heat distributor in the cell, the peaks with or without the distributor are compared. The peak area does not change, but the peak becomes broader without the distributor. The transition of potassium perchlorate is completed 12 min. after the peak is reached without the distributor, but it is completed after 3 min. at the same heating rate when the distributor is used. The time of the completion is almost the same for different samples.

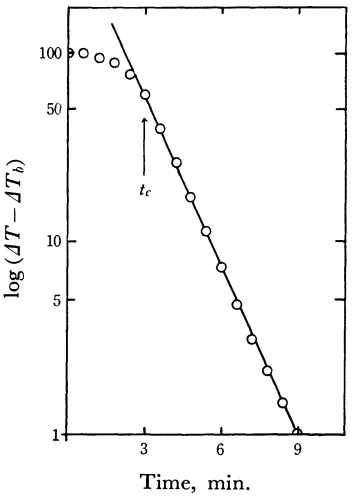

Fig. 12. The change of the temperature difference after the completion of the transformation of potassium perchlorate.

Discussion

Even after Boersma's suggestion of the inherent impossibility of quantitative differential thermal analysis, there have still been published a number of papers on the theme. For example, on the effect of the heating rate on the peak area, Barrall et al.[42] found, on several kinds of samples, that the peak area is decreased by a decrease in heating rate, showing zero area at a zero heating rate, with the type of apparatus where the microsample cell is suspended in an air oven. On the other hand, with a different type of apparatus such as (b) of Fig. 1, Barrall et al.[43] found a similar but more complicated dependency of the peak area of the mixture of silver nitrate; in this case the area is proportional to the heat of transition of the silver nitrate present when the areas at different heating rates are extrapolated to a zero heating rate. Ke[44] found the area of the melting of annealed Marlex 6000 to be independent of the heating rate. Suga et al.[45] reported similar findings except in the case of very low heating rates. In the cases mentioned

42) E. M. Barrall II, R. S. Porter and J. F. Johnson, *Anal. Chem.*, **36**, 2172 (1964).
43) E. M. Barrall II and L. B. Rogers, ibid., **34**, 1101 (1962).
44) B. Ke, *J. Polymer Sci.*, A, **1**, 1453 (1963).
45) H. Suga, H. Chihara, S. Seki, K. Nakatsuka and T. Shinoda, *J. Chem. Soc. Japan, Pure Chem. Sect. (Nippon Kagaku Zasshi)*, **82**, 24 (1961).

above, the area is compared among transitions of a single sample; therefore, the same sampling procedure should give the same proportionality coefficient.

The effect of the diluent is such that, if the sample content is low and if the packing state is changed slightly from run to run by fixing the particle size and the manner of packing the mixture, then the thermal conductivity and consequently the proportionality coefficient will become nearly constant. This effect was noted in the paper of Barrall et al.[43] on salicylic acid diluted with carborundum, and in Yamamoto's paper[46] on benzoic acid diluted with fused silica powder. However, as the diluent has other effects (e. g., the interaction with sample, resulting in a false peak),[47,48] the quantitative differential thermal analysis by using a diluent has limitations, besides the facts that the manner of packing has an influence on the area[46] and the sensitivity decreases because of a diluted active component.

With the type of apparatus in which the sample cell with the thermocouple on its outside is suspended in an air oven, Barrall et al.[42] found that the proportionality coefficient, calibrated with a few materials, shows a linear dependency on the temperature as has been observed in the present paper. David[49] compared with reported values the heats of the transition of eight samples calculated from the area and the proportionality coefficient calibrated on tin; he obtained satisfactory agreements with a similar apparatus. It should be noted here that, in the two papers[42,49] mentioned above, the thermocouple is located on the outside of the cell, that the air gap is between the cell and furnace wall, and that the observed transitions occur below 300°C. In these cases, the air gap would play the same role as the cell holder in the present paper if convection and radiation could be neglected. The results would be less satisfactory if the measurement were made above 300°C, where radiation transfers heat and David's theory would not hold.

Recently, Yagfarov[50] proposed a method of thermography with which one can obtain the values of specific heat, thermal conductivity and thermal diffusivity simultanously. The peak is obtained at the transformation of the sample by the principles of conventional differential thermal analysis; he postulated that the heat of transformation can be estimated from the peak and the thermal conductivity thus obtained. However, the thermal conductivity can not be obtained in the peak region because the thermal conductivity and the state of the packing of the sample have a tendency to change during the transformation. These difficulties were not discussed, and the heat of transformation estimated experimentally was not described, in his paper.

The results obtained in this research can not be of a very high precision, but they do seem encouraging. If the low interchangeability of the cell holder and its poor thermal contact with the block and the cell could be improved, the accuracy would be improved appreciably. In fact, a preliminary experiment with a ceramic cell holder shows an improved reproducibility, for the standard deviation is 3.3% for an average measurement.

However, the most serious defect of the differential thermal analysis as a technique for measuring the heat of transformation is the necessity of calibrating it with a sample of a known heat of transformation. Hence, the accuracy of the method depends on that of the other absolute method of heat measurement. In order to bring out the unique merits of differential thermal analysis, it should be applied to the field of higher temperatures and high pressures; research for developting the absolute differential thermal analysis is now keenly needed.

As an analytical technique, the method proposed in this paper seems to have fair advantages over the other types of differential thermal analysis, because it does not suffer from operational variables and because it improves the reproducibility of the peak of the thermogram. The new concepts presented in this paper, i. e., the response time and the sensitivity, would be helpful for designing new apparatuses.

Attempts are now in progress in our laboratory to improve the apparatus and to make the method an absolute one; this work will be reported on shortly. These improvements will reduce the differential thermal analysis to a dynamic operation of a calorimeter of Calvet's type;[51] it will be a calorimeter with unique features and unique applicability. Both this apparatus and Calvet's are based on the same theoretical back-grounds, so the theory can also be applied to a calorimeter of Calvet's type.

The capable assistance of Hiroshi Isozake in the assembly and operation of the apparatus is gratefully acknowledged. Thanks are also due to Professor Hirotaro Kambe of the Institute of Space and Aeronautical Science, The University of Tokyo, for his encouraging discussions.

Appendix

To derive the temperature change in the sample cell and the cell holder, the temperature is divided into three parts:

48) E. M. Barrall II and L. B. Rogers, ibid., **34**, 1106 (1962).
49) D. J. David, ibid., **36**, 2162 (1964).
50) M. S. Yagfarov, *Russ. J. Inorg. Chem.* (English translation), **6**, 1236 (1961).
51) E. Calvet, *Compt. rend.*, **226**, 1702 (1948); ibid., **236**, 486 (1953).

$$T = T_1 + T_2 + T_3 \tag{A-1}$$

where T_1 represents the temperature at the steady state, where T_1+T_2 is the initial transient temperature, and where T_3 is the additional temperature due to the heat of transformation. First, the temperature gradient at the steady state is considered; then the transient state and the peak are calculated by using the linearity of differentiation, which makes possible the above separation of the temperature. All these temperatures must be derived as functions of the coordinate for the arrangement of (c) in Fig. 1.

If we designate by q the heat flowing into the inner part per unit time through a cylindrical plane of a unit length, and the radius by r, q is the heat necessary to heat up the inner part at the rate of a at the steady state, and the temperature gradient at r occurs by the necessity of letting the heat q flow. Then, for $0 \leq r \leq R_i$:

$$q = \int_0^r 2\pi r a c_s \rho_s \mathrm{d}r \tag{A-2}$$

and for $R_i \leq r \leq R_o$:

$$q = \int_{R_i}^r 2\pi a c_h \rho_h \,\mathrm{d}r + \pi R_i^2 a c_s \rho_s \tag{A-3}$$

The temperature gradient is:

$$q = 2\pi r \lambda_s \partial T_{s1}/\partial r \qquad \text{for } 0 \leq r \leq R_i \tag{A-4}$$

and:

$$q = 2\pi r \lambda_h \partial T_{h1}/\partial r \qquad \text{for } R_i \leq r \leq R_o \tag{A-5}$$

By combining Eqs. A-2 and A-4, and Eqs. A-3 and A-5, the integration of them gives T_{s1} and T_{h1}: for $0 \leq r \leq R_i$:

$$T_{s1}(r) - T_{s1}(R_i) = a c_s \rho_s (r^2 - R_i^2)/4\lambda_s \tag{A-6}$$

and for $R_i \leq r \leq R_o$:

$$T_{h1}(r) - T_{h1}(R_o) = a c_h \rho_h (r^2 - R_o^2)/4\lambda_h + a R_i^2 \log (r/R_o)(c_s \rho_s - c_h \rho_h)/2\lambda_h \tag{A-7}$$

As the temperature of the metal block, $T_{h1}(R_o)$, is equal to at,

$$T_{s1}(r) = at - \frac{a}{4\lambda_h}\left[c_h \rho_h (R_o^2 - R_i^2) + 2R_i^2 (c_s \rho_s - c_h \rho_h) \log \frac{R_o}{R_i}\right] - \frac{a c_s \rho_s}{4\lambda_s}(R_i^2 - r^2) \tag{A-8}$$

$$T_{h1}(r) = at - \frac{a}{4\lambda_h}\left[c_h \rho_h (R_o^2 - r^2) + 2R_i^2 (c_s \rho_s - c_h \rho_h) \log \frac{R_o}{r}\right] \tag{A-9}$$

Secondly, the initial transient period must be taken into account. For this period, the next differential equations hold, because conditions and solutions must be added to those of the steady state to fulfil the overall conditions.

$$\lambda_s \nabla T_{s2} = c_s \rho_s \partial T_{s2}/\partial t \tag{A-10}$$

$$\lambda_h \nabla T_{h2} = c_h \rho_h \partial T_{h2}/\partial t \tag{A-11}$$

with the boundary conditions:

$$T_{h2} = 0 \qquad \text{at } r = R_o \tag{A-12}$$

$$\lambda_s \partial T_{s2}/\partial r = \lambda_h \partial T_{h2}/\partial r \qquad \text{at } r = R_i \tag{A-13}$$

$$T_{s2} = T_{h2} \qquad \text{at } r = R_i \tag{A-14}$$

and with the initial conditions:

$$T_{s2} = \frac{a}{4\lambda_h}\left[c_h \rho_h (R_o^2 - R_i^2) + 2R_i^2 (c_s \rho_s - c_h \rho_h) \log \frac{R_o}{R_i}\right] + \frac{a c_s \rho_s}{4\lambda_s}(R_i^2 - r^2) \tag{A-15}$$

$$T_{h2} = \frac{a}{4\lambda_h}\left[c_h \rho_h (R_o^2 - r^2) + 2R_i^2 (c_s \rho_s - c_h \rho_h) \log \frac{R_o}{r}\right] \tag{A-16}$$

Assuming the cylindrical symmetry, the solutions of the above partial differential equations are typical;[52] they are given below:

$$T_{s2} = \sum_{n=0}^{\infty} \alpha_n \boldsymbol{J}_0\left(r\sqrt{\frac{c_s \rho_s}{\lambda_s \tau_n}}\right)[\boldsymbol{J}_0(R_i x)\boldsymbol{Y}_0(R_o x) - \boldsymbol{J}_0(R_o x)\boldsymbol{Y}_0(R_i x)] \exp\left(-\frac{t}{\tau_n}\right) \tag{A-17}$$

$$T_{h2} = \sum_{n=0}^{\infty} \beta_n \boldsymbol{J}_0\left(R_i\sqrt{\frac{c_s \rho_s}{\lambda_s \tau_n}}\right)[\boldsymbol{J}_0(rx)\boldsymbol{Y}_0(R_o x) - \boldsymbol{J}_0(R_o x)\boldsymbol{Y}_0(rx)] \exp\left(-\frac{t}{\tau_n}\right) \tag{A-18}$$

where x is equal to the x used in Eq. 9, and where α_n's and β_n's are constants. In order to fulfil the boundary and initial conditions, A-12, A-13, A-14, A-15 and A-16, τ_n's are defined by the roots of Eq. 9, and α_n's and β_n's are determined to express the initial temperature distribution. By adding Eq. A-8 to Eq. A-17, and Eq. A-9 to Eq. A-18, we obtain Eqs. 7 and 8.

Thirdly, the other transient temperature is derived. The temperature distribution at the time of the completion of the transformation, t_c, can be expressed as a certain function of r, which is the initial condition for this case. As the same expressions of Eqs. A-10 to A-14 are applicable, the solutions, i. e., Eqs. 14 and 15, are derived similarly to Eqs. 7 and 8. It is apparent from the above considerations that T_3 is diminished to a negligibly small value, after a long enough time has elapsed, and then the additional temperature due to the heat of transformation reaches a form of peak.

Finally, the peak area from the beginning of the peak, t_i, to its end, t_e, is calculated.

$$\lambda \nabla T_3 = c\rho \partial T_3/\partial t + \Delta H \rho \partial m/\partial t \tag{A-19}$$

The initial and final conditions are as follows:

$$T_3 = 0 \qquad \text{at } t = t_i \tag{A-20}$$

$$T_3 = 0 \qquad \text{at } t = t_e \tag{A-21}$$

and the boundary conditions are:

$$T_3 = 0 \qquad \text{at } r = R_o \tag{A-22}$$

$$T_{s3} = T_{h3} \qquad \text{at } r = R_i \tag{A-23}$$

and:

$$\lambda_s \partial T_{s3}/\partial r = \lambda_h \partial T_{h3}/\partial r \qquad \text{at } r = R_i \tag{A-24}$$

The integration of Eq. A-19 from t_i to t_e gives:

$$\lambda \int_{t_i}^{t_e} \nabla T_3 \,\mathrm{d}t = c\rho \int_{t_i}^{t_e} \mathrm{d}T_3 + \rho \Delta H \tag{A-25}$$

52) H. S. Carslaw and J. C. Jaeger, "Conduction of Heat in Solids," Oxford University Press, Oxford (1959).

According to the initial and final conditions,

$$c\rho\int_{t_i}^{t_e} dT_3 = 0 \qquad \text{(A-26)}$$

and the integration of T_3 from t_i to t_e is the desired peak area, A. Then, the integration of Eq. A-25 over the volume, V, as with Boersma,[11] gives:

$$\lambda\int_V dV\Delta A = \int_V \rho\Delta H\, dV \qquad \text{(A-27)}$$

Namely,

$$\lambda\int_F dF\, \boldsymbol{grad}\, A = \rho V\Delta H \qquad \text{(A-28)}$$

where F is the surface of the cylinder; considering the cylinderical symmetry, we have:

$$F\lambda\frac{\partial A}{\partial r} = \rho V\Delta H \qquad \text{(A-29)}$$

Taking into account that the heat is produced or consumed in the sample only, Eq. A-29 is separated into two equations: for $R_i \leq r \leq R_o$:

$$\frac{\partial A(r)}{\partial r} = \rho_s\Delta H V_s/\lambda_h F(r) \qquad \text{(A-30)}$$

where V_s is the volume of the sample, and for $0 \leq r \leq R_i$:

$$\frac{\partial A(r)}{\partial r} = \rho_s\Delta H V(r)/\lambda_s(r) \qquad \text{(A-31)}$$

As $T_3=0$ at $r=R_o$, for $R_i \leq r \leq R_o$:

$$A(r) = \frac{M\Delta H \log(R_o/r)}{2\pi l\lambda_h} \qquad \text{(A-32)}$$

and for $0 \leq r \leq R_i$:

$$A(r) = \frac{M\Delta H}{2\pi l}\left[\frac{\log(R_o/R_i)}{\lambda_h} + \frac{(R_i^2-r^2)}{2\lambda_s R_i^2}\right. \qquad \text{(A-33)}$$

All the derived equations are functions of r, the position of the temperature-detection device, and if we let r equal R_i, i. e., if the temperature-detection devices are inserted at R_i, the equation becomes equal to Eq. 16. If r is made equal to 0 and if the radiation and convection can be neglected, the equation becomes applicable to the type (b) of Fig. 1. Equation applicable to the conventional method is also derived, when R_o is made equal to R_i and r, equal to 0.

Let us consider the case where the specific heat, the density, and the heat conductivity change abruptly to new values, c_s', ρ_s' and λ_s', at the temperature of transformation, T_t. The base line after the peak becomes different from the one prior to the peak, reflecting this change in thermal properties; Eq. 16 can not be applied to this case; for it, however, an expression can be derived for the apparatus of the type (c) in Fig. 1.

The heat flowing through the cylindrical plane in the cell holder with the radius of r, into the cell and the inner part of the cell holder from t_i to t_e is equal to the heat necessary to heat the inner part from the temperature distribution at t_i to the new temperature distribution at t_e, plus the heat of transformation. The temperature distributions at t_i and t_e must first be derived. As the sample at the outermost part of the cell begins to be transformed at t_i, the temperature at this point is equal to the temperature of the transformation. Therefore, for $0 \leq r \leq R_i$:

$$T_s = T_t - \frac{ac_s\rho_s}{4\lambda_s}(R_i^2 - r^2) \qquad \text{at } t = t_i \qquad \text{(A-34)}$$

and for $R_i \leq r \leq R_o$:

$$T_h = T_t + \frac{a}{2\lambda_h}R_i^2(c_s\rho_s - c_h\rho_h)\log\frac{r}{R_i} + \frac{ac_h\rho_h}{4\lambda_h}(r^2 - R_i^2) \qquad \text{at } t = t_i \qquad \text{(A-35)}$$

when $t=t_e$, at $r=R_o$:

$$T_h = T_t + a(t_e - t_i) + \frac{a}{2\lambda_h}R_i^2(c_s\rho_s - c_h\rho_h)\log\frac{R_o}{R_i} + \frac{ac_h\rho_h}{4\lambda_h}(R_o^2 - R_i^2) \qquad \text{(A-36)}$$

for $R_i \leq r \leq R_o$:

$$T_h = T_t + a(t_e - t_i) + \frac{a}{2\lambda_h}R_i^2(c_s\rho_s - c_h\rho_h)\log\frac{R_o}{R_i} + \frac{ac_h\rho_h}{4\lambda_h}(R_o^2 - R_i^2) - \frac{ac_h\rho_h}{4\lambda_h}(R_o^2 - r^2) - \frac{a}{2\lambda_h}R_i^2(c_s'\rho_s' - c_h\rho_h)\log\frac{R_o}{r} \qquad \text{(A-37)}$$

and for $0 \leq r \leq R_i$:

$$T_s = T_t + a(t_e - t_i) + \frac{a}{2\lambda_h}R_i^2(c_s\rho_s - c_h\rho_h)\log\frac{R_o}{R_i} + \frac{ac_h\rho_h}{4\lambda_h}(R_o^2 - R_i^2) - \frac{a}{4\lambda_h}R_i^2(c_s'\rho_s' - c_h\rho_h)\log\frac{R_o}{R_i} - \frac{ac_h\rho_h}{4\lambda_h}(R_o^2 - R_i^2) - \frac{ac_s'\rho_s'}{4\lambda_s}(R_i^2 - r^2) \qquad \text{(A-38)}$$

The heat necessary to bring the system from the state described by Eqs. A-34 and A-35 to the state described by Eqs. A-37 and A-38 includes the following: (1) the heat to heat up the sample from the initial temperature (Eq. A-34) to T_t with the specific heat of c_s and the density of ρ_s; (2) the heat of the transformation of the sample, $M\Delta H$; (3) the heat to raise the temperature of the sample from T_t to the temperature distribution of Eq. A-38 with the specific heat of c_s' and the density of ρ_s', and (4) the heat necessary to heat the cell holder from the state of Eq. A-35 to Eq. A-37. Now suppose that the transformation did not take place. Then, the base line would not change and the heat flowing through the cylindrical plane, with the radius r, during the interval is $a(t_e - t_i)[\pi R_i^2 c_s\rho_s + \pi(r^2 - R_i^2)c_h\rho_h]$. Therefore, it we represent the additional temperature due to the transformation by ΔT_t, which is the temperature difference between the peak and the extrapolated initial base line,

$$2\pi r\lambda_h\frac{\partial}{\partial r}\int_{t_i}^{t_e}\Delta T_t(r,t)\,dt = a(t_e - t_i)\pi R_i^2(c_s'\rho_s' - c_s\rho_s) + \frac{a\pi c_s'\rho_s'}{4\lambda_h}R_i^4\log\frac{R_o}{R_i}(c_s\rho_s - c_s'\rho_s') + \frac{a\pi}{8\lambda_s}R_i^4[(c_s\rho_s)^2 - (c_s'\rho_s')^2] + \Delta H\pi R_i^2\rho_s + \frac{ac_h\rho_h\pi}{4\lambda_h}(c_s\rho_s - c_s'\rho_s')(2r^2\log R_o + r^2 - 2r^2\log r - R_i^2) \qquad \text{(A-39)}$$

By integrating Eq. A-39 and making r equal to R_i, we obtain:

$$\int_{t_i}^{t_e} \Delta T_t \, dt = \frac{R_i^2 \rho_s \Delta H}{2\lambda_h} \log \frac{R_o}{R_i} + \frac{a(t_e - t_i)}{2\lambda_h} R_i^2 \log \frac{R_o}{R_i} (c_s' \rho_s' - c_s \rho_s) + \frac{a c_h \rho_h}{8\lambda_h^2} R_i^2 (c_s \rho_s - c_s' \rho_s') \left(R_o^2 - R_i^2 - R_i^2 \log \frac{R_o}{R_i} \right) + \frac{a R_i^4}{16 \lambda_s \lambda_h} \log \frac{R_o}{R_i} (c_s^2 \rho_s^2 - c_s'^2 \rho_s'^2) + \frac{a c_s' \rho_s'}{8\lambda_h^2} R_i^4 (c_s \rho_s - c_s' \rho_s') \left(\log \frac{R_o}{R_i} \right)^2 \quad \text{(A-40)}$$

The left side of Eq. A-40 is the area enclosed by the peak, the extrapolated initial base line and the straight line drawn perpendicularly at $t = t_e$. This equation can be converted to the next one by considering Eqs. 16 and 19:

$$M \Delta H = K \left[\int_{t_i}^{t_e} \Delta T_t \, dt - (\Delta T_{b2} - \Delta T_{b1}) \{ (t_e - t_i) - \tau_c \} \right] + a\pi R_i^4 \left(\frac{c_s^2 \rho_s^2}{\lambda_s} - \frac{c_s'^2 \rho_s'^2}{\lambda_s'} \right) \quad \text{(A-41)}$$

If some devices are used to decrease the temperature gradient in the cell, the last term of Eq. A-41 due to the change in the temperature distribution in the cell may be neglected; the corrected peak area is as is shown in Fig. 3 and Eq. 20.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2085—2094 (1966)

The Deterioration of Oxidative Polymerized Films

By Leo-Wang CHEN and Ju KUMANOTANI

The Engineering Research Institute, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received November 24, 1965)

The deterioration of oxidative polymerized films, such as films of polymerized oils, alkyd resins, and phenolic varnishes, was studied by means of dynamic-mechanical measurements, in addition to such conventional methods as infrared spectral and elementary analysis. The visco-elastic changes induced by thermo-oxidation were correlated with the network structure of the films. The baked films are more stable than the air-dried films. The aliphatic chains decomposed more easily when a comparison was made among air-dried film and baked film of alkyd resin modified by unsaturated fatty acid; this is because of the existence of more hydroperoxyl and conjugated carbonyl groups and the effect of the drying agent contained in the air-dried film. After thermo-oxidation, the glass-transition temperature and the degree of crosslinking of the film showed an increase, an increase which is considered to be the result of the oxidative decomposition and crosslinking of aliphatic chains. It was also observed that the impact strength of baked film decreased upon thermo-oxidation.

Polymerized oils, alkyd resins, and phenolic varnishes are representative of oxidative polymerizable prepolymers widely employed in the coating industry. The film formation is proceeded by the formation of hydroperoxide and then its decomposition leading to a network structure. The autoxidation being complicated, the film structure is much affected by such conditions as the temperature, the catalyst, and the time under which the varnish or film is treated. With this reaction complexity and the easy chemical modification of prepolymers, this is a field of study which correlates the physical properties and the structure of the crosslinking polymer. Not only practical requirements but also the study of the polymer reaction needs such investigation, but the reaction complexity and the difficulty of handling the network structure somewhat affect the carrying-out of this study.

The authors measured the viscoelastic properties, the line-width of the NMR spectra, and the molecular weight between crosslinks, besides such conventional analytical methods as infrared spectral and elementary analysis, in their study. Some information has already been obtained, such as the effect of chemical factors on the glass-transition temperature and the degree of crosslinking of alkyd films,[1] the correlation of the glass transition temperature measured by the dynamic-mechanical method and the line-width measurement (NMR) in relation to the chemical structure,[2] and the chemical and physical behavior of phenolic resins in films of phenolic varnishes.[3]

In this report, the deterioration of oxidative polymerized films induced by thermo-oxidation will be studied by means of dynamic-mechanical

measurements made in combination with infrared spectral analysis and other methods.

As the deterioration of polymer is of importance in respect to its polymer reactions and its practical requirements, several papers[4-7] regarding the degradation of oxidative polymerized films have been reported. These studies have involved degradation by ultraviolet rays, thermo-oxidative degradation, or aging, and have been carried by means of the analysis of infrared absorption spectra, oxygen absorption, and volatile materials, or by means of the mechanical-property measurement of films, independently or sometimes in combination.

As to the thermo-oxidative degradation of oxidative polymerized films, the films prepared from polymerized oil, alkyd resin, and phenolic varnishes will be studied, and air-dried and baked films will be compared as well.

Their viscoelastic change in correlation with the network structure will also be investigated in this report.

Experimental

Raw Materials.—*Drying Oil (O).*—A mixture of tung oil (iodine value 168, Wijs method) and linseed oil (iodine value 187) (1 : 1) was used.

Phenol Resins.—*p-t*-Butylphenol-formaldehyde resins were prepared by the conventional method; the oil-reactive resin (R) had a molecular weight of 650, as measured by a vapor pressure osmometer (Mechrolab, Inc.) m. p. 65—72°C, while the oil-nonreactive resin (N) had a molecular weight of 375, m. p. 55—62°C.

Linseed Oil Fatty Acid.—Commercially-available: iodine value 187.

Glycerol and Phthalic Anhydride.—They were chemically pure.

The Preparation of Prepolymers.—*Polymerized Oil.*—The drying oil was heated in air at 210°C for 5.5 hr. The heating was stopped near gelation, and the mixture was dissolved in an equal weight of mineral turpentine after it had been cooled to room temperature.

Phenolic Varnishes.—A mixture of oil and resin (6 : 4) was heated in air at 210°C. The heating was stopped near gelation, and the mixture was dissolved in an equal weight of mineral turpentine. The reaction time was 8 hr. for the oil-nonreactive resin (N–O), and 3 hr. for the oil-reactive resin (R–O). Another varnish was prepared by dissolving at room temperature, a mixture of polymerized oil and oil-nonreactive resin (6 : 4) in an equal weight of mineral turpentine containing 2—3% methyl ethyl ketone (N+PO).

Alkyd Resin.—An Equimolar mixture of linseed oil fatty acid, glycerol, and phthalic anhydride was put in a four-necked 500-ml. flask equipped with a sealed glass stirrer, a thermometer, a nitrogen gas inlet tube, and a Stark & Dean trap, and heated in an oil bath at 230°C for 9 hr. The varnish was prepared by dissolving the prepolymer ($\bar{M}_n$, 1710) in an equal weight of xylene.

Conditions of Film Formation.—*Polymerized Oil Film.*—The varnish, containing drying agents, naphthenates of cobalt (0.02%) and manganese (0.02%) was coated on tin plates, the coating and heating at 80°C for 2 hr. were repeated 10 times.

Films of Phenolic Varnishes.—The varnishes, containing drying agents, naphthenates of cobalt (0.02%) and manganese (0.02%), were coated on tin plates. For air drying, the procedure of coating and standing for one day at room temperature was repeated 10 times. For baking, the same procedure was used as with polymerized oil film.

Alkyd Films.—In the case of air drying, the varnish containing drying agents, naphthenates of cobalt (0.04%), manganese (0.04%), and lead (0.2%), was coated on tin plate and left to stand at room temperature two days. This procedure was repeated 4 times. In the case of baking, the varnish, without any drying agent being added, was coated on tin plate and heated at 105°C for 2 hr. in air. This procedure was repeated 4 times. The films were then stripped off by an amalgam method.

The Conditions of Thermal Treatment.—*Polymerized Oil Film.*—After it had stood in air for 3 months, the film was heated in air at 150°C for 3 hr., and then subsequently heated at 200°C for 3 hr.

Films of Phenolic Varnishes.—After they had stood in air for 3 months, the films were submitted to heating, just as in the case of the polymerized oil films.

Alkyd Films.—After it had stood in air for 2.5 months, the air-dried film was heated in air at 105°C for 5 hr., while the baked film, after it had stood in air a week, was submitted to heating just as in the case of the polymerized oil film.

The Dynamic-mechanical Measurement of Films.—The temperature (t) dependence of the shear modulus (G) and the logarithmic decrement (λ) of the film were measured by the torsional pendulum method.[8] The data obtained from the G-t and λ-t curves included the glass transition temperature as measured by the dynamic-mechanical method $(T_g)_d$; the temperature at which λ reaches a maximum (λ_{max}). As the frequency of measurement is in the range of 0.1-1 cycle/sec., the $(T_g)_d$ value is not far from that obtained by the dilatometric method.[9]

Shear modulus at high temperatures G_h; This is the shear modulus obtained from the plateau region at high temperatures. It is a measure of the degree of the crosslinking of film.[10-12] Shear modulus at room temperature G_r; This is the shear modulus at 20°C, noted as a measure of the rigidity of the film at room temperature.

Infrared Spectral Analysis of Films.—The change in the functional group in the process of film degradation was examined by the measurement of the infrared spectra.

A rock salt was coated with varnish and dried, and then thermo-treated under specified conditions, as mentioned previously, the infrared spectra were then measured. The chemical change in functional groups is reflected in changes in the optical density (D) or the ratio of those of related functional groups.

In infrared spectral analysis, the characteristic absorption bands employed are: ν_{3570} cm^{-1}: hydroxyl, hydroperoxyl, or carbonyl; ν_{2850} cm^{-1}: methyl or methylene of aliphatic chains; ν_{1590} cm^{-1}: the carbon-to-carbon linkages of phthalate; and ν_{980} cm^{-1}, trans ethylenic double bond, while D_{2850}/D_{1590} is expressed as a measure of the ratio of the aliphatic to the phthalate in films.

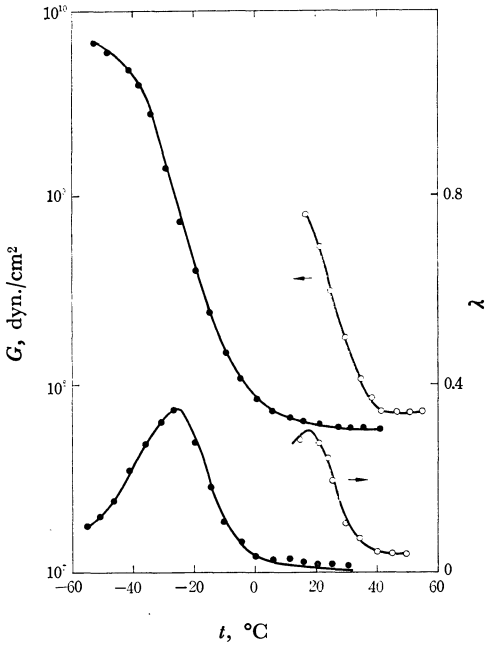

Fig. 1. Thermo-oxidative degradation of polymerized oil film observed in G-t, λ-t curves.
● Original film
○ After heating at 150°C for 3 hr.

The Degree of Swelling and the Soluble Portion of the Film.—The degree of swelling and the soluble portion of film were measured as follows:

The film (W_0) was dipped in chloroform at room temperature for more than a week; then the swollen film was weighed in another covered weighing bottle filled with chroloform until the weight was constant (W_s). The degree of swelling is expressed by $(W_s/W_0) \times 100$.

The swollen film was then dried in a vacuum (W_d), and the soluble portion of film was expressed by $(W_0 - W_d)/W_0 \times 100$.

Other measurements of the properties of the film, such as elementary analysis, thermograms*1 and impact strength*2 were also carried out.

Results and Discussion

The Thermo-oxidative Degradation of Polymerized Oil Film.—The G-t and λ-t curves of polymerized oil film are shown in Fig. 1, while the infrared spectra are shown in Fig. 2. The results are summarized in Table I.

It was observed when the baked polymerized oil film was thermo-treated in air that:

1) The $(T_g)_d$, G_r, and G_h of the film increased; namely, the hardness of film and the degree of the crosslinking of the film increased:

2) D_{2850}, D_{3570}, and D_{980} decreased; and

3) The weight loss amounted to 8.7% when the film was treated at 150°C for 3 hr. in air.

The Thermo-oxidative Degradation of Films of Phenolic Varnishes.—The G-t and λ-t curves of films of phenolic varnishes are shown in Fig. 3 and Fig. 4. The results are summarized in Table II.

It was observed when the films of phenolic varnishes were thermo-treated in air that:

1) The $(T_g)_d$, G_r, and G_h values of the films increased, and

2) The weight loss amounted to 10% or more

when the film was treated at 150°C for 3 hr. in air.

The infrared spectra changes involved in the thermal treating are shown in Figs. 5 and 6, and in Table III. The films prior to thermal treatment were a little different from that used for viscoelastic measurement; namely, each of the varnishes was coated on rock salt and dried for two days, followed by heating at 80°C for 10 hr. and subsequent heating at 150°C for 3 hr. and at 200°C for 3 hr. in air.

It was observed that D_{2850}, D_{3570}, and D_{980} decreased in this thermal treating.

The Thermo-oxidative Degradation of Alkyd Films.—The G-t and λ-t curves, the infrared spectra, and the thermogram of air-dried film are shown in Figs. 7, 8, and 9 respectively. The results are summarized in Table IV.

It was observed when the air-dried film was

thermo-treated in air that:

1) The $(T_g)_d$, G_r, and G_h values of the film increased, and the λ-t curve was broadened:

2) The weight loss amounted to 7% when the film was treated at 150°C for 3 hr. in air, and

3) D_{2850}/D_{1590} and D_{3570}/D_{1590} decreased intensively, whereas D_{1590} unchanged.

The G-t and λ-t curves, the infrared spectra, and the thermogram of baked film are shown in Figs. 10, 11, and 9 respectively. The results are

summarized in Table V. The results concerning the degree of swelling and the soluble portion of film, and impact strength of films are also tabulated in Table V.

It was observed when the baked film was heated in air that:

1) The $(T_g)_d$, G_r, and G_h values of the film increased:

2) D_{2850}/D_{1590} and D_{3570}/D_{1590} decreased less than in the case of air-dried film, and D_{1590} decreased also, and

3) The D_{980} decreased also.

It was generally observed when the oxidative polymerized films were thermo-treated that the glass transition temperature and the degree of the crosslinking of the film increased accompanying a decrease in the aliphatic chains and the trans ethylenic double bonds.

The increase in $(T_g)_d$ is considered to be the result of the oxidative decomposition and crosslinking of aliphatic chains. In relation to the network structure, the free aliphatic chains functioned as internal plasticizers; such a function was decreased by the oxidative decomposition of the aliphatic chain induced by thermal treating. Moreover, it may be suggested that such oxidative decomposition induces the decrease in the impact strength of the film.

A Comparison of Thermo-oxidative Degradation of Air-dried and Baked Films.— Smith[6] reported that the baked film alkyd resin (175°C-1 hr.) decomposed and dissipated completely after being heated at 200°C for 5 days. Miller[5] reported that the phthalate also suffered decomposition after the baked film of alkyd resin had been exposed (120°C; 1 hr. without the addition of any drying agent) to ultraviolet rays, they described the conjugated carbonyl as especially unstable, as had been recognized by others. FitzGerald[4] reported that the phthalates decomposed when the baked film of alkyd resin (175°C; 20 min., with the

addition of a drying agent: stored in air for one month) was thermo-treated (120°C-72 hr.), or exposed to ultraviolet rays. Such a decomposition was initiated at the unsaturated part of aliphatic chains and propagated to the glyceride part and the phthalate part; as a result, the alkyd molecules decomposed and dissipated.

When the thermo-oxidative degradations of air-dried and baked alkyd films were compared, it was found the aliphatic chain decomposed more in the case of air drying; nevertheless, it was treated

mildly, and the phthalate was unchanged.

As to baked film, the phthalate dissipated after this thermal treating; this result accorded with those obtained by others.

--△-- Air dried film, —●— Baked film

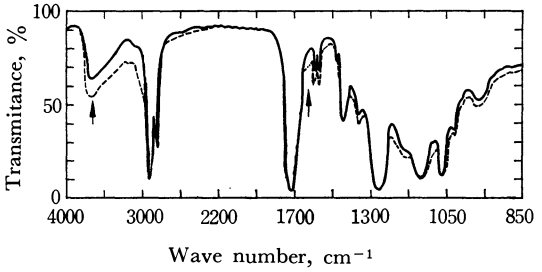

Fig. 16. Comparison of infrared spectra of air-dried and baked film of unsaturated fatty acid modified alkyd resin prior to thermo-oxidative degradation.
---- Air-dried film, —— Baked film

The easy decmoposition of air-dried film is also observed in films of phenolic varnishes and polymerized oil films (see Figs. 12, 13, and 14 and Table VI). Table VI is a comparison of the weight loss during thermal treatment, and Figs. 12—14 are thermograms of air-dried and baked films of phenolic varnishes or polymerized oil exposed in air for the same time and thermal treated under the same conditions.

The infrared spectra, G-t and λ-t curves, and elementary analysis of alkyd films prior to thermal treatment were compared. It was found that:

1) The absorptions near 3500 cm^{-1} and near 1600 cm^{-1}, which are due to conjugated carbonyl, of air-dried film were more intensive (see Fig. 16):

2) The $(T_g)_d$ values are the same, and the shear modulus of plateau region was not observed in air-dried film. The degree of crosslinking of air-dried film is small, suggesting a less crosslinked network structure (see Fig. 15), and

3) The oxygen combined per acyl group in film is nearly the same (see the last column of Table VII).

In combination with these results and the application of the mechanism of autoxidation, it may be suggested that the amount of hydroperoxyl group in air-dried film is more than that in baked film.

Another factor which should be taken account of in connection with easy decomposition of aliphatic chains in the network structure is the effect of drying agents. In this connection, the following five were prepared from a varnish of a composition similar to that of the varnish used in the above experiment.

Film 1.—The varnish, with drying agents (Co 0.02%, Mn 0.02%) added, was coated every other day (6 times) at room temperature.

Film 2.—The varnish, without any drying agents added, was coated and heated at 105°C for 2 hr.; this procedure was also repeated 6 times.

Film 3.—As with Film 2, except that drying agents were added (Co. 0.02%, Mn 0.02%).

Film 4.—The varnish, without any drying agents added, was coated and heated at 105°C for 8 hr.; this procedure was repeated 6 times.

Film 5.—As with Film 4 except that drying agents were added (Co 0.02%, Mn 0.02%).

And their D_{2850}/D_{1590} and D_{3570}/D_{1590} values are compared in Table VIII.

There is an effect of drying agents on the decomposition of aliphatic chains, but the decrease in D_{2850}/D_{1590} is less than that in the thermal treatment of air-dried film.

Therefore, it may be concluded that the easy decomposition of the aliphatic chain, without an accompanying dissipation of the phthalate in air-dried film, is due to the networks containing more hydroperoxyl and conjugated carbonyl groups and their consequent instability, as well as to the presence of drying agents.

From the above results, the extent to which autoxidation is induced by air-drying and baking, and how the structure of the network affects the thermo-oxidative degradation of oxidative polymerized films, have been established.

Summary

1) The aliphatic chains decomposed more easily, and the phthalate was rather more stable in oxidative thermal treatment in air-dried film than in baked film of unsaturated fatty acid-modified alkyd resin.

2) This is a result of the presence of more hydroperoxy and conjugated carbonyl groups, and of the drying agent in air-dried film.

3) After the thermo-oxidation of oxidative polymerized films, the glass transition temperature, the hardness of film, and the degree of crosslinking of film showed an increase: this is considered to be the result of the oxidative decomposition and crosslinking of aliphatic chains. It has been observed also that the impact strength of baked film decreased upon thermo-oxidation.

4) The drying agents contained in film accelerated the decomposition of aliphatic chains during thermal treatment.

(Received December 6, 1965)

The effects of ring substituents on the stability of silver ion complexes of benzene and styrene are discussed in terms of the delocalization energies as calculated by the simple LCAO MO method. It is demonstrated that the delocalization energy responsible for the formation of the σ-type molecular bond can predict the relative stabilities of the complexes; the calculated energies are linearly correlated with Hammett's sigma values. The π-type molecular bond energy arising from the delocalization of silver d-electrons decreases linearly with the increase in the σ-type bond energy. In cases where the two energies are comparable in magnitude, the substituent effects may well be controlled by the entropy term, as has previously been demonstrated experimentally. This apparent paradox encountered in the interpretation of substituent effects may best be reconciled by assuming that the behavior of the silver 4d-orbital in complexation is more closely associated with the entropy change than that of the 5s-orbital of the same atom.

Since Winstein and Lucas[1] first revealed evidence for the formation of silver ion complexes of olefins in the aqueous phase, the nature of such complexes has received considerable attention from physical and organic chemists. Thus, Andrews and Keefer[2] performed extensive measurements of the equilibrium constants for the silver ion complexation (argentation) of aromatic as well as olefinic compounds, hoping thereby to clarify the relation between the substrate structure and the complex stability. More light has recently been shed on these complexes through the structural studies of the isolated silver salt—substrate complexes, using the X-ray diffraction method[3,4] and the ultraviolet,[5,6] infrared[6,7] and NMR[5,8] spectroscopic techniques.

Admittedly, however, little is known about the nature of the complexation bonds formed between the silver ion and substrates. Dewar[9] proposed a complexation model in which the two components are bound by two types of molecular bonds; one is a *σ-type* bond formed by the delocalization of the carbon 2pπ electrons of the substrates onto a vacant 5s-orbital of the silver ion, while the other is a *π-type* bond formed by the *backward* delocalization of the silver 4d-electrons onto a vacant pπ* antibonding orbital of the substrates. Although there has been a growing tendency to accept the above customary picture, no direct confirmation of the role of the d-electrons has ever been provided.

Recently, Hosoya and Nagakura[6] made a theoretical analysis of the electronic structure of the cyclohexene - silver ion complex by evaluating the interactions among several possible electronic

configurations of the components. From the results of this analysis, they drew the conclusion that the *d*-electrons of the silver ion contribute appreciably to the stabilization of the ground state of the complex. On the other hand, Fukui et al.[10] used the simple LCAO MO approximation to calculate the delocalization energies of $2p\pi$ electrons alone and demonstrated that such energies could be used as a measure of the relative stability of the 1 : 1 argentation complexes of aromatic hydrocarbons.

It is to be expected that, in substituted aromatic hydrocarbons, the relative effects of substituents on the complex stability will be reversed, depending on which type of molecular bond is the more predominant, the σ-type or the π-type. According to Andrews and Keefer,[2b] the substituent effects in the case of benzene can roughly be interpreted in terms of the Hammett $\rho\sigma$ relationship;[11] the first equilibrium constants, K_1, of substituted benzenes are larger as the substituents are more electrondonating. A similar trend has been observed in our previous experimental work on substituted styrenes.[12] It would seem, then, that only the σ-type bond formation is important in the stabilization of complexes. However, it must be cautioned that, more precisely, such comparisons of substituent effects between theory and experiment should be directed toward the free-energy change in the complex formation rather than toward the enthalpy change, particularly when these changes are relatively small.

In the present paper, we will attempt to make theoretical examinations of the substituent effects observed for the stability of argentation complexes of benzene and styrene. The simple LCAO MO approximation will be used throughout in appreciation of its considerable simplicity. First, the above-mentioned simple delocalization model of Fukui et al.[10] will be tested for the substituted compounds. Second, a suggestion will be made as to the extent to which the d-electrons of silver would participate in the formation of argentation complexes. Finally, consequences of the above suggestion will be discussed, and the empiricism inherent in the present treatment will be assessed.

The pπ-Electron Delocalization Energies of the Complexes

In an attempt to interpret the relative stabilities of silver ion complexes of different aromatic hydrocarbons, Fukui et al.[10] have adopted Dewar's "bond-delocalization model" of the π-complex[13] in which only a pair of $2p\pi$ carbon orbitals of a particular unsaturated bond overlap longitudinally with a vacant orbital of a complexing ion located equidistant from the two carbons. Assuming that the interaction is sufficiently small, they applied the perturbation technique to calculating, within the framework of the simple LCAO MO approximation, the stabilization energy of the complex due to the delocalization of $p\pi$ electrons. The result was expressed in the form:

$$\Delta E_{rs}^{(p)} = 2\sum_{j}^{occ.} \frac{(c_{jr}+c_{js})^2}{m_j}\left(-\frac{\gamma^2}{\beta}\right) \qquad (1)$$

Here, r and s signify the carbon atoms constituting the bond at which the complexation takes place; γ is the resonance integral for the two weak bonds formed between the ion and the carbons, r and s; and the other symbols, which are associated with the isolated aromatic molecules,

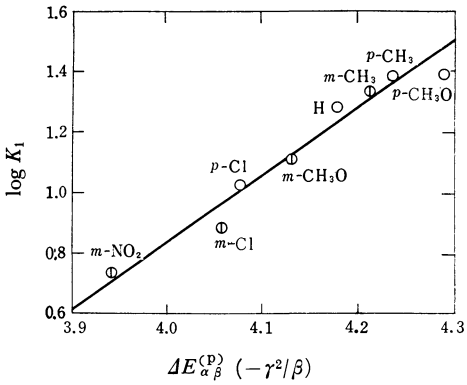

Fig. 1. Plots of the $p\pi$-delocalization energies of argentation complexes of substituted styrenes against log K_1.

have their usual meanings. The energy, $\Delta E_{rs}^{(p)}$, calculated from Eq. 1 has proven capable of providing a successful account of the relative stabilities of the silver ion complexes of aromatic hydrocarbons. The quantity, $\Delta E_{rs}^{(p)}$, will henceforth be referred to as the $p\pi$-delocalization energy.

In the silver ion complexes of substituted styrenes, there are good reasons for believing that the primary center for the coordination of the silver ion is an extracyclic double bond, i. e., the α-β bond.[12] Using Eq. 1, the $p\pi$-delocalization energies of the complexes of substituted styrenes are computed for the α-β bonds. The integral

parameters[14] used for the various heteroatoms and bonds are those given in a previous paper.[15] For *m*-nitrostyrene, the inductive model with $k = -1.1$ was used for the nitro group.

The calculated values of $\Delta E_{\alpha\beta}^{(p)}$ are listed in Table I, together with the first argentation constants, K_1, measured at 25°C.[12] Plots of log K_1 against $\Delta E_{\alpha\beta}^{(p)}$ give a good linear correlation, as is shown in Fig. 1; the larger the $\Delta E_{\alpha\beta}^{(p)}$ value, the more stable are the complexes.

For the silver ion - substituted benzene complexes, Andrews and Keefer[2a,b] suggested a structure in which the silver ion is located above the plane of the ring at a position equidistant from the six ring carbon atoms, forming covalent bonds with any of these six carbons. However, it has been confirmed by the X-ray diffraction studies that, in the silver perchlorate - benzene complex salt, the silver ion is located above a carbon-carbon bond of the benzene plane and that it interacts primarily with the two nearest carbon atoms.[3]

Although the structure is not known for the complexes formed from substituted benzenes, we have assumed the bond-delocalization model as depicted above and have calculated the pπ-delocalization energies, $\Delta E_{om}^{(p)}$ and $\Delta E_{mp}^{(p)}$, for ortho-meta and meta-para bonds, respectively, of substituted benzenes. The results of the calculations are given in Table II.

Table II shows that, for a given benzene derivative, the pπ-delocalization energies for ortho-meta and meta-para bonds are nearly equal in magnitude. Since these bonds are little hindered sterically, it may reasonably be assumed that ortho-meta and meta-para bonds contribute equally to the coordination of the silver ion. On the other hand, since the steric effects on argentation are fairly large for the bonds adjacent to the carbon-substitutent bonds,[1] a neglect of the coordination of the silver ion on such bonds will not cause an appreciable error. Thus, the number, *n*, of the bonds effective for silver ion complexation may be assumed to be 4 for all the monosubstituted benzenes considered, while it is 6 for benzene itself.

If the above assumptions are basically correct, all the plots of $\log(K_1/n)$ against $\Delta E_{om}^{(p)}$ and $\Delta E_{mp}^{(p)}$ would fall in the vicinity of a single line. This has been roughly substantiated, as can be seen

14) The π-electron densities, q_r, calculated for the meta and para ring carbons by the use of our parameters are in a linear correlation with Taft's σ°-values[16] of the substituents:
$\sigma_r^\circ = 9.68(1 - q_r)$[15]
15) T. Fueno, T. Okuyama and J. Furukawa, This Bulletin, **39**, 569 (1966).

n denotes the number of the bonds effective for the complexation. ⓘ, $\Delta E^{(p)}_{om}$; ○, $\Delta E^{(p)}_{mp}$

in Fig. 2. These results may be taken as suggesting the validity of our proposal on the structure of the silver ion - benzene complexes. The value, $\Delta E^{(p)}_{om} + \Delta E^{(p)}_{mp}$, may therefore be regarded as a measure of the relative stabilities of the silver ion complexes of substituted benzenes.

The Correlation of $\Delta E^{(p)}_{rs}$ with π-Electron Distributions

The pπ-delocalization energy, $\Delta E^{(p)}_{rs}$, can be transformed into[10]

$$\Delta E^{(p)}_{rs} = \{S^{(E)}_r + S^{(E)}_s + 2S^{(E)}_{rs}\}(-\gamma^2/\beta) \quad (2)$$

where $S^{(E)}_r$ and $S^{(E)}_s$ are the superdelocalizabilities for an electrophilic attack at the rth and sth carbon atoms respectively, and where $S^{(E)}_{rs}$ is a "bond-delocalizability" defined as[17]

$$S^{(E)}_{rs} = 2\sum_j^{occ.} c_{jr}c_{js}/m_j \quad (3)$$

Thus, the pπ-delocalization energy does not depend upon only the $S^{(E)}_r$ and $S^{(E)}_s$; an important contribution comes into play from the $S^{(E)}_{rs}$ as well.

When the substituents are located sufficiently far from the r-s bonds,[20] the sum of the bond terms, $S^{(E)}_{rs}$, with respect to the s atoms adjacent to a fixed atom, r, becomes identical with the π-electron density, q_r, at the position r. That is,

$$\sum_s{}' S^{(E)}_{rs} = 2\sum_j^{occ.}\sum_s{}' c_{jr}c_{js}/m_j = q_r \quad (4)$$

where the simple LCAO MO relation:

$$-c_{jr}m_j + \sum_s{}' c_{js} = 0 \quad (5)$$

valid under the above conditions, has been utilized.

In the case of ring-substituted styrenes, $S^{E}_{\alpha\beta}$ is in itself equal to the π-electron density on the β-carbon:

$$S^{(E)}_{\alpha\beta} = 2\sum_j^{occ.} c_{j\beta}{}^2 = q_\beta \quad (6)$$

Similarly, it can be shown that $S^{(E)}_\alpha$ is identical with Coulson's π-bond order, $p_{\alpha\beta}$, of the α-β bond:

$$S^{(E)}_\alpha = 2\sum_j^{occ.} c_{j\alpha}c_{j\beta} = p_{\alpha\beta} \quad (7)$$

According to the results of numerical calculations, the values of $S^{(E)}_\alpha$ are nearly constant, irrespective of the sort of ring substituents. On the other hand, $S^{(E)}_\beta$ increases almost linearly with

16) R. W. Taft, Jr., *J. Phys. Chem.*, **64**, 1805 (1960).
17) According to Ham and Ruedenberg,[18] the non-dimensional bond quantities defined by Eq. 3 are intermediate in nature between "molecular-orbital" bond orders and bond populations. Further, it has been shown by Ham[19] that, in the case of even alternant hydrocarbons, the above bond quantities are mathematically identical with Pauling's "resonance-theory" bond orders.
18) N. S. Ham and K. Ruedenberg, *J. Chem. Phys.*, **29**, 1215 (1958).
19) N. S. Ham, ibid., **29**, 1229 (1958).

an increasing q_β value. These trends were not affected by the type (methylene-anion type or nonconjugative) or the position (meta or para) of the substituents investigated, nor did they depend on the integral parameters, which were arbitrarily chosen for the substituents (see Fig. 3). The net result is, then, that the calculated values of $\Delta E_{\alpha\beta}^{(p)}$ and q_β are inherently in linear correlation with each other.

When we used the substituent parameters which had previously been adopted for the calculation of charge distributions in benzene derivatives,[15] the magnitudes of the imparted quantities, $S_\alpha^{(E)}$, $S_\beta^{(E)}$ and $S_{\alpha\beta}^{(E)}$, for substituted styrenes were found to be such as are listed in Table I. Comparisons of the $S_{\alpha\beta}^{(E)}$, i. e., q_β, with Hammett's σ-values revealed a satisfactory linear relationship between them, as is illustrated in Fig. 4.[21] Since the q_β in turn is in linear correlation with $\Delta E_{\alpha\beta}^{(p)}$, as has been stated above, the $\Delta E_{\alpha\beta}^{(p)}$ must also be linearly correlated with the σ-values (see Fig. 4). If the pπ-delocalization energy is a primary quantity governing the relative stabilities of the silver ion complexes, then the linearity found above between $\Delta E_{\alpha\beta}^{(p)}$ and σ will suffice to explain our previous observations that the argentation equilibria of ring-substituted styrenes fit the Hammett $\rho\sigma$ relation.[12]

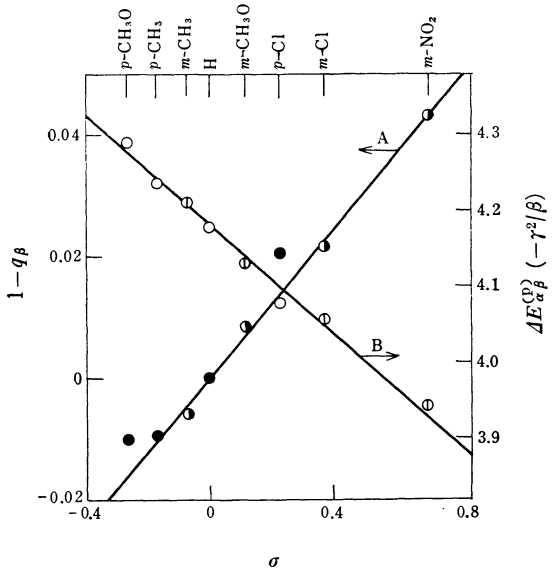

Fig. 4. Correlations of q_β and $\Delta E_{\alpha\beta}^{(p)}$ of substituted styrenes with the Hammett σ.
A, plots of $1-q_\beta$ vs. σ: ●, para; ◑, meta
B, plots of $\Delta E_{\alpha\beta}^{(p)}$ vs. σ: ○, para; ⓘ, meta

In the case of substituted benzenes, we may write the following identities:

$$\Delta E_{om}^{(p)} = (S_o^{(E)} + S_m^{(E)} + 2S_{om}^{(E)})(-\gamma^2/\beta)$$
$$\Delta E_{mp}^{(p)} = (S_m^{(E)} + S_p^{(E)} + 2S_{mp}^{(E)})(-\gamma^2/\beta) \quad (8)$$

where the subscripts o, m and p refer, respectively, to the ortho, meta and para ring positions with respect to the substituents. Again, from Eq. 4, we may write, to a good approximation, the equality:

$$S_{om}^{(E)} + S_{mp}^{(E)} = q_m \quad (9)$$

where q_m is the π-electron density on meta carbons.

The values of $S_o^{(E)}$, $S_m^{(E)}$ and $S_p^{(E)}$ were calculated for several monosubstituted benzenes. The results are included in Table II, where it may be seen that $S_o^{(E)}$ nearly equals $S_p^{(E)}$ with each compound. Aside from the p-CH_3O group, plots of $S_m^{(E)}$ and $S_p^{(E)}$ against the corresponding σ-values give a single straight line, as can be seen in Fig. 5.

Also plotted in Fig. 5 are the $\Delta E_{rs}^{(p)}$ values; for the sake of convenience, the $\Delta E_{om}^{(p)}$ values are plotted against σ_m, while the $\Delta E_{mp}^{(p)}$ values are plotted against σ_p. The differences between $\Delta E_{om}^{(p)}$ and $\Delta E_{mp}^{(p)}$ for given substituents are, on the whole, smaller than the differences of either $\Delta E_{om}^{(p)}$ or $\Delta E_{mp}^{(p)}$ between different substituents. If we assume, as before, that ortho-meta and meta-para bonds contribute equally to the complexation, then an average of the two energies may

20) The condition is fulfilled if the substituents and reaction centers are spatially separated to the extent that the auxiliary inductive effect of substituents on the Coulomb integral of the carbon in question is negligibly small.

21) Deviations in the p-chloro and p-methoxy points from Line A may suggest that the linearity between q_β and σ is only approximate and that it tends to be violated by the methylene-anion type para substituents.

perhaps be a convenient measure of the complexation ability. Thus, by combining Eqs. 8 and 9 with the approximation $S_o^{(E)} \simeq S_p^{(E)}$, we can write:

$$\langle E^{(p)} \rangle \equiv (\Delta E_{om}^{(p)} + \Delta E_{mp}^{(p)}) / 2 \simeq (S_p^{(E)} + S_m^{(E)} + q_m)(-\gamma^2 / \beta) \quad (10)$$

Equation 10 allows us to infer that, insofar as the pπ-delocalization energies in benzene complexes are concerned, the contribution of meta substituent effects might more or less outweigh that of para substituent effects. According to the results of numerical calculations, however, the variation in q_m with σ is less sensitive than that of $S_p^{(E)}$ and $S_m^{(E)}$, so that $\langle E^{(p)} \rangle$ is fairly well correlated with $(\sigma_m + \sigma_p)/2$. Such a relationship is marked with a broken line in Fig. 5. Thus, it may be more reasonable to correlate[22] $\log (K_1/n)$ with $(\sigma_m + \sigma_p)/2$ than to relate $\log K_1$ directly to σ_m, as Andrews and Keefer did previously.[2b]

At this point it is worthwhile to compare the slopes of the $\Delta E^{(p)}$-σ lines for substituted styrenes and benzenes, i. e., Lines B of Figs. 4 and 5. The slope ratio is 1 : 1.46, which is qualitatively understandable because the effects of substituents should increase as the distance between the substituents and the reaction center decreases. Interestingly, this ratio is close to the corresponding ρ ratio, -0.766[12]: -1.36[22]$=1 : 1.78$, derived from the Hammett plots of the argentation equilibrium constants.

The Contribution of the Silver *d*-Electrons

So far, the relative stabilities of the silver ion complexes have been considered in terms of the delocalization energies of pπ-electrons alone. The complexation model underlying the treatments has been a simplification of the Dewar model[9] in that the participation of the silver d-electrons in the complex formation has been ignored. In the case of unsubstituted hydrocarbons, the contribution of these d-electrons to the complex stabilities will parallel that of the pπ-electrons hitherto considered, because, in the Hückel approximation, the bonding and antibonding π-orbitals of the isolated hydrocarbons are spaced in pairs and the distributions of the phantom electrons in the antibonding π-orbitals are the same as in the pairing bonding orbitals. In substituted compounds, however, this parity of orbitals breaks down, and the relative effects of substituents on the complex stability may be reversed, depending on which electrons, pπ or d, exert the more predominant contribution to the complex formation. According to the recent work of Hosoya and Nagakura,[6] the two contributions are almost equally important to the stabilization of the ground state of silver-monoolefin complexes.

If the energy level of the 5s-orbital of the silver ion is $h_s\beta$ relative to the 2pπ Coulomb integral of a benzene carbon, Eq. 1 should be modified to

$$\Delta E_{rs}^{(p)} = 2 \sum_j^{occ.} \frac{(c_{jr} + c_{js})^2}{h_s - m_j} \left(-\frac{\gamma^2}{\beta}\right) \quad (11)$$

Likewise, we may express the delocalization energy, $\Delta E_{rs}^{(d)}$, of a pair of electrons originally belonging to the $4d_{xz}$ atomic orbital of the silver ion as

$$\Delta E_{rs}^{(d)} = 2 \sum_j^{unocc.} \frac{(c_{jr} - c_{js})^2}{h_d - m_j} \left(-\frac{\gamma_d^2}{\beta}\right) \quad (12)$$

where $h_d\beta$ is the energy level of the $4d_{xz}$ orbital of the silver ion in the complex relative to the Coulomb integral of a benzene carbon; γ_d is the resonance integral for the bonds formed by the overlap of the silver $4d_{xz}$ orbital and the $2p_z$ orbitals of the rth and sth carbon atoms of the substrate molecules; and the summation extends over the unoccupied π-orbitals of the substrates. The energy, $\Delta E_{rs}^{(d)}$, may be referred to as the d-delocalization energy.

In order to evaluate these delocalization energies exactly, it is necessary to know the precise values of the energy level quantities, h_s and h_d, for the silver ion in the complexes. At the level of the present approximations, however, little can be predicted for these values. Yet, it is merely the relative effects of various substituents that we are primarily concerned with here. Thus we have decided to avoid the difficulty by proceeding, for the time being, by assuming somewhat arbitrary values for h_s and h_d.

To begin with, we calculated the d-delocalization energies for the various styrenes, assuming that $h_d=0$. The results are given in the third column of Table III. Comparisons of these $\Delta E_{\alpha\beta}^{(d)}$ values with the $\Delta E_{\alpha\beta}^{(p)}$ values previously obtained (Table I) show that there exists a linear correlation between them, as can be seen in Fig. 6. Since the slope of this linearity is negative, the relative effects of substituents in relation to the strengths of the σ- and π-type complexation bonds would tend to act in directions to cancel each other out. Thus a question remains whether the variation in the total complexation *energy* from one substituted styrene to another should parallel that of $\Delta E_{\alpha\beta}^{(p)}$, which has previously been used as a measure of the complex stability. This point will be discussed in the following section.

Next, we calculated the pπ- and d-delocalization energies for styrenes, varying the magnitudes of h_s and h_d. Table III lists the results obtained

22) In fact, plots of $\log (K_1/n)$ against the average sigma result in as satisfactory a linear relation as the plots of $\log K_1$ vs. σ_m, within the limits of the accuracy of experimental data. This new linearity gives a reaction constant of $\rho=-1.36$, while the Andrews and Keefer value is $\rho=-1.60$.

○, para; ⦶, meta, calculated with $h_s=-0.5$ and $h_d=0.5$.

from the choices of $h_s=-0.5$ and $h_d=0.5$ and 1. Comparisons of the $\Delta E^{(p)}_{\alpha\beta}$ values calculated for $h_s=-0.5$ with those previously obtained with $h_s=0$ (Table I) show that these two sets of data run linear. The same is found to be true among the three sets of $\Delta E^{(d)}_{\alpha\beta}$ values (Table III), except for some minor irregularities. This implies that we may expect a linearity of the type given in Fig. 6 without a loss of generality, as long as the d—s separation energy for the complexed silver ion is such that $-0.5<h_s<0<h_d<1$.

Similar considerations hold for benzene derivatives. The results are found to be much the same as have been described for styrene derivatives.

Discussion and Conclusions

As has already been mentioned, the relative effects of substituents on the σ- and π-types of complexation energies act in opposite directions. If these effects are of comparable importance, as seems to be the case, it is conceivable that, in effect, the two contributions cancel each other out, so that the total complexation energies change but little within a given series of substituted compounds. This view is consistent with our previous observation that, for a few substituted styrenes, the differences in the enthalpy changes with respect to substituents, $\delta\Delta H$, are quite small despite the sensible differences in free energy change, $\delta\Delta F°$, the substituent effects thus being entropy-controlled in the ordinary temperature region.[12] A similar trend can be noticed in inspecting the argentation data for various α-olefins recently reported by Cvetanović et al.[25]

Nonetheless, it does appear that, at least in the cases of benzene and styrene, the effects of substituents on the stabilities of the silver ion complexes can be interpreted in terms of the pπ-delocalization energy, $\Delta E^{(p)}$, a contribution to the enthalpy change, ΔH. This apparent paradox may best be reconciled by invoking the conventionally accepted concept of the isokinetic relationship.[26] That is, the calculated $\Delta E^{(p)}$ somehow reflects the entropy contribution. In argentation equilibria of substituted compounds, the relationship is perhaps such that, the tighter a complexation bond, the greater is the accompanying entropy loss, $-\Delta S$, which in turn controls the substituent effects in prevalence over the contribution of ΔH.[12] Since $\Delta E^{(p)}$ is correlated with σ, whereas it antiparallels $\Delta E^{(d)}$, the entropy loss associated with $\Delta E^{(d)}$ should be a quantity which parallels σ. This would imply that the observed entropy loss is isokinetically associated more directly with $\Delta E^{(d)}$ than with $\Delta E^{(p)}$. It is, of course, hard to justify this implication theoretically. Offhand, however, this seems to be likely because of the directional properties of the silver d-orbitals in the complexes.

In conclusion, the pπ-delocalization energy, $\Delta E^{(p)}$, can successfully interpret the observed substituent effects on the argentation equilibria

23) Considering the singlet d-s separation energy (5.7 eV.[24]) of the free silver ion, we may guess that the difference between h_s and h_d for a complexed silver ion will be of the order of unity.

of benzene and styrene despite some warnings raised against the Hückel calculations of π-complex stability.[27] However, the conclusion is only ostensibly correct, because the binding energy arising from the contribution of silver d-electrons, $\Delta E^{(d)}$, is of comparable importance, as is $\Delta E^{(p)}$, and because the two energies join together to suppress the enthalpy contribution to the relative substituent effects. The indications of such simple treatments may naturally be crude, but they seem to be significant so long as complexes merely of identical geometry are being compared. It seems, then, that only by assuming an isokinetic correlation between $\Delta E^{(d)}$ and ΔS can the observed substituent effects be cast into such a semiempirical theory of the free energy correlations as has been developed previously.[15]

Catalytic Activities of Metal Oxides in the Oxidation of Propylene

By Toyosaburo TAKEUCHI, Michiaki HONMA* and Hideo TAKEDA

Faculty of Literature and Science, Toyama University, Gofuku, Toyama

(Received December 9, 1965)

The catalytic oxidation of propylene by the flow method was carried out in order to investigate the correlation between the activity and the physical properties of the catalyst, using the oxides of zinc, copper, nickel, cobalt, iron, manganese, chromium, vanadium and titanium, all of which were supported with alumina. The analysis by means of gas chromatography indicated that the main products of the reaction were carbon dioxide and water. An abrupt increase in the rate of conversion against the temperature, denoted by C_T, was irrespective of the amount of oxide and was characteristic of each oxide. The C_T was expressed as a function of the % d character of the metal of the oxide, as well as a function of the heat of formation per gram-atom of oxygen in the oxide. The mechanism of the abrupt change in the rate of conversion was discussed in relation to the ability of oxygen to be removed from the oxide and the amount of propylene adsorbing on the oxide during the reaction.

The usefulness of metal oxides in the catalytic oxidation of hydrocarbons has been extensively investigated by many workers.[1-5] However, many problems still remain for the establishment of the correlation between the physical properties of metal oxide and the catalytic activity. Recently, Kwan and his co-workers[6] have presented a rule of the catalytic activity of metallic oxides by the use of the experimental results given by Popovskii and Boreskov,[7] who studied the catalytic oxidation of hydrogen. Their rule claims that the activity of the oxidation can be expressed by a function of the heat of formation per gram-atom of the oxygen of the oxide.

This study will deal with the oxidation of propylene on various metallic oxides in order to ascertain whetehr the rule can be applicable to the oxidation of hydrocarbon. The catalytic activities of the oxides will also be discussed from the standpoint of the electronic property of the metal atom of the oxides. The % d character of the metal of the oxide will be taken into consideration for this purpose. The metallic oxides used were titanium(IV) oxide, vanadium(V) oxide, chrome(III) oxide, manganese(IV) oxide, iron(III) oxide, nickel(II) oxide, copper(II) oxide and zinc oxide.

Experimental

The test of the catalytic activity was carried out by a flow method using air. The apparatus used is shown in Fig. 1, where A is the reaction tube, whose diameter and length are 12 mm. and 200 mm. respectively. P is a premixer, and C is a damper of air coming from the compresser, D. F is a flow meter of the soap film. M is an oil manometer, and T is a trap cooled by a mixture of ice and sodium chloride in order to remove the water vapor present in a mixture of propylene and air. The volume of the reaction tube,

including an oil manometer of the U-type portions was about 200 cc.

0.5 g. of the oxide was used; it was replaced afresh for each run of the test. The glass fiber was packed at both sides of the catalyst. The ratio of propylene to air was always kept at 0.04—0.05. The flow rate of the mixed gas in the reaction tube was in the range from 100 to 120 cc./min. The analysis of the reaction products was made by means of gas chromatography, using helium as the carrier. The intervals of every analysis were 30 or 60 min. The fluctuation in the amounts of products could be found over about a 30 min. period in the initial stage. The average was taken for the evaluation of the activity. It was calculated from the values measured for five hours, except for the initial hour.

The catalysts, except for those of titanium dioxide and vanadium pentoxide, were prepared from the nitrates. 30—50 mesh γ-alumina was used as the carrier. It was immersed into about a 2 N solution of each nitrate for about 48 hr. at room temperature; then the precipitate was separated from the solution and ignited at 550°C in a furnace. Vanadium pentoxide was prepared by immersing alumina in a solution of meta-ammonium vanadate, which had been dissolved in nitric acid. Titanium dioxide was prepared by immersing alumina into the solution of titanium, which had been dissolved in hydrofluoric acid; then the precipitate was separated from the solution and ignited at 550°C.

Five oxides, i. e., cupric oxide, vanadium pentoxide, zinc oxide and chromium trioxide, were tested without a carrier in order to investigate the influence of the carrier on the oxidation of propylene. The powder of about 50 mesh was selected by sifting it before use. The B. E. T. areas of the catalysts were determined by using nitrogen or methane at −196°C. Nitrogen was used for the supported catalysts, while methane was used for the unsupported catalysts.

Results

The products of the oxidation of propylene were, in most cases, carbon dioxide and water. The products of the oxidation in the presence of vanadium pentoxide gave a stimulant smell. The gas chromatogram of the products, however, gave only the patterns of carbon dioxide and water.

The activity was represented as a percentage of the amount converted, which was determined from the amount of carbon dioxide produced. The results are summarized in Figs. 2 and 3. In Fig. 3, the results on pure alumina are also shown for the purpose of comparison. The alumina used for this purpose was prepared by heating it in vacuo at 450°C. The figures indicate that the percentage of the conversion on the oxides of nickel, manganese, chromium, iron, cobalt and vanadium changes markedly in a certain temperature range. However, no such remarkable change could be found either on pure alumina or on the supported oxides of copper, zinc and titanium. The temperature of the remarkable change was independent of the amount of the catalyst. It can be said, therfore, that the temperature is characteristic of each oxide. The inclination of the line at a point of remarkable change for the pure oxides (unsupported catalysts), except vanadium oxide, is steeper than those for the oxides combined with alumina (a supported catalyst). We denote the temperature of the remarkable change as C_T. The figures indicate that the C_T of chromium oxide and that of vanadium oxide are lowered by the presence of the carrier, while, C_T of cupric oxide is raised. The influence of the carrier is very small in the case of zinc oxide.

Figure 4 shows the correlation between C_T and ΔH, the heat of formation per gram-atom of the oxygen of the corresponding oxide. The figure shows that an approximate linear relation can be established for all the oxides except for the supported cupric oxide and chromium oxide. The rates of reaction were calculated by the following equation:

$$V = rFX/(1 + r)S$$

where V is the rate of reaction, X is the percentage of the propylene converted, and F is the space velocity of gas. S and r are the surface area of the catalyst and the mole ratio of propylene to air, (O_2 in air)/(propylene), respectively.

Figure 5 shows the correlation between log V and the reciprocal of the reaction temperature. The correlations are represented by broken lines, suggesting that the activation energies below and above C_T differ from each other. However, no systematic correlation between the activation energy and ΔH could be found in either temperature range, as has previously reported by Morooka and Ozaki.[8]

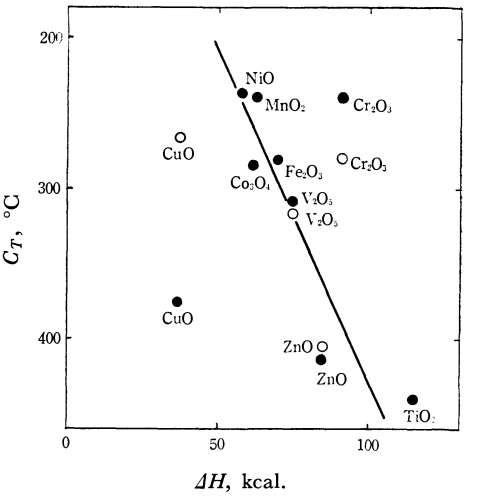

Fig. 4. Correlation between C_T and ΔH.
○ indicates unsupported oxide.

Discussion

The change of catalytic activity in the presence of alumina may suggest that a change of structure of oxide occurs. An experimental confirmation of the structural change of each supported oxide could not be made, nevertheless, the oxide whose activity is changed may be considered to have the spinel structure from the standpoint of valency.

The rates of the reaction in the temperature range above C_T could not be known accurately. The temperature would rise due to the accumulation of heat by the explosive fast reaction which could be supposed to occur, though the thermometer of the reaction tube always showed a constant temperature. Whatever may be the accurate value of the reaction rate above C_T, the change in the activation energy below and above C_T may suggest a change in the mechanism of the reaction, as is clear from the results in Fig. 5.

Hofer et al.[9] investigated the oxidation of ethylene and carbon monoxide on cupric oxide, cobalt

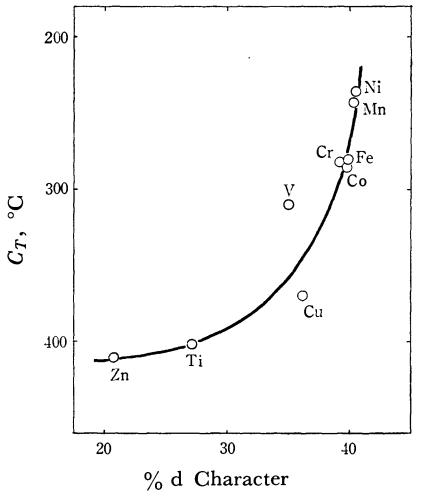

Fig. 6. Correlation between C_T and % d character of metal of oxide.

oxide and chromium oxide by means of gas chromatography; they reported the dependence of the amount of the product and that of the reactants adsorbed on the oxide upon the reaction temperature. Evidently from their data, a remarkable change in the amount of conversion takes place at the temperature where the amount of the reactants adsorbed on the oxide becomes nearly zero, though they put no scuh interpretation on thier results. An exception is found, however, in the reaction on copper oxide. They reported that the amounts of reactants adsorbed on the cupric oxide were nearly zero in the temperature range investigated. The extremely small value obtained from the measurement of adsorption on the copper oxide seems to result from the difficulty of accurate measurement of the amount of adsorption, because the surface of the copper oxide is particularly small, about 1/20 that of the other oxides. Considering from their results, the remarkable increase of the amount of conversed propylene may be due to the decrease of the adsorbed propylene to a certain concentration at the temperature of C_T. The ability of gas to be adsorbed on the metal oxides can be estimated from the heats of adsorption on them. Unfortunately, no information on the heats of adsorption of propylene on metal oxides has appeared in literatures so far. However, the heats of adsorption on oxides may be estimated, if we assume that the propylene is adsorbed on the metal atoms of the oxide, and that the cohesive binding between metal and oxygen occurs by the shift of the valence electron of 4p orbitals of the metal atom to oxygen, without affecting the d electron of the metal atom. By applying the valence bond theory of Pauling[10] to the metal oxides and the proposal by Beeck,[11] who found the correlation between the heat of adsorption and the % d character of metal, the correlation between the % d character of the metal atom of each oxide and C_T can be obtained. The results are shown in Fig. 6, where the % d character of all the metal atoms except for zinc are quoted from the list given by Pauling. The % d character of zinc was calculated by assuming 4.56 for its valence[12] and the resonance structure of $V(2)$ and $V(6)$, where V indicates the valence of the metal. The correlation in the figure seems to be more satisfactory than that between ΔH and C_T, because the deviation is smaller. The figure indicates that C_T increases with decreasing % d character. Since the heat of adsorption is connected with the ability of adsorption and since it decreases with increasing % d character of metal atom,[11] it can be said that the oxide of the lower C_T value has a smaller ability of adsorption of propylene than the oxide of the higher C_T value and that the surface of the catalyst would be covered more densely with oxygen than with propylene.

The reaction mechanism of the oxidation of hydrocarbon proposed by Bretton et al.[13] was the removal of hydrogen from the hydrocarbon at its first step. The same proposal has been made by Sachtler and De Boer[14] and by Adams and Jennings[15] for the oxidation of propylene. A satisfactory explanation of the difference in the mechanisms of the oxidation in the two temperature ranges below and above C_T is far from having been established at present. However, it can be concluded that the difference in C_T of various metal oxides may be due to the ability of oxygen to be removed from the oxide and that of propylene to be adsorbed on the metal atom of the oxide.

The Diffusion of Gases at High Pressures. I. The Self-diffusion Coefficient of Carbon Dioxide

By Shinji TAKAHASHI and Hiroji IWASAKI

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received December 9, 1965)

The self-diffusion coefficients of carbon dioxide were measured over a pressure range from 2 to 250 atm. at 25, 50, and 75°C. The measurements of self-diffusion through a plug of porous bronze were made using the radioactive tracer technique. The products of the density and the diffusion coefficient increase slightly with the density in the region of lower density, below about 10 mol./l., for both isotherms at 50 and 75°C, but they decrease in the region of higher density. These results agree with the results obtained by O'Hern et al., but not with Enskog's dense gas theory, and not with the values calculated by the generalized chart of Slattery et al.

The diffusion coefficient of gases at high pressure is not only an interesting physical property from the standpoint of the kinetic theory of gases, but it is also an important property for the analysis of the operations and design of apparatus in the chemical industry. Enskog[1,2] made some theoretical studies of the diffusion process in developing his kinetic theory of non-uniform gases, based on the assumption of a rigid spherical molecule. Slattery et al.[3] prepared a generalized chart for the self-diffusion coefficient of gases at high densities using Enskog's theoretical relations on transport properties and experimental data on the viscosity.

There have been some recent reports[4] on the gaseous diffusion coefficient at high densities measured by the use of either the radioactive or the stable isotope-tracer technique. However, the results have not indicated a definite relation between $D\rho$ and ρ (D: diffusion coefficient, ρ: density). For example, in the case of the self-diffusion coefficient of carbon dioxide, Drickamer et al. concluded that $D\rho$ decreases in accordance with Enskog's theory until $\rho = 0.067$ g./cc., whereas O'Hern et al. stated that $D\rho$ is constant independent of the density, and Becker et al. showed that $D\rho$ increases with the density. Thus, further investigation seems to be necessary in order to clarify the relation between $D\rho$ and the density in the high pressure range.

Additional measurements of the diffusion coefficient in the $^{14}CO_2$-$^{12}CO_2$ system, by a method similar to that of O'Hern et al., will be reported here. These measurements were made at pressures up to 50 atm. at 25°C, and up to 250 atm. at 50 and 75°C. The results will be compared with the values obtained by other investigators and with the values calculated by Enskog's equation and the generalized chart.

Apparatus

The diffusion cell, the major part of the apparatus, was nearly identical with that used by O'Hern et al., Mifflin et al., and Durbin et al., as is shown in Fig. 1. The principle of measurement procedure was as follows: a diffusion path, B, composed of porous metal was placed between two chambers, C and D, equal in volume. The concentration gradient of $^{14}CO_2$ was created between these two chambers through the porous plug, and the diffusion coefficient, D_{12}, in the $^{14}CO_2$-$^{12}CO_2$ system was calculated from the measurements of the change in the concentration of $^{14}CO_2$ with time.

Each chamber had a volume of 35 cc. and was connected to the diffusion path, B, which had a length of 40 mm. and a diameter of 18 mm. The diffusion path was a plug of sintered bronze powder; two types of plugs were used, one with a grain size of ϕ160—250 μ (I) and the other, with a grain size of ϕ60—70 μ (II). The concentration of $^{14}CO_2$ was measured by means of the ionization current in the chamber. The collecting electrode, I ($20\phi \times 15$ mm.), was made of invar

steel and was insulated from the stainless steel plug, F, by a surface-polished quartz disk, E ($30\phi \times 15$ mm.). The collecting electrode, the quartz disk, and the plug were cemented together by epoxy resin. The quartz disk had a 3ϕmm. hole in its center through which the lead-in wire, H, used for measuring the ionization current, projected. The lead-in wire was insulated from the steel pipe, not shown in Fig. 1, with metharylate resin insulators and was connected to a dynamic condenser electrometer manufactured by the Okura Electric K. K. The applied voltage was maintained at about 540 V., using 12 layer-built dry cells of 45 V. each. The quantity of $^{14}CO_2$ used for each measurement was in the range of 0.01—1 μCi, and the ionization current was in the range of 10^{-13}—10^{-11} amp. The results of a preliminary experiment* are shown in Fig. 2 and Fig. 3. As is apparent in these figures, a linear relationship exists between the amount of $^{14}CO_2$ and the ionization current under these experimental conditions. The ionization currents in each of the two chambers were measured by two electrometers, and the readings were recorded during the experiment.

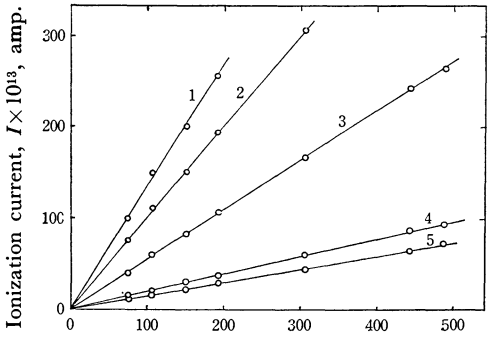

Fig. 3. Relations between the amount of $^{14}CO_2$ and ionization current at 50°C.
1: 10 atm., 2: 20 atm., 3: 50 atm., 4: 100 atm., 5: 200 atm.

An air thermostat was used. The temperature was kept within ±0.1°C by a combination of a platinum resistance thermometer, a Wheatstone bridge, and a photoelectric cell circuit,[5] and was measured by a platinum resistance thermometer calibrated against the freezing and boiling points of water and a PTR thermometer. The pressure was measured by a Bourdon gauge calibrated against a pressure balance of a free-piston type. The errors in pressure measurements were within ±0.02 atm. up to 20 atm., ±0.1 atm. in the 10—50 atm. range, and ±0.5 atm. in the 50—250 atm. range.

The radioactive $^{14}CO_2$ was generated by adding 60% $HClO_4$ to $Ba^{14}CO_3$; its specific radioactivity was approximately 1 μCi/cc. at N.T.P. The non-radioactive carbon dioxide, with a purity of over 99.9% and with a water content of less than 0.04%, was used after it had been dried over phosphorus pentoxide.

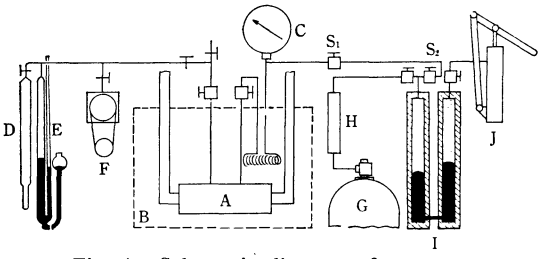

Fig. 4. Schematic diagram of apparatus.

* The experimental procedures were as follows: after the ionization chamber had been evacuated, a mixture of $^{14}CO_2$ and $^{12}CO_2$ was introduced into the chamber (70—500 mmHg). These pressures are shown as abscissae in Fig. 2 and Fig. 3. The amounts of $^{14}CO_2$ are proportional to these pressures. Then, the pressure of the chamber was raised to 10—200 atm. by introducing $^{12}CO_2$, and the ionization current was measured.

5) K. Date, G. Kobuya and H. Iwasaki, *Bulletin of The Chemical Research Institute of Non-Aqueous Solutions, Tohoku Univ.*, **10**, 67 (1961).

Experimental

The arrangement of the experimental apparatus is shown in Fig. 4. An air thermostat was adjusted to a pre-determined temperature and allowed to stand for approximately 24 hr. Cell A was then evacuated to approximately 10^{-2} mmHg by a vacuum pump, F. A suitable quantity of $^{14}CO_2$ was introduced through the gas burette, E, from the $^{14}CO_2$ container, D, into the left chamber in the cell. The non-radioactive carbon dioxide was introduced into the right chamber from the cylinder, G, through the drying tube, H, and compressed to a given pre-determined pressure by the oil pump, J. In this way a major portion of the $^{14}CO_2$ was collected in the left chamber and a large concentration gradient of $^{14}CO_2$ was created between the two chambers through the porous plug. Then, the diffusion cell was disconnected from the pressure system between the two valves, S_1 and S_2, and the voltage was applied to cell, A; the resulting ionization current was measured and recorded. An example is shown in Fig. 5.

Calculation

Assuming that the concentration gradient of $^{14}CO_2$ in the diffusion path is linear and that the concentration in each chamber is uniform, the following equations are obtained:

$$\ln(C_1 - C_2) = -KD_{12}t + \text{constant} \quad (1)$$

$$K = \frac{A}{L}\left(\frac{1}{V_1} + \frac{1}{V_2}\right) \quad (2)$$

where C_1 and C_2 are concentrations of $^{14}CO_2$ in chamber 1 and chamber 2, shown as C and D, respectively in Fig. 1, where D_{12} is the mutual diffusion coefficient in the $^{14}CO_2$-$^{12}CO_2$ system, and where t is the time. K is an apparatus constant; it is given by Eq. 2, where A and L are the effective cross section and the effective length of the diffusion path and where V_1 and V_2 are the volumes of chamber 1 and chamber 2 respectively. Since a linear relationship holds between the concentration of $^{14}CO_2$ and the ionization current, Eq. 1 may be written as:

$$\ln \Delta I = -KD_{12}t + \text{constant} \quad (3)$$

$$\Delta I = I_1 - \gamma I_2$$

$$\gamma = I_1'/I_2'$$

where I_1 and I_2 are the ionization currents in chamber 1 and chamber 2 respectively. I_1' and I_2' are the ionization currents in chamber 1 and chamber 2 respectively, when $^{14}CO_2$ is introduced into the chambers at the same concentration. According to Eq. 3, ln ΔI should be linear with t; this was experimentally proved, as is shown in Fig. 6, where common logarithms are used. If ΔI at time t_i and t_f are designated as $(\Delta I)_i$ and $(\Delta I)_f$ respectively, KD_{12} can be calculated by the following equation:

$$KD_{12} = \frac{6.3961\times10^{-4}}{\Delta t}\log\frac{(\Delta I)_i}{(\Delta I)_f} \quad (4)$$

where the terms are expressed as follows: K; 1/cm², D_{12}; cm²/sec., Δt; hr., and ΔI: amp. Hutchinson[6]

6) F. Hutchinson, *J. Chem. Phys.*, **17**, 1081 (1949).

verified the following relationship between the self-diffusion coefficient, D_{11}, and the mutual diffusion coefficient, D_{12} at normal pressure:

$$\frac{D_{11}}{D_{12}}=\left[\left(\frac{m_1m_2}{m_1+m_2}\right)\left(\frac{m_1+m_1}{m_1m_1}\right)\right]^{1/2}=\left(\frac{2m_2}{m_1+m_2}\right)^{1/2} \quad (5)$$

where m_1 and m_2 are masses of gaseous molecular species containing isotopes. Assuming that the above relationship also holds in the high pressure region, the D_{11} value in the $^{12}CO_2$ system was obtained by multiplying the D_{12} measured in this work by 1.011.

Results

When Diffusion Path I was Used.—In the 2—50 atm. pressure range, a type-I porous plug was used as the diffusion path. The values of $K_ID_{11}P$ obtained are shown in Fig. 7. The values of K_ID_{11} at 1 atm. were then obtained by extrapolation using the observed values of $K_ID_{11}P$. The apparatus constant, K_I was determined by the use of the values of D_{11} reported by Amdur et al.[7] at 1 atm. These are shown in Table I. The values of D_{11} calculated using K_I, which is given in Table I, are shown in Table II. The smoothed values of D_{11} obtained from the values in Table II are shown in Table III. The deviation of the

experimental value from the smoothed value reaches a maximum of 3.6%; on the average it is 0.9%.

When Diffusion Path II was Used.—When the type-I porous plug was used for the measurements at pressures over 100 atm., the plot of $\log \Delta I$ against t presented a convex curve downwards; thus, the assumption made for the derivation of Eq. 1 became invalid. However, a type-II porous plug gave no such trouble during experiments at higher pressures.

The values of $K_{II}D_{11}P$ obtained at 50 and 75°C and in the range of 20—250 atm. are shown in Fig. 8. From the smooth curves, the smoothed values of $K_{II}D_{11}P$ at 20, 30, 40, and 50 atm. were obtained; they are shown in the third column of Table IV. By using the smoothed values of D_{11} at 20—50 atm. shown in Table III, K_{II} was calculated; it is shown in the last column of Table IV. The values of D_{11} calculated using these K_{II} values are shown in Table V.

Discussion

From the standpoint of the kinetic theory of gases, Enskog[1,2] derived the following equations for the diffusion coefficient of gases at high pressures, assuming a rigid sphere as the molecular model:

$$D = (D_{11})^\circ/\chi \tag{6}$$

$$(D_{11})^\circ = \frac{3}{8}\sqrt{\frac{\boldsymbol{k}T}{\pi m}}\frac{1}{n\sigma^2\Omega^{(1,1)*}} \tag{7}$$

$$\chi = 1 + 0.625\left(\frac{2}{3}\pi n\sigma^3\right) + 0.2569\left(\frac{2}{3}\pi n\sigma^3\right)^2 + 0.115\left(\frac{2}{3}\pi n\sigma^3\right)^3 + \cdots \tag{8}$$

where $(D_{11})^\circ$ is a value which can be calculated from the relationship applicable at the normal pressure and which is approximately given by Eq. 7, where χ is the correction factor due to the pressure rise and is given by Eq. 8, where $\boldsymbol{k}$ is Boltzmann's constant, where m is the mass of the molecule, where n is the number of molecules in a unit volume, where $\Omega^{(1,1)*}$ is the reduced collision integral, and where σ is a constant related to the intermolecular potential. It can be seen from Eq. 7 that $(D_{11})^\circ$ is a function of the temperature alone in the vicinity of the normal pressure. By Enskog's theoretical equation (6), $D_{11}\rho = (D_{11})^\circ\rho/\chi$ and $D_{11}\rho$ is dependent not only on the temperature, but also on χ, that is, on ρ. Therefore, it is convenient to study the relationship between $D_{11}\rho$ and ρ.

In Fig. 9, $D_{11}\rho$ is plotted against ρ. The values of ρ were calculated by using the compressibility data of Michels et al.[8] The plot shows a close similarity to that of the results obtained by O'Hern et al. The values at 35°C, which were interpolated from our experimental values, were always higher than their experimental values, but the differences were never more than 5%. On the other hand, there were large deviations in the experimental values of Drickamer et al., and so their values could not be used for an accurate comparison. The relative values of $D_{11}\rho$, obtained by Becker et al., were expressed as 1.00 at 20°C and 15 atm., 1.08 at 40 atm., and 1.26 at 50 atm., and they showed a rapid increase with the pressure, thus indicating an entirely different tendency from the results obtained by the present authors.

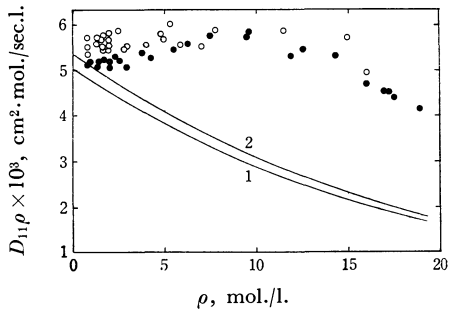

Fig. 9. Comparison of the measured values with the values calculated by Enskog's theory.
Experimental: ●—50°C, ○—75°C
Theoretical: 1—50°C, 2—75°C

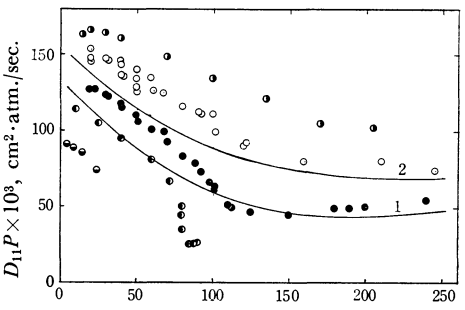

Fig. 10. Comparison of the measured values with the values calculated by the generalized chart.
Present work: ●—50°C, ○—75°C
O'Hern et al.: ◑—100°C, ◐—35°C, ◒—0°C
Calculated: 1—50°C, 2—75°C

The values calculated by substituting $\sigma = 3.996$ Å in Eq. 8 are shown as solid lines in Fig. 9. The deviations increase with the pressure, amounting to approximately 50% when $\rho = 10$ mol./l. Even if the decrease in σ with the pressure was taken into account in Eq. 8, in accordance with the consideration of O'Hern et al., a theoretical relation which fits the experimental values could not be obtained.

The values of $D_{11}P$ calculated from the generalized chart are shown as solid lines in Fig. 10. The deviation from our experimental values is approximately 20% in the vicinity of 50 atm., but it decreases over 100 atm.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2110—2114 (1966)

A Molecular Orbital Treatment of ^{13}C–H Spin-Spin Coupling Constants

By Teijiro YONEZAWA, Isao MORISHIMA and Mutsuo FUJII

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 24, 1965)

A molecular orbital interpretation of the directly-bonded ^{13}C–H spin-spin coupling constant without the concept of hybridization is presented. The observed values of J_{C-H} for some saturated and conjugated compounds are shown to be proportional to the square of the bond order between the 1S atomic orbital of the hydrogen atom and the 2S atomic orbital of the carbon atom, P^2, which is calculated using the extended Hückel molecular orbital method.

In a preliminary communication,[1] we pointed out that a molecular orbital method is successful in interpreting the ^{13}C–H spin-spin coupling constants of some aliphatic cyclic and unsaturated compounds. In the present paper, the full details of an MO treatment of ^{13}C–H spin-spin coupling constants will be presented.

Several investigators have directed their attention towards the elucidation of the factors affecting proton-^{13}C spin-spin coupling. Especially, the directly-bonded proton-^{13}C coupling constant, J_{C-H}, has been studied extensively.[2-7] These investigations have led to the conclusions that the Fermi contact term may play an essential role in the coupling, and that J_{C-H} depends solely upon the fractional S-character of the carbon hybrid atomic orbital.

The relation between J_{C-H} and the fractional S-character, ρ_{C-H}, of the carbon hybrid orbital used in the C–H bond may be expressed as Eq. 1 on the basis of semiempirical studies.[2,6]

$$J_{C-H} = 500\,\rho_{C-H}\ \text{c.p.s.} \qquad (1)$$

The additivity relation of substituent effects on J_{C-H} in substituted methanes and formyl compounds has been discussed by the aid of Eq. 1. Besides this relation, the relations between J_{C-H} and the C–C–C internuclear bond angle in the C–CH–C systems,[8,9] the C–H bond distances[2] and the electronegativity of the substituent have been investigated by several authors. Goldstein and Hobgood[7] and Veillard and Del Re[10] have calculated the fractional S-character, ρ_{C-H}, by the maximum overlap orbital method; they found that the ρ_{C-H} so obtained paralleled that estimated from the experimental J_{C-H} value obtained with Eq. 1.

In this paper, an attempt will be made to calculate the J_{C-H} values *ab initio* using the extended Hückel MO[11] method in which the parameters affecting the J_{C-H} value, that is, the bond distance, the bond angle and the electronegativity, are involved.

Theoretical

A molecular orbital treatment of spin-spin coupling was presented by McConnell[12] for proton-proton spin systems; this treatment gave a positive value for every J_{H-H} value, and was found to be less valuable than a valence bond treatment. Recently, Pople and Santry[13] have extended the MO theory of spin-spin coupling and have pointed out that the coupling constants calculated by an MO theory are not always positive. In fact, they obtained a negative J_{H-F} coupling constant in hydrogen fluoride without the introduction of an "average triplet excitation energy," ΔE. It has also been shown recently[14] that the geminal proton-proton coupling constnats in various systems can be interpreted well by this molecular orbital theory. However, since the J_{C-H} value for directly-bonded C–H is believed to be positive in sign, McConnell's procedure, as simplified by adopting an average excitation energy, ΔE, may be used.*

Table I. Coulomb integral of various atomic orbitals (eV.)

Atom	Orbital				
	1S	2S	2P	3S	3P
Hydrogen	−13.60	—	—	—	—
Carbon	—	−21.43	−11.42	—	—
Oxygen	—	−35.30	−17.76	—	—
Nitrogen	—	−27.50	−14.49	—	—
Chlorine	—	—	—	−25.26	−15.09

In a molecular orbital treatment of the C^{13}–H spin-spin coupling proposed by Muller[2] or Pople and Santry[13], they used a two-center molecular orbital localized in the C–H bond. On the other hand, in order to take into account the effect of neighboring atoms, (the bond distance, the valence angle, and so on,) on the electronic structure of the C–H bond, we used a delocalized molecular orbital obtained by a linear combination of the valence atomic orbitals of all the atoms in the molecule.

When we assume that J_{C-H} is exclusively determined by the Fermi contact term, it may be expressed by the equation[12]:

$$J_{C-H} = (1/h)(2\beta h)^2\gamma_C\gamma_H(1/\Delta E)(2\pi^2/3)P^2 \times (2S_C|\delta|2S_C)(1S_H|\delta|1S_H) \quad (2)$$

where $P=2\sum_i^{occ} a_{1S_H}b^i{}_{2S_C}$ and $a^i{}_{1S_H}$ and $b^i{}_{2S_C}$ are coefficients of the hydrogen 1S and the carbon 2S orbitals in the ith molecular orbital respectively.** ΔE is the mean excitation energy, which is assumed to be constant throughout this treatment. Then Eq. 2 may then be simply written as:

$$J_{C-H} = AP^2 \quad (3)$$

where A is a constant. It may be seen that J_{C-H} is proportional to the square of the bond order, P^2. In the present method, a molecular orbital is represented by a linear combination of valence atomic orbitals, that is, the 1S orbital of the hydrogen atom, the 2S, $2P_x$, $2P_y$ and $2P_z$ orbitals of the carbon, oxygen, nitrogen atoms and so on.[11] The orbital energy is given by solving the secular equation:

$$\det|H_{rs} - \varepsilon S_{rs}| = 0 \quad (4)$$

where H_{rs} is a matrix element and S_{rs} is the overlap integral between the rth and the sth atomic orbitals. The Coulomb integral, H_{rr}, of an atomic orbital is the negative value of the ionization potential[15] of the valence state of the neutral atom, which is tablulated in Table I, the resonance integral, H_{rs}, is expressed as:

** The bond order, P, used in Eq. 2 is related to that between the 1S atomic orbital of the hydrogen atom and the 2S atomic orbital of the carbon atom and so should be referred to as the "partial bond order."

Results

The values of the calculated P^2 values and the observed J_{C-H} values are cited in Tables II and III. In Table II, the compounds are classified systematically in four groups, a to d. In group a, saturated cyclic compounds are listed. Since cyclobutane is non-planar and has two groups of nonequivalent C–H bonds, the mean value of these two bond orders is indicated in the table. For the sake of simplicity, the calculation of J_{C-H} is carried out with respect to only one configuration, the chair form, for cyclohexane and the staggered form for ethane. In each group, a, b, c,

and d, one can find a linear relation between the calculated valued of P^2 and the observed J_{C-H} values, with a few discrepancies as to acetylene and allene in group c. These linear relations are exemplified in Fig. 1 and Fig. 2 for group a and group b respectively. We find also some discrepancies between different groups. For example, the nearly constant values of J_{C-H}/P^2 in group a and group b, the average values of which are obtained from Figs. 1 and 2, are not equal. The values of J_{C-H}/P^2, which is equal to the A constant, are estimated to be 2200 (c. p. s.) and 3600 (c. p. s.) for group a and group b in Table II respectively. The A value of group b is exceptionally large. It might be attributed to the parametrization of H_{rr}, H_{rs} or to the assumption of a constant excitation energy, ΔE; this question will be discussed in a later part.

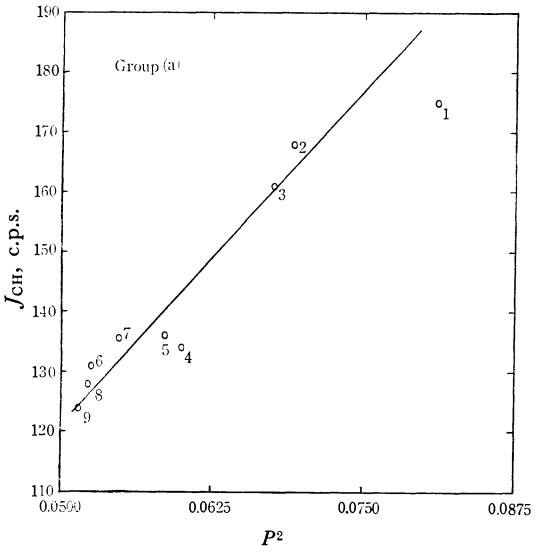

Fig. 1. A plot of the calculated values of P^2 versus observed J_{CH} for compounds of group a in Table II.

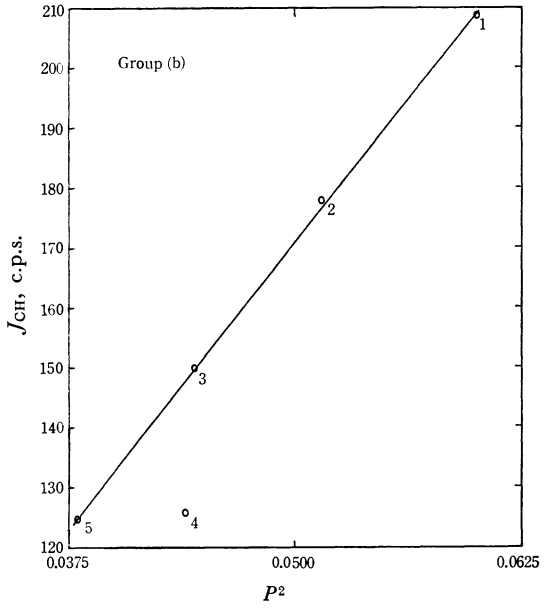

Fig. 2. A plot of the calculated values of P^2 versus observed J_{CH} for compounds of group b in Table II.

In Table III, in order to compare the J_{C-H} values, at the different positions in a molecule, we present the calculated P^2 values and the observed J_{C-H} values of aromatic compounds in group a and vinyl chloride compound in group b. In each compound, there seems to be a linear relation between P^2 and J_{C-H}. However, the interpretation of J_{C-H} for the C–H bond adjacent to the heteroatom is difficult by the present treatment. For example, the J_{C-H} for the ortho position of nitrobenzene, the $J_{C(2)-H}$ for pyridine, and the $J_{C(3)-H}$ for pyrimidine are all too large for the calculated P^2 value. In azulene, calculation is done in two ways. In Calculation I, the molecular shape for the azulene is assumed to be a regular pentagon and heptagon with the bond distances of R(C–C) = 1.40 Å and R(C–H) = 1.10 Å, while in Calculation II, we assume that the bond distances for $R(C_9–C_{10})$, other R(C–C) and R(C–H) are 1.48 Å, 1.40 Å, and 1.10 Å respectively, and that the $C_3–C_2–C_1$ bond angle is 95°. An exceptionally large J_{C-H} value at position 2 can be interpreted by the method of Calculation II, in which the bond angle at the carbon 2 is more acute than in Calculation I. On the contrary, for other positions the results by Calculation I seem to be better than those of Calculation II. Therefore, a more satisfactory agreement may be expected when the calculation is carried out assuming that the $C_3–C_2–C_1$ bond angle at position 2 is slightly more obtuse than 95°. At any rate, however, the molecular shape of azulene has not been definitely determined; the validity of the present results should be examined by future experiments.

Vinyl chloride in group b of Table III is given as an example to show the difference between the $J_{C-H(2)}$ value *cis* and the $J_{C-H(1)}$ value *trans* to the chlorine atom. In group c, we applied the present treatment to formamide-^{15}N in order to explain the difference between $J_{N-H(1)}$ and $J_{N-H(2)}$. Assuming that the magnitude of the coupling between nitrogen-15 and directly-bonded hydrogen is determined by the contact interaction, as in the case of ^{13}C–H coupling, the ^{15}N–H coupling constnat should be expressed by a relation similar to Eq. 2. The constant A in Eq. 3 for nitrogen–15 and hydrogen coupling no doubt differs from that for ^{13}C–H, since the product of the gyromagnetic ratios and the mean triplet

excitation energy are different for each coupling case.

Discussion

In the present treatment, only one coupling mechanism, the Fermi term, and the approximation of the mean excitation energy are assumed. Nuclear spin-spin interactions have been proposed to proceed by three different mechanisms, mechanisms which arise from: (1) the Fermi contact interaction, (2) the nuclear spin-electron orbital interaction, and (3) the electron-nuclear dipole-dipole interaction. It has been shown that[13] the coupling of protons with other directly-bonded nuclei derives principally from the contact term. In a molecular orbital treatment,[12,13] the contact term may be further divided into one- and two-electron contributions; the former has been commonly neglected.[12,13] However, the deviations from the linear relationship expressed by Eq. 1 have been observed, and the validity of the S-character calculated from the experimental J_{C-H} value with Eq. 1 has been criticized by Karabatsos.[18] This deviation may be attributed to the breakdown of one or more assumptions involved in Eq. 1 or to the neglect of another coupling mechanisms, such as the dipole-dipole interaction and the spin-orbital term.[18,19] The deviations from the linear correlation represented by Eq. 3 which are found in compounds of group c and group a in Table II might be partly due to this.

The second assumption, the mean excitation energy, ΔE, was taken only for the sake of simplicity in our work. Recently, this point has been reexamined by Pople and Santry[13] for proton-proton coupling[13] and F-H coupling; they showed that an MO treatment is successful in interpreting the sign of the coupling constant for each case. For C-H coupling, we also examined the sign of the $\pi_{SA,SB}$ term in Pople's equation[15] instead of $P^2/\Delta E$, where $\pi_{SA,SB}$ is written as:

$$\pi_{SA,SB}=4\sum_{i}^{occ}\sum_{j}^{unocc}(E_i-E_j)^{-1}C_{iSA}C_{iSB}C_{jSA}C_{jSB}$$

For a directly-bonded C-H spin-spin system, the sign of the calculated value of $\pi_{SC,SH}$ is positive for most compounds,* this leads to the positive value of J_{C-H}. From these considerations, the approximation of the mean exictation energy, ΔE, in the present treatment is rather crude, but it is qualitatively valid so far as the sign of J_{C-H} is concerned. These points should be investigated in future studies.

A few discrepancies found in Tables II and III may also be attributed partly to this assumption of the constant mean excitation energy. Namely, in Table II the fact that the J_{C-H}/P^2 for group b is larger than that for groups a, c and especially d means that the mean excitation energy of the compounds in groups a, c and d should decrease. Finally, the disagreement as to heterocyclic compounds in Table III may be partly attributed to the parametrization of Hoffmann's extended Hückel molecular orbital.

The calculations were carried out on the IBM 7090 at Japan IBM Co., with the permission of the UNICON Committee, whose help we hereby acknowledge.

The Relation between Ultrasonic Velocity and Viscosity in Aqueous Solutions of Electrolytes

By Satya PRAKASH, Som PRAKASH and Shobhay LAXMI

Ultrasonic Laboratories, Department of Chemistry, Allahabad University, India

(Received January 6, 1966)

From the experimental data on the ultrasonic velocity and viscosity of thorium nitrate, lanthanum acetate and lanthanum chloride, it has been found that the product of adiabatic compressibility and viscosity is fairly constant over the concentration range studied. From those data the relation between ultrasonic velocity and viscosity has been derived which can explain the variation in sound velocity with the concentration.

Prakash and Srivastava,[1] from their ultrasonic velocity and viscosity measurements in aqueous

1) S. Prakash and S. P. Srivastava, *Indian J. Chem.*, **2**, 499 (1964).

solutions of silver nitrate, have explained the decrease in sound velocity with the concentration as due to the relative variation in density and viscosity parameters. These conclusions were drawn from an empirical equation obtained from the experimental data on sound velocity and viscosity in aqueous solutions of silver nitrate. Here in this present work we have again found that the variation in ultrasonic velocity with the concentration can be explained on the basis of the proposed empirical equation. No theoretical explanation of this relation can, however, be given at this time.

Experimental

Ultrasonic velocities at the frequency of 5 Mc./sec. have been measured by the light diffraction method introduced by Debye and Sears.[2] The source of the ultrasonic waves was a generator comprising of an oscillator and a quartz transducer unit, operating at either of two frequencies, 1 Mc./sec. or 5 Mc./sec. The output of sound energy at 5 Mc./sec. was 3.5 W.; all the work was done at this frequency.

Solutions of thorium nitrate, lanthanum acetate and lanthanum chloride were prepared by dissolving pure substances (B. D. H. analar) in doubly-distilled water. The densities of these solutions were measured with the help of a relative density bottle, while the viscosities were measured with an accurate Ostwald viscometer. The errors in the measurement of the density and viscosity were 0.02 and 0.4 per cent respectively. The adiabatic compressibility, β, was calculated using the equation:

$$\beta = \frac{1}{V^2\rho}$$

where V is the ultrasonic velocity and ρ, the density of the solution.

The probable errors involved in the measurement of sound velocity and adiabatic compressibility are 0.13 and 0.24 percent respectively.

Results and Discussion

Several workers have reported that the presence of a heavy or complex ion in a solution decreases the ultrasonic velocity. Here thorium nitrate, lanthanum acetate and lanthanum chloride all have a heavy ion; nevertheless, it is interesting to note, the ultrasonic velocity does not decrease, but instead increases linearly with the increase in concentration.

Whenever an electrolyte is dissolved in water, its compressibility is decreased. This lowering in compressibility may be attributed due to the influence of the electrostatic pressure of the ions on the surrounding water molecules, thus increasing the total internal pressure and making the solution harder to compress. The variation of adiabatic compressibility in all the cases is quite normal. It decreases regularly with the increase in concentration.

The values of the velocity, adiabatic compressibility, density and viscosity are given in Tables I, II and III.

11	0.090	1551.3	41.33	1.059	43.42

Table III. Lanthanum chloride
Temp.: 30±0.1°C

Sample No.	Concn. mol./l.	Velocity m./sec.	Adiabatic compressibility β cm²/dyne $10\times^{12}$	Viscosity centipoise η	$\beta\times\eta\times 10^{12}$
1	0.042	1556.0	41.11	1.038	42.65
2	0.049	1556.5	40.96	1.043	42.74
3	0.056	1557.5	40.88	1.061	43.38
4	0.084	1564.0	40.42	1.070	43.27
5	0.112	1567.0	39.96	1.082	43.25
6	0.126	1569.0	39.53	1.096	43.31
7	0.140	1571.5	39.23	1.106	43.38

From the last column of the tables it can be seen that the product of adiabatic compressibility and viscosity is fairly constant over the concentration range studied. The average value of the constant is 43.38×10^{-12} cm²/dyne.

It follows, therefore that:

2) P. Debye and F. N. Sears, *Proc. Natl. Acad. Sci., U. S.*, **18**, 410 (1932).

$$\beta \times \eta = K \tag{1}$$

By combining the equation with the well-known equation:

$$\beta = \frac{1}{V^2\rho}$$

we have:

$$\frac{1}{V^2\rho} \times \eta = K \tag{2}$$

or:

$$V = \sqrt{\eta/K\rho}$$

or:

$$V = K'\sqrt{\eta/\rho} \tag{3}$$

where K' is another constant equal to $\sqrt{1/K}$. By differentiating Eq. 3 with respect to the concentration, we get;

$$\frac{1}{V_\infty} \cdot \frac{dV}{dC} = \frac{1}{2}\left[\frac{1}{\eta_\infty}\frac{d\eta}{dC} - \frac{1}{\rho_\infty}\frac{d\rho}{dC}\right] \tag{4}$$

This equation indicates that the variation in the ultrasonic velocity depends upon the magnitude of the viscosity and density parameters. Equation 4 can explain the anomalous variation in ultrasonic velocity with the concentration. Prakash and Srivastava[1] have explained the decrease in ultrasonic velocity in aqueous solutions of silver nitrate as due to the value of $1/\rho_\infty \cdot d\rho/dC$ being greater than $1/\eta_\infty \cdot d\eta/dC$.

The increase in ultrasonic velocity in thorium nitrate, lanthanum acetate and lanthanum chloride solutions can also be explained, on the basis of the above equation, as being due to the greater value of $1/\eta_\infty \cdot d\eta/dC$ than $1/\rho_\infty \cdot d\rho/dC$.

These experimental results indicate that the variation in ultrasonic velocity with the concentration is governed by two factors, the viscosity and the density of the medium.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2116—2126 (1966)

Sigma-Pi Interaction Accompanied by Stereoselection

By Kenichi FUKUI and Hiroshi FUJIMOTO

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received January 7, 1966)

A simple molecular orbital theoretical treatment of the sigma-pi interaction caused by chemical reactions of planar-conjugated systems has been developed. The problem of the streo-selection of the two alternative directions of configuration altering due to the hybridization change at the centers of interaction has been considered by means of a simple perturbation treatment. Two theoretical indices, which represent the conjugation stabilization by way of the sigma-pi and reagent-pi interactions, have been introduced for this purpose. The theoretical results are consistent with the results of experience so far accumulated in various organic reactions, such as additions, eliminations, substitutions, and rearrangements, of conjugated molecules.

The electronic wave function for planar-conjugated molecules is divided into the so called sigma and pi parts. The former is composed of the molecular orbitals (MO) which are symmetric with respect to the molecular plane and have the direction of extension on that plane, while the latter consists of the MO's antisymmetric with respect to that plane, to which their direction of maximum extension is perpendicular. The condition of this separability has been thoroughly discussed by Lykos and Parr.[1] When such a planar system is exposed to a certain perturbation, say, for instance, to a chemical interaction due to the approach of atoms, molecules, radicals, or ions from definite sides of the plane toward definite positions of the molecule, both the sigma and pi MO's will be affected. The change in MO's as well as in energies is obtainable from the usual perturbation calculation on an assumption of an unchanged molecular configuration.[2] However, the actual effect will cause a change in the nuclear distances

1) P. G. Lykos and R. G. Parr, *J. Chem. Phys.*, **24**, 1166 (1956); **25**, 1301 (1956).

2) Hosoya and Nagakura (H. Hosoya and S. Nagakura, Preprint of Symposium on Molecular Structure, Japan (1962), p. 48 (in Japanese)) calculated the deformation of MO's with the mixing of the 3s orbital with the $2p\pi$ orbitals due to the approach of a point charge to an ethylenic bond.

and valence angles near the center of approach, giving rise to changes in the hybridization of carbon atoms. Such an altering in the molecular configuration is not calculable by a mere perturbation treatment. The most favorable configuration would be obtained as the one which gives the minimum adiabatic potential due to the Born-Oppenheimer approximation adopted for the perturbed system. This procedure is not, however, simple enough to be practical for organic chemists.

This paper will present a simple MO treatment of organic chemical processes in planar-conjugated molecules, thus providing a method by which we can discuss very simply the direction of the configuration-altering of molecules associated with the hybridization change in carbon atoms. This configuration's frequent alterations arise stereospecifically; it is the purpose of the present paper to elucidate the rule which governs this stereoselection.

Simple Perturbation Treatment

Let us consider a planar-conjugated hydrocarbon molecule having several carbon $2p\pi$ atomic orbitals (AO). The carbon atom, t, has one π orbital, ϕ_t, and three sp^2 hybridized σ orbitals, χ_t, $\chi_{t'}$, and $\chi_{t''}$, to combine with neighboring carbon sp^2 orbitals or otherwise with hydrogen 1s orbitals, ζ_p's. The direction of the extension of these real hybridized orbitals conforms to the direction of bonding, so that they have always positive values in the region of their maximum extension (Fig. 1). All $2p\pi$ orbitals are taken as

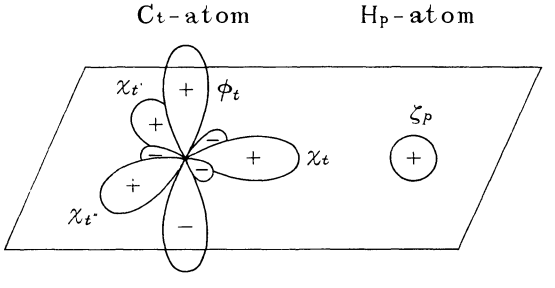

Fig. 1. The atomic orbitals.

having the same sign on the same side of the molecular plane. The total unperturbed wave function is assumed to be a product of the π part and the σ part, both of which are represented by a mere product of the usual simple Hückel MO's, which are written as:

$$\psi_i = \sum_t c_t^i \phi_t \qquad \text{for the } \pi \text{ part, and} \quad (1a)$$

$$\varphi_k = \sum_t b_t^k \chi_t + \sum_p d_p^k \zeta_p \qquad \text{for the } \sigma \text{ part,}^{3)} \quad (1b)$$

where ψ_i and φ_k are ith π MO and kth σ MO respectively. The first term on the right side of the latter equation signifies the summation with respect to each of three σ hybrids, namely:

$$\sum_t (b_t^k \chi_t + b_t^{k'} \chi_{t'} + b_t^{k''} \chi_{t''})$$

Instead of proceeding with the usual perturbation concept, we may here adopt the "method of perturbed secular determinant."[4)]* This method is suitable for calculating the energy difference between two systems for which the secular determinants differ slightly. The characteristic feature of this method is that it makes possible the calculation of the changes in energy, electron density, bond order, and other MO-theoretical quantities without an explicit knowledge of the change in the Hamiltonian operator or in that of wave functions.

The nonperturbed MO's of the π part are orthogonal to those of the σ part. The resonance integral between ϕ_t and χ_t's for the nonperturbed field is, of course, zero. Let us consider the configuration alteration which is indicated in Fig. 2, corresponding to the hybridization change due to chemical interaction with conjugated molecules. Figure 2 illustrates the case of a two-center interaction. Since, in all cases, our interest is limited to the direction of configuration alteration, each carbon atom is assumed to change its hybridized state from sp^2 to sp^x, where x is a definite number between 2 and 3. With this change the Coulomb integrals of a π orbital and a σ hybrid vary by $(\Delta\alpha)_\pi$ and $(\Delta\alpha)_\sigma$ respectively. The changes in the resonance integrals between a varied and the neighboring π AO's, and between a varied and the neighboring σ hybrids, are $(\Delta\beta)_\pi$ and $(\Delta\beta)_\sigma$ respectively, while the change in the resonance integral between the two σ hybrids of the same carbon atom[3)] is $(\Delta\beta)_\sigma'$. The resonance integral between the π orbital and a σ hybrid of the same carbon atom, say t, is designated by γ_t^σ. Since the way of taking the sign of basis orbitals is as illustrated in Fig. 1, we have two cases with respect to the value of γ^σ: namely, the one is the case of the carbons t and u of Fig. 2(i) (or the carbon t of ii), and the other is the case of the carbon u of Fig. 2(ii).

3) a) K. Fukui, H. Kato, T. Yonezawa, K. Morokuma, A. Imamura and C. Nagata, This Bulletin, **35**, 38 (1962); b) see also K. Fukui, H. Kato and T. * The term "perturbation" is here employed to imply the origin of the change in particular parameters in the secular determinant. The change in any quantum-mechanical quantity derived by solving it can be obtained by a procedure similar to the usual perturbation calculations.

(x: a number between 2 and 3)

Fig. 2. A schematic representation of the mode of two-center σ-π interaction with a conjugated molecule.
* The terms *syn-* and *anti-* are used in order to evade confusion with *cis-* and *trans*-configurations of the remaining double bonds.

In the former case γ^{σ} is clearly negative, while in the latter it is positive. In addition, we have to consider the interaction with the reagent system. The resonance integral for the overlapping at the rth π orbital of the conjugated molecule with the reagent system (mostly one or two independent systems) is denoted by γ_r^{R}.

The increase in the total energy, ΔE, is thus represented by the following equations:[4]

$$\Delta E = (\Delta E)_{\sigma} + (\Delta E)_{\pi} + (\Delta E)_{\mathrm{R}} + (\Delta E)_{\sigma\pi} + (\Delta E)_{\mathrm{R}\pi} \tag{4}$$

$$\begin{aligned}(\Delta E)_{\sigma} &= 2\sum_{k}^{\mathrm{occ}}\sum_{t}(b_t^k)^2(\Delta\alpha)_{\sigma} \\ &+ 4\sum_{k}^{\mathrm{occ}}\sum_{t}\left\{\sum_{u}^{nei} b_t^k b_u^k(\Delta\beta)_{\sigma} + \sum_{t'}^{\mathrm{sam}} b_t^k b_{t'}^k(\Delta\beta)_{\sigma}'\right\} \\ &+ 2\sum_{k}^{\mathrm{occ}}\sum_{l}^{\mathrm{uno}}\frac{1}{\eta_k-\eta_l}\left\{\sum_{t} b_t^k b_t^l(\Delta\alpha)_{\sigma}\right. \\ &+ \sum_{t}\sum_{u}^{\mathrm{nei}}(b_t^k b_u^l + b_u^k b_t^l)(\Delta\beta)_{\sigma} \\ &\left.+ \sum_{t}\sum_{t'}^{\mathrm{sam}}(b_t^k b_{t'}^l + b_{t'}^k b_t^l)(\Delta\beta)_{\sigma}'\right\}^2\end{aligned} \tag{5}$$

$$\begin{aligned}(\Delta E)_{\pi} &= 2\sum_{i}^{\mathrm{occ}}\sum_{t}(c_t^i)^2(\Delta\alpha)_{\pi} \\ &+ 4\sum_{i}^{\mathrm{occ}}\sum_{t}\sum_{u}^{\mathrm{nei}} c_t^i c_u^i(\Delta\beta)_{\pi} \\ &+ 2\sum_{i}^{\mathrm{occ}}\sum_{j}^{\mathrm{uno}}\frac{1}{\varepsilon_i-\varepsilon_j}\left\{\sum_{t} c_t^i c_t^j(\Delta\alpha)_{\pi}\right. \\ &\left.+ \sum_{t}\sum_{u}^{\mathrm{nei}}(c_t^i c_u^j + c_u^i c_t^j)(\Delta\beta)_{\pi}\right\}^2\end{aligned} \tag{6}$$

$$(\Delta E)_{\sigma\pi} = 2\left(\sum_{i}^{\mathrm{occ}}\sum_{k}^{\mathrm{uno}} - \sum_{k}^{\mathrm{occ}}\sum_{i}^{\mathrm{uno}}\right)\frac{1}{\varepsilon_i-\eta_k} \times\left(\sum_{t} c_t^i b_t^k \gamma_t^{\sigma}\right)^2 \tag{7}$$

$$\begin{aligned}(\Delta E)_{\mathrm{R}\pi} &= 2\left(\sum_{i}^{\mathrm{occ}}\sum_{l}^{\mathrm{uno}} - \sum_{l}^{\mathrm{occ}}\sum_{i}^{\mathrm{uno}}\right)\frac{1}{\varepsilon_i-e_l} \\ &\times\left(\sum_{r} c_r^i d_{r'}^l \gamma_r^{\mathrm{R}}\right)^2 + 2\left(\sum_{i}^{\mathrm{occ}}\sum_{l'}^{\mathrm{uno}} - \sum_{l'}^{\mathrm{occ}}\sum_{i}^{\mathrm{uno}}\right) \\ &\times\frac{1}{\varepsilon_i-e_{l'}}\left(\sum_{s} c_s^i d_s^{l'}\gamma_s^{\mathrm{R}'}\right)^2 + \cdots\end{aligned} \tag{8}$$

In addition to the right-side terms in Eq. 4, there may happen to exist zero-order terms which have no connection with stereochemical problems.

We may proceed further without mentioning the modification well-known to be necessary for the case of any type of degeneracy with respect to MO energies which may yield first-order terms in these equations in lieu of the corresponding second-order terms. The terms $(\Delta E)_{\sigma}$, $(\Delta E)_{\pi}$ and $(\Delta E)_{\mathrm{R}}$ signify the change in energy due to the interaction in the sigma, pi, and reagent parts respectively, while $(\Delta E)_{\sigma\pi}$ and $(\Delta E)_{\mathrm{R}\pi}$ are the conjugation stabilizations through sigma-pi and reagent-pi interactions respectively. In these equations occ and uno mean all the occupied and unoccupied MO's respectively, while nei and sam imply all neighboring orbitals and all hybrids of the same carbon atom respectively. When a radical plays a part, the terms due to the half-occupied orbital must not be doubled. The energy of ith π-MO and kth σ-MO are denoted by ε_i and η_k respectively. The summation with respect to t on the right sides of Eqs. 5 and 7 has the same meaning as in Eq. 1b. For the reagent part, e_l and $d_{r'}^l$ are the energy and the coefficient of r'th AO (at which the overlapping takes place with the rth π orbital of the reactant) of the Reagent System 1 (which is, of course, not limited to a conjugated system). Similarly, $e_{l'}$ and $d_s^{l'}$ are for Reagent System 2, and so forth. The term $(\Delta E)_{\mathrm{R}}$ represents the energy change in the reagent, which may have a form similar to $(\Delta E)_{\sigma}$ and $(\Delta E)_{\pi}$.

The stereoselectivity of this type of reaction is thus governed by the terms of $(\Delta E)_{\sigma\pi}$ and $(\Delta E)_{R\pi}$ since, in such a problem, $(\Delta E)_{\sigma}$, $(\Delta E)_{\pi}$ and $(\Delta E)_{R}$ are deemed as common in the two opposite configurations in Fig. 2. In addition, the geometrical circumstances in the interaction of the reagent system with the reactant system, or the interesting effect of neighboring-group participation, should never be left out of account; however, this is obviously a problem to be discussed in a separate paper.

The Parametrization

In order to calculate the value of ΔE, we need to evaluate the integrals of both σ and π parts on a unified basis. These we have already made available in several of our previous papers,[3] and also summarized in a recent paper in which we adopted a slightly different estimation.[5] In the present paper we will use the latter values, with slight modifications, plus the values of newly-evaluated integrals for aromatic skeletons, as are listed in Table I. These numerical values have been determined with reference to the analytical form of the Slater orbitals and the theoretical evaluation of the overlap integrals in order to be consistent with various empirical data.

Table I. The parameters employed for hydrocarbons

Coulomb integrals:
- for carbon p orbital: $\alpha-0.15\beta$
- sp^3 hybrid: $\alpha-0.10\beta$
- sp^2 hybrid: α
- sp hybrid: $\alpha+0.10\beta$
- for all hydrogens: $\alpha-0.20\beta$

Resonance integrals:
- for C–C single bonds:
  - sp^3-sp^3: 0.84β sp^3-sp^2: 0.88β sp^3-sp: 0.96β
  - sp^2-sp^2: 0.92β sp^2-sp: 0.98β sp-sp: 1.04β
- for C–C double bonds:
  - p-p (π): 0.30β
  - sp^2-sp^2 (σ): 1.00β sp^2-sp (σ): 1.04β
  - sp-sp (σ): 1.08β
- for C–C triple bonds:
  - p-p (π): 0.35β
  - sp-sp (σ): 1.13β
- for aromatic C–C bonds:
  - sp^2-sp^2: 0.96β
- for C–C bonds of polyenyl radicals:
  - sp^2-sp^2: 0.96β
- for two σ hybrids belonging to the same carbon:
  - sp^3-sp^3: 0.30β sp^2-sp^2: 0.38β sp-sp: 0.60β
- for C–H bond:
  - sp^3 carbon: 0.90β
  - sp^2 carbon: 0.94β
  - sp carbon: 0.96β

(α: the Coulomb integral of a carbon sp^2 hybrid
β: the resonance integral for two bonding carbon sp^2 hybrids in the ethylenic double bond.)

(The resonance integrals for C–C single bond other than sp^3-sp^3 are given for the single bonds of such types as C–C= (sp^3-sp^2), C–C≡ (sp^3-sp); =C–C= (sp^2-sp^2), and so on. Such a clasification obviously does not possess any essential meaning. The slight difference in these resonance integrals does not affect seriously the result.)

The Sigma-pi Interaction

The quantity, $(\Delta E)_{\sigma\pi}$, which has been introduced above is useful in various problems in which the hybridization change participates. We assume, in this connection, that the arbitrary value of r_t^{σ} in Eq. 7 is to be regarded as equal to $g_t\gamma^{\sigma}$, in which g_t is $+1$ (as in the case of the carbons t and u of Fig. 2(i) and the carbon t of ii) and -1 (in the case of the carbon u of Fig. 2 (ii) and γ^{σ} is a negative constant; thus we may difine a new index, which we tentatively denote by $h_{tu\cdots}$, as:

$$h_{tu\cdots} = (\Delta E)_{\sigma\pi}\beta/(\gamma^{\sigma})^2 = 2\left(\sum_i^{\text{occ}}\sum_k^{\text{uno}} - \sum_k^{\text{uno}}\sum_i^{\text{occ}}\right)\frac{(-\beta)}{\eta_k-\varepsilon_i} \times (c_t^i c'^k_t g_t + c_u^i c'^k_u g_u + \cdots\cdots)^2 \quad (9)$$

where $c'^k_t = b^k_t + b^k_{t'} + b^k_{t''}$, where β is the resonace integral between two bonding carbon sp^2 hybrids in the ethylene double bond, and where t, u,$\cdots$ imply the carbon atoms at which the hybridization change takes place.* Several of the simplest cases are specified by:

$$h_t = 2\left(\sum_k^{\text{occ}}\sum_i^{\text{uno}} - \sum_i^{\text{occ}}\sum_k^{\text{uno}}\right)\frac{(-\beta)}{\varepsilon_i-\eta_k}(c_t^i)^2(c'^k_t)^2 \quad (10a)$$

$$h_{tu}^{(syn)} = 2\left(\sum_k^{\text{occ}}\sum_i^{\text{uno}} - \sum_i^{\text{occ}}\sum_k^{\text{uno}}\right)\frac{(-\beta)}{\varepsilon_i-\eta_k} \times (c_t^i c'^k_t + c_u^i c'^k_u)^2 \quad (10b)$$

$$h_{tu}^{(ant)} = 2\left(\sum_k^{\text{occ}}\sum_i^{\text{uno}} - \sum_i^{\text{occ}}\sum_k^{\text{uno}}\right)\frac{(-\beta)}{\varepsilon_i-\eta_k} \times (c_t^i c'^k_t - c_u^i c'^k_u)^2 \quad (10c)$$

For the systems having a half-occupied level, i, the terms due to that level must not be doubled but must be summed over all the k's.

The index h_t represents the ease of hybridization of the tth π orbital, namely, the ease of mixing the s-nature into the p AO; thus we may refer to

5) K. Fukui in "Modern Quantum Chemistry," Vol. I, Ed. by O. Sinanoglu, Academic Press, New York (1965), p. 49.

* In the two-center interaction at the equivalent positions (t, u) of a molecule with C_{2h}-symmetry, in which we assume that $|g_u| = a|g_t|$ ($a>0$), it is easy to show that:

$$h_{tu}^{(syn)} - h_{tu}^{(ant)} = a\,[h_{tu}^{(syn)} - h_{tu}^{(ant)}]_{a=1}$$

it as the "hybridizability" of the tth pπ atomic orbital. This quantity is closely related to the problem of olefinicity (and, therefore, also to that of aromaticity), which will be discussed elsewhere.

The index h_{tu} is connected with the stability of the activated complex of the two-center reactions of conjugated molecules, a discussion of which will immediately follow.

Acyclic Two-center Interactions

Let us proceed further by dividing the problem into two cases, those of cyclic and of acyclic interactions. Also, let us limit the discussion to the two-center interaction only.

By an "acyclic two-center interaction" we mean a simultaneous or quasi-simultaneous interac-

*1 The value of $(\Delta E)_{R\pi}$ depends on the reagent orbital. The values presented here are tentatively calculated for the case of hydrogen migration.
The quantity β' corresponds to the resonance integral of an ethylenic p-p(π) bond. ($=0.3\beta$)

*2 This case corresponds to the 5,6-proton migration of cyclohexa-1,3-dienyl cation. Other cases are also to be interpreted similarly.

*3 The cyclic and acyclic cases were not distinguished in the theory of Woodward and Hoffmann (Ref. 16); namely e. g. the cases of 1,5-migrations of cyclopentadiene and all-*cis*-pentadiene. The former corresponds to the case of 1,2-interaction of cyclopentadienyl and the latter to that of 1,5-interaction of pentadienyl in this table.

*4 The values in case Ib are given for the systems each of which is composed of a vacant single orbital and the anion corresponding to the original reactant except the cases of cyclopropenyl and cycloheptatrienyl. In these two cases, the values are for a doubly-occupied single orbital with cyclopropenyl cation or cycloheptatrienyl cation. The zero-order terms due to electron transfer interaction are deemed as common both in *syn*- and *anti*-interactions.

*1 $\beta'=0.3\beta$
*2 This case corresponds to Cope rearrangements. The intramolecular rearrangements like that of *cis*-1,2-divinyl cyclobutane to cycloöcta-1,5-diene (cf. E. Vogel, *Ann.*, **615**, 1 (1958)) are also essentially a Cope rearrangement.
*3 These values correspond to the first order terms, $2|c_rc_r'\pm c_sc_s'|$ between two half-occupied orbitals in γ^R.

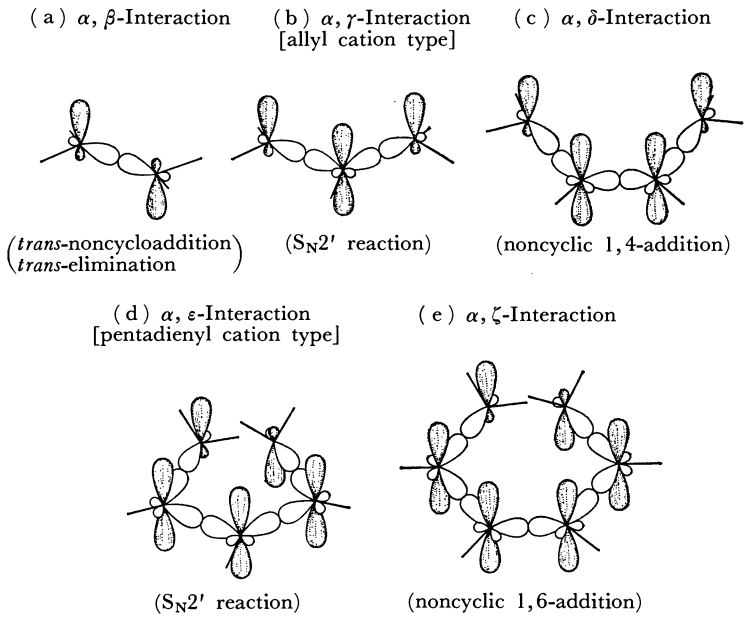

Fig. 3. A schematic representation of favorable configurations in noncyclic two-center interactions of conjugated molecules.

tion of two independent reagents with each of two positions of the reactant conjugated system. To this group may belong additions, eliminations, substitutions, rearrangements, and so forth. In such a case, if we concentrate our attention on the qualitative direction of the configuration alteration, *syn*- or *anti*- in Fig. 2, it is evident that we need to compare the magnitudes of the term $(\Delta E)_{\sigma\pi}$ only, since $(\Delta E)_{R\pi}$ is as an approximation common in these two configurations. A qualitative determination of the preferable configuration may be possible by a comparison of $h_{tu}^{(syn)}$ and $h_{tu}^{(ant)}$ of Eq. 10.

α, β-Interaction.—The two carbon atoms under consideration, neighboring each other in a conjugated system, are designated as α and β. Let us take the ethylene molecule as an example. The values of $h_{12}^{(syn)}$ and $h_{12}^{(ant)}$ are 3.1194 and 5.5244 respectively; thus, they exhibit the predominance of *anti*-interaction.[6] This is consistent with a number of well-known experimental results of *trans*-noncycloadditions[7] and *trans*-eliminations.[8] The results for the α, β-interactions in other conjugated systems are listed in Table II (I); all of them demonstrate the *anti*-interaction to be favorable.[9]

α, γ-Interaction.—Similarly, we can discuss the α, γ-interactions. The essential feature of S_N2' reactions is regarded as 1, 3-noncyclointeraction of the allyl cation type, because the leaving group takes off two electrons.* These reactions are known to proceed by means of a *syn*-configuration;[10] this is in accordance with the theoretical results obtained in Table II (II).

α, δ-, α, ε-, and α, ζ-Interactions. — These cases seem not yet to have been experimentally established. The theoretical results, however, predict the dominant configurations indicated in Fig. 3, a configuration which corresponds to the calculations of Table II (III, IV, V).

It may be noteworthy that, as is shown in Table II, the differences in the values of $h_{tu}^{(syn)}$ and $h_{tu}^{(ant)}$ become smaller as the two reaction centers become farther apart. Thus, in noncyclic 1, 6-additions, high stereospecificity is not to be expected.

9) The predominance of *trans*-addition has also been discussed as an orientation problem. See K. Fukui, *Tetrahedron Letters*, No. 28, 2427 (1965); see also a paper of the present authors to be published in the near future.

10) H. L. Goering, T. D. Nevitt and E. F. Silversmith, *J. Am. Chem. Soc.*, **77**, 4042 (1955); G. Stork and W. N. White, ibid., **78**, 4609 (1956). One of the present authors (K. F.) is grateful to Professor Stork for his private communication.

* The hybridized state of β-carbon is assumed to stay unchanged during the course of this reaction. A similar assumption is made in the discussion of other, more distant two-center interactions, and in cyclic cases.

Cyclic Two-center Interactions

The term "cyclic two-center interaction" signifies a chemical interaction corresponding to the transition state in which a conjugated reactant system interacts simultaneously at two positions with one "connected" reagent system. Thus, for instance, if we regard a diene in the Diels-Alder reaction as a conjugated reactant system, the associated dienophile is a reagent, while if we regard a dienophile as a conjugated reactant system, the associated diene is a reagent. The reagent is, of course, not necessarily a conjugated system; it may be any other system which is capable of interacting simultaneously with two positions of a conjugated system. It may be a proton in a protonated ethylene molecule, a phenyl cation in a phenonium ion, osmium tetroxide in an adduct to conjugated hydrocarbons, and so forth.[11]

MO-theoretical treatments for interactions of such a kind are not new.[12] To such treatments may belong the theoretical studies of the well-known Diels-Alder reaction, the Claisen and the Cope rearrangements, the 1, 3-dipolar cycloadditions, and so on. The significance of the symmetry of the highest-occupied (HO) MO and the lowest-vacant (LV) MO in the problem of selection rule for the Diels-Alder reaction was first pointed out by one of the present authors.[13] Hoffmann and Woodward discussed a similar selection rule for the occurrence of cycloadditions more generally, from the point of view of the MO symmetry conservation.[14]

The problem of the stereoselectivity of these reactions is presented in terms of $(\Delta E)_{R\pi}$ and $(\Delta E)_{\sigma\pi}$ in Eq. 4. However, it seems likely that, in this cyclic case, $(\Delta E)_{R\pi}$ is in general more determinative than $(\Delta E)_{\sigma\pi}$. The term $(\Delta E)_{R\pi}$ in Eq. 8 is reduced to the following form:

$$(\Delta E)_{R\pi} = \sum_i \sum_l \frac{\nu_i - \nu_l}{\varepsilon_i - e_l} \left(\sum_r c_r^i d_r^l \gamma_r^R \right)^2 \qquad (11)$$

where ν_i and ν_l are the numbers of electrons occupying the ith and the lth MO in the reactant and the reagent systems respectively. The sigma-type overlap stabilization of this type has already been discussed in several papers.[13,15] Several important cases will now be treated.

Case I. The reagent orbital is a single s orbital:

(Ia) When the reagent orbital is vacant:

$$(\Delta E)_{R\pi} = \sum_i \frac{\nu_i}{\varepsilon_i - e} (c_r^i \pm c_s^i)^2 (\gamma^R)^2 \qquad (12a)$$

(Ib) When the reagent orbital is half-occupied:

$$(\Delta E)_{R\pi} = \frac{1}{2} \left\{ \sum_i \frac{\nu_i}{\varepsilon_i - e} - \sum_i \frac{(2-\nu_i)}{\varepsilon_i - e} \right\} \times (c_r^i \pm c_s^i)^2 (\gamma^R)^2 \qquad (12b)$$

(Ic) When the reagent orbital is doubly-occupied:

$$(\Delta E)_{R\pi} = -\sum_i \frac{2-\nu_i}{\varepsilon_i - e} (c_r^i \pm c_s^i)^2 (\gamma^R)^2 \qquad (12c)$$

where ν_i is the number of π electrons occupying the ith MO of the reactant system, and where r and s are the centers of interaction. It is assumed that the absolute values of γ_r^R and γ_s^R are equal in the transition state, so that the upper and lower signs in parentheses are for *syn*- and *anti*-interactions respectively.

Case I, in particular the hydrogen migration belonging to Case Ib, was very recently discussed theoretically by Woodward and Hoffmann from a different point of view.[16] By Eqs. 12a—c, the results listed in Table III are obtained for the favorable mode of interaction in the ground-state reactions. The stabilization in some "nonclassical" carbonium ions, and also such reactions as the proton or carbonium cation migration in protonated conjugated hydrocarbons or carbonium cations, are covered by Case Ia; similarly, anion migrations belong to Case Ic. The well-known experimental results so far available are consistent with the theoretical results.

The reagent orbital is frequently a single p orbital. Similar arguments can easily show that such an orbital, when it is vacant, is allowed to enter into interaction simultaneously with two π orbitals of the reactant, for which the most favorable configuration is demonstrated to be "*syn*" in Table III, Case Ia. The well-known

11) For the discussion of such cases, see also the description of *cis*-1, 2-addition in Ref. 6.

12) See the many examples given, for example, in A. Streitwieser, Jr., "Molecular Orbital Theory for Organic Chemists," John Wiley & Sons, New York (1961).

14) R. Hoffmann and R. B. Woodward, *J. Am. Chem. Soc.*, **87**, 2046 (1965).

15) K. Fukui, *Tetrahedron Letters*, No. 24, 2009 (1965); cf. also Refs. 4 and 6.

16) R. B. Woodward and R. Hoffmann, *J. Am. Chem. Soc.*, **87**, 2511 (1965): These innovators have, no doubt, brought the first streaks of dawn into the field of theoretical stereochemistry through their elegant generalization (see Ref. 14 and also R. B. Woodward and R. Hoffmann, *J. Am. Chem. Soc.*, **87**, 395 (1965)). However, from the quantum-chemical point of view, their papers seem to leave a few points open to criticism. One of the present authors has recently made a comment (Ref. 15). In their discussion of "sigmatropic" reactions (*J. Am. Chem. Soc.*, **87**, 2511 (1965)), to take another instance, they determined the expected steric course by considering only the highest-occupied orbital (HO) symmetry, even in excited states. As was pointed out in Ref. 15, such a discrimination of HO would require proper grounds. Thus, the results of the prediction of excited-state reactions would probably be unreliable. Excited-state radical reactions are mostly too complicated to be treated by simple MO theories. In the ground-state reactions, the prediction by HO symmetry only almost coincides with that which is made by Eq. 12b.

*2 R. Criegee, *Ann.*, **522**, 75 (1936); R. Criegee, B. Marchand and H. Wannowius, idid., **550**, 99 (1938).

*3 These values are for the case of interaction with MnO_4^- (cf. C. J. Ballhausen and H. B. Gray, "Molecular Orbital Theory," W. A. Benjamin, New York (1964), p. 126). In these cases, only the z-components of the two adjacent oxygen atomic orbitals of the degenerate highest occupied orbitals are tentatively taken for the simplicity of calculation. The lowest vacant orbitals which belong to *E* are in favor of *syn* interaction except the case of butadiene 1,4.

*4 J. Boeseken, *Rec. trav. chim.*, **40**, 553 (1921); **47**, 683 (1928); K. B. Wiberg and K. A. Saegebarth, *J. Am. Chem. Soc.*, **79**, 2822 (1957).

*5 J. S. F. Pode and W. A. Waters, *J. Chem. Soc.*, **1956**, 717.

formation of phenonium ions and the singlet-state addition of carbenes, as well as the addition of atomic carbon to olefins,[17] which has recently been found, may involve this type of interaction.

When the reagent p orbital is half-occupied, too, the *syn* addition takes place if the symmetry relation is favorable. The formation of some epoxides, or the reaction with ozone may belong to this case.

Case II. The reagent orbitals are two bonding orbitals, which are equivalent to each other and which can enter into interaction with two orbitals of the reactant. Therefore, we have:

$$(\Delta E)_{R\pi} = \frac{1}{2}\left\{\sum_i \frac{\nu_i}{\varepsilon_i - e'}(c_r^i \mp c_s^i)^2 - \sum_i \frac{2-\nu_i}{\varepsilon_i - e}(c_r^i \pm c_s^i)^2\right\}(\gamma^R)^2 \qquad (13)$$

for the case of a reagent composed of two ethylenic π orbitals, where e and e' are the energies of bonding and antibonding orbitals respectively. The upper and lower signs stand for the *syn*- and *anti*-configurations respectively.

A comparison of the $(\Delta E)_{R\pi}$ values for two configurations of several conjugated systems indicates the dominant direction of change listed in Table IV; this is in agreement with our experience in dienes in Diels-Alder reactions, which belong to this case and which have already been treated by one of the present authors.[13] Excited-state reactions, in which the electron configuration of the reactant is assumed, can also be easily discussed in terms of Eq. 13.

Case III. The reagent orbitals are three

17) P. S. Skell and A. Y. Garner, *J. Am. Chem. Soc.*, **78**, 5430 (1956); P. S. Skell and R. R. Engel, ibid., **87**, 1135, 2493 (1965).

allylic π orbitals, two terminal orbitals of which interact with two reactant π orbitals. The well-known Claisen[18a] and Cope rearrangements[18b] are examples of this case. The $(\Delta E)_{R\pi}$ values in Table V demonstrate that, in experimentally-known cases, the theoretically-favorable configuration is *syn*. The 1, 3-dipolar addition occurs at *cis*- with respect dipolarophiles.

Case IV. The reagent orbitals are butadiene-type π orbitals, two terminal orbitals of which interact with two reactant π orbitals. The theoretical results are listed in Table VI. The Diels-Alder reaction is known to take place at *cis* positions in dienophiles.

Case V. The reagent is of another type. The additions of osmium tetroxide, manganate and permanganate anions, and so forth involve transition states in which the reagent system is considered to belong to none of cases, I to IV. The values of $(\Delta E)_{R\pi}$ are calculable separately by Eq. 11, leading to the conclusions indicated in Table VII, which are consistent with experience.

Through all these cases of cyclic interactions, the spatial circumstances of the transition state evidently require *syn* interaction in order for the reaction actually to take place. Therefore, the conclusion obtained in Tables III—VII affords a stereoselection rule: *syn* stands for the "sterically-allowed" case, and *anti*, the "streically-forbidden."

The explanation as to why the dimerization of butadiene yields 1, 2-divinyl cyclobutane compounds only, and not 1, 3-divinyl compounds,[19] is also an interesting example of Eq. 11, which gives a far larger $(\Delta E)_{R\pi}$ value for the formation of 1, 2- than 1, 3-divinyl compounds.

In all the cases mentioned above, we can easily see that the theoretical conclusion obtained from Eq. 11 for the ground-state reactions is in excellent agreement with that from the consideration of HO and LV only.[6] These orbitals are nothing but the frontier MO's, which are known to play a significant role in various reactions of organic molecules.

Thus, Eq. 11 has a wide applicability to various other problems of reactivity in conjugated systems, problems which are too manifold to systematize in a single paper. Considerations of them are to be published henceforth in sequence.

Spectroscopic Studies of Dialkylaluminum Alkoxides and the Trialkylaluminum-Ether Complex. II. Assignments of Observed Frequencies

By Ryokichi TARAO

Research Center, Chisso Co., Ltd., Kanazawa-ku, Yokohama

(Received January 20, 1966)

The polarization data on the Raman lines of $Al(CH_3)_3 \cdot (CH_3)_2O$, $[Al(CH_3)_2OCH_3]_3$, $[Al(C_2H_5)_2OCH_3]_3$, and $[Al(C_2H_5)_2OC_2H_5]_2$ have been obtained in the 3100—130 cm^{-1} region. Most of the infrared absorption bands and Raman lines of these four compounds in the skeletal vibration region (720—130 cm^{-1}) have been tentatively assigned with the aid of these polarization data and on the assumption that the symmetries of these four compounds are as given in the previous paper. The Raman spectra of $Al(CH_3)_3 \cdot (CD_3)_2O$, $[Al(CH_3)_2OCD_3]_3$, and $[Al(C_2H_5)_2OC_2D_5]_2$ have been measured in the 3100—130 cm^{-1} region. Most of the infrared absorption bands and Raman lines of $Al(CH_3)_3 \cdot (CH_3)_2O$, $[Al(CH_3)_2OCH_3]_3$, $[Al(C_2H_5)_2OCH_3]_3$, and $[Al(C_2H_5)_2OC_2H_5]_2$ in the CH-stretching region (3100—2700 cm^{-1}) have been assigned with the aid of the spectroscopic data of the above-mentioned partly-deuterated substances.

In a previous paper,[1] the author showed that dimethylaluminum methoxide $[Al(CH_3)_2OCH_3]_3$ and diethylaluminum methoxide $[Al(C_2H_5)_2OCH_3]_3$ take trimeric structures with the D_{3h} symmetry, that diethylaluminum ethoxide $[Al(C_2H_5)_2OC_2H_5]_2$ takes a dimeric structure with the V_h symmetry and that the trimethylaluminum-dimethyl ether complex, $Al(CH_3)_3 \cdot (CH_3)_2O$, takes the structure with the C_s symmetry; these assignments were made by comparing the infrared and Raman spectra of these four compounds in the skeletal vibration region (720—300 cm^{-1}). (The

1) R. Tarao, This Bulletin, **39**, 725 (1966).

assignments of the observed frequencies were impossible at that time except for $Al(CH_3)_3 \cdot (CH_3)_2O$.[2] The present paper will describe the results of the qualitative measurements of the degree of the depolarization of the Raman lines of these four compounds. The Raman spectra of three partly-deuterated substances, $Al(CH_3)_3 \cdot (CD_3)_2O$, $[Al(CH_3)_2OCD_3]_3$, and $[Al(C_2H_5)_2OC_2D_5]_2$, will also be measured. The tentative assignments for the infrared absorption bands and Raman lines of $Al(CH_3)_3 \cdot (CH_3)_2O$, $[Al(CH_3)_2OCH_3]_3$, $[Al(C_2H_5)_2OCH_3]_3$, and $[Al(C_2H_5)_2OC_2H_5]_2$ will be made with the aid of the polarization data and the spectroscopic data of the above-mentioned partly-deuterated substances.

Experimental

$Al(CH_3)_3 \cdot (CH_3)_2O$, $[Al(CH_3)_2OCH_3]_3$, $[Al(C_2H_5)_2OCH_3]_3$, and $[Al(C_2H_5)_2OC_2H_5]_2$ were prepared by the method described in the previous paper.[1] Deuterated materials (dimethyl-d_6-ether, methanol-d_3, and ethanol-d_5) were purchased from the Volk Co. (isotopic purity> 99%). $Al(CH_3)_3 \cdot (CD_3)_2O$ was prepared by the reaction of trimethylaluminum with dimethyl-d_6-ether, b. p. 72—73°C/42 mmHg. $[Al(CH_3)_2OCD_3]_3$ was prepared by the reaction of trimethylaluminum with methanol-d_3, b. p. 70.5—72°C/3.5 mmHg. $[Al(C_2H_5)_2OC_2D_5]_2$ was prepared by the reaction of triethylaluminum with ethanol-d_5, b. p. 114—116°C/12 mmHg. The Raman spectra were measured by the method described in the previous paper.[1] The polarization data of Raman lines

were taken by the use of parallel and perpendicular Polaroid cylinders placed alternately over the Raman tube.

Results and Discussion

$Al(CH_3)_3 \cdot (CH_3)_2O$.—In Table I the expected types of skeletal vibrational modes and the number of skeletal vibrations in each species are shown. All of the 15 possible skeletal vibrations are both infrared- and Raman-active. The tentative assignments in the skeletal vibration region (720—130 cm^{-1}) are given in Table IV. The infrared and Raman intensities and polarization data of the Raman lines support these assignments. The assignments in the 720—350 cm^{-1} region agree precisely with those assignments which have been made by comparing the infrared spectra of several related substances.[2]

Onishi showed that, for $Al_2(CH_3)_6$ and $Al_2(CH_3)_4Cl_2$, CH_3 symmetric deformation bands appear near 1200 cm^{-1} and that CH_3 rocking bands appear near 700 cm^{-1};[3] in accordance with these assignments, the bands near 1185 cm^{-1} and 710 cm^{-1} of $Al(CH_3)_3 \cdot (CH_3)_2O$ may be assigned to the CH_3 symmetric deformation ($AlCH_3$), superposed by CH_3 rocking (OCH_3), and to the AlC_3 degenerate stretching (A''), superposed by CH_3 rocking ($AlCH_3$), respectively.

As is shown in Table IV, $Al(CH_3)_3 \cdot (CH_3)_2O$ has seven to eight infrared bands and Raman lines in the 3100—2700 cm^{-1} region. These are very likely to be CH_3 degenerate stretchings, CH_3 symmetric stretchings, and overtones of CH_3 deformations of the $Al(CH_3)_3$ part and the $(CH_3)_2O$ part. The six Raman lines of $Al(CH_3)_3 \cdot (CD_3)_2O$ in the 2300—2000 cm^{-1} region are mainly due to

CD stretchings of the $(CD_3)_2O$ part (Fig. 1a). The infrared and Raman spectra of $(CD_3)_2O$ and their assignments have been reported by Kanazawa and Nukada.[4] They assigned the Raman lines at 2230, 2202, and 2185 cm^{-1} to CD asymmetric stretchings; a strongly polarized line of a medium intensity at 2137 cm^{-1} to an overtone or to a combination of CD_3 deformation vibrations, and a strongly polarized line of a very strong intensity at 2053 cm^{-1}, to CD_3 symmetric stretching. By taking their assignments into consideration, four principal Raman lines of $Al(CH_3)_3\cdot(CD_3)_2O$ in the 2300—2000 cm^{-1} region may be assigned as is shown in Table IV. This assignment explains the intensity and polarization data satisfactorily. The 2175 cm^{-1} line (CH_3 degenerate stretching) is polarized; this may be due to the possible superposition of one of the overtones of the CD_3 deformations. Four lines, those at 3035, 2989, 2957, and 2842 cm^{-1}, of the eight Raman lines of $Al(CH_3)_3\cdot(CH_3)_2O$ in the 3100—2700 cm^{-1} region disappear in the spectrum of $Al(CH_3)_3\cdot(CD_3)_2O$. These four lines are evidently due to CH stretchings of the $(CH_3)_2O$ part. The remaining four lines, those at 2926, 2887, 2820, and 2787 cm^{-1}, which exist also in $Al(CH_3)_3\cdot(CD_3)_2O$, are due to CH stretchings of the $Al(CH_3)_3$ part. The 2926, 2887, and 2820 cm^{-1} lines are assigned to CH_3 degenerate stretching, CH_3 symmetric stretching, and an overtone of CH_3 deformation of the $Al(CH_3)_3$ part respectively. These considerations lead to the assignments in the 3100—2700 cm^{-1} region given in Table IV.

$[Al(CH_3)_2OCH_3]_3$.—Table II shows the expected types of skeletal vibrational modes and the number of skeletal vibrations in each species. The assignments in the skeletal vibration region (720—130 cm^{-1}) may be made tentatively as in Table V. The selection rule, the infrared and Raman intensities and the Raman polarization data support these assignments. The same consideration as in the case of $Al(CH_3)_3\cdot(CH_3)_2O$ leads to the identification of the bands near 1200 cm^{-1} and 686 cm^{-1} of $[Al(CH_3)_2OCH_3]_3$ as a CH_3 symmetric deformation ($AlCH_3$), superposed by CH_3 rocking (OCH_3) and an AlC_2 symmetric stretching (E'), superposed by CH_3 rocking ($AlCH_3$), respectively.

The infrared and Raman spectra of $[Al(CH_3)_2OCH_3]_3$ and $[Al(CH_3)_2OCD_3]_3$ in the 3100—2700 cm^{-1} region are quite similar to the spectra of $Al(CH_3)_3\cdot(CH_3)_2O$ and $Al(CH_3)_3\cdot(CD_3)_2O$ discussed above (Fig. 1b). Analogous considerations lead to the assignments in the 3100—2700 cm^{-1}

region described in Table V.

$[Al(C_2H_5)_2OCH_3]_3$.—In Table II the expected types of skeletal vibrational modes and the number of skeletal vibrations in each species are shown. The tentative assignments in the skeletal vibration region (720—130 cm^{-1}) are shown in Table VI. The selection rule, the infrared and Raman intensities and the Raman polarization data support these assignments. Although no deuterated compound such as $[Al(C_2H_5)_2OCD_3]_3$ has been studied, the assignment in the 3100—2700 cm^{-1} region may be made with certainty by taking the assignments of $[Al(CH_3)_2OCH_3]_3$ and $[Al(C_2H_5)_2OC_2H_5]_2$ (discussed below) into consideration (Table VI).

$[Al(C_2H_5)_2OC_2H_5]_2$.—In Table III the expected types of skeletal vibrational modes and the number of skeletal vibrations in each species are shown. The tentative assignments in the skeletal vibration region (720—130 cm^{-1}) shown in Table VII may be made. In assigning 652, 634, 481, and 462 cm^{-1} vibrations to AlC_2 stretchings B_{1u}, B_{2g}, B_{3u}, and A_g respectively, the assignments made by Onishi and Shimanouchi for $Al_2(C_2H_5)_6$ are taken into consideration (AlC_2 stretchings of $Al_2(C_2H_5)_6$: A_g 564 cm^{-1}, B_{1u} 662 cm^{-1}, B_{2g} 643 cm^{-1}, B_{3u} 546 cm^{-1}).[5] The selection rule, the infrared and Raman intensities and the Raman polarization data support these assignments. Hoffmann showed that, for $Al_2(C_2H_5)_6$, CH_2 rocking bands appear near 626 cm^{-1};[6] in accordance with this assignment, the infrared band at 652 cm^{-1} is assigned to AlC_2 antisymmetric stretching superposed by CH_2 rocking (AlC_2H_5).

As is shown in Table VII, $[Al(C_2H_5)_2OC_2H_5]_2$

5) T. Onishi and T. Shimanouchi, *Spectrochim. Acta*, **20**, 325 (1964).
6) E. G. Hoffmann, *Z. Elektrochem.*, **64**, 616 (1960).

has six infrared bands and Raman lines in the 3100—2700 cm^{-1} region. These are very likely to be CH_3 degenerate stretchings, CH_2 antisymmetric strechings, CH_3 symmetric stretchings, CH_2 symmetric stretchings, and overtones of CH_3 deformations of the $Al(C_2H_5)_2$ part and the OC_2H_5 part. The six Raman lines of $[Al(C_2H_5)_2OC_2D_5]_2$ in the 2300—2000 cm^{-1} region are mainly due to CD stretchings of the OC_2D_5 group (Fig. 1c). These lines may be tentatively assigned as in Table VII. This assignment explains satisfactorily the intensity and polarization data. Only one Raman line at 2974 cm^{-1} among six Raman lines of $[Al(C_2H_5)_2OC_2H_5]_2$ in the 3100—2700 cm^{-1} region disappears in the spectrum of $[Al(C_2H_5)_2OC_2D_5]_2$. Four Raman lines, those at 2936, 2901, 2867, and 2790 cm^{-1}, of $[Al(C_2H_5)_2OC_2D_5]_2$ are assigned to CH_3 degenerate stretching superposed by an overtone of CH_3 deformation, CH_2 antisymmetric stretching, CH_3 symmetric stretching, and CH_2 symmetric stretching of the C_2H_5 group attached to aluminum respectively. This assignment explains satisfactorily the infrared and Raman intensities and polarization data. These consideration lead to the assignments in the 3100—2700 cm^{-1} region given in Table VII.

The Infrared and Raman Spectra of the Trimethylaluminum - Dimethyl Sulfide Complex

By Ryokichi TARAO

Research Center, Chisso Co., Ltd., Kanazawa-ku, Yokohama

(Received January 20, 1966)

The infrared and Raman spectra of a mixture of trimethylaluminum and dimethyl sulfide (molar ratio, 1 : 1) have been measured (IR: 3100—300 cm^{-1}, Raman: 3100—130 cm^{-1}). The spectra obtained are entirely different from the superposition of the spectra of the two components. Tentative assignments for most of the infrared bands and Raman lines have been suggested. The CS stretching vibration lines of dimethyl sulfide shift to frequencies lower by about 5 cm^{-1} when it is mixed with trimethylaluminum. These findings, together with the measurement of the Raman spectrum of the mixture in a 10-volume-percent benzene solution, indicate that the 1 : 1 mixture of trimethylaluminum and dimethyl sulfide forms a pure coordination complex, $Al(CH_3)_3 \cdot (CH_3)_2S$, which does not dissociate into its components appreciably in either the liquid state or the benzene solution.

Dimethyl sulfide forms a coordination complex when mixed with trimethylaluminum. It is known that the Al←S bond in this complex is much weaker than the Al←O bond in the trimethylaluminum - dimethyl ether complex, and that in the vapor phase the trimethylaluminum - dimethyl sulfide complex partially dissociates into trimethylauminum and dimethyl sulfide.[1] To make sure whether, in the liquid state, the mixture of trimethylaluminum and dimethyl sulfide (molar ratio, 1 ; 1) forms a pure coordination complex or whether it contains three chemical species (complex, trimethylaluminum, and dimethyl sulfide) as a result of the partial dissociation, as in the vapor phase, the infrared and Raman spectra of the complex (a 1 : 1 mixture) in the liquid state will be measured. Qualitative polarization data on Raman lines will also be obtained. No infrared or Raman spectrum of any trialkylaluminum - dialkyl sulfide complex has ever been reported, as far as the author is aware.

Experimental

When trimethylaluminum was mixed with dimethyl sulfide in a molar ratio of 1 : 1, considerable heat evolution was observed. Six milliltrters of the mixture was then transferred into a flask, distilled in vacuo into a Raman tube with a volume of 6 ml., and sealed off under reduced pressure. The Raman spectrum was measured in the 3100—130 cm^{-1} region in the liquid state with a Shimadzu GRS Raman spectrophotometer. The polarization data were taken by the use of parallel

and perpendicular Polaroid cylinders placed alternately over the Raman tube. Table I shows the results of these measurements, along with those of trimethylaluminum and dimethyl sulfide. Figure 1 shows the Raman spectrum chart of the trimethylaluminum-dimethyl sulfide complex. The Raman spectrum of the trimethylaluminum - dimethyl sulfide complex was also measured in the 10-volume-percent benzene solution. The infrared spectrum was measured in the 3100—300 cm^{-1} region in the liquid state with a Japan Spectroscopic Co. Model DS-402G infrared spectrophotometer. The procedure described before was used.[2]

Results and Discussion

As is shown in Table I, the Raman spectrum of the trimethylaluminum-dimethyl sulfide complex is quite different from the superposition of the spectra of trimethylaluminum and dimethyl sulfide. Not even very strong Raman lines of these components (592 and 311 cm^{-1} lines of trimethylaluminum, 2980 and 2911 cm^{-1} lines of dimethyl sulfide) can be found in the spectrum of the complex.

The principal infrared bands and Raman lines in the 3100—130 cm^{-1} region are tentatively assigned in Table II, taking the assignment for the trimethylaluminum - dimethyl ether complex[2,3] and Goggin and Woodward's assignment for the $[CH_3\text{-}Hg\text{-}S(CH_3)_2]^+$ ion[4] into consideration. The AlC_3 skeletal vibrations (three AlC_3 stretchings and two AlC_3 deformations) appear at practically the same frequencies, with the same intensities and with the same degree of depolarization (Raman) as in the case of the trimethylaluminum - dimethyl ether complex. Similarly, the CS stretchings, SC_2 scissors, and SC_2 wagging appear at almost the same frequencies as in the case of $[CH_3Hg\text{-}S(CH_3)_2]^+$ ion. Both the CS antisymmetric stretching (742 cm^{-1}) and the CS symmetric stretching vibration line (690 cm^{-1}) of dimethyl sulfide shift to frequencies lower by about 5 cm^{-1} when a complex is formed with trimethylaluminum (Table III). This corresponds closely with the shifts of the CO stretchings of dimethyl ether on forming a complex with trimethylaluminum.[2] The magnitudes of shifts are smaller than in the case of $[CH_3Hg\text{-}S(CH_3)_2]^+$.

The Raman spectrum of the trimethylaluminum - dimethyl sulfide complex in the 10-volume-percent benzene solution is merely a superposition of the spectrum of the complex and that of benzene. No line except for the lines of the complex and benzene is found. The positive evidence for the existence of an equilibrium formulated as follows:

$$Al(CH_3)_3 \cdot (CH_3)_2S \rightleftarrows 1/2\ Al_2(CH_3)_6 + (CH_3)_2S,$$

which exists in the vapor phase, is not found in either the liquid state or the benzene solution.

These findings suggest that the 1 : 1 mixture of trimethylaluminum and dimethyl sulfide forms a pure coordination complex, $Al(CH_3)_3 \cdot (CH_3)_2S$, which does not dissociate appreciably into its components in either the liquid state or the benzene solution. It is reasonable to assume that the complex takes a structure similar to that of trimethylaluminum - dimethyl ether complex, in which an unshared pair of electrons of the sulfur atom coordinates to the aluminum atom.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2135—2140 (1966)

The Exchange Reaction of Oxygen Atoms between Oxygen and Carbon Dioxide on Metal Oxides of the Fourth Period of the Periodic System*

By Tadamitsu KIYOURA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received January 24, 1966)

The exchange reactions of oxygen atoms between oxygen and carbon dioxide on metal oxides were studied by the static batch method in the temperature range from 150 to 600°C. The order of the catalytic activity of the oxides in the reaction was found to be; (higher activity) $Co_3O_4 > MnO_2 > NiO > Fe_2O_3 > Cr_2O_3 > V_2O_5 > TiO_2$. A very close similarity of the change in the reactivity of these oxides was found in the exchange between oxygen and oxides. There is an approximately linear relationship between the catalyst activity of the metal oxides and the heat of the formation of these oxides. At any temperature examined, carbon dioxide exchanged their oxygen atoms with those of oxide rapidly. The rate of isotopic exchange decreased in the following order on any oxide examined: CO_2-Oxide > O_2-Oxide > O_2-CO_2 on oxide. The exchange between oxygen and carbon dioxide was observed only when the exchange between oxygen and oxide took place. According to these results, it was concluded that the exchange between oxygen and carbon dioxide takes place through the exchange between these gases and oxygen atoms of oxide, and that the rate-determining step is the exchange with oxygen.

About twenty-five years ago Titani and his collaborators[1-3] investigated the isotopic oxygen exchange reaction between oxygen and water vapor on various kinds of metal oxides. They found that there is a regular relationship between the catalyst activity of the metal oxide and the position where the metal element is placed in the periodic system. From group to group, there is a progressive shift of the catalyst activity. For instance, in the case of the fourth-period elements, titanium oxide (the fourth group) has the lowest activity, and manganese oxide (the seventh group) has the highest activity, with the catalyst activity of the other fourth-period elements arranged in good order between these two elements. Recently Boreskov et al.[4,5] studied the homomolecular oxygen exchange reaction on metal oxides of the fourth-period elements, and discussed the relations between the catalyst activity and the physical and chemical properties of the oxides. However, to the author's knowledge, no systematic investigation has been made into the exchange reaction between oxygen and carbon dioxide on metal oxides. The present author has, therefore, investigated the exchange reaction between oxygen and carbon dioxide on metal oxides of the fourth period of the periodic system, hoping thereby to give an order of the catalyst activity of the oxides and a general picture of the reaction. In the isotopic exchange reaction $\Delta H \fallingdotseq 0$, so the influence of the heat of reaction can be ignored in the comparison of the catalyst activity. It is of interest to study the possible relations between the exchange reaction and the other oxidation reactions on an oxide catalyst. In the exchange reaction between oxygen and carbon dioxide on metal oxides, it may be expected that the catalyst activity of the metal oxides will show the same regular relations as that reported by Titani and his collaborators[1-3] and by Boreskov et al.[4,5] However, such a conclusion could hardly be regarded as certain before experiments have been performed to test this point. The results of the present experiment show that, in the exchange between oxygen and carbon dioxide, there is a regular relation in the catalyst activity of the metal oxides. In the investigation of the oxygen exchange reaction on an oxide catalyst, the measurement of the oxygen exchange between a reactant and an oxide catalyst provides a strong clue to the mechanism of the reaction; therefore, the exchange between oxygen and oxides, and that between carbon dioxide and oxides were studied in the initial step.

Experimental

Gases.—Heavy oxygen, $O^{18}O$, was prepared in our laboratory by the thermal diffusion method;[6] its concentration was 1.81 atom%. Carbon dioxide labeled with ^{18}O (1.79 atom%) was prepared by equilibrating samples of water enriched with ^{18}O

with tank carbon dioxide of a natural isotopic composition prepurified by pumping off the vapors not condensable at the temperature of liquid nitrogen. All the gases used were dried through a train of traps immersed in solid carbon dioxide. A search for impurities in the gases after purification was made by a mass spectrometer up to mass 100; it was found that they were mass-spectrometrically pure, except for traces of other inert gases.

Oxide Catalysts.—The methods of preparation and the specific surface area of the oxides are shown in Table I, together with the amount of the oxides used for the reaction.

For the purpose of comparing the catalyst activity of these oxides, the following precaution was taken, The amount of oxide used for the reaction was adjusted in order to give a fixed total surface area for the different oxides; therefore, the total surface area of a single portion of each oxide used for the reaction was about 3 m^2 except in the case of vanadium pentoxide.

Procedure.—The reaction was carried out by the static batch method. The reaction vessel was made of pyrex or of fused silica glass. In order to maintain a constant pressure of the gas at each reaction temperature (14 cmHg for CO_2–Oxide, and O_2–Oxide; 27 cmHg for O_2–CO_2 on oxide), reaction vessels of different volumes were chosen for the different reaction temperatures. A single portion of each oxide used for the reaction is listed in the last column of Table I. For the exchange between carbon dioxide and oxides or that between oxygen and oxides, a weighed amount of oxide was placed in the reaction vessel and then outgassed at 550°C for 3 hr., using a mercury diffusion pump, through a liquid nitrogen trap. (Manganese dioxide was, however, outgassed at 200°C for 1 hr.) Then the temperature of the reaction vessel was adjusted to the desired temperature, and 1.8 ml. (NTP) of the enriched carbon dioxide or heavy oxygen was introduced. At desired time intervals, the entire amount of gas was collected and the ^{18}O content of the gas was analyzed by the use of a mass spectrometer. For the exchange between oxygen and carbon dioxide on oxides, a 3.4-ml. portion (NTP) of the gas mixture of heavy oxygen and normal carbon dioxide in a ratio of 1 to 1 was used. The weight of oxides used, the outgassing and the other procedures were the same as those used in investigation of the exchange between gases and oxides.

Results and Discussion

The Isotopic Oxygen Exchange between Gases and the Reaction Vessel, and the Catalytic Action of the Reaction Vessel.—Within the limits of experimental error, the surface of the reaction vessel did not participate in the exchange reaction.

The Exchange between Carbon Dioxide and Metal Oxides in the Absence of Oxygen, and between Oxygen and Metal Oxides in the Absence of Carbon Dioxide.—The exchange reaction between carbon dioxide and oxides proceeded rapidly, and the quantitative measurement of the reaction rate was difficult in the ordinary static method. In any of the oxides examined, carbon dioxide actively exchanged its oxygen atoms with those of oxide, even below the temperature at which no exchange between oxygen and oxides was observed. As an example of the experimental results, the exchange between carbon dioxide and chromic oxide, and that between oxygen and chromic oxide are graphically shown in Fig. 1. From the shapes of the curves shown in Fig. 1, the temperature dependence of the rate of the exchange with carbon dioxide may be seen to be not very appreciable; therefore, the apparent energy of activation can be estimated within a few kcal./mol. Within ten minutes after introduction of the enriched carbon dioxide into the reaction vessel, the ^{18}O content of the carbon dioxide reached a definite value. This value was characteristic of the reaction temperature. At this stage of the reaction, an isotopic equilibrium was established

TiO_2	3.5×10^{-4} (450)	4.8×10^{-4} (500)	6.1×10^{-4} (550)	6.7×10^{-4} (600)	

between the carbon dioxide in the gas phase and a certain part of the oxide. After the fast initial reaction had finished, there was a slow downward drift of the ^{18}O content of the carbon dioxide. From Fig. 1, the definite ^{18}O content may be obtained by the extrapolation of the drift line to time zero. From this quantity, and from the amount of carbon dioxide and chromic oxide used, we calculated the amount of rapidly-exchangeable oxygen of the oxide, n_s (gram atom per gram of oxide). It was assumed that the ^{18}O content of the exchangeable part of the oxide becomes equal to that of the ambient gas. The values of n_s at different temperatures are tabulated in Table II. The n_s values of these oxides are in the order of 10^{-5} g. atom/m^2, and there is not very remarkable difference in these values in each oxide. The density of the oxygen atoms on the surface of the oxides is in the order of 10^{-5} g. atom/m^2; this agrees with the n_r values.

The surface area of these oxides was measured at the beginning and at the end of the reaction; the difference was within 15%.

As is shown in Fig. 1, the exchange with oxygen proceeded more slowly than that with carbon dioxide. The same results were obtained with the other oxides examined. We have calculated F_1, the fractional attainment of the equilibrium of the exchange reaction between oxygen and oxides, from Eq. 1, where $^{18}O_0$, $^{18}O_t$, and $^{18}O_\infty$, are the initial, at time t, and equilibrium ^{18}O contents of the oxygen gas respectively.

$$F_1 = [(^{18}O_0 - {}^{18}O_t)/(^{18}O_0 - {}^{18}O_\infty)]\times 100 \qquad (1)$$

A random distribution of ^{18}O between the oxygen gas and the exchangeable surface oxygen of the oxide being assumed, the value of $^{18}O_\infty$ was calculated through the value of n_s and through the amount of heavy oxygen and the oxide used. The value of $^{18}O_\infty$ is characteristic of the reaction temperature because the value of n_s depends on the temperature. The results obtained with chromic oxide are shown in Table III.

The rate of the exchange, R (g. atom/min.), is expressed by Mckay's equation:

$$R = -2.303[(a\cdot b)/(a+b)] \log (1-F_1/100)/t \qquad (2)$$

where a and b are the amount of heavy oxygen gas used and the amount of exchangeable surface oxygen of the oxide used respectively, where t

is the reaction time, and where F_1 is the fractional attainment of the exchange reaction.

Equation 2 requires a linear relationship between $\log(1-F_1/100)$ and t, which are shown in Fig. 2. The values of R, which are calculated from the slopes of Fig. 2, are shown in Fig. 3, together with those of the other oxides examined. The apparent energies of activation, A, were obtained from the slopes of Fig. 3; they are listed in Table IV.

The values of F_1 at various temperatures, 15 min. after the beginning of the reaction are shown in Fig. 4. From Fig. 4, the reactivity of the oxides was estimated by means of the temperature threshold of the reaction. The order of reactivity of these oxides in relation to the exchange with oxygen is in the following sequence:

(Higher activity) $Co_3O_4 > MnO_2 = NiO > Fe_2O_3 > Cr_2O_3 > V_2O_5 > TiO_2$

As is shown in Fig. 4, the temperature threshold of the reaction is characteristic of each metal oxide. Above this temperature, the chemisorbed state of oxygen is probably in the form of O^-. In the case of exchange reaction between oxygen and zinc oxide,[7] the temperature threshold is about 350°C. Kwan et al.[8] studied the adsorbed state of oxygen on zinc oxide by the ESR method; they reported that at about 370°C the adsorbed state is in the form of O^-.

The Exchange between Oxygen and Carbon Dioxide on Metal Oxides.—As an example, the case of chromic oxide used as a catalyst is shown in Fig. 5 and Table V. The exchange of oxygen occurred at a measureable rate around 400°C. This result is similar to that shown in Fig. 1. The number of ^{18}O that the carbon dioxide had gained was less than that the oxygen had lost. This difference may be ascribed to the

exchange with oxide. We have calculated F_2, the fractional attainment of the equilibrium of the reaction, from Eq. 3, where $CO^{18}O_t$ is the ^{18}O content of the carbon dioxide at time t, where $CO^{18}O_\infty$ is the ^{18}O content of the carbon dioxide when the reaction attains equilibrium, and where the numerical constant, 0.204, is the natural abundance of ^{18}O.

$$F_2=[(CO^{18}O_t-0.204)/(CO^{18}O_\infty-0.204)]\times 100 \quad (3)$$

A random distribution of ^{18}O among the oxygen, the carbon dioxide, and the exchangeable surface oxygen of the metal oxide being assumed, the value of $CO^{18}O_\infty$ was calculated using the amounts of the gases and the oxide used. The values of F_2 at different temperatures, 15 min. after the beginning of the reaction are shown in Fig. 4, together with those of the other oxides examined.

Using the results shown in Fig. 4, $\log[-\log(1-F_2/100)]$ was plotted against $1/T$. As is shown in Fig. 6, the plots give straight lines. The apparent energies of activation, obtained from the slopes of Fig. 6, are listed in Table VI. These values are very similar to those shown in Table IV.

For a measure of the catalytic activity of the oxides, the temperature threshold for the reaction was chosen. From Fig. 4, the temperatures

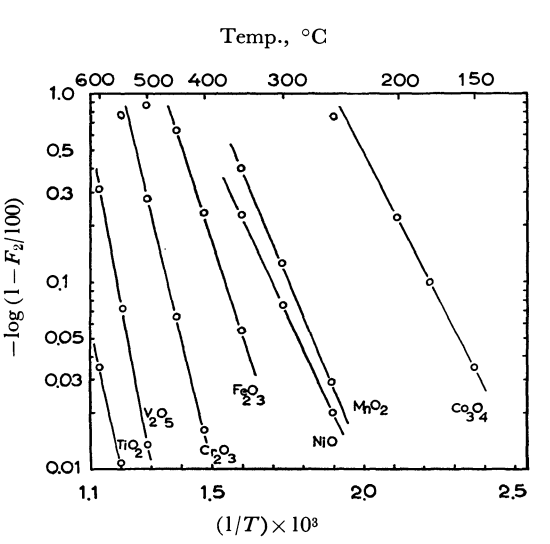

Fig. 6. Temperature dependence of $\log[-\log(1-F_2/100)]$.

at which the F_1 and F_2 reached 10% for the respective oxide, $t(10\%)$°C, may be obtained; these temperatures are summarized in Table VII. From Fig. 4 and Table VII, the order of the catalytic activity of these oxides in the reaction is found to be:

(Higher activity) $Co_3O_4>MnO_2>NiO>Fe_2O_3>Cr_2O_3>V_2O_5>TiO_2$

This is very close to the experimental results of the exchange between oxygen and oxide.

The following questions have been raised concerning the reaction mechanism:

(a) Does the reaction proceed through the interaction of the chemisorbed oxygen and the chemisorbed carbon dioxide?

(b) Does the reaction proceed through the exchange between these gases and the oxygen atoms of metal oxide ?

(c) Does the reaction proceed through both mechanisms a and b ?

As is shown in Table VII, the $t(10\%)$°C value was similar in both reactions, and the exchange between oxygen and carbon dioxide was observed only when the exchange between oxygen and oxide took place. The rate of the isotopic exchange

TABLE VI. THE APPARENT ENERGY OF ACTIVATION OF THE EXCHANGE BETWEEN $O^{18}O$ AND CO_2 ON VARIOUS OXIDES

Oxide catalyst	TiO_2	Cr_2O_3	Fe_2O_3	V_2O_5	Co_3O_4	NiO	MnO_2
A, kcal./mol.	41	30	24	41	15	15	17

TABLE VII. THE $t(10\%)$°C VALUES OF VARIOUS OXIDES

Oxide	TiO_2	V_2O_5	Cr_2O_3	Fe_2O_3	MnO_2	NiO	Co_3O_4
$t(10\%)$°C of F_1	605	530	440	345	260	260	150
$t(10\%)$°C of F_2	610	535	440	350	265	280	155

decreased in the following order on all the oxides examined:

$$CO_2\text{-Oxide} > O_2\text{-Oxide} \geq O_2\text{-}CO_2$$

Moreover, the apparent energies of activation, shown in Tables IV and VI, are similar in the two reactions. According to these results, it is natural to think, that the reaction proceeds through the b mechanism; that is, the reaction consists of two consecutive and simultaneous reactions, 4 and 5, with Reaction 5 being far more rapid than Reaction 4, where MO represents metal oxide.

$$O^{18}O + MO = O_2 + M^{18}O \quad (4)$$

$$CO_2 + M^{18}O = CO^{18}O + MO \quad (5)$$

The c mechanism was excluded, because $\log[-\log(1-F_2/100)]$ against $1/T$ gives straight lines over an appreciable wide range of reaction temperature (Fig. 6).

The catalytic activity of the oxides with respect to the exchange between oxygen and water vapor[1-3] is in the following sequence:

(Higher activity) $MnO_2 > Fe_2O_3 > Cr_2O_3 > NiO > V_2O_5 > TiO_2$

This is similar to the exchange between oxygen and carbon dioxide, with the exception of nickel oxide. A similar change in the catalyst activity of the oxides with respect to the homomolecular oxygen exchange,[4,5] the oxidation of hydrogen,[9] the oxidation of carbon monoxide,[10,11] and the oxidation of hydrocarbon[12] has been reported. The concept that the catalyst activity of the oxide is related to the heat of formation of the corresponding oxide was recently advanced by Tamaru[13] and by Kwan and his collaborators[14]. We also attempted to plot the $t(10\%)$°C (the measure of the catalyst activity) against the heat of formation of these oxides. The plots thus obtained are shown in Fig. 7. As this figure shows, there is an approximately linear relationship between the catalyst activity of the oxides and the heat of formation of these oxides. In other words, the weaker the oxygen bond of the metal oxide, the faster the rate of oxygen exchange reaction.

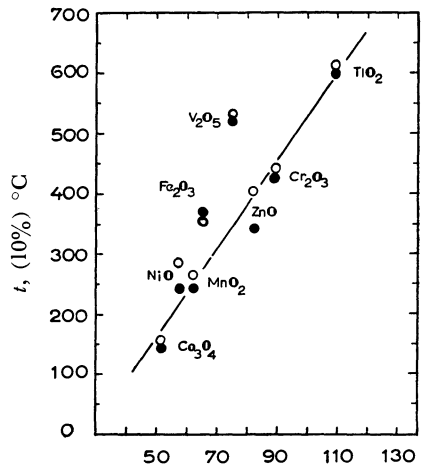

Fig. 7. The relation between the catalytic activity of metal oxides and the heat of formation of metal oxides.

Studies of the Alkaline Earth Complexes in Various Solutions. I. Barium(II) Complexes with Sulfate and Oxalate Ions in 1M Sodium Perchlorate Media

By Tatsuya SEKINE, Mitsuo SAKAIRI and Yuko HASEGAWA

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received January 25, 1966)

The distribution of barium(II) at a very low concentration was determined between a carbon tetrachloride solution of 0.1 M thenoyltrifluoroacetone and 0.2 M tributylphosphate and aqueous solutions of 1 M $Na(ClO_4)$ at 25°C. The net distribution ratio is decreased when a part of the perchlorate ions are replaced by sulfate or oxalate ions. This decrease was explained in terms of the complex formation of Ba^{2+} with these ligands. The stability constants were determined graphically from the experimental data as follows:

Ligand	$\log \beta_1$	$\log \beta_2$
SO_4^{2-}	0.66	1.42
$C_2O_4^{2-}$	0.58	2.20

(1 M $Na(ClO_4)$, 25°C)

The solubility of barium sulfate and oxalate has been reported by many authors, but the complex formation of barium ion with these anions in an aqueous solution has not been studied very much.[1] This may be due to the fact that the concentration of barium ions in sulfate or oxalate solutions is too low to be studied by such methods as the e.m.f. measurement, conductometry and spectropothometry.

In the present work, the authors studied the complex formation of barium with sulfate and oxalate ions in sodium perchlorate media at 25°C. A carrier-free radioactive barium-140 tracer was used to keep the barium concentration very low in order to prevent the formation of precipitates. The decrease in the free barium ion concentration in the aqueous phase caused by the complex formation was determined by a solvent extraction technique recently developed in our laboratory.[2] The stability constants were determined by a graphical method from the distribution data.

Experimental

Tracer.—Barium-140 was obtained from the Radiochemical Center, Amersham, England. It was diluted with a mixture of 0.1 M perchloric acid and 0.9 M sodium perchlorate.

Reagents.—All of the reagents used were of analytical grade. Thenoyltrifluoroacetone (TTA) was obtained from the Dojin Yakukagaku Co. Tributylphosphate (TBP) was obtained from the Tokyo Kasei Co. The TBP was washed with 0.1 M perchloric acid, water, 0.1 M sodium hydroxide, and several times with water respectively, and was finally equilibrated with a 1.0 M sodium perchlorate solution. Sodium perchlorate was prepared from sodium carbonate and perchloric acid and was recrystallized two times from water. The concentration of the stock sodium sulfate solution was determined from the weight of the residue left after a portion of the solution had been dried up in an air bath at 120°C. The stock sodium oxalate solution in 1 M $Na(ClO_4)$ was prepared by dissolving a weighed portion of sodium oxalate crystals in a sodium perchlorate solution.

Procedures.—All of the procedures were carried out in a thermostatted room at 25°C. Stoppered glass tubes (volume: 20 ml.) were used to equilibrate the organic and the aqueous phases. The tracer solution, various amounts of a sodium sulfate or sodium oxalate solution, a buffer solution, a sodium perchlorate solution and the organic solution were placed in the tubes. The aqueous phase was maintained at 1.0 M $Na(ClO_4)$; the aqueous phase always contained 1.0 M sodium ions and various amounts of sulfate or oxalate ions, together with perchlorate ions. A small amount of triethanolamine or sodium acetate (the initial concentration was 0.01 M) was added to the aqueous phase to buffer the hydrogen ion concentration. The organic phase was a mixture of 0.1 M TTA and 0.2 M TBP in carbon tetrachloride. The initial volume of the two phases was always 5.0 ml.

The two phases in the tubes were vigorously agitated by a mechanical shaker for fifteen minutes and then centrifuged for three minutes at 2000 r. p. m. A 2.0-ml. portion was pipetted from the two phases and transferred into small, stoppered glass test tubes for the measurement of the γ-radioactivity. Another portion of the aqueous phase was transferred into small glass vessels, and the hydrogen ion concentration was determined

potentiometrically using 0.0100 M $HClO_4$ + 0.99 M $NaClO_4$, as the standard of $-\log[H^+] = 2.00$. The solutions in the small glass test tubes were let stand for more than seventeen days, until the decay equilibrium was reached between barium-140 (the half life is 12.80 days) and lanthanum-140 (the half life is 40.22 hr.); the γ-radioactivity was then measured with a well-type (NaI) scintillation counter.

Statistical Treatment

The nth step of the complex formation of a dipositive metal ion, M^{2+}, with a dinegative ligand ion, L^{2-}, may be described as:

$$M^{2+} + nL^{2-} \rightleftarrows ML_n^{2-2n} \quad (1)$$

$$\beta_n = [ML_n^{2-2n}]/[M^{2+}][L^{2-}]^n \quad (2)$$

The distribution of this metal ion between an organic phase with an organophilic chelating acid, HA, and an aqueous phase with no complex-forming ligands may be described as:

$$M^{2+} + 2HA(org) \rightleftarrows MA_2(org) + 2H^+ \quad (3)$$

$$K = [MA_2]_{org}[H^+]^2/[M^{2+}][HA]_{org}^2 \quad (4)$$

Here the subscript "*org*" denotes a chemical species in the organic phase.

The net distribution ratio of the metal ion between the organic and the aqueous phase may be defined as:

$$D = [M(II)]_{org,\ total}/[M(II)]_{total} \quad (5)$$

The extraction constant may be defined as:

$$K_{ex} = D[H^+]^2[HA]_{org}^{-2}$$

When there is no complex-forming ligand in the aqeuous phase, the distribution ratio of the metal ion may be described as:

$$D_0 = [MA_2]_{org}/[M^{2+}] \quad (7)$$

The extraction constant is then:

$$K_{ex_0} = ([MA_2]_{org}/[M^{2+}])[H^+]^2[HA]_{org}^{-2} \quad (8)$$

Here the subscript "0" denotes a system where the ligands, L^{2-}, are absent in the aqueous phase. We see that the K_{ex_0} in Eq. 8 equals the K in Eq. 4; therefore, K_{ex_0} should give a constant value at a certain temperature.

When there is the complex-forming ligand in the aqueous phase at a certain concentration $[L^{2-}]$, the distribution ratio may be described from Eqs. 2 and 5 as:

$$D = [MA_2]_{org}/([M^{2+}]+[ML]+[ML_2^{2-}]+\cdots)$$

$$= ([MA_2]_{org}/[M^{2+}])(1+\sum_1^n \beta_n[L^{2-}]^n)^{-1} \quad (9)$$

The extraction constant is then:

$$K_{ex} = ([MA_2]_{org}/[M^{2+}])[H^+]^2[HA]_{org}^{-2} \times (1 + \sum_1^n \beta_n[L^{2-}]^n)^{-1} \quad (10)$$

By dividing Eq. 10 by Eq. 8, we obtain the following equation:

$$\frac{K_{ex}}{K_{ex_0}} = (1 + \sum_1^n \beta_n[L^{2-}]^n)^{-1} \quad (11)$$

Thus we may determine the stability constants, β_n, from Eq. 11.

When an organophilic neutral ligand, N, is added to the organic phase and the metal chelate forms adducts with N, the equilibrium may be described as:

$$MA_2(org) + lN(org) \rightleftarrows MA_2N_l(org) \quad (12)$$

$$\beta_{a,l} = [MA_2N_l]_{org}/[MA_2]_{org}[N]_{org}^l \quad (13)$$

When there is no complex-forming ligand, L^{2-}, in the aqueous phase and when there is an adduct-forming ligand in the organic phase at a constant concentration, $[N]_{c,\ org}$, the distribution ratio and the extraction constant are:

$$D = ([MA_2]_{org} + [MA_2N]_{org} + [MA_2N_2]_{org} + \cdots)/[M^{2+}]$$

$$= ([MA_2]_{org}/[M^{2+}]) \times (1 + \sum_1^l \beta_{a,l}[N]_{c,org}^l) \quad (14)$$

$$K_{ex_0} = ([MA_2]_{org}/[M^{2+}])[H^+]^2[HA]_{org}^{-2} \times (1 + \sum_1^l \beta_{a,l}[N]_{c,org}^l) \quad (15)$$

The extraction constant in Eq. 15 is $1+\sum_1^l \beta_{a,l}[N]_{c,org}^l$ times the constant in Eq. 8, but the former should also give a constant value at a certain temperature as long as the concentration of N is kept constant.

When there is a complex-forming ligand in the aqeuous phase at a concentration, $[L^{2-}]$, we may introduce the following equation by the same procedure;

$$K_{ex} = ([MA_2]_{org}/[M^{2+}])[H^+]^2[HA]_{org}^{-2} \times (1 + \sum_1^l \beta_{a,l}[N]_{c,org}^l) \times (1 + \sum_1^n \beta_n[L^{2-}]^n)^{-1} \quad (16)$$

From Eqs. 15 and 16 we may also see that Eq. 11 is valid even in a solvent extraction system where the distribution ratio is enhanced by the adduct formation (synergism).

The stability constants can be determined from the distribution data by a curve-fitting method[3-5] using Eq. 11.

It may be possible to discuss the problem more

3) L. G. Sillén, *Acta Chem. Scand.*, **10**, 186 (1956).
4) F. Rossotti and H. Rossotti, "The Determination of Stability Constants," McGraw-Hill Book Co., New York (1961).
5) T. Sekine and Y. Hasegawa, This Bulletin **39**, 240 (1966).

generally, but here we assume that only the first and the second complexes, ML and ML_2^{2-}, are formed in the aqueous solution.

When we replace K_{ex}/K_{ex_0}, $\beta_2^{1/2}[L^-]$ and $\beta_1\beta_2^{-1/2}$ with y, a and R respectively, we obtain the following equation instead of Eq. 11:

$$y = (1 + Ra + a^2)^{-1} \quad (17)$$

By introducing various values into R in Eq. 17, a family of standard curves represented by the following equations are obtained:

$$\begin{aligned} Y &= \log y = -\log(1 + Ra + a^2) \\ X &= \log a \end{aligned} \quad (18)$$

One of these curves will be found to fit the plot of the experimental data, $\log(K_{ex}/K_{ex_0})$ vs. $\log[L^{2-}]$. Since $\log a$ equals $^1/_2\log\beta_2+\log[L^{2-}]$, the value of $\log\beta_2$ can be obtained from the position of the experimental plot, $\log(K_{ex}/K_{ex_0})$ vs. $\log[L^{2-}]$, on the $\log a$ axis, and R equals $\beta_1\beta_2^{-1/2}$; that is, $\log\beta_1$ equals $\log R+^1/_2\log\beta_2$, then the β_1 value can be calculated from the values R and β_2.

Results

Perchlorate System.—It was concluded from another study[6] that the main barium complex species in a carbon tetrachloride solution of 0.1 M TTA (HA) and various amounts of TBP (L) is BaA_2L_2 in the higher TBP-concentration region. Therefore, the distribution equilibrium can be written as:

$$Ba^{2+} + 2HA(org) + 2L(org) \rightleftarrows BaA_2L_2(org) + 2H^+$$

Figure 1 gives the dependence of the distribution ratio of barium ions on the hydrogen ion concentration when the organic phase is a carbon tetrachloride solution of 0.1 M TTA and 0.2M TBP and when the aqueous phase is 1.0 M sodium perchlorate.

The plot falls on a straight line with a +2 slope, and the extraction constant calculated from the nineteen points in Fig. 1 is:

$$\log D_0[H^+]^2[HA]_{org}^{-2} = -10.01$$

These results seem to show that: (i) there is no complex formation of barium with TTA in the aqueous phase, and (ii) there is no extraction of barium complexes with perchlorate ions into the organic phase.

Thus we may conclude that the K_{ex_0} value obtained from these results can be used for the calculation of the stability constants by means of Eq. 11 (cf. Ref. 7).

Sulfate System.—The distribution ratio of barium(II) is decreased by the addition of sodium sulfate to the aqueous phase. Figure 2 gives the decrease in the extraction constant as a function of $\log[SO_4^{2-}]$. In these experiments the analytical concentration of sodium sulfate in the aqueous phase can be regarded as the concentration of sulfate ions, $[SO_4^{2-}]$, because the $-\log[H^+]$ was kept between 6.4 and 6.6 and the pK_a value of sulfuric acid in 1 M $Na(ClO_4)$ at 25°C is 1.02.[8]

The plot was found to fit a standard curve, $Y=-\log(1+0.9a+a^2)$, $X=\log a$. This indicates that

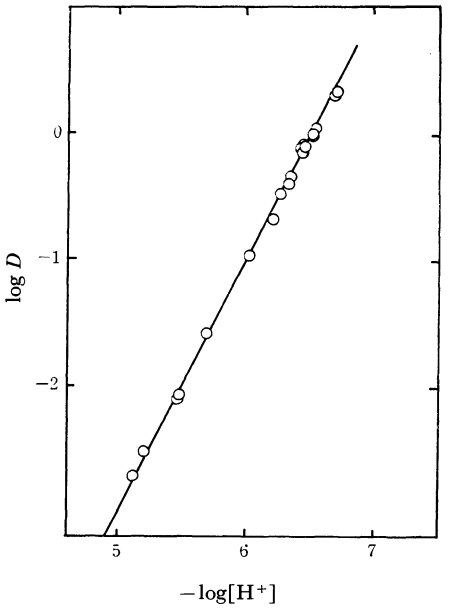

Fig. 1. Distribution ratio of barium(II) between 0.1 M TTA + 0.2 M TBP - carbon tetrachloride and 1.0 M $NaClO_4$, at 25°C. The straight line gives $\log D=-2\log[H^+]-12.01$. The extraction constant;
$\log K_{ex_0}=D[H^+]^2[HA]_{org}^{-2}=-10.01$

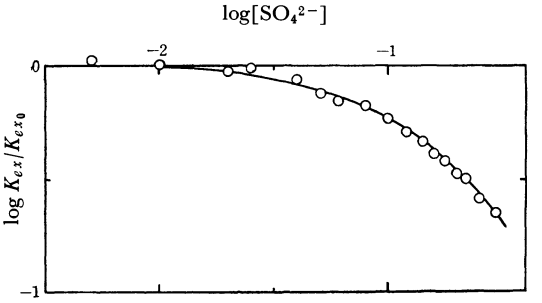

Fig. 2. Decrease in the extraction constant of barium(II) as a function of sulfate ion concentration. The solid curve was calculated by the following equation.
$Y=-\log(1+4.60[SO_4^{2-}]+26.3[SO_4^{2-}]^2)$;
$X=\log[SO_4^{2-}]$

both the $BaSO_4$ and $Ba(SO_4)_2^{2-}$ complexes are formed. The stability constants finally determined are given in Table I.

TABLE I. STABILITY CONSTANTS OF BARIUM(II) COMPLEXES IN 1 M $Na(ClO_4)$ AT 25°C

$\beta_n=[BaL_n^{2-2n}]/[Ba^{2+}][L^{2-}]^n$

Ligand	$\log \beta_1$	$\log \beta_2$
SO_4^{2-}	0.66	1.42
$C_2O_4^{2-}$	0.58	2.20

Oxalate System.—The distribution ratio of barium(II) is also decreased by the addition of sodium oxalate to the aqueous phase. Figure 3 gives the decrease in the extraction constant as a function of $\log[C_2O_4^{2-}]$. In these experiments, the analytical concentration of sodium oxalate in the aqueous phase can be regarded as the concentration of oxalate ions, $[C_2O_4^{2-}]$, because the $-\log[H^+]$ value was kept between 6.4 and 6.6 and because the pK_{a_2} value of oxalic acid in 1 M $Na(ClO_4)$ at 25°C is 3.54.[9] It was not possible to obtain a higher oxalate concentration, because the solubility of sodium oxalate in 1 M sodium perchlorate is not large.

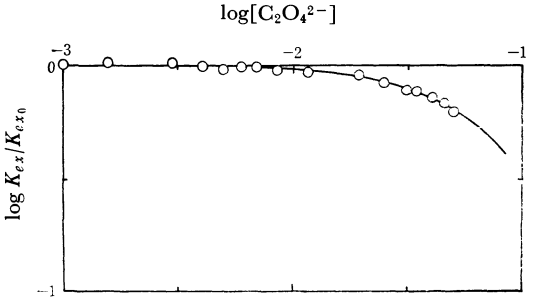

Fig. 3. Decrease in the extraction constant of barium(II) as a function of oxalate ion concentration. The solid curve was calculated by the following equation.
$Y=-\log(1+3.80[C_2O_4^{2-}]+159[C_2O_4^{2-}]^2)$;
$X=\log[C_2O_4^{2-}]$

The plot was found to fit a standard curve, $Y=-\log(1+0.3a+a^2)$, $X=\log a$. This indicates that both BaC_2O_4 and $Ba(C_2O_4)_2^{2-}$ complexes are formed. The stability constants finally determined are given in Table I.

Discussion

The solubility of barium sulfate and oxalate is very small. The previous data on the solubility products in dilute ionic media were around 10^{-10} for barium sulfate and around 10^{-8} for barium oxalate.[1,10]

Money and Davies[11] gave a stability constant for the barium oxalate complex at an infinite dilution at 18°C as $[BaC_2O_4]/[Ba^{2+}][C_2O_4^{2-}]=$ca. $10^{2.31}$, but this data canhot be compared directly with the present results because the concentrations of the electrolytes in the solutions are different. No data seem to have been presented on the stability of barium sulfate complexes.

In the present study, carrier-free barium-140 was always employed as the tracer, and the concentration of barium(II) was calculated to be less than 10^{-12} M if the barium impurity in the solution was neglected. It is difficult to estimate the amount of non-radioactive barium impurities in the system. However, we may conclude that the coprecipitation of the radioactive barium with the non-radioactive barium impurities in the system is negligible, because the recovery of the radioactivity from the two phases was always quantitative and the results in Figs. 2 and 3 are reproducible and reasonable.

The results in the table indicate that the stabilities of the barium complexes with these anions are much smaller than those of lanthanide and actinide complexes.[9,12] This seems to agree with the fact that the solubilities of barium sulfate and oxalate are not very much increased by an excess of these anions in aqueous solutions.

The authors are very grateful to Dr. Yukio Murakami of the Japan Atomic Research Institute for the offer of some materials. They are also grateful to Mr. Satoru Obuchi of the present laboratory for his experimental aid. This research was partly supported by the Matsunaga Science Foundation.

Physical Chemistry of Binary Plastic Crystals. I. The System of Carbon Tetrachloride and *t*-Butyl Iodide*

By Hideaki CHIHARA, Masako OTSURU** and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received February 18, 1966)

The binary system, carbon tetrachloride-*t*-butyl iodide, was studied by the proton magnetic resonance, the dielectric measurements and the X-ray diffraction. The complete phase diagram, constructed by the differential thermal analysis, shows a solid solution region where carbon tetrachloride is more than 50 mole%. Detailed studies of the solid solution containing 6.6 mole% of *t*-butyl iodide reveals that the solution can be described by the theory of regular solutions; its molecular polarization above the transition temperature obeys the Debye formula giving the dipole moment of *t*-butyl iodide a value of 1.6 debye units. The high-resolution nuclear magnetic resonance experiments with the same phase shows that carbon tetrachloride molecules diffuse in the solid solution with an energy of activation of 6.8 kcal./mole. The transition temperature varies with the composition, and below it the rotational motion of the solute molecules is more hindered. Pure *t*-butyl iodide shows motional narrowing around −150°C in the NMR line shape, above which temperature a reorienting molecular model can account for the magnitude of second moment of the nuclear magnetic resonance absorption.

Plastic crystals[1] are a class of molecular crystals which show enhanced plasticity in a temperature region below the melting point. Except in the case of inert monatomic crystals, they undergo one or more phase transitions accompanied with a large increase in entropy, due primarily to the acquisition of the molecular rotational or orientational degrees of freedom.

Thus, carbon tetrachloride is one of typical plastic crystals, having a phase transition at −47.7°C (225.5°K) with the entropy of transition, 4.86 cal./deg. mole. In its plastic phase between −47.7° and −22.9°C (m. p.), the molecules in solid carbon tetrachloride are in the state of hindered rotation, its potential barrier being estimated to be 2.4 kcal./mole.[2] The crystal structure in this plastic phase is that of face-centered cubic.[3]

If a compound having a permanent dipole moment is dissolved in a matrix of carbon tetrachloride and if they form a plastic solid solution, there will be a possibility of obtaining some information about the crystal field in the matrix compound by dielectric measurements. In the present study, *t*-butyl iodide was chosen as such a solute in the hope that one might get at an anomalous dispersion in a convenient radio-frequency region. The result turned out not to be the case, but instead, the plastic phase was found to be close to an ideal liquid solution and to be described by the theory of regular solutions. Some results obtained by proton magnetic resonance techniques will also be reported.

Similar studies have been described for the systems, CCl_4–$C(CH_3)_4$[4] and CCl_4–$C(CH_3)_3Cl$[5-7].

Experimental

Meterials.—Commercial special grade carbon tetrachloride was distilled after drying over calcium chloride; m. p. −22.9°C. The *t*-butyl iodide prepared by the method of Stone and Schechter[8] was purified through fractional distillation under reduced pressure and further under vacuum over mercury to minimize decomposition: Semi-microanalysis gave C, 26.21%; H, 4.94%; I, 68.63% (calcd. C, 26.10; H, 4.93; I, 68.97 %), a purity of some 99.5%; n_D^{20} 1.4920 (literature value 1.4890) and m. p. −37.0°C. NMR spectrum and gas chromatography detected no impurities. The X-ray powder diffraction spacings taken at −78°C are given in Table I.

Equipments.—The high-resolution NMR spectra were recorded on a Varian A-60 analytical spectrometer combined with an attachment for temperature variation.

The broad-line NMR spectra were obtained with a Robinson-type autodyne oscillator-detector operated at about 20 Mc./s. The temperature of the specimen was

determined with a Chromel-P-constantan thermocouple attached at the bottom of the specimen tube. The temperature drifted by about 2°C during a single sweep of magnetic field through resonance.

X-Ray powder diffraction photographs were taken by a camera of 35 mm. in diameter. The sample in a Li glass capillary (0.5 mm. in diameter) was chilled with a cold stream of nitrogen from its top. The temperature of the specimen was held constant to within a few degrees during exposure to nickel-filtered Cu$K\alpha$ radiation, ranging from 2.6 hr. for *t*-butyl iodide to 8—16 hr. for carbon tetrachloride or the mixtures.

The dielectric constant and loss were measured with the same equipments as have been described previously.[9] The sample container (see Fig. 1) consists of coaxial cylinders of Telex glass fitted inside with cylinders of platinum which serve as the measuring electrodes. The air capacitance of the cell is about 21 pF. This was inserted into a hole drilled through a heavy copper block to aid in slow change of the temperature. The specimens were frozen so as not to develop fissures or vapor snakes while freezing. The plastic nature of the crystal allowed its close fitting between the electrodes if maintained some degrees below the melting point. The dielectric constant of pure carbon tetrachloride agreed satisfactorily with the values obtained by Guillien[10] over the range of temperature examined. When the specimen was frozen quickly or was not annealed in the plastic phase, its dielectric constant appeared smaller.

The apparatus of the differential thermal analysis is the same as the one reported earlier.[11]

Results and Discussion

Pure *t*-Butyl Iodide.—The differential thermal analysis showed no solid-state transition between −196°C and the melting point, −37.0°C.

The temperature dependence of the dielectric constant ε' and the loss factor ε'' was measured between 1 kc./s. and 1 Mc/s. showing no discontinuity nor anomalous dispersion. Absolute values of ε' and ε'' were poorly reproducible because the crystal tended to fissure between the electrodes. ε'' increased toward the lower frequency: It gives linear plots against the reciprocal of the frequency, $1/f$, as shown in Fig. 2. The figure indicates that

the real part of the complex conductivity γ' obeys the formula

$$\gamma' = \varepsilon'' f / 1.8 \times 10^{12},$$

suggesting also that the low-frequency loss is due to d. c. conductivity. By fitting the Arrhenius type of equation

$$\gamma' = \gamma_0' \exp(-E/\boldsymbol{R}T),$$

the activation energy E was estimated to be 3.8 to 6.8 kcal./mole, varying from specimen to specimen, probably because it depends on the crystal packing between the electrodes, the size of crystallites, or the extent of dislocations. These values of E are rather small for the activation energy of diffusion through crystal lattice; the charge carriers may be small fragments of *t*-butyl iodide molecules produced by photochemical processes, moving through dislocations.

The proton magnetic resonance line shapes are reproduced in Fig. 3 at two representative temperatures. Figure 4 is a graph of the second moment plotted as a function of the temperature. It is 27.8 gauss^2 at -160°C and decreases to 2.4 gauss^2 at -100°C. Above the melting point, the observed resonance line was as narrow as the inhomogeneity of the magnet. To compare with these figures, theoretical values of the second moments were calculated by the method of Van Vleck.[12] The molecular parameters employed were H–H 1.79 Å, C–H 1.10 Å, and C–C 1.54 Å, the bond angles being assumed all tetrahedral. The contribution of the iodine spins was ignored. The dipolar interaction between three methyl groups was calculated as if the three protons of a methyl group collapsed into the center of the equilateral proton triangle. Table II is the result of such calculations.

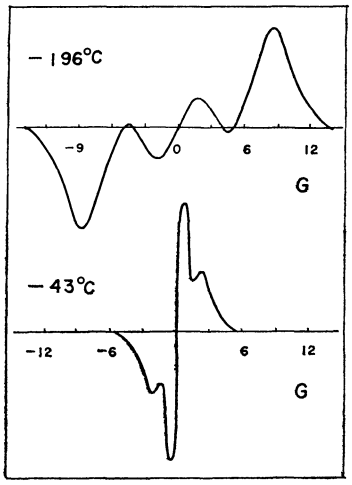

Fig. 3. The proton magnetic resonance (derivative) line shapes of *t*-BuI.

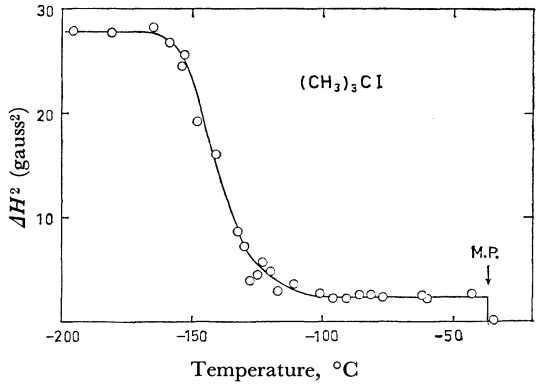

Fig. 4. Temperature dependence of the second moment of the proton magnetic resonance absorption of *t*-BuI.

Table II. Theoretical estimates of the second moments of solid *t*-butyl iodide in gauss^2

	Intra-methyl contribution (A)	Inter-methyl contribution in a molecule (B)	(A)+(B)
Rigid lattice	21.7	3.48	25.2
C_3-Rotation*	5.43	3.48	8.91
C_3'-Rotation*	0.64	0.87	1.51

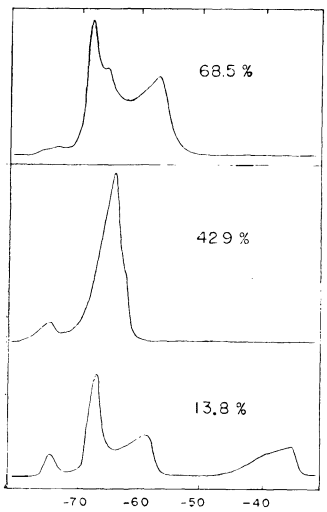
* C_3-Rotation denotes the rotation of methyl groups around the C–C bonds.
C_3'-Rotation denotes the axial rotation of a whole molecule around the C–I axis.

The comparison between the observed and the theoretical values of the second moment shows that the lattice is rigid at the lowest temperature and undergoes a change through motional narrowing to a state in which are taking place not only the rotation*[1] of the methyl groups around the C–C axes but also the axial rotation of the entire molecule around the C–I axis. This does not contradict with non-existence of phase transition of this solid because a cooperative effect must be involved if a transition is to be seen by thermal measurements. The NMR experiments thus indicate that no bulk diffusion is occurring in solid *t*-butyl iodide.

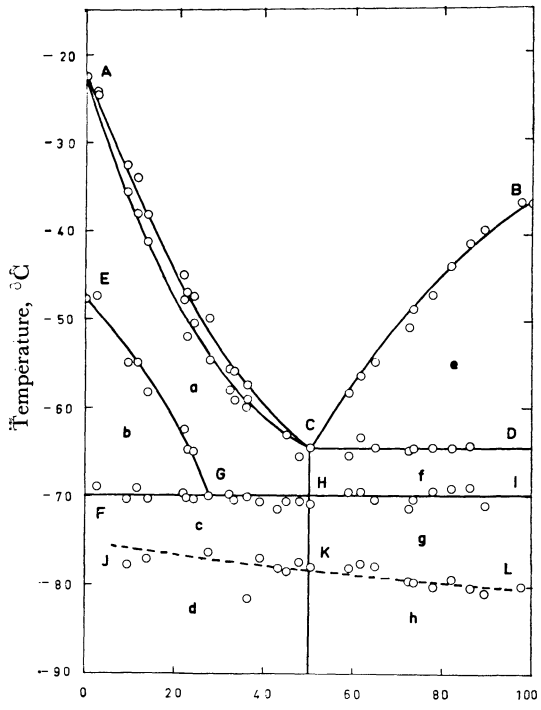
The Phase Diagram of the System, Carbon Tetrachloride-*t*-Butyl Iodide.—The phase diagram of the binary system was constructed by means of a series of differential thermal analysis (DTA) runs at different compositions. The heating rate was about 0.7—1.0°C/min. The phase diagram as well as typical DTA curves are shown in Figs. 5A and 5B in which capital letters indicate points and lower-case letters indicate areas on the phase diagram. Where the concentration was near the eutectic point C, the endothermic anomalies in the DTA curves were poorly resolved and therefore their temperatures are not very precise. While

*[1] No discrimination of the words, rotation or reorientation, is made in this paper.[2]

12) J. H. Van Vleck, *Phys. Rev.*, **74**, 1168 (1948).



(A)



(B)

Fig. 5. Some typical DTA curves (A) and the phase diagram (B) of the system, CCl_4 - *t*-BuI.

the state of aggregation in each area will be discussed in later Sections, it suffices here to mention that within a limited range of the concentration (carbon tetrachloride richer than about 50 mole%), the system forms a solid solution, and also that a phase transition corresponding to that of pure carbon tetrachloride may be seen at a lower temperature. Therefore in such a concentration range, it is expected that the solute, *t*-butyl iodide, behaves as a built-in probe to study the molecular motions in the binary solid.

The areas on the phase diagram will now be briefly characterized. The area a corresponds to the solid solution. The point E is the transition temperature of pure carbon tetrachloride and the line EG shows its variation with the composition. In the area b, pure carbon tetrachloride coexists with the solid solution having varying composition. At the line FI, phase separation into pure components occurs. The origin of the thermal anomaly* corresponding to the line JL is not apparent but it does not appear in either of the pure components and its magnitude on the DTA curves is not perfectly reproducible. While the DTA curves in Fig. 5A may be taken as indicating that the anomaly is more prominent nearer the point J, there is no such definite tendency. Since complete phase separation occurs below −70°C, this anomaly must be associated with some effect of the interface or boundary of phases. The point C is a kind of eutectic point and the system is invariant here. The area, f, therefore, represents the solid solution of the composition C and pure *t*-butyl iodide.

A few words must be added here about the possibility of the existence of a phase transition in solid *t*-butyl iodide. Baker and Smyth[13] reported the existence of a phase change at −75°C through their measurements of the dielectric constant. However, in the present study, no anomaly was observed at this temperature in the differential thermal analysis, the nuclear magnetic resonance, or the X-ray diffraction. Our measurements of

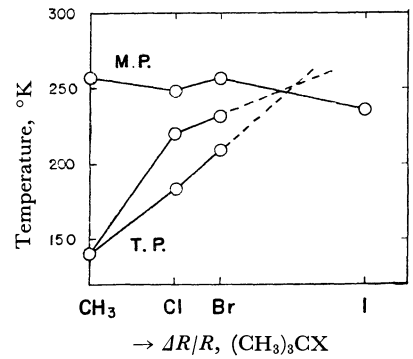


Fig. 6. Correlations between the temperatures of phase changes and the dissymmetry of molecules of $(CH_3)_3CX$.

* The shape of the thermal anomaly is not a fixed one; it is sometimes a sharp peak and sometimes a broad maximum or a lambda-type anomaly. The temperatures at which these anomalies occur also show considerable scatter on either side of the line JL.

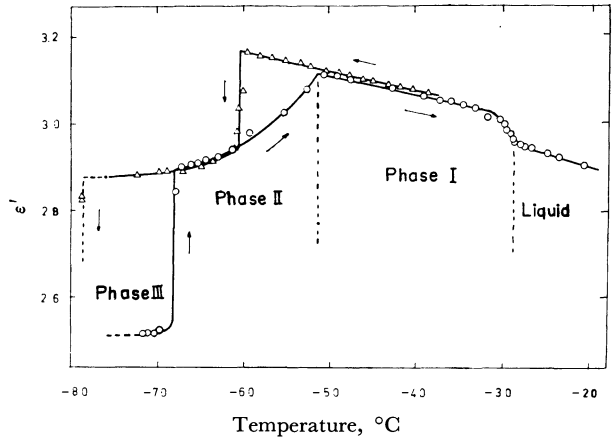

Fig. 7. Temperature dependence of the dielectric constant of a solid solution containing 6.6 mole % *t*-BuI at 15 kc./s.

the dielectric constant were not extended to a low enough temperature to show this because the contact of the specimen with the electrodes became poorer as we went down to lower temperatures. A comparison of the *t*-butyl compounds yields, however, an interesting diagram as shown in Fig. 6. Here, the melting point and the transition point are plotted as a function of the asymmetry parameter η of the molecules. The η is defined by

$$\eta = (R - R')/R = \Delta R/R$$

where R is the radius of the molecular sphere and R' is the distance from the central carbon atom to the periphery of the molecular sphere. Figure 6 suggests that *t*-butyl iodide would not have a transition in the solid state. A similar conclusion may be drawn from the type of analysis Miller and Smyth[14] developed for tetrahalomethanes.

A Solid Solution Containing 6.6—6.8 mole% of *t*-Butyl Iodide.—The solid solution containing 6.6—6.8 mole% of *t*-butyl iodide was chosen for detailed study because the peaks in the DTA curve are well resolved at such a concentration.

The precision of the equipments for the dielectric measurements did not permit us to work with a lower concentration of *t*-butyl iodide. The regions a, b, and c in the phase diagram (Fig. 5) will be referred to as the phases I, II, and III respectively.

Phase I.—The dielectric constant ε' at 15 kc./s. of the solid solution containing 6.6 mole% *t*-butyl iodide is shown in Fig. 7 through different phases. A good reproducibility of the ε' values indicates that close filling of the measuring cell with specimen has been attained. No dielectric dispersion and absorption were observed in the frequency range examined, therefore the results presented in Fig. 7 may be considered to represent the static dielectric constant.

We will first discuss the behavior of the system in Phase I. The negative slope in Phase I region in Fig. 7 is the same as in liquid solution phase. This is analogous to the case of many plastic crystals[1] in which the molecular rotational (or reorientational) degrees of freedom are fully excited, opposing the effect of electric field that tends to orient the molecular dipoles in its direction and decreasing the molecular polarization. There is small but definite change in ε' in going from Phase I to the liquid over a narrow temperature region between the solidus and the liquidus lines of the phase diagram, in accordance with the change in the density upon melting. The rotational motion of the *t*-butyl iodide molecules in the carbon tetrachloride matrix is not perfectly free in Phase I but must see a finite potential energy barrier hindering general rotation.[2] The X-ray diffraction pattern of Phase I was essentially the same as that of the Phase I of solid carbon tetrachloride which is known to be a plastic phase. This means that, so far as the orientational degrees of freedom are concerned, Phase I may be approximately regarded as a liquid solu totion; it is, therefore, of interest to examine what extent it may be.

The interactions between the solute molecules being ignored, the molecular polarization P_{12} of a dilute solution of polar molecules (suffix 1) in a non-polar solvent (suffix 2) is given by

$$P_{12} = \frac{\varepsilon - 1}{\varepsilon + 2} \cdot \frac{1}{d}(c_1M_1 + c_2M_2)$$

$$= \frac{4\pi N}{3}(c_1\alpha_1 + c_2\alpha_2) + \frac{4\pi Nc_2}{9kT} \cdot \mu^2$$

where c_1 and c_2 are mole fractions, M_1 and M_2 are the molecular weights, α_1 and α_2 are the optical polarizabilities, d is the density of the solution, and μ is the dipole moment of the solute molecule. Figure 8 shows a graph of the P_{12}

14) R. C. Miller and C. P. Smyth, ibid., **79**, 20 (1957).

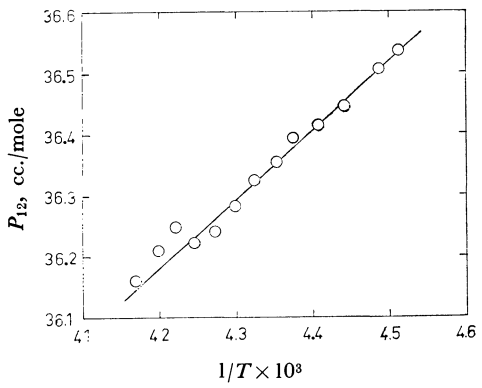

Fig. 8.

values plotted against the reciprocal of the temperature. In calculating P_{12} the density of the solution was assumed to be equal to that of pure carbon tetrachloride at corresponding temperature and evaluated from ε' values for pure carbon tetrachloride under the assumption of the temperature-independence of the molecular polarization of pure carbon tetrachloride. The plot is a good straight line, yielding a value of $\mu = 1.6 \times 10^{-18}$ e.s.u. for the dipole moment of *t*-butyl iodide. There are no literature values to be compared with this dipole moment but the C–I bond moment has been estimated to be about 1.2×10^{-18} e.s.u. The difference is small and it is hard to decide if the difference is a real one.

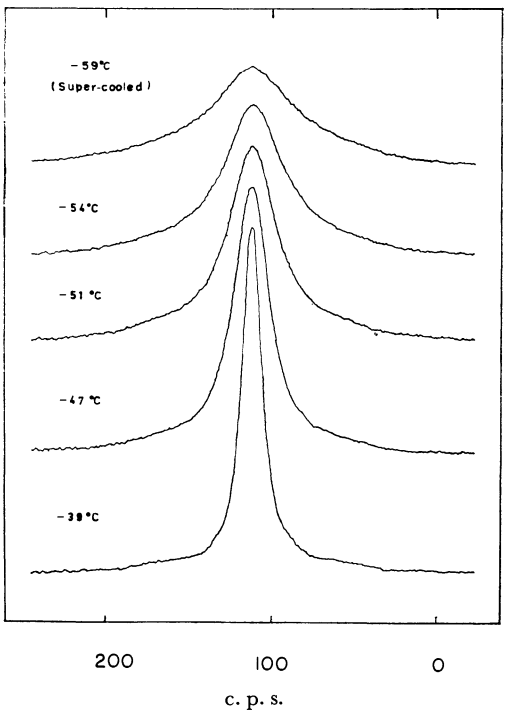

Fig. 9. High-resolution proton NMR of *t*-BuI in Phase I of the solid solution.

Having seen that the system may be regarded as a liquid solution with regard to molecular orientation, an attempt was made to study the proton magnetic resonance in the hope that we might see the effect of self-diffusion in Phase I.[15] Figure 9 shows the temperature dependence of the high-resolution NMR line shape for the sample containing 6.8 mole% *t*-butyl iodide. The experiment started from −59.5°C (with the supercooled Phase I) upwards. The line-width is so narrow as to indicate that the reorientational motion of *t*-butyl iodide molecules is fully excited; its variation with the temperature must then be due to diffusion of molecules in the solid solution. If one assumes, as is done frequently, that the line-width is determined by the spin-spin interaction time T_2, the half-peak width is inversely proportional to T_2. The time T_2 is now related to the diffusion coefficient D through Torry's equation[16]

$$T_2 = \frac{1}{c} \cdot b^4 D$$

By virtue of the relations[17]

$$D = b^2 \nu_D \cdot \exp(-\Delta G_d / \boldsymbol{R}T)$$
$$= D_0 \exp(-\Delta H_d / \boldsymbol{R}T)$$

we have

$$cT_2/b^4 = D_0 \exp(-\Delta H_d / \boldsymbol{R}T)$$

where ΔG_d is the Gibbs energy of activation, ν_D is the Debye cut-off frequency of the solid, c is a material constant independent of the temperature, b is the lattice parameter of the face-centered cubic lattice to which the equation is applicable. Because of the narrow temperature range studied, the b may be taken as a constant. The linear dependence of log T_2 on $1/T$ in Fig. 10 gives a value of 6.8 kcal./mole for ΔH_d of diffusion.

The origin of the residual line-width (Fig. 9)

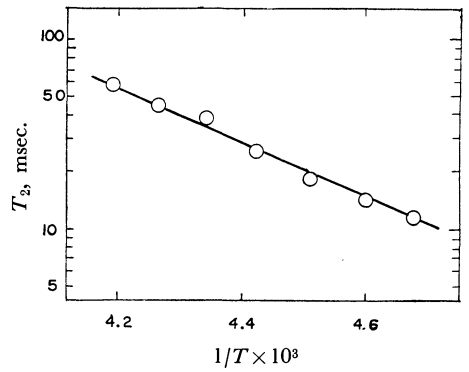

Fig. 10.

15) See for example, H. Suga and S. Seki, This Bulletin, **35**, 1905 (1962).
16) Quoted by H. A. Resing, *J. Chem. Phys.*, **37**, 2175 (1962).
17) C. Zener, *J. Appl. Phys.*, **22**, 372 (1951).

must now be investigated more closely. The state of distribution of *t*-butyl iodide in the carbon tetrachloride matrix is not at once obvious: The solute molecules possibly form small aggregates by dipole-dipole forces in order to relax the local distortion of the matrix lattice and thus to minimize the total strain energy. Because no bulk seggregation was observed in Phase I, there must be an equilibrium set of concentrations for single solute molecules, pairs of molecules, etc. Judging from the case of vacancy pairs in inert gas solid,[18] the concentration of the pairs and the higher multiples of molecules will be less than a few tenth of one per cent. Therefore, it will be safe to assume that most of the solute is distributed uniformly throughout the solid solution. A uniform distribution means that an average *t*-butyl iodide molecule is separated from other nearest *t*-butyl iodide molecules by about 300 Å and that each *t*-butyl iodide molecule sees only carbon tetrachloride molecules at its neighbors. The proton-chlorine interactions thus contribute predominantly to the residual line-width; the second moment contributed by this type of interaction is greater than that by the intermolecular proton-proton interaction by a factor of 10^2, by a rough computation. Another order-of-magnitude estimate can be made with regard to the line-width itself. The maximum local magnetic field which a proton sees is about 80 c. p. s. due to chlorine nuclei, whereas the field due to other protons amounts only to 20 c.p.s., assuming that the nuclei are bound rigidly at the f. c. c. lattice points. The observed line-width ranges between 15 and 60 c. p. s.

These arguments suggest that what is being observed is the narrowing of proton resonance caused by the diffusion of the carbon tetrachloride molecules. Therefore, the observed heat of activation, 6.8 kcal./mole, is that for diffusion of carbon tetrachloride relative to *t*-butyl iodide molecules. Here the *t*-butyl iodide molecules behave like a built-in probe to study the motion of the non-magnetic or weakly magnetic molecules (carbon tetrachloride).

There are no other experimental or theoretical values available for comparison with this value of ΔH_d, but it seems to be a reasonable value in view of the low value of the rotational potential barrier height, 2.4 kcal./mole.[2] In the case of metals, Nachtrieb[19] demonstrated a proportionality relation between ΔH_d and the heat of fusion ΔH_f with an empirical constant of proportion:

$$\Delta H_d = 16.5\ \Delta H_f$$

This relation gives ΔH_d a value of 9.9 kcal./mole for carbon tetrachloride. The reason for the observed value to be smaller is not immediately apparent; the small observed value may show failure of the Nachtrieb's relation in the case of molecular crystals or it may be an indication of local distortion of the carbon tetrachloride host lattice in the vicinity of the solute molecules.

The direct determinations of the relaxation times T_1 and T_2 at this and still lower concentrations of *t*-butyl iodide, and also similar investigations using other *t*-butyl halides will be helpful in a more quantitative understanding of the molecular motion. Studies along these lines are being undertaken.

Phases II and III.—The Phase II of the binary solid is an inhomogeneous phase because pure carbond tetrachloride (of the low-temperature modification) keeps segregating upon cooling below the transition temperature. This is seen by the X-ray diffraction pattern which is a super-impose of the low-temperature pattern of carbon tetrachloride and the pattern of the solid solution.

The dielectric constant ε' is still large in Phase II, although its temperature coefficient is positive in contrast to the case of Phase I, showing that the molecular reorientation tends to be restricted progressively upon cooling. The reason for this is two-fold: One is the effect of smaller kinetic energy at lower temperatures and the other is the increase in the solute concentration in the solid solution part. In conformity with such view, there is a Maxwell-Wagner type of absorption in ε'' at −68°C at low frequency side of Fig. 11. An anomalous absorption extends towards higher frequencies, showing a possibility of finding a maximum in ε'' between 10^8 and 10^9 c. p. s. The reorientational motion of *t*-butyl iodide in Phase II is apparently more heavily restricted than in Phase I but is easier than in pure *t*-butyl iodide in which the dispersion is considered to occur around 5×10^4 c.p.s.

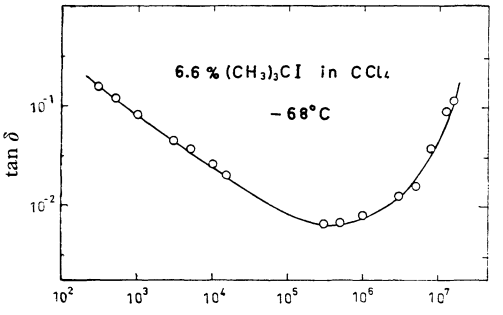

Fig. 11.

In Phase III the two components are completely separated (by X-ray diffraction). The dielectric constant changes discontinuously at the eutectic point (−70°C). The value of ε' (2.5) in this

phase is comparable to the high frequency limit (2.6) for pure *t*-butyl iodide and the low temperature limit (2.4) for pure carbon tetrachloride.

Comparison of the Systems CCl_4 - *t*-BuX where X is CH_3, Cl or I.—The published phase diagrams for the systems carbon tetrachloride - $C(CH_3)_4$[4] and carbon tetrachloride - *t*-butyl chloride[7] differ in many respects from the diagram given in Fig. 5 of the present paper. Only portion that may be compared is where the transition point of carbon tetrachloride varies with the concentration of the second component. This portion is

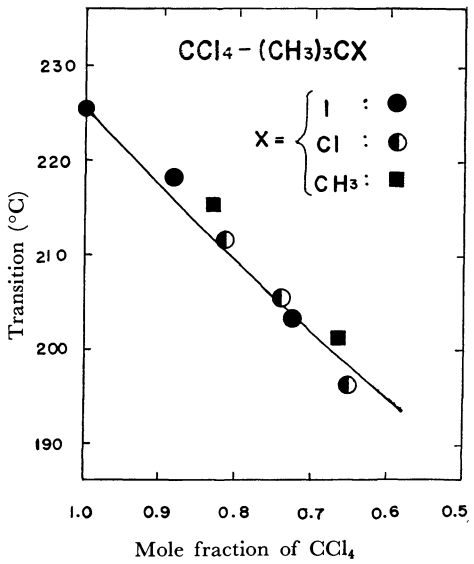

Fig. 12. Transition point lowering of CCl_4. The solid line corresponds to a theoretical prediction for a regular solution case with $w=350$ cal./mol.

depicted in Fig. 12. The solid line in the figure gives what one would expect if it is assumed that the plastic solid phase (Phase I) forms a regular solution; i. e. the equation of the solid line in the figure is given by

$$RT_0 \ln x + w(1-x)^2 = \Delta H\left(1-\frac{T_0}{T}\right)$$

and

$$w = 350 \text{ cal./mol.}$$

where x is the mole fraction of carbon tetrachloride, T_0 is the transition temperature of pure carbon tetrachloride, ΔH is its heat of transition, and T is the observed transition temperature. The parameter w is related to the heat of mixing of the two components. The deviation of the observed points from the solid line is small, which fact shows that the plastic crystals are good solid solvents and they are 'liquids' at least with regard to the molecular orientation.[20] Similar finding has also been obtained for the solid system, CO-N_2.[21]

The authors are grateful to Professor Masazumi Nakagawa and Mrs. Noriko Sorai of Osaka University for their kind advice and help in the synthesis of the *t*-butyl iodide. This research was supported by the Government Special Equipment Funds which were acknowledged with gratitude.

Dedication

This paper is dedicated to Professor Masao Kotani of Osaka University in celebration of his sixtieth birthday, who has a world-wide reputation for his scientific activity in so many different branches of physics and chemistry.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2153—2156 (1966)

Effect of Temperature on the Molecular Structure of Iodine Observed by Gas Electron Diffraction

By Takeshi UKAJI* and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received March 18, 1966)

The bond distance and its mean square amplitude for the iodine molecule were measured at 80°C, 300°C, and 500°C by gas electron diffraction. The observed temperature dependences of the above parameters were in good agreement with those calculated on the basis of an anharmonic-oscillator model and experimental spectroscopic constants.

Recent development in the technique of gas electron diffraction has made it possible to measure small changes in internuclear distances and mean square amplitudes with temperature. As first demonstrated for phosphorus(III) chloride by Hedberg and Iwasaki,[1] studies of this sort can be used effectively for investigating the effect of intramolecular vibrations on structure and for assessing the accuracy of the diffraction experiments made at high temperatures. The present study has been carried out as a primary step toward this goal.

Iodine is one of the most suitable molecules for the examination of the temperature effect because of its low vibrational frequency (214 cm^{-1}) and its chemical stability to several hundred degrees. Therefore, the bond distance and its mean square amplitude observed at different temperatures have been compared with those calculated from spectroscopic data. The results of the least-squares analysis have been tested by using theoretical molecular intensity function based on the probability distribution function of a one-dimensional anharmonic oscillator expanded to the fourth order.

Experimental and Analysis

Electron diffraction photographs were taken at 80°C, 300°C, and 500°C by the use of a diffraction unit with a high temperature nozzle, which has been reported elsewhere.[2] The accelerating voltage was 41.04 kV. Five plates for each temperature were selected for analysis. The temperature was measured by a thermocouple attached to the nozzle assembly. In order to measure the temperature of the vapor at the nozzle tip, the thermocouple was calibrated by the following procedure. Fine pieces of crystals of known melting points, such as 2-aminodiphenylamine [80°C], anthraquinone [286°C], and zinc iodide [445°C], were placed on top of the nozzle capillary, through which the iodine vapor was emitted into the diffraction chamber while the temperature was raised gradually. Melting of a fine edge of the crystal was observed under a microscope. It was found that the temperature of the vapor measured by the above procedure agreed with that of the nozzle indicated by the thermocouple within a few degrees.

Photographic densities were measured by a self-recording microphotometer with spinning of the plate around the center of the halos at about 600 r. p. m. The microphotometer charts were analyzed by the method described in previous papers.[3]

The bond distance r_a, the mean amplitude l_m, the phase parameter κ, and the index of resolution i were obtained from a least-squares analysis.[3] The experimental reduced molecular intensity was fitted to the following theoretical equation:

$$M(s) = iAC \exp(-l_m^2 s^2/2) \sin[s(r_a - \kappa s^2)]/sr_a \quad (1)$$

where A is a normalization constant, nearly equal to unity, which appears in the probability distribution function described below, and C is a known function of s related to the elastic and inelastic scattering factors of the iodine molecule. The mean internuclear distance r_g was calculated from the experimental r_a distance by

$$r_g = r_a + l_m^2/r_a \quad (2)$$

The probability distribution function for a one-dimensional anharmonic oscillator at the absolute zero temperature has been given by Kuchitsu and Bartell.[4] This function has recently

been extended in order that the equation may be valid for any nonzero temperature[5] by using a harmonic mean amplitude l_h^2 in place of the corresponding zero-point amplitude l_a^2 defined in Ref. 4,

$$P(x) = A(2\pi l_h^2)^{-1/2}(1+\sum_{n=1}^{\infty} c_n x^n)\exp(-x^2/2l_h^2) \quad (3)$$

where $x = r - r_e - \delta r$ (4)

$$l_h^2 = l_a^2(1+\chi)/(1-\chi) \quad (5)$$

$$l_a^2 = \hbar/8\pi^2\mu c\omega_e \quad (6)$$

and $\chi = \exp(-hc\omega_e/kT)$ (7)

The coefficients c_n in Eq. 3 can be calculated by a second-order perturbation method on the basis of a fourth-order potential function.[5,6] Numerical values of c_n for iodine, listed in Table I, were obtained by using the experimental values of ω_e, α_e, and x_e determined by ultraviolet spectroscopy.[7] The correction for the centrifugal distortion, δr, is equal to $kT/2\pi^2\mu c^2\omega_e^2 r_e$.

TABLE I. VALUES OF c_n (in Å^{-n} units)

c_n	80°C	300°C	500°C
c_0	0.997	0.996	0.995
c_1	0.256	0.105	0.059
c_2	−0.324	−0.163	−0.097
c_3	2.227×10^2	1.531×10^2	1.171×10^2
c_4	-8.828×10^2	-1.042×10^2	-0.900×10^2
c_5	0	0	0
c_6	2.480×10^4	1.172×10^4	0.686×10^4

The reduced molecular intensity of scattered electrons,

$$M(s) = C\int_{-\infty}^{\infty} P(x)dx[\sin s(r_e+\delta r+x)]/s(r_e+\delta r+x) \quad (8)$$

can be written in terms of c_n as

$$M(s) = AC(\sigma_1^2+\sigma_2^2)^{1/2}\exp(-l_h^2s^2/2)\sin[s(r_a+\phi(s))]/sr_e \quad (9)$$

where σ_1 and σ_2 are infinite polynomial functions of c_n given by

$$\sigma_1 = \sum_{n=0}^{\infty}(-1)^n\varepsilon_{2n+1}(l_h^2s)^{2n+1} \quad (10)$$

$$\sigma_2 = \sum_{n=0}^{\infty}(-1)^n\varepsilon_{2n}(l_h^2s)^{2n} \quad (11)$$

$$\varepsilon_n = \sum_{m=0}^{\infty}[(n+2m)!/2^m n!m!]d_{n+2m}l_h^{2m} \quad (12)$$

$$d_n = c_n - d_{n-1}/r_e \quad (13)$$

and $d_0=1$. The present calculation for iodine indicates the following features of Eq. 9. First, each polynomial function ε_n converges so rapidly that the summation of the first few terms of the series is sufficient for the calculation of $M(s)$. Second, the term $(\sigma_1^2+\sigma_2^2)^{1/2}\exp(-l_h^2s^2/2)$ can be substituted for nearly exactly by $\exp(-l_m^2s^2/2)$ with a parameter l_m taken as constant. The effective mean amplitude l_m can thus be given by

$$l_m \approx [l_h^2 - s^{-2}\ln(\sigma_1^2+\sigma_2^2)]^{1/2} \quad (14)$$

The plots of $l_h^2s^2-\ln(\sigma_1^2+\sigma_2^2)$ against s^2, shown in Fig. 1, can be approximated by straight lines for the temperature range studied. Third, the phase function $\phi(s)$ can be approximated by a quadratic function of s,

$$\phi(s) = (1/s)\arctan(\sigma_1/\sigma_2) - r_a = -\kappa s^2 + \cdots \quad (15)$$

The constant phase parameter κ can further be represented by[5]

$$\kappa \approx (1/6)a_3 l_h^4[1+8\chi/(1+\chi)^2] \quad (16)$$

in terms of a cubic anharmonic parameter a_3 of the potential function,[8]

$$V(x) = (1/2)f(x^2 - a_3x^3 + \cdots) \quad (17)$$

and the Boltzmann factor χ for temperature T. The plots of $\phi(s)$ at 80°C, 300°C, and 500°C against s^2 are shown in Fig. 2; they are found to be linear, except for a slight deviation found in the 500°C curve beyond 25 in the s-value. The values of κ predicted by Eq. 16 are practically equal to those obtained from the slopes of the $\phi(s)$ vs. s^2 curves shown in Fig. 2. It has thus been shown that Eq. 1 is a good approximation

8) K. Kuchitsu and Y. Morino, This Bulletin, **38**, 805 (1965).

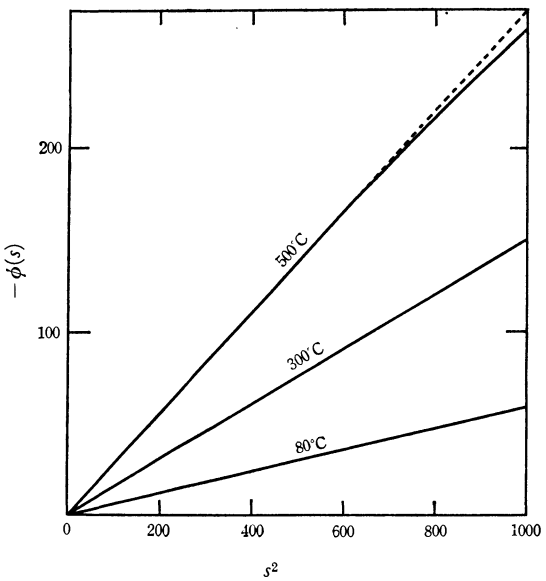

Fig. 2. Curves of $-\phi(s)$ (10^{-4} Å) of Eq. 9 plotted against s^2 for 80°C, 300°C and 500°C.

of Eq. 9 for iodine even at a temperature as high as 500°C.

Results and Discussion

The experimental r_g values derived from the least-squares analysis (exp) are compared in Table II with the corresponding values (calc) calculated by[5]

$$r_g = r_e + [(\varepsilon_0 + \varepsilon_1 r_e + 2\varepsilon_2 l_h^2)/(\varepsilon_0 r_e + \varepsilon_1 l_h^2)]l_h^2 \quad (18)$$

The values of l_m (calc) in Table II are determined from the slopes of the curves shown in Fig. 1, while that of κ(calc) in the same table are calculated by Eq. 15.

Table II. Comparison of the observed structural parameters with theoretical values

	80°C	300°C	500°C
r_g(calc)	2.6756 Å	2.6808 Å	2.6855 Å
r_g(exp)[a]	2.672_3 $\pm 0.003_4$	2.679_0 $\pm 0.001_8$	2.687_2 $\pm 0.002_3$

κ(exp)	39±84	100±112	130±102
i(exp)	0.986 ±0.051	1.003 ±0.093	0.924 ±0.105

a) Experimental errors represent the estimated limit of systematic errors plus 2.5 times the standard error obtained from the least-squares analysis. See Ref. 3.

A comparison of the observed molecular intensity (80°C) with the corresponding calculated intensity based on the optimized set of the parameters is illustrated in Fig. 3.

The least-squares fit to the observed molecular intesity is based on Eq. 1 with the structural parameters r_a, l_m, κ, and i. Since this procedure depends on the approximations stated above, it was thought desirable to examine the validity of this procedure. Iodine is a suitable molecule for this test, because the molecule is simple and its molecular parameters necessary for the calculation of the molecular intensity are precisely known.

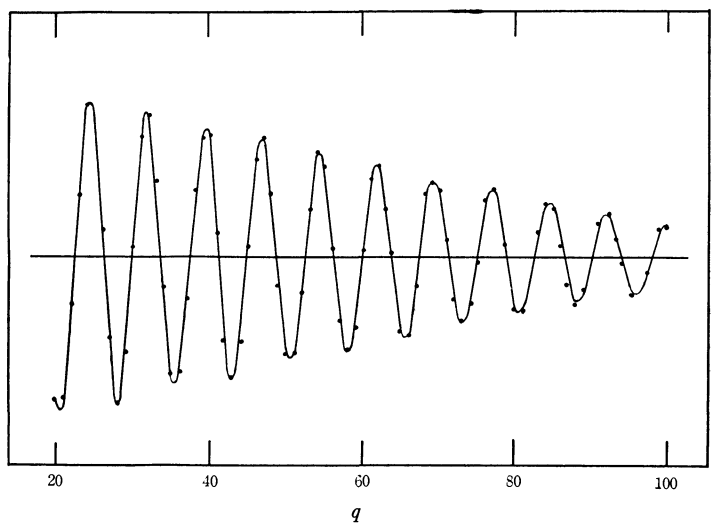

Fig. 3. Comparison of the observed and calculated molecular intensities plotted against $q=10s/\pi$. The solid line shows the experimental molecular intensity curve. The dots are the best-fit molecular intensities obtained from the least-squares analysis.

TABLE III. RESULTS OF THE LEAST-SQUARES ANALYSIS OF THE THEORETICAL $M(s)$ FUNCTION

κ(LS)	60±2	157±4	282±8

r_a(calc), l_e(calc): Average values based on the probability function given in Eq. 3.
l_m(calc): Effective amplitudes estimated from Eq. 14.
κ(approx): Calculated by Eq. 16.
(LS): Outputs of the least-sqares analyses of the theoretical $M(s)$ function given by Eq. 9.

Accordingly, the molecular intensity was calculated by Eq. 9 for integral q values ($q=10s/\pi$) in the region where the experimental data are present, and a least-squares fit was made to those calculated values as if they were experimental data. The output structural parameters thus obtained are compared in Table III with the corresponding rigorous values derived directly from the original equations 14, 15, and 18. The agreement indicates that in this case the present method of least-squares analysis should result in nearly exact estimates for the effective parameter values if it is applied to a perfect set of experimental data.

The experimental bond distance r_g agrees with the calculated values to within 0.1% for the three temperatures. The agreement of the experimental and calculated mean amplitudes is also satisfactory, except for a slight discrepancy in the value for 80°C. The observed values of the phase parameter κ for 80°C and 300°C are comparable with the theoretical counterparts within large experimental errors, while the discrepancy in the value at 500°C is even larger, probably because a systematic error is involved in the experimental molecular intensity for s beyond 25. No evidence was observed in the present study for the s-independent phase shift reported by Karle.[9]

The above comparison shows that the temperature effects on r_g and l_m as observed by the present experiment are for the most part in agreement with those expected by theory. Further efforts are being made to reduce experimental standard errors and to make similar high-temperature measurements on the structural parameters of other molecules.

The authors are indebted to Professor Yonezo Morino for his helpful advice. Their thanks are also due to Dr. Hideo Inuzuka of the Central Research Laboratory, Toshiba Electric Co. for his help in the construction of the high-temperature nozzle, and to the Ministry of Education for the financial support.

Dielectric Relaxation and Molecular Structure. II. Notes on Analysing Dielectric Data of Dilute Solutions

By Keniti HIGASI

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received March 25, 1966)

Dielectric data from dilute solution studies consist of two slopes, a' and a'', as defined by $\varepsilon'=\varepsilon_1'+a'c_2$ and $\varepsilon''=a''c_2$. In this article it is shown that the Debye equations for dilute solutions can be described by the use of a' and a''. These equations are obtained by replacing dielectric constant and loss, ε' and ε'' in Debye's equations for polar liquids by a' and a''. As applications of these new equations based on a' and a'' following topics are discussed: Symth's a', a'' plot in the complex plane; Scaife's method of polarizability plot; the familiar loss tangent method originated by Debye for obtaining the relaxation time in solution; and Gopola Krishna's new method for the same purpose.

To avoid the much disputed ambiguity[1] concerning the internal field correction, the dielectric relaxation time of a polar molecule is preferrably measured in dilute solutions of a non-polar solvent. However, the theoretical basis of the dilute solution method has not been well established. For instance, Smyth and his co-workers[2] in Princeton obtain two slopes, a' and a'', for dilute solutions of a polar substance in a non-polar solvent and make a plot of a' and a'' in the complex plane instead of the ε' and ε'' plot for the pure liquid. This procedure was justified graphically, that is, by plotting the dielectric constants and losses of solutions in the complex plane they obtained semi-circles which differed in size according to the concentration of the solute but had exactly the same shape with the semi-circle obtained by the a' and a'' plot. This proof is suggestive but may be better replaced by a mathematical expression in order to have a wider application of the a', a'' plot.

Thirty years ago Debye[3] devised a method of evaluating the relaxation time from the $\tan\vartheta$ values of dilute solutions. A number of researchers[4] have used the latter method since; however, it has not been made clear whether there is any correlation between the two methods, i. e., between the loss tangent method of Debye and the slope method by Smyth.

In this short article it is shown that by the use of two slopes, a' and a'', one can describe the equations of Debye for dielectric relaxation, and that the Smyth procedure of the a' and a'' plot can be examined from this result. Furthermore, the loss tangent method originated by Debye and also the new method proposed by Gopola Krishna[5] can be derived from the equations based on two slopes; and Scaife's method of the polarizability plot[6] will become equivalent to the dielectric constant plot for dilute solution if the two slopes are used in the analysis of dielectric data.

General Theory

With the use of complex dielectric constant, $\varepsilon^*=\varepsilon'-i\varepsilon''$, the complex polarizability $p(\omega)$ is defined by*

$$p(\omega) = p' - ip'' = \frac{\varepsilon^*-1}{\varepsilon^*+2} \tag{1}$$

Consider a dielectric system consisting of dilute solution of a polar substance in a non-polar solvent. If this system is provided with a single relaxation time τ which arises from the polar solute molecules, the dependence of $p(\omega)$ upon the angular frequency ω will be described by

$$p(\omega) = p(\infty) + \frac{p(0)-p(\infty)}{1+i\omega\tau} \tag{2}$$

where

5) K. V. Gopola Krishna, *Trans. Faraday Soc.*, **53**, 767 (1957).

6) B. K. P. Scaife, *Proc. Phys. Soc.*, **81**, 124 (1963).

* The molecular polarization $P(\omega)=p(\omega)M/d$, in which M is the average molecular weight and d is density, is frequently used instead. See Ref. 1, C. P. Smyth, p. 59, Eq. (2.37) and Ref. 1, C. J. F. Böttcher, p. 356, Eq. (10.44).

$$\left.\begin{aligned} p(\infty) &= \frac{\varepsilon_\infty - 1}{\varepsilon_\infty + 2} \\ p(0) &= \frac{\varepsilon_0 - 1}{\varepsilon_0 + 2} \end{aligned}\right\} \quad (3)$$

in which ε_0 is the static dielectric constant and ε_∞ is the dielectric constant measured at frequencies so high that the permanent dipoles are unable to rotate. Since both ε_0 and ε_∞ are real, $p(0)$ and $p(\infty)$ are both real quantities while $p(\omega)$ has the real and the imaginary parts which are given by

$$\left.\begin{aligned} p' &= \frac{(\varepsilon'-1)(\varepsilon'+2)+\varepsilon''^2}{(\varepsilon'+2)^2+\varepsilon''^2} \\ p'' &= \frac{3\varepsilon''}{(\varepsilon'+2)^2+\varepsilon''^2} \end{aligned}\right\} \quad (4)$$

And from Eq. 2

$$\frac{(p'-ip'')-p(\infty)}{p(0)-p(\infty)} = \frac{1}{1+i\omega\tau} \quad (5)$$

If the dielectric system has a distribution of relaxation times, the right side of Eq. 5 should be duly amended.

The so-called "slopes" a' and a'' are defined in the usual way.[2] The dielectric constant ε' and loss ε'' of the dilute solutions are assumed to be represented by the empirical equations:

$$\left.\begin{aligned} \varepsilon' &= \varepsilon_1' + a'c_2 \\ \varepsilon_0 &= \varepsilon_{10} + a_0c_2, \quad \varepsilon_\infty = \varepsilon_{1\infty} + a_\infty c_2 \\ \varepsilon'' &= a''c_2 \end{aligned}\right\} \quad (6)$$

in which subscript 1 refers to the pure solvent and 2 to the solute while subscript 0 refers to the zero frequency measurement in the static field and ∞ to the infinite frequency measurement (at a very high frequency). The concentration of the solute c_2 has been usually expressed in the units of mole fraction[2] but it will be seen later that any concentration units can be used instead.

From Eqs. 6 and Eqs. 4 the following relations are obtained since the square terms such as $(a'c_2)^2$, $(a''c_2)^2$ are negligible for dilute solutions.

$$\left.\begin{aligned} p' &= p_1' + b'c_2 \\ p'' &= b''c_2 \end{aligned}\right\} \quad (7)$$

and

$$\left.\begin{aligned} b' &\simeq \frac{3a'}{(\varepsilon_1'+2)^2\left[1+\frac{2a'c_2}{\varepsilon_1'+2}\right]} \\ &\simeq \frac{3a'}{(\varepsilon_1'+2)^2} \\ b'' &\simeq \frac{3a''}{(\varepsilon_1'+2)^2\left[1+\frac{2a'c_2}{\varepsilon_1'+2}\right]} \\ &\simeq \frac{3a''}{(\varepsilon_1'+2)^2} \end{aligned}\right\} \quad (8)$$

Consequently, there exists a simple relation:

$$\frac{b''}{a''} \simeq \frac{b'}{a'} \quad (9)$$

If we write for $p(0)$ and $p(\infty)$ which are both real

$$\left.\begin{aligned} p(0) &= p_1(0) + b_0c_2 \\ p(\infty) &= p_1(\infty) + b_\infty c_2 \end{aligned}\right\} \quad (10)$$

we obtain

$$b_0 \simeq \frac{3a_0}{(\varepsilon'_{10}+2)^2}, \quad b_\infty \simeq \frac{3a_\infty}{(\varepsilon'_{1\infty}+2)^2}$$

Since

$$\varepsilon_1' \simeq \varepsilon_{10} \simeq \varepsilon_{1\infty} \quad (11)$$

$$\frac{b_0}{a_0} \simeq \frac{b_\infty}{a_\infty} \simeq \frac{b'}{a'} \quad (12)$$

Relations 9 and 12 are important and will be discussed later. Introducing Eqs. 7 and 10 into Eq. 5, the left side of Eq. 5 becomes

$$\frac{(p'-ip'')-p(\infty)}{p(0)-p(\infty)} = \frac{p'_1-p_1(\infty)+c_2(b'-b_\infty-ib'')}{p_1(0)-p_1(\infty)+c_2(b_0-b_\infty)} \quad (13)$$

For non-polar solvents which have no dielectric loss, there is an approximate relation

$$p_1' \simeq p_1(0) \simeq p_1(\infty) \quad (14)$$

which arises from Eq. 11. Both Eqs. 11 and 14 are not rigorously valid for any non-polar solvent; but observed deviations are usually very small to be ignored.

By the use of Eqs. 9 and 12

$$\frac{b'-b_\infty-ib''}{b_0-b_\infty} = \frac{a'-a_\infty-ia''}{a_0-a_\infty} \quad (15)$$

From Eqs. 5, 13, 14 and 15 one obtains for the system of a single relaxation time

$$\frac{a'-a_\infty-ia''}{a_0-a_\infty} = \frac{1}{1+i\omega\tau} \quad (16)$$

Equation 16 becomes

$$\frac{a^*-a_\infty}{a_0-a_\infty} = \frac{1}{1+i\omega\tau} \quad (17)$$

in which a complex slope a^* introduced.

$$a^* = a' - ia'' \quad (18)$$

The usual Debye equation for the polar liquid is

$$\frac{\varepsilon^*-\varepsilon_\infty}{\varepsilon_0-\varepsilon_\infty} = \frac{1}{1+i\omega\tau_M} \quad (19)$$

where the complex dielectric constant ε^*, the static dielectric constant ε_0 and the high frequency dielectric constant ε_∞ are used in places of a^*, a_0 and a_∞ in Eq. 17.

The macroscopic relaxation time τ_M differs from τ defined by Eq. 2;[7]

7) C. J. F. Böttcher, Ref. 1, p. 357, Eq. (10.51)

$$\tau_M = \tau \frac{\varepsilon_0+2}{\varepsilon_\infty+2} \tag{20}$$

However, τ_M becomes identical with τ for dilute solutions in a non-polar solvent (cf. Eq. 11).

Debye Equations

From the real part of Eq. 16 we obtain

$$\frac{a'-a_\infty}{a_0-a_\infty} = \frac{1}{1+\omega^2\tau^2} \tag{21}$$

From the imaginary part

$$\frac{a''}{a_0-a_\infty} = \frac{\omega\tau}{1+\omega^2\tau^2} \tag{22}$$

Equations 21 and 22 provide two independent values of the relaxation times for a solute molecule from the measured values of a' and a'' at a single frequency in the dispersion range.

Combination of these equations will lead to a set of two equations which are independent to each other.

$$a' = a_\infty + \frac{1}{\tau}\left(\frac{a''}{\omega}\right) \tag{23}$$

and

$$a' = a_0 - \tau(\omega a'') \tag{24}$$

The latter equations are useful in checking the validity of the Debye equations of a single relaxation time.

If the Debye equation of a single relaxation time is valid for the system under consideration and if the measurement is conducted with sufficient accuracy, we would be able to determine the relaxation time by use of any equation above mentioned. Accuracy of such a procedure was carefully examined for a few examples by Higasi and Kiyohara.[8]

The equation derived originally by Debye for the same purpose is

$$\tan\vartheta = \frac{\varepsilon''}{\varepsilon'} \simeq \frac{(\varepsilon_1'+2)^2}{\varepsilon_1'} \frac{4\pi\mu^2 c_2}{2700\boldsymbol{k}T} \boldsymbol{N} \frac{\omega\tau}{1+\omega^2\tau^2} \tag{25}$$

in which c the molar concentration and $\boldsymbol{N}$ is the Avogadro number. Equation 25 is a modified form of Eq. 22. Since there is a relation[9] between the dipole moment μ and the two slopes a_0 and a_∞

$$\mu^2 \simeq B^2(a_0-a_\infty) \tag{26}$$

where

$$B^2 = \frac{1}{(\varepsilon_1'+2)^2} \frac{2700\boldsymbol{k}T}{4\pi\boldsymbol{N}} \tag{27}$$

Assuming $\varepsilon''=a''c_2$, $\varepsilon'=\varepsilon_1'$ for dilute solution Eq. 25 is shown to be identical with Eq. 22.

Gopola Krishna[5] proposed a new method of determining the relaxation time from microwave measurement at a single frequency. His equation is:

$$x = P + \frac{1}{\omega\tau} y \tag{28}$$

in which

$$x = p', \quad y = p'' \text{ and } P = p(\infty) \tag{29}$$

Cf. Eqs. 3 and 4. τ is calculated from the slope of the graph, x against y.

For dilute solutions of a non-polar solvent we have the following equations (cf. Eqs. 7 and 10).

$$p' = p_1' + b'c_2, \quad p'' = b''c_2$$

and

$$p(\infty) = p_1(\infty) + b_\infty c_2$$

Hence Eq. 28 can be rewritten

$$\frac{1}{\omega\tau} = \frac{x-P}{y} = \frac{p_1'-p_1(\infty)+(b'-b_\infty)c_2}{b''c_2}$$

And from Eqs. 9, 12 and 14

$$\frac{1}{\omega\tau} = \frac{a'-a_\infty}{a''} \tag{30}$$

Eq. 30 is identical with Eq. 23.

Concluding Remarks

1) In obtaining slopes a' and a'' as defined

$$\left.\begin{aligned}\varepsilon' &= \varepsilon_1' + a'c_2\\ \varepsilon'' &= a''c_2\end{aligned}\right\} \tag{6}$$

there is no restriction on the choice of the concentration unit for the solute since the linear relationship is little affected by such a choice.[10] Gram fraction, volume fraction or mole/litre can be used in place of the mole fraction usually employed. This will be evident at the inspection of Eq. 15 where all the c_2s are cancelled.

2) If a_0 is measured and a_∞ is estimated with reasonable accuracy, the relaxation time τ will be calculated either from the a' value or from a'' value measured at a single frequency in the dispersion range.

$$\tau = \frac{1}{\omega}\sqrt{\frac{a_0-a'}{a'-a_\infty}} \tag{31}$$

$$\tau = \frac{1}{\omega}[A \pm \sqrt{A^2-1}] \tag{32}$$

where

$$A = \frac{a_0-a_\infty}{2a''} \tag{33}$$

8) K. Higasi and O. Kiyohara, *Bull. Inst. Appl. Elec.*, **18**, 24 (1966).
9) K. Higasi, ibid., **4**, 231 (1952); *Bull. Inst. Phys. Chem. Research*, **22**, 865 (1943).
10) K. Higasi and K. Uchiyama, *Bull. Inst. Appl. Elec.*, **17**, 164 (1965).

If both a' and a'' are measured at a single frequency, τ will be calculated together with a_0 or a_∞.

$$\tau = \frac{1}{\omega}\frac{a_0 - a'}{a''} \tag{34}$$

$$\tau = \frac{1}{\omega}\frac{a''}{a' - a_\infty} \tag{35}$$

These equations are applicable only to the dilute solution system with a single relaxation time.

3) The ε', ε'' plot is based on the Cole-Cole equation:[11]

$$\frac{\varepsilon^* - \varepsilon_\infty}{\varepsilon_0 - \varepsilon_\infty} = \frac{1}{1 + (i\omega\tau_0)^{1-\alpha}} \tag{36}$$

where τ_0 is the most probable relaxation time and α is the Cole-Cole parameter for representing the distribution of the relaxation times. Similarly the a', a'' plot is based on the following equation;

$$\frac{a^* - a_\infty}{a_0 - a_\infty} = \frac{1}{1 + (i\omega\tau_0)^{1-\alpha}} \tag{37}$$

Equation 37 will be obtained from Eq. 5, if the right side of Eq. 5 is assumed to be equal to $1/[1+(i\omega\tau_0)^{1-\alpha}]$.

11) K. S. Cole and R. H. Cole, *J. Chem. Phys.*, **9**, 341 (1941).

From a measurement of a' and a'' at a single frequency in the dispersion region, one is able to find τ_0 and α by the following equations[12] which are derived from Eq. 37.

$$\tau_0 = \frac{1}{\omega}\left(\frac{A^2 + B^2}{C^2}\right)^{\frac{1}{2(1-\alpha)}} \tag{38}$$

$$1 - \alpha = \frac{2}{\pi}\tan^{-1}\frac{A}{B} \tag{39}$$

where

$$\left.\begin{aligned} A &= a''(a_0 - a_\infty) \\ B &= (a_0 - a')(a' - a_\infty) - a''^2 \\ C &= (a' - a_\infty)^2 + a''^2 \end{aligned}\right\} \tag{40}$$

Equations 38 and 39 for the Cole-Cole distribution are to be used only when all the values, a', a'', a_0 and a_∞ are obtained with high accuracy.

4) Compare the polarizability plot of $p' = p_1' + b'c_2$ vs. $p'' = b''c_2$ with the Cole-Cole plot of $\varepsilon' = \varepsilon_1' + a'c_2$ vs. $\varepsilon'' = a''c_2$. One will find that two semi-circles for dilute solutions should have the same shape, because there are proportionality relations between b''/a'', b'/a', etc. See Eqs. 9 and 12. Consequently the a', a'' plot becomes equivalent to the p', p'' plot[6] in this case.

Dielectric Relaxation and Molecular Structure. III. Relaxation Times of Aniline Derivatives in Benzene and Dioxane

By Kazuo CHITOKU and Keniti HIGASI

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received March 25, 1966)

A brief description is made of the experimental methods for measuring microwave dielectric constants and losses of solutions in the frequency range 10—50 Gc./sec. Dielectric data obtained in this experiment were analysed from the viewpoint of molecular interaction between the solute and the solvent molecules. Six benzene derivatives with the amino group, aniline (A), *N*, *N'*-dimethylaniline (B), *N*, *N'*-diethylaniline (C), 2, 6-dimethylaniline (D), *p*-nitroaniline (E) and *N*-methylaniline (F) were chosen as solutes. Benzene and dioxane were used as solvents. The relaxation times of A, D and E obtained in dioxane are about three or five times larger than the corresponding relaxation times in benzene. The relaxation times of B and C in dioxane were about twice or one and half of the corresponding values obtained in benzene. The dielectric behavior of F is intermediate between A and B. These results are attributable to the hydrogen-bond formation between an oxygen atom of the dioxane molecule and an amino-hydrogen atom (F) or atoms (A, D and E).

According to Eyring[1,2] the process of molecular rotation requires an activation energy sufficient to overcome the energy barrier separating the two mean equilibrium positions with opposite directions of the dipole; and hence, the relaxation time τ is given by the rate expression

$$\tau = \frac{h}{kT}\exp\left(\frac{\Delta F^*}{RT}\right) = \frac{h}{kT}\exp\left(\frac{-\Delta S^*}{R}\right)\exp\left(\frac{\Delta H^*}{RT}\right) \quad (1)$$

where h is the Planck constant, k is the Boltzmann constant, T is the absolute temperature, R is the gas constant; ΔF^*, ΔH^* and ΔS^* are the free energy, the enthalpy, and the entropy, of activation for dipole relaxation.

If two relaxation times τ_1 and τ_2 of the same substance are obtained at the same temperature in two different solvents 1 and 2, the ratio τ_2/τ_1 will be given by Eq. 2.

$$\frac{\tau_2}{\tau_1} = \exp\left(\frac{\Delta F_2^* - \Delta F_1^*}{RT}\right) = \exp\left(\frac{\Delta S_1^* - \Delta S_2^*}{RT}\right)\exp\left(\frac{\Delta H_2^* - \Delta H_1^*}{RT}\right) \quad (2)$$

in which ΔF_1^* and ΔF_2^* are the free energies of activation in the two solvents 1 and 2; and similarly, ΔS_1^*, ΔS_2^*, ΔH_1^* and ΔH_2^* represent the entropies and the enthalpies in the corresponding solvents.

In contrast to this, the familar Debye-Stokes equation[3] is expressed by

$$\tau = \frac{4\pi\eta a^3}{kT} \quad (3)$$

in which η is the viscosity of the liquid and a is the radius of the polar spherical molecule. This equation fails to explain why the relaxation time of a given polar molecule obtained in carbon tetrachloride differs from that obtained in cyclohexane in spite of the fact that these solvents have almost the same viscosity (Table I).

On the basis of Eq. 2, however, we can explain the observed difference between two relaxation times as indicating that ΔF_2^* in carbon tetrachloride is much larger than ΔF_1^* in cyclohexane. If ΔS_1^* is not much different from ΔS_2^*, the energy term ΔH^* in the activation process will become larger in carbon tetrachloride. One may say from this that carbon tetrachloride hinders much more effectively the rotation of the solute dipole than cyclohexane does. Perhaps the forces acting between the solute and carbon tetrachloride molecules are fairly large;* indeed, some molecular compounds with appreciable heats of formation have been detected in systems with carbon tetrachloride.[4] It is to be noted in this connection that the difference of ΔF^* by a few hundreds calories per mole results in a considerable difference in dielectric relaxation times.

For this reason dielectric relaxation times might be considered useful clue for studying interactions between the solute and solvent molecules. The present paper deals with an examination on this possibility.

Experimental Apparatus

Dielectric constants and losses are measured at four frequencies, 1 Mc./sec., 9.33 Gc./sec., 24.15 Gc./sec. and 48.00 Gc./sec. The detailed description of the apparatus and the experimental procedure is given in the following. The measurements at 1 Mc./sec. are based on the usual heterodyne beat method.

Measurements at Frequencies 9.33 and 24.15 Gc./sec.—Figure 1 shows the block diagram of 24.15 Gc. apparatus which is based on the standing wave method as developed by Heston, Franklin,

3) P. Debye, "Polar Molecules," Chemical Catalogue, New York (1929), Chapter 5.

* Or, one may consider cyclohexane an anomalous solvent instead (F. Hufnagel and H. Klip, *Z. Naturforsch.*, **18a**, 769 (1963).

4) A. Kuboyama, *Symposium on Electronic States*, **9**, 13 (1954); W. F. Wyatt, *Trans. Faraday Soc.*, **24**, 429 (1928), **25**, 43, 49 (1929); P. Traynard, *Bull. Soc. Chim.*, **12**, 98 (1945).

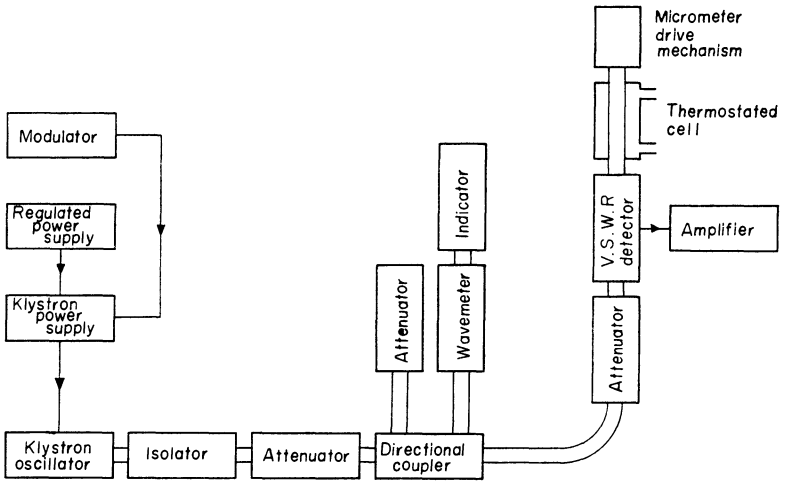

Fig. 1. Block diagram of 24 Gc. apparatus.

Hennelly and Smyth.[5] It consists of a klystron as the energy source, wave guides for transmitting the energy, and a traveling probe for detecting the energy (Fig. 1). A mica window is used in a wave guide to separate the wave guide into two parts, the top part of which forms the dielectric cell into which is put the solution being measured. A micrometer driven plunger is mounted in this cell (Fig. 2). The energy wave entres the wave guide, passes through the liquid, and then comes in contact with open circuited plunger, which reflects the wave back into the wave guide and produces a standing wave.

The experimental process is as follows. With the liquid in the cell and the plunger at the cell window, the traveling probe is set to a minimum

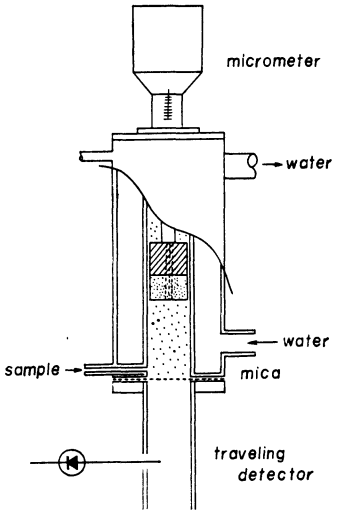

Fig. 2. Dielectric cell for use at 24 Gc.

power position. Then the plunger is turned upward, increasing the depth of the liquid, until another power minimum is noticed, i. e., a second node. The distance between two minima is equal to $\lambda_d/2$. For low loss materials the dielectric constant ε' is given by

$$\varepsilon' = \left(\frac{\lambda_0}{\lambda_d}\right)^2 + \left(\frac{\lambda_0}{\lambda_c}\right)^2 \qquad (4)$$

where λ_c is the cut-off wavelength, λ_0 is the free space wavelength, and λ_d is the wavelength in the dielectric filled guide of the cell.

The dielectric loss is determined by bringing the plunger down to the window and minimizing the powder with the probe. Then the plunger is brought up to the various successive minimum positions and the standing wave ratio, ρ, is measured from the width of the minimum. Values of ρ increase for successive minimum settings n. The dielectric loss factor ε'' is approximated by

$$\varepsilon'' = \frac{\lambda_0^2}{\lambda_d} \cdot \frac{2}{\pi\lambda_g} \cdot \frac{\partial(1/\rho_n)}{\partial n} \qquad (5)$$

Loss Measurements as Frequency of 48 Gc./sec.—The dielectric constants of solutions at this frequency have been measured by the same principle using an apparatus similar to that described in Fig. 1. The dielectric losses at this frequency are measured by use of the transmission method[6] (see Fig. 3). The dielectric cell is made of an inclined rectangular wave guide with a mica window down (Fig. 4). The power transmitted through the dielectric cell filled with solution is measured and compared with the original power

$$T = \frac{\text{Power transmitted}}{\text{Power received}} = e^{-sl} \qquad (6)$$

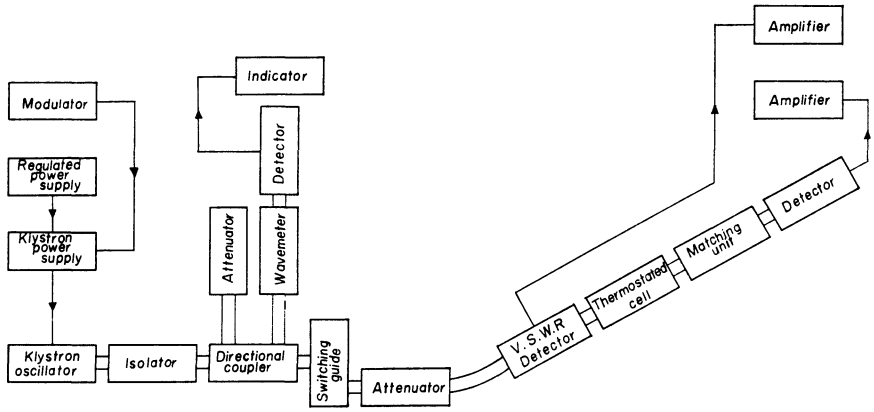

Fig. 3. Block diagram of 48 Gc. apparatus.

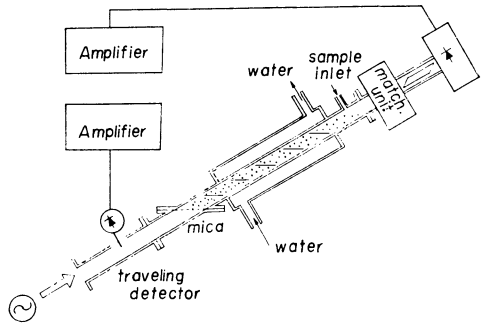

Fig. 4. Dielectric cell for use at 48 Gc.

in which S is defined the attenuation coefficient and l is the depth of the liquid in the cell which can be measured accurately. From values of S the dielectric loss is calculated by

$$\tan \delta = \frac{\varepsilon''}{\varepsilon'} = S \cdot Q \tag{7}$$

and Q is calculable, e. g., for the H_{10} mode

$$Q = \frac{\beta}{(\pi/a)^2 + \beta^2}$$

where β is the propagation constant $2\pi/\lambda_d$ and a is a constant depending on the dimension of the wave guide. From Eq. 6 one obtains

$$S = \frac{1}{l} \ln\left(\frac{1}{T}\right) \tag{8}$$

In order to eliminate the effects due to the meniscus of the liquid surface and the attenuation of the empty cell the measurements were made varying both the liquid depth and the concentration. By use of the attenuation coefficient, T_0, for the empty cell, values $\ln(T_0/T)$ are considered instead of $\ln(1/T)$ and the difference in $\ln(T_0/T)$ between the solution and the solvent is taken always. From these data one is able to calculate the effective value of S in Eq. 8 from which the desired difference in the $\tan \delta$ values between the solution and the solvent is obtained.

Experimental Materials

Aniline was kept in a cold, dark place with sodium hydroxid for several days and distilled under vacuum-(b. p. 81.0°C at 19 mm., n_D^{20} 1.5860). *p*-Nitroaniline was recrystallized with water and completely dried (m. p. 149.6—149.8°C). These materials were purchased from Wako Pure Chemical Industries (G. R. Grade). *N*, *N'*-Dimethylaniline (b. p. 72.3°C at 9 mmHg., n_D^{20} 1.5585), *N*, *N'*-diethyl aniline (b. p. 89.0°C at 8 mmHg., n_D^{20} 1.5420), 2, 6-dimethylaniline (b. p. 92.0°C at 9 mmHg, n_D^{20} 1.5610) and *N*-methylaniline (b. p. 75.0°C at 8 mmHg, n_D^{20} 1.5704) were distilled under vacuum. These four materials were obtained from Tokyo Kasei Kogyo Co., Ltd.

p-Dioxane was first boiled with HCl and water, then was treated with potassium hydroxide, completely dried with sodium and distilled at 101.4°C. n_D^{20} 1.4224, η 1.2836 cp. and ε'/1 Mc. 2.215 at 20°C. Because of the existence of wall losses ε'' were not measured exactly: estimated values are $\varepsilon'' \simeq$ 0.002/9 Gc., 0.004/24 Gc. and 0.005/48 Gc. Benzene was purified and sistilled in a usual manner at 80.3°C. n_D^{20} 1.5011, η 0.6466 cp. and ε' 2.282 at 20°. Apparent ε'' values were 0.0008/9 Gc., 0.003/24 Gc. and 0.004/48Gc. which are due partly to the wall loss and partly to the trace of water which can only be removed by weeks or months of drying treatment.[7] *n*-Hexane was purified and distilled with sodium at 67.8—68.0°C. n_D^{20} 1.3775, η 0.3238 cp. and ε' 1.9016 at 20°C. All these solvents are of G. R. Grade, Wako Chemical Industries.

Experimental Results

For dilute solutions with small concentration range ($c_2 \leq 0.05$), dielectric constant and loss

ε' and ε'' can be expressed as linear functions of concentration.[8]

$$\left.\begin{aligned}\varepsilon' &= \varepsilon_1' + a'c_2\\ \varepsilon'' &= \varepsilon_1'' + a''c_2\end{aligned}\right\} \quad (9)$$

in which c_2 is the weight fraction of a polar solute and ε_1'' is usually considered zero for a non-polar solvent. The polarity of *p*-dioxane is sometimes in question; two values are reported of either zero of 0.3—0.4 D.[9] The ε_1'' values for benzene and *p*-dioxane are insignificant.

The Debye equation for dilute solutions in a nonpolar solvent is expressed as[10]

$$\frac{a^*-a_\infty}{a_0-a_\infty} = \frac{1}{1+i\omega\tau} \quad (10)$$

in which ω is the angular frequency, τ is the relaxation time, a^* is the complex quantity defined by

$$a^* = a' - ia'' \quad (11)$$

And a_0 and a_∞ are the slopes a' at the static frequency and at the very high frequency, respectively. The equation representing a system with the Cole-Cole distribution of relaxation times is as follows.[10]

$$\frac{a^*-a_\infty}{a_0-a_\infty} = \frac{1}{1+(i\omega\tau_0)^{1-\alpha}} \quad (12)$$

in which τ_0 is the most probable relaxation time and α is the Cole and Cole parameter of distribution.

If the dielectric system under consideration is a

	Dioxane	$33._1$	0.17	1.80

superposition of two independent Debye dispersions, that is, if it has two relaxation times, τ_1 and τ_2, we have the following expression.

$$\frac{a^*-a_\infty}{a_0-a_\infty} = \frac{c_1}{1+i\omega\tau_1} + \frac{c_2}{1+i\omega\tau_2} \tag{13}$$

and

$$c_1 + c_2 = 1 \tag{14}$$

Dielectric data concerning aniline and its derivatives are often examined on the assumption of existence of two relaxation times.[11] Equation 13 might preferably be chosen for this reason if there were no risk of arbitrariness in such an analysis.

In the present paper, however, the usual a' and a'' plot[10,12] based on Eq. 12 is used to obtain τ_0 and α values. This is not to say that the Cole-Cole distribution better represents the actual situation. In fact, the a' and a'' plot is a preliminary step taken in view of a small number of data points, but it well afford a clue for finding an average effect of the dielectric relaxation.

Table II shows the values of two slopes, a' and a'', of six substances obtained in dilute solutions of either benzene or dioxane. By the use of a' and a'' recorded in Table II the a', a'' plot in the complex plane was made for each system and thus the average relaxation time τ_0 and the distribution constant α are obtained (see Table III). Dipole moments are also calculated by the Halverstadt-Kumler approximate equation[13] from the measurements at 1 Mc./sec.

It will be seen at the inspection at Table III that the distribution parameter α is not much different from zero throughout; one would feel that the Debye equations for a single relaxation time may be valid. The Debye equations based on a' and a'' are:[10]

$$\frac{a'-a_\infty}{a_0-a_\infty} = \frac{1}{1+\omega^2\tau^2} \tag{15}$$

$$\frac{a''}{a_0-a_\infty} = \frac{\omega\tau}{1+\omega^2\tau^2} \tag{16}$$

Combination of Eqs. 15 and 16 gives another set of equations:

$$\tau = \frac{1}{\omega}\frac{a_0-a'}{a''} \tag{17}$$

$$\tau = \frac{1}{\omega}\frac{a''}{a'-a_\infty} \tag{18}$$

The values of τ of aniline and 2, 6-dimethylaniline, both in benzene, calculated by use of these equations are recorded in Table IV.

It is interesting to find a gradual decrease of

TABLE IV. RELAXATION TIMES (p. sec.) CALCULATED FROM MEASUREMENTS AT A SINGLE FREQUENCY BY Eqs. 15—18

Equation	Data used	Frequency (Gc./sec.) 9.33	24.15	48.00
Aniline in benzene ($a_\infty=1.07$)				
I (Eq. 15)	$a'a_0\,a_\infty$	7.1_8	6.8_8	5.6_2
II (Eq. 16)	$a''a_0\,a_\infty$	7.6_9	7.2_3	5.5_1
III (Eq. 17)	$a'a''a_0$	6.8_5	6.9_0	5.5_7
IV (Eq. 18)	$a'a''\,a_\infty$	7.5_2	6.8_6	5.6_8
2,6-Dimethylaniline in benzene ($a_\infty=0.80$)				
I (Eq. 15)	$a'a_0\,a_\infty$	10.9_1	11.5_4	12.9_6
II (Eq. 16)	$a''a_0\,a_\infty$	10.6_7	14.3_1	8.8_7
III (Eq. 17)	$a'a''a_0$	11.0_2	13.0_8	9.4_9
IV (Eq. 18)	$a'a''a_\infty$	10.8_1	10.1_9	17.6_9

11) E. L. Grubb and C. P. Smyth, *J. Am. Chem. Soc.*, **83**, 4879 (1961); H. Kramer, *Z. Naturforsch.*, **15a**, 974 (1960); P. Knobloch, ibid., **20a**, 854 (1965).
12) A. D. Franklin, W. M. Heston, Jr., E. J. Hennelly and C. P. Smyth, *J. Am. Chem. Soc.*, **72**, 3447 (1950).
13) I. F. Halverstadt and W. D. Kumler, *J. Am. Chem. Soc.*, **64**, 2988 (1942).

the values of aniline with increase in the frequency; this tendency suggests that there may be another dispersion in the range of higher frequency which the a', a'' plot fails to detect. The observed a'' value at 48 Gc./sec. being too large the a', a'' plot is not satisfactory for 2, 6-diemthylaniline. An examination of τ values in Table IV shows that Eqs. 16 and 17 based on the use of a'' give smaller values of about 9 p. sec. This result is just as expected, however, the use of Eqs. 15 and 18 gives even a higher value than τ_0 11.0 p.sec.*

Discussion

The relaxation times of aniline measured in three solvents increase in the order: hexane 5.0 p.sec., benzene 6.7 p.sec. and dioxane 19.4 p.sec. This trend in τ values is in accordance of the order of viscosities of the solvent, hexane 0.3238 cp., benzene 0.6466 cp., and dioxane 1.2836 cp. which are approximately in the ratio of 1 : 2 : 4. It may be noticed, however, that the change of viscosity from hexane to benzene does not produce much change in relaxation time while its further change to *p*-dioxane resulted in a significant increase.

The effects of viscosity on the relaxation time have been studied in great detail,[14] and it has been confirmed that they are not usually so great as expected from Eq. 3. The observed increase of τ values from hexane to benzene may be regarded as normal.** On the contrary the appreciable increase of τ in dioxane may be considered anomalous, that is, this is an indication, one may infer, that there exists some other factor than the viscosity effect which contributes to the large value of aniline in dioxane.***

In order to examine the above point in more detail the ratio of the relaxation time τ_D obtained in dioxane to that of τ_B in benzene is calculated for six substances (A, B, C, D, E and F) and the result is shown in Table V.

It will be seen that the lowest τ_D/τ_B values are found in *N, N'*-dimethylaniline (B) and *N, N'*-diethylaniline (C). In these molecules two hydrogen atoms of the NH_2 group in aniline are replaced by two methyl or two ethyl radicals, both being inactive in the hydrogen-bonding effect.

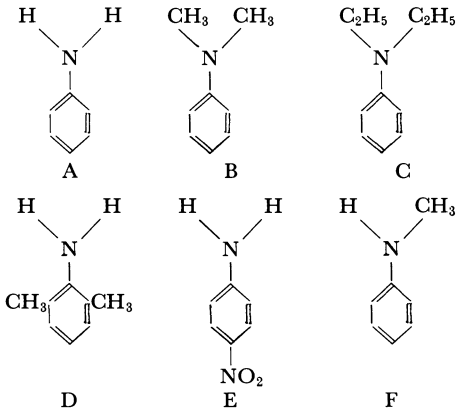

TABLE V. RATIOS OF RELAXATION TIMES, DIFFERENCES OF DIPOLE MOMENTS AND INTERACTION ENERGIES

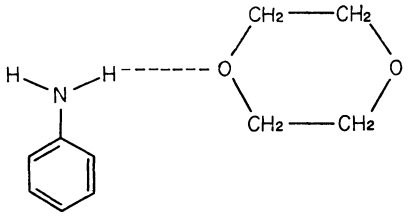
Substance	τ_D/τ_B	$\mu_D-\mu_B$	ΔF^* cal./mol.
Aniline (A)	2.90	0.25	640
N, N'-Dimethylaniline (B)	2.10	0.07	430
N, N'-Diethylaniline (C)	1.43	0.08	210
2,6-Dimethylaniline (D)	2.74	0.27	590
p-Nitroaniline (E)	4.63	0.61	900
N-Methylaniline (F)	2.21	0.15	460

In *N*-methylaniline (F) one finds the ratio τ_D/τ_B to be intermediate between that of aniline (A) and those of *N, N'*-disubstituted anilines (B and C). These results seem to indicate the formation of bonds between amino-hydrogen atoms in aniline and an oxygen atom of the dioxane molecule which leads to a high relaxation time in dioxane.



(I)

The hydrogen bond between the solute and the solvent becomes stronger with an increase in the electropositive nature of the aminohydrogen atoms. Indeed, this occurs in *p*-nitroaniline (E), because the molecule has a considerable contribution from the resonance structure II which has the formal positive unit charge at the nitrogen atom of the amino group.[15] Consequently the hydrogen

* The values a_∞ used in the above estimation of τ are obtained from intercepts of the a', a'' plot (Fig. 5)—it should be noted that a proper choice of a_∞ is very important in this calculation. See K. Higasi and O. Kiyohara, *Bull. Inst. Appl. Elec.*, **19**, 24 (1966).

** This statement is only approximately true, because interaction between solute and benzene is sometimes appreciable.

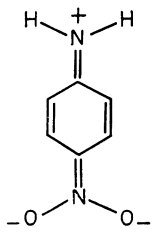
*** The hydrogen bonding of aniline has been studied by several workers, e. g., from ultraviolet study, J. C. Dearden and W. F. Forbes, *Can. J. Chem.*, **38**, 896 (1960); H. Baba, Private communication; By N. M. R., B. N. Rao et al., ibid., **40**, 963 (1962), and by dipole moment see Refs. 16 and 17.

14) See, for instance, K. Chitoku and K. Higasi, This Bulletin, **36**, 1064 (1963); K. Higasi, "Dipole Molecules and Chemistry," Hokkaido University, Sapporo (1965), Chapter 1; Krishnaji and A. Mansingh, *J. Chem. Phys.*, **42**, 2503 (1965).

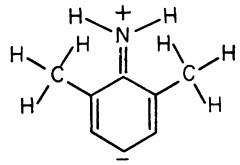
15) Y. Tsuzuki and K. Higasi, *Sci. Papers Inst. Phys. Chem. Res.*, **39**, 185 (1941).

bonding with dioxane is much stronger, producing the highest ratio of τ_D/τ_B for E in Table V.

Contrary to this the resonance structure III for D is less stabilized because of the steric effect of methyl groups. A slightly smaller ratio τ_D/τ_B for 2,6-dimethylaniline than that of aniline may be accounted for by this reason. To sum up, one would expect from the tendency of hydrogen bonding that the ratio τ_D/τ_B will have the order E>A>D>F>B≃C, while the observed order is: E>A>D>F>B>C, in good accord with the anticipation.



(II)



(III)

In Table V the differences between the dipole moments of the same substances measured in dioxane and benzene are recorded. It will be seen that the differences, $\mu_D-\mu_B$, has the order E>A≃D>F>B≃C again in fair agreement with the observed order of τ_D/τ_B. The values $\Delta\mu=\mu_D-\mu_B$ obtained by Smith and his co-workers[16] are E 0.62D>A 0.24D>F 0.18D>B 0.06D again in good agreement with the corresponding values in Table V.

The dipole moments of the 1 : 1 complex of aniline-dioxane is estimated as about 1.88D.[17] On forming a hydrogen bond between aniline and dioxane the apparent dipole moment increases on account of the electron migration effect from the benzene nucleus toward the amino group.[16] And this migration is most pronounced in *p*-nitroaniline (E), next in aniline (A) or in 2, 6-dimethylaniline (D) and then in *N*-methylaniline (F) while no such migration is possible in the remaining substances (B and C).

Next we shall turn to a question what we can conclude from this study on the binding energy of the hydrogen bond between the solute and solvent. By the use of Eq. 2 the value $(\Delta F_2^*-\Delta F_1^*)=\Delta\Delta F^*$ is obtained from τ_D/τ_B—this would represent $\Delta\Delta H^*\simeq\Delta H_2^*-\Delta H_1^*$ if $\Delta S_1^*\simeq\Delta S_2^*$. For aniline (A) $\Delta\Delta F^*$ amounts to 640 cal./mol. which must be associated with both the hydrogen bonding and the viscosity effects. If the latter effect is estimated as about 300 cal./mol., (an average of $\Delta\Delta F^*$ values for two non-hydrogen-bonding substances, B and C) the remaining value 340 cal./mol. may be regarded as arising chiefly from the hydrogen-bonding interaction between the solute and solvent molecules. The same estimation is made for other molecules with the result:

E 600 cal./mol.>A 340 cal./mol.>

D 290 cal./mol.>F 160 cal./mol.

The system of aniline and *p*-dioxane was studied by Few and Smith[17] by the polarization method. According to their estimate about 65% of the aniline is in the form of 1 : 1 complex with dioxane at infinite dilution in dioxane. The measured value $\Delta\Delta F^*$ is associated with the equilibrium mixture; and the energy difference for the complex $\Delta\Delta F^*$ (or possibly $\Delta\Delta H^*$) would be of the order of about 500 cal./mol.

Feodosév and Andreeva[18] found the heat of formation of the aniline-dioxane complex as 0.72 kcal./mol. from an isothermal calorimetric measurement of mixing heats. It is of interest to note that these values, $\Delta\Delta F^*$ (or $\Delta\Delta H^*$) and ΔH are of the same magnitude, although they refer to different mechanisms of the same origin. Both ΔF^* and ΔH^* are associated with the activation for dipole rotation[2] and even $\Delta\Delta H^*$ is not equal to ΔH in this sense, because the former is a part of the hydrogen-bonding energy effective in hindering the dipole rotation.

In Table VI the slopes a_0, a_∞ and a_D are recorded. The a_0 and a_∞ values, which are defined as the slopes a' at the static field and at the very high frequency, respectively, are obtained from the two intercepts of the semi-circles of the a', a'' plot with the abscissa in the complex plane (Fig. 5). The a_D values are obtained from refractivity measurements of dilute solutions and are given by $n^2=n_1^2+a_Dc_2$. Compare this equation with Eq. 9.

It will be seen at Table VI that the differences, $a_\infty-a_D$, are fairly large in some substances (A, D, E, etc.) in which they are not so small as expected to be arising from atomic polarizations.

	Dioxane	4.41	0.62	0.47	0.15

The dipole moment of a polar molecule is approximately given by

$$\mu = B(a_0 - a_D)^{1/2} \tag{19}$$

where

$$B = \frac{1}{2(\varepsilon_1 + 2)} \sqrt{\frac{27 M_2 \boldsymbol{k} T}{\pi \boldsymbol{N} d_1}} \tag{20}$$

when the concentration c_2 is expressed in the units of weight fraction.[19] The symbols M_2, d_1, $\boldsymbol{k}$, T, $\boldsymbol{N}$, etc. have the usual significance.

If the dipole moment associated with τ_0 and α is expressed by μ_0, one may calculate μ_0 by

$$\mu_0 = B(a_0 - a_\infty)^{1/2} \tag{21}$$

and one will find that μ_0 is smaller than μ, sometimes beyond the possible errors. If this difference is anomalously large, we shall suspect whether or not there is another dielectric absorption in the region of the higher frequency. Should such an extra absorption exist, the extra component of the molecular dipole moment would be estimated by

$$\mu^2_{\text{extra}} = \mu^2 - \mu_0^2 = B^2(a_\infty - a_D) \tag{22}$$

The value B of aniline in benzene is about 1.0D at room temperature and hence, μ_{extra} amounts to 0.9D. Caution must be taken if we find a large difference, $a_\infty - a_D$; this point is very important requiring for more detailed analysis. For instance. aniline is believed to have an absorption in the region of a very short wavelength of about 1 mm.[20]; and also from the present measurement at 48 Gc./sec. a very small value of about 1 p.sec. for aniline in benzene is calculated by use of $a_D = 0.20$ and Eq. 16. More experimental data in the millimetre wave region are desirable to characterize the dispersion of a very small relaxation time.

The present work has dealt with the "probable" relaxation time in the main dispersion region and found that this relaxation time becomes much larger when a hydrogen bond is formed between the solute and solvent molecules.

Thanks are due to Professor Hiroaki Baba for helpful discussion and Mr. Kiyoshi Uchiyama for measurements of static dielectric constant, density and refractive index.

20) C. P. Smyth, Private communications. See also Ref. 11, P. Knobloch who gives $\mu_{\text{extra}} \simeq \mu_2 = 0.9$D with $\tau_2 = 0.5$ p.sec. by use of a_D.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2169—2172 (1966)

The Simultaneous Extraction and Spectrophotometric Determination of Rhodium(III) with 2-Thenoyltrifluoroacetone

By Asha V. RANGNEKAR and S. M. KHOPKAR

Department of Chemistry, Indian Institute of Technology, Bombay, India

(Received September 8, 1965)

A method has been described for the extractive spectrophotometric determination of rhodium(III) with 2-thenoyltrifluoroacetone (TTA) in an acetone-xylene mixture. The bright yellow rhodium(III)-TTA chelate solution in an acetone-xylene solvent mixture obeys Beer's law over the concentration range of 1.95—19.5 μg. of rhodium per ml. Around pH 6.0 quantitative extraction is possible with 0.015 M TTA - acetone - xylene. The colour of the complex is quite stable up to 72 hr. Rhodium(III) can be extracted in the presence of a large number of ions.

Of the β-diketones used as chelating agents, 2-thenoyltrifluoroacetone (TTA) has proved to be one of the most versatile chelating and extracing agents for the liquid-liquid extraction and spectrophotometric determination of numbers of elements.[1] During the solvent extraction studies of palladium[2] with this reagent, it was found that rhodium(III) also gives a bright yellow-coloured complex in a TTA-acetone mixture in the presence of xylene.

The separation of rhodium from iridium, lanthanum, cerium and zirconium was accomplished by using pyridine.[3] Similarly, the pyridine-thiocyanate complex[4] in hexone was measured spectrophotometrically at 380 mμ. The extractive separation of rhodium from iridium in a hydrobromic-perchloric acid solution was carried out with isopentyl alchool.[5] The separation of rhodium(III) from platinum and palladium was done with diantipyrylpropyl methane.[6] Linder[7] attempted the extraction of rhodium with 0.50 M TTA - acetone - benzene solutions, but the method proved to be laborious and time consuming. So far no systematic work has been carried out on the simultaneous extraction and spectrophotometric determination of rhodium with TTA.

In this paper a method will be described for the liquid-liquid extraction of rhodium at micro-levels with a 0.015 M TTA - acetone - xylene solution. The optinum conditions, as established from the critical investigation of various influencing factors, will also be presented.

Experimental

Apparatus and Reagents.—A type C♯ϕ 4 quartz spectrophotometer with 10-mm. quartz cells and a Cambridge pH meter (Marshal model were used).

2-Thenoyltrifluoroacetone (B. D. H. Anal R), about a 0.015 M solution in acetone, was used. A stock solution of of rhodium(III) was prepared by dissolving one gram of $RhCl_3 \cdot 3H_2O$ (Johnson Matthey and Co., Ltd., London) in 500 ml. of water containing ~0.5% hydrochloric acid. The solution, on standardization,[8,9] was found to contain 78.2 μg. of rhodium per ml.

General Procedure.—An aliquot of a rhodium chloride solution containing about 78.2 μg. of rhodium per ml. was taken. Then 0.1 ml. of 60 per cent perchoric acid was added to the solution. The pH of the solution was then adjusted to the desired pH by the addition of 0.01 M hydrochloric acid or 0.01 M sodium hydroxide. The final volume of the aqueous phase was made up to 25 ml. in each case.

During the studies of the effect of salting-out agents or diverse ions, each one of them was added to the solution before the adjustment of the pH value.

The solution, after adjustment to pH=6.0 unless otherwise specified, was transfered to a 250-ml. separatory funnel. Then 10 ml. of 0.015 M TTA in acetone was added to it. Immediately after the addition of the reagent, 10 ml. of xylene was added to the mixture. After the separatory funnel had been properly stoppered, it was shaken briskly for about 10 min. The layers were then allowed to settle and separate. The organic phase was carefully withdrawn to a 10-ml. volumetric flask. The absorbance of a bright yellow-coloured complex was measured at 430 mμ against the

reagent blank. The amount of rhodium present was calculated from the Beer's law plot.

The reagent blank was prepared as follows, 10 ml. of 0.015 ml. TTA - acetone was equilibrated with 10 ml. of xylene. The phases were then allowed to settle and to separate. The organic phase was used directly as the reagent blank.

Results and Discussion

Absorption Spectra.—The absorption spectrum of the solution of the rhodium(III)-TTA complex (Rh=7.60×10^{-6} M) is shown in Fig. 1. The

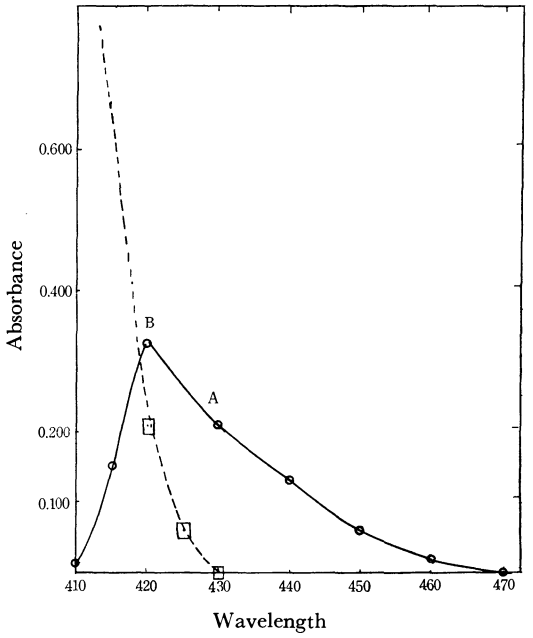

Fig. 1. Absorption spectra.
A. Absorption spectrum of Rh(III) - 2-Thenoyltrifluoroacetone chelate in acetone-xylene mixture. Rh(III)=7.60×10^{-6} M, TTA=1.5×10^{-3} M, pH=6.0 versus reagent blank.
B. Absorption spectrum of the reagent blank solution versus solvent mixture.

bright yellow rhodium(III)-TTA solution absorbs strongly around 420 mμ. The reagent blank at this wavelength also shows some absorbance. The absorbance of the complex gradually decreases, until it becomes negligible beyond 480 mμ. The reagent itself shows an insignificant absorbance at 430 mμ; hence, all the absorbance measurements were carried out at this wavelength. The molecular extinction coefficient at 430 mμ, on the basis of rhodium contents, is 276±9.5. On account of strong absorbance of the reagent itself, tests were not made below 410 mμ.

The Effect of the Amount of Acetone in the Solvent Mixture.—The complex of rhodium with TTA is soluble in acetone and, although very little, in xylene. The addition of xylene to the aqueous phase extracts the complex into the organic phase. Acetone is miscible only in the aqueous phase. The solubility of the acetone in the organic phase at the pH of extraction is practically negligible. Hence, for all practical purposes, it may be assumed that the volume of an organic phase, namely, 10 ml. of xylene, is the same both before and after the extraction of rhodium.

For the clean-cut separation of two layers, the ratio of acetone to xylene must, however, be controlled. From the experimental observations it was found that the optimum ratio of acetone to xylene is 1 : 1 (by volume). If the ratio is changed from 1 : 1 to 1 : 2 or 1 : 3 or even more at the time of extraction, the enhanced volume of xylene in the organic phase produces turbidity and inhibits the colorimetric determination of rhodium.

The Effect of the pH Value.—The solvent extraction behaviour of the rhodium(III)-TTA system was studied over the pH range from 1.0 to 7.0. On plotting the graph of the percentage extraction as the function of pH (Fig. 2), it was observed that the extraction commences around pH ~2.0; then it steadily increases, becoming quantitative around pH=6.0. In the pH region of 2.5—3.5, the extraction is quite large, but incomplete, while in the pH region from 5.2 to 6.2 the extraction tends to be complete. It is possible to extract rhodium(III) quantitatively at pH 6.0 with 0.015 M TTA - acetone in the presence of

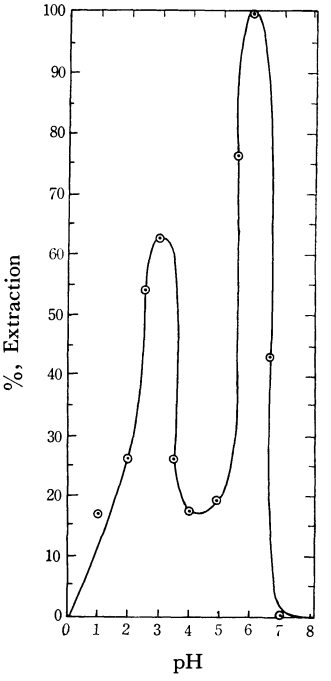

Fig. 2. Extraction of Rh(III)-TTA complex with acetone-xylene as the function of pH.

xylene. It is not worthwhile attempting extraction at pH >6.5, however, as rhodium may precipitate as the hydroxide. Furthermore, the extraction curve drops sharply beyond pH 6.5 and terminates at pH 7.0; the pH of the solution remains unaltered after extraction in the pH region of 1.0—7.0. Moreover, the reagent, TTA, possesses the advantage of being very effective in the acid regions as compared with other β-diketones.[10]

The Effect of Salting-out Agents.—Such salting-out agents as chlorides of magnesium, barium, sodium and potassium were tested in order to observe their effect on the extraction of rhodium by TTA (Table I). It was found that

Table I. Effect of salting-out agents

Salting-out agent	Concn.	Absorbance at 430 mμ	% Extraction
None	—	0.210±0.010	100
$MgCl_2$	1 M	0.155	73.8
$BaCl_2$	1 M	0.100	47.6
NaCl	1 M	0.210	100
KCl	1 M	0.100	47.6
$HClO_4$ 60%	0.10 ml.	0.210	100
	0.15 ml.	0.195	92.8
	0.2 ml.	0.195	92.8

none of them have a pronounced effect upon the extractability of rhodium. The effect of the addition of different volumes of 60% perchloric acid on the extractability of rhodium was also studied. The presence of perchloric acid in the aqueous phase enhances the extraction. This may be explained as follows:—

i) It might provide a higher concentration of the complexing anion in the system, a concentration which, by mass action, would increase the concentration of the complex and enhance the extraction, or

ii) The dielectric constant of the aqueous phase might decrease with an increase in the ionic concentration, or

iii) By binding of the water molecules by the anions, it might become unavailable as a free solvent, or

iv) It may have a pronounced effect upon the activity coefficient of the ions participating in the formation of the complex.

In general, large ionic size and the charge of an ion such as the perchlorate ion play an important role in enhancing the extraction.

Beer's Law Plot.—The absorbance of different amounts of rhodium(III) extracted at pH 6.00 were noted against the reagent blank at 420, 430, and 440 mμ. The results in Table II show that

Table II. Beer's law

Rhodium(III) taken, μg.	420 mμ	430 mμ	440 mμ
62.56	0.260	0.170	0.120
78.20	0.310	0.210	0.130
101.66	0.430	0.280	0.200
117.30	0.490	0.320	0.250

the system conforms to Beer's law at 430 mμ over the concentration range of 1.95—19.5 μg. of rhodium per ml.

The Stability of the Colour of the Complex.—The absorbance of an acetone-xylene solution of a rhodium-TTA complex was measured at 430 mμ at lapsed times of 1, 2, 4, 7, 16, 24, 48, 72 and 96 hr. The corresponding absorbances were 0.210, 0.210, 0.210, 0.210, 0.210, 0.210, 0.210, 0.215 and 0.220. This clearly shows that the colour of the complex is quite stable up to 72 hr. It undergoes about a 2.1% decomposition beyond this time.

The Effect of Different Concentration and Volumes of the Reagent.—The effect of varying volumes as well as varying concentrations of the reagent on the extraction behaviour was studied. The results in Table III show that in no case does acetone play a vital role in influencing the extractability of rhodium, either at varying volumes and at varying concentrations of the reagent. It can be also seen that the use of 5, 10 or 20 ml. of 0.015 M TTA gives a constant value for the absorbance when the rhodium concentration is kept constant. This amply supplements the above observation.

Table III. Effect of different volume and concentration of the reagent
(Rh=78.2 μg., pH=6.0)

TTA concn. M	TTA added ml.	Absorbance at 430 mμ
0.015	10	0.210±0.010
0.015	20	0.210
0.015	5	0.210
0.015	2	0.0
0.0015	10	0.030
0.0075	10	0.080
0.010	10	0.150
0.025	10	0.220
0.050	10	0.235

Since the absorbance at 0.015 M TTA is quite large, it is recommended that this concentration be used in all the determinations in preference to the higher concentration of the reagent. Moreover, the latter are also uneconomical.

The use of lower concentrations, such as 0.0075 and 0.0015 M, are unsuitable, as very little of the reagent is actually available for the complete

a) Interference eliminated by complexation with EDTA.
b) Interference eliminated by formation of cyanide complexes.
c) Interference eliminated by anion exchange resin.

complexation of the metal ion, resulting in incomplete extraction.

The Effect of Diverse Ions.—The effect of the presence of diverse ions on the extraction of rhodium was also studied. It was seen that lead, aluminum, beryllium, thorium, thiosulphate, EDTA(-disodium salt), acetate, oxalate, phosphate showed no interference (Table IV). However, the ions giving characteristic colour reactions with TTA, such as copper, cerium, uranium, iron, cobalt, nickel and chromium, interfere. The interferences due to common cations, such as copper, cobalt, iron, and nickel, can be eliminated by converting them into suitable anionic cyanide complexes, which, in general, are not extracted by this reagent. Similarly, the interferences due to such ions as thallium, chromium, zinc, and manganese can be eliminated by converting them to suitable anionic EDTA complexes. The interferences due to a few anions can be eliminated by passing the solution over a strongly basic anion exchange resin such as Dowex 1-X8 before the extraction step.

About 78.2 μg. of rhodium was taken up and extracted as per the "general procedure" at pH 6.0. The organic phase was separated, and the absorbance of a bright yellow-coloured complex was measured at 430 mμ. From eight runs with 78.2 μg. of rhodium(III), the absorbance noted was 0.210+0.010. The standard deviation was ±1.2%. The method permits the simultaneous extraction and spectrophotometric determination of rhodium within 30 min. As little as 76 γ of rhodium per ml. can be detected.

Continuous Determination of Nitric Oxide and Nitrogen Dioxide in the Atmosphere

By Saburo YANAGISAWA,*1 Noboru YAMATE,*2 Shumpo MITSUZAWA*3 and Masaki MORI*4

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei, Tokyo

(Received October 9, 1965)

Continuous determinations of nitric oxide and nitrogen dioxide in the atmospheric air by the use of a modified Saltzman reagent will be described. Measurement was made intermittently, once every 30 min., by an automatic continuous analyzer equipped with a single-path colorimeter. The response of the analyzer was obtained as an average of the concentration of nitrogen oxides over a period of 25 min. Two bubblers were used for absorbing nitrogen oxides into the modified Saltzman reagent, whose transmittance was measured for the determination. One bubbler was designed to absorb nitrogen dioxide, and the other, nitric oxide plus nitrogen dioxide after the oxidation of the nitric oxide by permanganate. The oxidizing efficiency of the permanganate was 96—100 per cent. The acetic acid in the Saltzman reagent was replaced with *n*-propyl alcohol in the modified Saltzman reagent; the spontaneous coloration and corrosive quality of the reagent was decreased by this substitution. The concentration of nitric oxide was obtained from the difference between the two responses of the analyzer, while the concentration of nitrogen dioxide could be read directly from the indication of the recorder. The transmittance ratio method was applied to the measurements, accurate determinations were possible, even at high blank values. Therefore, the reagent was used repeatedly by cycling it on the basis of measuring the difference in the coloration of the reagent before and after the absorption of nitrogen oxides. The analyzer could be used for a long period without changing the reagent.

The maximum allowable concentration and the warning concentration of nitrogen dioxide are 5 p. p. m. and 0.5 p. p. m. respectively,[1] but those of nitric oxide are not known in the present stage of our knowledge. As these oxides are interchangeable under atmospheric conditions, the determination of nitric oxide should be made together with that of nitrogen dioxide for purposes of air-pollution control.

Some apparatuses for the determination of nitrogen dioxide have been designed by several researchers.[2,3] Among these Thomas and his coworkers developed a continuous-determination apparatus for both nitrogen oxides provided with a triple-path colorimeter.[4] A continuous analyzer for nitrogen oxides equipped a single-path colorimeter will be described in this paper.

This analyzer determines the amoung of nitrogen oxides once every 30 min. by integrating them in the liquid absorber, whose transimittance is measured for the determination of the nitrogen oxides. A transmittance ratio method developed by Hisky[5] and by Bastian[6] was applied to the analyzer accurate measurements were then possible, even at high values of the blank. The absorber can be repeatedly used in the system, and the differences in the transmittances of the liquid, before and after the absorption of the gases, indicate the average concentrations of the nitrogen oxides during the period being considered.

Nitrogen dioxide gives color to the color-developing reagent, which is simultaneously the absorber of the gas, and nitric oxide reacts with the reagent after being oxidized to nitrogen dioxide by a sulfuric acid solution of potassium permanganate. Saltzman reagent was modified and successfully used for this purpose.

g. of sulfanilic acid, 1 g. of *N*-(1-naphthyl)-ethylenediamin dihydrochloride, and 200 ml. of *n*-propyl alcohol (or *s*-butyl alcohol) into distilled water, and then make up the volume to 20 l.

Standard Solution.—Dissolve 0.154 g. of sodium nitrite, which has been dried at 105—110°C for 3 hr., into distilled water, and make up the volume to 1 l.; then dilute 10 ml. of this solution to 1 l. Each milliliter of the solution thus prepared is equivalent to 0.001 ml. of nitrogen dioxide gas in the standard state (0°C, 760 mmHg).

Oxidizing Solution.—Dissolve 25 g. of potassium permanganate in 500 ml. of a 2.5% solution of sulfuric acid.

The Modification of Saltzman Reagent

Saltzman reagent[7] is prepared by dissolving 100 g. of sulfanilic acid, 1 g. of *N*-(1-naphthyl)-ethylenediamine dihydrochloride and 100 ml. of acetic acid into distilled water, and making up the volume to 20 l. This reagent is colored spontaneously over a long period; this color interferes with the measurement of the absorbance of the reagent-NO_2 complex. This reagent also corrosively attacks the metallic and plastic parts of the analyzer. Thus, acetic acid was eliminated from the reagent in order to avoid the corrosion of the apparatus. On the other hand, 200 ml. of *n*-propyl alcohol (or *s*-butyl alcohol) was tentatively added to lower the surface tension of the reagent and to increase its gas-collection efficiency, for the reason that the acetic acid was added to Saltzman reagent was to minimize the surface tension of the reagent. Moreover, the acetic acid in Saltzman reagent lowers the pH of the solution. However, it was found that the pH of the solution was sufficiently low even if acetic acid was omitted, as it was 1.5.

The changes in the spontaneous coloring with the time of Saltzman reagent and the modified reagent are shown in Table I. It is believed that the discoloration is accelerated by the light and the temperature. In view of this, the reagent solution tanks in the equipment were all made dark boxes.

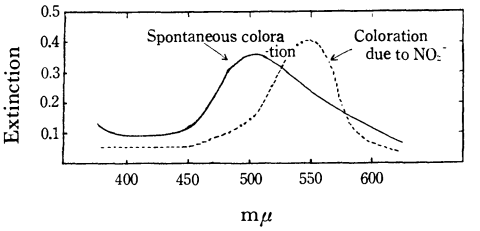

Fig. 1. Spontaneous coloring of Saltzman reagent.

Saltzman reagent and the modified reagent take, respectively, 12 min. and 15 min. to reach a full color development at 20°C. The gradient of the working curve resulting from the modified reagent was 10.6 % lower than that from Saltzman reagent.

Oxidation of Nitric Oxide

The reagent is colored by a coupling reaction with nitrogen dioxide, but not by nitric oxide, so nitric oxide must be oxidized before the reaction with the reagent.

There have previously been established three ways to oxidize nitric oxide; gas-phase oxidation, by a solid catalyzer, and liquid-phase oxidation. It is known that the oxygen-oxidation or air-oxidation method is effective in oxidizing nitric oxide

7) B. E. Saltzman, *Anal. Chem.*, **32**, 135 (1960).

of a higher concentration,[8] but the reaction takes place very slowly for nitric oxide of a lower concentration, such as one in atmospheric air; this method of oxidation, therefore, is not applicable to the continuous determination of nitric oxide in atmospheric air.[9] Thomas reported that an ozone concentration of 0.3 p. p. m. was suitable for oxidizing the air sample in his continuous analyzer,[4] but it is not easy to keep the concentration of ozone constant, and, furthermore, ozone decomposes the reagent sometimes it even oxidizes the atmospheric nitrogen. Therefore, the ozone-oxidation method was not used in this research.

Silica gel and active carbon are often used as oxidizing agents of nitric oxide,[10] but they are not preferably used because they are effective only for nitric oxide of a higher concentration, and also because they absorb nitrogen dioxide. Among the liquid-phase oxidizing agents, potassium permanganate in a sulfuric acid solution, potassium bichromate in a sulfuric acid solution, and hydrogen peroxide in a sulfuric acid solution, etc., 2.5% of potassium permanganate dissolved in 2.5% sulfuric acid has been used by several researchers for the oxidation of nitric oxide with Saltzman reagent.[11,12]

The oxidizing agant is placed in a vessel made of glass, and the air sample is bubbled through a ball filter of fritted glass (G-1), 30 mm. in outside diamater.

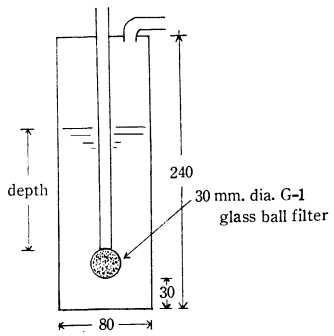

Fig. 2. The oxidation vessel.

The relation between the oxidizing efficiency and the depth of the oxidizing liquid is shown in Table II.

Table II. The relation between the depth of the oxidizing liquid and the oxidizing efficiency

Depth of liquid cm.	Volume of liquid ml.	Oxidizing efficiency: 2.5% $KMnO_4$-2.5% H_2SO_4 solution	Oxidizing efficiency: 2.5% $KMnO_4$-15% H_2SO_4 solution
5	270	96%	100%
9	560	100%	100%
15	840	100%	100%

In these experiments 2.7 p. p. m. of nitric oxide in nitrogen was passed through at a rate of 150 ml./min. for 5 min. As is shown in Table II, the oxidizing efficiency is higher at higher concentrations of sulfuric acid, at which concentrations the oxidizing reagent decomposes itself over a long period. 2.5% sulfuric acid was used for the practical oxidation by placing a glass tube with a ball filter of fritted glass deeper than 10 cm. below the surface of the oxidizing liquid, through this tube the air sample was dispersed into the liquid.

Apparatus

A schematic diagram of the gas and liquid flow system is show in Fig. 3, while the program of the operation of the analyzer is shown in Table III. The valves (V_1—V_5) are operated for the periods indicated in Table III; the analysis operation advances toward the right with the passage of time, and the solenoid valves, the timer, the piston pump and the programmer motor are actuated in the framed parts.

The gas-absorbing bubbler is shown in Fig. 4. The air sample is introduced into the absorbing bubbler, which contains 50 ml. of the reagent,

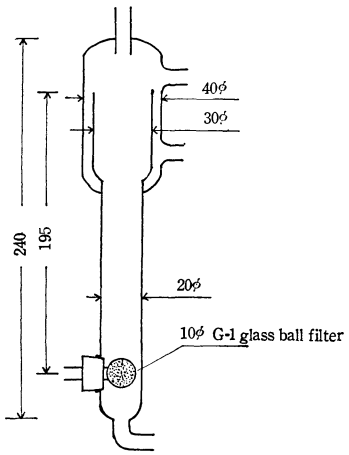

Fig. 4. The absorbing bubbler.

the volume being measured by an over-flow system. The absorbing efficiency of this bubbler by gas sample was 96—98% under the actual conditions of analysis.

The air sample is divided into two parts, one is led into the first bubbler directly, while the other is led through the oxidizing liquid to the second bubbler. The air sample is bubbled for 25 min. at a constant rate of 150 ml./min. by means of a piston pump. The nitrogen dioxide in the air sample is integrated during a 25 min. period in the first bubbler, and both nitric oxide and nitrogen dioxide, in the second bubbler. Then, the transmittances of the reagents for the determinations of nitrogen oxides are measured in a colorimetric cell in the order of the reagent blank, the reagent colored by nitrogen dioxide, and that colored by both nitrogen dioxide and nitric oxide. The ratios of the transmittances of the working reagents, which show the concentrations of nitrogen dioxide and of nitric oxide plus nitrogen dioxide, are plotted on the recorder in a logarithmic scale as the averages of 25-min. measurements. The concentration of nitric oxide is obtained by subtracting the concentration of nitrogen dioxide from that of the sum of nitric oxide and nitrogen dioxide.

Thomas used the reagent repeatedly by treating it with active carbon,[4] but generally the reagent used for the continuous determination is discarded without re-processing.[2,3] In this experiment, the reagent was not re-processed and used repeatedly, and the reagent blank was determined in each determination, for the re-processing system was considered not very reproducible and it might make the apparatus rather complicated. Correct determinations can be made in the range of the linear part of the calibration curve, even if the reagent itself is colored; therefore, a transmittance-ratio method[5,6] was applied to the analyzer, and accurate measurements were possible even at higher values of the blank. The larger volume of the reagent reservoir could be helpful for a long-run determination. The reagent was replaced when it reached a definite absorbance, as was determined by monitoring by an absolute transmittance meter.

The electric circuit is shown in Fig. 5.

In the first step, the blank reagent is led into the colorimetric cell, and the switch, S, is connected to (1); at this stage a voltage corresponding to a

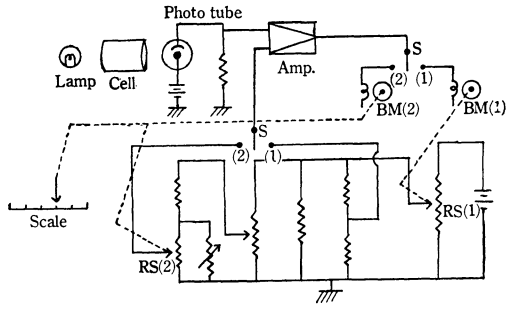

Fig. 5. Diagram of instrument circuit.

photo-current appears at both ends of the sliding resistance, RS(2), as a result of automatical balancing by RS(1). Then, the reagent colored is led to the cell; a voltage corresponding to the photo-current in this stage is represented by the position of the contact point of the sliding resistance when the switch, S, is connected to (2). The transmittance ratio of two optical measurements are represented by the voltages in this stage of the resistances. Then, each transmittance ratio of the reagents, that of nitrogen dioxide to the blank and that of nitrogen dioxide plus nitric oxide to the blank, is plotted on the recorder separately, and the indications are read out in a logarithmic scale graduated from 0 to 5 p. p. m.

Examples

Three of these analyzers are used at the National Institute of Hygienic Science, Tokyo.

Analytical data on nitrogen dioxide and nitric oxide collected at the Continuous Air-monitoring Station of the Institute, Kasumigaseki, Tokyo, from January through December, 1964, are shown in Table IV. An example of the determination

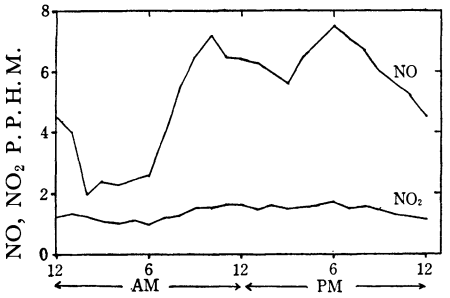

Fig. 6. An example of analysis of the atmospheric air.

is shown in Fig. 6, in which the average concentrations of the nitrogen oxides during the period from January to March, 1964, is graphically displayed, along with the time of day. The avarage concetration of nitric oxide was several times that of nitrogen dioxide; it seems that these results were intensely affected by pollution from the automobiles near the Monitoring Station.

This analyzer has played an improtant role in monitoring air pollution and in analyzing the mechanism of that pollution in Japan.

Conclusions

Saltzman reagent has been modified and acetic acid has been replaced with *n*-propyl alcohol (or *s*-butyl alcohol) as a surface-active agent, decreases in the spontaneous coloration and in the corrosive quality of the reagent have resulted, and better results of the determination have been obtained in the continuous analysis.

The intermittent measurement system of the continuous analyzer has made the apparatus simpler, and the data obtained are convenient for statistical data processing.

The re-cycling of the reagent has made it possible to run a continuous determination for a long time, even for more than a month in the winter time.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2178—2180 (1966)

The Direct Complexometric Titration of Thallium(III) Using Iron(III)-Sulfosalicylate Complex as Metal Indicator

By R. C. AGGARWAL and A. K. SRIVASTAVA

Chemistry Department, Lucknow University, Lucknow (U. P.), India

(Received December 28, 1965)

The iron(III)-sulfosalicylate complex has been used as the indicator for the direct complexometric determination of thallium(III). This indicator permits the rapid and accurate determination of both micro and macro quantities of thallium(III). The titrations are best carried out at about pH 2.6. Most of the divalent cations, such as calcium, strontium, barium, magnesium, manganese and mercury, and trivalent cations, such as chromium and aluminum, do not interfere in the determination.

Thallium(III) reacts with ethylenediaminetetraacetic acid (EDTA) to form a 1 : 1 complex. This reaction has been recently used as the basis for both the direct[1,2] and the indirect[3,4] titrimetric determination of thallium(III) using such metal indicators as xylenol orange, 1-(2-pyridylazo)-2-naphthol (PAN) and 4-(2-pyridylazo)resorcinol (PAR). In a previous communication[5] we reported on the use of familiar dyes, methylene blue and methyl violet, as metal indicators for the direct complexometric determination of thallium(III). Since colored-metal complexes were not used as indicators earlier in the titrimetric determination of thallium(III), a direct complexometric titration of it has been carried out using the iron(III)-sulfosalicylate complex as an indicator; the results obtained will be described in this communication. The use of sulfosalicylic acid for the indirect complexometric determination of thallium(III) has been previously reported.[6]

The determination of thallium(III) using the iron(III)-sulfosalicylate complex as an indicator is based on the facts that in spite of the greater stability of the iron(III)-EDTA complex[7] as compared with the thallium(III)-EDTA complex,[8] EDTA combines with free thallium(III) ions in preference to the iron(III) present as the sulfosalicylate complex, and that when all the thallium(III) ions have combined with EDTA, the violet color of the indicator is discharged due to the formation of the almost colorless iron(III)-EDTA complex, which is much more stable than the iron(III)-sulfosalicylate complex.

Experimental and Results

A 0.05 M solution of the disodium salt of EDTA was prepared by dissolving 18.615 g. of this salt in doubly-distilled water and by then making up the volume to a liter. The strength of the solution was checked by titrating it against calcium carbonate, using calcon as the metal indicator.

A stock solution of thallium(III) nitrate was prepared by dissolving thallium metal in nitric acid and by then oxidizing it to thallium(III)

Thallium(III) found, mg.	28.61	29.63	30.66	30.66	30.66	30.66	28.61	27.08

Note: 1 The volumes of EDTA given in Table I and the succeeding Tables II and III are corrected for blank.
2 The data recorded in Tables I, II and III represent the mean value of the multiple determination, standard deviation being within 0.5%.

with alkaline bromine. The thallium(III) hydroxide thus precipitated was washed well with water and dissolved in a minimum quantity of dilute nitric acid. The solution was then shaken with an excess of thallium(III) hydroxide in order to minimize the acidity of the solution. The thallium content of the solution was estimated by titrating it with a EDTA solution standardized as above, using xylenol orange as the metal indicator.

The iron(III)-sulfosalicylate complex indicator was prepared by mixing 10 ml. of a 0.05 M ferric alum solution and 30 ml. of 0.05 M sulfosalicylic acid, and by then making up the volume to 100 ml. Five-hundredths milliliters of this indicator was used throughout the experiment.

Buffer solutions with pH values in the 2.2—4.00 range were made by mixing requisite quantities of 0.01 M solutions of potassium hydrogen phthalate and hydrochloric acid.

The solutions of various metal ions used for interference studies were prepared by dissolving the requisite amounts of analytical-grade reagents in doubly-distilled water; they were standardized, where necessary, by the determination of their metal contents by usual methods.

The Effect of pH.—Determinations of thallium(III) were carried out at various pH values (adjusted with a pH meter using glass and calomel electrodes) in order to find out the optimum hydrogen ion concentrations for titration. The data recorded in Table I show that the indicator is pH-dependent and that it works well only in a limited pH range, from 2.3 to 3.0.

Titration Procedure.—A solution containing 10.22 to 91.98 mg. of thallium (III) was taken and diluted to about 20 ml. with doubly-distilled water; its pH was adjusted to about 2.6 by potentiometric titrations with dilute ammonium hydroxide; a requisite amount of a buffer solution was added to maintain the pH; 0.5 ml. of the iron(III)-sulfosalicylate complex indicator was added,

and the solution was titrated with a 0.05 M EDTA solution until the violet color of the solution was discharged. A blank titration with 0.5 ml. of the indicator was also carried out under similar conditions, and the necessary correction was made in the determinations. The blank correction amounted to 0.05 ml. of the 0.05 M EDTA solution. The results obtained are shown in Table II.

The Effect of Foreign Ions.—Since EDTA forms fairly stable complexes with large number of cations, many of them may be expected to interfere in the titrimetric determination of thallium(III). The determination of thallium(III) was carried out at pH 2.6 in the presence of almost equivalent amounts of many di- and tervalent cations; the results obtained are recorded in Table III. The divalent metal ions, such as calcium, strontium, barium, magnesium, manganese, and mercury, and the tervalent metal ions, such as chromium and aluminum, do not interfere, but gallium, indium, bismuth, cerium and most of the colored metal ions interfere in the determination of thallium(III).

The authors' grateful acknowledgements are due to the Head, Chemistry Department, Lucknow University, Lucknow, for providing laboratory facilities, and to the Council of Scientific and Industrial Research, New Delhi, for awarding a junior Research Fellowship to one of them (A. K. S.).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2180—2183 (1966)

Proton Magnetic Resonance Spectra of Cobalt(III) Hexammine-type Polyamine Complexes[1)]

By Hayami YONEDA

Chemistry Department, Wakayama University, Masago-cho, Wakayama

and Yukiyoshi MORIMOTO

Research Laboratories, Fujisawa Pharmaceutical Company, Higashiyodogawa-ku, Osaka

(Received January 31, 1966)

The proton magnetic resonance spectra of [Co *en*$_3$]Cl$_3$, [Co *tn*$_3$]Cl$_3$, [Co *pn*$_3$]Cl$_3$ and [Co *den*$_2$]Cl$_3$ (*den*=diethylenetriamine) dissolved in trifluoroacetic acid were measured. All of the observed spectra consist of broad bands, which were assigned on the basis of intensity considerations and by comparing them with the spectra of the corresponding deuterated species. In case of the ethylenediamine complex, the double-resonance method was applied, measurements at different temperatures were made, and the origin of the breadth of the bands was discussed. The NH_2 signals of the ethylenediamine and trimethylenediamine complexes show AB-type features. This was confirmed by comparing the spectra obtained at 60 Mc. and at 100 Mc. The AB-type features of the NH_2 signal were explained in terms of the crystal structure of the complex.

Although the study of Werner-type complexes by the use of the proton magnetic resonance technique is an attractive subject to the coordination chemist, relatively few works have been reported. This is because most of Werner-type complexes are not soluble in ordinary organic solvents, and because in aqueous solutions, the strong signal of water prevents the observation of the signals of ligands and, moreover, rapid proton exchange makes it difficult to pick up the signals of ligands separately. To avoid this difficulty, Clifton and Pratt[2)] measured the proton magnetic resonance spectra of several cobalt(III) ammine complexes dissolved in acidified heavy water; they thus succeeded in obtaining fairly satisfactory results.

Recently we found that an acid itself, if it is a liquid and dissolves a sample, could be used for the NMR measurement of the complex.[3)] Among the several acids we tried, trifluoroacetic acid proved to be the most suitable for this purpose. In this paper we should like to report on several interesting features of the NMR spectra of cobalt(III) polyamine complexes.

1) A part of this article was presented at the 15th Symposium of Coordination Chemistry, Kanazawa University, October, 1965.

2) P. Clifton and L. Pratt, *Proc. Chem. Soc.*, **1963**, 339. S. Hayashi made the same kind of measurements using heavy water; *J. Chem. Soc. Japan, Pure Chem. Sect. (Nippon Kagaku Zasshi)*, **85**, 256 (1964); **86**, 364 (1965).

3) During this work we learned that W. L. Jolly, A. D. Harris and T. S. Briggs had reported the use of concentrated sulfuric acid as a solvent for NMR studies of cobalt(III) ammine complexes; *J. Inorg. Chem.*, **4**, 1064 (1965).

Experimental

The complexes used in the measurement were tris-ethylenediamine cobalt(III) chloride [Co *en*$_3$]Cl$_3$, tris-trimethylenediamine cobalt(III) chloride [Co *tn*$_3$]Cl$_3$, tris-propylenediamine cobalt(III) chloride [Co *pn*$_3$]Cl$_3$ and bis-diethylenetriamine cobalt(III) chloride [Co *den*$_2$]Cl$_3$. The spectra of the free ethylenediamine as well as of its trifluoroacetic acid salt were also measured. The trifluoroacetic acid used in the measurement is of the spectrograde (Merck Company).

The apparatus used was a Varian A60 Analytical NMR spectrometer. In some cases, a Varian HR100 NMR spectrometer was also used. Tetramethylsilane was used as the internal standard throughout the measurements.

Results and Discussion

The NMR spectrum of the free ethylenediamine dissolved in carbon tetrachloride consists of two sharp signals of an equal intensity; the peak appearing in the higher field (−64 c. p. s.) is assigned to the NH_2 protons, and the other, in the lower field (−156 c. p. s.), to the CH_2 protons. (The NH_2 protons of alkylamine dissolved in carbon tetrachloride have their signals in higher fields than the CH_3 and CH_2 protons.) However, this situation is reversed in the case of the protonated ethylenediamine dissolved in an acid. By protonation the NH_2 group becomes the NH_3^+ group, and its signal is shifted to −459 c. p. s. On the other hand, the CH_2 signal is shifted to −237 c. p. s. (The assignment of the signals can easily be made from intensity consideration.) The spectrum of the [Co *en*$_3$]$^{3+}$ complex is expected to have a character intermediate between those of the free and protonated ethylenediamine species. Actually, it has two signals of an equal intensity. While the signal in the higher field (−190 c. p. s.) shows no fine structure, the other in the lower field, has a doublet structure (−292 and −310 c. p. s.), and each doublet component carries a shoulder. In order to assign these signals, the spectrum of the amino-deuterated complex was also measured. In the deuterated complex, the NH_2 group is converted to the ND_2 group, and the signal due to the NH_2 protons should disappear. In the actual deuterated complex, the signal in the lower field disappears. Therefore, this is assigned to the NH_2 protons. Consequently, the signal in the higher field is assigned to the CH_2 protons. The general features of the spectrum are rather coloser to those of the protonated ethylenediamine than to those of the free ethylenediamine. Therefore, we assume that the nature of the coordinated ethylenediamine is closer to that of the protonated ethylenediamine.

In Fig. 1, the NMR spectra of [Co *tn*$_3$]Cl$_3$, [Co *pn*$_3$]Cl$_3$ and [Co *den*$_2$]Cl$_3$ are also shown. Of these, the spectrum of [Co *tn*$_3$]Cl$_3$ is similar to that of [Co *en*$_3$]Cl$_3$. The signal on the left-hand side (−282 and −267 c. p. s.) has a doublet structure and disappears in the deuterated species. Therefore, it is assigned to NH_2. The middle one (−170 c. p. s.) and the one on the right-hand side in the spectrum (−130 c. p. s.) are assigned to the CH_2 adjacent to NH_2 and to the middle CH_2 respectively. The spectrum of the [Co *pn*$_3$]$^{3+}$ complex has five bands which correspond to CH_3 (−92 c. p. s.), CH_2 (−185 c. p. s.), CH (−210 c. p. s.), and two kinds of NH_2 (ca. −280 and ca. −310 c.p.s.). The spectrum of the [Co *den*$_2$]$^{3+}$ complex has the most diffuse pattern among the four complexes. From intensity considerations, the bands are assigned to CH_2 (−205 c. p. s.), NH_2 (−280 and −310 c. p. s.), and the middle NH (−435 c. p. s.).

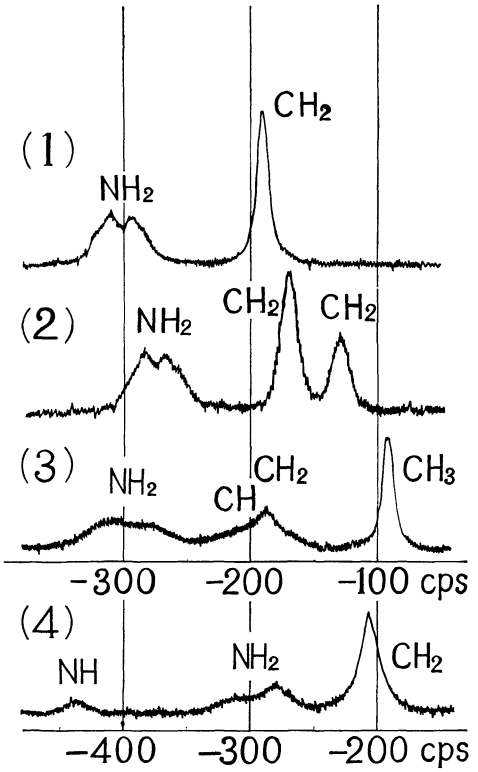

Fig. 1. NMR spectra of four complexes.
(1) [Co *en*$_3$]Cl$_3$, (2) [Co *tn*$_3$]Cl$_3$, (3) [Co *pn*$_3$]Cl$_3$, (4) [Co *den*$_2$]Cl$_3$

All these spectra consist of broad bands. This seems to be characteristic of polyamine complexes. In polyamine complexes, there are several kinds of possibilities which cause signal broadening. To obtain a deeper insight, further experiments were made involving the [Co *en*$_3$]$^{3+}$ complex. First, the NMR spectra of the complex at 70 and 10°C were measured. Though the temperature effect is very small within this temperature range, we can clearly observe a definite tendency for the bands to be broadened at low temperatures and to be sharpened at high temperatures. Secondly,

TABLE I. NH_2 SIGNALS OF [Co *en*$_3$]Cl_3 AND [Co *tn*$_3$]Cl_3 MEASURED AT 60 AND 100 Mc. (c. p. s. UNIT)

		Shoulder	Main peaks		Shoulder
[Co *en*$_3$]Cl_3	60 Mc.	−284	−292	−310	−319
	100 Mc.	−476.5	−485	−520.6	−529
		Coupling constant 8.5 c. p. s.			
		Chemical shift 0.43 p. p. m.			
[Co *tn*$_3$]Cl_3	60 Mc.	−257	−267	−282	−292
	100 Mc.	−431	−440	−473	−483
		Coupling constant 9.5 c. p. s.			
		Chemical shift 0.40 p. p. m.			

the double resonance technique was applied to the pair of CH_2 and NH_2 signals (more exactly, a component of the NH_2 signal). The irradiation of either signal causes a slight sharpening of the other. In the case of the CH_2 band, the value of the half-width decreases to nearly 60% of the original. (Similarly, a sharpening of the CH_2 band takes place in the deuterated [Co *en*$_3$]$^{3+}$ complex. In this case, the value of the half-width is approximately one half of the original.) Therefore, the spin-spin coupling between the CH_2 and NH_2 protons is one of the origins of the band-broadening. In addition, in polyamine complexes, many protons which are magnetically different and crowded around the central metal ion and fixed in a relatively rigid, cage-like framework. The situation is somewhat like that in a solid. Therefore, a complete time-averaging of local fields is not realized. The authors should like to regard this situation as the main origin of band-broadening. The tendency of the temperature effect is consistent with this view. In the case of the NH_2 signal, the irradiation of the CH_2 signal does not change the essential features of the band. Consequently, the diffuse pattern may be attributed mainly to the quadrupole relaxation of the nitrogen nucleus.

The NH_2 signal of the [Co *en*$_3$]$^{3+}$ and [Co *tn*$_3$]$^{3+}$ complexes seems to have the characteristics of the AB-type pattern. To confirm this point, the NMR spectra of both the complexes at 100 Mc. were also measured. The results are listed, along with those obtained at 60 Mc., in Table I. As expected, at 100 Mc. the separation between the main peaks of the doublet components increases, while the separation between the main peak and its shoulder is kept constant. This is characteristic of the AB-type. Thus, it has been proved that two kinds of magnetically-unequivalent protons exist in the NH_2 group.

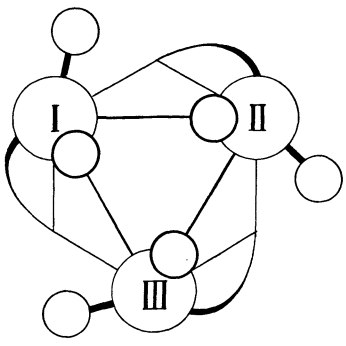

Fig. 2. Structure of the [Co *en*$_3$]$^{3+}$ complex.
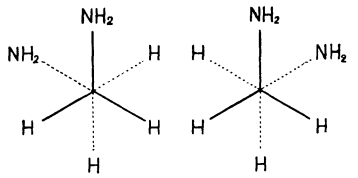
Small circles represents hydrogens.
Large circles represents nitrogens.

The structure of the [Co *en*$_3$]$^{3+}$ complex was analyzed by Nakatsu et al.[4] According to their report, the complex has a threefold axis, and all three ethylenediamine ligands coordinated to the cobalt(III) ion have a nonplanar twisted structure of optically the same configuration.[5] In this structure, if we assume the nitrogen atom to have a regular tetrahedral configuration, we can easily distinguish two kinds of protons attached to it. The situation is illustrated in Fig. 2, which shows the upper part of the complex viewed along the threefold axis. Among the six N–H bonds in Fig. 2, three are directed upwards from the N(I)-N(II)N(III) plane and the other three outwards nearly perpendicularly to the threefold axis. In this way the upper three H(A) atoms form a regular triangle, while the lower three H(B) atoms form a larger, regular triangle. The same situation holds in the lower part of the complex. Although the structure of the [Co *tn*$_3$]$^{3+}$ complex has not yet been elucidated by X-ray analysis, a similar situation may be assumed. Here it is worth noting that this kind of doublet pattern does not appear in an aqueous solution. In an acidified aqueous solution, the NH_2 signal appears as a broad single band with no fine structure. This indicates that

4) K. Nakatsu, Y. Saito and H. Kuroya, This Bulletin, **29**, 428 (1956); **30**, 158 (1957).

5) When the ethylenediamine molecule takes a twisted structure, two optically-isomeric forms are possible, as is shown below. These are figures viewed along the C–C axis. The full lines represent the upper side of the molecule, the dotted lines, the lower side.



k form *k'* form

a frequent flipping[6] of the coordinated ethylenediamine takes place, through which all the NH_2 protons are magnetically equalized. Such a flipping is presumed to be eased by proton dissociation from the NH_2 group. The feature of the NH_2 signal in an aqueous solution can thus be understood. On the contrary, neither proton dissociation nor proton exchange takes place in trifluoroacetic acid solution (the spectrum of the deuterated complex in trifluoroacetic acid solution does not show a time-change). Therefore, no flipping of the coordinated ethylenediamine occurs.

6) By "flipping" we mean that the coordinated ethylenediamine turns over from the *k* form to *k'*, and vice versa, keeping its two coordination positions fixed.

Last, it must be added that two kinds of the CH_2 protons also exist in the above-mentioned stereomodel of the $[Co\ en_3]^{3+}$ complex. Therefore, the doublet pattern of the CH_2 signal should be observed. However, this is not the case. This is probably either because the relative chemical shift is too small to be observed, or because all the CH_2 protons are equalized through the rocking motion of the CH_2 group.

The authors would like to express their thanks Dr. Kenkichi Nukada, Basic Research Laboratory, Toyo Rayon Company for his measurement at 100 Mc. They also wish to express their thanks to Dr. Masao Ohara, Head of Research Laboratories, Fujisawa Pharmaceutical Company for his encouragement during this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2183—2187 (1966)

The Separation of Zirconium and Hafnium by Tributyl Phosphate - Celite Reversed-phase Partition Chromatography*

By Kaoru UENO and Michio HOSHI

Japan Atomic Energy Research Institute, Tokai, Ibaraki

(Received February 22, 1966)

The distribution ratios, K_d, for zirconium and hafnium were measured in the hydrochloric acid - TBP - celite system, the acid concentration being varied from 5 N to 8 N. The data obtained showed that the separation factor for the above elements, $K_{d_{Zr}}/K_{d_{Hf}}$, is fairly high, —4, in the 7—8 N hydrochloric acid range. Thus, the separation of these elements was carried out in 7.1 N hydrochloric acid by the use of a TBP-celite column.

Recently the technique of reversed-phase partition chromatography has been increasingly used for the separation of metal ions of similar chemical behavior. Fiedelis and Siekierski[1,2] demonstrated the application of this technique to the separation of the rare earth metals, using tributyl phosphate absorbed on kieselguhr as the stationary phase and nitric acid in various concentrations as the eluant. Crawley[3] used tributyl phosphate on kieselguhr for the separation of zirconium and hafnium in a nitric acid solution. The decontamination factor of zirconium in the recovery of 90% of the hafnium, calculated on the basis of his experimental data, was within 10^2, although hafnium was separated from zirconium excellently.

The present paper will show the mutual separation of zirconium and hafnium by reversed-phase partition chromatography, performed using tributyl phosphate absorbed on the celite as the stationary phase and hydrochloric acid as the mobile phase in order to obtain purified zirconium and hafnium.

Experimental

Reagents.—Commercial-quality tributyl phosphate was purified in the usual way.[4] Zirconium and hafnium chloride solution were prepared from analytical reagent-quality zirconium oxide and hafnium oxide respectively. All the other reagents used were of an analytical grade. hafnium-181 and zirconium-95 free from niobium-95 were chosen as the radioactive tracers for hafnium and zirconium respectively.

Batch Equilibrations.—A half grams of the TBP-celite was placed into a cylindrical vessel, then 5 ml. portions of hydrochloric acid in various concentrations were added, and finally a known quantity of zirconium-95 or hafnium-181 solution. The vessels were then closed and shaken vigorously at room temperature for 10, 30 and 60 min.

* Reported at the 8th Discussion Meeting on Radiochemistry, Osaka, November, 1964.

1) S. Siekierski and I. Fidelis, *J. Chromatog.*, **4**, 60 (1960).

2) I. Fidelis and S. Siekierski, ibid., **5**, 161 (1961).

3) R. H. A. Crawley, *Nature*, **197**, 377 (1963).

4) D. F. Peppard, W. J. Driscoll and J. L. Maier, *J. Inorg. Nucl. Chem.*, **3**, 215 (1956).

After that, the aqueous layers were taken and centrifuged. Activities in 1 ml. aliquots of aqueous solutions, the equilibrium activities, C_f, were measured for the given systems. The distribution ratios, K_d, were obtained from the following equation: $K_d = \frac{C_0/5 - C_f}{C_0/5} \times 2$, where C_0 is the initial activity of the zirconium-95 or hafnium-181 added to the system. According to the equation given above, K_d values represent the ratios of activities of metal ions per gram of celite to that per milliliter of the solution.

Column Separation.—The column studies of zirconium and hafnium were carried out with a TBP-treated celite bed 0.8 cm. in diameter and 10.5 cm. high.

The material, TBP-celite, was transferred into a column, and the bed was pressed with a glass rod to eliminate air bubbles. The column was then conditioned with the same concentration of hydrochloric acid as the eluant. When one milliliter of the labeled zirconium or hafnium solution was placed on the top of the bed, it adsorbed completely. Then elution was started with eluants composed of various concentrations of hydrochloric acid. The elution rate was held at 1 ml./cm²/min.

The activity of 2 ml. samples of the eluate was determined by counting γ-rays with a well-type scintillation counter.

Results

The Separation Factor for Zirconium and Hafnium.—The first tests were made of the shaking-time dependence of the distribution ratios, K_d, between TBP-celite—hydrochloric acid with tracer-scale zirconium and hafnium in different concentrations of hydrochloric acid. As is shown in Fig. 1, the K_d values of these ions became almost constant in a shaking time of less than 10 min. Therefore, the batch equilibrium of both ions is attained in 10 min.

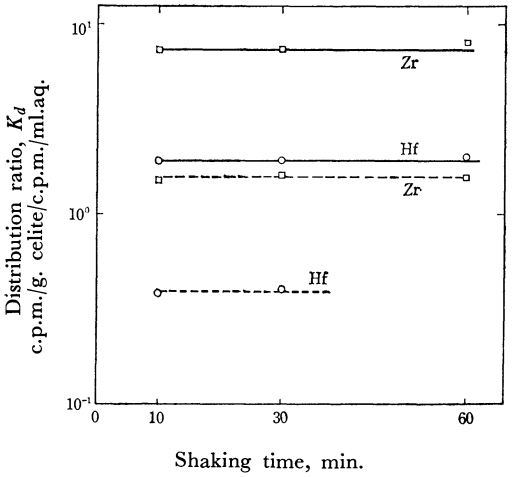


Fig. 1. Shaking time dependence of distribution ratio.
—— 7.35 N HCl
---- 6.85 N HCl
Weight ratio: TBP (1:2) celite

The K_d values of zirconium and hafnium as a function of the acid concentration are shown in Fig. 2. From these data, it may be seen that the K_d values of zirconium and hafnium increase linearly within the concentration of from 7 to 8 N of hydrochloric acid, and that hafnium is eluted more easily than zirconium by the eluant. The separation factor of these ions, $K_{d_{Zr}}/K_{d_{Hf}}$, is about 4 at each point of this acidity range.

The Loading Capacity of TBP-Celite.—The loading capacity of TBP-celite with the weight ratio of 1 : 2 was determined by the batch-equilibrium method described above. In this case, the

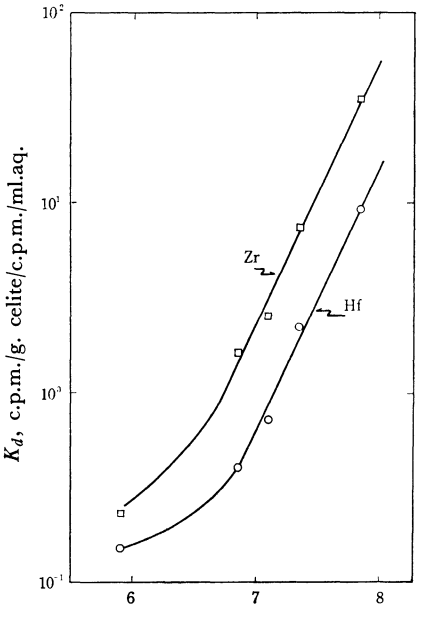

Fig. 2. K_d values of Zr and Hf dependent on HCl concentration.

Weight ratio: TBP(1:2) celite

quantity of zirconium oxide in the solution was changed, while the acid concentration was kept at 9 N hydrochloric acid. As is shown in Fig. 3, the loading capacity is about 70 mg. zirconium oxide per 1 gr. TBP-celite. This number agrees with the value calculated on the assumption that the composition of the complex is $ZrO(NO_3)_2$-$(TBP)_2$.

The Separation of Zirconium and Hafnium by the Column Method.—*Acid Dependence.*—Figure 4 shows elution curves for both hafnium and zirconium. The curves for hafnium were obtained with 6.85, 7.10 and 7.35 N hydrochloric acid, and those for zirconium, with 6.85 and 7.10 N. Factors other than the acidity were kept constant. With an increase in the hydrochloric acid concentration, the curve becomes broader and the peak eluate positions are shifted to the right. Figure 5 shows the linear relationship between the peak eluate volumes in TBP-celite-reversed phase chromatography and the corresponding distribution ratio, K_d, obtained by the batch method. The values obtained fall along straight lines, with very little deviation. This fact shows the good reliability of the TBP-celite reversed-phase chromatography.

The Effect of the Amount of TBP Absorbed on the Celite.—In order to check this effect, TBP-celite absorbents with the weight ratios of 1 : 1, 1 : 2 and 1 : 4 were prepared. Figure 6 shows the relationships between the weight ratio of TBP-celite and the peak eluate volumes in this reversed-phase chromatography. The column with increasing TBP weight ratios makes the elution curve broader, and the peak eluate position shifts right for both zirconium and hafnium. This results is

similar to those obtained from a study of the hydrochloric acid concentration dependence on the elution curves.

Miscellaneous Conditions for the Separations of Zirconium and Hafnium.—In the course of this work it has been observed that the peak eluate volumes of zirconium and hafnium for a 1 : 2-weight-ratio TBP-celite column are almost independent of the amounts of these elements in the range from tracer scale to 50 mg./ml. of hydrochloric acid. After these experiments, using 7.1 N hydrochloric acid as the eluant, the separation was checked in detail with 10 mg. of zirconium and a small quantity of hafnium labeled with Hf-181. The radioactivities of hafnium in the eluate became detectable at 4 ml.; the concentration in the eluate rose to a maximum at 14 ml. and then fell off roughly symmetrically to an undetectable level.

The mutual separation of 10 mg. of hafnium and a small amount of zirconium labeled with zirconium-95 was effected, using 7.1 N hydrochloric acid as the eluant. The activities of zirconium in the eluate began to come through at 30 ml., reaching a maximum at 65 ml. and then falling gradually.

These elution curves of hafnium or zirconium are very similar to the curves obtained with pure hafnium or zirconium respectively. Several column tests like these two showed that mixtures of the two ions in weight ratios, Zr/Hf, from 1 : 1000 to 1000 : 1 bring about no change in the shapes and locations of the elution curves of zirconium and hafnium.

Finally, other factors, such as the grain size of the celite or the conditioning time with water or hydrochloric acid, were also examined. No remarkable difference caused by these factors was observed. Hafnium is separated with hydrochloric acid, leaving zirconium in the column; the zirconium remaining is easily eluted with less than

				99		3.6×10^2

0.01 N of oxalic acid, which is also very effective in stripping zirconium from the TBP-celite column.

From the results described above, the decontamination factors of zirconium or hafnium were calculated. These values are shown in Table I, in which values higher than 10^3 indicate that no detailed calculations could be made because of the statistical error of the counting method.

Conclusion

The mutual separation of zirconium and hafnium with reversed-phase partion chromatography, using 7.1 N hydrochloric acid as the eluant and 1 : 2-weight-ratio TBP-celite as the stationary phase, can be carried out very simply.

The authors wish to express their gratitude to Dr. Tomitaro Ishimori for his kind guidance, and to Drs. Kan Kimura and Eiko Akatsu and Mr. Kenju Watanabe for the valuable advice and discussion given during this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2187—2190 (1966)

Infrared Spectroscopic Study on Ion Association of Hexacyanoferrate(III) and Hexacyanoferrate(II) Ions

By Nobuyuki TANAKA, Yumiko KOBAYASHI and Minoru KAMADA

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received February 25, 1966)

The ion association of hexacyanoferrate(III) and hexacyanoferrate(II) anions with univalent or bivalent cations in aqueous solutions has been studied by the measurement of the infrared absorption band due to the C≡N stretching vibrations. All the solutions measured in which ion-pairs with hexacyanoferrates(III) predominated gave an absorption maximum at 2121 cm^{-1}, and those in which ion-pairs with hexacyanoferrates(II) predominated, at 2020 cm^{-1}, although hexacyanoferrates(III) and hexacyanoferrates(II) of potassium and alkaline earth metals gave different spectra from each other in solid state. No difference in absorption band obtained with different solutions was supported by the distance between two ions in ion-pair, which was estimated from the structures of hexacyanoferrate(III) and hexacyanoferrate(II) ions and the closest approach of the ion-pair; this indicates that there is no direct interaction between the complex anion and the cation, but one or more water molecules interpose between the two ions.

A number of investigations on ion-pair formation in solutions have been made by the conductometric method, but only a few, by the measurements of Raman and infrared spectra. Hester and Plane[1] measured Raman spectra of aqueous solutions of some metal nitrates, sulfates and perchlorates and discussed on the interionic (inner-sphere) association of metal ions with these anions from the change in the symmetry and the force constant estimated from the Raman spectra. Fronaeus and Larsson[2,3] obtained infrared spectra of some metal thiocyanato complexes both in solution and in solid state and correlated the changes in absorption frequency and intensity with the structure and the bonding characteristics of the complexes. Larsson studied[4] also on the infrared spectra of hexamminecobalt(III) ions in aqueous solutions of some electrolytes in order to know of the kind of the bonding forces of the outer-sphere complexes.

This investigation was undertaken for the purpose of obtaining some information of the bonding character of the outer-sphere ion association of hexacyanoferrate(III) and hexacyanoferrate(II) ions with univalent and bivalent cations.

Experimental

Materials.—Magnesium, calcium and barium hexacyanoferrates(III) were prepared from potassium hexacyanoferrate(III) by the following procedure. More than three equivalents of perchloric acid was

added to one equivalent of potassium hexacyanoferrate(III) to precipitate potassium perchlorate. The solution of hydrogen hexacyanoferrate(III) thus obtained was neutralized with magnesium hydroxide, and then magnesium hexacyanoferrate(III) was precipitated by the addition of magnesium chloride in excess. Calcium and barium hexacyanoferrates(III) were prepared in the same way. All the materials obtained were recrystallized three times from water and washed by water, ethanol and ether. Calcium hexacyanoferrate(II) was obtained from potassium hexacyanoferrate(II) in a similar way.

Measurements of Infrared Spectra.—Infrared spectra were measured by using a Hitachi EPI-2G infrared spectrophotometer equipped with a potassium bromide foreprism and a grating double monochrometer. Cells with windows of sodium chloride and those of calcium fluoride were used. In the former case, polyethylene pouch was used to prevent the dissolution of the window material. Platinum foil of 0.05 mm. thick was used for a spacer. Infrared spectra of solid samples were measured by the potassium bromide disk method and the Nujol mull method. The spectra were precisely recorded in the region of 1900 to 2300 cm^{-1}. The internal standard method was adopted when the accurate determination of relative wave numbers was required.

Results

Infrared absorption due to the C≡N stretching vibration was measured with the solutions of potassium hexacyanoferrate(III) of various concentrations. The concentration of ion-pair $K^+[Fe(CN)_6]^{3-}$ present in the solution was calculated in the following way. The concentration association constant of potassium hexacyanoferrate(III), K_c, was calculated from the reported value of the thermodynamic association constant ($\log K_a = 1.3$[5]), using activity coefficients which were obtained from the diagram given by Ringbom.[6] In order to increase the accuracy in the measurements of wave numbers, an absorption band due to the C N stretching vibration of potassium hexacyanoferrate(II) at 2047 cm^{-1} was used as the internal standard, to which the C≡N stretching bands of all hexacyanoferrates(III) were referred. The results obtained with aqueous solutions of potassium hexacyanoferrate(III) are shown in Table I. Absorptions due to the C≡N stretching vibration gave maxima at 2121 cm^{-1} in all cases.

The solutions which contained 0.04 M potassium hexacyanoferrate(III) and 0.2 M magnesium, calcium or barium chloride, and the saturated solutions of magnesium, calcium and barium hexacyanoferrates(III) gave also the absorption due to the C≡N stretching vibration at 2121 cm^{-1}. In the former solutions 70—80% of hexacyanoferrate(III) ions present in the solutions existed in the form of ion-pairs $M^{2+}[Fe(CN)_6]^{3-}$. The calculation was made with the same procedure as in the case of ion-pairs $K^+[Fe(CN)_6]^{3-}$, using the

$K^+[Fe(CN)_6]^{4-}$	2.3[10]	4.5	2.4	2.18
$Ca^{2+}[Fe(CN)_6]^{4-}$	3.77[11]	5.8	3.7	1.84

* See Fig. 3 for l.

concentration association constants of $M^{2+}[Fe(CN)_6]^{3-}$ which were converted from the thermodynamic association constants[7] of $10^{2.79}$ for Mg^{2+}-$[Fe(CN)_6]^{3-}$, $10^{2.83}$ for $Ca^{2+}[Fe(CN)_6]^{3-}$ and $10^{2.88}$ for $Ba^{2+}[Fe(CN)_6]^{3-}$. The absorption spectra of potassium, magnesium, calcium and barium hexacyanoferrates(III) in solid state were measured and compared with the spectra of the solutions of those compounds. They are shown in Fig. 1.

The solutions of hexacyanoferrate(II) salts were also subjected to the measurements of absorption spectra, and compared with each other. The absorption spectra of these solutions were also compared with those of the solids. In this measurement the absorption at 2349 cm^{-1} of carbon dioxide was taken as the internal standard. In the case of the solutions only one absorption band was observed at 2020 cm^{-1} with all the solutions of various concentrations both for potassium and calcium hexacyanoferrates(II). In solid state, however, the spectra of the calcium salt differed from those of the potassium salt. The results are shown in Fig. 2.

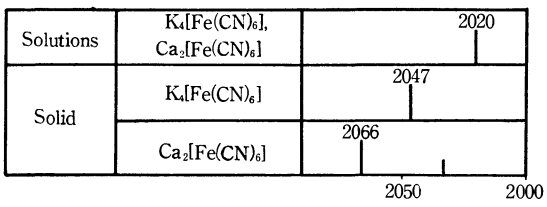

Fig. 2. Wave numbers of the absorption bands of hexacyanoferrates(II) in aqueous solution and in solid state. Solutions contain each complex by 0.02 M up to saturation. For solid state, crystalline water is not described.

Discussion

The solutions of various hexacyanoferrates(III) gave the same frequency and shape of absorption band due to the C≡N stretching vibration under widely different conditions, although these compounds gave different absorption spectra from each other in solid state. The same was found with hexacyanoferrates(II). The absoprtion bands due to the C≡N stretching vibration observed in solid state were at higher frequencies than those observed with the solutions in all cases except potassium hexacyanoferrate(III). One of the explanations of the phenomena is that the complex anion has no direct interaction with a metal cation but it forms an ion-pair with a hydrated metal cation.

Fronaeus and Larsson state[8] in their report that, because a sulfate ion bonds to a metal ion in the form of outer-sphere complex, the disturbance of the symmetry may be so small that its spectra will be identical with those of the free sulfate ion. Since no non-aqueous solvent in which hexacyanoferrates(II) and hexacyanoferrates(III) are soluble in required concentrations was found, an experimental approach to the examination of direct interaction of a complex anion and a metal cation was not successful. Alternatively, the possibility of existence of one or more water molecules between the complex anion and the metal cation was examined by the calculation of the distance of these two ions in ion-pair.

The relation between the closest approach of two ions in ion-pair, a, and the association constant, K, is given by the equations,[9]

$$K = \frac{4\pi N}{1000}\left(\frac{|z_i z_j| e^2}{\varepsilon \boldsymbol{k} T}\right)^3 Q(b) \qquad (1)$$

$$Q(b) = \int_2^b x^{-4} \exp(x)\, dx \qquad (2)$$

where

$$x = \frac{|z_i z_j| e^2}{r \varepsilon \boldsymbol{k} T} \qquad (3)$$

and

11) C. W. Davies, *J. Chem. Soc.*, **1945**, 460.

$$b = \frac{|z_i z_j| e^2}{a\varepsilon \boldsymbol{k} T} \quad (4)$$

N represents the Avogadro number, ε dielectric constant, z the charge of ion, $\boldsymbol{k}$ the Boltzmann's constant and r the distance between two ions in ion-pair. For infinitely dilute aqueous solutions at 25°C, Eqs. 1. and 4 are written as,

$$\log K = 0.4386 + 3\log|z_i z_j| + \log Q(b) \quad (5)$$

$$\log a = \log|z_i z_j| - 7.1468 - \log b \quad (6)$$

The values of a for various ion-pairs of hexacyanoferrate(III) and hexacyanoferrate(II) ions with the metal cations were calculated with Eqs. 5 and 6, and given in Table II.

The positions of water molecule interposing between a complex anion and a metal cation is assumed to be located on the face of the octahedron of a hexacyanoferrate ion as shown in Fig. 3.[12]

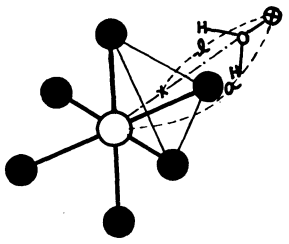

Fig. 3. The possible position of a hydrated metal ion forming an ion-pair with a hexacyanoferrate ion. ○ indicates Fe atom, ● C≡N group and ⊗ a center of a hydrated metal cation.

From the crystal structure of potassium hexacyanocobaltate(III)[13] similar to hexacyanoferrate(III), the Fe-C distance is estimated to be about 2.5 Å and the C-N distance about 1.15 Å. In the case of hexacyanoferrates(II), Marcus[14] reported that the Fe-C distance in the iron cyanide ions may be assumed to be 1.85 Å, which equals the Fe-C bond distance in $Fe(CNCH_3)_6^{2+}$. This value agrees with the Fe-C distance calculated from the crystal structure of potassium hexacyanoferrate(II)[15]; the Fe-C and the C-N distance were calculated to be about 1.9 Å and 1.18 Å, respectively. Using these distances and the values for the closest approach the available distance for the hydrated metal ion, l, was calculated for the univalent and bivalent cations, which are given in Table II. The ionic radii of hydrated metal ions were considered to be the ionic radii of the metal ions plus 0.85 Å.[16] From these values and the available distance for the hydrated metal ions given in Table II, it may be concluded that a water molecule or molecules interpose between the metal cation and the complex anion when they are in the state of ion-pair. This, in turn, suggests that there is no direct interaction between univalent and bivalent cations and hexacyanoferrate(III) and hexacyanoferrate(II) ions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2191—2194 (1966)

The Radiation-Induced Addition Reaction of Thiols to Chlorofluoroolefins

By Kan INUKAI, Teruo UEDA and Hiroshige MURAMATSU

Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya

(Received August 23, 1965)

The addition of thiols to chlorofluoroethylenes was carried out under γ-ray irradiation; chlorofluoroethyl alkyl sulfides were thus obtained. Chlorofluoroethyl alkyl sulfoxides and sulfones were prepared by the oxidation of the sulfides. The dehydrohalogenation of chlorofluoroethyl alkyl sulfides yielded chlorofluorovinyl alkyl sulfides, whose structure indicated that the thiyl radical attacked the difluoromethylene side of the asymmetrical dichlorodifluoroethylene. Chlorofluorovinyl sulfoxides and sulfones were also synthesized from the sulfides by oxidation with hydrogen peroxide.

The free radical addition of thiols to olefins[1] is well known, and a variety of sulfur-containing compounds, such as thiols[2] and hydrogen sulfide[3], have been added to fluoroolefins using peroxide, or under ultraviolet or X-ray irradiation. The base-catalyzed addition of thiols[4,5] to fluoroolefins has also been studied extensively.

In this paper, the addition of RSH, where R is methyl, ethyl, or isopropyl, to 1, 1, 2-trichloro-2-fluoroethylene, 1, 2-dichloro-1, 2-difluoroethylene, and 1, 1-dichloro-2, 2-difluoroethylene will be described. By the oxidation of 1 : 1 adducts (the chlorofluoroethyl alkyl sulfides), both the corresponding chlorofluoroethyl alkyl sulfoxides and sulfones were prepared. The chlorofluorovinyl alkyl sulfides, sulfoxides, and sulfones were also synthesized by the dehydrohalogenation of the 1 : 1 adducts, followed by oxidation.

The reactants were irradiated in a glass tube at a rate of $0.6—0.7\times10^5$ r./hr. for a period of 3—4 weeks at room temperature. The irradiation conditions of each run are listed in Table I, along with the yields as calculated on the basis of the amounts of olefins added. The addition to 1, 2-dichloro-1, 2-difluoroethylene and 1, 1-dichloro-2, 2-difluoroethylene gave mainly 1 : 1 adducts in appreciable yields. Since a mixture of thiols and chlorofluoroethylenes gave no products upon standing in a dark at room temperature for a month, the reactions under the radiation seem to be through a free-radical mechanism. The general reaction is:

$$RSH + CFX{=}CClX \xrightarrow{\gamma\text{-ray}} RSCFXCHClX$$

where X=F or Cl; R=CH_3, C_2H_5, or i-C_3H_7.

Table I. Irradiation conditions in addition of RSH to chlorofluoroolefins

R	Molar ratio of RSH to olefin[a]	Total dose r.	Yield[b] of 1 : 1 adduct g.(%)	RSSR, g.	$(RS)_2C{=}CFCl$ g.
		$CFCl{=}CFCl$			
C_2H_5	1.0	2.2×10^7	12.5(17.0)	3.8	2.0
C_2H_5	1.5	3.5×10^7	17.5(23.9)	3.5	10.5
i-C_3H_7	1.0	3.5×10^7	13.5(17.2)		2.0
		$CF_2{=}CCl_2$			
CH_3	1.0	2.2×10^7	48.2(71.0)	1.5	
C_2H_5	1.0	2.2×10^7	44.5(61.0)	2.5	
i-C_3H_7	1.0	3.5×10^7	57.5(73.3)		

a) Fifty grams of the olefin were used in each run.

b) Based on the amounts of olefin added.

The reaction of trichlorofluoroethylene and tetrachloroethylene with thiols gave no addition products, and the yields of the addition products with 1, 1-dichloro-2, 2-difluoroethylene were higher than those of 1, 2-dichloro-1, 2-difluoroethylene. These facts seem to indicate that asteric interference between the bulky sulfur and chlorine atom may have an effect on the reactivity of olefins. The physical properties of the 1 : 1 adducts are shown in Table II.

The alkyl disulfides, which were identified by a comparison of their infrared spectra and gas chromatogram with those of authentic samples, were generally formed as by-products. In the reaction of 1, 2-dichloro-1, 2-difluoroethylene with thiols, an appreciable amount of a viscous compound was obtained, together with the 1 : 1 adduct and alkyl disulfide. Further, the amount of the compound increased with an increase in the ratio of the thiol to the ethylene. From its infrared spectrum, molecular weight, and elemental analysis,

the structure of the compound was determined to be $(RS)_2C=CFCl$. The formation of the compound is probably a result of the sequence of the radical dehalogenation. The radical dehalogenations from the intermediate radicals with bulky neighboring groups were often observed in radical-induced addition reactions, in, for example, those of polyhalobutene,[6] 1, 2-dichlorotetrafluorocyclobutene, and 1, 2-dichlorohexafluorocyclopentene.[7]

The direction of the attack of the thiyl radical on asymmetrical dichlorodifluoroethylene was determined by the dehydrohalogenation of the 1 : 1 adduct with potassium hydroxide; chlorofluorovinyl alkyl sulfide was thus yielded. The formation of

1-fluoro-2, 2-dichlorovinyl alkyl sulfides showed that the RS radical was added to the CF_2 side. If the thiyl radical would attack the CCl_2 side, 1-chloro-2, 2-difluorovinyl alkyl sulfides would be obtained. The physical properties of the chlorofluorovinyl alkyl sulfides prepared are shown in Table III.

The chlorofluoroethyl alkyl sulfoxides and sulfones were synthesized by the oxidation of the corresponding chlorofluoroethyl alkyl sulfides with hydrogen peroxide in acetic acid, at 40—45°C and at 75—80°C respectively. The oxidation of the chlorofluorovinyl alkyl sulfides run under similar conditions yielded the corresponding chlorofluorovinyl alkyl sulfoxides and sulfones.

$$RSCFXCHClX \xrightarrow[AcOH]{H_2O_2} \begin{cases} \rightarrow RSOCFXCHClX \\ \rightarrow RSO_2CFXCHClX \end{cases}$$

$$RSCFXCHClX \xrightarrow{KOH} RSCF=CClX \xrightarrow[AcOH]{H_2O_2} \begin{cases} \rightarrow RSOCF=CClX \\ \rightarrow RSO_2CF=CClX \end{cases}$$

Attempts to dehydrohalogenate the chlorofluoroethyl alkyl sulfoxides and sulfones were found to lead to the decomposition of the sulfoxides and sulfones. The physical properties of chlorofluoroethyl and chlorofluorovinyl alkyl sulfoxides and sulfones are listed in Tables IV and V respectively.

Experimental[8]

The Addition Reactions of Thiols to Chlorofluoroolefins.—A mixture of 23.5 g. (0.38 mol.) of ethanethiol and 50 g. (0.38 mol.) of 1, 1-dichloro-2, 2-difluoroethylene was sealed in a glass tube (ca. 300 ml. in capacity) and irradiated to a total dosage of 2.2×10^7 r. The contents of the tube were then washed out with a diluted solution of sodium hydroxide and extracted with ether. The distillation of the extract under reduced pressure gave 44.5 g. (0.22 mol., 61% yield) of 1, 1-difluoro-2, 2-dichloroethyl ethyl sulfide, b. p. 61—62°C/20 mmHg, and 2.5 g. of ethyldisulfide, which was identified by a comparison of its infrared spectra and gas chromatogram with those of an authentic sample.[9] The addition reactions of thiols to 1, 2-dichloro-1, 2-difluoroethylene were carried out under similar conditions. In these cases, appreciable amounts of the viscous compounds were obtained, together with the 1 : 1 adduct and alkyl disulfide. In the addition of ethanethiol, a compound with a b. p. of 87—89°C/10 mmHg, $\nu_{C=C}$ 1587 cm^{-1}, n_D^{20} 1.5215, d_4^{20} 1.207, was isolated using a preparative gas chromatograph. From its infrared spectrum, molecular weight, and elemental analysis, the structure was assumed to be $(C_2H_5S)_2C=CFCl$.

Found: MR_D 50.64; F, 9.2; Cl, 18.2; mol. wt. 200.[10] Calcd. for $C_6H_{10}FClS_2$: MR_D 49.99; F, 9.5; Cl, 17.7; mol. wt. 200.5.

The irradiation conditions and yields are summarized in Table I.

The Dehydrohalogenation of Chlorofluoroethyl Alkyl Sulfides.—A mixture of 30.0 g. (0.15 mol.) of 1, 1-difluoro-2, 2-dichloroethyl ethyl sulfide and 17.5 g. (0.31 mol.) of powdered potassium hydroxide in a 100 ml. flask equipped with a reflux condenser and a stirrer was heated at 120—125°C for 1.5 hr. The reaction mixture was then poured into water and extracted with ether. The extract was dried and distilled to give 22.0 g. (0.13 mol., 82% yield) of 1-fluoro-2, 2-dichlorovinyl ethyl sulfide, b. p. 52—54°C/20 mmHg.

In a similar manner, the other chlorofluoroethyl alkyl sulfides were treated with potassium hydroxide; they thus gave the corresponding halovinyl alkyl sulfides, whose physical properties are shown in Table III.

8) All temperature readings are uncorrected.

10) Determined by a mass spectrometer.

The Oxidation of Chlorofluoroethyl Alkyl Sulfides and Chlorofluorovinyl Alkyl Sulfides.— In a 100 ml. flask equipped with a stirrer and a reflux condenser were placed 12.0 g. (0.058 mol.) of 1, 1-difluoro-2, 2-dichloroethyl isopropyl sulfide and 8.0 g. (0.071 mol.) of hydrogen peroxide (30% aqueous solution) in acetic acid (50 ml.). The mixture was then stirred for 5 hr. at 40—45°C. After the acetic acid had been distilled off, the reaction mixture was washed with a sodium carbonate solution and extracted with ether. The extract was dried and distilled to give 11.5 g. (0.051 mol., 89% yield) of 1, 1-difluoro-2, 2-dichloroethyl isopropyl sulfoxide, b. p. 75—77°C/3 mmHg, ν_{SO} 1033 cm^{-1}.

Using the same procedure, the other chlorofluoroethyl and chlorofluorovinyl alkyl sulfides were oxidized to the corresponding sulfoxides in yields of about 70%.

In a 200 ml. flask there was placed 23.0 g. (0.11 mol.) of 1, 1-difluoro-2, 2-dichloroethyl isopropyl sulfide in acetic acid (20 ml.). Fifty grams (0.44 mol.) of hydrogen peroxide (30% aqueous solution) in 100 ml. of acetic acid were then added drop by drop over a period of 1 hr. After it had been continuously stirred for an additional 4 hr. at 75—80°C, the mixture was washed with an aqueous sodium carbonate solution and extracted with ether. The distillation of the extract gave 23.5 g. (0.098 mol., 92% yield) of 1, 1-difluoro-2, 2-dichloroethyl isopropyl sulfone, b. p. 86—88°C/3 mmHg; m. p. 32—34°C.

By the same procedure, the other chlorofluoroethyl and chlorofluorovinyl sulfides were oxidized to the corresponding sulfones in yields of about 80%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2194—2201 (1966)

The Isomers of the Hydrogenation Products of Bisphenol A. The Separations and Configurations of Three Isomers of 2, 2-Bis-(4-hydroxycyclohexyl)propane and Two of 2-(4-Hydroxy-cyclohexyl)-2-(*p*-hydroxyphenyl)propane[1]

By Akira TERADA

Government Industrial Research Institute, Osaka; Oyodo-ku, Osaka[2]

(Received October 20, 1965)

Hydrogenations of bisphenol A (I) over Raney nickel (W-1) and Urushibara nickel A and B have been carried out, and three stereoisomers of 2,2-bis(4-hydroxycyclohexyl)propane (II) and two of 2-(4-hydroxycyclohexyl)-2-(*p*-hydroxyphenyl)propane (III) have been isolated from the products. The configurations and the preferred conformations of the II isomers, *cis-cis* (m. p. 174—175°C), *cis-trans* (164—165.5°C) and *trans-trans* (188—189°C), and of the III isomers, *cis* (159—161°C) and *trans* (150.5—151.5°C), have been determined by means of the infrared and nuclear magnetic resonance spectra, inversions over sodium to the stable isomers, and other methods. When heated with purified methanol, 2, 2-bis(4-ketocyclohexyl)propane prepared from the chromium trioxide oxidation of an isomeric mixture of II afforded 2, 2-bis(4, 4-dimethoxycyclohexyl)propane, m. p. 140.5—141.5°C. The recrystallization of III_t from benzene yielded $III_t \cdot C_6H_6$. Treating III_c with acetic anhydride gave 2-(3-cyclohexenyl)-2-(*p*-hydroxyphenyl)propane (where *c*: *cis* and *t*: *trans*).

The catalytic hydrogenation of 2, 2-bis(*p*-hydroxyphenyl)propane, bisphenol A (I), under high pressure gives an isomeric mixture of 2, 2-bis(4-hydroxycyclohexyl)propane (II) and 2-(4-hydroxycyclohexyl)-2-(*p*-hydroxyphenyl)propane (III). This reaction was discussed by Jordan in 1925, who mentioned that, under 10—15 atm. of hydrogen pressure using a less active nickel catalyst, the compound III was mainly obtained as a glassy solid, besides the recovered starting material, while none of the saturated compound II was observed.[3] However, he also observed that the use of a colloidal palladium catalyst gave an oily mixture with an aromatic odor and containing the II isomers. Braun also used a less active nickel catalyst at the temperature of 260°C and under 50 atm. of hydrogen pressure for this reaction; he obtained only hydrogenolysis products, which were presumably cyclohexanol, 4-isopropylcyclohexanols, phenol and *p*-isopropylphenol. However, using decalin as a solvent and using a more active nickel catalyst, he succeeded

in preparing III in a good yield, besides a small amount of II.[4]

After these investigations it seems that there have been no other reports concerning the preparation of II,[5] and that no investigator has isolated the isomers of II and III, or discussed the configurations.[7] The present study was undertaken in order to isolate these isomers and in order to determine the configuration of the hydroxyl groups, preferred conformations and chemical behavior. These compounds are particularly useful in the production of polyester resins as polyalcohol components.[8]

The above-quoted reports and reports of other analogous hydrogenations have suggested that the use of a more active catalyst[9] and a higher hydrogen pressure would be necessary, and that this would increase the yield of II rather than that of III and prevent the formation of the hydrogenolysis products. Accordingly, the experiments herein are carried out under about 100 kg./cm^2 of initial hydrogen pressure over each of three kinds of nickel catalyst, Raney nickel (W-1), and Urushibara nickel A and B,[12] all of which can easily be prepared and all of which possess considerably high activities.

With regard to the aspects of the hydrogenation, the reaction temperatures and the pressure changes were measured to elucidate the mechanism of the hydrogen absorption. By hydrogenation up to 210°C using a large amount of Urushibara nickel A or B, only products containing III as a major component were obtained, and even at temperatures as high as 260°C the hydrogenations were not completed, whereas over Raney nickel at 260°C, the hydrogen absorption was completed, giving II in an almost theoretical yield. These observations led us to conclude that the hydrogenation takes place step-by-step on each of the phenolic benzene rings, as has generally been recognized hitherto in the usual hydrogenations of biphenyl compounds,[10,13] we also concluded that Urushibara nickel A and B were unsuitable for the hydrogenation of a benzene nucleus of this kind.

Usually a glassy solid was obtained as the hydrogenation product after the resulting solution had been filtered to remove the catalyst and then concentrated to dryness. The residue was spearated into the components either by fractional crystallization or by extraction with aqueous alkali, as is summarized in Fig. 1 and as is described in the Experimental section.

Since analogous compounds, like the II diols, often produce the molecular compound among their stereoisomers, for instance, in the cases of bis(4-hydroxycyclohexyl)[14] and 4-cyclohexylcyclohexanol,[16] each of the products, II_I, II_{II} and II_{III}, obtained here was confirmed to be a single compound through the regenerative hydrolysis of the diacyl compound to the original diol.

The assignment of the configurations of the hydroxyl groups in II_I, II_{II} and II_{III} was initially given from their infrared spectra. The band positions of the secondary alcohol groups in many cyclohexane rings of such compounds as steroids,[17,18] 2-decalols[17] and alkylcyclohexanols[19] generally differ according as it is axial or equatorial. The equatorial hydroxyl groups in such alicyclic ring systems absorb in the 1040—1050 cm^{-1} region, and the axial, at 1000—1010 and 950—960 cm^{-1}. Also, the axial and equatorial acetates both show absorption peaks in the region of about 1230 cm^{-1}, but the axial one shows more complex bands than the equatorial.[17,18] II_I had bands at 1072 and 1048; II_{II}, at 1062, 1020 and 952; and II_{III}, at 1011 and 958 cm^{-1}. The

5) Kalina and Brůthans have reported on this hydrogenation after this investigation was completed. They used various cyclohexanol derivatives as solvents and obtained a white, transparent mass as the product.[6]

6) M. Kalina and V. Brůthans, Czech. Pat. 103572 (1962); *Chem. Abstr.*, **58**, 13846 (1963).

7) The *trans-trans* ($II_{t\text{-}t}$), *cis-trans* ($II_{c\text{-}t}$) and *cis-cis* ($II_{c\text{-}c}$) forms of II, and the *trans* (III_t) and *cis* (III_c) of III are considered to be their configurations between the hydroxyl and isopropylidene groups.[3]

8) Brit. Pat. 464762 (1937); 792485 (1958); 808485 (1958); German Pat. 1011148 (1957); Belgian Pat. 546375 (1959); U. S. Pat. 2828278 (1958).

9) Many examples of the hydrogenation procedure for hydroxybiphenyl compounds and many studies of the activities of various nickel catalysts in analogous reactions have been reported. For instance, Yoshitake[10] examined in detail the activities of several kinds of nickel catalysts in the case of the hydrogenation of *o*-phenylphenol; he reported that the activity sequence was in the following order: Raney nickel>stabilized nickel>flaked nickel>reduced nickel. Morita[11] used Urushibara nickel B and nickel Kieselguhr for the hydrogenation of *o*- and *p*-phenylphenols and observed that only the phenolic nuclei were saturated when the former catalyst was used, and that the latter catalyst was not suitable for his purpose because of its low activity.

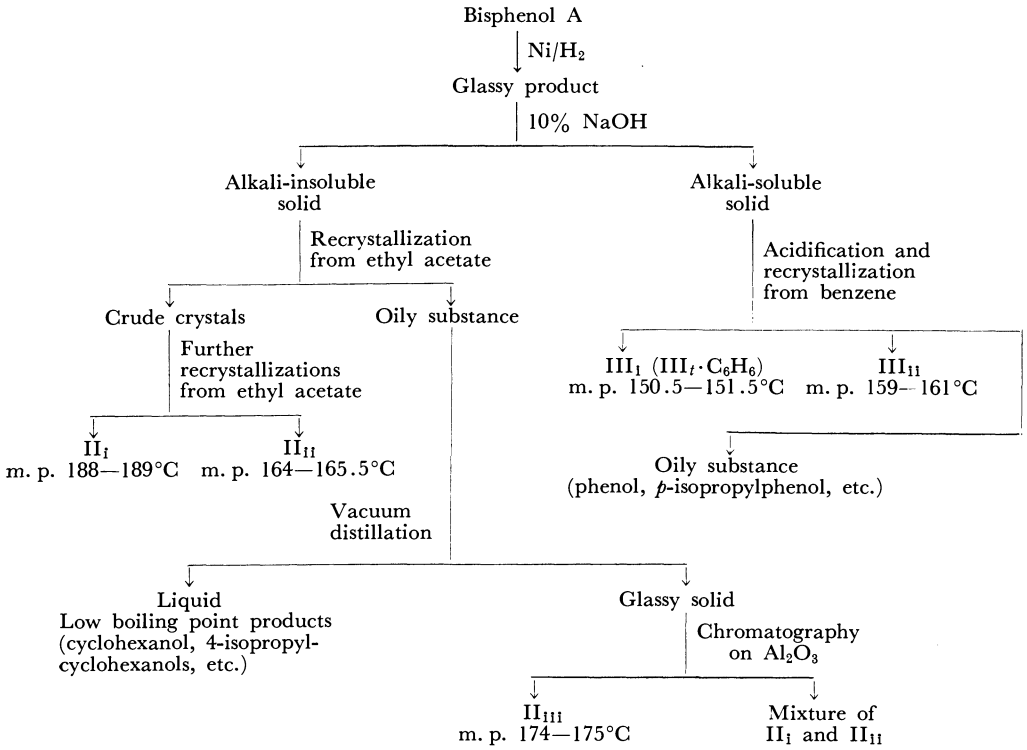

Fig. 1. Separation procedure.

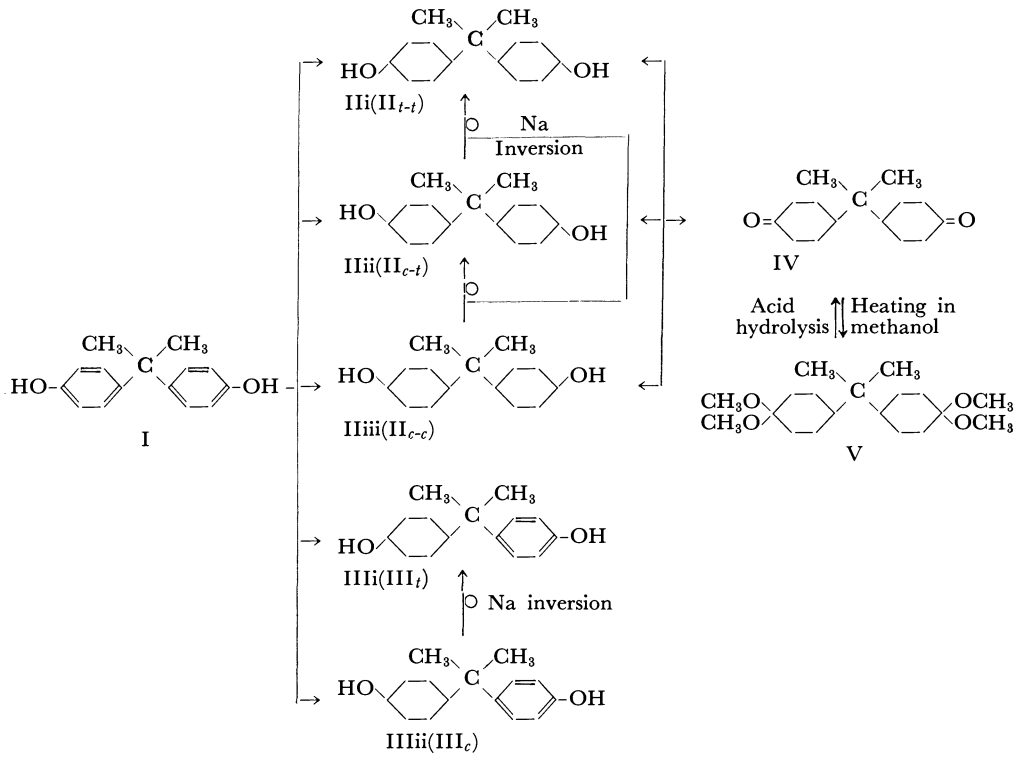

Fig. 2

diacetate of II_{III} showed the most complex absorption bands among the three isomers, that of II_{II} was next, and that of II_I was the simplest. Therefore, the two hydroxyl groups at C_4 and C_4' of II_I were concluded to be both equatorial; one of those of II_{II} was equatorial and another axial, and all of those of II_{III} were axial.

Generally, the cyclohexanes having equatorial hydroxyl groups are more stable than the corresponding axial isomers; therefore, when a polycyclic secondary alcohol is equilibrated with alkali metal, the isomer which is preponderant in the reaction product will be that which has equatorial hydroxyl.[10,15,20] When II_{II} and II_{III} were each heated with sodium, II_I was preferentially obtained. Since it is most probable that the isopropylidene groups attached to both C_1 and C_1' of the two cyclohexane rings of II isomers are arranged equatorially, the configurations of the hydroxyl groups in II_I with respect to the isopropylidene should be both *trans* ($II_{t\text{-}t}$), *cis* and *trans* ($II_{c\text{-}t}$) in II_{II}, and all *cis* ($II_{c\text{-}c}$) in II_{III}. The adsorption of these isomers on activated aluminum oxide also indicated the same conclusion, that to be expected from the above results. The *cis*, *cis* isomer was least strongly adsorbed, followed by the *cis*, *trans*, and *trans*, *trans* isomers in that order.[21] Thus, the above-mentioned conclusions from the infrared spectrum studies were also supported by these other results, as well as by the nuclear magnetic resonance spectra of the diacetates, as will be shown in the Experimental section.

The oxidation of the isomeric mixture of II with chromium trioxide gave the diketone compound IV in a good yield. The recrystallization of this diketone from purified methanol afforded the tetramethyl diketal, 2, 2-bis(4, 4-dimethoxycyclohexyl)propane, while when other carbinols, such as absolute ethanol or propanol, were used, no formation of ketal was observed.

The diketone IV promptly absorbed two moles of hydrogen on hydrogenation over a platinum catalyst and gave a mixture of the diol containing $II_{c\text{-}t}$ mainly, plus $II_{c\text{-}c}$ and $II_{t\text{-}t}$ in minor amounts in that order.

On the acidification of the alkali extract of the hydrogenation product with mineral acid, a mixture of phenolic compounds was deposited as a glassy solid mass. Crystallization from benzene yielded a phenolic material, III_I, m. p. 150.5—151.5°C. The infrared spectrum of III_I showed the absorption peaks of phenolic groups, *p*-disubstituted benzene and equatorial ring alcohol, while its ultraviolet spectrum showed a peak of the phenolic compound at 278 mμ, the intensity of which was approximately half that of bisphenol A. These results led us to the conclusion that III_I still possessed a phenolic benzene ring, besides a cyclohexanol ring. Drying III_I in vacuo at the boiling point of xylene quantitatively removed one mole of the benzene, but the melting point was unchanged. It was, therefore, concluded that the benzene was the solvent of crystallization and that the molecular formula of III_I was $C_{15}H_{22}O_2 \cdot C_6H_6$, while III_I was concluded to be the *trans* isomer, III_t, by the above spectral analysis. The diacetate was also prepared in order to confirm that the III_t was a single compound.

Crystals of III_{II} were deposited from the mother liquor, from which III_t had completely been removed. Recrystallization from benzene gave the other isomer, III_{II}, melting at 159—160°C; this was concluded to be the *cis* isomer, III_c. The configuration of the hydroxyl group was also recognized as axial by means of a study of the infrared spectrum and by the sodium inversion to III_t. The acetylation of III_c using acetic anhydride in the presence of potassium acetate gave an oily mixture whose infrared spectrum showed strong bands of hydroxyl, and weak bands of acetyl groups and also of the carbon-carbon double bond. After the phenyl urethane formation, it was found that the main product in the acetylation was 2-(3-cyclohexenyl)-2-(*p*-hydroxyphenyl)propane. The following explanation was proposed for the formation of this dehydrated compound. Since the hydroxyl group in the cyclohexane ring of III_c was axial, it was easily dehydrated and gave the cyclohexene derivative rather than the diacetoxyl compound.[22]

As to the preferred conformations of both the cyclohexane rings to the isopropylidene group in II isomers, the following remarks may be made. If it can be assumed that all of the energy barriers of internal rotation among the methyl, methylene and methylidene groups are equivalent by neglecting the detailed stereochemical factors, the conformations II: A (*gauche*)[23] and II: B (*anti*),[23] (Fig. 3) each of which has four *gauche* interactions like *n*-butane, are less strained than the other possible conformations. However, if one of the cyclohexane rings is placed as II: A with respect to the isopropylidene group, and another ring, as II: B (i. e., II: A + II: B = II: D), the internuclear distance between the two carbon atoms, C-2 and C-6', will approach about 2.5 Å, and the axial hydrogen atom attached to C-2 and the equatorial atom attached to C-6' must face each other at about 0.73 Å.[24] On the other hand, when both the

20) W. Klyne, Ref. 17, p. 57.
21) Analogous facts were observed by Ungnarde[16] and Wilds et al.[14] in the cases of hydrodiethylstilbestrols and bis(4-hydroxycyclohexane).
22) Some analogous examples can be found in the case of *cis*, *cis*-perhydrodiethylstilbestrol.[15]
23) Correlations between isopropylidene methyls and the two bonds of the cyclohexane ring (C-1–C-2, and C-1–C-6).
24) Measured by Dreiding molecular models.

cyclohexane rings are "*anti*" configurations with respect to the isopropylidene group (II:C), each of the two pairs of the methylene carbon atoms, C-2:C-6′ and C-6:C-2′, will also approach each other at a distance of about 2.5 Å, and the four axial hydrogen atoms attached to these four carbon atoms must face each other in each pair. Therefore, these two steric arrangements, II:C and II:D, are actually impossible and the other conformation, II:E, is the most probable. The II:E conformation is a combination of two II:A conformations, where the two chair cyclohexane rings are contrarily twisted 60° (the projected valency angles about the carbon-carbon bonds between the isopropylidene and each of the rings) from the completely-eclipsed situations with the isopropylidene methyls. The two bonds, C-1-C-6 and C-1′-C-6′, and the bisector of the bond angle of CH_3–C–CH_3 should, therefore, be coplanar.

Regarding the preferred conformation of III, if it can also be assumed that all the steric strains among the methyl, methylene, and the carbon atoms at the junction of the benzene ring are equivalent, as in II isomers, the conformations of III:A and III:B shown in Fig. 3 should have equal relative stabilities and be more probable than the other possible conformations. However, while only one methylene group (C-2) in III-C is near to the hydrogen atom attached to an ortho position of the benzene ring, two of the methylene groups in III:D (C:2 and C:6) will approach two of the ortho hydrogens. Hence, a whole-molecular conformation such as III:C is energetically more probable.

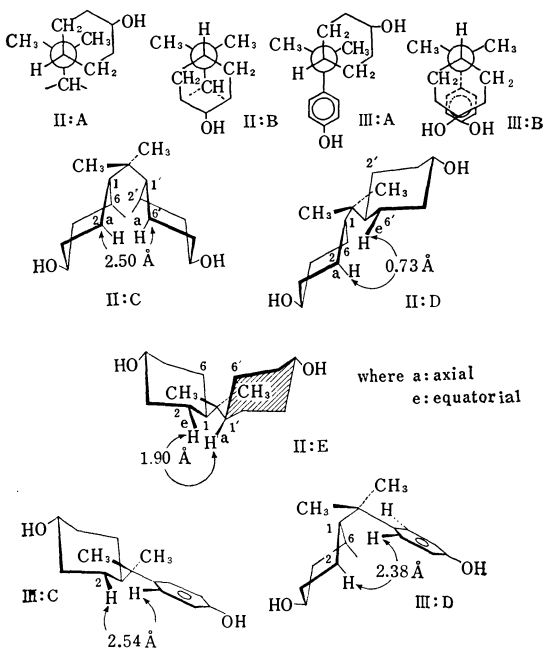

Fig. 3

Experimental

The Hydrogenation of Bisphenol A over Raney Nickel Catalyst (W-1).—Fifty grams of bisphenol A dissolved in 120 ml. of absolute ethanol and 20 ml.[25] of Raney nickel (W-1) were charged in a one-liter stainless-steel autoclave and shaken under 94 kg./cm² of initial hydrogen pressure. The temperature was allowed to rise up to 260°C during a period of 120 min. in order to complete the hydrogen absorption. The resulting solution was filtered, and the solvent was removed under diminished pressure. The obtained glassy solid was refluxed and stirred in 400 ml. of 10% sodium hydroxide for 5 hr. in order to remove any phenolic component; then the remaining crystalline solid was repeatedly washed with large amounts of hot water. This yielded 51.0 g. (96%) of an isomeric mixture of II, m. p. 133—153°C.

$II_{t\text{-}t}$. — One recrystallization of the above-obtained crystalline mixture from ethyl acetate gave 35.1 g. of the first crop, which had a melting point of 147—183°C. From the mother liquor 10.0 g. of other crystals, the second crop, m. p. 133—153°C, were recovered. The further recrystallization of the first crop from the same solvent gave an analytical sample of II_1 ($II_{t\text{-}t}$), m. p. 188—189°C.

Found: C, 74.94; H, 11.75. Calcd. for $C_{15}H_{28}O_2$: C, 74.95; H, 11.74%.

ν_{max}^{Nujol} 3310 (OH); 1072, 1048 cm^{-1} (equatorial alcohol).

$II_{c\text{-}t}$.—Repeated recrystallizations of the second crop, obtained above, from ethyl acetate gave an analytical sample of II_{II} ($II_{c\text{-}t}$), m. p. 164—165.5°C. The melting point was depressed when it was mixed with $II_{t\text{-}t}$.

Found: C, 74.75, 74.91; H, 11.68, 11.58. Calcd. for $C_{15}H_{28}O_2$: C, 74.95; H, 11.74%.

ν_{max}^{Nujol} 3360 (OH); 1062 (equatorial alcohol); 1020, 952 cm^{-1} (axial alcohol).

All the mother liquors from the above recrystallization procedures were combined separately with the corresponding fractions of the other experimental runs described later, and stored for used in the detection of $II_{c\text{-}c}$.

III_t.—Upon acidification with dilute hydrochloric acid of the alkaline extract obtained above, a viscous oil was isolated. After sufficient washings with hot water, 2.0 g. of powder were obtained. Crystallization from benzene gave 0.15 g. of III_i ($III_t \cdot C_6H_6$), m. p. 150.5—151.5°C.

Found: C, 80.18, 80.35; H, 9.27, 9.15; C_6H_6; 26.42;[26] mol. wt. (Rast), 170. Calcd. for $C_{15}H_{22}O_2 \cdot C_6H_6$: C, 80.74; H, 9.02; C_6H_6, 26.28%; mol. wt., 312.46.

ν_{max}^{KBr} 3454, 3130 (OH, broad); 1961, 1813 (benzene); 1612, 1595, 1518 (phenyl); 1242 (phenol); 1046 (equatorial alcohol); 832 cm^{-1} (*p*-disubstituted benzene).

λ_{max}^{EtOH} 224.1, 255, 278 mμ (ε, 10600, 1080, 2300).

The drying course using a thermobalance under

25) Measured in the volume as a precipitate in absolute ethanol.

26) Weight loss upon drying at the boiling point of xylene under a vacuum until a constant weight was obtained.

atmospheric pressure showed that the dissociation temperature of the benzene was as low as below 80°C.

ν_{max}^{KBr} of benzene-free III_t: 3410, 3240 (OH, broad); 1878, 1613, 1596, 1517 (phenyl); 1250 (phenol); 1060 (equatorial alcohol); 831 cm^{-1} (*p*-disubstituted benzene).

The mother liquor collected and gathered from the above recrystallization procedures of $III_t \cdot C_6H_6$ was combined with similar fractions of the later experimental runs, and they stored for use in the detection of III_c.

The Hydrogenation of Bisphenol A with Urushibara Nickel-A.—*Reduction up to 220°C.*—The hydrogenation of 50.0 g. of I in 100 ml .of absolute ethanol over 10 ml.[25] of a U-Ni-A catalyst was carried out under 100 kg./cm^2 of initial hydrogen pressure, with the temperature rising up to 220°C over a period of 225 min. After working-up as usual, a sirupy product was obtained; this was, as usual, separated into alkali-insoluble and soluble portions. The crystallization of the insoluble part from ethyl acetate gave the following crops: (a) m. p. 141—170°C; 15.0 g. (28.5%); (b) m. p. 140.5—149°C; 7.45 g. (14.1%), and (c) m. p. 130—140°C; 2.07 g. (3.9%); the total of 24.5 g. (46.5%). These crops were identified as follows; the fraction a consisted mainly of $II_{t\text{-}t}$, and the b, of $II_{c\text{-}t}$, as was confirmed by mixed-melting-point tests.

The acidification of the alkali-soluble portion with hydrochloric acid gave 6.5 g. of crude crystals of III, which were mostly III_t.

Reduction up to 260°C.—This was carried out under 100 kg./cm^2 of initial hydrogen pressure, using 30 ml. of a U-Ni-A. The reaction temperature was raised up to 260°C over a period of 195 min. After working up as usual, 18.5 g. (35%) of crystals insoluble in alkali were obtained, m. p. 142—150°C, 17.9 g., these crystals contained mainly $II_{c\text{-}t}$, with $II_{t\text{-}t}$ the remainder.

From the alkaline solution, a solid mass (phenolic material) was recovered on acidification. Crystallization from benzene-acetone gave 30 g. of a crude crystalline mixture with a melting point of 97°C. Another recrystallization from benzene yielded 19.1 g. (27.9%) of a pure sample of $III_t \cdot C_6H_6$.

The Hydrogenation of Bisphenol A over Urushibara Nickel-B.—*Reduction up to 220°C.*—This was carried out as usual, using 70 ml. of a U-Ni-B[12] under 92 kg./cm^2 of initial hydrogen pressure. The temperature was allowed to rise up to 220°C over a period of 135 min. After working-up as usual and subsequent crystallization from benzene, 33.5 g. of crystals were obtained, m. p. 97—137°C. This product was easily soluble in ethyl acetate and in alkali, and gave no crystals from the ethyl acetate solution on cooling. Therefore, this fraction consisted of phenolic compounds and no saturated ones. Recrystallization from benzene-acetone gave 21.1 g. (32%) of $III_t \cdot C_6H_6$.

The concentration of the above-obtained mother liquor gave 2.4 g. (4.6%) of other crystals, m. p. 173—185°C, a crude $II_{t\text{-}t}$.

The finally-remaining oily substance (29 g.) was stored for use in the detection of the other isomers of II and III.

Reduction up to 260°C.—This was carried out as usual under a 103 kg./cm^2 initial hydrogen pressure, using 82 ml. of a U-Ni-B. The temperature was allowed to rise up to 263°C over a period of 195 min. Working-up as usual yielded 43 g. (81%) of an alkali-insoluble product, m. p. 122—148°C. Recrystallization from ethyl acetate gave the following crops: (a) m. p. 167—182°C, 15 g. (28%), which mainly consisted of $II_{t\text{-}t}$; (b) m. p. 156—159°C, 13 g. (24%), almost all $II_{c\text{-}t}$; and (c) m. p. 132—150°C, 4.4 g. (8%).

The Diacetate of $II_{t\text{-}t}$.—A mixture of 1.0 g. of $II_{t\text{-}t}$, 0.2 g. of anhydrous sodium acetate, and 1.67 g. of acetic anhydride was heated in a boiling-water bath for 5 hr. After cooling, the solution was poured into ice-water and neutralized with sodium bicarbonate powder. The white precipitate was then collected on a filter, washed with water, and dried to give the crude crystals, 1.30 g. (96%). Recrystallization from methanol gave the analytical sample, m. p. 136—138°C.

Found: C, 70.32; H, 9.92. Calcd. for $C_{19}H_{32}O_4$: C, 70.33; H, 9.94%.

ν_{max}^{Nujol} 1736, 1730 (C=O, acetate); 1259, 1244 (acetate); 1038, 1019 cm^{-1} (C–O).

NMR[27], (70 mg./0.45 ml. of CCl_4): 5.58 τ (axial hydrogens at C-4 and C-4').

The Dibenzoate of $II_{t\text{-}t}$. — One gram of $II_{t\text{-}t}$, 3 g. of pyridine, 5 ml. of dioxane, and 3 g. of benzoyl chloride were mixed and heated under reflux for 2 hr. This mixture, after the usual work-up, gave 1.45 g. (78%) of the dibenzoate of $II_{t\text{-}t}$ as white needles, m. p. 192—193°C, these needles were insoluble in both ethanol and methanol.

Found: C, 77.61; H, 7.99. Calcd. for $C_{29}H_{36}O_4$: C, 77.64; H, 8.09%.

ν_{max}^{Nujol} 1708 (C=O, benzoate); 1274 cm^{-1} (benzoate).

The Hydrolysis of the Diacetate of $II_{t\text{-}t}$.—A mixture of 0.15 g. of the diacetate in 3 ml. of methanol with 0.3 g. of sodium hydroxide in 2 ml. of water was refluxed for 3.5 hr. After concentration and then dilution with water, white crystals (0.10 g., 90%) separated out; these crystals melted at 188—189°C and did not depress the melting point of an authentic sample of $II_{t\text{-}t}$.

The Diacetate of $II_{c\text{-}t}$.—This was prepared as has been described in the case of $II_{t\text{-}t}$. After working-up, 1.35 g. of the crude diacetate melting at 70—74°C were obtained. Recrystallization from ethanol gave 1.05 g. (77%) of the analytical sample, m. p. 75.5—76.5°C.

Found: C, 70.44; H, 9.83. Calcd. for $C_{19}H_{32}O_4$: C, 70.33; H, 9.94%.

ν_{max}^{Nujol} 1742, 1730 (C=O, acetate); 1266, 1243, 1221 (acetate); 1039, 1019 cm^{-1} (C-O).

NMR, 70 mg./0.45 ml. of CCl_4): 5,10 τ (equatorial hydrogen at C-4); 5.58 τ (axial hydrogen at C-4').

The Dibenzoate of $II_{c\text{-}t}$. — One gram of the diol was benzoylated in the same manner as $II_{t\text{-}t}$. After working-up as usual the resulting oil was crystallized from methanol to give a crude dibenzoate of $II_{c\text{-}t}$. Another recrystallization from methanol gave 1.4 g. (76%) of the analytical sample, melting at 105—105.5°C.

Found: C, 77.51; H, 8.08. Calcd. for $C_{29}H_{36}O_4$: C, 77.64; H, 8.09%.

ν_{max}^{Nujol} 1710 (C=O, benzoate); 1276 cm^{-1} (benzoate).

The Hydrolysis of Diacetate of $II_{c\text{-}t}$.—A sample

27) The nuclear magnetic resonance spectra were obtained by Dr. Keishi Kotera, the Osaka Research Laboratory of Tanabe Seiyaku Co., on a Japan Electron Optics Laboratory 60 MC spectrometer, using dilute solutions in carbon tetrachloride, with tetramethylsilane as an internal standard.

of 0.30 g. of the diacetate of II_{c-t} was hydrolyzed as in the case of that of II_{t-t}; this gave 0.21 g. (94%) of II_{c-t}, m. p. 163—164°C. This sample showed no melting-point depression on admixture with the original sample of II_{c-t}.

The Isolation of II_{c-c}. — A mother liquor obtained from all the separation procedures for II_{t-t} and II_{c-t} was concentrated under reduced pressure, and then heated in methanol with an excess of sodium ethoxide in order to remove the still-remaining phenolic compounds as water-soluble sodium salts.

After the removal of the solvent and sufficient washings with hot water, the remaining glassy solid was dissolved in benzene and passed through an activated-aluminum oxide column; this gave crystals from an elute using ethyl acetate. Recrystallization from ethyl acetate gave a sample melting at 167—170°C. The melting point was depressed on admixture with II_{t-t} or II_{c-t}. Therefore, this was confirmed to be the last isomer of II, II_{c-c}.

Found: C, 75.10, 75.14; H, 11.85, 11.78. Calcd. for $C_{15}H_{28}O_2$: C, 74.95, H, 11.74%.

The Diacetate of II_{c-c}. — This was prepared as that of II_{t-t}, using 0.5 g. of II_{c-c}; 0.68 g. (theoretical yield) of white crystals, m. p. 113.5—115°C, was thus obtained. Another recrystallization from methanol gave the analytical sample, m. p. 117—117.5°C.

Found: C, 70.33, H, 9.97. Calcd. for $C_{19}H_{32}O_4$: C, 70.33, H, 9.94%.

ν_{max}^{Nujol} 1735 (broad, C=O, acetate); 1260, 1251, 1220, 1217, 1209 (acetate); 1009 cm^{-1} (C–O).

NMR, (75 mg./0.45 ml. of CCl_4): 5.15 τ (equatorial hydrogens at C-4 and C-4').

The Dibenzoate of II_{c-c}.—A sample of 0.5 g. of II_{c-c} was benzoylated as usual. The recrystallization of the product from methanol gave white needles (0.66 g., 71%), m. p. 152—153°C.

Found: C, 77.61; H, 8.07. Calcd. for $C_{29}H_{36}O_4$: C, 77.64; H, 8.09%.

ν_{max}^{Nujol} 1710 (C=O, benzoate); 1608, 1589 (phenyl); 1280, 1272 cm^{-1} (benzoate).

The Hydrolysis of the Dibenzoate of II_{c-c}.— A solution of 0.24 g. of the dibenzoate in 4 ml. of acetone, and 2 ml. of water containing 0.10 g. of sodium hydroxide were mixed and refluxed for 6 hr. After the solvent had been removed, the resulting crystals were gathered on a glass filter, washed with water, and dried. Recrystallization from benzene - petroleum benzine gave 0.10 g. (77%) of II_{c-c}, m. p. 174—175°C.

Found: C, 74.86, 75.04; H, 11.71, 11.62. Calcd. for $C_{15}H_{28}O_2$: C, 74.95; H, 11.74%.

ν_{max}^{Nujol} 3380 (OH); 1012, 959 cm^{-1} (axial alcohol).

The Sodium Inversion of II_{c-t} to II_{t-t}. — One gram of II_{c-t} was dissolved in 1 ml. of xylene. To this solution at 160°C, 0.4 g. of sodium was added in small portions. The reaction system evolved hydrogen gas, and after a while it precipitated some solids. After reaction at 180°C for 12 hr., the reaction mixture was decomposed by the drop-by-drop addition of ethanol and water. The precipitate was gathered on a glass filter, washed with water, dried, and weighed (0.96 g. (96%)), m. p. 175—184°C. Recrystallization from ethyl acetate gave an analytical sample, m. p. 188—189°C, which was identical with an authentic sample of II_{t-t}.

The Sodium Inversion of II_{c-c} to II_{t-t}. — This was carried out as above, using 0.50 g. of II_{c-c}; it gave 0.35 g. (70%) of a pure sample of II_{t-t}.

2, 2-Bis(4-ketocyclohexyl)propane (IV)[28]. — An isomeric mixture of II (54.0 g., m. p. 150—178°C) was dissolved in 250 ml. of glacial acetic acid. To this solution, under stirring and cooling at 17—18°C, there was added, drop by drop over a period of about 2 hr., 55.0 g. of chromium trioxide in a dilute acetic acid (250 ml. of glacial acetic acid and 40 ml. of water). After another one hour's reaction, 275 ml. of isopropyl alcohol was added under water-cooling; the solution was then allowed to stand overnight. Concentration under reduced pressure and the pouring of the remaining product into water precipitated powdery white crystals. After filtration and drying, 41.0 g. (78%) of the crude diketone, m. p. 159—163°C, was obtained. Recrystallization from benzene raised the melting point to 162.5—163°C (lit.,[4] m. p. 158—160°C).

Found: C, 76.36; H, 10.18. Calcd. for $C_{15}H_{24}O_2$: C, 76.23; H, 10.24%.

ν_{max}^{Nujol} 1718 cm^{-1} (six-membered-ring ketone).

Disemicarbazone.—This was prepared as usual, m. p. 220—223°C (decomp.) (lit.,[4] 220—223°C). Another melting point, 238—239°C (decomp.), was observed when the disemicarbazone was measured with a rapid temperature rise.

The Formation of 2, 2-Bis(4, 4-dimethoxycyclohexyl)propane (V) and the Regeneration of the Original Diketone IV by Acid Hydrolysis.—When the diketone IV was heated in purified methanol and the solution was concentrated, fair white plates of the tetramethyl diketal, m. p. 140.5—141.5°C, were obtained in a theoretical yield.

Found: C, 69.11; H, 10.80. Calcd. for $C_{19}H_{36}O_4$: C, 69.47; H, 11.05%.

ν_{max}^{Nujol} no peak in the region of six-membered-ring ketone; 1161, 1100, 1040 cm^{-1} (tetramethyl diketal).

Similar procedures using other alcohols, such as ethanol or propanol, gave no reaction, and only the original diketone was recovered.

The tetramethyl diketal (1.00 g.) in a mixed solution of 15 ml. of acetone and 5 ml. of water containing 2.0 ml. of concentrated hydrochloric acid was refluxed for 2 hr. After the addition of 15 ml. of water to the reaction system and the removal of the acetone by distillation, crystals of IV were recovered.

The Rapid Hydrogenation of the Diketone IV over Platinum Black Catalyst.—A solution of 1.00 g. of IV in 35 ml. of glacial acetic acid was shaken with 0.37 g. of a platinum black catalyst and hydrogen under atmospheric pressure at room temperature. After 55 min., 110% of the theoretical amount of hydrogen was absorbed. Working-up as usual gave 1.05 g. of a sirup which was subsequently separated chromatographically, using 120 g. of an activated aluminum oxide, into three main fractions. The first fraction, eluted with ether-methanol, was 200 mg. (19.7%) of crude crystals, containing II_{c-c} mainly. The second was 636 mg. (62.5%) of a sirup consisting mainly of II_{c-t}, plus some II_{t-t}. These two fractions were confirmed

28) This procedure followed the analogous method by Wilds et al. used for the preparation of bicyclohexyl-4, 4'-dione.[14]

by a study of their infrared spectra and by mixed-melting-point tests with authentic samples after repeated recrystallizations from benzene. The third fraction consisted of 32 mg. (3.1%) of almost pure crystals of $II_{t\text{-}t}$, m. p. 183—185°C.

The Diacetate of III$_t$.—A solution of 1.33 g. of $III_t \cdot C_6H_6$ in 2.0 g. of acetic anhydride containing two drops of concentrated sulfuric acid was heated in a boiling-water bath for 1.5 hr. After working-up as usual and recrystallization from methanol, 0.67 g. (49%) of crystals melting at 108—109.5°C was obtained.

Found: C, 71.75; H, 8.30. Calcd. for $C_{19}H_{26}O_4$: C, 71.67; H, 8.23%.

ν_{max}^{Nujol} 1760, 1227 (phenyl acetate); 1730, 1249 (acetate of secondary alcohol); 1610, 1511 (phenyl); 1039, 1022 (C–O); 841 cm^{-1} (*p*-disubstituted benzene).

The Isolation of III$_c$.—The mother liquor collected from the purification of the alkali-soluble product, which was almost free from III_t, was repeatedly extracted with a hot alkali solution in order to separate it from alkali-insoluble materials. On acidification, from the extract there separated a viscous oil which deposited crystals when left standing. Recrystallization from benzene gave an analytical sample melting at 159—161°C, this was concluded to be III_c by a mixed-melting-point test with an authentic sample of III_t and by the following analyses.

Found: C, 76.82; H, 9.51. Calcd. for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

ν_{max}^{Nujol} 3445, 3220 (OH); 1613, 1597, 1509 (phenyl); 1231 (phenol); 1008, 944 (axial alcohol); 825 cm^{-1} (*p*-disubstituted benzene).

The Sodium Inversion of III$_c$ to III$_t$.—A sample of 0.50 g. of III_c in 0.50 g. of xylene was refluxed with 0.20 g. of sodium at 180°C for 10 hr. After the solution had been treated with ethanol and then water, and acidified with dilute hydrochloric acid, the isolated product was worked-up as usual and recrystallized from benzene-acetone to give 0.21 g. (42%) of crystals melting at 147.5—150°C. Further recrystallization gave an analytical sample which was found to be identical with an authentic sample of III_t by a mixed-melting-point test.

The Reaction of III$_c$ with Acetic Anhydride.—A mixture of 0.20 g. of III_c and 0.1 g. of potassium acetate in 1.0 ml. of acetic anhydride was heated in a boiling-water bath for 10 hr., and then poured into ice-water and neutralized with sodium bicarbonate. The oily product which separated was taken up in benzene, washed with water, and dried over anhydrous sodium sulfate. After the removal of the solvent, there was obtained 0.34 g. of an oily mixture which did not crystallize upon the usual treatment. This mixture was, therefore, vacuum-distillated in order to purify it; it gave one fraction, boiling in the range of 120—160°C/0.55 mmHg without decomposition. The distillate almost entirely solidified like a wax after it had stood for a while, but it still was not pure enough to analyze. Therefore, a chromatographic separation of this distillate through a silica gel column was carried out. Elution with benzene-ether (2 : 3) gave 240 mg. (76%) of crude crystals melting below 60°C; these crystals were concluded, by the following tests, to be 2-(3-cyclohexenyl)-2-(*p*-hydroxyphenyl)propane formed by the dehydration, not the diacetate of III_c.

Found: C, 82,13, 82.10; H, 9.31, 9.29. Calcd. for $C_{15}H_{20}O$: C, 83.28; H, 9.32%.

ν_{max}^{Liquid} 3330 (OH); 3040, 2990 (=CH); 1230 (phenol); 827 cm^{-1} (*p*-disubstituted benzene).

Phenyl Carbamate.—This was prepared as usual from 200 mg. of the above-obtained crude sample and 0.50 g. of phenyl isocyanate; it was obtained as a waxy crystalline product melting at 100—110°C. By a chromatographic separation using a silica gel column and subsequently-repeated recrystallizations from petroleum benzine and then ethanol-water, the melting point was raised to 116—117.5°C, 2-(3-cyclohexenyl)-2-(*p*-phenylaminocarboxyphenyl)propane.

Found: C, 78.53; H, 7.73; N, 4.35. Calcd. for $C_{22}H_{25}NO_2$: C, 78.77; H, 7.51; N, 4.18%.

ν_{max}^{KBr} 3350 (bonded NH); 3057, 3018 (unsaturated CH); 1740—1709 (amide I); 1652 (RHC=CHR', *cis*); 1615, 1600, 1500 (phenyl); 1543 (amide II); 848 cm^{-1} (*p*-disubstituted benzene).

The author wishes to thank Dr. Isao Shiihara, Government Industrial Research Institute of Osaka, for his excellent aid to this research, and Mrs. Masako Hayashi for the elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2202—2205 (1966)

Studies of *C*-Substituted Tartaric Acid. II. On the Configurations of Isomeric 2-Methyltartaric Acids, 1, 2-Dihydroxycyclohexane-1, 2-dicarboxylic Acid and 2, 3-Dimethyltartaric Acids

By Susumu TATSUMI

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received November 5, 1965)

The assignments of the erythro-threo configuration to isomeric 2-methyltartaric acids and the cis-trans configuration to isomeric 1, 2-dihydroxycyclohexane-1, 2-dicarboxylic acids were made on the basis of the infrared absorption spectra of their calcium salts. Thus, the isomer of 2-methyltartaric acid, with a m. p. of 146°C, corresponds to the erythro form, and the other isomer, with a m. p. of 161°C, to the threo form; also the one isomer of isomeric 1, 2-dihydroxycyclohexane-1, 2-dicarboxylic acids with a m. p. of 154°C corresponds to the cis (meso) form, and the other, with a m. p. of 180°C, to the trans (racemic) form. The configurations of the compounds are discussed in comparison with those of tartaric acid and 2, 3-dimethyltartaric acid, the latter of which was recently decided by optical resolution by present author (S. Tatsumi, This Bulletin, in press.).

2-Methyltartaric acid, 1, 2-dihydroxycyclohexane-1, 2-dicarboxylic acid and 2, 3-dimethyltartaric acid are interesting substances in relation to tartaric acid from the stereochemical point of view. In the previous paper[1] it has been reported that two racemic forms of 2-methyltartaric acid, the melting points of which are 146°C (Ia) and 161°C (Ib), were prepared and that both racemic substances were then resolved into their optically active isomers. In an earlier publication from our laboratory,[2] it was also reported that a Raney nickel catalyst treated with aqueous solutions of these optically active hydroxy acids has an asymmetric activity in the hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate, and that a high asymmetric activity is obtained when the catalyst is treated with optically active Ib, while opticallyactive Ia has only a low asymmetric effect on Raney nickel under the same conditions. Thus it has been supposed that the difference in the asymmetric effects of Ia and Ib depends upon their erythro-threo isomerism. However, there have been no reports on the configurations of isomeric 2-methyltartaric acids.

1, 2-Dihydroxycyclohexane-1, 2-dicarboxylic acid,*1 which is a kind of *C*, *C'*-disubstituted tartaric acid, was prepared from 1, 2-cyclohexanedione and then separated into two optically inactive isomeric forms, the melting points of which are 154°C (IIa) and 180°C (IIb).*1 It is, however, unknown at the present time which steric isomer is cis (meso) and which is trans (racemic).

On the other hand, the present author and others[1] have reported that 2, 3-dimethyltartaric acid has two optically inactive modifications, the melting points of which are 180°C (IIIa) and 187°C (IIIb), and that IIIb could be resolved into two optically active isomers, while IIIa could not. This shows clearly that IIIb corresponds to the threo (racemic) form and IIIa, to the erythro (meso) form.

In the present study, the configurations of the isomeric 2-methyltartaric acids and 1, 2-dihydroxycyclohexane-1, 2-dicarboxylic acids were assigned on the basis of a study of the infrared spectra of their calcium salts in comparison with the configurations of meso and racemic tartaric acid (IVa and IVb) and those of meso and racemic 2, 3-dimethyltartaric acid. There have been several reports[3] on the configurations of aliphatic or alicyclic diol, but these cannot always be applied to an α, α'-dihydroxydicarboxylic acid. In the present paper, the configurations of isomeric *C*-substituted and *C*, *C'*-disubstituted tartaric acids are also predicted.

The physical constants and analytical data of the acids and their salts used in the present work are listed in Table I.

Experimental

Materials.—Ia (or Ib) and IIIa (or IIIb) were prepared from α-acetoxyacetoacetate and diacetyl respectively by the method described in the previous

paper.[1] IIa*[1] (or IIb*[1]) was prepared from 1,2-cyclohexanedione, and IVa (or IVb) was prepared from glyoxal by Pollak's procedure.[4]

The calcium salts were obtained by the neutralization of aqueous solutions containing the acids and an equimolar amount of calcium chloride, with a sodium hydroxide solution. The barium salts were obtained similarly by the neutralization of aqueous solutions of the acids with a barium hydroxide solution. The data for these acids and salts are listed in Table I.

Spectra.—The infrared spectra were recorded using a Shimadzu IR spectrophotometer; further details were also recorded using a Perkin-Elmer Model 221 spectrophotometer equipped with a lithium fluoride prism.

Results and Discussion

The Infrared Spectra of the Salts.—The spectra of Ia-calcium salt (Ia-Ca) and Ib-calcium salt (Ib-Ca) are shown in Fig. 1.

A characteristic difference between the spectrum of Ia-Ca and that of Ib-Ca was observed in the region around 3600 cm^{-1}. In this region Ia-Ca had a single sharp band, while Ib-Ca did not. A similar difference between the spectra of IIa-Ca and IIb-Ca was also observed, as is shown in Fig. 2. It is likely that these differences depend on the erythro-threo or meso-racemic (cis-trans) configurations of the salts.

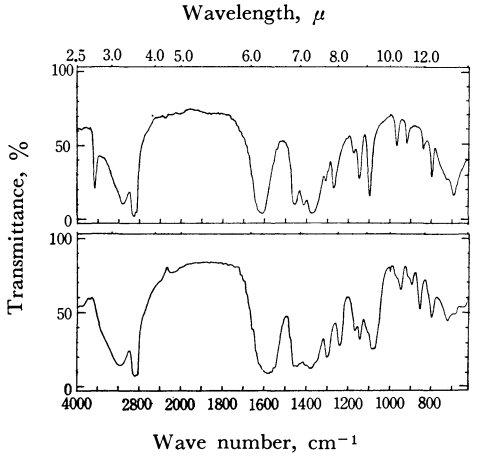

Fig. 1. Infrared spectra (Nujol) of:
Ia-Ca (upper curve)
Ib-Ca (lower curve)

4) F. Pollak, *Monatsh.*, **15**, 469 (1894).

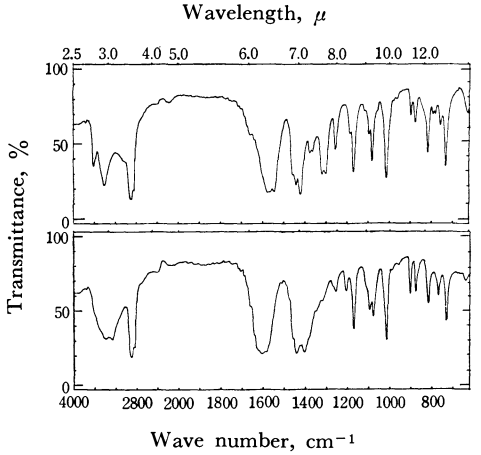

Fig. 2. Infrared spectra (Nujol) of:
IIa-Ca (upper curve)
IIb-Ca (lower curve)

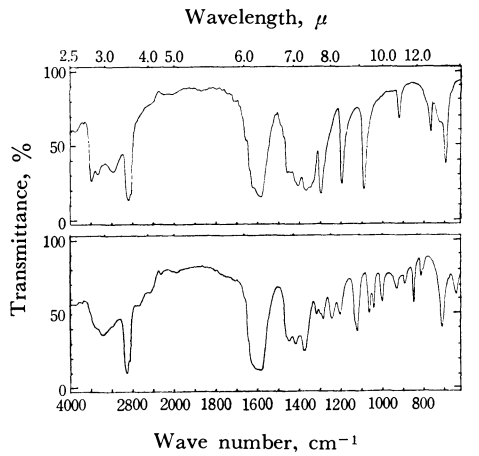

Fig. 4. Infrared spectra (Nujol) of:
IVa-Ba (upper curve)
IVb-Ba (lower curve)

To explain the configurations of these substances, the spectra of IIIa-Ba, IIIb-Ba, IVa-Ba and IVb-Ba, the configurations of which are well known, were measured and compared with the results described above. The spectra of these compounds of known configurations are shown in Figs. 3 and 4.

As is shown in Figs. 3 and 4, both IIIa-Ba and IVa-Ba had sharp bands similar to those of Ia-Ca and IIa-Ca shown in Figs. 1 and 2 in the region around 3600 cm^{-1}. IIIb-Ba and IVb-Ba did not have these bands, however, and thus were like Ib-Ca and IIb-Ca in this characteristic point.

On the other hand, as has been reported in the previous paper[1], IIIa and IIIb correspond to the erythro (meso) and threo (racemic) forms respectively; the optical resolution of the former is possible, but that of the latter is impossible. Moreover, IVa is the erythro (meso) form, and IVb is the threo (racemic) form.

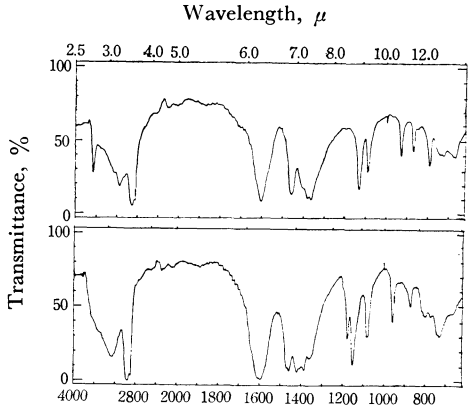

Fig. 3. Infrared spectra (Nujol) of:
IIIa-Ba (upper curve)
IIIb-Ba (lower curve)

Thus, from the configurations of these acids and the spectra of their salts, it may be supposed that both Ia and IIa are to be assigned to the same erythro or meso (cis) configuration as IIIa and IVa, and both Ib and IIb*2, to the same threo or racemic (trans) configuration as IIIb and IVb.

For further details of the spectrum in the 3600 cm^{-1} region, measurements were made of the spectra of the salts using a lithium fluoride prism. The observed frequencies were then calibrated against that of atmospheric vapor. Sharp bands of Ia-Ca, IIa-Ca, IIIa-Ba and IVa-Ba were observed at 3597, 3546, 3605 and 3554 cm^{-1} respectively, and no regular change in the intensity ratio with the concentration was observed. However, there were no similar bands in the spectra of Ib-Ca, IIb-Ca, IIIb-Ba and IVb-Ba. Hence, these bands must be due to intramolecular hydrogen bonds, which appear clearly only in the

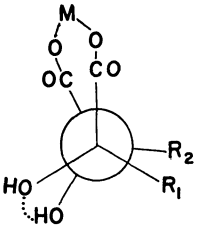

Fig. 5. Projections of the salts of:
Ia-Ca; M=Ca, $R_1=CH_3$ $R_2=H$
IIa-Ca; M=Ca, $(R_1)\text{-}CH_2\text{-}CH_2$ / $(R_2)\text{-}CH_2\text{-}CH_2$
IIIa-Ba; M=Ba, $R_1=R_2=CH_3$
IVa-Ba; M=Ba, $R_1=R_2=H$

*2 Subsequently, IIb corresponding to the racemic form was resolved into the optically active isomers and the present assignment was proved to be correct. Details of this work will be published in this Bulletin in the near future.

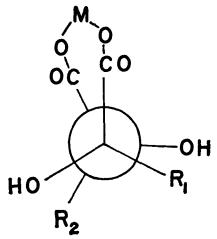

Fig. 6. Projections of the salts of:
Ib-Ca; M=Ca, $R_1=CH_3$, $R_2=H$
IIb-Ca; M=Ca, $\begin{matrix}(R_1)\text{-}CH_2\text{-}CH_2\\ \quad\quad\quad\quad\quad\quad|\\ (R_2)\text{-}CH_2\text{-}CH_2\end{matrix}$
IIIb-Ba; M=Ba, $R_1=R_2=CH_3$
IVb-Ba; M=Ba, $R_1=R_2=H$

erythro- or cis-type salts because of the definite conformational structure formed by the fixing of two carboxyl groups to a calcium or a barium metal, and by two fixing groups, carboxyl-metal and the alicyclic ring, as is shown in Fig. 5. It is likely that Ib-Ca, IIb-Ca, IIIb-Ba and IVb-Ba, which do not have intramolecular hydrogen bonds, have the threo or trans form and that they have the conformation shown in Fig. 6.

The configurations of isomeric 2-methyltartaric acids given above support the findings on their asymmetric hydrogenation effects upon a Raney nickel catalyst obtained in previous work.[2]

Summary

The configurations of isomeric 2-methyltartaric acids and 1, 2-dihydroxycyclohexane-1, 2-dicarboxylic acids have been determined on the basis of a study of the infrared spectra of their calcium salts in comparison with those of the barium salts of isomeric tartaric acids and 2, 3-dimethyltartaric acids, the configurations of which were already known. Both barium meso tartaric acid and barium meso 2, 3-dimethyltartaric acid have a sharp band due to intramolecular hydrogen bonds; however, the racemic salts do not. Similar differences have been observed in the spectra of the calcium salts prepared from isomeric 2-methyltartaric acids and isomeric 1, 2-dihydroxycyclohexane-1, 2-dicarboxylic acids. It has been concluded that these are due to a definite conformational structure caused by the fixing of two carboxyl groups with a metal. Thus, the form of 2-methyltartaric acid, with a m. p. of 146°C, was identified as the erthro form, and the form with a m. p. of 161°C, as the threo form. Further, the form of 1, 2-dihydroxycyclohexane-1, 2-dicarboxylic acid, with a m. p. of 154°C, was identified as the cis or meso form, and the other form, with a m. p. of 180°C, as the trans or racemic form.

The author wishes to express his hearty thanks to Dr. Yoshiharu Izumi of this Institute for his constant guidance throughout this study. He is also much indebted to Professor Tatsuo Miyazawa of the Molecular Biophysics Division of this institute for his valuable advice and discussion on the infrared spectra. He wishes to thank to Mr. Masami Imaida for experimental help, and Miss. Kiku Koike for elemental microanalyses. This research was made possible by the support of Ajinomoto Co., Inc., Tokyo.

Vinyl Polymerization. CXLVI.[1] The Influence of Dibenzoyl Disulfide Derivatives on Radical Polymerizations

By Kazuichi TSUDA and Takayuki OTSU

Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received November 19, 1965)

In order to study the effects of aromatic sulfur derivatives on radical polymerizations, dibenzoyl disulfide (DBDS) and its derivatives were prepared and used as initiators or chain transfer agents for the polymerizations of styrene and methyl methacrylate. All of these derivatives failed to act as initiators of thermal polymerizations, but they did prove effective photosensitizers. The rates of polymerizations were found not to be proportional to the square-root concentration of the initiator (DBDS) used. The sulfur radical derived from the photo-dissociation of DBDS affected not only the initiation reaction, but also the termination reaction. The chain transfer constants to DBDS derivatives in the polymerization of styrene and methyl methacrylate showed no linear relationship with Hammett's equation ($\log C/C_0=\rho\sigma$), but a linear relationship was obtained when a modification of Hammett's equation ($\log C/C_0=\rho\sigma+\gamma E_R$) was applied. From the plot obtained by the use of $\log C/C_0=\rho\sigma+\gamma E_R$, the γ value, which indicates the extent of resonance stabilization in the transition state was found to be 6.0 upon the polymerization of styrene at 60°C. Under similar conditions, however, the γ-value for benzoyl peroxide was calculated as 3.0 from the results of Cooper. This difference may be explained from an increased 3d-orbital resonance stabilization of DBDS in the transition state.

Several studies of the decomposition of organic peroxides have been made in order to clarify the relation between the structure of the peroxides and the abilities of their spontaneous and induced decompositions into free radicals. Not many systematic studies have yet been made, however, of the radical decomposition of organic peroxides. Pierson[2,3] reported the influence of several aromatic disulfides on the polymerization of styrene initiated by 2, 2'-azobisisobutyronitrile. Further studies were carried out by Otsu[4] on the use of diphenyl disulfide derivatives as chain-transfer agents in the polymerization of styrene. Tsuda et al.[5] have studied the influence of several sulfur compounds, which correspond to oxygen compounds, on radical polymerizations of styrene and methyl methacrylate.

The present paper will deal with the effect of the structure of di-substituted DBDS on their spontaneous decomposition (initiating activity) and induced decomposition (chain transfer ability) in the thermal or photo-polymerization of styrene and methyl methacrylate.

The nuclear-substituted DBDS substances used in this study have the following substituents: *p,p'*-OCH_3, *p,p'*-CH_3, *p,p'*-H, *p,p'*-Cl, *p,p'*-Br, *p,p'*-CN and *p,p'*-NO_2.

Experimental

The Preparation of *p, p'*-Disubstituted DBDS.—*Dibenzoyl Disulfide (DBDS).*—The preparation of DBDS was carried out according to the method of Frank and Blegen,[6] m. p. 128.0—128.5°C. (Found: C, 61.21; H, 3.80; S. 23.38. Calcd. for $C_{14}H_{10}O_2S_2$: C, 61.28; H, 3.67; S, 23.37%.)

p,p'-Dibromodibenzoyl Disulfide (Br-DBDS).—Br-DBDS was prepared from *p*-bromobenzoic acid which had been obtained from *p*-nitrotoluene,[7] the same as in the case of DBDS; m. p. 146.0—147.0°C. (Found: C, 39.05; H, 1.97; S, 14.90; Br, 37.15. Calcd. for $C_{14}H_8O_2S_2Br_2$: C, 38.91; H, 1.87; S, 14.84; Br, 36.83%.)

p,p'-Dichlorodibenzoyl Disulfide (Cl-DBDS).—Cl-DBDS was prepared from *p*-chlorobenzoic acid which had been obtained by the oxidation of *p*-chlorotoluene,[8] the same as in the preparation of DBDS; m. p. 122.5—123.0°C. (Found: C, 49.26; H, 2.45; S. 18.39; Cl, 20.60. Calcd. for $C_{14}H_8O_2S_2Cl_2$: C, 48.99; H, 2.35; S, 18.68; Cl, 20.65%).

p,p'-Dimethoxydibenzoyl Disulfide (MeO-DBDS).—Commercial anisic acid was recrystallized (m. p. 183.0—183.5°C), and MeO-DBDS was obtained by the same manner as DBDS. The MeO-DBDS thus obtained was light pink in color; m. p. 119.0—120.0°C. (Found:

1) Vinyl Polymerization. CXLV: S. Aoki, T. Otsu and M. Imoto, *Makromol. Chem.*, in press.

C, 57.38; H, 4.30; S, 18.97. Calcd. for $C_{16}H_{14}O_4S_2$: C, 57.47; H, 4.22; S, 19.18%.)

p, p' - Dimethyldibenzoyl Disulfide (Me - DBDS). — *p*-Toluic acid, an oxidation intermediate of *p*-xylene to telephthalic acid, was recrystallized first from toluene and then from benzene; m. p. 178.5—179.0°C. Me-DBDS was prepared from *p*-toluic acid by the same manner as DBDS; m. p. 118.0—119.0°C. (Found: C, 63.30; H, 4.70; S, 21.09. Calcd. for $C_{16}H_{14}O_2S_2$: C, 63.55; H, 4.67; S, 21.15%.)

p, p'-Dinitrodibenzoyl Disulfide (NO_2-DBDS). — According to the method mentioned above, NO_2-DBDS was prepared from *p*-nitrobenzoic acid. This material was yellow in color and was an amorphous substance; m. p. 183.0—183.5°C. with decomp. (Found: C, 46.40; H, 2.40; S, 17.47; N, 7.64. Calcd. for $C_{14}H_8O_6N_2S_2$: C, 46.15; H, 2.22; S, 17.60; N, 7.68%.)

p, p'-Dicyanodibenzoyl Disulfide (CN-DBDS).—From *p*-cyanobenzoic acid,[9] CN-DBDS was prepared by the same manner as DBDS. The CN-DBDS thus obtained was orange in color and was an amorphous material; m. p. 179.5—180.0°C with decomp. (Found: C, 58.87; H, 2.59; S, 19.15; N, 8.47. Calcd. for $C_{16}H_8O_2N_2S_2$: C, 59.24; H, 2.49; S, 19.77; N, 8.64%.)

The Purification of Materials.—It was rather difficult to remove impurities from the DBDS derivatives thus obtained, so recrystallization was repeated from 5 to 10 times in dichloroethane or ethyl acetate.

The 2, 2'-azobisisobutyronitrile (AIBN) which was used as the initiator was purified by recrystallization three times from ethanol; m. p. 102.0—102.5°C.

Styrene (St) and methyl methacrylate (MMA) were purified by the ordinary method.

Polymerization Procedure.—Bulk polymerization by the ordinary glass-tube method was employed. In the case of NO_2-DBDS, however, benzene solution polymerization was adopted, because this disulfide was not dissolved in these monomers.

Thermal polymerizations were conducted at 60°C, under shaking and in the absence of light. Photopolymerizations were done at 25°C, using ultraviolet-ray irradiation. None of the polymerizations were allowed to proceed beyond 10% conversion. It was noted that the addition of NO_2-DBDS or CN-DBDS caused the mixture to grow yellowish-white during the polymerization. After polymerization, the polymer was precipitated by the addition of an excess of methanol, washing with methanol, and then drying under a vacuum. A trace of a yellow substance similar to sulfur was obtained when the polymer, monomer and methanol precipitant were removed. No further examination of this substance was made.

The Determination of the Chain Transfer Constant.—The intrinsic viscosity $[\eta]$ was determined in benzene at 30°C by using Ubbelohde's viscometer. The number-average degree of polymerization ($\overline{P_n}$) was calculated by Eqs. 1 and 2;

For polystyrene[10]: $\log \overline{P_n} = 3.205 + 1.37 \log [\eta]$ (1)

For polymethyl methacrylate[11]:

$$\log \overline{P_n} = 3.420 + 1.13 \log [\eta] \quad (2)$$

The chain transfer constants (C) to DBDS derivatives were calculated by Mayo's equation (3):

$$1/\overline{P_n} = 1/\overline{P_0} + C \cdot [S]/[M] \quad (3)$$

where [S] and [M] are the initial concentrations of the DBDS derivatives and the monomers respectively.

Results

DBDS Derivatives Used as Initiators in Thermal Polymerization.—Table I shows the results of the thermal polymerization of St and MMA when DBDS derivatives were employed as initiators at 60°C.

As is shown in Table I, it may safely be said that DBDS derivatives do not act as initiators in the thermal polymerizations of St and MMA. Recently, it has been found that DBDS derivatives also do not act as initiators of the thermal polymerization of St and MMA at 80°C and 100°C.[12]

of polymerization in the absence and in the presence of DBDS derivatives. Figure 1 shows the correlation between R/R_0 and the concentration of the DBDS derivatives. It may be seen that CN-DBDS and NO_2-DBDS remarkably retard the polymerization of MMA. These facts agree with the results shown in Table I. In order to estimate the chain transfer constants of DBDS derivatives, the plots obtained by Eq. 3 are shown in Figs. 2 and 3. The chain transfer constants to DBDS derivatives are shown in Table II.

The Photo-polymerization of DBDS Derivatives. — The results of the photo-polymerization of St and MMA conducted using DBDS derivatives as photo-sensitizers are shown in Table III.

* Absence of DBDS

As may be clearly seen from Table III, the DBDS derivatives employed here were effective sensitizers in the photo-polymerizations of both monomers. The relations between the concentrations of the DBDS derivatives employed as sensitizers and the rates of polymerizations are shown in Fig. 4. Unlike as in the ordinary radical polymerizations, the rate of polymerization had no linear relationship depending on the square-root concentration of the DBDS derivatives; it gave a maximum, indicating that the sulfur radical produced by the photo-decomposition of DBDS derivatives acts as both initiator and terminater of the polymerization.

Similar phenomena were observed in the photo-polymerization of these monomers in the presence of AIBN. The results are shown in Fig. 5.

Discussion

As is clear from Table I, DBDS derivatives do not serve as initiators of the thermal polymerization of St and MMA. It is obvious from this finding that DBDS derivatives, unlike benzoyl peroxide, do not decompose into free radicals under the present conditions. This may be attributable to the difference between the bond-dissociation energy

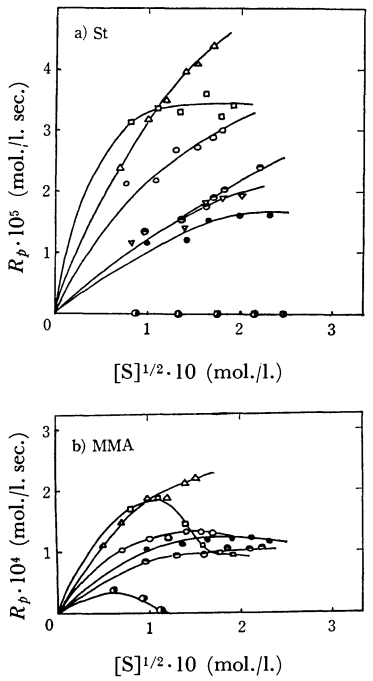

Fig. 4. Effects of DBDS on the rate of photo-polymerization of St and MMA at 25°C.
Marks are the same as in Fig. 1.

of the –O–O– linkage in benzoyl peroxide (about 30 kcal./mol.) and that of the –S–S– linkage in alkyl disulfide (about 70—73 kcal./mol.). As

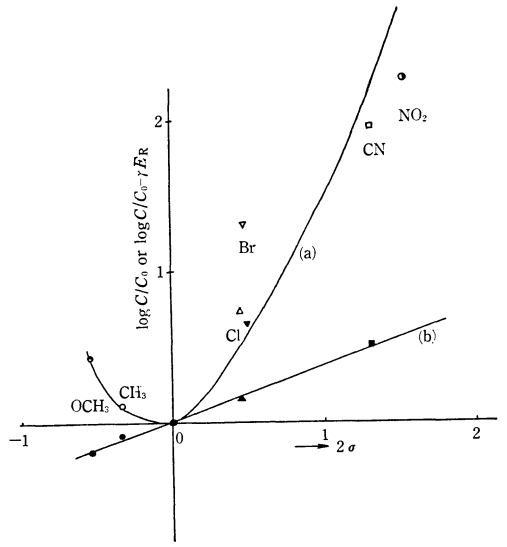

Fig. 6. Plots by Eqs. 4 and 5 for the chain transfer to DBDS in the polymerization of St.

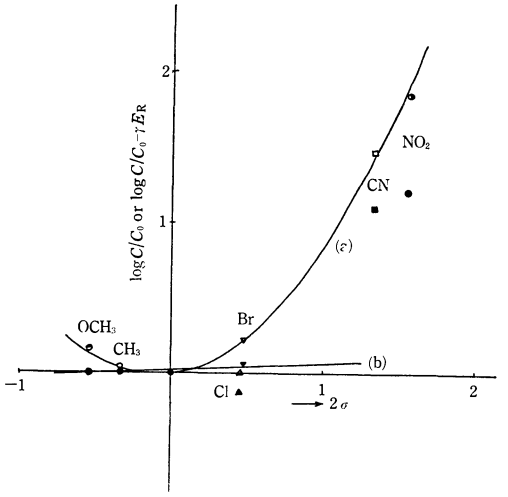

Fig. 7. Plots by Eqs. 4 and 5 for the chain transfer to DBDS in the polymerization of MMA.

shown in Table III, all DBDS derivatives except NO_2-DBDS could act as effective sensitizers of the photo-polymerization of these monomers. NO_2-DBDS was found to inhibit thermal and photo-polymerizations.

Contrary to the ordinary kinetic behavior, an abnormal correlation between the rate of polymerization and the concentration of DBDS derivatives in the photo-polymerizations was observed, as is shown in Figs. 4 and 5. These results can be explained by noting that the sulfur radical produced by the application of ultraviolet rays can not only initiate but also terminate the polymerization. Almost the same behavior was observed in

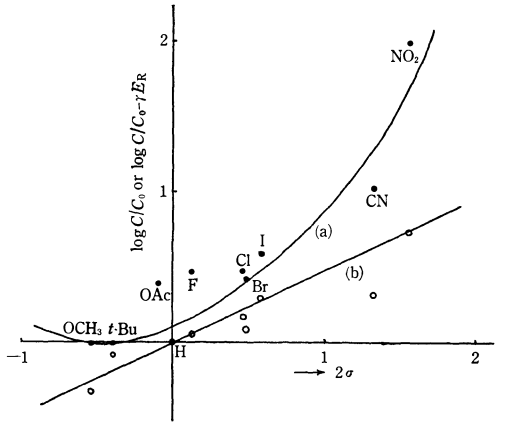

Fig. 8. Relationship between $\log C/C_0$ or $\log C/C_0 - \gamma E_R$ and σ constants calculated from the chain transfer to benzoyl peroxide derivatives in the polymerization of St:
a) plotted by Eq. 4, b) plotted by Eq. 5.

the polymerization of MMA initiated by tetraethyl thiuram disulfide.[13]

In order to clarify the relation between the reactivites of DBDS derivatives toward the attack of radicals and their structures, especially those of their substituents, the chain-transfer constants of those derivatives were plotted with the σ values, according to Hammett's equation (4);

$$\log C/C_0 = \rho\sigma \qquad (4)$$

were C and C_0 are the chain-transfer constants of substituted and of unsubstituted DBDS, respectively, σ is Hammett's substituent constant, and ρ is the reaction constant. The results are shown in Figs. 6 and 7; they do not give a straight line. Such parabola-type relations have been observed in many radical reactions.[14,15]

Recently, Yukawa and Tsuno[16] have derived a modified Hammett's equation by considering the resonance contribution in electrophilic ionic reactions. On the other hand, Yamamoto et al.,[17] who are now working in our laboratory, have proposed another modified Hammett's equation (5) for radical reactions:

$$\log C/C_0 = \rho\sigma + \gamma E_R \qquad (5)$$

where the γ value is the extent of the resonance stabilization and E_R is the resonance substituent constant, as was estimated by Yamamoto et al.[15,17] ρ is the reaction constant, and σ is Hammett's polar term. It was then shown that Eq. 5 could be nicely applied in various types of radical reactions (over 120 examples).

When Eq. 5 was applied to the present chain-transfer reactions of DBDS derivatives, the fairly good straight lines illustrated in Figs. 6 and 7 were obtained. From these figures, the values of γ and ρ were obtained as follows:

For St: $\gamma = 6.0$ $\rho = 0.36$

For MMA: $\gamma = 1.5$ $\rho = 0.07$

In 1952, Cooper[18] determined the chain-transfer constant to substituted benzoyl peroxides in the polymerization of St. When Cooper's results are plotted by Hammett's equation (4) and Yamamoto's equation (5), Fig. 8 is obtained. Figure 9 is obtained by the same plots of the chain-transfer constants to substituted diphenyl disulfides.[4] The ρ and γ values from Figs. 8 and 9 are summarized in Table IV.

TABLE IV. γ, ρ VALUES FOR CHAIN TRANSFER REACTION

Attacking radical	Chain transfer agent	γ	ρ
PSt	DBDS	6.0	0.36
PMMA	DBDS	1.5	0.07
PSt	BPO*	3.0	0.38
PSt	DPDS**	4.0	0.23

* BPO: Benzoyl peroxide
** DPDS: Diphenyl disulfide

The value of DBDS toward the attack of a polystyryl radical is larger than that of benzoyl peroxide, because the resonance stabilization of sulfur is exceedingly strong. As has been pointed out by Oae,[19] the resonance stabilization in the reactions involving a sulfur compound may be considered

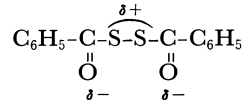
to be made greater by the existence of the 3d orbital resonance of the sulfur atom in the transition state than those involving an oxygen compound.

The decrease in γ values for the attack of the PMMA radical compared with that of the PSt radical may be considered to reflect the difference in the degree of contribution of the resonance effect in their transition states, but this point is not clear at the present time.

The ρ values obtained are positive, indicating that the –S–S– linkage in DBDS is $\delta+$ as is shown below;



This is also true in benzoyl peroxide, as was pointed out by Imoto et al.[20] The fact that almost the same ρ values were obtained in both DBDS and benzoyl peroxide (Table IV) might indicate that the polar contribution of the two compounds in their transition states did not differ from each other.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2211—2215 (1966)

The Autoxidation of *p*-Xylene Catalyzed with Cobalt Monobromide in Acetic Acid

By Yoshio KAMIYA, Tadahiko NAKAJIMA and Kōichiro SAKODA

Department of Fuel Technology, The University of Tokyo, Hongo, Tokyo

(Received November 26, 1965)

The rate of the cobalt-catalyzed autoxidation of *p*-xylene by adding sodium bromide reaches the steady state within several minutes and increases remarkably at high cobalt concentrations. Although *p*-tolualdehyde as well as water, the main oxidation products of *p*-xylene at the initial stage, strongly affect the rate of oxidation, the apparent rate is kept constant over a long period. When cobalt dibromide is used, a pronounced induction period can be observed at high cobalt concentrations, and the rate of oxidation starts to decrease after a short while. The effect of the ratio of sodium bromide to cobalt has shown that cobalt monobromide is an effective catalyst for the propagation step. The rate of the oxidation of *p*-xylene is found to be of the order of from 1.5 to 2.0 with respect to cobalt at concentrations from 10^{-3} to 5×10^{-2} mol./l. and at temperatures from 65 to 95°C, and to be first-order with respect to the *p*-xylene concentration; these findings show excellent agreement with the theory. When cobalt is partly replaced by manganese, a strong synergistic effect can be observed.

Although several papers[1-5] have been published on the autoxidation of methyl-substituted benzene catalyzed with cobalt bromide, the reaction mechanism is still far from certain. We have shown very recently that the rate of the cobalt-catalyzed autoxidation of tetralin[6] in acetic acid is increased remarkably in the presence of sodium bromide and have kinetically proved that this effect can be attributed to the participation of a new type of propagation reaction between cobalt monobromide and the tetralyl peroxy radical; the kinetic scheme can be represented as follows:

$$\mathrm{ROOH} + (\mathrm{Co})_2 \xrightarrow{k_1'} \text{radical} \xrightarrow{\mathrm{RH}} \mathrm{R}\cdot \quad (1)$$

$$\mathrm{R}\cdot + \mathrm{RH} \xrightarrow{k_2} \mathrm{RO_2}\cdot \quad (2)$$

$$\mathrm{RO_2}\cdot + \mathrm{RH} \xrightarrow{k_3} \mathrm{ROOH} + \mathrm{R}\cdot \quad (3)$$

$$\mathrm{RO_2}\cdot + \mathrm{Co^{2+}BrH} \xrightarrow{k_3'} \text{products} + (\mathrm{Co^{2+}} + \mathrm{Br}\cdot) \quad (4)$$

$$(\mathrm{Co^{2+}} + \mathrm{Br}\cdot) + \mathrm{RH} \xrightarrow{k_4} \mathrm{Co^{2+}BrH} + \mathrm{R}\cdot \quad (5)$$

$$\mathrm{RO_2}\cdot + \mathrm{RO_2}\cdot \xrightarrow{k_6} \text{products} + \mathrm{O_2} \quad (6)$$

$\mathrm{Co^{2+}BrH}$ represents the cobalt-hydrogen bromide complex, which we suggest is the effective catalyst

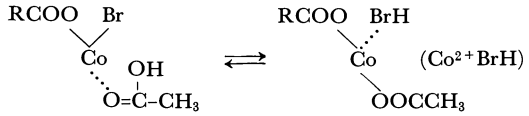
for the propagation and the alternative structure of cobalt monobromide in acetic acid.



However, the reaction scheme in the autoxidation of *p*-xylene catalyzed with cobalt bromide should be considerably different from the one shown above; the rate of the cobalt-catalyzed autoxidation of *p*-xylene in acetic acid is extremely slow at temperatures as low as 80°C, even at the cobalt concentration of 5×10^{-2} mol./l., and so the rate of propagation step must be very slow. Previously,[6] it has been suggested that another propagation reaction 7 between $Co^{2+}BrH$ and the peroxy radical, proceeds to a minor extent as compared with Eq. 4, because the steady state concentration of tetralin hydroperoxide observed increases a little when sodium bromide is added to the solution.

$$RO_2\cdot + Co^{2+}BrH + RH \xrightarrow{k_3''} ROOH + (Co^{2+} + Br\cdot) + R\cdot \qquad (7)$$

When the hydroperoxide is formed by Eq. 7 instead of Eq. 4, and when k_2 and k_4 are large enough compared with k_3' and k_3'', the overall rate of oxidation under stationary-state conditions is given by:

$$-dO_2/dt = [k_3' + k_3''(RH)](k_1'/2k_6)^{1/2}\cdot (Co)(Co^{2+}BrH)(ROOH)^{1/2} \qquad (8)$$

When the rate of hydroperoxide decomposition equals its rate of formation,

$$-dO_2/dt = k_3''(RH)[k_3' + k_3''(RH)]\cdot (Co^{2+}BrH)/2k_6 \qquad (9)$$

Provided k_3' is much larger than $k_3''(RH)$, as in the case of tetralin autoxidation,

$$-dO_2/dt = k_3'k_3''(RH)(Co^{2+}BrH)^2/2k_6 \qquad (10)$$

Experimental

The experimental techniques[7] have been described previously. *p*-Xylene was oxidized at 65, 80 or 95°C using a 50-ml. long-necked flask in a 1 : 1 (by volume) acetic acid - *p*-xylene solution except when noticed. The bromides used were sodium or ammonium bromides and cobalt dibromide. Cobalt, manganese and copper were used as decanoates. The amount of *p*-tolualdehyde was determined by gas chromatography using 2.5 m. of a PEG succinate ester column at 180°C. The *p*-toluic acid was titrated with an aqueous solution of sodium hydroxide in the presence of EDTA as a chelating reagent after drying off the solvent with an infrared lamp.

Results and Discussion

Oxygen Absorption Curve.—The rate of cobalt-catalyzed autoxidation of *p*-xylene in acetic acid increases slowly as the oxidation proceeds and as *p*-tolualdehyde is accumulated in the solution. On the other hand, when sodium bromide is added the rate reaches the steady state in several minutes and is increased by a factor of three hundred at cobalt concentration of 5×10^{-2} mol./l. and at the sodium bromide concentration of 1×10^{-1} mol./l. Typical oxygen absorption curves are shown in Fig. 1 at the cobalt concentration of

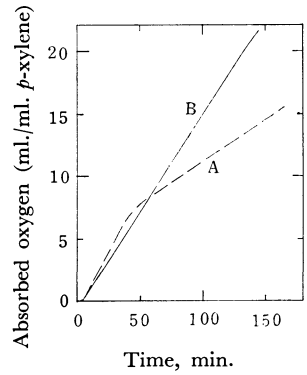

Fig. 1. Oxygen absorption curves in the autoxidation of *p*-xylene in acetic acid catalyzed with 10^{-2} mol./l. $CoBr_2$ (A) and with 10^{-2} mol./l. $CoDe_2$ and 2×10^{-2} mol./l. NaBr (B) at 80°C.

2×10^{-2} mol./l. With cobalt decanoate and sodium bromide, the rate of oxidation is kept constant over a long period. Generally, the addition of ammonium bromide instead of sodium bromide results in about a 10% lower rate. On the other hand, with cobalt dibromide the initial rate is about 20% higher than that obtained with cobalt and sodium bromide, but the rate suddenly decreases after 30 min. (that is, the catalyst is deactivated). Hay and Blanchard[8] obtained similar results in the autoxidation of cumene. They concluded that these results can be attributed to the formation of phenol due to the decomposition of cumene hydroperoxide by hydrogen bromide. However, in the case of *p*-xylene almost no phenolic inhibitor is formed by the decomposition of *p*-xylene hydroperoxide. In the present state these peculiar results remain unclarified.

Benzyl bromide, reported by Takegami[5] and his coworkers to be one of the most effective organic bromides for the oxidation of *p*-toluic acid, has been shown to have a moderate effect on the rate of oxidation, showing the value of 1.9×10^{-4} mol./l.sec. compared with 8.0×10^{-4} mol./l.sec. in the case of NaBr at cobalt 5×10^{-2} mol./l. and at the bromide-to-cobalt ratio of 3.0.

8) A. S. Hay and H. S. Blanchard, ibid., **43**, 1306 (1965).

A high concentration of cobalt dibromide shows a very pronounced induction period, during which the rate of oxygen absorption is extremely small. This induction period can be increased by increasing the concentration of cobalt dibromide as well as by decreasing the temperature; it can become, for example, 37 min. at cobalt 2×10^{-2} mol./l., and more than 120 min. at cobalt 1×10^{-1} mol./l. at 65°C. The induction period due to cobalt dibromide can be entirely eliminated in the presence of an equimolar amount of sodium acetate; this shows that cobalt monobromide is the effective catalyst, as has been observed in the autoxidation of tetralin. As is shown in Fig. 2,

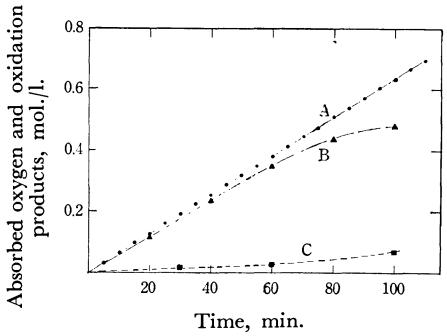

Fig. 2. Absorbed oxygen (A) and oxidation products, *p*-tolualdehyde (B) and *p*-toluic acid (C), as a function of time in the oxidation of *p*-xylene in acetic acid with 2×10^{-2} mol./l. cobalt and 4×10^{-2} mol./l. NaBr at 65°C.
—— O_2 ---- *p*-Tolualdehyde
····· *p*-Toluic acid

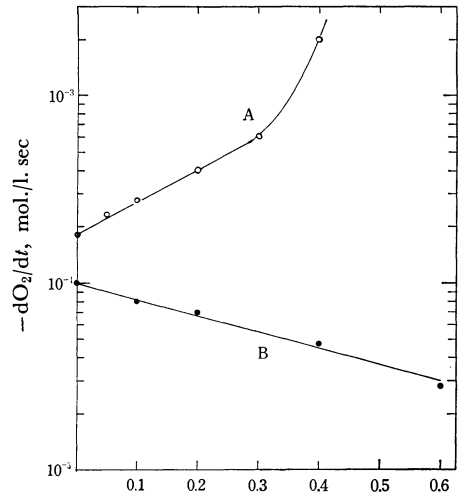

Fig. 3. The effect acid of *p*-tolualdehyde (A) at 80°C and of *p*-toluic acid (B) at 65°C.
○ *p*-Tolualdehyde, 80°C, Co: 2×10^{-2} mol./l., NaBr: 4×10^{-2} mol./l.
● *p*-Toluic acid, 65°C, Co: 2×10^{-2} mol./l., NaBr: 4×10^{-2} mol./l.

the oxidation products at the initial stage are mainly composed of *p*-tolualdehyde, accompanied by an equimolar amount of water and relatively small amounts of *p*-toluic acid and *p*-toluyl alcohol. The rate of oxidation should be increased as the aldehyde is accumulated, since the effect of aldehyde on the rate is remarkable, as Fig. 3 shows. On the other hand, water is found to deactivate the catalyst strongly; i. e., the rate is decreased by a factor of three by adding 0.69 mol. of water to 1.0 mol. of *p*-xylene at 2×10^{-2} mol./l. of cobalt and 4×10^{-2} mol./l. of sodium bromide, but it is not affected when 0.069 mol. of water is added. Moreover, as *p*-xylene is consumed the rate of oxidation should tend to decrease, because the rate is proportional to *p*-xylene, as Figs. 3 and 7 show. In spite of various effects, however, the apparent rate of oxidation is kept constant over a long period. Therefore, the rate of autoxidation of *p*-xylene catalyzed with cobalt monobromide is apparently independent of the hydrocarbon concentration in the course of oxidation, and it is first-order with respect to the initial hydrocarbon concentration (see Fig. 7).

The Ratio of Sodium Bromide to Cobalt.— The effect of the ratio of sodium bromide to cobalt is shown in Figs. 4 and 5. Just as in the case of tetralin oxidation, the rate shows a limiting value at a 1 : 2 ratio of sodium bromide to cobalt at temperatures below 80°C. It is confirmed that the increase in the rate of oxidation upon the addition of bromide is due not to free hydrogen bromide but to cobalt monobromide, since the rate reaches a limit or nearly so at sodium bromide/cobalt 1.0. At this ratio, the concentration of free hydrogen bromide should be extremely low, because most of the bromide can be complexed with cobalt and the equilibrium constant of Eq. 11 is very small:

$$CH_3COOH + NaBr \rightleftarrows HBr + CH_3COONa \quad (11)$$

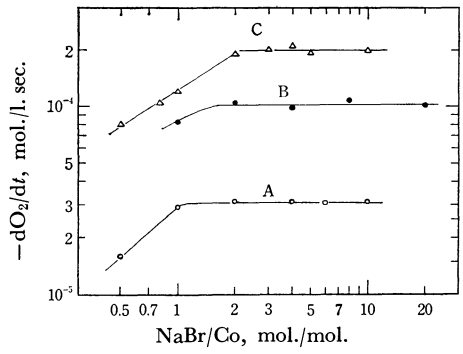

Fig. 4. The steady rate of oxidation of *p*-xylene in acetic acid as a function of the ratio of NaBr/Co, with 5×10^{-2} mol./l. cobalt at 65°C (A), with 2×10^{-2} mol./l. cobalt at 65°C (B) and with 2×10^{-2} mol./l. cobalt at 80°C (C).

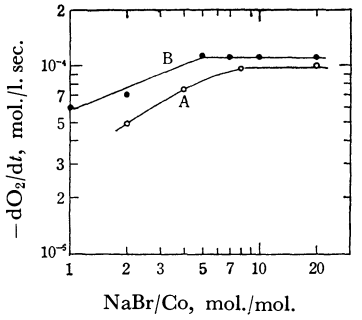

Fig. 5. The steady rate of oxidation of *p*-xylene as a function of the ratio of NaBr/Co in acetic acid with 1×10^{-2} mol./l. cobalt at 95°C (A) and in butyric acid with 5×10^{-2} mol./l. cobalt at 80°C (B).

Although, at 95°C, the rate of oxidation tends to increase until sodium bromide/cobalt is reached at 8.0, as is shown in Fig. 5, the rate has shown a limiting value at sodium bromide/cobalt 2.0 at such higher cobalt concentrations as 5×10^{-2} mol./l. These results might be due to the decrease of the concentration of hydrogen bromide by the formation of inactive organic bromides. The organic bromides can be expected to increase at high temperatures, but the influence on the rate of oxidation will be small at high concentrations of sodium bromide.

It has already been proved that hydrogen bromide is not effective in the initiating reaction, since with just the addition of hydrogen bromide to the solution, in the absence of metal salt or an initiator, the oxidation of tetralin[6] does not proceed, and the induction period[8] due to a phenol can not be decreased.

The Effect of Cobalt Concentration.—The limiting rates of the oxidation of *p*-xylene, as the ratio of sodium bromide to cobalt is varied, are plotted against the cobalt concentration at temperatures from 65°C to 95°C in Fig. 6. At all temperatures the curves show the same characteristics. The rate of oxidation is nearly second-order with respect to cobalt at concentrations below 2×10^{-2} mol./l.; the order in cobalt tends to decrease to the extent of 0.75 as the cobalt is increased. (Incidentally, quite a similar relation was obtained at the *p*-xylene concentration of 1.22 mol./l.). The rate of oxidation is required to be second-order with respect to cobalt according to Eqs. 8 and 10, provided $Co^{2+}BrH$ is proportional to cobalt. Therefore, $Co^{2+}BrH$ seems to be almost proportional to cobalt at low concentrations, but the order of $Co^{2+}BrH$ with respect to cobalt seems to decrease a little as the amount of cobalt is increased.

The Effect of the *p*-Xylene Concentration.—The rate of the autoxidation of *p*-xylene is plotted against the concentration of *p*-xylene in

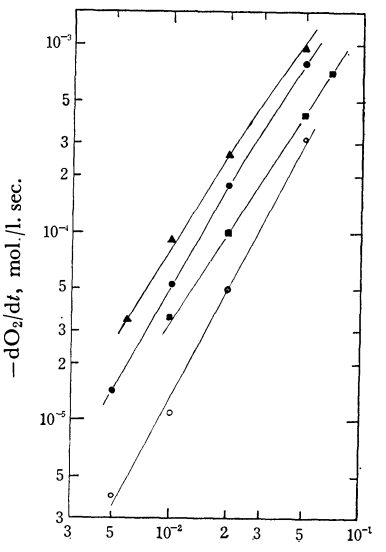

Fig. 6. The maximum rate of oxidation of *p*-xylene in acetic acid in the presence of NaBr as the ratio of NaBr/Co is varied as a function of cobalt concentration.

- ■ 65°C, *p*-xylene/acetic acid 1/1 (ml./ml.) NaBr/Co 2

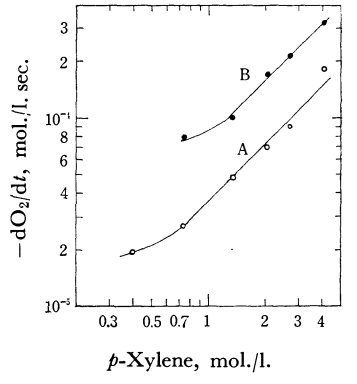

Fig. 7. The steady rate of oxidation of *p*-xylene in acetic acid as a function of *p*-xylene concentration with 2×10^{-2} mol./l. cobalt and 4×10^{-2} mol./l. NaBr at 80°C (A) and with 5×10^{-2} mol./l. cobalt and 1×10^{-1} mol./l. NaBr at 65°C (B).

Fig. 7 at 65°C and 80°C; it is found to be exactly first-order with respect to *p*-xylene, as is required by Eq. 10, showing excellent agreement with the theory. On the other hand, the rate tends to be independent of *p*-xylene at low concentrations; this result suggests that the following reaction

becomes more important than Eq. 7 at low concentrations of *p*-xylene:

$$Co^{2+}BrH + RO_2\cdot \xrightarrow{k_3'''} (Co^{2+} + Br\cdot) + ROOH \qquad (12)$$

When Eq. 7 is replaced by Eq. 12, the rate of oxidation, instead of with Eq. 10, can be represented by:

$$-dO_2/dt = k_3'k_3'''(Co^{2+}BrH)^2/2k_6 \qquad (13)$$

The Effect of Acid Strength.—When a higher fatty acid is used instead of acetic acid, the rate of oxidation shows a lower value as the carbon number of the fatty acid is increased. However, further experiments show that the rate reaches a limit at a higher ratio of sodium bromide to cobalt in a higher fatty acid solvent. For example, at a cobalt concentration of 2×10^{-2} mol./l., the rate of oxidation in butyric acid shows a maximum value of 1.1×10^{-4} mol./l.sec. at the sodium bromide/cobalt ratio of 4.0 as compared with the maximum rate of 1.8×10^{-4} mol./l.sec. at a sodium bromide/cobalt ratio of 2.0 in acetic acid. When bromoacetic or chloroacetic acids are used instead of acetic acid, the initial rate of oxidation results in a small decrease (about 10%), and the catalyst is gradually deactivated as the reaction proceeds.

The Synergistic Effect of the Metal Catalyst.—When 20% of the cobalt is replaced by manganese, an approximately five-fold increase in the rate of the oxidation of *p*-xylene was observed, showing that the metals are strongly synergistic, as is shown in Fig. 8. As has previously been suggested,[9] manganeous salt easily reacts with peroxy radicals and terminates the chain. Therefore, the synergistic effect may occur when manganese increases the rate of Eq. 7 because of a strong affinity to the peroxy radical. However, the synergistic effect due to manganese and the rate of oxidation catalyzed with manganese bromide are rapidly decreased as oxidation proceeds; i. e., the manganese is found to be deactivated easily. In contrast to the synergistic effect of manganese, cupric salt has shown a very strong antagonistic effect, showing that the rate of the oxidation of *p*-xylene is reduced by a factor of ten when 20% of the cobalt is replaced by copper.

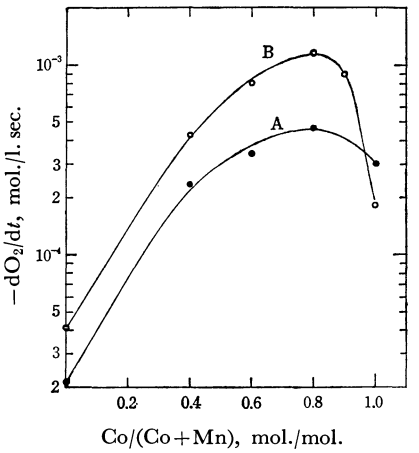

Fig. 8. The mixing effect of cobalt with manganese at 5×10^{-2} mol./l. of total metal concentration and 1×10^{-1} mol./l. NaBr at 65°C (A) and at 2×10^{-2} mol./l. of total metal concentration and 4×10^{-2} mol./l. NaBr at 80°C (B).

The authors wish to express their thanks to Professor Singo Ando for his continued advice and encouragement throughout the course of this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2216—2219 (1966)

Studies of Thio Acids. VII.[1] The Synthesis of Thiopalmitic Acid and Thiomyristic Acid*[1]

By Yoshio HIRABAYASHI, Masateru MIZUTA and Tetsuro MAZUME*[2]

Faculty of Engineering, Gifu University, Kagamigahara-shi, Gifu

(Received December 25, 1965)

Thiopalmitic acid, $C_{15}H_{31}COSH$ (m. p. 30.8—31.3°C), and thiomyristic acid, $C_{13}H_{27}COSH$ (m. p. 19.8—20.3°C), were synthesized by the reaction of sodium hydrogen sulfide in ethanol with palmitoyl and myristoyl chlorides respectively. The infrared absorption spectra of thiopalmitic and thiomyristic acids indicate that both acids assumed the thiolic acid form. Dipalmitoyl disulfide (m. p. 76.0—76.5°C) and ethyl palmitate, and dimyristoyl disulfide (m. p. 70.5—71.5°C) and ethyl myristate were isolated as by-products.

Auger et al.[2] reported that the melting point of thiopalmitic acid ($C_{15}H_{31}COSH$) was 71°C, while the melting point of thiomyristic acid ($C_{13}H_{27}COSH$) was lower than 25°C. On the other hand, in a previous paper of this series,[3] it was reported that the melting point of thiostearic acid was 39.8—40.3°C. Such an irregular relationship between the number of carbon atoms and the melting point in the homologous series of higher aliphatic thio acids seems doubtful considering the fact that, in the series of higher fatty acids having odd or even carbon atoms, the melting point rises monotonically with the increasing number of carbon atoms.

For the purpose of solving the above question and obtaining extensive knowledge of the properties of the above thio acids, the present authors made the synthesis of thiopalmitic and thiomyristic acids by a method different from that of Auger et al. and then studied the properties of these thio acids and by-products.

Palmitoyl or myristoyl chloride prepared from palmitic or myristic acid and thionyl chloride by the usual method was added, drop by drop, to an ethanol solution of sodium hydrogen sulfide (prepared from metallic sodium, absolute ethanol, and hydrogen sulfide) with heating. The resulting solution was acidified to produce the crude product. By the fractional crystallization of the crude product from palmitoyl chloride, thiopalmitic acid was obtained in the form of colorless crystals (m. p. 30.8—31.3°C), together with small amounts of dipalmitoyl disulfide (colorless crystals of m. p. 76.0—76.5°C) and ethyl palmitate. On the other hand, the crude product from myristoyl chloride was divided into an acidic fraction and a neutral fraction. By the fractional crystallization of the acidic fraction, thiomyristic acid was obtained in the form of colorless crystals (m. p. 19.8—20.3°C), together with small amounts of dimyristoyl disulfide (colorless crystals of m. p. 70.5—71.5°C) and ethyl myristate. The neutral fraction was confirmed to consist mainly of ethyl myristate.

The separation of thiopalmitic or thiomyristic acid from the respective by-products was achieved by fractional crystallization from petroleum ether or hexane; it was difficult to achieve it by fractional crystallization from other solvents or by fractional distillation under reduced pressure. The quantities of the by-products depended upon the conditions of the reaction. In particular, the formation of

ethyl palmitate or myristate made the separation of the corresponding thio acid difficult in fractional crystallization. The mechanism of the formation of these by-products may be similar to that of the synthesis of thiostearic acid.[3]

The ultraviolet absorption spectra of thiopalmitic and thiomyristic acids in cyclohexane solutions*3 are shown in Fig. 1. Thiopalmitic acid shows a band at $\lambda_{max}=221.5$ mμ ($\varepsilon=1670$), while thiomyristic acid shows a band at $\lambda_{max}=$ 221.0 mμ ($\varepsilon=1740$). Both the spectra indicate inflections at longer wavelengths and are nearly identical with that of thiostearic acid in shape.[3]

In the infrared absorption spectrum of thiopalmitic acid measured by the potassium bromide-disk method (Fig. 3), an absorption band for the S–H group appears at 2545 cm^{-1} and an absorption band for the C=O group appears at 1665 cm^{-1}. On the other hand, in the infrared absorption spectrum of thiomyristic acid as measured by the liquid film method (Fig. 4), an absorption band for the S–H group appears at 2548 cm^{-1} and an absorption band for the C=O group appears at 1708 cm^{-1}. However, in the spectra of both acids, no absorption bands for the C=S group are observed. These facts indicate that the synthesized thiopalmitic and thiomyristic acids assume the thiolic acid form; this is in accordance with the view of Sheppared[4] and Crouch[5] that thioacetic acid has the thiolic acid form, and with the view of Hirabayashi et al.[3] that thiostearic acid also has the thiolic acid form.

As has been mentioned above, Auger et al. reported that thiopalmitic acid which was synthesized by the phenyl ester-sodium hydrogen sulfide method had the melting point of 71°C. As has previously been reported,[6] in this synthetic method a large quantity of diacyl disulfide is produced. Accordingly, judging from the melting point and synthetic method described by Auger et al., the substance which was reported to be thiopalmitic acid by Auger et al. is really dipalmitoyl disulfide or some substance in which dipalmitoyl disulfide is a principal component.*5 As a result of the present experiments, the melting point of thiopalmitic acid*6 should be corrected to 30.8—31.3°C, and the melting point of thiomyristic acid, which has been ambiguous, has been determined to be 19.8—20.3°C.

The relations between the number of carbon atoms and the melting point of higher aliphatic thio acids and diacyl disulfides are shown in Fig. 2.

*4 Since the calculated amounts of each element in thiopalmitic acid and dipalmitoyl disulfide are nearly equal to each other, it is very difficult to distinguish and identify the one from the other by the results of elementary analysis. In the report of Auger et al., only the value of sulfur obtained by elementary analysis is described; the neutralization value for distinguishing them is not described. Moreover, it must be taken into consideration that it is possible to convert thiopalmitic acid into dipalmitoyl sulfide by the elimination of hydrogen sulfide during recrystallization or storage.

*5 E. g., in "Beilstein, Handbuch der Organischen Chemie," or E. E. Reid, "Organic Chemistry of Bivalent Sulfur IV," Chemical Publishing, New York (1962), p. 61, etc., the melting point of thiopalmitic acid has been given as 71°C, as given by Auger et al.

Experimental

The Synthesis of Palmitoyl Chloride and Myristoyl Chloride.—The synthetic method used here was essentially identical with that described earlier for stearoyl chloride.[3]

Palmitoyl chloride (100 g.), with a b. p. of 148—149°C/2 mmHg, was synthesized in a 93.0% yield by the reaction of palmitic acid (100 g.; m. p. 61.5—62.0°C; neutralization value, 218.2) with freshly-distilled thionyl chloride (100 g.).

Myristoyl chloride (86 g.), with a b. p. of 145—148°C/5 mmHg, was synthesized in a 93.5% yield by the reaction of myristic acid (85 g.; m. p. 53.5—54.0°C; neutralization value, 245.9) with freshly-distilled thionyl chloride (85 g.).

The Preparation of a Sodium Hydrogen Sulfide-Ethanol Solution.—This was carried out according to the method described in a previous paper.[3]

The Synthesis of Thiopalmitic Acid.—The palmitoyl chloride (85 g.) was added, drop by drop and over a period of several minutes, to the above sodium hydrogen sulfide - ethanol solution (prepared from 20.0 g. of metallic sodium, 300 ml. of absolute ethanol, and hydrogen sulfide) while the solution was being vigorously stirred and heated at 65—70°C (molar ratio; $C_{15}H_{31}COCl$: NaSH=1 : 2.8). Then the mixture was refluxed on a water bath for 1 hr., after which the ethanol was separated under a vacuum in the current of hydrogen to give a white jelly residue. The residue was dissolved in 1 l. of water, acidified with dilute hydrochloric acid, and extracted with ether. The ether layer was washed with water in order to remove the excess hydrochloric acid. An insoluble white matter suspended between the ether and the water was filtered off (0.8 g. (A)). The ether layer was dried over anhydrous sodium sulfate, and a crude product (78.0 g.) (B) was obtained by distilling off the ether (light yellow colored; m. p. 28—29°C (partly 45°C); neutralization value, 180.4; and sulfur content, 10.2 (by the iodine method) or 10.8% (by Kitamura's method)). By the fractional crsytallization of the product B (77.0 g.) from benzene, thiopalmitic acid (43.9 g., m. p. 30.8—31.3°C) was obtained as colorless crystals.

Found: neutralization value, 205.8; C, 70.26; H, 11.95; S, 11.64 (the iodine method), 11.80 (Kitamura's method).

Calcd. for $C_{16}H_{32}OS$: neutralization value, 205.9; C, 70.52; H, 11.84; S, 11.77%.

From the higher-melting point fraction and the product A, dipalmitoyl disulfide (3.4 g.) was obtained as colorless crystals (from benzene); m. p. 76.0—76.5°C, undepressed on admixture with an authentic specimen. (Found: S, 11.80. Calcd. for $C_{32}H_{62}O_2S_2$: S, 11.81 %. UV, Fig. 1; IR, Fig. 3).

From the lower-melting point fraction, ethyl palmitate was isolated.

As a result of the fractional crystallization, the compositions of the products (A and B) were found to be as follows: thiopalmitic acid 82.5%, dipalmitoyl disulfide 5.0%, and ethyl palmitate 12.5%.

The Synthesis of Thiomyristic Acid.—The myristoyl chloride (86.0 g.) was added, drop by drop and over about a 10-min. period, to the above sodium hydrgoen sulfide - ethanol solution (prepared from 32.0 g. of metallic sodium, 320 ml. of absolute ethanol, and hydrogen sulfide) while it was being vigorously stirred and heated at 70—75°C (molar ratio; $C_{13}H_{27}COCl$: NaSH=1 : 3.7). Then, the mixture was refluxed on a water bath for 1 hr., after which the ethanol was separated under a vacuum in the current of hydrogen to give a white jelly residue. Water (1.5 l.) was added to the residue, and the ether-soluble matter (neutral fraction) therein was extracted several times with ether. Concurrently, the aqueous layer was acidified with dilute hydrochloric acid and extracted with ether (acidic fraction). Each ether layer was washed with water and dried over anhydrous sodium sulfate. When the ether was distilled off, there remained the neutral fraction (6.5 g.; m. p., below 25°C; neutralization value, 42.6; S, 2.4 (by the iodine method) or 2.5% (by Kitamura's method)) and the acidic fraction (78.0 g.; m. p., below 25°C; neutralization value, 221.9; S, 12.1 (by the iodine method) or 12.4% (by Kitamura's method)). By the fractional crystallization of the acidic fraction (70.0 g.) from hexane, thiomyristic acid (48.5 g.; m. p. 19.8—20.3°C) was obtained as colorless crystals.

Found: neutralization value, 228.8; C, 68.51; H, 11.70; S, 12.94 (the iodine method); 13.10 (Kitamura's method). Calcd. for $C_{14}H_{28}OS$: neutralization value, 229.5; C, 68.79; H, 11.55; S, 13.12%.

From the lower-melting point fraction, ethyl myristate was isolated, while from the higher-melting point fraction dimyristoyl disulfide (2.2 g.) was obtained as colorless crystals (from hexane), m. p. 70.5—71.5°C; undepressed on admixture with an authentic specimen. (Found: S, 13.20. Calcd. for $C_{28}H_{54}O_2S_2$: S, 13.17 %. UV, Fig. 1; IR, Fig. 4).

As a result of the fractional crystallization, the compositions of the acidic part were found to be as follows: thiomyristic acid 87.5%, dimyristoyl disulfide 3.5%, and ethyl myristate 9.0%.

On the other hand, the neutral fraction was confirmed by further recrystallization to consist of ethyl myristate (81.6%) and thiomyristic acid (18.4%).

The Synthesis of Dipalmitoyl Disulfide and Dimyristoyl Disulfide.—An iodine solution (ca. 1 N) was added, drop by drop, to a solution of thiopalmitic acid (3.0 g.) or thiomyristic acid (3.0 g.) in ether (20 ml.)-ethanol (20 ml.) until coloring was observed; the reaction mixture was then kept at room temperature for 1 hr.. The deposit was filtered off and thoroughly washed with ethanol to give a crude product.

The crude product from thiopalmitic acid was recrystallized repeatedly from benzene to give colorless, flaky crystals (2.5 g.) with a m. p. of 76.0—76.5°C.

Found: C, 70.59; H, 11.66; S, 11.80 (Kitamura's method). Calcd. for $C_{32}H_{62}O_2S_2$: C, 70.79; H, 11.51; S, 11.81%. UV (cf. Fig. 1): $\lambda_{max}^{cyclohexane}$, 224 mμ ($\varepsilon$=4260).

The crude product from thiomyristic acid was recrystallized repeatedly from hexane to give colorless, flaky crystals (2.5 g.) with a m. p. of 70.5—71.5°C.

Found: C, 68.83; H, 11.38; S, 13.20 (Kitamura's method). Calcd. for $C_{28}H_{54}O_2S_2$: C. 69.08; H, 11.18; S, 13.17%. UV (cf. Fig. 1): $\lambda_{max}^{cyclohexane}$, 223 mμ ($\varepsilon$=4260).

Infrared Absorption Spectra.—The infrared absorption spectra of thiopalmitic acid, dipalmitoyl disulfide, thiomyristic acid, and dimyristoyl disulfide are

shown in Figs. 3 and 4. A Hilger H-800 infrared spectrophotometer was used for the measuring.

Thiopalmitic Acid.—In the spectrum measured by the potassium bromide-disk method, the S–H stretching band appeared at 2545 cm^{-1} and the C=O stretching band appeared at 1665 cm^{-1}. An absorption band, probably due to the S–H group, appeared at around 862 cm^{-1}. In the spectrum measured by the Nujol-mull method,*6 the S–H stretching band was not evident; however, the C=O stretching band shifted to 1714 cm^{-1}. In the spectrum measured in a chloroform solution, the C=O stretching band shifted to 1707 cm^{-1}.

Thiomyristic Acid.—In the spectrum measured by the liquid film method, the S–H stretching band appeared at 2548 cm^{-1} and the C=O stretching band appeared at 1708 cm^{-1}. Since the thiomyristic acid used in the measuring was retained in the liquid state in a vacuum desiccator for a considerable period after the isolation from the reaction product, a part of the converted product, dimyristoyl sulfide, was contained in the sample.*7 Accordingly, absorption bands appeared at 1763 and 926 cm^{-1} which did not appear in the spectra of such homologues as thiostearic or thiopalmitic acid; the two bands corresponded to the high-intensity absorption bands at 1766 and 932 cm^{-1} which appeared in the spectrum of distearoyl sulfide ($C_{17}H_{35}COSOCC_{17}H_{35}$).[7]

Dipalmitoyl Disulfide and Dimyristoyl Disulfide.—In the spectra measured by the potassium bromide-disk method, the C=O stretching bands appeared at 1712 in dipalmitoyl disulfide and at 1715 cm^{-1} in dimyristoyl disulfide.

*6 A part of the sample is melted or dissolved in Nujol in the preparation of paste because of its low melting point.

*7 When thiomyristic acid was retained in a vacuum desiccator in the liquid state, it was converted into dimyristoyl sulfide by the elimination of hydrogen sulfide. This will be reported on later in detail.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2219—2223 (1966)

Studies of Thio Acids. VIII.[1] The Reaction of Thiostearic Acid with Alcohols*1

By Yoshio HIRABAYASHI, Masateru MIZUTA and Tetsuro MAZUME*2

Faculty of Engineering, Gifu University, Kagamigahara-shi, Gifu

(Received December 29, 1965)

The products obtained by heating thiostearic acid in methanol, aqueous methanol, ethanol, or aqueous ethanol have been found to consist of hydrogen sulfide, distearoyl sulfide, methyl or ethyl stearate, thiostearic acid, and stearic acid, the last of which has been detected only in the case of aqueous alcohols. On the basis of the above results, the following scheme may be involved, at least in part, in the formation of carboxylic ester and hydrogen sulfide by heating the thio acid in alcohols:

$$2RCOSH \rightarrow RC\overset{O}{\diagdown}\underset{S}{\diagup}\overset{O}{\diagup}CR + H_2S$$

$$RC\overset{O}{\diagdown}\underset{S}{\diagup}\overset{O}{\diagup}CR + R'OH \rightarrow RCOOR' + RCOSH$$

Reid et al.[2] have reported that hydrogen sulfide and a normal ester (C_6H_5COOR) were formed by the reaction of thiobenzoic acid with a primary alcohol, while water and a thiol ester (C_6H_5COSR) were formed by the reaction of benzoic acid with a primary mercaptan. On the other hand, Stewart and McKinney[3] have reported that the reaction of thioacetic acid with primary, secondary, or tertiary alcohols in benzene solutions proceeds by either or one of the two ways shown by Eqs. A and B:

$$RCOSH + R'OH \rightarrow RCOOR' + H_2S \quad (A)$$

$$RCOSH + R'OH \rightarrow RCOSR' + H_2O \quad (B)$$

The present paper relates to a study of the detection of additional products obtained on heating thiostearic acid in alcohol. This study suggests that the reaction of thiostearic acid with alcohol may also proceed by way of an intermediate (distearoyl sulfide), and that the production of hydrogen sulfide is not so simple as is shown in the reaction of Eq. A. Namely, when the thio acid is heated in an alcohol, diacyl sulfide is formed as an intermediate, together with hydrogen sulfide; the diacyl sulfide may then give carboxylic ester and thio acid in the reaction with the alcohol.[4] Accordingly, the formation of hydrogen sulfide and the carboxylic ester may not undergo the reaction of Eq. A alone. On the other hand, the formation of thiol ester (Eq. B) could not be verified in this study.

Experimental*3 and Results

The Heating of Thiostearic Acid in Alcohols.—Experimental Method.—A mixture of thiostearic acid with absolute methanol, aqueous methanol, absolute ethanol, or with aqueous ethanol (in accordance with corresponding experiments) was placed in a round-bottomed flask (500 ml.) fitted with a reflux condenser with a calcium chloride tube; the mixture was then heated for 20 hr. on a water bath, with a gradual passing of dried nitrogen gas through the mixture (solution). Hydrogen sulfide was evolved during the heating in each experiment. After the heating had stopped, the alcohol or the water immediately distilled off under reduced pressure at below 60°C, and a reaction product was obtained (only when aqueous methanol was used, was the reaction product extracted with ether when the distillation had been nearly completed). The conditions of each experiment are shown in Table I.

TABLE I. THE EXPERIMENTAL CONDITIONS

Exp.	$C_{17}H_{35}COSH$[a] g.	ROH, ml.	Heating-temp., °C
I	5.0	abs. CH_3OH, 340	65
II	3.0	88% CH_3OH, 553[b]	
III	4.5	abs. C_2H_5OH, 450	78
IV	4.5	85% C_2H_5OH, 450	

a) The characteristics of thiostearic acid used in the experiments were as follows: m.p 39.8—40.3°C; neutralization value 185.4; sulfur content 10.55% (Kitamura's method).
b) A minimum quantity was used for the dissolution of thiostearic acid at the heating-temperature.

The Investigation of the Products.*4—*Exp. I.*—The characteristics of the reaction product I were as follows: m.p. 59—63°C, N.V. 121.7, $S(J)_{NV}$ 6.32%, S(K) 8.24%.

Its ultraviolet absorption spectrum is shown in Fig. 1, in which the intensity of the absorption maximum at 221 mμ is lower and the absorption in the region of 240—250 mμ is intensified as compared with the ultraviolet absorption spectrum of thiostearic acid.[5]

The reaction product I (2.6 g.) in an ether solution was separated into an acidic part (A) and a neutral part N by treating it with an aqueous solution of potassium carbonate. The characteristics of each part were as follows:

(A): Y 1.7 g., N.V. 162.4, $S(J)_{NV}$ 8.91%, S(K) 9.02%
(N): Y 0.9 g., N.V. 63.3, $S(J)_{NV}$ 2.94%.

The ultraviolet absorption spectrum of A was essentially identical with that of thiostearic acid, and that of N exhibited an absorption maximum at 238 mμ (Fig. 1). Therefore, each part was repeatedly recrystallized from benzene and hexane to give, eventually, the several fractions shown in Table II; their ultraviolet absorption spectra are given in Fig. 1.

The results of the above experiments, confirm that N-1 was distearoyl sulfide (no depression of melting point was observed when its further recrystallized product was admixed with a synthesized authentic sample; the two substances exhibited identical ultraviolet absorption spectra) and that A-2 was thiostearic acid (its characteristics and ultraviolet absorption spectrum were identical with those of thiostearic acid); A-3 was mostly thiostearic acid. It was found from the characteristics that N-3 consisted of an ester (about 85%), distearoyl sulfide, and thiostearic acid, which could not be separated by the above treatment. If the ester be methyl thiostearate ($C_{17}H_{35}COSCH_3$), a high-intensity absorption should appear in the neighborhood of 230 mμ,[6] but it was not actually shown in the absorption

TABLE II. THE CHARACTERISTICS OF THE FRACTIONS OBTAINED FROM THE PRODUCT I (2.6 g.)

F	Y, g.	M.p., °C	N.V.	$S(J)_{NV}$, %

curve. The ester was identified as methyl stearate on further recrystallization.

Exp. II.—The characteristics of the reaction product II were as follows:

m. p. 38—42°C, N. V. 137.0, $S(J)_{NV}$ 7.51%, S(K) 8.49%.

Its ultraviolet absorption spectrum is shown in Fig. 2, which is essentially identical with that of the reaction product I.

The reaction product II (2.5 g.) was then separated into an acidic part (A) and a neutral part (N) by the same treatment as was used in Exp. I. The ultraviolet absorption spectrum of A was essentially identical with that of thiostearic acid, while that of N did not exhibit a sharp absorption maximum at 238 mμ and so was different from that of the N of the reaction product I (Fig. 2). Since N was obtained in a small amount, it was again combined with A; the combination was repeatedly recrystallized from benzene and hexane to give, eventually, the several fractions shown in Table III. Their ultraviolet absorption spectra are shown in Fig. 2.

As a result of the above experiments, it was found that the main component of 1 was distearoyl sulfide; that of 2 was stearic acid, and that of 3, 4, 5, and

Table III. The characteristics of the fractions obtained from the product II (2.5 g.)

4	0.4	38.5—39.5	158.9	9.32[c]
5	0.3	37—38	155.2	8.99
6	0.2	34.5—35.5	144.1	7.37

S(K): a) 8.61; b) 10.14; c) 9.47%.

especially 6 was thiostearic acid, containing an ester. This ester is assumed to be methyl stearate from its characteristics and from the ultraviolet absorption spectra of the fractions; the approximate contents of methyl stearate in 3, 4, 5, and 6 were 4, 14, 16, and 22% respectively.

Exp. III.—The characteristics of the reaction product III were as follows:

m. p. 36—40°C, N. V. 129.7, $S(J)_{NV}$ 7.21%, S(K) 7.90%.

Its ultraviolet absorption spectrum is shown in Fig. 3, in which the intensity of the absorption maximum at 221 mμ is lower and that of the absorption in the 240—250 mμ region is higher than in the ultraviolet absorption spectrum of thiostearic acid.

The distearoyl sulfide present in I and II might be decomposed in the treatment with alkali.[4] Hence, the separation of the product into neutral and acidic parts was omitted, and the reaction product III (3.8 g.) was repeatedly recrystallized from benzene and hexane to give, eventually, the several fractions shown in Table IV (cf. Fig. 3).

Table IV. The characteristics of the fractions obtained from the product III (3.8 g.)

F	Y, g.	M. p., °C	N. V.	$S(J)_{NV}$ %	S(K) %
1	0.45	80.5—81.5	—	—	6.01
2	0.2	76—78	—	—	7.67
3	0.3	60—70	165.5	5.53	7.69
4	0.9	38—40	173.5	10.24	10.42
5	0.3	32.5—34.5	—	—	—
6	1.5	30.5—31.5	106.5	5.77	6.14

As a result of the above experiments, it was found that 1 was distearoyl sulfide, 2 was distearoyl sulfide containing a small amount of thiostearic acid, 4 was thiostearic acid, and 5 and 6 were mixtures of thiostearic acid and an ester. The fraction 6 is assumed not to be a mixture of thiostearic acid and ethyl thiostearate, judging from its characteristics; it is reasonable to consider that the ester part consists of ethyl stearate similar to the methyl stearate in the reaction products I and II; the ethyl stearate content in 6 was about 43%.

Exp. IV.—The characteristics of the reaction product IV were as follows:

m. p. 55—60°C, N. V. 95.9, $S(J)_{NV}$ 3.59%, S(K) 4.51%.

Its ultraviolet absorption spectrum, shown in Fig. 4, is very different from those of the reaction products I, II, and III.

Fig. 4. Ultraviolet absorption spectra of product IV and its fractions (shown in Table V) in cyclohexane.

IV; product IV, a; fraction 1, b; fraction 2, c; fraction 3, d; fraction 5

The reaction product IV (3.8 g.) was repeatedly recrystallized from benzene and hexane to give, eventually, the several fractions shown in Table V. Their ultraviolet absorption spectra are shown in Fig. 4.

As a result of the above experiments, it was found that 1 was distearoyl sulfide, 2 was mostly distearoyl sulfide, 3 was stearic acid containing a small amount of distearoyl sulfide, and 5 was a mixture of ethyl stearate (about 65%), thiostearic acid, and distearoyl sulfide (a trace).

TABLE V. THE CHARACTERISTICS OF THE FRACTIONS OBTAINED FROM THE PRODUCT IV (3.8 g.)

F	Y g.	M. p. °C	N. V.	$S(J)_{NV}$ %	S(K) %
1	0.9	80.5—81.5	—	—	6.08
2	0.2	76—80	—	—	—
3	0.8	68—69	160.8	1.42	1.52
4	0.1	60—63	—	—	—
5	1.7	29.5—31	44.5—68.6	2.59—3.61	4.41

Discussion

When thiostearic acid was heated in methanol, ethanol, aqueous methanol, or aqueous ethanol, hydrogen sulfide was evolved, and the products consisted of distearoyl sulfide, methyl or ethyl stearate, thiostearic acid, and stearic acid (the last product was obtained only in the case of aqueous alcohols). These results are summarized in Table VI.

TABLE VI. THE COMPONENTS OF THE PRODUCTS OBTAINED BY HEATING THIOSTEARIC ACID IN ALCOHOLS

Alcohol	Component of product ($R=C_{17}H_{35}-$, $R'=CH_3-$ or C_2H_5-)				
	RCOSOCR	RCOSH	RCOOR′	RCOOH	RCOSR′
abs. CH_3OH	○	○	○	×	×
aq. CH_3OH	○	○	○	○	×
abs. C_2H_5OH	○	○	○	×	×
aq. C_2H_5OH	○	○	○	○	×

The mark " ○ " means presence and " × " means absence.

On the basis of the above data, it may be concluded that the reaction consists of the following processes:

1. Distearoyl sulfide is formed according to Eq. 1.
2. Thiostearic acid is re-formed from the distearoyl sulfide and the alcohol according to Eq. 2, by which the stearic ester is also formed, whereas the formation of the thiolester according to Eq. 3 does not occur.
3. The re-formed thiostearic acid repeats the reaction of Eqs. 1 and then that of 2.
4. When aqueous alcohol is treated, thiostearic acid is re-formed, together with the stearic acid formed by partial reaction with water, as is shown in Eq. 4.

$$2RCOSH \rightarrow RC(=O)S(=O)CR + H_2S \quad (1)$$

$$RC(=O)S(=O)CR \xrightarrow{R'OH} RCOSH + RCOOR' \quad (2)$$

$$RC(=O)S(=O)CR \xrightarrow{R'OH} \not\rightarrow \quad (3)$$

$$RC(=O)S(=O)CR \xrightarrow{H_2O} RCOSH + RCOOH \quad (4)$$

$$RCOSH + R'OH \longrightarrow RCOOR' + H_2S \quad (5)$$

$$RCOSH + R'OH \longrightarrow RCOSR' + H_2O\ (?) \quad (6)$$

As has been described in a previous paper,[4] the reaction of Eq. 2 has been confirmed by investigating the properties of distearoyl sulfide. Accordingly, it is not reasonable to say that hydrogen sulfide and the carboxylic ester are formed only in the reaction of thio acid with alcohol (Eq. 5); they may be formed by the two reaction processes, Eqs. 1 and 2, and 5.

The above reaction mechanisms are not confined to the reaction of thiostearic acid only, but could be applied equally well to that of other thio acids.

Stewart and McKinney[3] have reported that Eqs. 5 and/or 6 occurred when thioacetic acid was heated with methanol, ethanol, isopropanol, or triphenylcarbinol in benzene. Their experiments

and discussion were based on the assumptions that hydrogen sulfide was produced according to Eq. 5 alone and that the acid (thioacetic acid) disappeared according to both Eqs. 5 and 6; if both reactions of Eqs. 5 and 6 took place simultaneously, the amount of hydrogen sulfide formed would be less than that of the acid disappearing.

However, the following facts have been confirmed in the reaction of thiostearic acid with alcohol: the evolution of hydrogen sulfide is due to the formation of an intermediate, diacyl sulfide, and/or to the reaction of Eq. 5; the thio acid and the carboxylic ester are formed by the reaction of the diacyl sulfide with an alcohol[4]; the thiol ester is not identified in the product. Stewart and McKinney assumed the occurrence of the reactions of Eqs. 5 and 6 by the estimation of hydrogen sulfide and residual acid without considering the formation and behavior (measurements for the estimate of residual acid) of the diacyl sulfide; they then discussed the mechanism of the esterification of the alcohol with the carboxylic acid, but it seems to be important to consider the presence of diacyl sulfide as an intermediate.

Asymmetric Hydrogenation with Modified Raney Nickel. VIII

By Yoshiharu IZUMI, Susumu TATSUMI and Masami IMAIDA

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received January 6, 1966)

Asymmetric hydrogenation catalysts were prepared by modifying Raney nickel with aqueous solutions of D-tartaric acid, monomethyl D-tartrate, L-*erythro*- and D-*threo*-2, 3-dihydroxybutyric acid, L-malic acid, (+)-*erythro*- and (−)-*threo*-3-methylmalic acid, L-citramalic acid and L-methylsuccinic acid. Their asymmetric activities in the hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate were compared with each other in order to study the effect of the chemical structure of the modifying reagent on the activity. Monomethyl D-tartrate, L-*erythro*- and D-*threo*-2, 3-dihydroxybutyric acid are less effective in asymmetric activity than D-tartaric acid. On modification with these three reagents, optimum asymmetric activities were obtained under acidic conditions. With D-tartaric acid, however, while high asymmetric activities were obtained at pH 5—9, there was a considerable decrease in activity at lower pH values. This suggests that the β-carboxyl group of tartaric acid plays an important role in the modification. (−)-*threo*-3-Methylmalic acid is more effective in asymmetric activity than L-malic acid, while (+)-*erythro*-3-methylmalic acid and L-citramalic acid are less effective. It has been suggested that these differences are related to hindrances due to the methyl groups on the α- or β-asymmetric centers, and also related to the correlations of the configurations of the asymmetric centers of 3-methylmalic acids. L-Methylsuccinic acid has little asymmetric effect on Raney nickel.

Previous papers in this series[1-7] have reported on the asymmetric hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate using Raney nickel catalysts modified with various optically active 2-amino acids and 2-hydroxy acids. High asymmetric activities were generally observed when Raney nickel was modified with such optically active dihydroxy dicarboxylic acids as D-tartaric acid, (+)-*threo*-2-methyltartaric acid and (+)-*threo*-2, 3-dimethyltartaric acid.[6] An especially high asymmetric activity was obtained by modification with (+)-*threo*-2-methyltartaric acid. On the contrary, optically active hydroxy monocarboxylic acids had rather low asymmetric effects upon Raney nickel.[3]

In the present work, the asymmetric activities of Raney nickel catalysts modified with monomethyl D-tartrate, L-*erythro*- and D-*threo*-2, 3-dihydroxybutyric acid were tested and compared with that of the catalyst modified with D-tartaric acid; this was done in order to study the role of the β-carboxyl group of D-tartaric acid and in order to elucidate the difference in the asymmetric effects

Table I. The optical rotation of modifying reagent

Modifying reagent	Optical rotation, $[\alpha]_D^{20}$	Value in literature
(+)-*erythro*-3-Methylmalic	+9.1° (*c* 3.7, H_2O)	—
(−)-*threo*-3-Methylmalic acid	−5.3° (*c* 3.2, H_2O)	—
L-Citramalic acid	+23.2° (*c* 3, H_2O)	+23.2° (*c* 4.4, H_2O)[8]
L-Methylsuccinic acid	−11.5° (*c* 5, H_2O)	−11.7° (*c* 3, H_2O)[12]
Monomethyl D-tartrate monohydrate	+18.1° (*c* 3, H_2O)	+18.4° (*c* 10, H_2O)[10]
L-*erythro*-2, 3-Dihydroxybutyric acid	+10.3° (*c* 3.2, H_2O)	+8.8° (—, H_2O)[13]
D-*threo*-2, 3-Dihydroxybutyric acid	+15.9°(*c* 2.1, H_2O)	+15.5° (—, —)[14]

of a hydroxy dicarboxylic acid and a hydroxy monocarboxylic acid.

In spite of the high asymmetric effect with (+)-*threo*-2-methyltartaric acid, only a very low effect was observed on modification with (−)-*erythro*-2-methyltartaric acid.[6] It was suggested that the difference in the effects of these two reagents on Raney nickel is related to the erythro-threo isomerism, that is, that it results from the configurational difference between the two diasymmetric centers in these molecules.

In the present work, the asymmetric activities of catalysts modified with (+)-*erthro*- and (−)-*threo*-3-methylmalic acid were also compared with each other, and with that of a catalyst modified with L-malic acid, in order to study the effect of the configuration of the modifying reagent upon the catalyst. Raney nickel was also modified with L-citramalic acid, in which the hydrogen atom on the asymmetric α-carbon of malic acid is replaced by a methyl group, in order to study the role of an α-substituted group in the formation of an asymmetric catalyst. L-Methylsuccinic acid was also tested as a modifying reagent.

The optical purities of the modifying reagents used in the present study are listed in Table I.

Experimental

The methods of the preparation of the Raney nickel catalyst, the hydrogenation of methyl acetoacetate, and the measurement of the asymmetric activity of the catalyst were as described in a previous paper.[3]

Modifying Reagents. — (+)-*erythro*-3-Methylmalic acid,* (−)-*threo*-3-methylmalic acid,* L-citramalic acid[8] and L-methylsuccinic acid[9] were prepared from the corresponding racemic acids. Monomethyl D-tartrate monohydrate was prepared by a slight modification of Markward's procedure.[10] L-*erythro*-2, 3-Dihydroxybutyric acid and D-*threo*-2, 3-dihydroxybutyric acid were prepared from L-allothreonine and D-threonine respectively.[11]

Results and Discussion

Modifications with Monomethyl D-Tartrate Monohydrate, L-*erythro*- and D-*threo*-2, 3-Dihydroxybutyric Acid.—Measurements were made of the asymmetric activities of catalysts modified at 0°C with aqueous solutions of monomethyl D-tartrate monohydrate, L-*erythro*- and D-*threo*-2, 3-dihydroxybutyric acid, the pH values of which had been adjusted to specified values with a sodium hydroxide solution.

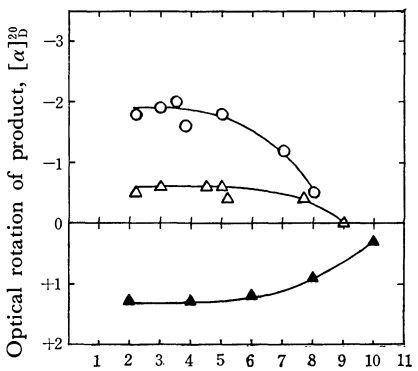

Fig. 1. Modifications with monomethyl D-tartrate, L-*erythro*- and D-*threo*-2, 3-dihydroxybutyric acid. (Modified at 0°C for 15 min.)

○ Monomethyl D-tartrate
△ D-*threo*-2, 3-Dihydroxybutyric acid
▲ L-*erythro*-2, 3-Dihydroxybutyric acid

As is shown in Fig. 1, the catalysts modified with monomethyl D-tartrate monohydrate and D-*threo*-2, 3-dihydroxybutyric acid gave levorotatory products predominantly, while that modified with L-*erythro*-2, 3-dihydroxybutyric acid gave dextrorotatory products. In all cases, the optimum asymmetric activity was observed under acidic condi-

tions, and there was a considerable decrease in activity under alkaline conditions. These asymmetric activity curves were similar in character to those obtained on modifications with optically active monohydroxy monocarboxylic acids[3]; however, they were quite different from that obtained with D-tartaric acid.**

On modification with D-tartaric acid, optimum asymmetric activities were observed at pH 5—9; there was a considerable decrease in activity at both lower and higher pH values, as is shown in Fig. 2.

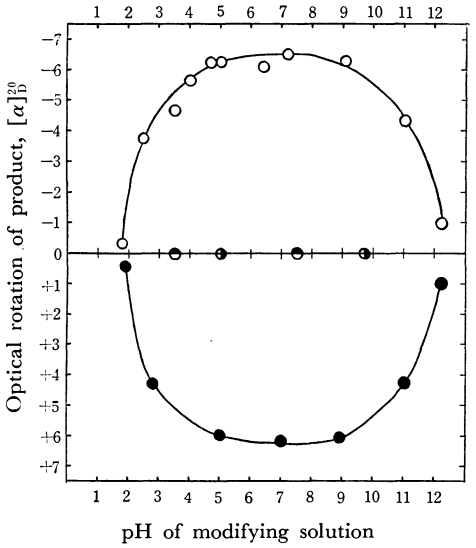

Fig. 2. Modifications with optically active and inactive tartaric acid. (Modified at 0°C)

○ D-Tartaric acid ◑ DL-Tartaric acid
● L-Tartaric acid ◓ *meso*-Tartaric acid

Both monomethyl D-tartrate and D-*threo*-2, 3-dihydroxybutyric acid are characterized by the lack of the free β-carboxyl group of D-tartaric acid. Therefore, in the modification with D-tartaric acid, the diminution of asymmetric activity under acidic conditions is clearly due to the free β-carboxyl group of the reagent. It is likely that both carboxyl groups of D-tartaric acid are adsorbed freely on the surface of nickel metal in the absence of alkali, and that with a decrease in acidity one is desorbed from the nickel metal and then produces a massive steric hindrance which regulates the approach of the hydrogenation substrate to the catalyst. On the other hand, in modifications with monomethyl D-tartrate and D-*threo*-2, 3-dihydroxybutyric acid, their adsorption forms on the surface of the metal similarly under all acidic conditions, since the ester and methyl groups are less affected by the modifying conditions.

Modifications with L-Malic Acid, (+)-*erythro*- and (−)-*threo*-3-Methylmalic Acid.— Raney nickel was modified with L-malic acid, (+)-*erythro*- and (−)-*threo*-3-methylmalic acid in order to study the role of a β-substituted methyl group and the effect of the configuration at the β-carbon of the modifying reagent upon asymmetric hydrogenation. The asymmetric activities of the resulting catalysts were then compared. The results are shown in Fig. 3.

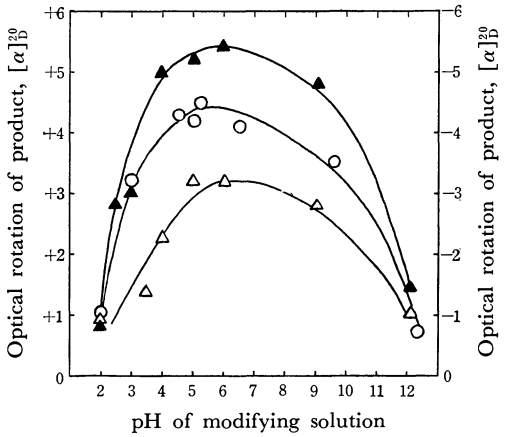

Fig. 3. Modifications with L-malic acid, (+)-*erythro*- and (−)-*threo*-3-methylmalic acid. (Modified at 0°C)

The left scale is used for L-malic acid, and the right scale for (+)-*erythro*- and (−)-*threo*-3-methylmalic acid.

○ L-Malic acid
▲ (−)-*threo*-3-Methylmalic acid
△ (+)-*erythro*-3-Methylmalic acid

The catalysts modified with (+)-*erythro*- and (−)-*threo*-3-methylmalic acid produced levorotatory methyl 3-hydroxybutyrate predominantly, while that modified with L-malic acid produced dextrorotatory methyl 3-hydroxybutyrate. Optimum asymmetric activities were obtained under nearly neutral modifying conditions; there was a considerable diminution in activity under both acidic and alkaline conditions, as was observed upon modification with D-tartaric acid. Moreover, (−)-*threo*-3-methylmalic acid was more effective in asymmetric hydrogenation than was L-malic acid, while (+)-*erythro*-3-methylmalic acid was less effective. The difference between these reagents is clearly due to the β-methyl group of the modifying reagent. On the other hand, by

** The modification with D-tartaric acid had already been reported on in Part II of this series.[2] Subsequent studies of modifications with optically active and inactive tartaric acid gave the results shown in Fig. 2.

referring to the findings of Baker,[15] the same configuration can evidently be assigned to the α- and β-asymmetric centers of (−)-*threo*-3-methylmalic acid, while those of (+)-*erythro*-3-methylmalic acid are opposite in configuration. Accordingly, it is likely that the difference between (−)-*threo*-3-methylmalic acid and (+)-*erythro*-3-methylmalic acid is related to the above different configurations of the modifying reagents.

Modification with L-Citramalic Acid (L-2-*C*-Methylmalic Acid).—Modification with L-citramalic acid was performed at 0°C; the asymmetric activity of the resulting catalyst was then compared with that of the catalyst modified with L-malic acid in order to study the effect of an α-*C*-substituted group on the asymmetric hydrogenation. The results are shown in Fig. 4.

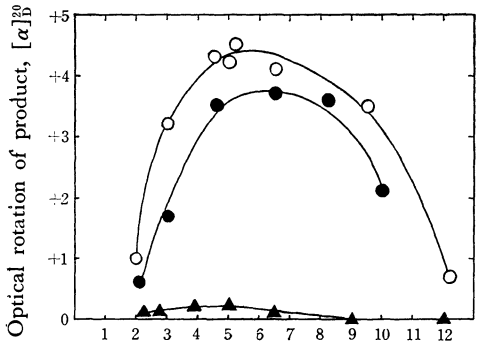

Fig. 4. Modifications with L-malic acid, L-citramalic acid and L-methylsuccinic acid. (Modified at 0°C)
○ L-Malic acid
● L-Citramalic acid
▲ L-Methylsuccinic acid

L-Citramalic acid was less effective in asymmetric hydrogenation than was L-malic acid. The difference is evidently caused by the methyl group on the asymmetric α-carbon atom of L-citramalic acid. Similar differences were observed between the modifications with glutamic acid and α-*C*-substituted glutamic acids.[5] These results clearly show that, to obtain an effective asymmetric catalyst, the α-asymmetric carbon atom of the modifying reagent should not possess a bulky substituted group in addition to the hydroxyl group, carboxyl group and β-carbon chain.

Modification with L-Methylsuccinic Acid.—The asymmetric activity of the catalyst modified with an aqueous solution of L-methylsuccinic acid was also measured.

As is shown in Fig. 4, L-methylsuccinic acid had little or no effect upon Raney nickel under any of the acidic and alkaline conditions tested. These results are in marked contrast to the high asymmetric activities obtained on modification with L-malic acid. Since in L-methylsuccinic acid the hydroxyl group of L-malic acid is replaced by a methyl group, it is clear that the α-hydroxyl group of the modifying reagent plays an important role in the asymmetric modification, and that it is indispensable for the preparation of a catalyst possessing a high asymmetric activity.

This research was supported by Kawaken Fine Chemicals Co., Ltd., Tokyo, and Ajinomoto Co. Inc., Tokyo.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2227—2229 (1966)

The Nitration and Halogenation of Palladium Acetylacetonate*

By Akira KASAHARA, Katsuyasu UJI-IE and Keiko TANAKA

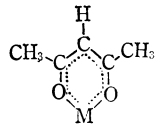
Department of Chemistry, Faculty of Liberal Arts and Science, Yamagata University, Yamagata

(Received January 11, 1966)

The pseudo-aromatic divalent palladium acetylacetonate has been found to undergo electrophilic substitution at the central carbon of the chelate ring. The mononitro (decomp. p. 240—245°C, λ_{max} 325 mμ) and dinitro (decomp. p. 250—255°C, λ_{max} 324 mμ) palladium acetylacetonates were prepared by treating palladium acetylacetonate with a mixture of copper nitrate trihydrate and acetic anhydride; they were characterized by their infrared and NMR spectra. The halogenation of palladium acetylacetonate was accomplished with *N*-halosuccinimides in chloroform. Dichloro (decomp. p. 205—210°C, λ_{max} 345 mμ), dibromo (decomp. p. 240—245°C, λ_{max} 345 mμ) and diiodo (decomp. p. 195—200°C, λ_{max} 324 mμ) derivatives were isolated and characterized by their spectra.

Recently, a variety of electrophilic substitutions at the central carbon atoms of metal acetylacetonates and related chelate systems have been reported by several authors[1-16]; these substitutions indicate the conspicuous pseudo-aromatic nature of the six-membered rings. By such a process, chloro,[6,13,15] bromo,[6,13] iodo,[6] thiocyano,[7,14] nitro,[4,11,15] acetyl,[4,14] butyryl,[14] benzoyl,[14] formyl,[11] dimethylaminomethyl,[16] chloromethyl,[16] phenylthio[14] and chlorothio[14] groups have been introduced into the stable rings of tris-acetylacetonates of chromium(III), cobalt(III) and rhodium(III).

Previously, Nakamoto, McCarthy and Martell[17] have discussed the relationships between the infrared spectra and the stability of the divalent acetylacetonate; they claimed that the stability of the divalent acetylacetonates decreased in the order of palladium>copper>nickel>cobalt>zinc, and that the stability of the palladium derivative is to be attributed to the exceeding delocalization of the π-electrons as well as of the α-electrons of the metal around all the chelate rings (cf. Fig. 1).



Strong chelate
M=Pd(II)

Fig. 1.

This consideration suggests that palladium acetylacetonate has the pseudo-aromatic structure and may undergo electrophilic substitutions.

This paper will describe the nitration and halogenation of this relatively stable divalent acetylacetonate of palladium. Although palladium acetylacetonate was destroyed by mineral acids, this acetylacetonate was stable in glacial acetic acid. The attempted nitration of palladium acetylacetonate (I) with N_2O_4 in methylene chloride resulted in the destruction of the chelate ring, but a mixture of copper nitrate trihydrate in acetic anhydride proved very effective in the nitration of palladium acetylacetonate (I), and the pure dinitro-chelate (II) was isolated in a high yield by the hydrolysis of the reaction mixtures. The treatment of palladium acetylacetonate (I) with a limited amount of this nitrating agent at 0°C for 4 hr. afforded a 46% yield of mononitro-chelate (III). These nitro-acetylacetonates (II

and III) were characterized by analyses and by infrared and nuclear magnetic resonance spectroscopy.

It has been reported that the strong doublet in the 1500—1600 cm^{-1} region of the infrared spectra of metal acetylacetonate is usually united into a singlet by the replacement of the hydrogen at the central carbon by other groups.[6,8,11] On the other hand, the dinitro-chelate (II) exhibits two strong bands in this region. The lower band, at 1525 cm^{-1}, seems to arise from an asymmetric nitro-stretching frequecny. There are no absorption peaks at 1200 cm^{-1} in the spectra of this dinitro-chelate (II). The medium band at 1199 cm^{-1} in the spectra of palladium acetylacetonate (I) has previously been assigned to the bending mode of the hydrogen at the central carbon atom,[17] and Collman et al.[11] have claimed that the absence of this peak is an excellent measure of the complete replacement of metal acetylacetonates at the central carbon.

The proton spin-resonance spectra summarized in Table I provide conclusive proof of the structure assigned to the dinitro-chelate (II). The dinitro-chelate (II) exhibits only one signal, at 7.73τ, whereas the unsubstituted palladium acetylacetonate (I) gives signals at 7.97τ and 4.65τ, with integrated intensities of 6 : 1. The higher field signal (7.97τ) may thus be assigned to the methyl protons, and the lower signal, to the ring hydrogen. The presence of electronegative nitro groups is probably responsible for the shift to a lower field of the methyl proton signal (7.73τ) in the dinitro-chelate (II).

TABLE I. PROTON MAGNETIC RESONANCE SPECTRA AT 60 Mc./sec.

NMR data is presented as τ value and deuteriochloroform was used as solvent.
Relative peak intensities in parentheses.

The structure of the mononitro-chelate (III) was confirmed by its nuclear magnetic resonance spectra (cf. Table I). The mononitro-chelate (III) exhibits proton signals at 7.92, 7.75 and 4.56τ, with relative intensities of 6 : 6 : 1. These signals are assigned to the methyl groups on the unsubstituted ring, the methyl groups on the nitrated ring, and the hydrogen on the unsubstituted chelate ring respectively. A further support for the assigned structure of the mononitro-chelate (III) was obtained from the infrared spectrum. The nitro group gave rise to an asymmetric nitro-stretching frequency at about 1520 cm^{-1}, whereas the appearance of a band at 1200 cm^{-1} indicated the presence of at least one unsubstituted chelate ring. A doublet at 1584 and 1550 cm^{-1} also indicated that not all acetylacetonate rings were substituted at the central carbon.

The structure of the mononitro derivative was further confirmed by the replacement of the other ring by electrophiles. The mixed ligand chelates IV and V were obtained by the chlorination and bromination of the mononitro-chelate (III).

Also, the introduction of halogen into the palladium acetylacetonate ring has been studied. The treatment of a glacial acetic acid solution of palladium acetylacetonate (I) with bromine resulted in the decomposition of the chelate ring. Collman et al.[6] have reported previously that *N*-halosuccinimides are effective halogenating agents for metal acetylacetonates in glacial acetic acid or in chloroform. The treatment of palladium acetylacetonate (I) with *N*-halosuccinimides in chloroform gave dichloro-, dibromo- and diiodochelate (VI, VII and VIII respectively) in high yields. These halogenated chelates showed only one signal, at about 7.5 τ, in their nuclear magnetic resonance spectra. The infrared spectra of these chelates (VI, VII and VIII) exhibit a single peak in the 1500—1600 cm^{-1} region and no absorption at 1200 cm^{-1}, providing further evidence of the complete replacement of all chelate rings at the central carbon.

Experimental[18]

Palladium Acetylacetonate (I).—This compound was prepared by the procedure of Grinberg.[19]

Bis(3-nitro-2, 4-pentanediono)-palladium (II). — A mixture of 2.4 g. (10 mmol.) of copper nitrate trihydrate and 70 ml. of acetic anhydride was stirred for 45 min. at 0°C. At the end of this time, a portion of the copper nitrate had been dissolved to form a deep blue solution. To this solution there was then added one gram (3.3 mmol.) of palladium acetylacetonate (I), and the resulting mixture was stirred for 4 hr. at 0°C, and then for one more hr. at room temperature.

18) All melting points are uncorrected. The infrared spectra were measured in KBr disks with a Hitachi EPS-2 infrared spectrometer, while the ultraviolet absorption spectra were measured in a chloroform solution with a Hitachi recording spectrophotometer, model EPU-2.

19) A. A. Grinberg and I. Simonova, *Zhur. Priklad. Khim.*, **26**, 880 (1953); *Chem. Abstr.*, **47**, 11060 (1953).

The solution was decomposed by stirring it for two hr. with 500 ml. of 1 : 1 ice-water which had been buffered with 10 g. of sodium acetate. The fine pale yellow precipitate was collected on a filter, washed with water, and then recrystallized from benzene. The yield of bis(3-nitro-2, 4-pentanediono)-palladium (II) was 0.97 g. (72%). It darkened from about 220°C and decomposed at 250—255°C. IR spectrum (KBr): 1581, 1525 (NO_2), 1468, 1420, 1346, 1102, 932, 826 (NO_2) and 702 cm^{-1}; UV spectrum ($CHCl_3$): λ_{max} mμ (log ε) 324 (3.95).

Found: C, 30.46; H, 3.01; N, 6.85. Calcd. for $C_{10}H_{12}O_8N_2Pd$: C, 30.45; H, 3.06; N, 7.09%.

(2, 4-Pentanediono) - (3 - nitro-2, 4-pentanediono)-palladium (III). — A mixture of 0.79 g. (3.3 mmol.) of copper nitrate trihydrate and 20 ml. of acetic anhydride was stirred for 45 min. at 0°C. To this solution there was then added one gram (3.3 mmol.) of palladium acetylacetonate (I). The resulting mixture was stirred for 4 hr. at 0°C, allowed to come to room temperature, and then stirred for one more hour. The reaction mixture was poured into a mixture of 100 g. of ice, 100 ml. of water, and 5 g. of sodium acetate, and then stirred for one hour. The water layer was extracted three times with chloroform, and the combined chloroform extracts were washed with a 5% aqueous sodium bicarbonate solution and then water. After solution had been dried over sodium sulfate, the solvent was removed under a vacuum. The resulting yellow residue was purified by recrystallization from benzene and obtained in a 46% yield (0.65 g.). It darkened at about 190°C and decomposed at 240—245°C. The purity of this product was checked by the chromatography of a small portion on alumina, using chloroform as the eluent. IR spectrum (KBr): 1584, 1550, 1520 (NO_2), 1475, 1370, 1345, 1200 (C–H bending), 1078, 823 (NO_2) and 745 cm.$^{-1}$. UV spectrum ($CHCl_3$): λ_{max} mμ (log ε) 325 (396).

Found: C, 34.95; H, 3.91; N, 4.12. Calcd. for $C_{10}H_{13}O_6NPd$: C, 34.35; H, 3.75; N, 4.00%.

Bis(3-chloro-2, 4-pentanediono)-palladium (VI). —A solution of 600 mg. (2.0 mmol.) of palladium acetylacetonate (I) and 1.06 g. (8.0 mmol.) of *N*-chlorosuccinimide in 50 ml. of chloroform was heated at reflux for 20 min., washed with a 5% aqueous sodium sulfite solution, and then washed with water. After the organic layer had been dried over sodium sulfate, the solvent was removed under a vacuum. The residue was recrystallized from benzene, and 580 mg. (77%) of bis(3-chloro-2, 4-pentanediono)-palladium (VI), m. p. 205—210°C (decomp.), was obtained. IR spectrum (KBr): 1550, 1452, 1367, 1041, 928 and 690 cm^{-1}. UV spectrum ($CHCl_3$): λ_{max} mμ (log ε) 345 (4.09).

Found: C, 32.19; H, 3.38; Cl, 18.64. Calcd. for $C_{10}H_{12}O_4Cl_2Pd$: C, 32.13; H, 3.21; Cl, 19.01%.

Bis(3-bromo-2, 4-pentanediono)-palladium (VII). —A mixture of *N*-bromo-succinimide (1.424 g., 8.0 mmol.) and palladium acetylacetonate (I) (600 mg., 2.0 mmol.) in 50 ml. of chloroform was boiled for ten minutes, washed with an aqueous sodium sulfite solution, and then washed with water. The chloroform solution was dried over sodium sulfate, the chloroform was removed, and the resulting solid was recrystallized from benzene. The yield of bis(3-bromo-2, 4-pentanediono)-palladium was 630 mg. (68%). It decomposed at 240—245°C. IR spectrum (KBr): 1545, 1445, 1347, 1025, 927 and 694 cm^{-1}. UV spectrum ($CHCl_3$): λ_{max} mμ (log ε) 345 (3.94).

Found: C, 26.10; H, 2.81; Br, 33.92. Calcd. for $C_{10}H_{12}O_4Br_2Pd$: C, 25.97; H, 2.61; Br, 34.63%.

Bis(3-iodo-2, 4-pentanediono)-palladium (VIII). —A mixture of *N*-iodo-succinimide (1.8 g., 8.0 mmol.) and palladium acetylacetonate (600 mg., 2.0 mmol.) in 70 ml. of chloroform was stirred at room temperature for one hour, washed with an aqueous sodium bisulfite solution, and then washed with water. After the chloroform solution had been dried, the solvent was removed under a vacuum and the resulting solid was recrystallized from benzene. Yellow crystals (650 mg., 60%) of bis-(3-iodo-2, 4-pentanediono)-palladium were obtained. They decomposed at 195—200°C. IR spectrum (KBr): 1548, 1445, 1351, 1025, 927 and 691 cm^{-1}. UV spectrum ($CHCl_3$): λ_{max} mμ (log ε) 324 (3.84).

Found: C, 21.13; H, 1.87; I, 45.62. Calcd. for $C_{10}H_{12}O_4I_2Pd$: C, 21.97; H, 2.19; I, 46.51%.

(3-Chloro-2, 4 - pentanediono)(3 - nitro - 2, 4-pentanediono)-palladium (IV).—This compound was prepared from (2, 4-pentanediono)(3-nitro-2, 4-pentanediono)-palladium (III) and *N*-chloro-succinimide in chloroform by the usual manner (70% yield). The yellow crystals darkened at 193—198°C and decomposed at 230°C. IR spectrum (KBr): 1523 (NO_2), 823 (NO_2) and no peak at 1200 cm^{-1}. UV spectrum ($CHCl_3$): λ_{max} mμ (log ε) 325 (4.08).

Found: C, 30.41; H, 2.96; N, 3.47. Calcd. for $C_{10}H_{12}O_6NClPd$: C, 31.25, H, 3.12; N, 3.62%.

(3 - Bromo - 2, 4 - pentanediono) (3 - nitro-2, 4-pentanediono)-palladium (V).—This compound was prepared from mononitro-chelate (III) and *N*-bromo-succinimide in chloroform by the usual manner (75% yield). It darkened at 190—195°C and decomposed at 220—225°C. IR spectrum (KBr): 1524 (NO_2), 826 (NO_2) and no peak at 1200 cm^{-1}. UV spectrum ($CHCl_3$): λ_{max} mμ (log ε) 235 (4.11).

Found: C, 28.55; H, 3.01; N, 3.37. Calcd. for $C_{10}H_{12}O_6NBrPd$: C, 28.03; H, 2.80; N, 3.27%.

The authors wish to express their deep gratitude to Professor Sekio Mitsui of Tohoku University for his helpful discussions and to the Kawaken Fine Chemicals Co., Ltd., for the donation of palladium chloride.

Studies of Organic Catalytic Reactions. IV.[1] A Redox Reaction between Unsaturated Organic Compounds and Primary Alcohols in the Presence of Nickel Catalysts

By Koji SAKAI, Takehiko ITO and Ken-ichi WATANABE

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received January 17, 1966)

Styrene, mesityl oxide, benzonitrile and nitrobenzene are reduced when heated with primary alcohols, such as methanol, ethanol, 1-butanol and benzyl alcohol, in the presence of nickel catalysts. On the other hand, aldehydes are obtained by the dehydrogenation of the primary alcohols. The relative reactivity of the functional groups for the reduction is as follows: $C=C > C\equiv N > NO_2 > C=O$. The carbonyl group and the benzene nucleus can not be reduced under these reaction conditions. A selective reduction occurs in the reaction with mesityl oxide. The lower limit of the reaction temperature depends on the combination of the two species of the hydrogen donor (primary alcohol) and the acceptor compounds. The use of a large excess of alcohols for the reduction is effective in this redox reaction. In the reaction between styrene and benzyl alcohol, the ratio of the decreased amount of styrene to the increased amount of ethylbenzene is always 1 : 1, as determined by gas chromatographic analysis.

It has been found that a redox reaction occurs between some kinds of unsaturated organic compounds and primary alcohols when they are heated in the presence of nickel catalysts. The ethylenic bond is reduced to the saturated bond, while nitrile and nitro groups are reduced to the corresponding amino groups. The carbonyl group and the benzene nucleus can not be reduced under these reaction conditions. A trace of benzyl alcohol was obtained in the reaction with benzaldehyde. On the other hand, primary alcohols afford the corresponding aldehydes by dehydrogenation. When primary alcohols alone are refluxed with the catalysts, the velocity of dehydrogenation is extremely slow. Of course, this redox reaction does not proceed without catalysts.*1

It is well-known that secondary alcohols are excellent hydrogen donors in the reaction with metallic catalysts. Some studies of the redox reaction with metallic catalysts have been reported in which 2-propanol,[2] cholesterol[3] and benzhydrol[3] are employed. Borneol is also useful.*2 Newham and Burwell[2] reported that, in the presence of large amounts of hydrogen at temperatures of 115—150°C, the reaction 2-propanol + 2-butanone = acetone + 2-butanol occurs as a coupled surface reaction on metallic copper at about 2.5 times the rate of the net hydrogenation. The redox reaction between cholesterol and cyclohexanone with Raney nickel affords cholestenone in 80% yield.[3]

In the present paper, it may be concluded that primary alcohols may generally be used for the reduction of some types of organic compounds, though the reactivity is lower than when secondary alcohols are used. On the other hand, this redox reaction is specifically useful for the preparation of aldehydes from primary alcohols under mild reaction conditions.

Styrene, mesityl oxide, benzonitrile, nitrobenzene, acetophenone and benzaldehyde were used as the hydrogen acceptors, while methanol, 1-butanol and benzyl alcohol were used as the hydrogen donors. Ethanol could also be used. In order to investigate the reaction process, the use of benzyl alcohol was advantageous. The catalysts used were Raney nickel W-7 (R-Ni), Urushibara nickel-B

*2 Unpublished: The redox reaction between borneol and carbonyl compounds has been studied in our laboratory with regard to the studies of the dehydrogenation and dehydration of exo- and endo-borneol on metallic catalysts. When borneol and cyclohexanone are heated in xylene (140°C) in the presence of nickel catalysts, the redox reaction occurs predominantly.

(U-Ni-B)*3 and a stabilized nickel (S-Ni)*4, all can also be used for the catalytic hydrogenation. The use of a large excess of alcohols for the reaction seems to be useful for the effective reduction of the organic compounds.

Results and Discussion

The results of the experiments are shown in Table I. As is shown in Exp. Nos. 5, 11 and 12, the reduction of carbonyl groups hardly ever proceeds under these reaction conditions. This may be due to the oxidation-reduction potentials of the correlating compounds (donor-acceptor) in the reactions. A study of oxidation-reduction potentials in the catalytic reactions was presented by Adkins and his co-workers.[4] With regard to the reaction temperatures, their lower limits depend on the combination of the two species. When the reaction temperature is lower than the limit for the reaction, only a little reduction takes place with the adsorbed hydrogen on the catalysts used.

According to Table I, it may be concluded that the relative reactivity of the functional groups for the reduction is as follows: C=C>C≡N>NO_2>C=O. The selective reduction can be applied

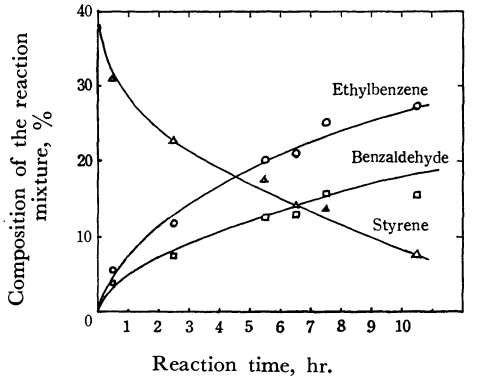

Fig. 1. The redox reaction between styrene and benzyl alcohol in the presence of U-Ni-B.
Sample: Styrene 25 g. and benzyl alcohol 50 ml.
Catalyst: U-Ni-B containing 4 g. Ni
Reaction temperature: 100°C

to compounds that have both C=C and C=O groups together.

The Reduction of Styrene and Mesityl Oxide.—With a combination of styrene and benzyl alcohol, the reaction occurred preferably at 100°C, no reaction took place below 80°C, and the polymerization of styrene occurred at 120°C. When the mole ratio of styrene to benzyl alcohol was ca. 1 : 2 (Exp. Nos. 1 and 2, Table I, Fig. 1), unreacted styrene was recovered even after twelve hours' reaction. When about ten times as much alcohol as styrene was used (Exp. No. 3), almost all the styrene was reduced in eleven hours in the presence of much more of the catalyst than in other cases. Methanol was not a suitable hydrogen donor for styrene (Exp. No. 4). The formaldehyde formed by the dehydrogenation of methanol was expelled out of the reaction system during the refluxing. Isobutyl methyl ketone was mainly obtained by the selective reduction of mesityl oxide (Exp. No. 5).

The Reduction of Benzonitrile and Nitrobenzene.—The reaction with the combination of benzonitrile and benzyl alcohol took place above 160°C, but with 1-butanol instead of benzyl alcohol, the reaction proceeded at the reflux temperature (ca. 120°C). A mixture of primary and secondary amines was obtained by the reduction of benzonitrile. The activity of S-Ni is relatively low, so much more of it should be used than when other catalysts are used (Exp. No. 8). It may be presumed that a part of the benzylamine reacts with aldehydes to form the corresponding Schiff base during the reaction. However, the formation and existence of the aldehyde as the free form were confirmed by gas chromatographic analysis, and also by the formation of 2, 4-dinitrophenylhydrazone from the reaction mixture. In Exp. Nos. 6 and 7, benzamide was obtained in varying amount. The U-Ni-B used in these reactions may have contained some water that remained after the preparation process, even though the catalyst was washed with alcohols. It has been reported[1,5] that nitriles are hydrated to the corresponding amides when refluxed in water with catalysts for hydrogenation (the nickel catalysts are the best), in which case no acid or base is necessary. Therefore, water should be excluded from the reaction system as far as possible. The reduction of nitrobenzene seemed to proceed slowly. Even after a twenty-hour reaction with an excess of alcohol, the yield of aniline was low (Exp. No. 9). Amines formed by the reduction of benzonitrile and nitrobenzene may be adsorbed on the catalysts and may interfere with the adsorption of the alcohols. This may be one of the reasons for their low reactivity.

The Combination of Hydrogen Donor and Acceptor.—On the whole, it may be concluded that a suitable combination of the two species of hydrogen donor and acceptor compounds in the reaction is essential if we are to expect successful redox reactions to occur. Further, this combination may determine the preferable temperature in the individual reaction. Actually, the effect of the reaction temperature on the reactions is delicate; its lower limit depends on the combination of species employed.

The Investigation of the Reaction Process.—During the reaction between styrene and benzyl alcohol, the diminution of styrene and the formation of ethylbenzene and benzaldehyde were investigated by gas chromatographic analysis (Fig. 1). In Fig. 1, the quantity percentage of styrene indicates ca. 37 when the reaction starts, which means that ca. 63 per cent of the reaction mixture is benzyl alcohol. After the reaction has proceeded for four hours, about a half of the styrene remains (ca. 18 per cent as determined by gas chromatographic analysis, Fig. 1), while about an equal percentage of ethylbenzene is formed. According to the graphic curves of styrene and ethylbenzene, the ratio of the decreased amount of styrene to the increased amount of ethylbenzene throughout the reaction is always ca. 1 : 1. This fact indicates that the reduction proceeds almost quantitatively. On the other hand, benzaldehyde is formed by the dehydrogenation of benzyl alcohol, and the proportion of the benzaldehyde formed to the ethylbenzene should be 1 : 1 if no other reaction occurs. However, some hydrogen adsorbed on the catalysts works for the formation of ethylbenzene. The shapes of the graphic curves show this.

Experimental

The Reduction of Styrene (Exp. No. 2).—In a 200-ml. three-necked, round flask equipped with a reflux

5) K. Watanabe, This Bulletin, **32**, 1280 (1959); **37**, 1325 (1964).

condenser, a stirrer and a thermometer, were placed 25 g. of styrene, 50 ml. of benzyl alcohol and 4 g. of Raney nickel. The contents were then stirred for 6 hr. at 100°C. After the reaction had been completed, the catalyst was separated by filtration. A part of the filtrate was analyzed by gas chromatography. The yield of ethylbenzene was 68.6%; unreacted styrene, benzaldehyde, and a trace of toluene were detected. When the filtrate was distilled, ca. 17.5 g. of the crude ethylbenzene fraction was obtained, b. p. 129—131°C. The ethylbenzene was also identified by infrared spectrum analysis. Benzaldehyde was identified as 2, 4-dinitrophenylhydrazone, m. p. 237°C, from an aliquot of the filtrate. The latter was recrystallized from ethanol and identified by infrared spectrum analysis, too. Gas chromatography: column, 30% Carbo-wax 1500 on Celite 30—40 mesh; length, 2 m.; temp., ca. 180°C; flow rate, 14—20 cm./sec.; carrier gas, H_2; relative retention times of the components: ethylbenzene 1, styrene 1.33, benzaldehyde 2.83, benzyl alcohol 7.29, and (toluene 0.9). Gas chromatograph apparatus: Yanagimoto-GCG 220 Type, Yanagimoto Mfg. Co., Ltd., Kyoto, Japan.

The Reduction of Mesityl Oxide (Exp. No. 5).—The reaction procedure was almost the same as in Exp. No. 2. After fifteen hours' reaction at 100°C, the reaction mixture was analyzed by gas chromatography as follows: the column and the conditions of analysis were the same as in Exp. No. 2; relative retention times of the components: isobutyl methyl ketone 1, mesityl oxide 1.27, benzaldehyde 3.42, and benzyl alcohol 8.79. The yeild of the reduction product, isobutyl methyl ketone, was 66.5%.

The Reduction of Benzonitrile (Exp. No. 6).—The reaction procedure was almost the same as in Exp. No. 2. After ten hours' reaction at 160°C, the catalyst was separated by filtration. A part of the filtrate was then analyzed by gas chromatography. The column and the conditions of analysis were the same as in Exp. No. 2; relative retention times of the components: benzaldehyde 1, benzonitrile 1.26, benzyl alcohol 2.54, and (toluene 0.29). The filtrate was acidified with concentrated hydrochloric acid, and then extracted with ether. From the ether extract, 3 g. of benzamide were obtained, m. p. 127—128°C. When the acidic solution was carefully evaporated to dryness, 10 g. of amine salt were obtained. The amine salt was decomposed with an alkaline solution, benzylamine was obtained as an acetyl derivative, 6.5 g.; m. p. 58.3—59.8°C. Dibenzylamine was detected by Hinsberg's method.[6] The quantity of the primary amine in the amine product obtained was ca. 60%. When 1-butanol was used instead of benzyl alcohol (Exp. No. 7), *n*-butyraldehyde was obtained as 2, 4-dinitrophenylhydrazone, recrystallized from ethanol, m. p. 119—120°C; it was also identified by infrared spectrum analysis.

The Reduction of Nitrobenzene (Exp. No. 9).—The reaction procedure was also the same as in Exp. No. 2. After fifteen hours' reaction at 180°C, the catalyst was separated by filtration. A part of the filtrate was then analyzed by gas chromatography. The column and the conditions of analysis were the same as in Exp. No. 2; relative retention times: benzaldehyde 1, nitrobenzene 1.26, benzyl alcohol 2.6, and (toluene 0.27). A very small quantity of a precipitate was obtained from the filtrate. It was washed with water and then identified as benzylideneaniline by infrared spectrum analysis. The filtrate was acidified with concentrated hydrochloric acid, and then extracted with ether to take off the unreacted nitrobenzene, benzyl alcohol, and benzaldehyde. When the water part (acidic) was evaporated to dryness, amine salt was obtained. It was decomposed with an alkaline solution and extracted with ether. From the ether solution, 3.5 g. of aniline were obtained by distillation, b. p. 182—184°C.

The authors wish to express their hearty thanks to Professor Kazuo Hata for his kind advice.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2234—2242 (1966)

Studies of Peptide Antibiotics. VI. Syntheses of Cyclic Penta and Decapeptides with a Glycyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl Sequence

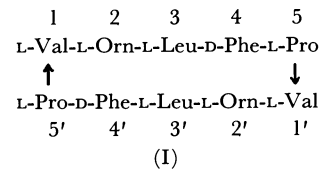
By Michio KONDO, Haruhiko AOYAGI, Tetsuo KATO and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Fukuoka

(Received January 17, 1966)

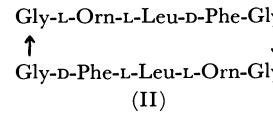
A cyclic decapeptide dihydrochloride, cyclo-(glycyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl)$_2$·2HCl, which is an analog of gramicidin S, and a cyclic pentapeptide monohydrochloride, cyclo-glycyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl·HCl, were synthesized in order to compare their antibacterial activities with that of gramicidin S. The cyclization reaction via two linear decapeptide active esters was found to yield the same cyclic bezyloxycarbonyl-substituted decapeptide; this was converted by hydrogenolysis to the cyclic decapeptide dihydrochloride mentioned above. The cyclization reaction of a linear pentapeptide active ester, in which the glycines are both terminal amino acid residues, yielded a cyclic benzyloxycarbonyl-substituted pentapeptide exclusively. When another linear pentapeptide active ester and a pentapeptide azide were also subjected to cyclization reaction, they afforded the same cyclic benzyloxycarbonyl-substituted pentapeptide; this was then hydrogenolyzed to the corresponding cyclic pentapeptide monohydrochloride. The effects of the two cyclic peptide hydrochlorides on the bacterial growth were tested; no retardation of growth was observed with any of the microorganisms tested.

For a study of the relationsihp between the chemical structure and the biological activity of such antibacterial cyclic peptides as gramicidin S (I) and tyrocidine A, various cyclic peptides which possess several characteristic features have been prepared and their biological activities have been tested, as has been described in previous papers from this laboratory. It was observed that some of them,[1] such as a cyclic hexapeptide related to gramicidin S, were devoid of antibacterial activity, but an analog of gramicidin S, 5, 5'-sarcosine-gramicidin S,[2] was as active as gramicidin S against several microorganisms. Furthermore, 5, 5'-glycine-gramicidin S was found to possess approximately 10 times as much activity as gramicidin S in a synthetic medium.[3] The result shows that the replacement of the proline residues by glycines or sarcosines in the sequence of gramicidin S does not reduce the activity, and that the side chain of proline is not indispensable to its full activity. In order to investigate whether or not the valine residues in the 1- and 1'-positions of gramicidn S might be replaced by an amino acid of a smaller molecule, glycine, without a decrease in the antibacterial activity, we attempted to prepare 1, 1', 5, 5'-glycine-gramicidin S (II). The present paper will describe the syntheses and antibacterial properties of this cyclic decapeptide (II) and of the cyclic pentapeptide, cyclo-glycyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl (III), which is related to II.

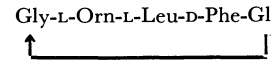


(I)

The structure of gramicidin S, with numbers indicating the positions of the individual amino acid residues.



(II)



(III)

The protected cyclic decapeptide (XXVI), which was converted to II by hydrogenolysis, was synthesized via two different routes, shown in Figs. 1 and 2.

Figure 1 indicates one route for the synthesis of XXVI via the linear decapeptide active ester (XXV), in which glycylglycine is the C-terminal

sequence. The *C*-terminal tetrapeptide derivative (VI) was prepared by a step-by-step elongation by means of the dicyclohexylcarbodiimide method and the mixed anhydride method. Syntheses of *p*-methoxybenzyloxycarbonyl-δ-benzyloxycarbonyl-L-ornithylglycine benzyl ester by the coupling of diacylornithine (VIII) with the glycine ester were attempted by several methods as a preliminary experiment for the preparation of diacylpentapeptide ester (X) by the coupling of VIII with the tetrapeptide ester (VII); it was found that the reaction of the diacylornithine active ester (IX) with the glycine ester gave the pure compound in the best yield. In fact, the reaction of IX with VII afforded the crystalline pentapeptide derivative (X) in a good yield. The azide, which was derived from XIII, was then made to react with XII to give the protected decapeptide (XIV) in a 68% yield. XIV was converted to the *p*-nitrophenyl ester (XV) by the action of di-*p*-nitrophenyl sulfite, and the removal of the *p*-methoxybenzyloxycarbonyl group from XV with trifluoroacetic acid gave the amorphous decapeptide *p*-nitrophenyl ester trifluoroacetate (XXV). The cyclization reaction of XXV in pyridine gave the crude benzyloxycarbonyl-substituted cyclic peptide (XXVI), which was then purified by passing it through columns of acidic and basic ion exchangers; the yield of the crystalline XXVI from XIV was found to be 21% after recrystallization. The molecular weight determination by the micro Rast method demonstrated that the molecular size of this compound corresponded to that of cyclic decapeptide (XXVI).

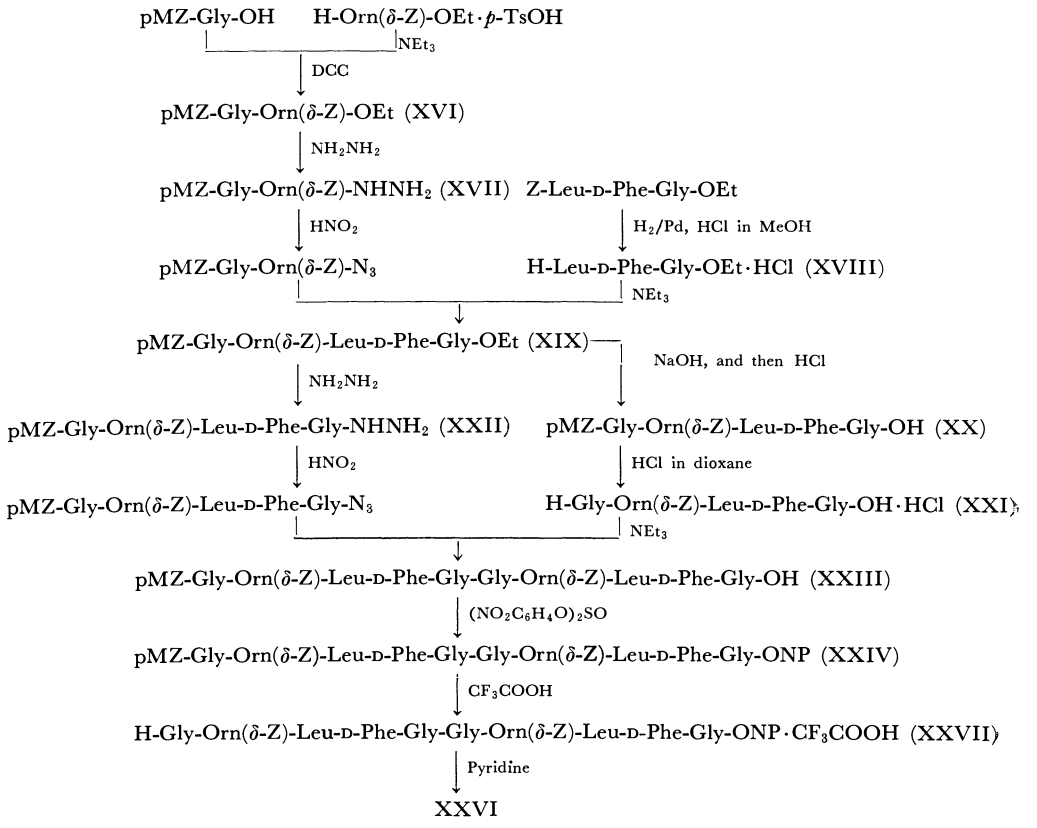

Fig. 2.

The final product (II·2HCl) was obtained as colorless crystals containing four moles of the water of crystallization. Its homogeneity was demonstrated by carboxymethyl(CM) cellulose column chromatography (Fig. 6) and by paper electrophoresis (Fig. 7).

The protected cyclic decapeptide (XXVI) was obtained again via another route, this time from the linear decapeptide active ester (XXVII), as is shown in Fig. 2, in which the glycines are the *N*- and *C*-terminal amino acid residues. It should be noted that the sequence of reactions presented in Fig. 2 is similar to that used for the preparation of 5, 5'-sarcosine-gramicidin S.[2] The cyclization reaction of XXVII gave the crystalline product (XXVI) in a yield of 36% from XXIII. From a comparison of melting points and specific rotations, this product is demonstrated to be identical with the protected cyclic decapeptide (XXVI) prepared from XXV.

The synthesis of the protected cyclic decapeptide (XXVI) was further attempted by the dimerization reaction of a pentapeptide active ester (XXX). However, the benzyloxycarbonyl-substituted cyclic peptide obtained in a yield of 23% from XI was found to be a monomer, shown as XXXI, by the results of the molecular weight determination.

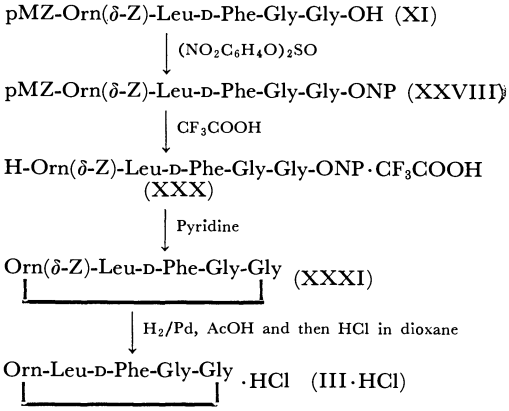

Fig. 3.

The hydrogenolysis of XXXI in the presence of an equivalent amount of hydrogen chloride yielded a cyclic pentapeptide hydrochloride (III·HCl). The experiments of CM-cellulose column chromatography showed that the product (III·HCl) gives only one peak, which is at a position different from that of the cyclic decapeptide (II·2HCl).

The cyclizations of pentapeptides via different routes were also performed, as Figs. 4 and 5 show. Although it has been reported that cyclic hexa-

glycyl was obtained in a good yield from triglycine azide,[4] the linear pentapeptide azide, which was derived from XXXII, gave only a very small amount of the protected cyclic pentapeptide (XXXI) (Fig. 4). It should be noted, in this connection, that a paper from this laboratory has reported that the yield of the cyclization of pentaglycyl-ε-benzyloxycarbonyl-L-lysine azide attempting to obtain the corresponding cyclic hexapeptide was very poor.[5]

Fig. 5.

Figure 5 shows the reaction sequence for the cyclization of the pentapeptide active ester, in which the glycines are both terminal amino acid residues. The cyclization reaction of the pentapeptide active ester (XXXIII) in a large amount of pyridine gave crude, protected cyclic peptide (XXXIV), which was found to contain only protected cyclic pentapeptide (XXXI), and not even a trace of the protected cyclic decapeptide (XXVI), from the criteria of CM-cellulose chromatography and paper electrophoresis of the hydrogenolyzed material of XXXIV. The protected cyclic pentapeptide (XXXI) in an analytically-pure state was obtained in a yield of 37% (from XX) after the recrystallization of XXXIV from methanol and ether. This result is of great interest, for it is in contrast with the fact that the cyclization reaction of L-valyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanyl-glycine (or -sarcosine) active ester[2,3] yielded an appreciable amount of the protected cyclic decapeptide by the dimerization reaction, besides a large amount of the monomeric cyclic pentapeptide.

The antibacterial activities of 1, 1', 5, 5'-glycine-gramicidin S (II) and cyclic pentapeptide (III) toward several microorganisms were also examined. Neither compound had any retarding effect on the growth of the microorganisms, even at so high level as 100 γ per ml. of assay medium. From these findings, it appears that the valine residues in the gramicidin S sequence are of importance for the activity, for 5, 5'-glycine-gramicidin S showed a strong activity. In this connection, it is of interest to note that 1, 1'-glycine-2, 2'-lysine-gramicidin S, which has a structure similar to that of II, was found to possess some antibacterial activity.[6]

To clarify the effectiveness of the valine residues in gramicidn S further, the syntheses of several analogs of gramicidin S in which the valine residues are replaced by appropriate amino acids are in progress in this laboratory.

Experimental

All the melting points are uncorrected. The optical rotations were measured on a Yanagimoto Photometric Polarimeter, OR-20 type. Prior to analysis, the compounds were dried to a constant weight over phosphorus pentoxide at 80°C and 2 mmHg, except in the case of II·2HCl and III·HCl.

Benzyloxycarbonyl-D-phenylalanylglycylglycine Ethyl Ester (IV).—To a solution of benzyloxycarbonyl-D-phenylalanine (6.0 g.), glycylglycine ethyl ester hydrochloride (3.9 g.) and triethylamine (2.8 ml.) in chloroform (80 ml.), dicyclohexylcarbodiimide[7] (4.12 g.) was added at 0°C. The reaction mixture was stirred for 2 hr. at 0°C and then kept overnight in a refrigerator. The mixture was evaporated in vacuo, and the residue was extracted with ethyl acetate (120 ml.). After the dicyclohexylurea thus formed was filtered off, the filtrate was washed successively with a 4% sodium bicarbonate solution, 3% hydrochloric acid, and water, and then dried over anhydrous sodium sulfate. The filtered solution was evaporated in vacuo; the residual oil solidified after ether had been added. Recrystallization from ethyl acetate-ether gave 5.9 g. (67%); m. p. 95—96°C; $[\alpha]_D^{20}$ +17.3° (*c* 2, dimethylformamide).

Found: C, 62.36; H, 6.19; N, 9.63. Calcd. for $C_{23}H_{27}O_6N_3$: C, 62.57; H, 6.16; N, 9.52%.

D-Phenylalanylglycylglycine Ethyl Ester Hydrochloride (V).—IV (8.83 g.) was subjected to hydrogenolysis in the presence of palladium black and 0.43 N methanolic hydrogen chloride (50.6 ml.). The filtrate from the catalyst was then evaporated to dryness in vacuo; yield of oil, 6.9 g. (100%); R_f 0.85.[8]

Benzyloxycarbonyl-L-leucyl-D-phenylalanylglycylglycine Ethyl Ester (VI).—To a chilled solution of benzyloxycarbonyl-L-leucine (5.17 g.) and triethylamine (2.72 ml.) in tetrahydrofuran (40 ml.), isobutyl

chloroformate (2.52 ml.) was added. After 15 min., a mixture of V (6.9 g.), triethylamine (2.72 ml.), and chloroform (40 ml.) was added to the solution. The reaction mixture was allowed to stand overnight and then evaporated to dryness in vacuo. The residual oil was dissolved in ethyl acetate (150 ml.), and the solution was wahsed successively with 4% sodium bicarbonate, 3% hydrochloric acid and water, dried over sodium sulfate, and then evaporated to dryness in vacuo. The product was obtained as an oil; yield, 8.32 g. (75%).

L-Leucyl-D-phenylalanylglycylglycine Ethyl Ester Hydrochloride (VII).—VI (6.1 g.) was treated as has been described in the case of V. The product was obtained as a hygroscopic powder; yield, 4.7 g. (94%); R_f 0.87.[8]

p-Methoxybenzyloxycarbonyl-δ-benzyloxycarbonyl-L-ornithine (VIII).—A mixture of δ-benzyloxycarbonyl-L-ornithine (2.67 g.), sodium bicarbonate (2.52 g.), water (100 ml.), dioxane (150 ml.), and *p*-methoxybenzyloxycarbonyl azide[9] was stirred for 60 hr. at room temperature. The solution was then evaporated in vacuo in order to remove dioxane. After it had been extracted with ether, the solution was acidified with 0.5 M citric acid (40 ml.) and then extracted with ethyl acetate. The organic layer was dried over sodium sulfate and evaporated to dryness in vacuo. The residual oil was solidified by the addition of petroleum ether; yield, 3.42 g. (79%). For analysis, a part of the product was recrystallized from ethyl acetate-petroleum ether; m. p. 73—75°C; $[\alpha]_D^{20}$ −2.3° (*c* 2, dimethylformamide).

Found: C, 60.96; H, 6.22; N, 6.77. Calcd. for $C_{22}H_{26}O_7N_2$: C, 61.38; H, 6.09; N, 6.51%.

p-Methoxybenzyloxycarbonyl-δ-benzyloxycarbonyl-L-ornithine p-Nitrophenyl Ester (IX).—To a stirred solution of VIII (3.34 g.) and *p*-nitrophenol (1.31 g.) in ethyl acetate (25 ml.), dicyclohexylcarbodiimide (1.60 g.) was added at 0°C. The stirring was continued for 2 hr. at 0°C, and then for 3 more hours at room temperature. The dicyclohexylurea which precipitated was filtered off and washed with ethyl acetate, and the combined filtrates were evaporated to dryness. The cyrstalline residue was recrystallized from hot ethanol; yield, 3.34 g. (78%); m. p. 123—124°C; $[\alpha]_D^{20}$ −14.1° (*c* 2, dimethylformamide).

Found: C, 60.63; H, 5.25; N, 7.80. Calcd. for $C_{28}H_{29}O_9N_3$: C, 60.97; H, 5.30; N, 7.62%.

p-Methoxybenzyloxycarbonyl-δ-benzyloxycarbonyl-L-ornithylglycine Benzyl Ester.—*a) MA Method.*—The mixed anhydride prepared from VIII (1 mmol.) was coupled with the glycine benzyl ester (1 mmol.), following the procedure used in the preparation of VI. The crude product was recrystallized from ethyl acetate-ether; yield, 60 mg. (21%); m. p. 141—143°C. The melting point of this product was not depressed by admixture with the product (m. p. 143—144°C) obtained by the ONP-method.

b) DCC Method.—The same product was obtained by the carbodiimide method in the usual manner; yield, 144 mg. (50%); m. p. 141—143°C.

c) ONP Method.—The product was prepared with IX (1mmol.) and the glycine benzyl ester in the usual manner; yield, 188 mg. (65%); m. p. 143—144°C; $[\alpha]_D^{20}$ −3.0° (*c* 2, dimethylformamide).

Found: C, 64.44; H, 6.47; N, 7.53. Calcd. for $C_{31}H_{35}O_8N_3$: C, 64.46; H, 6.11; N, 7.28%.

p-Methoxybenzyloxycarbonyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycylglycine Ethyl Ester (X).—To a solution of VII (4.7 g.) and triethylamine (1.87 ml.) in dimethylformamide (14 ml.), IX (5.68 g.) was added, and the solution was allowed to stand overnight at room temperature. Cold water (100 ml.) was then added slowly to it, and the mixture was kept in a refrigerator for several hours. The crystals were collected by filtration and washed with 4% sodium bicarbonate, M citric acid, and water. They were then recrystallized from dioxane-ether; yield, 6.12 g. (71%); m. p. 172—174°C; $[\alpha]_D^{16}$ +1.5° (*c* 2, dimethylformamide); R_f 0.92.[10]

Found: C, 61.60; H, 6.58; N, 10.01. Calcd. for $C_{43}H_{56}O_{11}N_6$: C, 62.00; H, 6.78; N, 10.09%.

p-Methoxybenzyloxycarbonyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycylglycine (XI).—To a solution of X (510 mg.) in methanol (8 ml.), 1.03 N sodium hydroxide (0.71 ml.) was added. The solution was then allowed to stand overnight at room temperature. After the addition of water (60 ml.), the solution was concentrated in vacuo in order to remove methanol. It was extracted with ether and acidified with 1.22 N hydrochloric acid (0.61 ml.) under cooling. After they had been stored in a refrigerator for several hours, the crystals were collected by filtration, washed with water, and dried. Recrystallization from methanol-ether gave 420 mg. (84%); m. p. 190—192°C; $[\alpha]_D^{16}$ −0.7° (*c* 2, dimethylformamide); R_f 0.72.[10]

Found: C, 60.10; H, 6.66; N, 10.49. Calcd. for $C_{41}H_{52}O_{11}N_6 \cdot H_2O$: C, 59.84; H, 6.61; N, 10.21%.

δ-Benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycylglycine Hemitrifluoroacetate (XII).—To a mixture of XI (916 mg.) and anisole (0.4 ml.), trifluoroacetic acid (4 ml.) was added at 0°C. After it had been permitted to stand for 40 min. at 0°C, the solution was evaporated in vacuo. The residue was triturated with ether (20 ml.) and washed repeatedly with ether by decantation. Crystals were filtered off with the aid of ether; yield, 783 mg. (96%); m. p. 183—184°C; $[\alpha]_D^{20}$ +13.2° (*c* 2, dimethylformamide). R_f 0.85[8] and 0.64.[10]

Found: C, 54.28; H, 6.68; N, 11.71. Calcd. for $C_{32}H_{44}O_8N_6 \cdot 1/2CF_3COOH \cdot 2H_2O$: C, 54.10; H, 6.66; N, 11.45%.

An attempt to crystallize the CF_3COOH-free pentapeptide failed.

p-Methoxybenzyloxycarbonyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycylglycine Hydrazide (XIII).—A solution of X (440 mg.) and hydrazine hydrate (0.53 ml.) in dimethylformamide (4 ml.) was allowed to stand for 2 days at 30°C. The solution was then concentrated in vacuo to a small volume. The hydrazide which precipitated upon the

addition of water (20 ml.) was collected and recrystallized from methanol-ether; yield, 352 mg. (80%); m. p. 201—202°C; $[\alpha]_D^{16}$ +2.1° (*c* 2, dimethylformamide).

Found: C, 59.76; H, 6.60; N, 13.36. Calcd. for $C_{41}H_{54}O_{10}N_8$: C, 60.13; H, 6.65; N, 13.68%.

***p*-Methoxybenzyloxycarbonyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycylglycyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycylglycine (XIV).** — The following operations were carried out in a cold room. Into a chilled solution of XIII (820 mg.) in dimethylformamide (12 ml.), 1.22 N hydrochloric acid (2.45 ml.) and sodium nitrite (83 mg.) in water (2 ml.) were stirred. After 5 min., cold water (80 ml.) was added to the solution. The azide, which precipitated as a white mass, was collected by filtration and washed with cold water, 4% sodium bicarbonate, and water, and then dried under a vacuum in a desiccator. The azide was added to a solution of XII (735 mg.) and triethylamine (0.28 ml.) in dimethylformamide (15 ml.). The mixture was stirred for 3 days at 0°C and then evaporated in vacuo. The precipitate which formed upon the addition of ethyl acetate (8 ml.) and ether (4 ml.) was collected, washed with 0.5 M citric acid, and water, and dried. Recrystallization from dioxane-ether did not raise the melting point. The yield was 971 mg. (66%); m. p. 235°C (decomp.); $[\alpha]_D^{16}$ +0.4° (*c* 2, dimethylformamide); R_f 0.87,[10] R_f of the hydrogenolyzed product of XIV, 0.52[10] and 0.69[8].

1.10 g. (98%); m. p. 188—191°C; $[\alpha]_D^{20}$ −7.6° (*c* 2, dimethylformamide); R_f 0.87[8] and 0.69[10].

Found: C, 55.48; H, 6.96; N, 12.12. Calcd. for $C_{32}H_{45}O_8N_6Cl \cdot H_2O$: C, 55.28; H, 6.82; N, 12.09%.

***p*-Methoxybenzyloxycarbonylglycyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycine Hydrazide (XXII).**—XIX (1.67 g.) was converted to the hydrazide (XXII) as has been described in the case of XIII; yield, 1.60 g. (97%). For analysis, a part of the product was recrystallized from methanol-ether; m. p. 163—164°C; $[\alpha]_D^{20}$ −2.5° (*c* 2, dimethylformamide).

Found: C, 59.47; H, 6.65; N, 13.38. Calcd. for $C_{41}H_{54}O_{10}N_8 \cdot 1/2H_2O$: C, 59.48; H, 6.67; N, 13.54%.

***p*-Methoxybenzyloxycarbonylglycyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycylglycyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycine (XXIII).**—To XXII (828 mg.) in dimethylformamide (10 ml.), 1.22 N hydrochloric acid (2.45 ml.) and sodium nitrite (83 mg.) in water (1 ml.) water added at 0°C. After 7 min., cold water (70 ml.) was added to the solution. The azide which formed was extracted with ethyl acetate (100 ml.), and the extract was treated as has been described in the case of XIX. The solution of the azide was added to a solution of XXI (695 mg.) and triethylamine (0.28 ml.) in dimethylformamide (25 ml.). Then, the desired acyldecapeptide (XXIII) was obtained by the procedure used in the preparation of XIV. It was recrystallized from dioxane-ether; yield, 1.01 g. (70%); m. p. 239—242°C; $[\alpha]_D^{20}$ −0.6° (*c* 2, dimethylformamide); R_f 0.75[10]; R_f of hydrogenolyzed product of XXIII, 0.68[8] and 0.35[10].

Found: C, 60.92; H, 6.68; N, 11.78. Calcd. for $C_{73}H_{94}O_{18}N_{12} \cdot H_2O$: C, 60.65; H, 6.62; N, 11.63%.

***p*-Methoxybenzyloxycarbonylglycyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycylglycyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycine *p*-Nitrophenyl Ester (XXIV).**—A solution of XXIII (723 mg.) and di-*p*-nitrophenyl sulfite (1.62 g.) dissolved in pyridine (7.5 ml.) was allowed to stand overnight at room temperature and then treated in the manner described in the case of XV. The powder obtained weighed 770 mg. The *p*-nitrophenyl-ester content of this product was estimated to be 81%. The product was used for the next reaction without further purification.

Cyclo-(glycyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl)$_2$ (XXVI). — *a) From XV.*—To XV (890 mg.) and anisole (0.5 ml.), trifluoroacetic acid (4 ml.) was added at −5°C. After 20 min., the solution was evaporated in vacuo at 0°C, and the residue was triturated with ether. The decapeptide *p*-nitrophenyl ester trifluoroacetate (XXV) was collected in a cold room by filtration, washed with ether, and dissolved in dimethylformamide (18 ml.) containing glacial acetic acid (0.4 ml.). The solution was then stirred, drop by drop, into pyridine (180 ml.) which had been kept at 60—65°C over a period of 6 hr.; the stirring was then continued for an additional 2 hr. at the same temperature. After the solvent had been removed, the residue was dissolved in a mixture of methanol (200 ml.) and water (80 ml.). The insoluble substance was removed by filtration, and the filtrate was passed successively through columns (2.5×10 cm.) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were then washed with the same solvent (300 ml.), the combined effluents were evaporated to dryness in vacuo, and the product was suspended in water (20 ml.), collected by filtration, and dried (174 mg.). This substance was then recrystallized from methanol-ethyl acetate-ether; yield of the air-dried product, 153 mg. (21% from XIV); m. p. 274—275°C (decomp.); $[\alpha]_D^{20}$ −5.0° (*c* 0.51, dimethylformamide); R_f 0.90.[10]

Found: C, 60.56; H, 6.83; N, 13.31. Calcd. for $C_{64}H_{84}O_{18}N_{12} \cdot H_2O$: C, 60.83; H, 6.86; N, 13.30%.

The air-dried product lost 1.40% of its weight after it had been dried for 2 hr. at 115°C, 2 mmHg. Calcd. for H_2O: 1.43%. The molecular weight[13] was determined by the micro Rast method using a solvent of hexahydro-*p*-aminobenzoic acid lactam.[14]

Found: 1100. Calcd. for $C_{64}H_{84}O_{18}N_{12}$: 1245.

b) From XXIV.—XXIV (765 mg.) was converted to the decapeptide active ester trifluoroacetate (XXVII) as has been described above. XXVII was allowed to react in pyridine (180 ml.), after with a treatment similar to that mentioned above was further carried out to give a crude cyclic product (284 mg.). This was recrystallized from methanol-ethyl acetate-ether; yield of the air-dried product, 233 mg. (36% from XXIII); m. p. 274—276°C (decomp.); $[\alpha]_D^{20}$ −4.9° (*c* 1, dimethylformamide); R_f 0.90.[10]

Found: C, 60.70; H, 6.82; N, 13.35. Calcd. for $C_{64}H_{84}O_{14}N_{12} \cdot H_2O$: C, 60.83; H, 6.86; N, 13.30%.

The molecular weight was determined by the micro Rast method described above. Found: 1030. Calcd. for $C_{64}H_{84}O_{14}N_{12}$: 1245.

Cyclo-(glycyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl)$_2$ Dihydrochloride (II·2HCl). — A solution of XXVI (84 mg.) in glacial acetic acid (2 ml.) was subjected to hydrogenolysis in the presence of palladium black. The filtrate from the catalyst was evaporated to dryness in vacuo. The residue was dissolved in a mixture of methanol (1 ml.) and dioxane (1 ml.), and then 0.4 N hydrogen chloride in dioxane (0.5 ml.) was added to the solution. After the solution had then been evaporated in vacuo, the resulting crystals were filtered with the aid of a mixture of ether and petroleum ether (1 : 1); yield of the air-dried product, 59 mg. (84%); m. p. 239—242°C (decomp.); $[\alpha]_D^{20}$ −42.0° (*c* 0.5, acetic acid); R_f 0.88[8] and 0.65.[10] The amino acid analysis[3] gave the molar ratio of 1.9 : 1.1 : 1.0 : 1.1 for glycine, ornithine, leucine and phenylalanine.

Found: C, 51.52; H, 7.47; N, 14.91. Calcd. for $C_{48}H_{74}O_{10}N_{12}Cl_2 \cdot 4H_2O$: C, 51.37; H, 7.37; N, 14.98%.

The air-dried product lost 6.6% of its weight after it had been dried over phosphorus pentoxide for 3 hr. at 80°C; 2 mmHg. Calcd. for $4H_2O$: 6.4%.

***p*-Methoxybenzyloxycarbonyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycylglycine *p*-Nitrophenyl Ester (XXVIII).**—To a solution of XI (393 mg.) in a mixture of dimethylformamide (1 ml.) and pyridine (1,2 ml.), di-*p*-nitrophenyl sulfite

13) The molecular weight determination by the use of an osmometer of Mechrolab, Inc., could not be applied to the protected cyclic decapeptide (XXVI) and pentapeptide (XXXI) because these products are insoluble in methanol or dioxane at room temperature.

14) G. Went, *Ber.*, **75**, 425 (1942).

(640 mg.) was added. The mixture was then allowed to stand overnight at room temperature. After evaporation, the residual oil was triturated with petroleum ether and washed with a mixture of ether and petroleum ether (1 : 1) by decantation until no yellow color could be discerned on the addition of a sodium hydroxide solution to the washings. The product was collected by filtration and dried. It weighed 373 mg. The *p*-nitrophenyl ester content of this product was estimated to be 70%.

***p*-Methoxybenzyloxycarbonylglycyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycine *p*-Nitrophenyl Ester (XXIX).**—A solution of XX (403 mg.) and di-*p*-nitrophenyl sulfite (975 mg.) dissolved in pyridine (3 ml.) was allowed to stand overnight at room temperature; then it was treated as above. The *p*-nitrophenyl ester content of this product was estimated to be 94%.

Cyclo-glycyl-δ-benzyloxycarbonyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl (XXXI). — *a) From XXVIII.*—XXVIII (368 mg.) and anisole (0.2 ml.) were dissolved in trifluoroacetic acid (1 ml.) at −5°C. After 20 min., the solution was concentrated to a small volume in vacuo at 0°C, and then the residue was triturated with ether. The *p*-nitrophenyl ester trifluoroacetate (XXX) collected was dissolved in dimethylformamide (4 ml.) containing glacial acetic acid (0.1 ml.). The solution was stirred, drop by drop, into pyridine (80 ml.), which had been kept at 55—60°C over a period of 4 hr.; the stirring was then continued for an additional 2 hr. at the same temperature. After the solvent had been removed, the residue was dissolved in a mixture of methanol (50 ml.) and water (20 ml.). The insoluble substance was filtered off, and the filtrate was passed through columns of Dowex 1 and Dowex 50. The columns were eluted with the same solvent, the combined effluents were evaporated to dryness in vacuo, and the residue was collected by filtration with the aid of water (77 mg.). It was recrystallized from methanol-ether; yield, 71 mg. (32% form XI); m. p. 282—283°C (decomp.); $[\alpha]_D^{15}$ −49.7° (*c* 1.01, dimethylformamide); R_f 0.79.[10]

Found: C, 61.63; H, 6.67; N, 13.41. Calcd. for $C_{32}H_{42}O_7N_6$: C, 61.72; H, 6.80; N, 13.50%.

The molecular weight was determined by the micro Rast method. Found: 600. Calcd. for $C_{32}H_{42}O_7N_6$: 623.

b) From XIII.—To XIII (234 mg.) and anisole (0.1 ml.), trifluoroacetic acid (0.32 ml.) was added at −5°C. After 30 min., the solution was evaporated in vacuo at 0°C, and the residue was triturated with ether. The hydrazide ditrifluoroacetate (XXXII) was collected by filtration. To a solution of XXXII in water (2 ml.), 0.1 N hydrochloric acid (3.1 ml.) and sodium nitrite (22.3 mg.) in water (0.5 ml.) were added at −5°C. After 15 min., the reaction mixture was added to a solution of water (200 ml.) containing sodium bicarbonate (1.2 g.) and dioxane (100 ml.) at 0°C. The mixture was stirred for 2 days at 0°C; then it was brought to pH 5.0 with N hydrochloric acid. The mixture was evaporated in vacuo, and the residue was collected by filtration with the aid of 5 ml. of water (120 mg.). This was treated in a mixture of methanol (90 ml.) and water (30 ml.). The insoluble substance was filtered off, and then the filtrate was passed through columns, as has been mentioned above. The combined effluents were evaporated in vacuo to dryness; yield of crude product, about 8% from XIII. A solution, after the hydrogenolysis of the crude product in methanol containing hydrogen chloride, showed only one spot on paper and thin-layer chromatograms, a spot which was in a position identical with that of III·HCl obtained from XXX or XXXIII.

c) From XXIX.—XXIX (460 mg.) was converted to the pentapeptide active ester trifluoroacetate (XXXIII) by the method described for XXX. XXXIII was allowed to react in pyridine (160 ml.), and the reaction mixture was treated as has been described in the case of XXXI a). The combined effluents obtained after passing through the ion-exchangers were evaporated to dryness; the crude product which resulted weighed 136 mg. (XXXIV). A few mg. of XXXIV was subjected to hydrogenolysis, and the solution was submitted to CM-cellulose column chromatography and paper electrophoresis. The chromatography showed only one peak or spot resulting from presence of III. Therefore, it was concluded that the product (XXXIV) contains only protected cyclic pentapeptide (XXXI). XXXIV was recrystallized from methanol-ether; yield, 115 mg. (37% from XX); m. p. 281—282°C (decomp.); $[\alpha]_D^{20}$ −50.1° (*c* 1, dimethylformamide); R_f 0.80.[10]

Found: C, 61.70; H, 7.04; N, 13.35. Calcd. for $C_{32}H_{42}O_7N_6$: C, 61.72; H, 6.80; N, 13.50%.

The molecular weight was determined by the micro Rast method. Found: 610. Calcd. for $C_{32}H_{42}O_7N_6$: 623.

Cyclo-glycyl-L-ornithyl-L-leucyl-D-phenylalanylglycyl Hydrochloride (III·HCl).—A solution of XXXI (53.2 mg.) in glacial acetic acid (1 ml.) was subjected to hydrogenolysis in the presence of palladium black, and then treated with the method which has been described in the case of II·2HCl. Yield of the air-dried product, 38.2 mg. (85%); m. p. 270—272°C (decomp.); $[\alpha]_D^{20}$ −54.4° (*c* 0.5, acetic acid); R_f 0.81[8] and 0.61.[10] The amino acid analysis[3] gave the molar ratio of 1.9 : 1.1 : 1.0 : 1.0 for glycine, ornithine, leucine and phenylalanine.

Found: C, 53.47; H, 7.09; N, 15.17. Calcd. for $C_{24}H_{37}O_5N_6Cl\cdot H_2O$: C, 53.08; H, 7.23; N, 15.47%.

The air-dried product lost 3.19% of its weight after it had been dried over phosphorus pentoxide 3 hr. at 80°C; 2 mmHg. Calcd. for H_2O: 3.31%.

Chromatography and Electrophoresis of II, III and Gramicidin S (I).—A sample (0.5—1 mg.) was dissolved in 0.2—0.3 ml. of 0.2 M pyridinium acetate containing 30% methanol (pH 5.1); the solution was then applied to a column (0.9×50 cm.) with carboxymethyl cellulose (Eastmen Organic Chem. 7796), and development was continued with the same solvent. Two-ml. fractions were collected at a flow rate of 20 ml. per hour. The peptide content in the fractions was determined by the method described by Yemm and Cocking.[15] Gramicidin S was used as a control. The results are shown in Fig. 6. In order to determine the sensibilities for ninhydrin with the cyclic peptides, II and III, a solution containing 1 μ mole of III and 0.5 μ mole of II was also submitted to column chromatography; the ratio of intensities caused by ninhydrin between III and II was found to be 5 : 4 by calculating

the areas in a chromatogram of the optical density-fraction number.

Electrophoresis on Toyo Roshi No. 52 paper was carried out with a formic acid - acetic acid - methanol - water (1 : 3 : 6 : 10, v/v; pH 1.8) solvent system for 3 hr. at 500 V./30 cm. The peptides were detected with ninhydrin. Figure 7 shows that II migrates faster toward the cathode than III, and that the mobility of

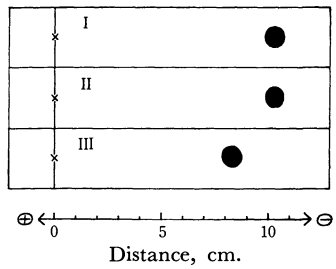

Fig. 7. Paper electrophoresis of II, III and gramicidin S (I).

II is indistinguishable from that of gramicidin S (I).

Microbiological Assays. — The microorganisms employed are *E. coli*, *P. vulgaris*, *S. aureus*, *B. subtilis* and *M. avium*. A minimum amount of compound for complete inhibition of growth was determined by a dilution method with a bouillon agar medium and with a synthetic medium. Synthetic cyclic peptides II and III exhibited no antibacterial activity against any of the microorganisms tested even at levels of 100 γ per ml. of assays medium, whereas gramicidin S exhibited considerable activity against some of the microorganisms.

The authors wish to express their thanks to Dr. Motoo Shibata of Takeda Chemical Industries, Ltd. for the microbiological assays. The authors are also indebted to Ajinomoto Co., Inc. and Kyowa Hakko Kogyo Co., Ltd. for supplying some amino acids.

Studies of Peptide Antibiotics. VII. The Synthesis of Cyclo-D-phenylalanyl-D-leucyl-L-ornithyl-L-valyl-D-ornithyl-L-prolyl

By Tetsuo KATO and Nobuo IZUMIYA

Laboratory of Biochemistry, Faculty of Science, Kyushu University, Fukuoka

(Received March 14, 1966)

A cyclic hexapeptide, cyclo-D-phenylalanyl-D-leucyl-L-ornithyl-L-valyl-D-ornithyl-L-prolyl, was once reported to be an antibiotic gramicidin J_2, and the synthesis of the compound was described also. However, the natural occurrence of gramicidin J_2 was denied recently. For the purpose of comparing its antibacterial activity, if any, with gramicidin S, the synthesis of this compound was carried out. *p*-Methoxybenzyloxycarbonyl-D-phenylalanyl-D-leucyl-*δ*-benzyloxycarbonyl-L-ornithyl-L-valyl-*δ*-benzyloxycarbonyl-D-ornithyl-L-proline *p*-nitrophenyl ester was prepared, and, after the selective cleavage of *p*-methoxybenzyloxycarbonyl group, the hexapeptide ester was transformed to the cyclic benzyloxycarbonyl hexapeptide, which was then hydrogenated to afford the desired cyclic hexapeptide as dihydrochloride. The effects of the synthesized cyclic peptide on bacterial growth have been examined. No antibacterial activities were observed in reaction to the microorganisms utilized here.

A number of polypeptide antibiotics, such as gramicidin S, have three characteristic features in common; namely, the occurrence of D-amino acids, basic amino acids, and a cyclic structure in the molecule. For a study of the relationship between the chemical structure and the biological activities of peptide antibiotics, some dipeptide anhydrides, which are the simplest compounds possessing the characteristics mentioned above, were synthesized; however, these were all devoid

of any antibacterial activity.[1] A cyclic hexapeptide, cyclo-L-valyl-L-ornithyl-L-leucyl-D-phenylalanyl-L-prolylglycyl, which contains the partial amino acid sequence found in gramicidin S and tyrocidines, was then prepared, and its biological activity examined. However, in spite of its apparent resemblance to those natural antibiotics, this compound also was found to be inactive.[2] Thus, it was concluded that even the occurrence of a hexapeptide ring structure may not be a sufficient condition for a molecule to exhibit antibacterial activity. These results prompted the present study of another cyclic hexapeptide, cyclo-D-phenylalanyl-D-leucyl-L-ornithyl-L-valyl-D-ornithyl-L-prolyl (XXIV), which has been demonstrated to be an antibiotic named gramicidin J_2.[3]

D-Phe-D-Leu-L-Orn-L-Val-D-Orn-L-Pro

XXIV

Previously Noda[3] isolated an antibiotic peptide from a culture of *Bacillus brevis Nagano* and proposed its chemical structure to be that shown as XXIV. He furthermore reported a method of the chemical synthesis of the compound corresponding to XXIV, and described that the product synthesized was identical with natural gramicidin J_2.[4] Nevertheless, Kurahashi[5] and Otani and Saito[6] reported that natural gramicidin J_2 is the same compound as gramicidin S, a cyclic decapeptide.

To elucidate the ambiguity described above, the present authors attempted to synthesize the cyclic hexapeptide with the structure of XXIV and to test its antibacterial activity.

The sequence of reaction employed for the synthesis of the acylhexapeptide ester (XVII) is indicated in Figs. 1 and 2. The proline residue was selected as the *C*-terminal amino acid in a linear hexapeptide in order to avoid otherwise possible racemization. *p*-Methoxybenzyloxycarbonyl and benzyloxycarbonyl groups were employed for the selective blocking of the *N*-terminal amino group and the δ-amino group of ornithine residue respectively.

As is shown in Fig. 1, the *C*-terminal dipeptide derivative, the *t*-butyloxycarbonyl-δ-benzyloxycarbonyl-D-ornithyl-L-proline ethyl ester (IV), was prepared via three different methods: (a) the mixed anhydride method,[7] (b) the active ester method using the diacyl D-ornithine *p*-nitrophenyl ester (III),[8] and (c) the dicyclohexylcarbodiimide method.[9] The last method gave the highest yield. The protected tripeptide ester (IX) was secured via two ways; (a) stepwise elongation from *C*-terminal amino acid, and (b) fragment condensation via the azide method. The former method gave a slightly better yield, but the latter method furnished two well-defined crystalline intermediate compounds, VII and VIII.

As is shown in Fig. 2, the *N*-terminal tripeptide derivative, the *p*-methoxybenzyloxycarbonyl-D-phenylalanyl-D-leucyl-δ-benzyloxycarbonyl-L-ornithine ethyl ester (XV), was obtained via stepwise elongation and converted to the corresponding hydrazide (XVI). However, the protected hexapeptide ester (XVII), derived from the azide of XVI and X, showed resistance to saponification. Hence, the preparation of the protected hexapeptide (XX) was carried out as is shown in Fig. 3.

Figure 3 indicates the route for the synthesis of the cyclic hexapeptides (XXIII, XXIV). XX was prepared by the coupling reaction of tripeptide azide (from XVI) with neutral free tripeptide (from XIX), and then XX was converted to the protected hexapeptide *p*-nitrophenyl ester (XXII). The removal of the *p*-methoxybenzyloxycarbonyl group from XXII by treatment with trifluoroacetic acid yielded the hexapeptide *p*-nitrophenyl ester trifluoroacetate. The cyclization reaction of the trifluoroacetate in pyridine gave the benzyloxycarbonyl-substituted cyclic peptide (XXIII), which was then purified by passing it through columns of Dowex 50 (H^+ form) and Dowex 1 (OH^- form). The molecular-weight determination using a vapor pressure osmometer demonstrated that the molecular size of XXIII corresponds to that of cyclic hexapeptide. The final product, XXIV, was obtained, upon the hydrogenolysis of XXIII in the presence of two equivalents of hydrogen chloride, as crystalline dihydrochloride, with five moles of water. The treatment of XXIII with hydrogen bromide in acetic acid furnished the corresponding cyclohexapeptide hydrobromide (the hydrobromide of XXIV). The homogeneity and identity of the two products ($XXIV \cdot 2HCl \cdot 5H_2O$ and hydrobromide of XXIV) was established by paper, thin-layer, and carboxymethyl cellulose column chromatography and by paper electrophoresis.

The chromatographic behavior and several other characteristics of the synthesized product, $XXIV \cdot 2HCl \cdot 5H_2O$, were compared with those

of gramicidin S. These two cyclic peptides were quite different from each other in chromatographic behavior. Moreover, such constants as the specific rotation of XXIV·2HCl·5H$_2$O observed were quite different from those of XXIV·2HCl reported by Noda.[4] Table I compares the physical constants and R_f values of XXIV·2HCl·5H$_2$O synthesized in this paper and described by Noda,[4] and those of gramicidin S.

The antibacterial activity of XXIV·2HCl·5H$_2$O and gramicidin S in reaction to several microorganisms were examined. XXIV·2HCl·5H$_2$O had no retarding effect on the growth of the microorganisms, even at so high a concentration as 100γ per ml. of the assay medium. Gramicidin S, however, showed substantial activity under these conditions. It should be noted that the antibacterial activity of the product, XXIV·2HCl, synthesized by Noda[4] was reported to be the same as that of gramicidin S.

The findings described in this paper are in marked disagreement with the observations of Noda.[4] The authors have no explanation for the discrepancy between their results and those of Noda.[4,12]

Experimental

All the melting points are uncorrected. The paper chromatography was carried out on Toyo Roshi No. 52 paper. The thin-layer chromatography was carried out on Merck silica gel G. The developing solvent commonly used was *n*-butanol - acetic acid - pyridine - water (4 : 1 : 1 : 2 v/v). Spots of materials possessing a free amino group on a thin-layer plate were detected by spraying ninhydrin, and those of the amino-group-blocked materials, by spraying 47% hydrobromic acid and then ninhydrin. Prior to analysis, the compounds were dried over phosphorus pentoxide to a constant weight at 80°C and 2 mmHg.

Amino Acids.—The amino acids used were as follows: D-phenylalanine, $[\alpha]_D^{24}$ +33.5° (*c* 2, water) (lit. for the L-isomer, −34.5°[13]), was obtained from acetyl-DL-phenylalanine through the asymmetric hydrolytic action of hog renal acylase.[14] D-Leucine, $[\alpha]_D^{24}$ +15.5° (*c* 2, 5 N HCl) (lit. for L-isomer −16.0°[13]), L-ornithine hydrochloride, $[\alpha]_D^{24}$ +21.8° (*c* 2, 5 N HCl) (lit. +22.2°[13]), L-valine, $[\alpha]_D^{24}$ +27.7° (*c* 2, 5 N HCl) (lit. +28.3°[13]), and L-proline, $[\alpha]_D^{24}$ −59.7° (*c* 2, 5 N HCl) (lit. −60.4°[13]), were commercial products. D-Ornithine hydrochloride, $[\alpha]_D^{24}$ −22.6° (*c* 2, 5 N HCl) (lit. for L-isomer +22.2°[13]), was obtained from DL-ornithine hydrochloride through optical resolution, using D-glutamic acid as the resolving reagent.[15]

δ-Benzyloxycarbonyl-D-ornithine (I).—This compound was obtained according to the procedure for the L-isomer.[16] Yield, 87%; m. p. 255°C; $[\alpha]_D^{24}$ −21.1° (*c* 1, 6 N HCl), −21.3° (*c* 1, 50% acetone + 2 eq. HCl) (lit. for L-isomer +17.0°[16]).

Found: C, 58.47; H, 6.85; N, 10.53. Calcd. for $C_{13}H_{18}O_4N_2$: C, 58.63; H, 6.81; N, 10.52%.

α-*t*-Butyloxycarbonyl - δ - benzyloxycarbonyl - D - ornithine (II).—To a stirred solution of I (2.295 g., 8.6 mmol.) and sodium bicarbonate (2.94 g., 35 mmol.) in water (50 ml.) at 50°C, a solution of *t*-butyloxycarbonyl azide[17] (2.419 g., 17 mmol.) in dioxane (50 ml.) was added. After 2 days' stirring at 45°C, the reaction mixture was evaporated to a half volume and extracted with ether. The aqueous layer was then acidified and extracted with ethyl acetate, and the organic layer was dried and evaporated. The residual oil weighed 2.574 g. (82%).

α-*t*-Butyloxycarbonyl - δ - benzyloxycarbonyl - D - ornithine *p*-Nitrophenyl Ester (III).—A solution of II (733 mg., 2 mmol.), dicyclohexylcarbodiimide[9] (412 mg., 2 mmol.) and *p*-nitrophenol (333 mg., 2.4 mmol.) in tetrahydrofuran was stirred for 3 hr. at 0°C, and then for 2.5 hr. at room temperature. After filtration,

the solution was evaporated to an oil. After the addition of a mixture of ether and petroleum ether (1 : 1, 4 ml.), the solution was stored in a refrigerator overnight. The crystals were filtered off, washed with a mixture of ether and petroleum ether (1 : 1), and dried (683 mg.). Recrystallization from ethyl acetate - ether - petroleum ether gave 611 mg. (63%); m. p. 108°C.

Found: C, 59.13; H, 6.00; N, 8.62. Calcd. for $C_{24}H_{29}O_8N_3$: C, 59.23; H, 5.99; N, 8.69%.

α-*t*-Butyloxycarbonyl-δ-benzyloxycarbonyl-D-ornithyl-L-proline Ethyl Ester (IV).—*a) The Dicyclohexylcarbodiimide Method.*[9]—To a solution of II (1.042 g., 2.85 mmol.), L-proline ethyl ester *p*-toluenesulfonate[18] (967 mg., 3 mmol.), and triethylamine (0.46 ml.) in tetrahydrofuran (6 ml.), dicyclohexylcarbodiimide (618 mg.) was added at 0°C. After the stirring had been continued for 2 hr. at 0°C, and for more 2 hr. at room temperature, the mixture was left to stand overnight. The mixture was then evaporated in vacuo, and the residue was diluted with ethyl acetate (20 ml.). The solution which was separated from the dicyclohexylurea by filtration was washed successively with water, a 4% sodium bicarbonate solution, water, 10% citric acid, and water, and then dried over anhydrous sodium sulfate. The filtrate separated from the salt was evaporated in vacuo. The residual oil weighed 1.316 g. (89%).

b) The p-Nitrophenyl Ester Method.—A solution of III (488 mg., 1 mmol.), L-proline ethyl ester *p*-toluenesulfonate[18] (378 mg., 1.2 mmol.), and triethylamine (0.15 ml.) in chloroform (4 ml.) was prepared and treated as usual.[8] Yield, 266 mg. (53%).

δ-Benzyloxycarbonyl-D-ornithyl-L-proline Ethyl Ester Hydrochloride (V).—To a solution of IV (488 mg., 1 mmol.) in ethyl acetate (5 ml.), 4.38 N hydrogen chloride in ethyl acetate (5 ml.) was added; the reaction mixture was then allowed to stand for 2 hr. at room temperature. After it had been evaporated to dryness, the residual oil weighed 377 mg. (88%).

δ-Benzyloxycarbonyl-D-ornithine Ethyl Ester *p*-Toluenesulfonate (VI).—This compound was prepared according to the procedure of Kato et al.[1] Yield, 80%; $[\alpha]_D^{21}$ −8.9° (*c* 2, dimethylformamide) (lit. for L-isomer +8.9°[1]).

Found: C, 56.47; H, 6.67; N, 5.95. Calcd. for $C_{22}H_{30}O_7N_2S$: C, 56.63; H, 6.48; N, 6.01%.

***t*-Butyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-D-ornithine Ethyl Ester (VII).**—To a freshly-prepared mixed anhydride of *t*-butyloxycarbonyl-L-valine[17] (2.004 g., 9.22 mmol.), triethylamine (1.29 ml., 9.22 mmol.) and isobutyl chloroformate (1.20 ml., 9.22 mmol.)[7] in tetrahydrofuran (20 ml.), a solution of VI (4.301 g., 9.22 mmol.) and triethylamine (1.29 ml.) in chloroform (20 ml.) was added. The mixture was then washed and dried as has been described for IV. To the dried solution, a mixture of ether and petroleum ether was added, and the solution was stored in a refrigerator. The crystals which precipitated were collected and dried (3.97 g.). Recrystallization from ethyl acetate - ether - petroleum ether gave 3.505 g. (77%); m. p. 123—125°C; $[\alpha]_D^{20}$ −8.2° (*c* 1, acetic acid).

Found: C, 60.70; H, 7.73; N, 8.30. Calcd. for $C_{25}H_{39}O_7N_3$: C, 60.83; H, 7.96; N, 8.51%.

***t*-Butyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-D-ornithine Hydrazide (VIII).**—A solution of VII (987 mg., 2 mmol.) and hydrazine hydrate (2 ml., 40 mmol.) in dimethylformamide (4 ml.) was allowed to stand for 2 days at room temperature. Upon the addition of water (40 ml.), colorless crystals of VIII were precipitated; these were filtered off, washed with water, and dried (912 mg., 95%); m. p. 174°C; $[\alpha]_D^{20}$ −9.6° (*c* 1, ethanol).

Found: C, 57.60; H, 7.61; N, 14.33. Calcd. for $C_{23}H_{37}O_6N_5$: C, 57.60; H, 7.78; N, 14.60%.

***t*-Butyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-D-ornithyl-L-proline Ethyl Ester (IX).** — *a) From V and t-Butyloxycarbonyl-L-valine.*—To a freshly-prepared mixed anhydride gel of *t*-butyloxycarbonyl-L-valine[17] (100 mg., 0.46 mmol.), triethylamine (0.064 ml.), and isobutyl chloroformate (0.060 ml.) in tetrahydrofuran (2 ml.), a solution of V (205 mg., 0.46 mmol.) and triethylamine (0.064 ml.) in chloroform (3 ml.) was added. The mixture was treated as has been described for VII. The oily residue obtained weighed 215 mg. (79%).

b) From VIII and L-Proline Ethyl Ester. — The following operations were carried out in a cold room. Into a chilled solution of VIII (735 mg., 1.53 mmol.) in a mixture of glacial acetic acid (2 ml.) and dimethylformamide (4 ml.), N hydrochloric acid (1.7 ml.), 116 mg. of sodium nitrite, and additional N hydrochloric acid (1.7 ml.) were stirred. After 7 min., cold water (40 ml.) was added. The azide which was precipitated as a white mass was extracted thrice with ethyl acetate; the combined extract was washed successively with cold water, a saturated sodium bicarbonate solution, and water, and then dried over anhydrous sodium sulfate. The filtered azide solution was added to a solution of L-proline ethyl ester *p*-toluenesulfonate[18] (483 mg., 1.53 mmol.) and triethylamine (0.21 ml.) in dimethylformamide (10 ml.), and the mixture was stirred for 3 days at 0°C. The solution was evaporated and washed successively with water, a 4% sodium bicarbonate solution, water, 10% citric acid, and water, and then dried over anhydrous sodium sulfate. The filtrate was evaporated in vacuo; the oily residue weighed 728 mg. (81%).

L-Valyl-δ-benzyloxycarbonyl-D-ornithyl-L-proline Ethyl Ester Hydrochloride (X).—A solution of IX (215 mg., 0.36 mmol.) in 2.6 N hydrogen chloride in ethyl acetate (2.8 ml., 7.2 mmol.) was allowed to stand for 2 hr. at room temperature, and then evaporated to dryness in vacuo; the residue weighed 194 mg. Recrystallization from acetone-ether gave 148 mg. (77%) as hygroscopic crystals. R_f 0.93 on paper.

***t*-Butyloxycarbonyl-D-leucine (XI).** — This compound was prepared according to the general procedure of Schwyzer et al.[17] As a slight alteration, sodium bicarbonate was used instead of magnesium oxide, and a 1.2 equivalent of *t*-butyloxycarbonyl azide was utilized per equivalent of amino acid; yield, 76% (lit. for L-isomer 73%,[17] 72%,[19]); m. p. 84°C (lit. for L-isomer 78—81°C[17] 74—80°C[19]); $[\alpha]_D^{21}$ +25.2° (*c* 2, acetic acid) (lit. for L-isomer −24.0°C[19]).

Found: C, 53.04; H, 9.39; N, 5.73. Calcd. for

***t*-Butyloxycarbonyl-D-leucyl-δ-benzyloxycarbonyl-L-ornithine Ethyl Ester (XII).**—To a solution of XI (2.493 g., 10 mmol.) and dicyclohexylcarbodiimide[9] (2.06 g., 10 mmol.) in absolute tetrahydrofuran (20 ml.) at 0°C, a solution of δ-benzyloxycarbonyl-L-ornithine ethyl ester *p*-toluenesulfonate[11] (4.665 g., 10 mmol.) and triethylamine (1.4 ml., 10 mmol.) in chloroform (20 ml.) was added. The mixture was stirred for 3 hr. at 0°C and then allowed to stand overnight at room temperature. After the solvent had been removed by evaporation in vacuo, the resultant oily residue was dissolved in ethyl acetate (50 ml.) and the mixture was stored in a refrigerator for several hours. After it had been filtered from the formed dicyclohexylurea, the solution was washed and dried as has been described for IV(a). The filtrate was evaporated in vacuo, and the residual oil was solidified after pertoleum ether (20 ml.) had been added and the mixture had been stored in a refrigerator for several days. Recrystallization from ethyl acetate-petroleum ether gave 3.913 g. (77%); m. p. 88°C; $[\alpha]_D^{21}$ +11.0° (*c* 2, acetic acid).

Found: C, 61.77; H, 8.05; N, 8.46. Calcd. for $C_{26}H_{41}O_7N_3$: C, 61.52; H, 8.14; N, 8.28%.

D-Leucyl-δ-benzyloxycarbonyl-L-ornithine Ethyl Ester Hydrochloride (XIII).—To a solution of XII (254 mg., 0.5 mmol.) in ethyl acetate (2 ml.), 4.38 N hydrogen chloride in ethyl acetate (2.3 ml., 10 mmol.) was added. When, after 3 hr. at room temperature, the solution was evaporated to dryness in vacuo, hygroscopic crystals were obtained (211 mg., 96%). R_f 0.93 on paper.

***p*-Methoxybenzyloxycarbonyl-D-phenylalanine (XIV).**—To a solution of D-phenylalanine (1.652 g., 10 mmol.) and sodium bicarbonate (2.52 g., 30 mmol.) in water (30 ml.), a solution of *p*-methoxybenzyloxycarbonyl azide[20] (2.693 g., 13 mmol.) in dioxane (30 ml.) was added; the reaction mixture was stirred for 48 hr. at room temperature, and then evaporated in vacuo. The residual aqueous solution was extracted twice with ether (20 ml. each) and acidified with 10% citric acid (40 ml.). The acidified mixture was extracted thrice with ethyl acetate (30 ml. each), and the combined extract was washed with water, dried over sodium sulfate, and evaporated. The residual oil solidified upon the addition of petroleum ether. Recrystallization from ethyl acetate-petroleum ether gave 2.555 g. (77%); m. p. 81—88°C; $[\alpha]_D^{24}$ −5.7° (*c* 2, acetic acid) (lit. for L-isomer +5.7°[20]).

Found: C, 65.61; H, 6.05; N, 4.53. Calcd. for $C_{18}H_{19}O_5N$: C, 65.64; H, 5.82; N, 4.25%.

***p*-Methoxybenzyloxycarbonyl-D-phenylalanyl-D-leucyl-δ-benzyloxycarbonyl-L-ornithine Ethyl Ester (XV).**—To a solution of XIV (988 mg., 3 mmol.) and triethylamine (0.42 ml.) in tetrahydrofuran (10 ml.), isobutyl chloroformate (0.4 ml., 3 mmol.) was added at 0°C. After 20 min., a solution of XIII (1.40 g., 3 mmol.) and triethylamine (0.42 ml.) in chloroform (10 ml.) was added thereto, and the reaction mixture was allowed to stand overnight at room temperature. The mixture was then concentrated in vacuo, and water (100 ml.) and petroleum ether were added. The crystals were collected by filtration, washed with 10% citric acid, water, a 4% sodium bicarbonate solution, and water, and then dried; 1.598 g. (74%). Recrystallization from ethanol-ether-petroleum ether gave 1.394 g. (65%); m. p. 159°C; $[\alpha]_D^{21}$ +8.4° (*c* 2.01, acetic acid).

Found: C, 64.84; H, 6.95; N, 7.86. Calcd. for $C_{39}H_{50}O_9N_4$: C, 65.16; H, 7.01; N, 7.82%.

***p*-Methoxybenzyloxycarbonyl-D-phenylalanyl-D-leucyl-δ-benzyloxycarbonyl-L-ornithine Hydrazide (XVI).**—XV was converted to the hydrazide as in the case of VIII. Yield, 97%; m. p. 205°C; $[\alpha]_D^{24}$ +9.7° (*c* 1.0, dimethylformamide).

Found: C, 63.10; H, 6.94; N, 11.95. Calcd. for $C_{37}H_{48}O_8N_6$: C, 63.05; H, 6.86; N, 11.93%.

***p*-Methoxybenzyloxycarbonyl-D-phenylalanyl-D-leucyl-δ-benzyloxycarbonyl-L-ornithyl-L-valyl-δ-benzyloxycarbonyl-D-ornithyl-L-proline Ethyl Ester (XVII).**—Into a chilled solution of XVI (310 mg., 0.44 mmol.) in a mixture of glacial acetic acid (2.5 ml.) and dimethylformamide (2 ml.), 1.09 N hydrochloric acid (0.5 ml.), 33 mg. of sodium nitrite, and additional 1.09 N hydrochloric acid were stirred. After 6 min., cold water (20 ml.) was added. The azide which precipitated was filtered off, washed successively with cold water, a sodium bicarbonate solution, and water, and then dried under a vacuum in a desiccator. The azide was added to a solution of X (236 mg., 0.44 mmol.) and triethylamine (0.061 ml.) in dimethylformamide (4 ml.), and the mixture was stirred for 3 days at 0°c. The insoluble substance was removed by filtration. The precipitate which formed upon the addition of water (40 ml.) to the filtrate was collected, washed with 0.5 M citric acid, a 4% sodium bicarbonate solution and water, and dried. Recrystallization from dioxane-ether gave 366 mg. (71%); m. p. 168—170°C; $[\alpha]_D^{22}$ −14.4° (*c* 2, acetic acid).

Found: C, 63.02; H, 7.06; N, 9.51. Calcd. for $C_{62}H_{82}O_{14}N_8 \cdot H_2O$: C, 63.03; H, 6.99; N, 9.49%.

XVII was only partially saponified, even if it was treated with ten equivalents of alkali for 48 hr. at 30°C.

***t*-Butyloxycarbonyl-L-valyl-δ-benzyloxycarbonyl-D-ornithyl-L-proline (XVIII).**—To a solution of IX (728 mg., 1.23 mmol.) in methanol (6 ml.), N sodium hydroxide (1.61 ml.) was added; the solution was then allowed to stand for 3 hr. at room temperature. After the addition of water (6 ml.), the solution was evaporated in vacuo. After filtration, the solution was acidified with 0.5 M citric acid (6 ml.) and extracted with ethyl acetate three times (20 ml. each); then the combined extract was dried over anhydrous sodium sulfate. The filtrate from the salt was evaporated in vacuo to yield an oily product; 654 mg. (94%).

L-Valyl-δ-benzyloxycarbonyl-D-ornithyl-L-proline Hydrochloride (XIX).—To a solution of XVIII (654 mg., 1.16 mmol.) in dioxane (2 ml.), 4.2 N hydrogen chloride in dioxane (5.5 ml.) was added. After 2 hr. at room temperature, the solution was evaporated in vacuo to afford hygroscopic powder. Yield, 522 mg. (90%); R_f 0.61 on paper, 0.54 on silica gel.

***p*-Methoxybenzyloxycarbonyl-D-phenylalanyl-D-leucyl-δ-benzyloxycarbonyl-L-ornithyl-L-valyl-δ-benzyloxycarbonyl-D-ornithyl-L-proline (XX).**—The powder of azide drived from XVI (895 mg., 1.27 mmol.), N hydrochloric acid (2.8 ml.), and sodium nitrite

20) F. Weygand and K. Hunger, *Chem. Ber.*, **95**, 1 (1962).

(97 mg.) in a mixture of acetic acid (8 ml.) and dimethylformamide (2 ml.) were collected, washed, and dried as in the case of XVII. Then the azide was added to a solution of XIX (619 mg., 1.21 mmol.) and triethylamine (0.169 ml.) in dimethylformamide (10 ml.), and the mixture was stirred for 3 days at 0°C. Then the filtered solution was evaporated in vacuo, and the residual oil solidified upon the addition of ethyl acetate (4 ml.) and ether (20 ml.). The collected precipitate was washed with 10% citric acid and water. Recrystallization from dioxane - methanol - ether gave 893 mg. (65%); m. p. 163°C; $[\alpha]_D^{21}$ −15.7° (*c* 2, acetic acid).

Found: C, 63.26; H, 7.01; N, 9.77. Calcd. for $C_{60}H_{78}O_{14}N_8$: C, 63.47; H, 6.93; N, 9.87%.

D-Phenylalanyl-D-leucyl-L-ornithyl-L-valyl-D-ornithyl-L-proline Diacetate (XXI). — XX (9.0 mg., 0.007 mmol.), dissolved in a mixture of methanol (0.5 ml.), acetic acid (0.2 ml.) and water (0.3 ml.), was subjected to hydrogenolysis in the presence of palladium black. After being filtered from the catalyst, the solution was evaporated to dryness in vacuo. The hygroscopic powder which remained was collected with the aid of ether; yield, 6.3 mg.; R_f 0.43 on paper, and 0.47 on silica gel. The amino acid analysis gave the molar ratio of 1.0 : 1.0 : 2.2 : 0.8 : 1.1 for phe : leu : orn : val : pro.

***p*-Methoxybenzyloxycarbonyl-D-phenylalanyl-D-leucyl-δ-benzyloxycarbonyl-L-ornithyl-L-valyl-δ-benzyloxycarbonyl-D-ornithyl-L-proline *p*-Nitrophenyl Ester (XXII).**—To a solution of XX (795 mg., 0.7 mmol.) in pyridine (14 ml.), di-*p*-nitrophenyl sulfite[21] (1.814 g., 5.6 mmol.) was added. The reaction mixture was allowed to stand for 24 hr. at room temperature. After the solvent had been evaporated, the oily product was triturated in petroleum ether and washed repeatedly with a mixture of ether and petroleum ether (1 : 1) by decantation. The residual solid was filtered off and washed with a mixture of ether-petroleum ether until no yellow could be discerned upon the addition of N sodium hydroxide to the filtrate. The yield was 826 mg. The *p*-nitrophenyl-ester content in this product was spectrophotometrically estimated to be 80% by measuring the optical density of the compound at 412 mμ.[10,22]

Cyclo-D-phenylalanyl-D-leucyl-δ-benzyloxycarbonyl-L-ornithyl-L-valyl-δ-benzyloxycarbonyl-D-ornithyl-L-proyly (XXIII).—Anisole (0.5 ml.) and trifluoroacetic acid (4 ml.) were added to XXII (826 mg.) below 0°C. The solution was then evaporated in vacuo at 0°C, and the residue was triturated with ether. The hexapeptide *p*-nitrophenyl ester trifluoroacetate was collected in a cold room, washed with a mixture of ether and petroleum ether and dried in vacuo. The dried trifluoroacetate was then dissolved in dimethylformamide (10 ml.) containing 0.2 ml. of acetic acid, and the solution was stirred, drop by drop, into pyridine (200 ml.) which had been kept at 60°C over a period of 4 hr.; the stirring was then continued for an additional 2 hr. at the same temperature. After the solvent had been removed, the residue was dissolved in a mixture of methanol (50 ml.) and water (20 ml.). The insoluble substance was removed by filtration, and the filtrate was passed successively through the columns (2×10 cm. each) of Dowex 1 (OH^- form) and Dowex 50 (H^+ form). The columns were washed with the same solvent (140 ml.), and the collected effluent was evaporated to dryness in vacuo. The residual product was dissolved in methanol, and the solution was evaporated. The residue was triturated and pulverized in a mixture of ether and petroleum ether (1 : 1). Recrystallization from ethyl acetate - ether - petroleum ether gave 322 mg. (48% form XX); m. p. 184°C; $[\alpha]_D^{24}$ +7.3° (*c* 1.01, acetic acid).

Found: C, 64.22; H, 7.59; N, 11.26. Calcd. for $C_{51}H_{68}O_{10}N_8$: C, 64.26; H, 7.19; N, 11.75%.

The molecular weight of XXIII was determined by a model 301 A Osmometer, Mechrolab Inc. (solvent methanol).[23]

Found: 955. Calcd. 953.

Cyclo-D-phenylalanyl-D-leucyl-L-ornithyl-L-valyl-D-ornithyl-L-prolyl Dihydrochloride (XXIV·2HCl).—XXIII (48.6 mg., 0.05 mmol.), dissolved in methanol (0.5 ml.) containing 0.48 N methanolic hydrogen chloride (0.23 ml.), was subjected to hydrogenolysis in the presence of palladium black. After being filtered from the catalyst, the solution was evaporated to dryness in vacuo. The residual crystals were then collected with the aid of a mixture of acetone and ether, and dried in air. Yield, 37.4 mg. (81%); m. p. 242—244°C (decomp.); $[\alpha]_D^{23}$ +6.6° (*c* 1.02, acetic acid); R_f 0.73 on paper, 0.69 on silica gel. The amino acid analysis gave the molar ratio of 1.0 : 1.1 : 2.3 : 1.0 : 1.2 for phe, leu, orn, val, and pro.

Found: C, 49.79; H, 7.90; N, 12.88. Calcd. for $C_{35}H_{58}O_6N_8Cl_2\cdot 5H_2O$; C, 49.58; H, 8.08; N, 13.22%.

The air-dried product lost 8.8% of its weight after being dried over phosphorus pentoxide at 80°C (2 mmHg) to a constant weight. Calcd. for $4H_2O$: 8.5%.

The molecular weight of XXIV·2HCl·$5H_2O$ was determined by the procedure described above (solvent methanol).[23]

Found: 340. Calcd. for $1/3\times(C_{35}H_{56}O_6N_8\cdot 5H_2O\cdot 2HCl)$: 283.[24]

Cyclo-D-phenylalanyl-D-leucyl-L-ornithyl-L-valyl-D-ornithyl-L-prolyl Hydrobromide (Hydrobromide of XXIV).—Ten mg. of XXIII was dissolved in 2 N hydrogen bromide in acetic acid (0.2 ml.). After 45 min., the reaction mixture was evaporated in vacuo, and acetic acid (0.2 ml.) and ether (0.5 ml.) were added. The precipitate was filtered off, repeatedly washed with ether, and dried in vacuo. The hygroscopic powder obtained weighed 6.6 mg. Its homogeneity was established by paper (R_f 0.73), thin-layer (R_f 0.68), and carboxymethyl cellulose column chromatography (Fig. 4), and by paper electrophoresis (Fig. 5).

The Chromatography and Electrophoresis of XXIV and Related Compounds.—A sample (0.5 mg. —1mg.) was dissolved in 0.2—0.3ml. of 0.2M pyridinium acetate contining 30% methanol (pH 5.0); the solution was then applied to a column (0.9×50 cm.) with carboxymethyl cellulose (Eastman Organic Chem. 7796),

22) M. Ohno and N. Izumiya, This Bulletin **38**, 1839 (1965).

23) The authors are indebted to Mr. Michinori Waki of this laboratory for the molecular-weight determination.

24) This compound appears to dissociate into three molecules under the conditions under which the determination of the molecular weight was carried out.

TABLE II. INHIBITORY ACTIVITY OF XXIV·2HCl·5H$_2$O AND GRAMICIDIN S ON MICROORGANISMS

Minimum inhibitory concentrations, μg./ml.

	Escherichia coli	*Proteus vulgaris*	*Staphylococcus aureus*	*Bacillus subtilis*	*Mycobacterium avium*
XXIV·2HCl·5H$_2$O	>100	>100	>100	>100	>100
Gramicidin S·H$_2$SO$_4$·8H$_2$O	>100	>100	5	5	>100

Medium used was Stephenson-Whetham's medium (modified); K_2HPO_4 0.1%, NaCl 0.1%, $MgSO_4 \cdot 7H_2O$ 0.05%, Na-glutamate 0.4%, casamino acid 0.2%, yeast-extract 0.05% and agar 2.0%, pH 7.0. The same results were obtained on bouillon agar medium.

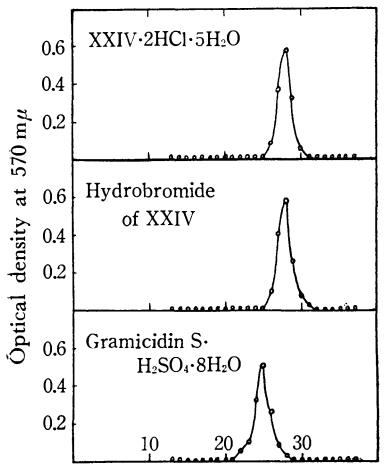

Fig. 4. Carboxymethyl cellulose column chromatography of three compounds.

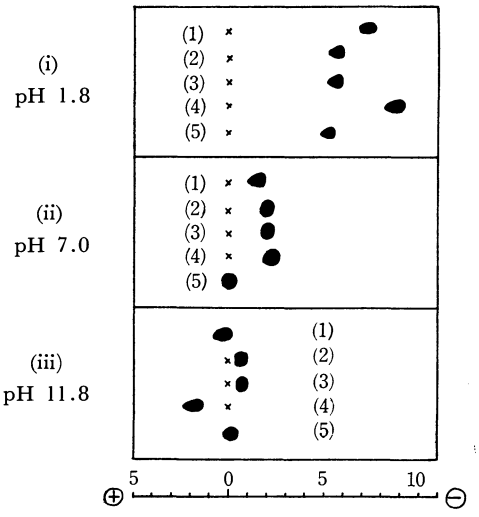

Fig. 5. Paper electrophoresis of (1) XXI, (2) XXIV·2HCl·5H$_2$O, (3) hydrobromide of XXIV, (4) L-lysine hydrochloride, and (5) gramicidin S·H$_2$SO$_4$·8H$_2$O.

and development was continued with the same solvent. Two milliliter fractions were collected at a flow rate of 20 ml. per hour. The peptide content of the fractions was determined by the method described by Yemm and Cocking.[25] Gramicidin S was used as the control. As is shown in Fig. 4, the same chromatographic pattern was obtained for XXIV·2HCl·5H$_2$O and for the hydrobromide of XXIV.

Paper electrophoresis was carried out under these conditions: paper, Toyo Roshi No. 52; voltage gradient, 500 V./30 cm.; charged period, 2 hr.; solvent system, (i) formic acid - acetic acid - methanol - water (1 : 3 : 6 : 10, v/v) (pH 1.8), (ii) 0.02 M sodium citrate buffer - methanol (1 : 1, v/v) (pH 7.0), and (iii) triethylamine - concentrated ammonium hydroxide - methanol - water (1 : 1 : 20 : 40, v/v) (pH 11.8). L-Lysine hydrochloride and gramicidin S sulfate were used as the reference compounds. Figure 5 demonstrates the electrophoretic patterns of XXI, XXIV·2HCl·5H$_2$O, the hydrobromide of XXIV, lysine and gramicidin S. The mobility of XXIV·2HCl·5H$_2$O with relation to lysine was 0.64 in solvent i, and 0.95 in solvent ii; it was indistinguishable from one of the hydrobromides in each solvent.

Microbiological Assays. — The microorganisms employed are shown in Table II. The minimum amount of the compounds needed for the complete inhibition of growth was determined by a dilution method with a bouillon agar medium and with a synthetic medium. As Table II shows, the cyclic hexapeptide XXIV·2HCl·5H$_2$O was found to be devoid of activity in reaction against any of the microorganisms utilized, even at high concentrations of the test compound, whereas gramicidin S exhibited considerable activity in reaction against some of the microorganisms at substantial concentrations.

The authors wish to express their thanks to Dr. Motoo Shibata of Takeda Chemical Industries, Ltd., for his microbiological assays. Thanks also due to Ajinomoto Co., Inc., and Kyowa Hakko Kogyo Co., Ltd., for supplying some amino acids.

Cyclopropene Derivatives. IV.*1 The Reactions of Acylcyclopropene

By Naruyoshi OBATA and Ichiro MORITANI*2

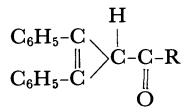
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received January 24, 1966)

The reactions of acylcyclopropenes, such as 3-benzoyl-1, 2-diphenyl- and 3-acetyl-1, 2-diphenyl-cyclopropene, were investigated. These ketones gave normal hydrazones with 2, 4-dinitrophenylhydrazine. With *p*-toluenesulfonylhydrazine, the acetyl compound gave ordinary hydrazone, but the benzoyl derivative did not give its hydrazone. The reaction with hydrazine hydrate caused the expansion of the cyclopropene ring and produced pyridazine derivatives in both the ketones. The carbenic decomposition of 3-acetyl-1, 2-diphenylcyclopropene *p*-toluenesulfonylhydrazone with sodium methoxide in diglyme gave diphenylacetylene and 3, 4-diphenyl-6-methylpyridazine. On irradiation with ultraviolet light, 3-benzoyl-1, 2-diphenylcyclopropene produced 1, 2, 4, 5-tetraphenylbenzene. In the case of 3-acetyl-1, 2-diphenylcyclopropene, the same benzene derivative and 1, 2, 4, 5-tetraphenyl-3, 6-diacetyltricyclo[3, 1, 0, $0^{2,4}$]hexane were obtained. The latter material was transformed into a benzene derivative upon further irradiation. Tricyclohexane could be an intermediate in the transformation of ketones to a benzene derivative.

A series of investigations of the cyclopropenyl derivatives have been made by Breslow and his co-workers.[1] They report the facile ring expansion of the cyclopropene in a number of cases.[1] Since it is known that the olefinic group plays an important role in a carbene reaction[2] and in the photochemical reaction[3], the reaction of cyclopropenylcarbene and the photochemistry of cyclopropenylketone are of great interset. Unusual reaction products other than the ring-expanded one might be formed. In this respect, the thermal decomposition of 1, 2-diphenylcyclopropenyldiazoethane and the photochemical reaction of 3-acyl-1, 2-diphenylcyclopropene will be investigated here.

The Reaction of Methyl-1, 2-diphenylcyclopropene-3-yl Carbene.—It has been shown[4] that the reaction of 3-benzoyl-1, 2-diphenylcyclopropene with hydrazine hydrate gives a ring-expanded isomer, dihydropyridazine, whereas the reaction with hydroxylamine gives an unrearranged cyclopropenyl oxime. It seems, therefore, that a ring expansion in the hydrazone formation is not inevitable in the cyclopropenyl ketone. Accordingly, the reactions of 3-benzoyl-1, 2-diphenylcyclopropene (Ia) and 3-acetyl-1, 2-diphenylcyclopropene (Ib) with some hydrazines were investigated.



Ia: R=C_6H_5

Ib: R=CH_3

The reaction of ketone Ia with hydrazine hydrate gave a mixture of yellow and white materials. The yellow material gradually changed to the white one during recrystallization from ethanol or benzene. The white material was purified and identified as 3, 4, 6-triphenylpyridazine (IIIa), m. p. 171—172°C. The spectral study of a crude yellow material, m. p. 167—178°C, showed that the material contained the N-H group and a less extended conjugating system. Therefore, the yellow material could be the dihydropyridazine (IIa) reported by Breslow.[4],*3 It seems that IIa is formed by the reaction of ketone Ia with hydrazine hydrate, but that IIa is oxidized to IIIa, presumably by oxygen in the air, during the recrystallization. Such an easy oxidation of the dihydropyridazine to the pyridazine is observed in many cases.[5]

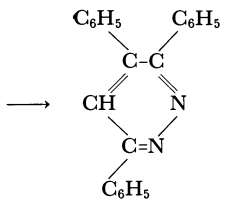
(IIa)



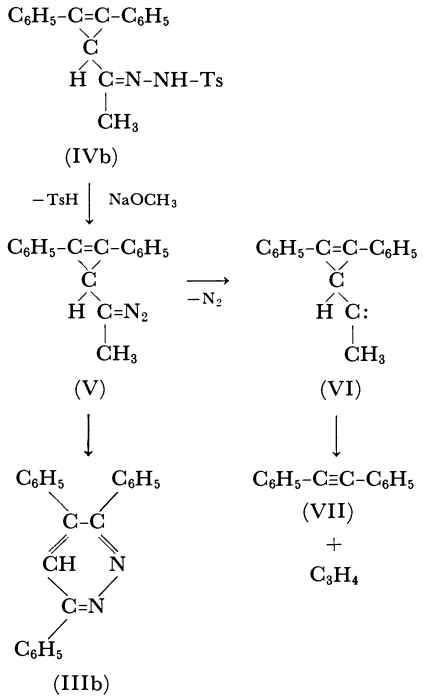
(IIIa)

The same result was also obtained in the reaction of ketone Ib with hydrazine hydrate.

Unlike the reaction with hydrazine, however, ketone Ia and Ib gave 2, 4-dinitrophenylhydrazone with no skeletal rearrangement.[6] The existence of the 1, 2-diphenylcyclopropenyl group in the resulting hydrazones was clearly shown by the characteristic patterns in infrared and ultraviolet spectra.[7] The 2, 4-dinitrophenyl group might diminish the nucleophilic character of β-nitrogen and prevent its further attack on a cyclopropene ring. In a similar way, the reaction of ketone Ib with *p*-toluenesulfonylhydrazine also gave an unrearranged cyclopropenylhydrazone. However, ketone Ia failed to react under the same reaction conditions.

Since the preparation of the hydrazone without any ring expansion was successful, the reaction of cyclopropenylcarbene was also studied. A solution of *p*-toluenesulfonylhydrazone (IVb) of ketone (Ib) in diglyme was added dropwise to a solution of sodium methoxide in diglyme at 140°C. Gas was evolved gently. The collected gas was analyzed by means of a mass spectrometer. A mother peak for C_3H_4, probably methylacetylene and/or allene, was found in addition to a large amount of nitrogen. The reaction products were isolated and separated by alumina-column chromatography. From a hydrocarbon fraction, diphenylacetylene (VII) was obtained in a 28.4% yield. No other hydrocarbon could be detected in the products. From a later fraction of the chromatography, 3, 4-diphenyl-6-methylpyridazine (IIIb) was isolated in a 26.1% yield.

The diazo compound V of the desired structure, formed by the base catalyzed decomposition of *p*-toluenesulfonylhydrazone (IVb), produced methyl-1, 2-diphenylcyclopropene-3-yl carbene (VI), which then splits into two olefinic materials, diphenylacetylene (VII) and C_3H_4. If a ring expansion in carbene VI occurs, the compound derived from cyclobutadiene might be formed. If the intramolecular addition of carbene VI to a double bond occured, the tetrahedrane derivative might be formed. However, such was not the case in the present experiment. A pyridazine, IIIb, was formed by the ring expansion of the diazo compound V.



(IVb)

(V)

(VI)

(VII)

(IIIb)

A similar splitting of the three-membered ring in the carbene reaction has been reported by Friedman and Shechter.[8] Cyclopropylcarbene, prepared similarly from the corresponding *p*-toluenesulfonylhydrazone, gave ethylene, acetylene and cyclobutene.

Recently, Masamune and Kato[9] decomposed 3-formyl-1, 2-diphenylcyclopropene *p*-toluenesulfonylhydrazone with sodium methoxide at −20°C under irradiation with ultraviolet light. The major reaction product was also diphenylacetylene in this case, but a tetrahedrane derivative was also obtained in a 0.05—0.1% yield. In the present experiment, *p*-toluenesulfonylhydrazone (IVb) was investigated under very similar conditions, but

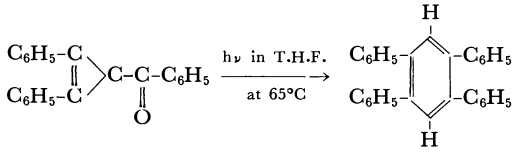
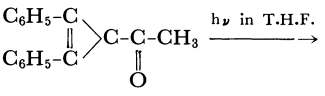
no evolution of nitrogen gas was observed at such a low temperature. Sodium salt of *p*-toluenesulfonylhydrazone was apparently formed, but its decomposition to a diazo compound might require a much higher temperature. In the present study we failed to obtain the tetrahedrane derivative.

The Photochemical Reaction of 3-Acyl-1, 2-diphenylcyclopropene.—A solution of 3-acylcyclopropene in tetrahydrofuran was irradiated by a high-pressure mercury lamp. The products were then separated by means of alumina-column chromatography. 3-Benzoyl-1, 2-diphenylcyclopropene (Ia) gave a hydrocarbon when eluted by petroleum ether and a glassy material when eluted by benzene or ether. The structure of the hydrocarbon was established to be 1, 2, 4, 5-tetraphenylbenzene (VIII) by comparison with an authentic material prepared through a known route.[10] The yield of VIII was 25.3%.

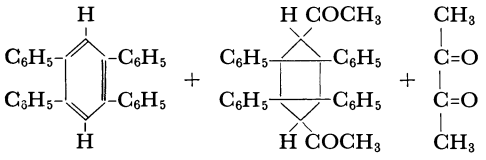


(Ia) (VIII)

Under the same conditions, the 3-acetyl derivative (Ib) gave a new compound IX in addition to tetraphenylbenzene (VIII), biacetyl (X), and a glassy material. When IX was dissolved in tetrahydrofuran and irradiated further under the same conditions, VIII was formed in a 43.4% yield, besides a glassy material. Consequently, it is clear that IX is the intermediate in the transformation of a cyclopropenyl ketone (Ib) to 1, 2, 4, 5-tetraphenylbenzene (VIII).

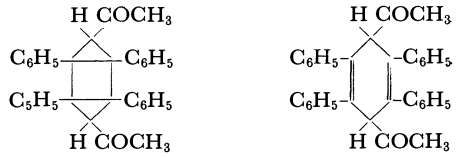


(Ib)



(VIII) (IX) (X)

Compound IX is considered to be 1, 2, 4, 5-tetraphenyl-3, 6-diacetyltricyclo[3, 1, 0, $0^{2,4}$]hexane on the basis of the following observations.[11] The spectral study of IX in the infrared and ultraviolet region shows clearly that the 1, 2-diphenylcyclopropene skeleton is absent in the compound IX. The analytical results and the molecular weight determination indicate that IX must be a dimeric material of the Ib ketone. Since IX has been found to be a precursor of VIII, it should have a structure which gives 1, 2, 4, 5-tetraphenylbenzene. Therefore, the compound IX may be considered to be either 1, 2, 4, 5-tetraphenyl-3, 6-diacetyltricyclo[3, 1, 0, $0^{2,4}$]hexane (IXa) or 1, 2, 4, 5-tetraphenyl-3, 6-diacetylcyclohexa-1, 4-diene (IXb):



(IXa) (IXb)

In the infrared region, IX exhibited characteristic absorptions at 1700 cm^{-1} and at 1020 cm^{-1}. The carbonyl stretching frequency observed corresponds to that expected for cyclopropylketone.[12] The 1020 cm^{-1} absorption is due to the cyclopropane skeleton. The ultraviolet absorption spectrum of IX showed a broad maximum at 226 mμ (log ε 4.21) and a shoulder at 275 mμ (log ε 3.74). It has been reported that 1, 2-diphenylcyclopropane[13] exhibits maxima at 234 mμ (log ε 4.10) and at 275 mμ (log ε 3.95), whereas *cis*-α, α'-dimethylstilbene[14] shows a maximum at 252 mμ (log ε 3.94). The proton magnetic resonance spectrum of IX exhibited a multiplet (20 hydrogens) at 2.85 τ, a singlet (2 hydrogens) at 4.80 τ*4 and a singlet (6 hydrogens) at 8.25 τ. Chemically, IX did not discolor a solution of potassium permanganate in acetone at room temperature after one hour, whereas *cis*-stilbene did. All these results are consistent with the tricyclohexane structure (IXa). The stereochemistry of this compound is not yet known. The yield was 6.7%.

Consequently, it may be suggested that the cyclopropenylketone Ib dimerizes preferentially to the cyclobutane derivative, IX. Further irradiation caused an α-cleavage and produced a biradical of a tricyclohexane, which then rearranged to a benzene derivative.

In an attempt to produce a cyclopropenyl radical, Breslow[16] obtained a dimer, bis-cyclopropenyl. This dimer rearranges to benzene derivatives on

*4 This absorption was identified as a tertiary proton in the tricyclohexane structure. Though similar proton appeared at a higher field (6.73—7.82 τ)[15] in methyl *trans, cis*-1, 2-diphenylcyclopropane-1-carboxylate, the deshielding effect might be more effective in IX because of the rigid ring system.

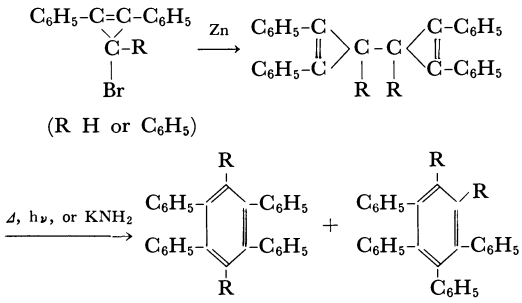
heating, by irradiation or by treatment with potassium amide.



From a structural consideration, the ketones Ia and Ib in the present experiment are also capable of taking such a dimerization route, because one of the common photoreactions of the ketone is the α-cleavage.[17] When a carbon-carbon bond on one side of a calbonyl group is preferentially cleaved, a cyclopropenyl radical is produced; it may dimerize as above, or it may abstract a hydrogen from the solvent. However, this was not the case in the ketones Ia and Ib. In a hydrocarbon fraction of the product none of the monomeric or dimeric hydrocarbons were detected other than a tricyclohexane and tetraphenylbenzene. Moreover, the isolation of a tricyclohexane as an intermediate clearly established that the reaction path was the preferential dimerization of the double bond in a cyclopropene skeleton. The α-cleavege followed it. A similar photodimerization of a cyclopropene derivative has recently been reported.[18] Irradiation with ultraviolet light on 1, 3, 3-trimethylcyclopropene-1 in acetone in the presence of benzophenone results in the formation of two stereoisomeric dimers, tricyclo[3, 1, 0, $0^{2,4}$]hexanes.

There is an interesting possibility for this dimerization, that is, the carbonyl group may be absorbing most of the light, while the double bond is doing most of the reaction, as has been found in some other cases.[19] In the present experiment, no evidence is available as a basis for deciding whether most of the light is absorbed by the carbonyl or by the double bond. However, the diphenylcyclopropene system absorbs the light at an appreciably longer wavelength with a high intensity.[6,7] It is more likely, therefore, that the double bond in a diphenylcyclopropene is more easily excited than a carbonyl group and forms a cyclobutane ring. The cycloaddition of two double bonds under irradiation is well known and has been discussed recently by Hoffmann and Woodward.[20]

In conclusion, the carbene reaction and photochemical reactions of the cyclopropene derivatives did not give simply ring-expanded materials as have been observed in many reactions. Cyclopropenylcarbene split into two olefinic compounds. Ultraviolet light caused a dimerization of olefin in the cyclopropene ring. Tricyclohexane derivatives were intermediates for the transformation of cyclopropenylketone to a benzene derivative.

Experimental*5

The Reaction of 3-Benzoyl-1, 2-diphenylcyclopropene (Ia) with Hydrazine Hydrate, 3, 4, 6-Triphenylpyridazine (IIIa).—A mixture of 1.07 g. (3.6 mmol.) of 3-benzoyl-1, 2-diphenylcyclopropene and 1.08 g. (21 mmol.) of hydrazine hydrate in 20 ml. of ethanol was heated under reflux for 15 hr. After the solution had cooled down, a mixture of yellow and white crystals, m. p. 135—175°C, was obtained. Repeated recrystallization of a mixture from ethanol-benzene gave white crystals, 3, 4, 6-triphenylpyridazine (IIIa), m. p. 171—172°C (reported 171°C)[21]; 0.75 g. (66.8%).

Found: C, 85.49; H. 5.17; N, 9.12; mol. wt. 299,
Calcd. for $C_{22}H_{16}N_2$: C, 85.69; H, 5.23; N, 9.09%; mol. wt. 308.4.

In the infrared region, two characteristic peaks of IIIa were observed at 1560 cm^{-1} and 1580 cm^{-1}. The ultraviolet maximum in ethanol was 269 mμ (log ε 4.3) reported 273 mμ (log ε 4.4).[22] A three-hour reaction caused a recovery of the starting material. The same material was prepared from ω-desylacetophenone and hydrazine hydrate.[21] A mixed melting point determination of two samples showed no depression. The infrared and ultraviolet spectra of two samples were superimposable, also. The attempted recrystallization of yellow crystal gave a material which melted at 167—178°C, and which showed peaks at 3300 cm^{-1} (νN–H), 1635 cm^{-1} and 1590 cm^{-1} in the infrared spectrum. The ultraviolet spectrum of this impure yellow material showed broad maxima at 250 mμ and 310 mμ.

The Reaction of 3-Acetyl-1, 2-diphenylcyclopropene (Ib) with Hydrazine Hydrate, 3, 4-Diphenyl-6-methylpyridazine (IIIb).—A solution of hydrazine hydrate (0.23 g. (4.4 mmol)), and 3-acetyl-1, 2-diphenylcyclopropene (Ib) (0.46 g. (1.9 mmol.)) in 4 ml. of ethanol was heated under reflux for 20 hr. After the solution had cooled down, yellow crystal, m. p. 135—149°C, was obtained. This compound could not be purified by repeated recrystallization from ethanol or benzene. The evaporation of the mother liquid gave white crystals, 2, 4-diphenyl-6-methylpyridazine (IIIb), m. p. 122—123°C (petroleum ether); 0.15 g.

(36.3%). Moreover, a solution of the yellow crystals in ether was gradually discolored in two days and 3, 4-diphenyl-6-methylpyridazine was obtained quantitatively. The structure of IIIb was established by the following observation.

Found: C, 82.75; H, 5.78; N, 11.35; mol. wt. 242. Calcd. for $C_{17}H_{14}N_2$: C, 82.90; H, 5.73; N, 11.67%; mol. wt. 246.3.

The characteristic infrared absorptions were at 1565 cm^{-1} and 1580 cm^{-1}. The ultraviolet maximum in ethanol was at 242 mμ (log ε 4.1). The NMR showed a multiplet (11 hydrogens) at 2.80 τ and a singlet (3 hydrogens) at 7.13 τ. Characteristic IR peaks of the impure yellow crystals, m. p. 150—156°C, were shown at 3300 cm^{-1} (νN–H), 1630 cm^{-1} and 1590 $cm.^{-1}$

2, 4-Dinitrophenylhydrazone of Ia and Ib.—The preparation of materials has already been described.[6] The characteristic infrared absorptions of 2, 4-dinitrophenylhydrazone of Ia, m. p. 193—194°C, were at 3250 cm^{-1} (νN–H) and 1825 cm^{-1} (νC=C in cyclopropene). The ultraviolet maxima of this compound in ethanol were at 228 mμ (log ε 4.25), 235 mμ (log ε 4.32), 296 mμ (log ε 4.25), 315 mμ (log ε 4.30) and 332 mμ (log ε 4.29). 2, 4-Dinitrophenylhydrazone of Ib, m. p. 210—211°C, showed characteristic IR peaks at 3300 cm^{-1} (νN–H) and 1830 cm^{-1} (νC=C in cyclopropene). The ultraviolet maxima of this compound in ethanol were at 228 mμ (log ε 4.33), 236 mμ (log ε 4.30), 295 mμ (log ε 4.24), 312 mμ (log ε 4.28) and 330 mμ (log ε 4.26).

3-Acetyl-1, 2-diphenylcyclopropene *p*-Toluenesulfonylhydrazone (IVb).—A solution of 3-acetyl-1, 2-diphenylcyclopropene (Ib) (0.14 g. (0.6 mmol.)) and *p*-toluenesulfonylhydrazine (0.16 g. (0.86 mmol.)) in 5 ml. of ethanol was heated under reflux for 0.5 hr. The product was then collected and recrystallized from benzene, m. p. 180—181°C (decomp.) The yield was 0.22 g. (93.0%).

Found: C, 71.86; H, 5.51. Calcd. for $C_{24}H_{22}N_2SO_2$: C, 71.61; H, 5.51%.

In the infrared spectrum the characteristic absorptions were observed at 3200 cm^{-1} (νN–H), 1820 cm^{-1} (νC=C in cyclopropene) and 1160 cm^{-1} (νSO_2). The ultraviolet maxima in ethanol were at 227 mμ (log ε 4.34), 234 mμ (log ε 4.32), 294 mμ (log ε 4.26), 302 mμ (log ε 4.36), 312 mμ (log ε 4.39) and 329 mμ (log ε 4.25).

At room temperature, a starting material was recovered after one day, whereas acetone and acetophenone reacted successfully.

The Reaction of 3-Benzoyl-1, 2-diphenylcyclopropene (Ia) with *p*-Toluenesulfonylhydrazone.—A solution of 3-benzoyl-1, 2-diphenylcyclopropene (Ia) (0.089 g. (0.30 mmol.)) and *p*-toluenesulfonylhydrazine (0.057 g. (0.32 mmol.)) in 5 ml. of ethanol was heated under reflux for 24 hr. After cooling, the precipitated material was found to be a starting ketone. After one week under reflux, however, no crystalline material was separated from the solution any more. The removal of the solvent gave a tarry material; *p*-toluenesulfonylhydrazone could not be obtained. In a separate experiment, the reaction was carried out in acetic acid at 90°C for 10 hr., but a tarry material resulted here also.

The Carbenic Decomposition of 3-Acetyl-1,2-diphenylcyclopropene *p*-Toluenesulfonylhydrazone (IVb) in the presence of Sodium Methoxide.—A solution of 3-acetyl-1, 2-diphenylcyclopropene *p*-toluenesulfonylhydrazone (IVb) (2.04 g. (5.1 mmol.)), in dry diglyme (40 ml.), was added drop by drop to a solution of sodium methoxide (0.31 g. (5.9 mmol.)), in dry diglyme (40 ml.), over a period of two hours at 120°C, at which temperature nitrogen gas was evolved gradually. Nitrogen gas and the volatile material was collected in a gas buret, and the latter was analyzed by mass spectrometer. We observed a mother peak corresponding to the C_3H_4 fragment in the mass spectrum. After it had cooled down, the reaction mixture was poured into a large amount of water. The organic material was extracted with ether several times. The combined ether solution was washed successively with ten 30-ml. portions of water to remove most of the diglyme. After the solution had been dried with anhydrous magnesium sulfate, the ether was removed by evaporation and the residue was subjected to column chromatography. Activated alumina (100 g.) was used. Elution with petroleum ether resulted in 0.26 g. (28.4%) of diphenylacetylene (VII), m. p. 59—60°C (reported 61°C).[23] Elution with ether gave 0.33 g. (26.1%) of 3, 4-diphenyl-6-methylpyridazine (IIIb), m. p. 123—123.5°C (petroleum ether). In a separate experiment, *p*-toluenesulfonylhydrazone (IVb) was decomposed in the presence of copper powder at 120°C. The result was the same; the yields of VII and IIIb were 24.3 and 11.1% respectively.

The Photochemical Transformation of 3-Benzoyl-1, 2-diphenylcyclopropene (Ia).—3-Benzoyl-1, 2-diphenylcyclopropene (Ia) (0.602 g. (2.03 mmol.)), was dissolved in dry tetrahydrofuran (400 ml.) and irradiated by a high-pressure mercury lamp. The reaction was followed by a study of the ultraviolet spectrum. After the solution had been irradiated one and a half hours, the characteristic ultraviolet peaks near 300 mμ present in the staring ketone disappeared. The tetrahydrofuran was evaporated, and the residue was subjected to column chromatography. Activated alumina (90 g.) was used. Elution with petroleum ether gave 0.098 g. (25.3%) of 1, 2, 4, 5-tetraphenylbenzene (VIII), m. p. 260—261°C (petroleum ether) (reported 262—263°C).[10]

Found: C, 93.86; H, 5.84. Calcd. for $C_{30}H_{22}$: C, 94.20; H, 5.80%.

The ultraviolet maxima in ethanol were at 252 mμ (log ε 4.65) and 282 mμ (log ε 4.24).

The same material was prepared from 3, 4-diphenylcyclopentadienon and diphenylacetylene at 275°C.[10] A mixed melting point determination of the two samples showed no depression. The infrared and ultraviolet spectra of the two samples were also superimposable. Elution with benzene, followed by that with ether, resulted in a glassy material (0.32 g.) which was not studied further.

The Photochemical Transformation of 3-Acetyl-1, 2-diphenylcyclopropene (Ib).—3-Acetyl-1, 2-diphenylcyclopropene (Ib) (0.78 g. (3.3 mmol.)) was dissolved in dry tetrahydrofuran (350 ml.) and irradiated by a high-pressure mercury lamp at 65°C. After two hours of irradiation, most of the solvent was removed by evaporation; and the separated solid was collected

23) L. F. Fieser, "Experiments in Organic Chemistry," Maruzen Co., Tokyo, Japan (1963), p. 181.

from the oily residue. The recrystallization of the solid material from ligroin-benzene resulted in 0.052 g. (7.6%) of 1, 2, 4, 5-tetraphenyl-3, 6-diacetyl-tricyclo-[3, 1, 0, $0^{2,4}$]hexane (IX), m. p. 285—287°C (with decomp.)

Found: C, 87.13; H, 6.10; mol. wt. 451. Calcd. for $C_{34}H_{28}O_2$: C, 87.15; H, 6.02%; mol. wt. 468.6.

In the infrared region, IX exhibited its characteristic absorptions at 1700 cm^{-1} and at 1020 cm^{-1}. The ultraviolet maxima in ethanol were at 226 mμ (log ε 4.21) and a shoulder at 275 mμ (log ε 3.74). The NMR showed a multiplet (10 hydrogens) at 2.85τ, a singlet (1 hydrogen) at 4.80, and a singlet (3 hydrogens) at 8.25τ.

The concentration of the mother liquid of recrystallization gave a material melting at 260—261°C, 1, 2, 4, 5-tetraphenylbenzene (VIII). The combined residue of recrystallization was subjected to column chromatography. From the hydrocarbon fraction, additional portions of VIII were obtained. The yield of VIII was 0.133 g. (20.3%).

The Photolysis of 1, 2, 4, 5-Tetraphenyl-3, 6-diacetyl-tricyclo[3, 1, 0, $0^{2,4}$]hexane (IX).—Tricyclohexane (IX) (25 mg. (0.053 mmol.)) was dissolved in dry tetrahydrofuran (300 ml.), and the solution was irradiated by a high-pressure mercury lamp for 4.5 hr. The temperature of the solution was kept at 50°C during the photolysis. Tetrahydrofuran was removed, and the residue was subjected to column chromatography. Activated alumina (30 g.) was used. Elution with petroleum ether gave 8.9 mg. (43.4%) of 1, 2, 4, 5-tetraphenylbenzene (VIII). Elution with ether resulted in a glassy material, but this was not studied further.

The Reaction of *p*-Methoxystyrene-α-^{14}C with Lead Tetraacetate

By Yasuhide YUKAWA and Nobuyoshi HAYASHI

The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received January 27, 1966)

The reaction of *p*-methoxystyrene with lead tetraacetate in glacial acetic acid should proceed mainly through the rearrangement of the carbon skeleton. The possibility of the hydrogen migration can not be ruled out, but its extent should be only 7% even if it is involved.

It has been known that lead tetraacetate is an effective oxidizing reagent not only for the fission of 1, 2-glycols, but also for the introduction of acetoxy groups into unsaturated compounds. The mechanism of the reaction of lead tetraacetate on the olefinic compounds is not so straightforward. There is a considerable variation in the products depending on the olefin used and on the conditions of the reaction. The normal reaction should be the addition of two acetoxy groups to a carbon-carbon double bond, but an abnormal reaction giving the rearranged product has usually been observed.

Criegee et al.[1] reported that the reaction of *p*-methoxystyrene in glacial acetic acid with lead tetraacetate gave *p*-methoxyphenylacetaldehyde diacetate. The most plausible mechanism of this reaction is the 1, 2-nucleophilic rearrangement of the *p*-anisyl group, as has been suggested by Criegee:

$$CH_3OC_6H_4CH{=}CH_2$$
(I)

$$\xrightarrow[AcOH]{Pb(OAc)_4} CH_3OC_6H_4\underset{\displaystyle OAc}{\underset{|}{CH}}\text{-}CH_2Pb(OAc)_3$$

$$\longrightarrow CH_3OC_6H_4\underset{\displaystyle OAc}{\underset{|}{CH}}\text{-}CH_2\overset{\oplus}{}$$

$$\longrightarrow \overset{\oplus}{C}H\text{-}CH_2C_6H_4OCH_3 \quad (\text{OAc})$$

$$\longrightarrow (AcO)_2CH\text{-}CH_2C_6H_4OCH_3$$
(II)

However, it can just as well be explained by the 1, 2-migration of hydrogen. The following mechanisms may, therefore, be suggested:

$$CH_3OC_6H_4CH{=}CH_2$$
(I)

$$\xrightarrow[AcOH]{Pb(OAc)_4} CH_3OC_6H_4\overset{\oplus}{C}H\text{-}CH_2Pb(OAc)_3$$

$$\longrightarrow CH_3O_6H_4CH_2\text{-}\overset{\oplus}{C}HPb(OAc)_3$$

$$\longrightarrow CH_3OC_6H_4CH_2\underset{\displaystyle Pb(OAc)_3}{\underset{|}{CH}}OAc$$

$$\longrightarrow CH_3OC_6H_4CH_2CH(OAc)_2$$
(II)

1) R. Criegee, P. Dimroth, K. Noll, R. Simons and C. Weis, *Chem. Ber.*, **90**, 1070 (1957).

$$CH_3OC_6H_4CH{=}CH_2 \quad \text{(I)}$$

$$\xrightarrow[AcOH]{Pb(OAc)_4} CH_3OC_6H_4CH(Pb(OAc)_3)-CH_2OAc$$

$$\longrightarrow CH_3OC_6H_4CH_2-\overset{\oplus}{C}HOAc$$

$$\longrightarrow CH_3OC_6H_4CH_2CH(OAc)_2 \quad \text{(II)}$$

In the present paper, the confirmation of the actual migrating group by means of the carbon-14 tracer technique will be reported.

It was found that styrene itself gives phenylacetaldehyde diacetate with lead tetraacetate in acetic acid. However, *p*-methoxystyrene was selected as the starting material in view of the powerful migrating aptitude of the *p*-anisyl group and the experimental convenience of the separation and purification of the reaction product. *p*-Methoxystyrene-α-^{14}C (I) was obtained, through *p*-anisaldehyde-carbonyl-^{14}C, from *p*-anisic acid-carbonyl-^{14}C, which had been prepared from *p*-methoxyphenyl magnesium bromide and carbon dioxide-^{14}C.

The treatment of *p*-methoxystyrene-α-^{14}C with lead tetraacetate in glacial acetic acid gave *p*-methoxyphenylacetaldehyde-diacetate-^{14}C, namely, 2-methoxyphenylethyl-1, 1-diol diacetate-^{14}C (II), as white needles. The specific radioactivity of II was 2.53 μc./mmol.

On the oxidation of II with an aqueous solution of potassium permanganate, followed by acidification, the fission products, carbon dioxide and anisic acid, were obtained. The specific activity of the carbon dioxide was 2.15 μc./mmol., which corresponds to 85% of the activity of the reaction product, II. This indicates that the rearrangement of the anisyl group is the major process of the reaction. The specific activity of anisic acid was 0.16 μc./mmol. This corresponds to 6.7% of the activity of II, suggesting the rearrangement of anisyl group up to 93.3%. The decrease in the activity of the carbon dioxide can be attributed to the formation of low-activity carbon dioxide by the further oxidation of anisic acid by permanganate. The activity of the anisic acid suggests hydrogen migration to a maximum extent of 7%.

In conclusion, the reaction of *p*-methoxystyrene with lead tetraacetate in glacial acetic acid should proceed mainly through the rearrangement of the carbon skeleton. The possibility of the hydrogen migration can not be ruled out, but its extent should be only 7% even if it is involved.

Experimental

The Preparation of *p*-Methoxystyrene-α-^{14}C. — *p*-Anisic acid-carboxyl-^{14}C was prepared by the Grignard carboxylation of *p*-bromoanisole (15 mmol.) with carbon dioxide liberated from barium carbonate (10 mmol.) (labeled: 1 mc./8.5 mg; unlabeled; 1.97 g.) by the usual method.[2] The acid was obtained in a 60% yield, m. p. 182—183°C; 0.9 g. The specific radioactivity was determined to be 90 μc./mmol.; total activity 533 μc. by the Van-Slyke-Folch wet combustion method.[3]

The labeled anisic acid was converted into the acid chloride with thionyl chloride, and the chloride was reduced to the aldehyde by the Rosenmund method. The resultant aldehyde, diluted to 15 g. with the unlabeled aldehyde, was then added to the Grignard solution from 17 g. of methyl iodide. This mixture was allowed to stand overnight and decomposed with ice and diluted sulfuric acid. The ethereal layer was separated, dried, and evaporated. On the distillation of the residue, 7.4 g. of the styrene (I), b. p. 92—97°C/16 mmHg was obtained.

The Reaction of *p*-Methoxystyrene with Lead Tetraacetate.—*p*-Methoxystyrene-α-^{14}C (2.7 g.) was added to a suspension of 10 g. of lead tetraacetate in 20 ml. of acetic acid. The mixture was then stirred for 2 hr. at room temperature and poured onto ice water. The oil which separated was taken up into ether, and the solvent was evaporated. The residue was solidified on keepting it in an ice-box and recrystallized from petroleum ether, giving fine needles of II, m. p. 49—50°; 1.9 g. The specific activity of the II obtained was 2.53 μc./mmol.

The diacetate II (0.4 g.) was oxidized in the usual manner by boiling it for 2 hr. in an aqueous acetone solution of alkaline potassium permanganate. After the manganese dioxide was been removed by filtration, the filtrate was acidified and the carbon dioxide liberated was absorbed into a barium hydroxide solution. The barium carbonate obtained showed a specific activity of 2.15 μc./mmol. By ether extraction, 0.1 g. of the anisic acid was obtained from the above acidified filtrate. The specific activity of this product was 0.16 μc./mmol.

The Relative Reactivities of Alkyl Acrylates in Their Radical Copolymerizations*

By Takayuki Otsu, Toshio Ito, Tomiya Fukumizu and Minoru Imoto

Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received February 3, 1966)

In order to clarify the effect of the alkyl groups in alkyl acrylates (RA) on their reactivities to the attack of a radical, the copolymerization of RA (M_2) with styrene (M_1) has been carried out at 60°C. From the results obtained, the monomer reactivity ratios and the Q_2 and e_2 values were determined. It was found that the relative reactivities ($1/r_1$) of RA to a polystyryl radical were correlated only by the polar substituent constant (σ^*) of the alkyl group in RA, not by their steric substituent constant (E_s) in Taft's equation:

$$\log(1/r_1) = \rho^*\sigma^* + \delta E_s$$

According to the above equation, the ρ^* and δ values were obtained as 0.56 and 0, respectively. It was also observed that the Q_2 and e_2 values for RA were correlated by Taft's σ^* substituent constant.

In a previous paper,[1,2] it has been reported that the relative reactivities of alkyl methacrylates to attack by polymer radicals are correlated only by the polar substituent constants (σ^*) of their alkyl groups in Taft's equation (1)[3]:

$$\log(\text{rel. reactivity}) = \rho^*\sigma^* + \delta E_s \qquad (1)$$

where E_s indicates the steric substituent constants of alkyl groups, and where ρ^* and δ are reaction constants. This result strongly indicated that the relative reactivities of alkyl methacrylates depended on the polar character of their alkyl groups, not on their steric characters.

Recently, we have obtained the same linear correlations between the reactivities of alkyl acrylates (RA) or nuclear-substituted phenyl methacrylates to attack by a polystyryl radical and the σ^* constants of alkyl groups or σ constants of para and meta substituents on the benzene ring, respectively. Some of these results have been reported in a previous short communication.[4] The present paper will present detailed results of the copolymerization of some RA with styrene. The RA used in this study were as follows: ethyl acrylate (EA), isopropyl acrylate (IPA), benzyl acrylate (BzA), 2-chloroethyl acrylate (CEA), and 2-cyanoethyl acrylate (CNEA).

Experimental

Materials.—The commercial EA was used after purification by the ordinary method. The other RA were prepared by the esterification of acrylic acid, methyl acrylate or acroyl chloride with the corresponding alcohols. The products thus obtained were distilled under reduced pressure until the absorption of unreacted alcohols disappeared in the infrared spectra. These RA were then used after redistillation in a nitrogen atmosphere. The physical constants of the RA used are shown in Table I.

Table I. Physical properties of RA monomers

RA	b. p. °C/mmHg	n_D^{20}	d_4^{20}
EA	99/760	1.4020	0.913[a]
IPA	52/100	1.4070	0.893[a]
BzA	65/1	1.5180	1.057[a]
CEA	60/19	1.4487	1.121
CNEA	64/2	1.4417	1.062[b]

a) From data summarized by Clarke.[5]
b) Data of Rehberg et al.[6]

The styrene used as a reference monomer in the copolymerization was purified by the ordinary method and was distilled before used.

2, 2'-Azobisisobutyronitrile (AIBN), a radical initiator, was recrystallized twice from ethanol.

Benzene, methanol, petroleum ether, and the other solvents were purified by the usual technique.

Copolymerization Procedure.—The copolymerizations of RA (M_2) with styrene (M_1) were carried out in an ordinary sealed-glass tube in the presence of 6.1

$\times 10^{-3}$mol./l. of AIBN at 60°C. The resulting copolymer was precipitated by the addition of a large amount of methanol or petroleum ether, and then reprecipitated from the benzene - petroleum ether system for the copolymer of EA and IPA, or the benzene-methanol system for the other copolymers. Most of the copolymerizations were run to five percent conversion.

The composition of the copolymer was determined from chlorine analysis (CEA copolymer), nitrogen analysis (CNEA copolymer), and carbon analysis (other copolymers). The monomer reactivity ratios, r_1 and r_2 were calculated by the method of Fineman and Ross.[7]

Results and Discussion

The results of the copolymerizations of RA with styrene are summarized in Table II. From this table, it may be observed that the rate of these copolymerizations increases with an increase in the concentration of RA in the monomer mixture. The monomer reactivity ratios, r_1 and r_2, and Alfrey-Price Q_2 and e_2 values of RA were found to be as is shown in Table III.

As can be seen from Table III, the relative reactivities, $1/r_1$, of RA toward the attack of a polystyryl radical increased with the increase in the electron-attracting nature of their alkyl substituents. When $\log(1/r_1)$ were plotted against the σ^* constant of the alkyl group according to Eq. 1, a straight line, with $\rho^*=0.56$ was obtained, as Fig. 1 shows.

However, the plot of $\log(1/r_1)-\rho^*\sigma^*$ (where $\rho^*=0.56$) against the E_s constant of the alkyl group also gave a straight line, with $\delta=0$, as is shown in Fig. 2. This result strongly indicated that the relative reactivities of RA toward a polystyryl radical were dependent on the polar character of their alkyl substituents, not on their steric characters. A similar correlation was also observed for the relative reactivities of alkyl methacrylates;[1,2] in this case, the ρ^* and δ values were found to be 0.33 and 0 respectively. The increased ρ^* value in this case might be understood from the fact that the e_2 values for RA were larger than those for alkyl methacrylates.

Figure 3 shows the relationship between the Q_2

* Calculated from σ^* value for $CNCH_2$-group.

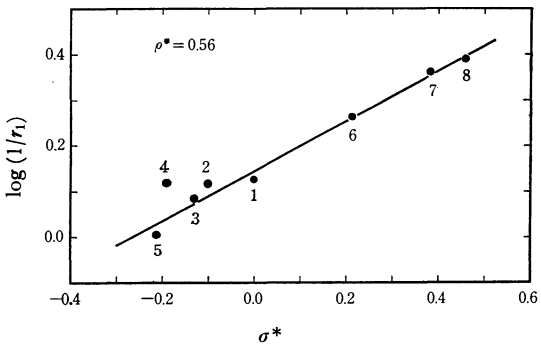

Fig. 1. The correlation between the relative reactivities of RA toward a polystyryl radical and σ^* constants of alkyl groups: 1, CH_3; 2, C_2H_5; 3, *n*-C_4H_9; 4, *i*-C_3H_7; 5, *s*-C_4H_9; 6, $C_6H_5CH_2$; 7, $ClCH_2CH_2$; 8, $CNCH_2CH_2$.

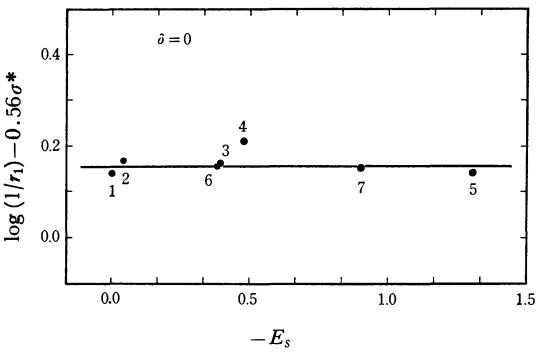

Fig. 2. The correlation between $\log(1/r_1) - \rho^*\sigma^*$ and E_s constants of alkyl groups: 1, CH_3; 2, C_2H_5; 3, *n*-C_4H_9; 4, *i*-C_3H_7; 5, *s*-C_4H_9; 6, $C_6H_5CH_2$; 7, $ClCH_2CH_2$.

and e_2 values of RA and the σ^* constant of the alkyl groups. From this figure, it is obvious that both Q_2 and e_2 values for RA increase as a function of the electron-attracting nature of the alkyl substituents, as in the case of alkyl methacrylates.[1,2] As compared with both acrylate and methacrylate series, it was observed that the change in the Q_2 values of RA effected by the σ^* constant of the alkyl groups was smaller than that of alkyl methacrylates, while the change in e_2 values was larger. These differences are perhaps understandable from the consideration that the effects of hyperconjugation and the electron-releasing nature due to the α-methyl group in alkyl methacrylates were important factors.

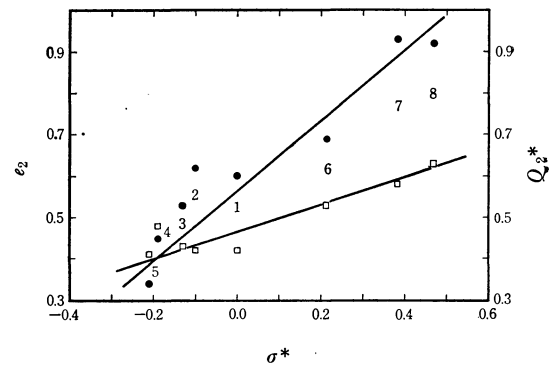

Fig. 3. The correlation between Q_2, e_2 values of RA and σ^* constants of alkyl groups: 1, CH_3; 2, C_2H_5; 3, *n*-C_4H_9; 4, *i*-C_3H_7; 5, *s*-C_4H_9; 6, $C_6H_5CH_2$; 7, $ClCH_2CH_2$; 8, $CNCH_2CH_2$.

Table IV shows the results of the measurement of the infrared spectra of RA monomers in liquid film. From this table, it was observed that the carbonyl-streching frequencies in RA were shifted

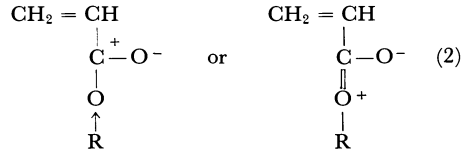
to longer wavelengths roughly as the electron-releasing character of the alkyl substituent increased. The same behavior has also been observed in a number of aliphatic or aromatic aldehydes, ketones, and acid esters.[10] Accordingly, the introduction of an electron-releasing substituent in RA makes their carbonyl groups more polar, and enhances the nature of the single-bonding of their carbonyl groups, as is shown in Eq. 2.



(2)

This contribution leads to the isolation of the vinyl group from its conjugated structure with the carbonyl group, and results in a decrease in Q_2 values, as well as of the e_2 values of RA as a function of the electron-releasing nature of their alkyl substituents. Such a consideration was supported by the results of ultraviolet spectroscopic study of RA and other vinyl monomers.[11]

The Mechanism of the Alkaline Fusion of Diphenylsulfone[1]

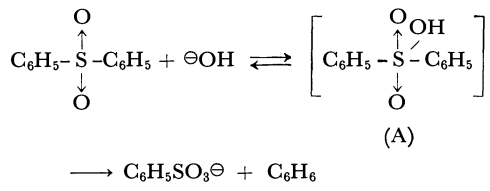
By Shigeru OAE and Naomichi FURUKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received February 7, 1966)

Diphenylsulfone-1-^{14}C was treated with fused potassium hydroxide at 300°C for 7 hr. in a sealed metal tube. The yield of phenol, as determined by the isotope dilution technique, was found to be almost quantitative. The distribution of ^{14}C in the resulting phenol was determined by degradating it by the usual method. Practically all the activity of ^{14}C in the phenol was found at the position 1, which corresponded to the originally-labeled position in the diphenylsulfone-1-^{14}C used. This indicates that the mechanism of the alkaline fusion of diphenylsulfone proceeds thruogh a simple S_N2-type mechanism, not the elimination-addition mechanism.

The treatment of diphenylsulfone with potassium hydroxide at a high temperature was first performed several decades ago by Otto,[2] who claimed to have obtained diphenyl and phenol as the main final products of the reaction. Many years later, Ingold and Jessop[3] studied the reaction more precisely; they observed that the main products of this reaction were benzene and benzenesulfonic acid. From the product analysis, they suggested that the mechanism of the reaction involved the primary attack of the hydroxide ion on the sulfur atom, thus expanding the valence shell to decet and forming an incipient complex that collapsed immediately to form the sulfonic acid and benzene, as is shown below.



(A)

$\longrightarrow C_6H_5SO_3^{\ominus} + C_6H_6$

Although the hypothesis of valence-shell expansion in the sulfur atom is very attractive in view of the many well-elucidated examples in other reactions,[4] it has to be tested with more rigorous experiments. We have previously investigated this reaction using ^{18}O-labeled potassium hydroxide[5] in order to test Ingold's mechanism; we found that there was no simultaneous ^{18}O incorporation in diphenyl sulfone during the reaction. This suggested that the reaction was a simple synchronous S_N2-type displacement reaction at the sulfur

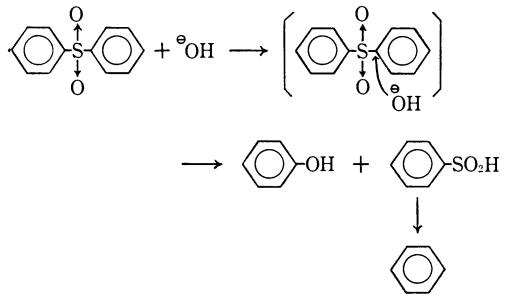
atom. However, all these past experiments do not give any hint as to the mechanism of the formation of phenol.

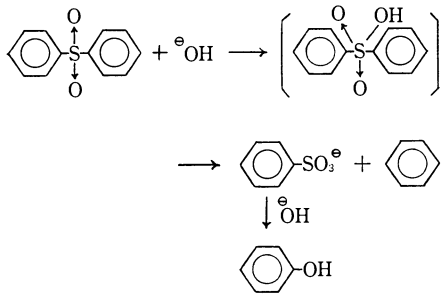
A question still remains whether phenol is formed directly by the nucleophilic attack on the sulfone group by the hydroxide anion (Mechanism I), or through the initial formation of benzenesulfonic acid, followed by substitution with the hydroxide anion (Mechanism II). Moreover, in such strong alkaline conditions as were used in the reaction, the elimination-addition mechanism involving a benzyne-type intermediate[6] also has to be considered (Mechanism III).

The three different mechanisms conceivable for the reaction may be summarized as follows:

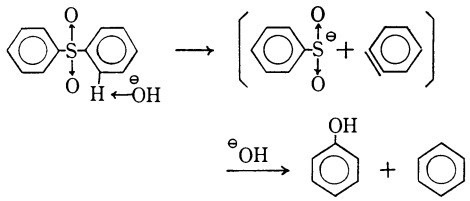
I. Simple S_N2-type mechanism:



II. Through-sulfonic-acid mechanism:



III. Elimination-addition mechanism:



Both the mechanisms I and III involve the formation of phenol and sulfinic acid, which eventually give benzene and which are quite reasonable since benzenesulfinic acid is known to decompose to benzene when treated with molten alkali at a relatively low temperature.[7] According to the mechanism II, benzene is formed, together with benzenesulfonic acid, which is then converted directly to phenol through a simple S_N2-type mechanism.[8] In this paper, we wish to present a detailed account of the mechanistic investigation of the alkaline fusion of diphenyl sulfone using the sulfone labeled with ^{14}C at position 1 of the benzene ring. When the reaction proceeds through the mechanism I or II, the ^{14}C activity in the phenol will be found only at the 1 position, whereas if the reaction proceeds through the mechanism III, half of the total ^{14}C activity in the phenol may be expected to be found at the 1 position, while the remaining 50% should be distributed equally between the 2 and 6 positions.

Results and Discussion

Diphenyl sulfone-1-^{14}C was synthesized according to the following scheme (Fig. 1):

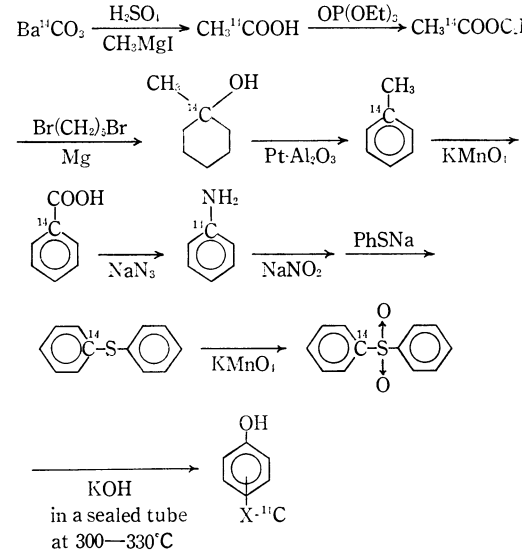


Fig. 1.

The method of degrading phenol is illustrated schematically in Fig. 2. A detailed account of the scheme has been presented elsewhere.[8] The yield of phenol was determined by the conventional isotopic dilution technique, which will be described in detail in the Experimental section.

The results of the degradation of the resulting phenol are shown below:

The results clearly indicate that all the ^{14}C activities of the phenol were found at position 1 of the sulfone where ^{14}C was originally labeled. This

excludes the elimination-addition mechanism involving a benzyne-type intermediate, since the mechanism requires half of the ^{14}C activities to be at the position 1, while the remaining half are divided equally between the two ortho positions.

Now that the mechanism III is excluded from the ^{14}C tracer experiment, the next problem is to make a choice between the mechanisms I and II. Earlier works related to nucleophilic substitutions on various aryl arylsulfonates suggest that the hydroxide ion prefers to attack the sulfone group rather than the aryl carbon.[9,10] Although a reaction in a fused alkali may be somewhat different from that in aqueous media, the same trend of nucleophilic selectivity would be found in both reactions, since the negative hydroxide ion attacks the positively-charged sulfur atom of the sulfone group more readily than the neutral benzene carbon. Moreover, the successful isolation of benzenesulfonic acid in the reaction by Ingold and his group, as well as by us, appears to suggest strongly that the hydroxide ion preferentially attacks at the sulfone group, as is illustrated by mechanism II.

Experimental

The Preparation of Diphenylsulfone

Aniline-1-^{14}C.—Aniline-1-^{14}C was synthesized starting from barium carbonate-^{14}C through 7 steps. The synthetic method has been described previously.[8]

Diphenylsulfide-1-^{14}C.—Thiophenol (3.0 g.) was dissolved in 40 ml. of a 20% potassium hydroxide solution. To this solution there was added benzenediazonium chloride-1-^{14}C prepared from 1.9 g. of aniline and 1.7 g. of sodium nitrite in 8 ml. of water, with the temperature kept at 70°C with vigorous stirring. After the addition had been completed, the mixture was stirred for 2 more hr. at the same temperature. Then the solution was extracted with ether. The ether solution was washed with water and dried over magnesium sulfate. After the ether had been evaporated, the residue was distilled under reduced pressure. Diphenylsulfide-1-^{14}C (2.8 g.) was thus obtained in a 76% yield (b. p. 124°C/3 mmHg).

Diphenylsulfone-1-^{14}C.—Diphenylsulfide-1-^{14}C (2.8 g.) was oxidized with 4.4 g. of potassium permanganate in 15 ml. of acetic acid. After the addition of potassium permanganate, the reaction mixture was warmed on a water bath for 1 hr. at 50°C. Then the mixture was quenched with a large amount of water. To this solution sulfur dioxide gas was introduced in order to decompose the excess potassium permanganate. The precipitate was then filtered and washed with water. The crude diphenylsulfone was recrystallized from *n*-hexane - benzene. The yield was 2.6 g. in a 81% yield (m. p. 128°C).

The Alkaline Fusion of Diphenylsulfone-1-^{14}C.—Diphenylsulfone-1-^{14}C (1.00 g.) was fused with 3.0 g. of potassium hydroxide in a small nickel tube which had a cork stopper equipped with a capillary tube to collect the benzene evolved. The tube was immersed in a potassium nitrate salt bath at the initial temperature of 240°C. Then the temperature was raised gradually to 300—330°C, at which temperature the reaction tube was kept for 7 hr. The reaction began at 250°C. After cooling, the reaction mixture was dissolved in water. To this mixture authentic phenol was added as a carrier. The mixture was acidified with concentrated hydrochloric acid, and then steam-distilled. The distillate was saturated with sodium chloride and extracted with ether, and the etheral solution was dried over magnesium sulfate. After the ether had evaporated off, the residue was distilled; phenol-*x*-^{14}C boiling at above 180°C was thus collected. The yield was determined by the isotope dilution method using the equation:

$$xS_0 = (a - x)S \qquad x = \frac{aS}{S_0 - S}$$

where x is the unknown weight of the phenol produced, where S_0 and S are the ^{14}C activities in the initial and diluted phenol respectively, where S_0 represents the activity of the diphenyl sulfone-1-^{14}C available in the reaction, and where a is the authentic, weighed amount of pure phenol for dilution.

From the experimental figure (S_0: 9738 c. p. m.; S: 1448 c. p. m; a: 2.22 g.), x was calculated to be 0.39 g. (91% of the theoretical yield).

The Degradation of Phenol-x-^{14}C.—The degradation of phenol-x-^{14}C was carried out following a method described previously.[8]

The counting of ^{14}C was performed according to the conventional Van-Slyke wet combustion method. The activities were measured for cyclohexanonesemicarbazone, barium carbonate and dibenzoyl pentamethylenediamine, with pellets of these samples weighing 132 mg., 181 mg., and 218 mg. respectively. The measurements of ^{14}C was performed with an Aloka 2π-gas flow G. M. counter, using Q-gas as the counting gas. The data are shown in Table I.

The Reaction of Organodisilanes with *N*-Bromosuccinimide[1)]

By Hideki SAKURAI, Akira HOSOMI, Jun-ichi NAKAJIMA and Makoto KUMADA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received February 17, 1966)

The reactions of three hexaorganodisilanes with *N*-bromosuccinimide in carbon tetrachloride or in chloroform were carried out. Hexamethyldisilane afforded trimethylbromosilane (82.9—100%) and *N*-trimethylsilylsuccinimide (73.5—79.5%). No bromomethylpentamethyldisilane was obtained. Similarly, 1, 2-diphenyltetramethyldisilane gave phenyldimethylbromosilane and a small amount of bromobenzene. The *N*-silyl compound could not be isolated, but succinimide was obtained as a decomposition product. Phenylpentamethyldisilane gave trimethylbromosilane and phenyldimethylbromosilane in 67.4 and 12.3% yields respectively. A possible reaction mechanism was discussed.

N-Bromosuccinimide (NBS) is known as an efficient brominating agent, especially for allylic carbons;[2)] it may react via a free radical chain mechanism in non-hydroxylic solvents.

Since the introduction of a halogen into a methyl group of hexamethyldisilane or other related compounds is a highly desirable operation in the field of organosilicon chemistry, we have investigated the reaction of hexamethyldisilane with NBS, primarily in the hope of preparing (bromomethyl)-pentamethyldisilane. However, contrary to our expectation, the reaction led to a cleavage of the silicon-silicon bond, even in non-polar solvents. In view of these findings, it became of interest to investigate the reaction for variously substituted disilanes, since NBS is known to react as a positive halogen donor to an olefin only in polar protic solvents.[3)]

While the present work was in progress, Calas, Frainnet and Dentone[4)] have also briefly described the formation of methyldiethylbromosilane and *N*-methyldiethylsilylsuccinimide by the reaction of 1, 2-dimethyltetraethyldisilane with NBS.

In the present paper, we wish to report some of our own results especially from the mechanistic point of view.

Results and Discussion

The reaction of the three organodisilanes employed here with NBS leads to the cleavage reaction, giving bromosilanes and *N*-silylsuccinimides instead of (bromomethyl)disilanes. The results are summarized in Table I. It is interesting to note that trimethylbromosilane was a major product in the reaction of phenylpentamethyldisilane with NBS.

NBS has been considered to undergo a reaction in which the initial attack on the substrate in the bromination is possibly by the succinimido radical and in which the chain-propagating step is the attack on the second NBS molecule by the resulting carbon radical.[5)]

Hydrogen atoms of hexamethyldisilane have been

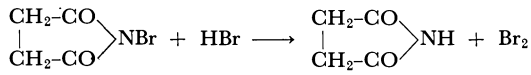
c) Possibly, decomposition compound of $C_6H_5(CH_3)_2SiN(COCH_2)_2$.

shown to be abstracted by a number of electron-seeking radicals, such as benzoyloxy,[6] *t*-butoxy[7] and trichloromethyl[7] radicals. Therefore, it may be expected that hexamethyldisilane can be brominated by chain reactions involving homolytic hydrogen abstraction by succinimido radicals in non-polar solvents. Accordingly, the reaction of hexamethyldisilane with NBS does not involve this sort of free-radical-chain mechanism.

Alternatively, recent evidence[8,9] indicates that the mechanism of NBS bromination may actually involve bromine molecules rather than NBS as the chain-carrying species; namely, NBS may function only by producing bromine molecules at a low concentration:

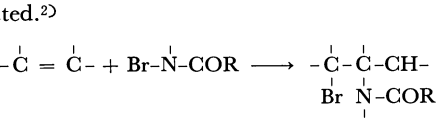


$$Br_2 \rightleftarrows 2Br\cdot$$

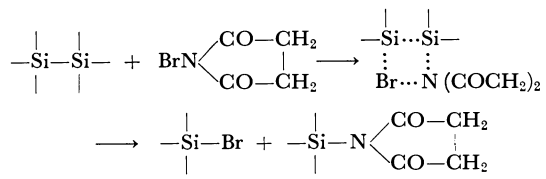
$$Br\cdot + RH \longrightarrow HBr + R\cdot$$

If this is the case, the cleavage of the silicon-silicon bond may be expected, since hexaalkyldisilanes are considerably reactive towards bromine molecules.[10] In fact, immediately after a first portion of hexamethyldisilane had been added to a cold suspension of NBS, a red color of bromine developed throughout the reaction. Moreover, the fact that diphenyltetramethyldisilane requires a higher temperature to complete the reaction may indicate that some sort of electrophilic attack on the silicon-silicon bond occurs.[10]

However, such a mechanism is not sufficient to account for the formation of *N*-silylsuccinimides. The simplest mechanism consistent with the facts seems to be one in which an intermediate of a four-center type is involved. In general, the silicon-silicon bond undergoes a variety of electrophilic and oxidative cleavage reactions. Many examples suggest that the cleavage reactions may resemble the corresponding electrophilic addition reactions to the carbon-carbon double bond.[11] *N*-Bromoamides are also known to have a tendency to form an addition compound with a carbon-carbon double bond; some of these addition compounds have been isolated.[2]



Therefore, although the possibility of a mechanism involving molecular bromine can not be excluded, the product distribution in the reaction of phenylpentamethyldisilane with NBS suggests that the probable mechanism for this reaction is the direct attack of NBS on the silicon-silicon bond through a four-center transition state. Such a process must be likely in carbon tetrachloride or chloroform, since the solvents have no nucleophilic power and since no separation of ions, which is improbable in a weakly polar reaction, is necessary.



The bromine atom may orient to the more negative silicon atom, so that trimethylbromosilane is formed as a major product in the reaction of phenylpentamethyldisilane with NBS.

Experimental

Materials.—NBS,[12] hexamethyldisilane,[13] phenylpentamethyldisilane,[14] and 1, 2-diphenyltetramethyldisilane[15] were prepared by the reported procedure.

The Reaction of Hexamethyldisilane with NBS in Chloroform.—To a stirred and externally-cooled suspension of 37.5 g. (0.21 mol.) of NBS in 50 ml. of dry chloroform, there was added, drop by drop, 34 g. (0.23 mol.) of hexamethyldisilane. Immediately after a first portion of hexamethyldisilane had been added, the red color of bromine developed. After the addition had been completed, the solution was stirred at room temperature for 1 hr., then an almost complete decolorization occurred. The mixture was then submitted to distillation to give the following fractions: (a) chloroform and trimethylbromosilane, boiling up to 80°C (110 g.); and (b) fraction boiling at 120°C (18 mmHg) (27 g.). The redistillation of Fraction a through a 35 cm. column packed with glass helicoils gave 31 g. of trimethylbromosilane, b. p. 80°C, contaminated with a small amount of chloroform. The mixture was analyzed by titrating the hydrolyzable bromine and so estimated to contain 26.8 g. (0.175 mol., 82.9%) of trimethylbromosilane. Fraction b was quite hygroscopic and decomposed to succinimide, m. p. 123—125°C, and hexamethyl disiloxane upon treatment with water. The redistillation of Fraction b gave pure *N*-trimethylsilylsuccinimide, n_D^{20} 1.4732, d_4^{20} 1.0684, MR_D 44.99 (calcd. 45.18).

Found: Si, 16.7. Calcd. for $C_7H_{13}O_2NSi$: Si, 16.4%.

The Reaction of Hexamethyldisilane with NBS in Carbon Tetrachloride.—To a stirred suspension of 37.5 g. (0.21 mol.) of NBS in 50 ml. of dry carbon tetrachloride, 31 g. of hexamethyldisilane was added in virtually the manner described above. After work-up, *N*-trimethylsilylsuccinimide (25 g., 73.5%) and trimethylbromosilane (33.7 g., 100% by titration) were obtained.

The Reaction of 1, 2-diphenyltetramethyldisilane with NBS in Carbon Tetrachloride.—1, 2-Diphenyltetramethyldisilane (20 g., 0.074 mol.) in 100 ml. of dry carbon tetrachloride was added to a stirred suspension of 13 g. of NBS (0.073 mol.) in 30 ml. of carbon tetrachloride. External heating was necessary to keep the reaction proceeding. After the addition was complete, the reaction mixture was submitted to distillation. After the carbon tetrachloride has been removed, b. p. 75°C, a fraction boiling at 118—125°C (50 mmHg) (12.5 g.) was obtained. The gas chromatographical analysis of the fraction indicated the presence of phenyldimethylbromosilane (main component) and bromobenzene. The amount of phenyldimethylbromosilane was determined by titration to be 12.0 g. (yield 76.6%). The distillation residue, possibly *N*-phenyldimethylsilylsuccinimide, could not be distilled off successfully, but 4.9 g. (67.7%) of succinimide was obtained as a decomposition product, b. p. 148°C (2 mmHg).

The Reaction of Phenylpentamethyldisilane with NBS in Carbon Tetrachloride.—Phenylpentamethyldisilane (15 g., 0.072 mol.) was allowed to react with NBS (13 g., 0.073 mol.) in carbon tetrachloride in the same manner. Moderate heating was necessary to initiate the reaction. After work-up as described above, 74 g. of a mixture of carbon tetrachloride and trimethylbromosilane, b. p. 75—78°C, 3 g. of a mixture of phenyldimethylbromosilane and bromobenzene, 63°C (31 mmHg), and 5.5 g. (77.1%) of succinimide were obtained. The amounts of trimethylbromosilane and phenyldimethylbromosilane were determined by titration to be 7.4 g. (67.4%) and 1.9 g. (12.3%) respectively.

The authors are indebted to the Tokyo Shibaura Electric Co., Ltd., for its gifts of chlorosilanes and a methylchlorosilane residue.

This research was supported in part by a grant-in-aid of the Ministry of Education and by the Kawakami Memorial Foundation, to which the authors' thanks are due.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2266—2269 (1966)

The Reactions of Oximes with Lead Tetraacetate. The Scope of the Reactions

By Yasuhide YUKAWA, Mitsuru SAKAI and Shigeo SUZUKI

The Institute of Scientific and Industrial Research, Osaka University, Sakai, Osaka

(Received March 7, 1966)

A detailed study of the reaction of oximes by lead tetraacetate has been made. It has been found that the reaction gave nitrogen and the respective aldehydes or ketones in good yields. In the reaction, which can be applied to general oximes, the order of yields was: aliphatic aldoximes > aliphatic ketoximes > alicyclic ketoximes > aromatic ketoximes > aromatic aldoximes. Some limited mechanistic implications are presented and discussed on the basis of the results obtained. Stoichiometrically, it has been found that 2 moles of oxime react with 1 mole of lead tetraacetate to produce 2 moles of aldehyde or ketone and 1 mole of nitrogen.

Many interesting results of the reactions with lead tetraacetate have been observed in a wide variety of organic substrates. In addition to its utility in cleaving glycols and in oxidizing alcohols to aldehydes, lead tetraacetate can be used to introduce methyl or acetoxy groups into suitably-activated positions in organic compounds.[1] More recently, we have found that 1, 2-dioximes could be dehydrogenated and cyclized to form furoxane derivatives quantitatively by adding the dioxime to an acetic acid solution of lead tetraacetate.[2] In the last few years, we have been interested in the reactions of lead tetraacetate, particularly those with olefins and oximes.[3] A thorough search of the literature has revealed that lead tetraacetate-oxime reactions had not previously been investigated in detail. Iffland and Criner,[4] for instance, reported that lead tetraacetate was capable of oxidizing cyclohexanone oxime. Their study was carried out at 0°C for 5 hr. in dichloroethane. They supposed that this reaction product was 1-acetoxy-1-nitrosocyclohexane, but they gave no evidence for this assignment.

In the present paper, we wish to report the results of lead tetraacetate-oxime reaction. The interaction between the two species yields aldehyde or ketone, lead acetate and acetic acid. The scopes, limitations, and synthetic applications of various lead tetraacetate-oxime reactions will be presented in this paper. The kinetic and mechanistic aspects of these reactions will be discussed in a succeeding paper.

Results

The reaction of aldoximes or ketoximes in acetic acid with lead tetraacetate proceeds smoothly, with the evolution of nitrogen, to give the corresponding carbonyl compounds in good yields. The procedure consists of stirring the reactants at 70°C in acetic acid and quenching the reaction mixture by pouring in cold water. A reasonable equation for the over-all reaction seems to be Eq. 1:

$$\begin{matrix} R \\ R' \end{matrix}\!\!>\!C{=}NOH + \frac{1}{2}Pb(OAc)_4 \longrightarrow \begin{matrix} R \\ R' \end{matrix}\!\!>\!C{=}O + \frac{1}{2}N_2 + \frac{1}{2}Pb(OAc)_2 + AcOH \quad (1)$$

Standard conditions, a one-hour heating at 70°C with a half-equivalent of lead tetraacetate, were employed throughout the present work in order to compare the reactions of different oximes. Product assignments were made by a comparison of the infrared spectra and vapor-phase chromatogram of the products with those of authentic samples. The products were also isolated from the reaction mixture by means of distillation and vapor-phase chromatography. The analytical gas chromatography of nitrogen was performed, using helium as the carrier gas, on a column of Molecular sieve 13X at 25°C.

The reaction was applied to more than thirty oximes of various types. The pertinent data are summarized in Table I.

As is indicated in Table I, seven aliphatic aldoximes, seven aromatic aldoximes, ten aliphatic

TABLE III. THE OXIDATION OF ACETOPHENONE OXIME BY VARIOUS OXIDANTS

Acetophenone oxime, 0.05 mol.; Oxidants, 0.03 mol.; Solvents, 50 ml.

Oxidant	Solvent	Temp., °C	Time, hr.	Yield, % Acetophenone	N_2
Lead tetraacetate	Acetic acid	70	2	92	95
Periodic acid	Dioxane	25	0.5	43	20
Potassium ferricyanide	H_2O-EtOH	60	4	0	0
Sodium bismuthate	Acetic acid	25	0.5	70	60
Mercuric sulfate	Acetic acid	120	2	35	—
Cupric sulfate	Pyridine	80	2	30	15
Potassium dichromate	Acetic acid	80	2	40	45
Mercuric acetate	Acetic acid	80	2	20	5
Cerium nitrate	Acetic acid	25	1	41	20
None	Acetic acid	120	2	1.5	0

The reactions of the unsaturated oximes are interesting because lead tetraacetate can easily attack unsaturated compounds. However the presence of a double bond does not affect the reaction so seriously, though it does lower the yield. It appears to be necessary to choose suitable conditions in such a case. The reaction of citral oxime with lead tetraacetate was investigated under various conditions, which are summarized in Table II.

In these studies, a slight modification of the usual reaction conditions was employed. The best yield of citral (82%) was obtained when acetic acid was used as a solvent and an equivalent mole of anhydrous sodium acetate was added. The yield dropped to 45% when pyridine was employed. In this reaction, lead tetraacetate would act toward oximes as an oxidizing agent, but not as a hydrolyzing agent. It was desirable to compare it with other oxidizing agents. The reactions of acetophenone oxime with periodic acid, potassium ferricyanide, sodium bismuthate, mercuric sulfate, mercuric acetate and cerium nitrate were therefore carried out. The reaction conditions employed and the results obtained are summarized in Table III. Lead tetraacetate and sodium bismuthate were more efficient oxidizing agents than either periodic acid or cerium nitrate. In the absence of an oxidizing agent, only a small percentage of the acetolysis product was obtained. The above results indicated that lead tetraacetate is a suitable oxidizing agent for the conversion of acetophenone oxime to acetophenone.

Experimental

All melting points and boiling points are uncorrected. The melting points were taken on a Yanagimoto melting-point apparatus. The infrared spectra were determined using a Hitachi double-beam spectrophotometer. The vapor-phase chromatographic analyses were carried out on a Yanagimoto Model GCG-3 vapor fractometer. The elemental analyses were performed by the Micro-analytical Laboratories of our Institute.

Materials.—The glacial acetic acid was purified with chromium trioxide as before.[6] All of the oximes were prepared in the same manner, using the corresponding carbonyl compounds, hydroxylamine hydrochloride and sodium bicarbonate. The melting points of these oximes are given in Table I.

General Procedure.—Lead tetraacetate was prepared according to the method of Dimroth and Schweizer.[7] It was moistened with acetic acid for storage. The reagent was filtered under suction and dried in a vacuum-desiccator over potassium hydroxide pellets for 6 hr. The resulting white crystalline material was then usually about 98% pure, as estimated by iodometric titration. When reactions were carried out in a solvent other than acetic acid, the lead tetraacetate obtained as above was repeatedly washed with the appropriate solvent and, after filtration, was dried in a vacuum desiccator: in these cases, a brownish material was obtained.

Oximes (0.05 mol.) in glacial acetic acid (30 ml.) was added, drop by drop over a 1 hr. period, to a stirred suspension of lead tetraacetate (0.025 mol.) in glacial acetic acid (20 ml.). The addition of an oxime to lead tetraacetate in acetic acid at room temperature caused an immediate green coloration of the solution. During the addition the reaction mixture was kept at 70°C, and the reaction proceeded rapidly with the evolution of nitrogen. The analytical gas chromatography of nitrogen was performed on a Yanagimoto Model GCG-3, with helium as the carrier gas on a column of Molecular sieve 13X at 25°C. The green reaction mixture gradually turned into a clear yellow solution. After stirring had continued for an additional hour, the solution was poured into ether (50 ml.) and 20 ml. of water was added. The resultant precipitates in the etheral solution had dissolved into the washing water, and no lead dioxide was observed. The etheral layer was washed with 20 ml. of water, six 20 ml. portions of 5% sodium bicarbonate, and two 20 ml. portions of water. The ethereal solution was dried over magnesium sulfate. The ether was removed, and the remaining liquid was distilled through a spinning-band column.

The Reaction of Menthone Oxime with Lead Tetraacetate in Dichloroethane.—To a stirred

7) O. Dimroth and R. Schweizer, *Ber.*, **56**, 1375 (1923).

solution of 3.5 g. (0.021 mol.) of menthone oxime in 50 ml. of dichloroethane, 10.0 g. (0.023 mol.) of lead tetraacetate was added. The temperature was maintained at 0—5°C with cooling. After about 1 hr. of stirring, the solution was deep blue. The resulting mixture was poured into cold water. The dichloroethane layer was separated and dried, and the dichloroethane was evaporated under reduced pressure. The distillation of the residue gave 4.0 g. (85%) of 1-acetoxy-1-nitroso-2-isopropyl-5-methylcyclohexane, b. p. 92°C/3.5 mmHg, $\lambda_{max}^{alc.}$ 680 mμ (ε 18).

Found: C, 63.62; H, 9.70. Calcd. for $C_{12}H_{21}NO_3$; C, 63.41; H, 9.31%.

We wish to thank the Shiono-koryo Company for the kindness of providing us with samples of citral, menthone, carbomenthone and pulegone. We are also indebted to Mr. Tsuneyo Shishido and Takuzo Fujino of the Microanalytical Section of this laboratory for microanalyses.

The Rotatory Dispersion and Stereochemistry of Organic Compounds. XII.[1] The Circular Dichroism of Hexose Nitrates

By Yojiro TSUZUKI, Koko TANABE, Kikuhiko OKAMOTO and Noriko YAMADA

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received March 19, 1966)

Circular dichroism has been measured of eighteen nitrates of hexoses (glucose, mannose and altrose), and its correlation with the rotatory dispersion as well as the ultraviolet absorption has been established, verifying even a number of suggestions made as regards the sign of some ambiguous Cotton effects (Tsuzuki et al., This Bulletin, **39**, 1391 (1966)), which has eventually led to some significant conclusions.

It was reported for the first time by Mitchell[2] that nitrochromophore ($-NO_2$) is of significance in the studies of rotatory dispersion (RD). Some interesting results were really shown with several nitro-compounds,[3,4] and recently investigations were made on the rotatory dispersion, circular dichroism (CD) and ultraviolet absorption (UV) of a number of compounds containing nitrochromophore.[5,6] Thanks to these studies, the NO_2-chromophore proved to be quite useful in investigating configurational problems for organic compounds. Particularly comparison of CD and UV was found advantageous to the analysis of complex or obscure Cotton effects.

As already reported,[1,7-9] the nitrate chromophore exhibited an optically active absorption and proved to be of great use to the configurational studies of sugars and hydroxy-carboxylic acids, especially with respect to the conformation and optical contribution of the hydroxyl groups.

The rotatory dispersion of compounds with nitrate chromophore exhibits a Cotton effect around 300 mμ, but its absorption is so weak that it becomes often difficult in sugar derivatives to discern the character of the Cotton effect, since it is overlapped by the strong, background optical rotation, particularly due to the C_1- and C_2 groups.

In a previous paper[1] some RD curves were analyzed and the Cotton effects were characterized with the help of the corresponding CD studies. The present authors will deal in this paper with CD measurement of a number of related compounds shown in Table I, whose RD studies were already published, and will confirm their views expressed on the correlation between the rotatory dispersion and stereochemistry of these compounds by studying comparatively the RD and CD curves together with the ultraviolet absorption curves, and further will inquire into the relation between the ultraviolet absorption and the steric influence.

Results and Discussion

In Fig. 1 are given the RD and CD curves of the α-C_1-nitrate of glucopyranose (I), where those of galactopyranoside (II)[1] are reproduced for comparison's sake. The agreement of these two compounds in sign of circular dichroism undoubtedly indicates that the Cotton effect is due to the α-C_1-ONO_2 chromophore. That the peak of CD (II, 263.5 mμ) is a little red-shifted as compared with that of CD (I, 273 mμ) is to be attributed to the steric effect of the C_4-OAc group of L-configuration in the galactoside (II).

In Fig. 2 are shown the RD and CD curves of 1, 3, 4, 6-tetra-*O*-acetyl-2-*O*-nitro-α-D-glucopyranoside (III) and those of its anomer (IV). The CD (III) has a negative sign, which confirms the view[7] that the RD curve (III) shows a negative Cotton effect. The CD (IV) exhibits a positive sign in agreement with the positive Cotton effect (IV). The CD curves III and IV are nearly equal in optical rotatory strength, both originating in the C_2-ONO_2 chromophore of D-type, but they are opposite in sign, that is undoubtedly attributed to the respective α- and β-form of the C_1-OAc

Table I. Nitrate compounds

Number	Name
I[1]	2,3,4,6-Tetra-*O*-acetyl-1-*O*-nitro-α-D-glucopyranose
II[8]	2,3,4,6-Tetra-*O*-acetyl-1-*O*-nitro-α-D-galactopyranose
III[7]	1,3,4,6-Tetra-*O*-acetyl-2-*O*-nitro-α-D-glucopyranose
IV[8]	1,3,4,6-Tetra-*O*-acetyl-2-*O*-nitro-β-D-glucopyranose
V[8]	Methyl 4 : 6-*O*-ethylidene-β-D-glucopyranoside 3-nitrate
VI[1]	1,2:5,6-Diisopropylidene-3-*O*-nitro-α-D-glucofuranose
VII[1]	Methyl 4 : 6-*O*-benzylidene-α-D-altropyranoside 3-nitrate
VIII[8]	Methyl 2,3,6-tri-*O*-acetyl-4-*O*-nitro-β-D-glucopyranoside
IX[8]	Methyl 2,3,4-tri-*O*-acetyl-6-*O*-nitro-α-D-glucopyranoside
X[8]	Methyl 4 : 6-*O*-ethylidene-α-D-glucopyranoside 2 : 3-dinitrate
XI[8]	Methyl 4 : 6-*O*-ethylidene-β-D-glucopyranoside 2 : 3-dinitrate
XII[1]	Methyl 4 : 6-*O*-ethylidene-α-D-mannopyranoside 2 : 3-dinitrate
XIII[1]	Methyl 4 : 6-*O*-benzylidene-α-D-altropyranoside 2 : 3-dinitrate
XIV[1]	Methyl 6-*O*-acetyl-2,3,4-tri-*O*-nitro-β-D-glucopyranoside
XV[8]	Methyl 2,3-di-*O*-acetyl-4 : 6-di-*O*-nitro-β-D-glucopyranoside
XVI[1]	Methyl 2,3,4,6-tetra-*O*-nitro-β-D-glucopyranoside
XVII[1]	Methyl 2,3,4,6-tetra-*O*-nitro-α-D-glucopyranoside
XVIII	1,2,3,4,6-Penta-*O*-nitro-α-D-glucopyranose

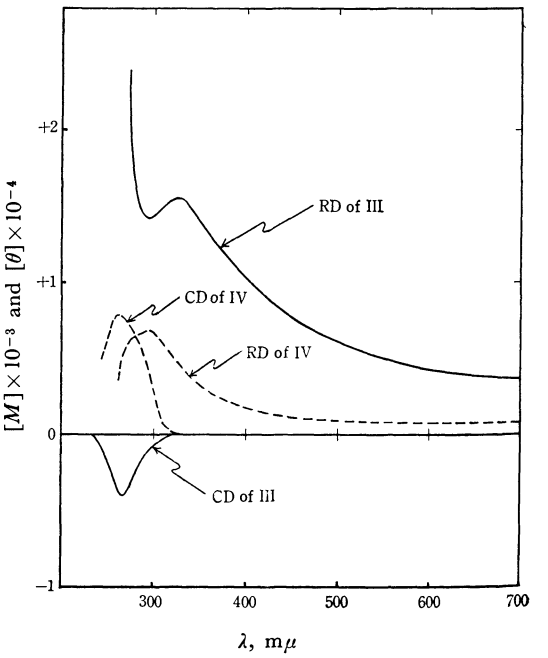

Fig. 2. RD and CD of C_2-nitrate of glucose.

group, which predominates over others in optical rotation.

Figure 3 shows the CD curves of three C_3-nitrates (V-VII), and reproduces their RD curves. Small as its ellipticity is, the CD curve (V) of methyl 4 : 6-*O*-ethylidene-β-D-glucopyranoside is negative in sign. The RD curve was discussed in a previous paper[8] to have a negative Cotton effect by analyzing the curve with the help of Drude equation as well as configurational studies.

The positive CD (VI) of 1, 2 : 5, 6-diisopropylidene-3-*O*-nitro-α-D-glucofuranose is consistent

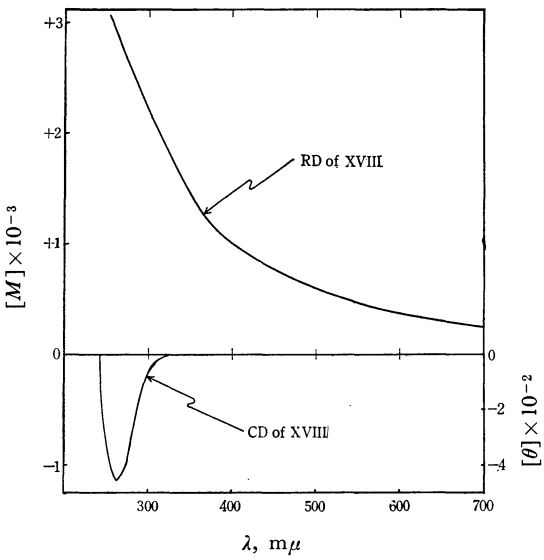

Fig. 7. RD and CD of pentanitrates of glucopyranose.

with the weakly positive Cotton effect (RD VI). The ellipticity is smaller in C_3-nitrates (V and VI) than in C_1-nitrate (Fig. 1) and in C_2-nitrate (Fig. 2). The complex circular dichroism of 4 : 6-*O*-benzylidene-α-D-altropyranoside 3-nitrate (VII) has a negative sign, one of the peaks of which (270 mμ) may be associated with the negative Cotton effect appearing in the RD curve as already demonstrated.[1] The negative maximum 242 mμ exhibited in the CD curve (VII) is due to the benzylidene radical, qualified by the D-configuration of C_4.[10]

In Fig. 4 are exhibited the RD and CD of glucopyranose C_4-nitrate (VIII) and C_6-nitrate (IX). The positive circular dichroism (VIII) now justifies the dicision of the weak Cotton effect (RD VIII) to be positive in sign.[8]

As already reported, the C_6-nitrate (IX) shows a nearly plain dispersion curve[8] and only a shoulder in the UV absorption spectrum in the region 265 to 280 mμ, but displays a distinct circular dichroism of positive sign at 267 mμ. This suggests the existence of an optically active absorption in this region, although hidden by the strong background rotation of α-methylglucopyranoside.

The positive sign of this "hidden" Cotton effect can be expected from the rule proposed by the present authors in a previous paper,[1] which states that the Cotton effect due to a nitrate of the β-configuration in α-glucosides is positive, for the C_6-nitrate in this case is linked to the β-configurated C_5-atom.

In Fig. 5 are given the RD and CD curves of some C_2, C_3-dinitrates of hexose derivatives (X-XIII). As already demonstrated[1,8] the sign of the Cotton effect due to the chromophore is controlled and determined in di-, tri- as well as tetranitrates always by the configuration of the asymmetric center, which contributes most strongly to optical rotation. The rotatory dispersion of methyl 4 : 6 - *O* -ethylidene - α - D-glucopyranoside 2 : 3-dinitrate (X) exhibits a weakly negative Cotton effect[8] because of the C_2-chromophore of D-configuration in the α-series, regularly contributing to negative rotation. And the distinct, negative circular dichroism really supports this conclusion.

On the contrary its anomer (XI) shows a positive Cotton effect,[8] being dominated by the C_2-chromophore in the β-series, quite in harmony with the positive circular dichroism (XI).

By comparing the compounds X and XI with each other in circular dichroism, it will be noted that their CD curves take a form of symmetry, because they are associated primarily with the optically active absorption due to the C_2-chromophore. However, methyl 4 : 6-*O*-ethylidene-α-D-mannopyranoside 2 : 3-dinitrate (XII) exhibits a positive Cotton effect,[1] which is further evidenced by the positive circular dichroism (Fig. 5).

The ellipticity of compound XII is large as compared with that of compound XI, since the C_2- and C_3-chromophores both contribute to positive rotation in compound II, while the C_2- and C_3-chromophores of compound XI are respectively a positive and a negative contributor, so that its circular dichroism becomes less positive.

In Fig. 5 are reproduced the RD and CD curves of methyl 4 : 6-*O*-benzylidene-α-D-altropyranoside 2 : 3-dinitrate (XIII) already reported.[1] Here it should be pointed out that a negative maximum appears in circular dichroism at 240 mμ characteristic of the benzylidene group, which may be due to the C_4-contribution, as observed in another benzylidene derivative (VII, Fig. 3).

Figure 6 exhibits the RD and CD curves of the di-, tri- and tetra-nitrates of glucopyranose (XIV—XVII). The positive circular dichroism (XIV) confirms the sign of the Cotton effect (RD XIV) of methyl 6-*O*-acetyl-2, 3, 4-tri-*O*-nitro-β-D-glucopyranoside (XIV) which was determined to be positive. This rotatory dispersion was dominated by the dextro-rotatory C_2-chromophore, which is characteristic of the D-configuration in the β-glucoside. Methyl 2, 3-di-*O*-acetyl-4, 6-di-*O*-nitro-β-D-glucopyranoside (XV) also shows a positive Cotton effect, the sign of which is verified by the positive circular dichroism (XV). This Cotton effect can be explained in the following way: in the α-glucoside the D-configurated C_4-chromophore contributes to positive rotation, and although the C_5-asymmetric center contributes to negative one, as may be expected from the behavior of

10) The RD of compounds containing benzene ring has recently been reported to display Cotton effect in the region 258 to 260 mμ. L. Verbit, *J. Am. Chem. Soc.*, **87**, 1617 (1965).

C_6-nitrate (IX), the former predominates over the latter in the absorption region. The positive Cotton effect of methyl 2, 3, 4, 6-tetra-*O*-nitro-β-D-glucopyranoside (XVI)[1] agrees, as shown in Fig. 6, with the CD (XVI) in sign, and its anomer (XVII) on the contrary exhibits a negative circular dichroism (267 mμ). Although the RD curve (XVII) presents only a slight shoulder in the region from 285 to 325 mμ, it was interpreted to have a negative Cotton effect due to the C_2-ONO_2 chromophore overlapped by the stronger α-glucosidic positive rotation. Thus the interpretation has now been confirmed by the CD measurement.

In Fig. 7 is given the RD curve of penta-*O*-nitro-α-D-glucopyranose (XVIII), which shows a more or less apparent anomaly about 285 to 315 mμ, though no distinct Cotton effect can be observed. The compound XVIII exhibits a negative circular dichrosim (Fig. 7), probably because the dominant C_2-ONO_2 effect in this α-glucoside series becomes negative in sign.

As may be seen from Figs. 5, 6 and 7 the C_2-chromophore always determines the circular dichroism as well as the rotatory dispersion excepting the cases where steric hindrance interferes, since the C_2-group is most influential in the optical rotation of these sugars.

Conclusions

1) Anomalous rotatory dispersion curves of sugar nitrates have been analyzed and verified by CD measurement, the wavelength of CD_{max} always coinciding with the region of the ultraviolet absorption.

2) The CD_{max} of sugar nitrates lies in the region 260 to 270 mμ, and is red-shifted by steric hindrance.

3) The C_6-nitrates of the α-series (glycosides) exhibit positive circular dichroism, in accordance with the rule found by the present authors,[1] since the C_5-configuration is of L-type.

4) Each anomer has an ellipticity of nearly equal strength.

5) The contribution to the ellipticity conforms to the order of the rotatory contribution, namely,

$$C_2 > C_3 > C_4 > C_5$$

Experimental

The circular dichroism was measured with a JASCO optical rotatory dispersion recorder of the ORD/UV-5 type at 25° to 30°C in chloroform (but XVIII in ethanol) in the wavelength region from 350 to 230 mμ. The rotatory dispersion was measured with a Rudolph spectropolarimeter.

Resonance Effect in Hammett Relationship. IV. Linear Free Energy Relationship based on the Normal Substituent Constants*

By Yasuhide YUKAWA, Yuho TSUNO and Masami SAWADA

The Institute of Scientific and Industrial Research, Osaka University, Higashiasakayama, Sakai

(Received April 7, 1966)

A set of normal substituent constants, σ^0, was derived from the rates of alkaline hydrolysis of *m*- and *p*-substituted ethyl phenylacetates in 60% (v/v) aqeuous acetone at 25.0°C. The obtained values of σ^0-constants were generally identical with Taft's values within experimental uncertainty. On the basis of the derived σ^0, substituent effects on the general electrophilic reactions were correlated excellently by the equation, $\log k/k_0=\rho(\sigma^0+r\Delta\bar{\sigma}_R^+)$, where $\Delta\bar{\sigma}_R^+$ corresponds to the exaltation of Brown and Okamoto's σ^+ from σ^0. The similar treatment could be applied also to the nucleophilic reactions. The utility of this equation for the estimation of resonance contribution and for the consideration of reaction mechanisms are discussed.

The general failure of the Hammett equation[1] to correlate electrophilic reactivities led to the suggestion of the use of alternate substituent constants, denoted by σ^+, derived from the substituent effect in an electrophilic reaction.[2-5] Various authors proposed their own set of σ^+ values from the individual reference reaction.[3-5] Later, Brown and Okamoto have proposed the familiar σ^+ constants, defined by the substituent effects on the solvolysis rates of phenyldimethylcarbinyl chlorides, and demonstrated the utility of their σ^+ to the prediction of electrophilic reactivities.[5] The exalted contribution of electron releasing *para* substituents can be attributed to the additional delocalization by resonance of the positive charge produced at the reaction site. The σ^+ treatment stands on an assumption that the substituent constant in electrophilic reactions remains a constant relative to the marked change in ρ. However, the degree of the resonance delocalization must depend on the amount of charge produced or the electron deficiency of the reaction site. Accordingly, the σ^+ of respective *para* substituents should be subject to variation with reactions. It should be inevitably required for *para* substituents to add a second term, taking into account such an exalted resonance contribution.[3,6]

At this point of view, the relationship (1) was proposed[6] for the correlation of substituent effects on general electrophilic reactions,

$$\log k/k_0 = \rho(\sigma + r\Delta\sigma_R^+) \qquad (1)$$

where r is a constant depending on the resonance effect in the reaction, and $\Delta\sigma_R^+$ measures the capacities of substituents to supply electrons by resonance. $\Delta\sigma_R^+$ values were defined by the increments of Brown and Okamoto's σ^+ from σ. The applicability of Eq. 1 was demonstrated in the original paper[6] with the excellent results for 35 representative electrophilic reactivities. Thereafter, Eq. 1 has been utilized in order to correlate various reactivities and elucidate the reaction mechanism by a number of investigators.[7,8] These are reviewed entirely in several recent articles.[9-11] Analogous equations have been proposed[7a,12,13] in these few years, but none of them appears more useful practically or more

general to cover a wide variety of reactions.

While the relationship (1) is conventionally based on the σ-standard and the resonance parameter $\Delta\sigma_R^+$ was defined originally by $\sigma^+ - \sigma$, it is evidently known that the Hammett σ-constant involves in itself the σ^+-type exalted resonance contribution to a considerable extent. Taft[14,15] and Wepster[16] have proposed independently that the unexalted or normal substituent constants, σ^0 or σ^n, should be taken as the standard of the benzene subtituent contribution instead of σ. Of course, for the practical purpose, it is believable that the original definition of the relationship (1) must be the best choice of the standard.[17] However, in view of further development of this type of approach and performing the theoretical analysis of the substituent effect, the additional resonance contribution to the unexalted effect, σ^0, should be fully included into the additional resonance term corresponding to $r\Delta\sigma_R^+$. It was therefore attempted to develop an alternate treatment of substituent effects based on the σ^0-standard.

In this connection, σ and σ^+ on which our original treatment is based are the most familiar to the organic chemist and well established sets of substituent constants. While the σ^0-constant was derived by Taft[14,15] statistically from the reactions free from the mutual conjugative interaction between substituent and the reaction site, the numerical values do not appear to be so precise because of the lack of sufficient data available at that time. As similar to the pK_a of benzoic acids for σ, the σ^0 should be defined by the substituent effect on the dissociation of phenylacetic acids. In practice, however, the effects are so small relative to the experimental uncertainty to evaluate the precise constants. Accordingly, first of all, the more reliable experimental σ^0-values have been determined on the basis of the substituent effects on alkaline hydrolysis of ethyl phenylacetates. In the present paper are reported and discussed the determination of σ^0-constants and the development and generality of the alternate treatment based on the σ^0-constants obtained.

Experimental

Most of phenylacetic acids were prepared by the Willgerodt reaction of the appropriate acetophenones.[18] The modified procedure using sulfur and morpholine was employed; the morpholides were separated, washed and hydrolyzed with concentrated potassium hydroxide solution. This method was generally successful except for *p*-chloro and *p*-bromo derivatives. Another method generally employed was the hydrolysis of the nitriles prepared from the correspondingly substituted benzyl halides. *m*-Fluoro and *m*-chloro derivatives were obtained from the corresponding benzoic acids by the Arndt-Eistert reaction.[19] The other substituted derivatives were prepared by the convenient method in the literature (see Table I). The acids were purified by the recrystallization or the distillation of the esters, followed by the recrystallizations of regenerated acids. The acids were esterified by the standard method and finally the esters were fractionated or recrystallized immediately before the rates of their hydrolysis were measured. Any impurities or undesirable isomers were not detected by vapor phase chromatography. The physical constants of these materials were listed in Table I.

Acetone which had been treated with potassium permanganate was distilled, dried over potassium carbonate and fractionated. It was diluted with freshly boiled, deionized water to give a 60% (v/v) aqueous acetone.

Kinetic Measurement.—The rates of the hydrolysis of all these phenylacetic esters were determined in 60% aqueous acetone solution at 25.00±0.01 °C by following the decrease of conductance of the solution. The procedure employed for this measurement was essentially the same as that described by Hancock.[20] The initial concentrations of alkali and the ester were precisely equal (0.01—0.005 M) and the reaction was followed up to the extent of 90% reaction. The initial conductance was determined by the reading of conductance of alkaline solution alone. All runs showed strictly second order kinetics, while in some cases slight deviations from the kinetic plot was observed in the initial 5—10% reaction period. The rate constants from different runs agreed within 1% except for *p*-bromo derivative, which did not give a precise second order rate constant and the average deviation of repeated runs was about 3% for this derivative. The rate constants obtained are listed in Table II.

Of the slow reacting derivatives, the rates were determined also by means of the titration method under the same condition as the above. The procedure employed was essentially the same as that described in

the literature.[21] The equal initial concentration of round 0.01 M for alkali and ester was employed for all runs. The aqueous acetone solution of sodium hydroxide was frequently prepared and standardized. More than triplicated runs were carried out for respective esters. The respective run, which involved more than 12 measurements convering two half-lives, followed the second order kinetic law, with slight fluctuation of few points. The average deviation of a run was estimated to be within 2%, and the reproducibility of repeated runs to be ±3%. The aveaged rate constants obtained were identical within experimental uncertainty with those by means of the conductivity measurement.

Results and Discussion

The Standard σ^0-Constnat.—A difficulty in the determination of precise σ^0-constants arises from the low susceptibility to the substituent change of the insulated reactivity, the reactivity free from the mutual conjugative interaction between substituent and reaction site. In view of comparatively large substituent effects, alkaline hydrolysis of substituted phenylacetic esters is

the most appropriate reference reaction of σ^0-constants. While the rates of alkaline hydrolysis of ethyl phenylacetates were available in the literature[22] for several derivatives in 60% aqueous acetone solution, data were not enough to determine precise σ^0-constants. Thus the more extensive study of this reaction was carried out for a variety of substituted derivatives in order to derive a reliable set of σ^0-constants. According to the preliminary experiments, the reaction proceeded rather too fast in this solvent at 25°C to follow by the usual titration method. This might cause the large experimental error in the results. Therefore the rates were determined by following the change in electric conductivity of the solution during reaction. The results were satisfactory in all the case. When we had finished the series of experiments, additional data for the same reaction by means of titration method were published.[23] They agreed to our results for most of derivatives but did not for several derivatives, such as *p-t*-butyl and *m*-nitro derivatives. Accordingly, the re-examination was undertaken for slow reacting derivatives by means of titration method, while this confirmed our results from the conductivity measurement, which appeared to give more accurate results in comparison with the other method. The disagreement of highly reactive derivatives, especially a large deviation of *m*-nitro derivative,[22] might be responsible to the experimental difficulty in titration measurement. The recent data on the alkaline hydrolysis of the same esters in aqueous alcohol,[24] in which the reaction proceeds considerably slow (ca. 5 times), are much closely related to the present results in spite of different solvents. For the other derivatives, the excellent reproducibility of data from the repeated runs evidently estimates the high reliability of our results due to conductivity measurements. The further support of our results is the fact that the effects of substituents, $\log k/k_0$,

obtained can be correlated linearly with those on the dissociation of phenylacetic acids[25] as illustrated in Fig. 1. This can be compared with the linear free energy correlation between hydrolysis of benzoic esters and the pK_a of benzoic acids.

As would be anticipated, for all *meta* substituents and conjugatively electron attracting *para* substituents, a precisely linear Hammett correlation was obtained (Fig. 2). The ρ value is equal to 0.978 with standard deviation of +0.010 and the correlation coefficient 0.999. On the basis of this correlation, the apparent substituent constants of this reaction were calculated. The resulted constants are generally identical with Taft's σ^0 values within usual uncertainty, and expected to be more reliable than the latter. This set of substituent constants in Table III can correlate precisely the substituent effects on the hydrolysis of substituted benzyl benzoates.[26] The unexalted reactivities which recently have become available in the literature can be also correlated excellently with the above set, as summarized in Table IV. The excellent results in the table indicate that the present set can be generally utilized as the standard σ^0-constant. In the following treatment therefore the values in Table III will be used as the standard σ^0-constants.

It is of interest to note that the effects of alkyl groups in the present reaction follow clearly the inductive order, while they appear to follow the Baker-Nathan order in aqueous alcohol.[24] The analogous behavior of alkyl groups was also noted in the saponification of benzoic esters,[27] and also in the other reactions.[23,28] The substituent effect is sensitive to conditions of reaction.[15,16] Taft has suggested the solvent dependency of σ^0-constants of particular substituents, such as *p*-methoxy group,[14] but this was not distinctly significant in the reactivities sited. The further investigation of the dependency of σ^0-constants upon reactions, solvents and the other conditions is under progress in this laboratory[26] and will be published in near furure.

Correlations of Reactivities.—In view of the general utility of Eq. 1 using $\Delta\sigma_R^+$ as the resonance substituent constants, the increment of Brown and Okamoto's σ^+ to the σ^0 is expected

to be capable of being the resonance substituent constant. The increment $\sigma^+ - \sigma^0$ in fact runs precisely parallel to $\Delta\sigma_R^+$ for corresponding substituents, as shown in Fig. 3. The correlation can be given by :

$$\Delta\sigma_R^+ = 0.74(\sigma^+ - \sigma^0).$$

The quantity, $\sigma^+ - \sigma^0$, can correlate also linearly the exalted resonance contribution involved in Hammett σ-values, $\sigma - \sigma^0$, with a proportionality constant of 0.26.[29] These facts evidently suggest that the individual set of these increments is measuring in the different scale the identical quantities capable of being the resonance substituent parameter. The replacement of the standard from σ to σ^0 does not result the change in the form of the equation. Thus the alternate relationship can be represented by Eq. 2,

$$\log k/k_0 = \rho(\sigma_0 + r\Delta\bar{\sigma}_R^+) \qquad (2)$$

where a new set of resonance substituent parameters, $\Delta\bar{\sigma}_R^+$, was defined by $\sigma^+ - \sigma^0$ in Brown and Okamoto's scale.

29) An anomaly arises in *p*-fluoro group in this correlation; only fluoro group deviates measurably from the correlation line. A satisfactory explanation of the deviation is not immediately available, but the deviation of this group is not significant in the other benzoic reactivities, such as hydrolysis of benzoic esters or the reaction of benzoic acids with diphenyldiazomethane. Therefore, the deviation does not deny the applicability of the present treatment for fluoro group.

Equation 2 has been applied successfully to correlate representative electrophilic reactivities including the benzoic reactivities, by using the method of least squares. The results are summarized in Table V and several examples are illustrated in figures. Our previous result on the decomposition of diazoacetophenones in acetic acid[3] was correlated excellently with an r-value of 0.667 as shown in Fig. 4. For our recent data of the hydrolysis of m- and p-substituted α-phenylethyl chlorides in 80% aqueous acetone at 45°C,[30] Hammett equation resulted a scattered plot but Eq. 2 gave an excellent straight line for the same data using an r of 1.16. This can be compared in Figs. 5 and 6. The precision of the correlations can be easily estimated by standard deviations and correlation coefficients in Table V. The excellent result covering a wide variation of ρ and a variety of reactions evidently confirms the generality of this empirical relationship (2).

Most of the correlations in Table V were obtained primarily on the basis of reactivities of selected substituents. Dimethylamino-, amino, hydroxy-, and some others were not included into the calculations of correlations, because σ^0 and $\Delta\sigma_R^+$ values for these groups are not equivalently reliable as those for the other well-behaving substituents. Whereas the inclusion of these groups into calculations usually did not result the significant change in the correlation.

ρ and r in Eq. 2 might be practically covariant and compensate for variations of each other. Our treatment is essentially based as the standard.

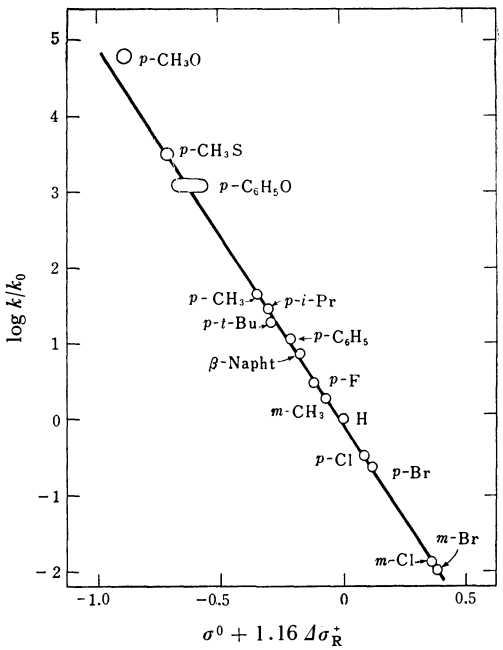

Fig. 6. Application of Eq. 2 to the solvolysis of α-arylethyl chlorides.

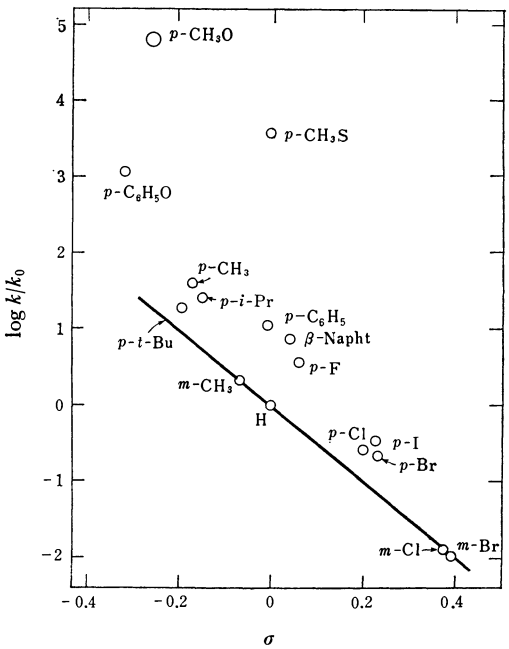

Fig. 5. Hammett plot of solvolysis of α-arylethyl chlorides.

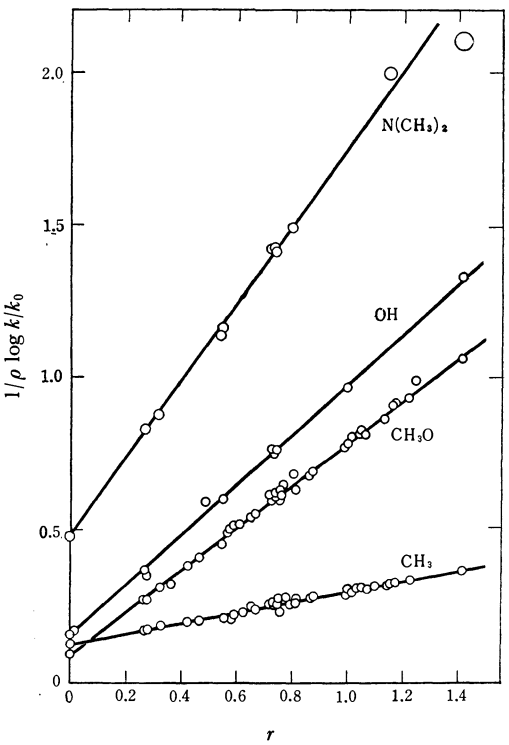

Fig. 7. Dependency of the effects of *para* substituents on r.

30) Y. Yukawa, Y. Tsuno and Y. Kusuyama, to be published.

on the ρ_m value, which should be the general basis of the Hammett type linear free energy correlations.[3,15,16] Certainty of the resulted correlation or r must depend on the reliability of ρ-value, and accordingly depend on the number of *meta* substituents involved in the series. ρ values obtained by the least squares application of Eq. 2 were generally found to agree with values calculated from *meta* reactivities alone. This should be an important fact to support our treatment, and thus r-value is not merely a mathematical compensating parameter but appears to be a parameter characteristic of the reaction practically independent of ρ-value.

Figure 7 illustrates the variation of apparent substituent constants, $1/\rho \log k/k_0$, of respective groups as a function of r for varied reactions. The respective substituents indicates clearly the first order dependence upon r. Since the gradient corresponds to $\Delta\bar{\sigma}_R^+$ and the intercept to σ^0 of respective substituents, the linear dependency is an evidence for the constancy of $\Delta\bar{\sigma}_R^+$ parmameters of these groups independent of reactions. Dimethylamino and hydroxy groups also indicate clearly the linear dependency covering over a remarkable variation of reactivities. Here again it should be mentioned that these groups were not included in the calculation of r values. Thus this should be the strong support to the certainty of the present relationship for a wide variety of substituents including these strongly conjugative substituents. Unfortunately, data are not sufficiently available in the literature for *p*-amino, *p*-methylmercapto and *p*-phenoxy groups to examine the validity of parameters. Additional data must be awaited.

The present type equation is expected to be applied for the correlation of conjugatively electron attracting *para* substituents in the nucleophilic reactions.[31] This can be realized by Eq. 3,

$$\log k/k_0 = \rho(\sigma^0 + r\Delta\bar{\sigma}_R^-) \qquad (3)$$

using the difference, $\sigma^- - \sigma^0$, as the resonance substituent constant, $\Delta\bar{\sigma}_R^-$. The dissociation of phenols or anilines will be perhaps the extreme case of this equation; these were referred to $r=1$. The linear correlation in Fig. 8 is illustrating the application of Eq. 3 to the dissociation of substituted thiophenols[32] which requires $r=0.52$. NMR chemical shifts of the acetylenic proton of substituted phenylacetylenes[33] resulted an excellent correlation in terms of r of 0.63 for *para* electron attracting groups. Yoshioka et al.[34] reported

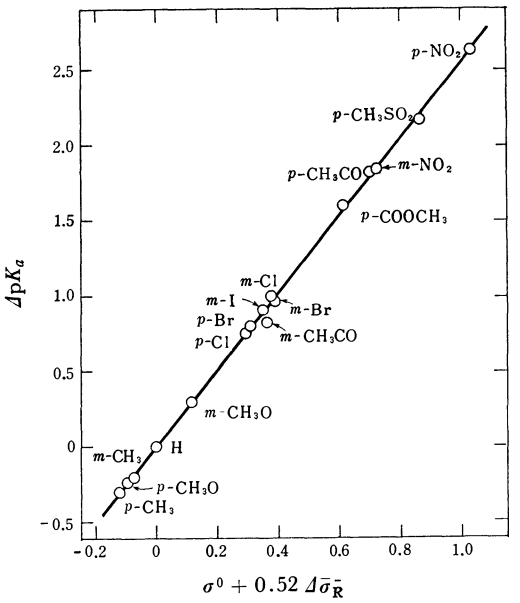

Fig. 8. Application of Eq. 3 to the dissociation of substituted thiophenols.

that the dissociations of several series of sulfonanilides were correlated linearly, giving r's close to 0.5. Although further examination may have to be required for Eq. 3, few other data of this reactivity class are available in the literature. However, these results may be sufficient to suggest that the present type treatment can be applicable not only to electrophilic but nucleophilic reactions.

From the general success of the present type and original treatments, and also from a precise proportionality between $\Delta\sigma_R^+$ and $\Delta\bar{\sigma}_R^+$, it can be conclusive that there should exist a general measure of the resonance capacity of substituents. The substituent effect on reactivities can be represented by the generalized form,

$$\log k/k_0 = \rho(\sigma^0 + \phi) \qquad (4)$$

where ϕ represents the exalted contribution of *para* substituents, exclusively attributable to the resonance contribution. The present result shows that ϕ can be given by

$$\phi = r\Delta\bar{\sigma}_R^+ \quad \text{and/or} \quad = r\Delta\bar{\sigma}_R^- \qquad (4')$$

for conjugatively electron releasing *para* substituents in electrophilic reactions and electron attracting *para* substituents in nucleophilic reactions, respectively. This is an actual establishment of the linear free energy relationship for the exalted resonance contribution. Equation 4 associated with 4' is in the other view the separation of substituent effect into the substituted phenyl polarity and the polarizability effects.

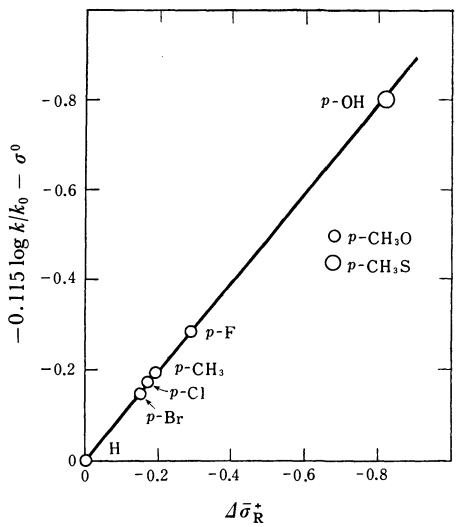
As pointed out frequently,[11,14,15,35] ψ term is susceptible to various factors such as the loss of resonance due to steric inhibition, specific solvation, and beyond the question experimental errors. An excellent result with the present treatment should be an evidence supporting that only the polar contribution, inductive and resonance contributions, is the dominant factor of the given reactivity. The ordinary effects, such as the dependency of resonance upon solvation or desolvation, will be included in r and also in ρ as a common factor. On the other hand, the deviation from the correlation should be taken as an evidence for the existence of some specific effects of particular substituents. An illustrative example of the case is the bromination of polymethylbenzenes. Illuminati reported the substituent effect on the nuclear bromination of substituted durenes, isodurenes and mesitylenes, where only the desired attacking nuclear position is opened.[36] On the basis of Eq. 2, the additional resonance contribution, ψ, to this reaction is separated using $\rho = -8.69$. Figure 9 shows the plot of ψ-values against



Eig. 9. Resonance contribution in the bromination of polymethylbenzenes.

$\Delta\bar{\sigma}_R^+$. The points for alkyl- and halo-groups fall on a line giving an r of 1.00 whereas methoxy and methylmercapto groups deviate from the line. The deviation might be attributed to the steric loss of resonance interaction with the ring due to the twisting from the coplanarity by adjacent methyl groups. The resonance contribution of the other groups may not be affected sterically, so that they satisfy the linear relation with $\Delta\bar{\sigma}_R^+$. *p*-Hydroxy groups, of which the rate is estimated from that of the 2, 6-dimethyl derivative,[12] is also usually free from such an effect and thus satisfies the correlation. Illuminati has pointed out the inhibition of resonance only for *p*-nitro group on the basis of the Hammett correlation, while he did not verify that of methoxy or methylmercapto group, simply because the lack of any reliable standard correlation. The considerably lower r than that of the bromination of monosubstituted benzenes can be explained reasonably in terms of the incorporated stabilization of the transition state by the electron releasing methyl groups in the polymethylbenzene case. The slightly low ρ value is referred to the same reason and also to the steric contribution of methyl groups to the reaction center.

One of the characteristic features of our treatment is the introduction of the variable r for variations of resonance from reaction to reaction. In our concept, r must be a measure of the degree of resonance interaction between substituent and reaction site. As mentioned previously,[6,11] r remains approximately a constant for reactions which have the closely similar structure of the transition state. In the case of dissociations of substituted benzoic acids, ρ-parameter varies considerably with respect to the change in the condition such as solvent change, whereas r remains so constant as to give a constant σ-value for respective substituents. In the carbonium ion reactions, trityl derivatives gave an approximately constant r of 0.8, and the benzhydryl provided r-value close to 1.1.

In the series of solvolysis reactions, cumyl chlorides have an r-value of unity by the definition, α-phenylethyl chlorides provide a precise r value of 1.16, and benzyl derivatives r-value round 1.5.[37] The changes of r can be attributed to variations of the degree of aryl participation in competition with electron donation by the adjacent methyl group. The variation in ρ does not provide any useful indication.

In the case of Beckmann rearrangement of acetophenone oximes (16 and 17), the change of the leaving group resulted the distinctly different ρ values but comparable r values. Closeness of r might be a suggestion of the close similarity of the transition state. Change in ρ provides few information about the mechanism. On the contrary, the solvolysis of cumyl and neophyl

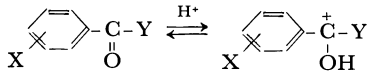
35) C. D. Ritchie and W. F. Sager, "Progress in Physical Organic Chemistry," Vol. II, Interscience, New York (1964), Chapt. 6, p. 323.

37) The definite r-value can not be determined for this reactivity; as for example, the solvolysis of benzyl tosylates appears to involve the change in the reaction mechanism due to substituent changes. Accordingly, even ρ_m value can not be accurately determined for this reaction. (J. K. Kochi and G. S. Hammond, *J. Am. Chem. Soc.*, **75**, 3445 (1953); F. T. Fang, J. K. Kochi and G. S. Hammond, ibid., **80**, 563 1958).

derivatives (1 and 15) resulted comparable ρ-values but different r-values, suggesting the different structures of transition states.

The gas phase pyrolysis of substituted α-phenylethyl acetates, studied by Smith et al.,[38] can be compared interestingly with the solvolysis of phenylethyl chlorides in an aqueous acetone.[30] The pyrolysis of acetates gave a remarkably small ρ but a comparable r value with that for the solvolysis of the chlorides indicating the resemblance of the transition states of both reactions.

In the series of the protonation equilibria of the benzoyl derivatives (No. 34, 38, 39 and 42),



where Y's are H, CH_3, OH and NH_2, r-value decreases from 1.16 to 0.36 in the increasing order of electron donating capacities of Y-substituents. This can be explained reasonably in terms of the competitive participation of aryl and Y-substituent groups. ρ parameter appears to be a complicated resultant of the pertinent factors, while the condition of reactions is nearly the same. From these facts, r-parameter can be discernible as the more appropriate measure of the electronic requirement of the transition state than ρ-parameter.

A theoretical approach to the present-type linear free energy relationship (2 and 3) has been recently carried out by Fueno and Furukawa.[39] Hammett σ and various σ^+-type substituent constants were calculated as the delocalization energy changes of substituted benzyl-type carbonium ions by the perturbation and also variation methods.[40] The results suggested that the variation of estimated Coulomb parameter k in $\alpha+k\beta$ for the reaction site, assumed as a heteroatom ion, was proportional to the change in r of the present study. Thus the experimental r, the degree of resonance contribution, appears to be compatible with the degree of delocalization estimated from M. O. approximation.

Theoretically both r and ρ should be responsible to the variation of electron density at the reaction site, accordingly, both parameters might be correlated in some way with each other. Norman[12] has proposed recently Eq. 5 for the correlation of aromatic electrophilic reactions,

$$1/\phi \log k/k_0 = \sigma_G + \phi\sigma_P \qquad (5)$$

where ϕ is the electron demand constant, σ_G is a measure of the ground state polarization and σ_P the polarizability constant of a substituent. In view of the formal similarity to our relationship, he has attempted to rationalize his Eq. 5 in terms of our parameters.[41] σ_G can be equated to σ^0. σ_P might correspond to our resonance parameter in its concept and reasonably be expected to be proportional to the latter. Further correspondence requires that r value has to be parallel to ρ values of various reactions, provided ϕ being equal to ρ. In view of the nature of ρ, such a parallelism will be observable only in the closely limited reaction series. Norman has demonstrated the existence of linearity between both parameters for 6 aromatic electrophilic substitution reactions. Whereas, Eaborn has indicated the other examples against this.[42] In Fig. 10 are figured out both parameters

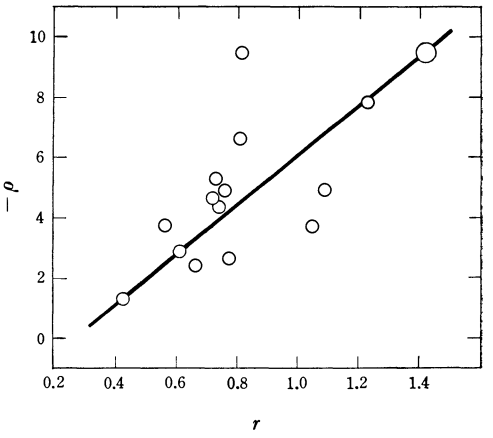


Fig. 10. Relation between ρ and r of aromatic electrophilic substitutions.

for aromatic substitutions obtained in the present investigation. The resulted correlation is clearly far out of the accuracy of usual linear free energy correlations, even if a linearity may exist. Generally the present result does not necessarily agree with Norman's assumption. Norman equation appears to be describing the limited theoretical model of the ideal aromatic substitution reaction, while such an ideal series of reactions can not easily be observed experimentally.

Of the empirical treatments of the substituent effect, Taft equation[14,15] has been most generally accepted.[2] The separation of the substituent effect into inductive and resonance effects appears to be most likely and physically meaningful. His equation is often employed in the literature

to electrophilic reactivities as the form,[43]

$$\log k/k_0 = \rho_I\sigma_I + \rho_R\sigma_R^0 \qquad (6)$$

where σ_R^0 may be replaced by σ_R or σ_R^+. The precision of the fit is usually comparable with that of the present treatment. According to Taft's definition,[14] σ_I is a constant of respective substituents independent of reactions, and ρ_I has to be equal to ρ_m value. However, on applying Eq. 6 to -R *para* substituents in the electrophilic reaction, it is found that the best ρ_I value obtained is not always equal to ρ_m value.[44] The statistically most probable ρ_I of a given reaction significantly varies depending on the choice of his resonance parameters. For instance, the application of Eq. 6 to Brown's reference reaction of σ^+[5] results the ratios of σ_I/σ_m of 1.00 (by definition), 1.35 and 1.50, dependent on the use of σ_R^+, σ_R and σ_R^0, respectively. These variations exceed distinctly the limit of the common uncertainty; more interestingly, they are rather systematic. The similar difficulties are not rarely observed in Taft's treatment, and are inevitable from the mutual non-linearity of his resonance parameters for respective substituent. Thus, any set of his resonance parameters can not accomplish generally the linear resonance free energy relationship. These treatments might be perhaps the overextension or a kind of incorrect use of Taft equation. As Taft mentioned by himself,[14,15] individual set of his resonance parameters should be employed limitedly for its appropriate reactivity class, otherwise, the correlation obtained means merely a mathematically best result and either ρ_I or ρ_R resulted will lend little help to the elucidation of the mechanism of a given reaction. While Taft equation is conceptually reasonable and meaningful, the present treatment (4) togehter with (4') has the advantage of Taft's one in the view point of the linear resonance free energy relationship.

The insulated aryl reactivities can be separated conceptually into mesomeric and inductive effects. Accordingly, Eq. 4 for general reactivities can be rewritten in the form,

$$\log k/k_0 = \boldsymbol{I} + \boldsymbol{R}_0 + \boldsymbol{\Psi} \qquad (7)$$

where $\boldsymbol{I}$ and $\boldsymbol{R}_0$ represent the inductive and mesomeric effects in the insulated reactivities. Either $\boldsymbol{R}_0$ or $\boldsymbol{\Psi}$ is essentially responsible to the inherent resonance capacity of respective substituents. Hence it might be plausible to expect that both $\boldsymbol{R}_0$ and $\boldsymbol{\Psi}$ terms can be described by a common resonance parameter inherent in the individual substituent. As usual, $\boldsymbol{R}_0$ could be replaced by Taft's σ_R^0, whereas, σ_R^0 is not exactly proportional to $\Delta\bar{\sigma}_R^+$ and is incapable of being linear free energy description of $\boldsymbol{\Psi}$ contributions. The general applicability of our $\Delta\bar{\sigma}_R^+$ for the $\boldsymbol{\Psi}$ contribution would lead to the expectation that a measure of the conceptual $\boldsymbol{R}_0$ will be practically realizable from our resonance parameters. The estimated $\boldsymbol{R}_0$-parameter might not be exactly equal to Taft's σ_R^0 parameter, and as a sequence, this might estimate a different scale of the inductive effect for the aryl-residue from Taft's σ_I scale. Such an analysis of the substituent effect should be of great importance and interest, to obtain some informations about the essential implication of the present treatment and also the nature of the substituent effect. The analysis along this line has been recently carried out in this laboratory and will be the subject of a forthcoming publication.

Authors are indebted to Professor J. E. Leffler and Professor G. S. Hammond for helpful discussions. Special thanks are due to Professor R. W. Taft who has always encouraged us and also has given us invaluable suggestions and advices to this work.

The Synthesis, Resolution and Configuration of β-Hydroxyvaline[1]

By Jun-ichi OH-HASHI and Kaoru HARADA

Institute of Molecular Evolution and Department of Chemistry, University of Miami, Coral Gables, Florida, U. S. A.

(Received April 9, 1966)

DL-β-Hydroxyvaline was synthesized from sodium β, β-dimethylglycidate by aminolysis with benzylamine, followed by hydrogenolysis. *N*-Benzoyl-DL-β-hydroxyvaline was resolved by use of (−)-α-methylbenzylamine to yield (−)-*N*-benzoyl-β-hydroxyvaline. The configuration of VI was determined by converting it to methyl *N*-benzoyl-β-chlorovalinate (I) and subsequent hydrogenolysis of I yielded (−)-methyl *N*-benzoylvalinate (II). From II, optically pure D-(−)-valine was obtained upon hydrolysis.

The finding of β-hydroxyvaline in nature has been reported.[2-4] However, later investigations showed that the natural occurrence of the amino acid was questionable.[5-8] Syntheses of the racemic amino acid have been reported by use of the addition reaction of mercuric acetate and bromine to β, β-dimethylacrylic acid.[5,9-11] Ammonolysis of ethyl β, β-dimethylglycidate resulted in β-amino α-hydroxy derivative.[12-14] Recently Kaneko and Inui[15] synthesized and characterized racemic β-hydroxyvaline and an α-hydroxy-β-aminoisovaleric acid which were separated from the reaction mixture of ammonolysis of sodium β, β-dimethylglycidate (I).

Optically active β-hydroxyvaline has not been prepared. In this investigation, DL-β-hydroxyvaline was prepared by treatment of I with benzylamine in aqueous condition in a way similar to the method employed by Liwschitz et al.[16,17] in which they obtained only α-amino β-hydroxy

acids. The resulting *N*-benzyl-β-hydroxyvaline (II) was debenzylated by hydrogenolysis with palladium on charcoal. The prepared DL-β-hydroxyvaline (III)[18] was benzoylated and was resolved by (−)-methylbenzylamine[19,20] to yield (−)-*N*-benzoyl-β-hydroxyvaline (−)-amine salt (V). From the salt V, (−)-*N*-benzoyl-β-hydroxyvaline (VI) was isolated. Free (−)-β-hydroxyvaline (VII) was obtained by hydrolysis of VI. To determine the configuration of the resolved (−)-β-hydroxyvaline (VII), (−)-*N*-benzoyl-β-hydroxyvaline (VI) was converted to the methyl ester (VIII) by the use of diazomethane. The ester VIII was treated with thionyl chloride to convert VIII to β-chloro ester (IX). The β-chloro ester was catalytically hydrogenolyzed by the use of palladium on charcoal to yield methyl *N*-benzoyl-valinate (X) as was done in the study of β-phenylserine.[21] The ester X was hydrolyzed and optically pure D (−)-valine (XI) was obtained. Accordingly, the α-carbon atom of (−)-β-hydroxyvaline is assigned the D-configuration. The schematic route of this work is shown in Fig. 1.

Attempts to obtain active glycidic acid by resolution were unsuccessful, because of instability of the free glycidic acid.

Experimental[22]

DL-*N*-Benzyl-β-hydroxyvaline (II).—A mixture of sodium β, β-dimethylglycidate (I),[15] 6.9 g. (0.05 mol.), water, 7 ml., and benzylamine, 8.0 g., was heated under reflux for 6 hr. After cooling, the excess of benzylamine was removed by distillation in vacuo. The pH of the aqueous solution was adjusted to 5.5 with concentrated hydrochloric acid. The precipitated crystals of DL-*N*-benzyl-β-hydroxyvaline (II) were separated by filtration and washed with acetone, then ether. The crude product, 7.6 g. (68%), was recrystallized from *N*, *N*-dimethylformamide. Yield, 6.9 g. (62%), m. p. 204°C.

Found: C, 64.38; H, 7.80; N, 6.35. Calcd. for $C_{12}H_{17}NO_3$: C, 64.55; H, 7.67; N, 6.27%.

DL-β-Hydroxyvaline (III).—DL-*N*-Benzyl-β-hydroxyvaline (II), 2.2 g. (0.01 mol.), was dissolved in 50 ml. of 50% methanol. To this solution, 1.0 g. of 5% palladium on charcoal was added and the hydrogenolysis was carried out at room temperature. When the hydrogen uptake ceased, the catalyst was removed by filtration. The filtrate was concentrated in vacuo. The crystalline residue was recrystallized from water and methanol. Yield, 1.21 g. (93%). This was further purified from water and ethanol, 1.13 g. (85%), m. p. 218°C (decomp.), [reported m. p. 226—227°C (decomp.)[15]]. Infrared spectrum showed[15] absorption bands at 1670, 1620, 1600, 1560, 1420 cm^{-1} (amino acid), 1145 cm^{-1} ($\rangle$C–OH). R_f value 0.44, BuOH : AcOH : H_2O=4 : 1 : 2. The compound showed a single peak in the Phoenix model K-5000 automatic amino acid analyzer.

Found: C, 45.12; H, 8.57; N, 10.42. Calcd. for $C_5H_{11}NO_3$: C, 45.10; H, 8.33; N, 10.52%.

DL-*N*-Benzoyl-β-hydroxyvaline (IV).—DL-β-Hydroxyvaline (III), 6.65 g. (0.05 mol.), was dissolved in 25 ml. of 2 N sodium hydroxide solution. The solution was chilled in an ice bath and benzoylated in the usual Schotten-Baumann method with a total of 7.0 g. of benzoyl chloride and 25 ml. of 2 N sodium hydroxide solution. Upon completion of the addition of reagents, the reaction mixture was shaken for 15 min. at room temperature and then acidified to pH 3.0 under cooling with concentrated hydrochloric acid. DL-*N*-Benzoyl-β-hydroxyvaline (IV) was extracted with ethyl acetate 2 times (100 ml.×2) and this ethyl acetate layer was washed with water. The ethyl acetate solution was dried with anhydrous sodium sulfate. After evaporation of ethyl acetate in vacuo, 8.9 g. (75%) of crude IV was obtained. Contaminating benzoic acid was removed from the product by boiling with 30 ml. chloroform and subsequently filtering this mixture. These crystals were purified by recrystallization from ethanol and ether. Yield, 8.3 g. (70%), m. p. 156°C (decomp.), [reported 155—157°C (decomp.)[15]]. Infrared spectrum showed bands at 1720 cm^{-1} (–COOH), 1635; 1520 cm^{-1} (–CONH–); 1152 cm^{-1} ($\rangle$C–OH). The benzoyl derivative seems to correspond to the stable form of IV reported by Kaneko and Inui.[15] (The unstable form was reported m. p. 135—136°C.[15])

Found: C, 60.73; H, 6.53; N, 5.80. Calcd. for $C_{12}H_{15}NO_4$: C, 60.75; H, 6.37; N, 5.90%.

(−)-α-Methyl Benzylamine Salt of *N*-Benzoyl-β-hydroxyvaline (V). — DL-*N*-Benzoyl-β-hydroxyvaline (IV), 94.8 g. (0.4 mol.), and (−)-α-methylbenzylamine, 48.4 g. (0.4 mol.), ($[\alpha]_D^{25}$=42.3°, benzene), were dissolved in 50 ml. methanol. The solvent was evaporated in vacuo. The residual syrup was dissolved in hot acetone (150 ml.). After cooling, crystallization of (−)-α-methylbenzylamine salt (V) began by seeding with an authentic specimen which was obtained in another crystallization experiment. After standing overnight in a refrigerator, the crystals were filtered and washed with cold acetone. The crystals, 51.8 g. (72%), were purified from a hot mixture of methanol and acetone (5 : 95). Yield, 47.3 g. (66%), m. p. 155°C, $[\alpha]_D^{25}$= −22.9° (*c* 2.32, water).

Found: C, 67.12; H, 7.43; N, 7.64. Calcd. for $C_{20}H_{26}N_2O_4$: C, 67.02; H, 7.31; N, 7.82%.

(−)-*N*-Benzoyl-β-hydroxyvaline (VI).—(−)-α-Methylbenzylamine salt (V), 36.0 g. (0.1 mol.), was dissolved in 100 ml. of water. To this solution, 110 ml. of 2 N sodium hydroxide was added. The alkaline solution was extracted with ether twice (100 ml.×2) to remove (−)-α-methylbenzylamine. Concentrated hydrochloric acid was added to the aqueous solution to bring the pH to 3.0. (−)-*N*-Benzoyl-β-hydroxyvaline (VI) was extracted with ethyl acetate (100 ml.×2).

18) III showed a single spot in paper chromatography and also showed a single peak in the Phoenix model K-5000 automatic amino acid analyzer.
19) W. Theilacker, *Chem. Ber.*, **87**, 690 (1954).
20) W. Leither, ibid., **64**, 2831 (1931).
21) K. Vögler, *Helv. Chim. Acta*, **33**, 2111 (1950).
22) All temperature measurements are uncorrected. All optical rotation measurements were carried out by the use of the Rudolph model 80 polarimeter with PEC-101 photometer. Elemental analyses were carried out by Micro-Tech Laboratories, Inc., Skokie, Illinois, U. S. A. Infrared absorption spectra were recorded by the use of the Perkin Elmer Model 137 B Infracord Spectrophotometer.

The ethyl acetate solution was washed with water and dried with anhydrous sodium sulfate. After evaporation of ethyl acetate in vacuo, 20.7 g. (87%) of crude VI was obtained. This was recrystallized from methanol and ether. Yield, 19.7 g. (83%), m. p. 112°C, $[\alpha]_D^{25} = -30.5°$ (*c* 2.01, ethanol). Infrared spectrum showed bands at 1745 cm^{-1} (–COOH); 1645, 1550 cm^{-1} (–CONH–); 1150 cm^{-1} (>C–OH). The optically active *N*-benzoyl-β-hydroxyvaline also showed polymorphism which was detected by infrared spectrographically as was reported for DL-*N*-benzyl-β-hydroxyvaline.[15]

Found: C, 60.85; H, 6.32; N, 5.70. Calcd. for $C_{12}H_{15}NO_4$: C, 60.75; H, 6.37; N, 5.90%.

(—)-β-Hydroxyvaline (VII).—A mixture of (—)-*N*-benzoyl-β-hydroxyvaline (VI), 2.37 g. (0.01 mol.), and 5 N hydrochloric acid, 50 ml., was refluxed for 5 hr. After cooling, the precipitated benzoic acid was separated by filtration. The filtrate was extracted with chloroform (50 ml.×2) to remove the residual benzoic acid. After evaporation of the hydrochloric acid solution under reduced pressure, the residual syrup was dissolved in 50 ml. of water. The solution was treated with silver carbonate to remove hydrogen chloride. This mixture was filtered and washed with water. Hydrogen sulfide gas was bubbled through the solution. Silver sulfide was removed by filtration. The filtrate was concentrated in vacuo. A yield of 1.18 g. of (89%) of crude VII was obtained. This was recrystallized from water and ethanol, 0.997 g. (75%), m. p. 208°C (decomp.), $[\alpha]_D^{25} = -13.5°$ (*c* 4.82, 5 N HCl). Infrared spectrum showed bands at 1660, 1600, 1555, 1418 cm^{-1} (amino acid), 1145 cm^{-1} (>C–OH). R_f value 0.44, BuOH : AcOH : H_2O=4 : 1 : 2. The phenomenon of polymorphism of the compound was also observed by infrared spectra. Infrared absorption curve varied depending on the ratio of water and ethanol in the recrystallization.

Found: C, 45.08; H, 8.31; N, 10.69. Calcd. for $C_5H_{11}NO_3$: C, 45.10; H, 8.33; N, 10.52%.

***N*-Benzoyl-β-hydroxyvaline Methyl Ester (VIII).**—(—)-*N*-Benzoyl-β-hydroxyvaline (VI), 2.37 g. (0.01 mol.), was dissolved in 20 ml. of methanol. To this solution, diazomethane in ether solution was added. After the reaction was completed, excess diazomethane was decomposed by adding 5 per cent acetic acid in methanol solution. After evaporation of the solvent under reduced pressure, the residual syrup was dissolved in ethyl acetate. The solution was washed with sodium bicarbonate, then water. The ethyl acetate solution was dried with anhydrous sodium sulfate. After evaporation of the solution in vacuo, an oily residue was obtained. This did not crystallize.

(±)-*N*-Benzoyl-β-hydroxyvaline methyl ester, (±)-VIII, was obtained from IV by diazomethane. Yield, 92%, m. p. 105°C.

Found: C, 62.36; H, 6.75; N, 5.55. Calcd. for $C_{13}H_7NO_4$: C, 62.14; H, 6.82; N, 5.57%.

***N*-Benzoyl-β-chlorovaline Methyl Ester (IX).**—*N*-Benzoyl-β-hydroxyvaline methyl ester (VIII) (oil obtained above) was chilled in an ice bath and 1.2 ml. of thionyl chloride was added. This mixture was warmed in a water bath (about 40°C) to dissolve the oil. After 4 hr., 10 ml. of water was added to the reaction mixture to decompose the excess thionyl chloride. The mixture was extracted with ethyl acetate. The ethyl acetate layer was washed with water, aqueous sodium bicarbonate, and water. The ethyl acetate solution was dried with anhydrous sodium sulfate. After evaporation of ethyl acetate in vacuo, a yellow oil was obtained. This did not crystallize.

(±)-IX was obtained from (±)-VIII by treatment with thionyl chloride under the same conditions as above.

***N*-Benzoylvaline Methyl Ester (X).**—The yellow oil IX was dissolved in 50 ml. of 80% methanol. To this solution, 2.0 g. of sodium acetate, 2.0 ml. of acetic acid, and 2.0 g. of 5% palladium on charcoal were added and the hydrogenolysis was carried out at room temperature. When hydrogen uptake ceased, the catalyst was removed by filtration. The filtrate was concentrated in vacuo. This residue was dissolved in water and extracted with ethyl acetate. The ethyl acetate layer was washed with aqueous sodium bicarbonate and then with water. The ethyl acetate layer was dried with anhydrous sodium sulfate. After evaporating the ethyl acetate in vacuo, 1.5 g. (63.8% based on VI) of *N*-benzoylvaline methyl ester (X) was obtained. This was recrystallized from ethanol and ether. Yield, 1.3 g. (55% based on VI), m. p. 128°C. The specific rotation is too samll to measure in alcohol or in chloroform. The direction of rotation seems to be slightly (+).

Found: C, 66.29; H, 7.33; N, 6.01. Calcd. for $C_{13}H_{17}NO_3$: C, 66.36; H, 7.28; N, 5.95%.

N-Benzoyl-DL-valine methyl ester, (±)-X, was obtained from (±)-IX. Yield, 64.2% [based on (±)-VIII], m. p. 86°C.

Found: C, 66.10; H, 7.23; N, 5.97%.

D(—)-Valine (XI).—The mixture of *N*-benzoylvaline methyl ester (X), 4.7 g. (0.02 mol.), and 5 N hydrochloric acid, 50 ml., was refluxed for 6 hr. After cooling, the precipitated benzoic acid was separated by filtration. The filtrate was extracted with chloroform (50 ml.×2) to remove the residual benzoic acid. After evaporating the hydrochloric acid solution in vacuo, residual crystals were dissolved in a minimum amount of absolute alcohol at room temperature and pyridine was added to the solution. Crude D-(—)-valine (XI), 1.78 g., was obtained. This was recrystallized from water and ethanol. Yield, 1.50 g. (65%), m. p. 310°C (sublimation, sealed capillary), $[\alpha]_D^{25} = -28.7°$ (*c* 2.92, 5 N HCl).[23]

Found: C, 51.05; H, 9.68; N, 12.01. Calcd. for $C_5H_{11}NO_2$: C, 51.26; H, 9.46; N, 11.96%.

In a similar way, DL-valine was obtained from (+)-X. Yield, 75%. Found: C, 51.02; H, 9.47; N, 11.80%.

This work was supported by Grant No. NsG-689 of the National Aeronautics and Space Administration, U. S. A. The authors wish to express their thanks to Dr. S. W. Fox for his discussion and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2290—2294 (1966)

The Effects of Some Antioxidants on the Elastomers Derived from Carboxy-terminated Polybutadiene

By Harusuke Tokui

Daicel, Ltd., Yuraku-cho, Chiyoda-ku, Tokyo

and Kiroku Yamazaki

Institute of Space and Aeronautical Science, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received March 18, 1966)

The capability of several sorts of conventional antioxidants was studied by means of the tensile and the swelling tests of the elastomers derived from the carboxy-terminated polybutadiene prepolymer. When exposed for one year, the elastomers containing no antioxidants deteriorated remarkably; they became brittle and, without exception, no longer looked like the so-called "elastomers." Many kinds of the antioxidants worked out and were found to be effective; their capabilities were evaluated as almost the same as far as the tensile properties of the exposed material were concerned. The changes in the reciprocal value of the average chain length between cross-links, $1/M_c$, in the course of the exposure, however, would be a convenient semi-quantitative measure of the induced cross-linking reaction. With this assumption, the swelling test might prove that, among the additives covered, the amine-type antioxidants were most effective in preventing the deterioration induced by the over-cross-linking reaction of the elastomer. The relationship between the amount of the sol-fraction and the cross-linking density for the exposed specimens was fitted to that of the random cross-linking and the scission of the polymer with a random distribution of chain lengths.

The conventional composite propellants are composed of an inorganic oxidizing material, several sorts of additives, and a polymeric resin fuel. The fuel resin also acts as a binder; a lot of solid materials are finely dispersed therein. It should give the grain of good mechanical properties as well as of high energy. It is quite difficult, however, to combine good mechanical properties with the conventional resinous materials, since the required quantities of solid ingredients usually amount to 75—85% or more of the grain.

On the other hand, from the point of view of energy, fuel binders of a low heat of formation, and the low molecular weight of the burnt gas are plausible.

The starting materials should be liquid at an ambient temperature; they should be able to be cured after the solid components are dispersed therein. From these standpoint, the synthesized elastomeric materials (such as polysulfide, polyurethane and polybutadiene rubbers) are at present preferred as fuel binders for composite propellants.

Work on the cross-linking reactions of carboxy-terminated polybutadiene, which is believed to be an excellent fuel binders, has been reported by the present authors.[1] It may deteriorate easily on aging, and then cause physical or chemical changes which would offer serious problems, especially for storability, since it is a kind of diene-type rubber.

The changes in tensile properties and the values of the equilibrium swelling in the course of the one-year exposure were determined in order to evaluate the capability of the antioxidants.

The effect of some conventional antioxidants will also be described.

Materials

The following antioxidants were tested:

	Commercial name	Maker*
(Amine Type)		
N, N'-Diphenyl-*p*-phenylenediamine	Nocrac DP	O
N, N'-Di-(2-naphthyl)-*p*-phenylenediamine	Nocrac White	O
Phenyl-α-naphthylamine	Nocrac PA	O
Phenyl-β-naphthylamine	Nocrac D	O
Blend of phenyl-β-naphthylamine and diphenyl-*p*-phenylenediamine	Nocrac HP	O
Blend of phenyl-α-naphthylamine and diphenyl-*p*-phenylenediamine	Nocrac 500	O
Octyl diphenylamine	D. D. A.	Bayer

The antioxidants, the carboxy-terminated prepolymers, HC-434 (Thiokol Chem.) and Butarez CTL (Phillips Petr. Co.), and the cross-linking agent, tris[1-(2-methyl)aziridinyl]phosphine oxide [MAPO] (Interchemical Co.), were used as received.

Experimental

The polybutadiene prepolymer, MAPO, an accelerator, and the antioxidant were mixed thoroughly and then cured as an elastomer sheet 2 mm. thick. While the quantities of the prepolymer, the curing agent and the accelerator were kept constant, the quantity of the antioxidant recommended by the maker was added.

Dumbbell-shaped specimens (JIS-K-6301, No. 3-type) were die-cut from the sheet and used for both the tensile and the exposure tests.

The details of the elastomer preparation, the tensile test, and the process of the equilibrium swelling have already been described.[1]

The specimens were fixed on polyethylene-lined plywood plates which faced south and which were inclined at a 30° angle. They were then exposed on the roof of the Central Research Laboratory of Daicel, Ltd. (171 Ohi-mura Tsuruoka, Iruma-gun, Saitama Pref., Japan; longitude 139°30′ E; latitude 35°52′ N). The weathering test was carried out from Oct. 29, 1964, to Oct. 30, 1965. After the samples had been exposed, both the tensile and the swelling tests were performed again with the aged specimens.

Results and Discussion

Table I illustrates the changes in the tensile properties upon exposure. Obviously, the specimens containing no antioxidant deteriorated most. They were no longer the so-called "elastomeric material" after the exposure; they turned very brittle, and showed an extremely poor elongation. The elastomers with the antioxidant still retained the elongation values of 100—150% at the breaking point for the exposed specimens; they thus proved the capability of the antioxidant.

It is an interesting fact that the former faded from brown to light yellow and increased in transparency, while the latter did not, but became rather opaque and turned dark brown upon exposure.

After the specimens had been exposed for one year, their tensile moduli were increased remarkably. This seems undoutedly due to the cross-linking reaction caused by sunlight and air. It could not be a measure of the deterioration of the material, however, because almost all of the exposed specimens produced small cracks upon being stretched. These cracks should cause a local concentration of the stress and so induce failure.

From the results of the tensile tests, it may be concluded roughly that the effectiveness of these additives against aging are all nearly the same.

The swelling data are compiled in Table II.

The content of the sol in the elastomer, and the average molecular weight of the chain between cross-links, M_c, decreased after exposure, while the density of the polymer increased slightly. Indeed, some of the specimens were warped concave to the exposed surface in the course of the exposure.

These results show that the cross-linking reaction of the chains of the network structure, and that of the residual impregnated sol fraction, took place.

Assuming that the density of the elastomer is unity, and that $1/M_c$ equals the moles of the effective chain of the network per unit mass; then the change of $1/M_c$ caused by the exposure would be proportional to the number of sites where the cross-linking reaction has occurred.

Charlesby[2] defined the cross-linking density, q, as in Eq. 1:

$$q = k M_0/M_c \quad (1)$$

where M_0 is the molecular weight of the monomer unit.

* Density of the polymer
** Solfraction of the polymer
(Dashed notation means the states of the postexposure)

k means the average number of cross-links per effective chain. When two functional carboxy-terminated polybutadienes are cured with a trifunctional compound, MAPO, in such a manner that no terminal sections result, the k-value should be 2/3, while in the case of conventionally-cured rubbers with sulfur or peroxides, that value should be 1.0. In this study, the degree of the cross-linking reaction during the exposure is defined as $(q'-q)$. (The dashed notation means the state of the post-exposure.)

Since the quantity of the cross-linked sol fraction caused by the exposure is relatively small, it might be assumed that k' is nearly equal to k. On this assumption, $(q'-q)$ is represented by Eq. 2:

$$(q' - q) = k M_o (1/M_c' - 1/M_c) \quad (2)$$

The values of $(1/M_c - 1/M_c')$, tabulated in Table II, is proportional to the degree of the cross-linking reaction; the smaller the value, the lower the degree of cross-linking. This should be a semi-quantitative measure of the effectiveness of the antioxidants in preventing the cross-linking reaction.

Apparently, the amine-type antioxidants are the most effective. It should be noticed, however, that the capability of the antioxidants can not be evaluated only from the effect in preventing the cross-linking reaction.

Antigene NBC was not compatible in the pre-cured medium, and it bloomed remarkably on the elastomer surface.

The relationship between the quantity of the sol fraction, S, and the cross-linking density, q, has been studied by Charlesby[2] and by Bristow[3,4]. For the random cross-linking and the scission of a polymer having a random distribution of chain lengths, they deduced the following Eq. 3:

$$S + S^{1/2} = p/q + 1/q\,\overline{Y}_n \quad (3)$$

where p: the density of the main fracture of the chain.

$\overline{Y}_n$: the number average chain length of the polymer.

Assuming that the k-value in Eq. 1 is 2/3, the quantity of $(S+S^{1/2})$ is plotted versus $1/q$ in Fig. 1. A good linearity was observed for the exposed elastomers. The cross-linking and scission processes occurred at random in the system, so that the initial polymer should have a random distribution of chain lengths; this connection, however, is not very stringent, because the cross-linking reaction can occur optionally at any site of the network structure.

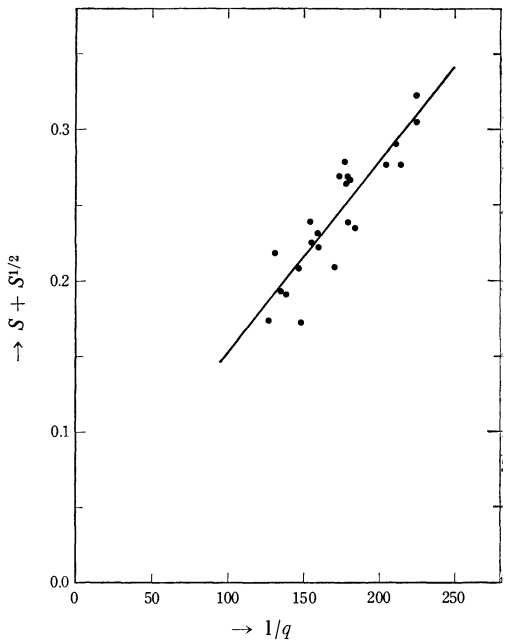

Fig. 1. Plot of $S+S^{1/2}$ versus $1/q$ for exposed elastomers.

The plot of $(S+S^{1/2})$ versus $1/q$ for the unexposed elastomer deviated from the line remarkably, since the cross-linking took place only at aboth ends of the prepolymer chain. From these facts, it may be assumed that the cross-linking reaction caused by the exposure was so effective that it randomized the relatively regular distribution of the initial cross-linking sites.

Conclusions

The elastomer derived from the carboxy-terminated polybutadiene prepolymer (cured with MAPO) showed a fatal deterioration tendency in the course of a one-year exposure test. Several sorts of antioxidants were tested; it was found that they were all effective as far as the experiments showed.

From the tensile data, it was roughly observed that all these antioxidants were almost equally effective; the swelling test, however, proved that the amine-type compounds were most effective among the antioxidants tested in preventing the cross-linking reaction caused by the exposure.

The plot of $(S+S^{1/2})$ versus $1/q$ for the exposed elastomers showed a good linearity, proving that the random crosslinking and scission of the polymer resulted from the exposure.

The authors offer their deep thanks to Mr. Toshimitsu Iwase for his assistance in the experiment.

NOTES

The Water Penetration of Emulsion Polymer Films

By Soichi MUROI

Pioneering Research Laboratories, Asahi Chemical Industry, Co., Ltd., Nakadai, Itabashi-ku, Tokyo

(Received October 4, 1965)

Many studies[1-4] have been made of the mechanism of polymer film formation from emulsions, but little attention has been paid to the mechanism of water penetration into emulsion films.[5] The properties of the films deposited from polymer emulsions may be said to be essentially different from those of solution-cast or milled polymer films, considering the fact that the emulsion films more easily undergo several changes when exposed to water or water vapor a swelling and whitening of the films, accompanied by a deterioration of the mechanical properties and a decrease in adhesion to the substrate.

The present study was made in order to clearly establish the mechanism of water penetration into emulsion films. For this purpose vinyl acetate (VAc)-butyl acrylate (BA) copolymer emulsions were selected as samples because of their enormous consumption in the paint industry and in other fields.

Experiments

Materials.—Emulsions were prepared by the usual method. They were prepared by using 2% of sodium polyoxyethylene nonylphenyl sulfate as an emulsifier and 0.3% of ammonium persulfate (based on the monomer) as an initiator.

Solid polymers free from water-soluble substances were obtained as follows: an emulsion state was destroyed by freezing; small masses of the polymer so obtained were then washed with water for 7 days and dried at 50°C for 4 days.

The films used in the study were prepared by drying the chosen emulsion or solution on a leveled glass plate. The films so obtained then were left to stand at 20°C under 65% R. H. for more than 4 days.

Methods.—The weight of the water absorbed (Q) was determined as follows. Samples (4×5 cm.) were cut from the film and weighed on a direct reading balance. They were then immersed in water at 20°C, taken out at appropriate intervals, blotted quickly with a hard filter paper, and weighed. Five samples were used for each measurement, and the values obtained were averaged. The films 70±10 micron thick were used for the measurements. The film thickness was measured by a thickness gauge.

Results and Discussion

The Water-Absorption Behavior of Emulsion Film in Aqueous Solutions.—When an emulsion is dried, its particles approach each other and eventually touch, thus forming a continuous polymer network. The spherical particles deform, flow together and interpenetrate, leaving small deposits of water which contain the water-soluble substances originally present in the emulsion. As the last water evaporates through the polymer network and the spaces between the fused particles (channels), small clots of the water-soluble substances remain behind.[5,6]

Water penetrates into the clots through the polymer network and channels when the emulsion film is immersed in water. Simultaneously, the polymer network absorbs water to attain an equilibrium. Therefore, it is reasonable to consider that the driving force for the water penetration is given by the difference between the vapor pressure inside the film and that of the external phase to which the film is exposed.

To check this assumption, the films deposited from the VAc-BA (75 : 25) copolymer emulsion were immersed in aqueous solutions of various concentrations of ammonium chloride, sucrose and glucose. The value of Q is plotted against the square root of the time in Fig. 1.

The diagram shows that Q initially increases linearly as a whole with the square root of the time, and that it then gradually approaches an equilibrium value. Although Q soon reaches the equilibrium in a rather concentrated solution, it continues to increase slowly in water or in a diluted

solution, even after an extended time of immersion. The values of Q after a sufficient time of immersion decrease with an increase in the concentration of the solutions, approaching zero as the concentration of the solutions approaches saturation.

The results obtained here suggest that, as expected, the force for water penetration decreases with a reduction in the activity of the external phase (the vapor pressure of the external phase). This may be seen distinctly in Fig. 2, which gives the relationship between the activity of water in the external phase and the value of Q after 100 min. The activity was determined by calculation. Figure 2 shows that Q begins to increase rapidly beyond the activity value of 0.9, almost regardless of the solute nature. This may show that the water-soluble substances contain some water and that, consequently, the activity of water inside the film is rather high.

Another experiment determined the Q of the film deposited from an emulsion which had been dialyzed in a cellophane dialysis tube for 7 days. The dialysis of the emulsion was conducted under such conditions that the emulsifier in the emulsion was not removed; the resulting emulsion was stable. The value of Q for the film after immersion for 7 days ($\sqrt{\text{min.}} \fallingdotseq 100$) was only 18%, against 87% for the untreated emulsion film (it must be noted that these values involve the weight of the water absorbed by the copolymer itself 6.8% as is seen in Table I). On the basis of the results obtained here, it can be said that even a small amount of

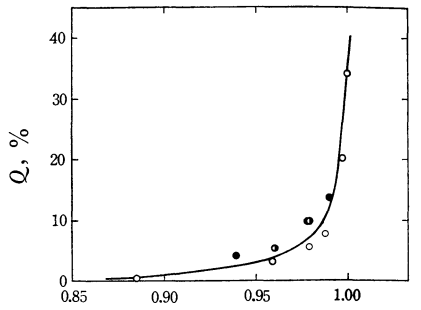

Fig. 2. Relationship between activity of water in aqueous solutions and Q after 100 min. ○: ammonium chloride solution, ●: sucrose solution, ◑: glucose solution.

the salts present in the film, salts which are derived from the initiator and the impurities contained in the emulsifier, may play a leading role for water penetration, whereas the emulsifier may have rather less effect. This may be attributed to the difference in their solubilities in the copolymer.

In a subsequent experiment, films which had been 60% pre-swollen by immersing in water for about 48 hr. ($\sqrt{\text{min.}} \fallingdotseq 54$) were dehydrated by immersing them in aqueous solutions of different concentrations. The dehydration rates of the pre-swollen films are much higher than their water absorption rates, as is shown in Fig. 3. For example, it takes about 48 hr. for the original emulsion film to absorb 60% of the water, as has been mentioned above, while the pre-swollen film is almost completely dehydrated in about 36 min. in 5 N aqueous ammonium chloride. This fact indicates that, in water absorption, water must penetrate into a film against the resistance of the polymer

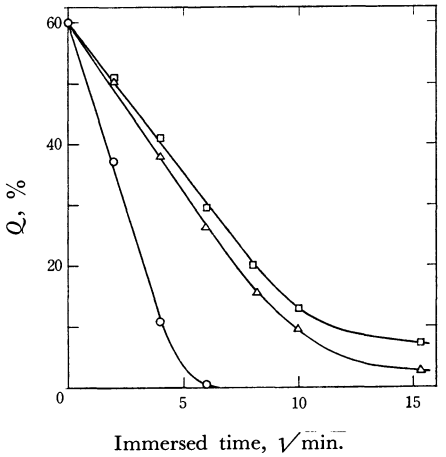

Fig. 3. Dehydration of pre-swollen emulsion films in aqueous ammonium chloride at different concentrations.
○: 5 N, △: 0.5 N, □: 0.1 N

network, while in dehydration there is no such resistance.

The Effect of the Modulus of the Polymer Network on Water-Absorption Behavior.—The water-absorption behavior of the films with different moduli, prepared from the emulsions of VAc with BA in different copolymerization compositions, was determined over extremely extended immersion periods. The results are shown in Fig. 4. The moduli of the copolymers are expressed in terms of Young's moduli of solution-cast films, which have the copolymerization compositions corresponding to those of the respective emulsion films and are free from water-soluble substances, as Table I shows.

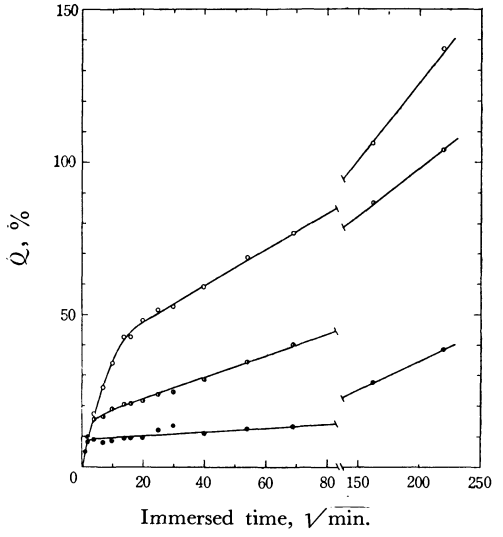

Fig. 4. Effect of modulus of polymer network on water absorption behavior.
●: PVAc, ◑: VAc/BA 90/10, ○: VAc/BA 75/25

TABLE I. YOUNG'S MODULUS AND WATER ABSORPTIVITY OF SOLUTION-CAST FILMS FREE FROM WATER SOLUBLE SUBSTANCES

VAc : BA	Young's modulus (dyne/cm²)10⁹	Q after 7 days, %
100 : 0	9.6	13.7
90 : 10	4.2	9.9
75 : 25	1.4	6.8

The values of Q for all emulsion films initially increase at the same rate linearly against the square root of the time, but the rate sharply decreases at a certain Q, in correspondence with the modulus of the film (polymer network). The values of the breaks increase with a decrease in the modulus of the polymer network. The water absorptivity of the film increases with the reduction in its modulus, that is, with the increase in the BA component in the copolymer. On the other hand, the solution-cast film free from water-soluble substances, contrary to the tendency of the emulsion film, shows a small decrease in Q (after 7 days' immersion) with an increase in the BA component, as Table I shows.

It is evident from the results obtained here that the resistance to water penetration is due to the resistance of a polymer network to deformation. On the other hand, it is of great interest to note that Q did not attain an equilibrium but continued to increase slowly, even after one month ($\sqrt{\text{min.}} \fallingdotseq 208$).

The Water-Absorption Behavior of Solution-Cast Film Prepared from Emulsion Film.—The water-absorption behavior of the emulsion film and the solution-cast film, which have exactly the same composition, is compared in Fig. 5. The cast film was deposited from the solution which had been prepared by dissolving the VAc-BA (75 : 25) copolymer emulsion film in ethyl acetate.

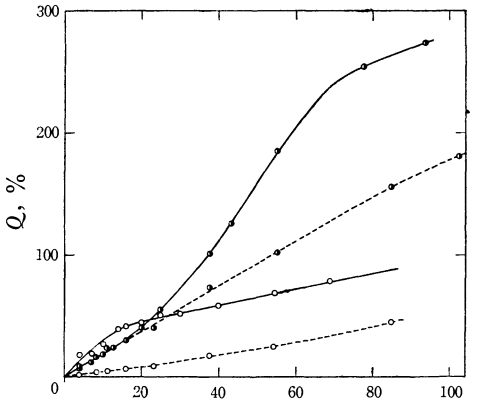

Fig. 5. A comparison between water absorption behavior of emulsion film and that of solution-cast film prepared from the emulsion film.
——: original film, ----: film after a water absorption-redrying cycle, ○: emulsion film, ◑: solution-cast film

The water absorption rate in the initial stage is more rapid for the emulsion film than for the cast film, but in the later stage the Q of the cast film is a few times of that of the emulsion film.

The cast film may show such high water absorptivity because the clots of the water-soluble substances originally present in the emulsion film are kept undissolved in ethyl acetate and, consequently, the film prepared from this solution has the same structure as that of the original emulsion film. In addition, less water-soluble substances might be extracted from the cast film than from the emulsion film because the former has fewer channels. For such reasons, the cast film would ultimately absorb much more water than the emulsion film.

In order to verify this assumption, the weight of the film before and after immersion-redrying were ascertained. The films were immersed in

water until the water absorption rates broke. It took about 400 hr. to reach that stage for the cast film, and 24 hr. for the emulsion film. Then they were redried at 20°C under 65% R. H. for 4 days. The weight reductions of the films, based on the original weight, were 0.6% for the cast film and 1.9% for the emulsion film.

The water-absorption behavior of the redried films was then again ascertained. The water absorptivities of the films are markedly lowered, as is shown by the dotted lines in Fig. 5. Obviously, this results from the decrease in the water-soluble substances in the films.

In a subsequent experiment, the water absorptivities of solution-cast films prepared from solutions of the VAc-BA (75 : 25) copolymer emulsion films in various solvents were determined. The results are shown in Table II.

TABLE II. EFFECT OF SOLVENTS USED FOR DISSOLUTION OF EMULSION FILM ON WATER ABSORPTIVITY OF RESULTING CAST FILM

Solvent	Q after 7 days, %
Carbon tetrachloride	110
Toluene	137
Acetone	140
Methanol	58
Formic acid	63

According to the values of Q in Table II, they may be classified into two groups; the first group showing higher values, and the second, lower values, than that of the emulsion film. The former films are prepared by those solvents which dissolve salts only with difficulty, while the latter are prepared by those solvents which dissolve salts to some extent.

It seems that in the film of the lower-Q value group the water-soluble substances are dispersed unimolecularly, while in the film of the higher-Q value group, they are dispersed as clots, as has been mentioned above. This difference in film structure may affect the water absorptivity. It is not known, however, how the difference in film structure can be related to that in water absorptivity.

Conclusion

From the results obtained so far, it can be understood that there is no essential difference between the water absorption behavior of emulsion films and that of solution-cast films. Emulsifiers and salts are necessarily attendant on emulsion films, and, consequently, they absorb extremely much water. Furthermore, emulsion films are obliged to have a rather low modulus because of their forming mechanism. On the other hand, solution-cast or milled films have no limitation on their formation, and films of a rather high modulus are often used. Emulsion films may generally be regarded to absorb water much more easily than solution-cast or milled films because of the difference in the factors mentioned above.

As far as the present study has so far discovered, the water-resistance of PVAc emulsion film cannot be improved by the copolymerization of a higher acrylic ester.

Octahedral Complexes of Nickel(II) Formate with Amines

By Gopal NARAIN

Department of Chemistry, University of Lucknow, Lucknow (U. P.), India

(Received November 4, 1965)

Three hexaco-ordinated complexes of nickel-(II) formate with ammonia, ethylenediamine and propylenediamine have been prepared. Conductivity measurements indicate the complexes to be non-electrolytes. Molecular weight measurements confirm this. The visible absorption spectrophotometric measurements show a number of bands corresponding to the various permitted transitions of the metal. A discussion of the structure in the light of these transitions is presented.

A large number of nickel ammine complexes of inorganic salts have been prepared, but comparatively very little work has been done on organic salts of nickel.[1-3] Moreover, the nature of the anion is found to be a contributing factor to the stability of the complexes.[4] An attempt has, therefore, been made to prepare some amine complexes of nickel(II) formate and to study their absorption spectra and the effect of formate ions on the properties of the complexes.

Experimental and Results

Synthesis.—*i) Biformatotetra(ammine)nickel(II).*—Five hundred milligrams of nickel(II) formate was placed in a calcium chloride tube fitted with a cotton wool plug at the bottom. The tube was then attached to the neck of a flask containing an excess of liquid ammonia and left overnight. The tube was taken out in the morning, and dried first over calcium chloride and then over phosphorus(V) oxide. The complex is blue in colour and is soluble in formamide. (Found: Ni, 26.89; N, 25.66; NH_3, 31.06. Mol. wt., 201. Cond., 0.43 mhos. Calcd. for $C_2H_{14}O_4N_4Ni$: Ni, 27.08; N, 25.8; NH_3, 31.33%. Mol. wt., 216.7)

ii) Biformatobis(ethylenediamine)nickel(II).—A five hundred milligrams portion of nickel(II) formate was shaken in acetone with a calculated quantity of amine for two hours; the reaction mixture was then left overnight, filtered the next morning, and dried over phosphorus(V) oxide. The complex is violet in color and is soluble in formamide and alcohol. (Found: Ni, 21.65; N, 20.58, en, 44.19. Mol. wt, 253. Cond., 0.51 mhos. Calcd. for $C_6H_{18}O_4N_4Ni$: Ni, 21.84; N, 20.84; en, 44.67%. Mol. wt, 268.7)

iii) Biformatobis(propylenediamine)nickel(II).—This was prepared as ii). The complex is violet in colour and is soluble in formamide and alcohol (Found: Ni, 19.4; N, 18.58; pn, 49.44. Mol. wt., 278. Cond., 0.26 mhos. Calcd. for $C_8H_{22}O_4N_4Ni$: Ni, 19.79; N, 18.87; pn, 49.9%. Mol. wt., 296.7)

The Determination of the Base and the Molecular Weight.—The methods used have already been outlined by the author.[5]

Visible Absorption Spectra.—The spectra were recorded on a Unicam S. P. 500 spectrophotometer in formamide and in alcohol.

Discussion

The results of analysis show the molecular formulae to be $Ni(HCOO)_2(am)_4$ and $Ni(HCOO)_2(am)_2$, where am represents ammonia, ethylenediamine and propylenediamine. The conductivity and molecular weight measurements in formamide indicate the complexes to be non-electrolytes; hence, it is suggested that formate ions, besides neutralizing the charge of the metal, are also coordinated to it. The formulae of the complexes are thus to be written as $[Ni(HCOO)_2(am)_4]^0$ and $[Ni(HCOO)_2(am)_2]^0$. The coordination number thus becomes six in all the cases. The violet colour of the bidentate amine complexes is in contrast with the blue or green colour observed for all other octahedral complexes. It is known that the greater the strength of the coordinate bond between a nickel atom and a ligand, the greater is the deviation from the usual colour.[6]

The terms arising from the d^8 ground state are:

$$3d^8 = F, P, G, D \text{ and } S$$

Ballhausen,[7] on the basis of a series of calculations, found that at least three of four transitions are to be expected for octahedral complexes. The complexes presently under investigation also show four sharp bands in alcohol and formamide. In alcohol the bands occur in the vicinity of 345, 550, 815 and 920 mμ while in formamide, they occur near 350, 560, 825 and 925 mμ. The slight positive shift in the positions of the bands results from the higher polarity of formamide; this changes the energies, which in their turn change the frequencies of the absorption bands.

Further, the comparison of these spectra with the spectra of other known octahedral nickel complexes (bands in the vicinity of 350, 550, 800 and

5) G. Narain, *Z. anorg. u. allgem. Chem.*, to be published.

6) R. S. Nyholm, *Chem. Revs.*, **53**, 263 (1953).

7) C. J. Ballhausen, *Dan. Mat-fys. Medal*, **29**, No. 4 (1954).

925 mμ) shows a fair agreement between the two. Moreover, as has been reported by Frenelius,[8] the ν_3/ν_1 ratio is 1.82 for all octahedral nickel(II) complexes irrespective of the ligands used for coordination. If the 925 mμ band in this case is considered to be the ν_1 band, the ν_3/ν_1 ratio also turns out to be 1.82.

8) C. Fernelius and W. Manch, *J. Chem. Ed.*, **38**, 192 (1961).

The four absorption bands arise from the following transitions of the electrons:

Position of the absorption band	Transition
925 mμ (ν_1)	$A_{2g} \rightarrow T_{2g}$
825 mμ (ν_2)	$A_{2g} \rightarrow E_g$
560 mμ (ν_3)	$A_{2g} \rightarrow T_{1g(F)}$
350 mμ (ν_4)	$A_{2g} \rightarrow T_{1g(P)}$

Drynap Reduction. II.* The Reduction of Nitrobenzene with a Commercial Sodium-Lead Alloy

By Katsumi TABEI and Kuniomi NATOU

Tokyo College of Pharmacy, Kashiwagi 4, Shinjuku-ku, Tokyo

(Received November 29, 1965)

Recently the commercial sodium-lead alloy, "Drynap," was introduced and recommended by one of the present authors as a mild reducing agent in place of sodium amalgam.[1] Nitrobenzene was submitted to Drynap reduction under various conditions.

Acetic acid or hydrochloric acid was chosen as the neutralizing agent, while ethanol or water was used as the reaction solvent. The reduction products were separated through an alumina column and checked by thin-layer chromatography. The product in each experiment was identified by mixed-melting-point determination.

As expected, aniline (over 70% yield; m. p. 114°C; as acetanilide) was the main product of the reduction of nitrobenzene in an aqueous suspension with the alloy and hydrochloric acid. The yield was rather poor (about 20%) with an ethanol solvent, and a large amount of nitrobenzene (about 70%) was recovered. The above-mentioned decrease in the yield may be due to the production of insoluble lead chloride, which covers the surface of the alloy. A small amount of azobenzene (m. p. 68°C; below 3% yield) and hydrazobenzene (m. p. 125—126°C; below 1% yield) was detected as a by-product in the above two experiments.

By using acetic acid as the neutralizing agent, however, nitrobenzene was reduced to azobenzene in a yield greater than 45%, while the yield of aniline decreased (about 25%) either in ethanol or in a water solvent. Efficient stirring, a higher temperature, and a longer reaction time seemed to raise the yield of aniline. Azoxybenzene (m. p. 36°C; yield 3—10%) and hydrazobenzene (below 1% yield) were obtained as by-products.

Without using an acid, nitrobenzene was also reduced to azobenzene in 60—80% yields by vigorously stirring Drynap into an ethanolic solution or an aqueous suspension. In this experiment, small amounts of hydrazobenzene and azoxybenzene were obtained as by-products.

From the above results, it may be concluded that the Drynap reduction of nitrobenzene in a hydrochloric acid solution gives the same product as in an ordinary reduction with mineral acid and such metals as zinc, iron, and tin, and that, in acetic acid or a neutral solution, the reaction gives the same results as in the case of sodium amalgam or sodium ethoxide.[2,3]

Experimental

Materials.—Nitrobenzene and aniline of G. R. grade were used after distillation. Azobenzene, hydrazobenzene, azoxybenzene, and phenylhydroxylamine were derived from nitrobenzene by the usual method[4] and were purified.

Reduction Procedure.—Five grams (0.04 mol.) of nitrobenzene dissolved in 80 ml. of ethanol or suspended in 80 ml. of water was reduced by the addition of 50 g. (corresponding to 0.2 atom of sodium metal) of Drynap (in small portions) at 35—40°C. In acidic reduction, 0.5 mol. of an acid was also added.

After one hour, the ethanol was removed with an

* AB represents azobenzene, HAB: hydrazobenzene, AOB: azoxybenzene.

ethanol solvent, and the reduction mixture was extracted with ether. The ether extract was washed with water (and a 5% sodium hydrogen carbonate solution) and dried over sodium sulfate.

After the evaporation of the ether, the extract was dissolved in benzene, and a small portion of the benzene solution was subjected to thin-layer chromatography in order to check the reduction product. Most of the benzene solution was passed through an alumina column, and each reduction product was collected as a fraction.

In the case of an aqueous suspension, the reaction mixture was extracted with ether and the extract was treated in the way described above.

Each product was purified by recrystallization or by distillation, and was identified by means of mixed-melting-point determination and by thin-layer chromatography. The results are tabulated in Table I.

Thin-layer Chromatography. — The thin-layer chromatoplate (0.5 mm.) used for the check of the product was made with Wako Gel B-10 (silica gel). The spot of the sample was developed with benzene at 18—20°C. The spot of each component developed was detected either by exposing the plate to iodine vapor or by letting the plate stand under ultraviolet light after spraying sulfuric acid on it and heating it at 105°C for 15 min. The R_s values (the ratio of the R_f value to that of azobenzene) were compared with those of the authentic compounds: azobenzene: 1.00; nitrobenzene: 0.97; *p*-hydroxyazobenzene: 0.95; azoxybenzene: 0.89; hydrazobenzene: 0.79; aniline: 0.35; phenylhydroxylamine: 0.15.

The authors wish to thank the Wako Pure Chemical Co., Ltd., for its gift of Drynap.

The Infrared Spectra of *S*-Alkylisothiouronium Salts

By Masahisa HASHIMOTO and Satoshi ARAKAWA

Research Laboratory, Dainippon Pharmaceutical Co., Ltd., Ebie, Fukushima-ku, Osaka

(Received January 6, 1966)

The infrared spectra of thiourea[1,2] and its metal co-ordination complex[3] have been examined by several authors. Kutzelnigg and Mecke made the vibration assignment of the isothiouronium ion.[4] Stam examined the crystal structure of *S*-methylisothiouronium sulfate by X-ray analysis.[5] However, no reports on the characteristic absorption bands of *S*-alkylisothiouronium salts and their deuterated compounds have yet appeared.

The infrared spectra of *S*-alkylisothiouronium salts ($R\text{-}S\text{-}C\langle^{NH_2}_{NH}\cdot HX$) have two characteristic absorption bands in the region from 1675 to 1420 cm^{-1}. On deuteration, they shift to a lower frequency, and two new bands appear in the region from 1198 to 1140 cm^{-1}. These bands were observed in almost the same region when the alkyl groups and salts of *S*-alkylisothiouronium compounds were substituted. Isothiouronium compounds are important as agents protecting against radiation and as the medium of the sulfur-containing compounds. In this note the characteristic absorption bands of *S*-alkylisothiouronium compounds will be presented.

Experimental

The Preparation of Compounds.—Most of the compounds used in this experiment were prepared by

the method described in "Organic Syntheses."[6,7] Their purity was examined by elementary analysis. 1-Phenyl-propenylisothiouronium chloride and ethylene-diisothiouronium bromide were obtained from Dr. Nishimura of this laboratory.[8] Deuterated compounds were obtained by the treatment with deuterium oxide in a sealed tube and by drying in vacuo.

Infrared Spectra.—The infrared spectra were recorded on a Perkin-Elmer model 21 infrared spectrophotometer, equipped with a sodium chloride prism, in the region from 5000 to 650 cm^{-1}. The spectra of crystals were measured in a potassium bromide disk. Deuterated compounds should be measured in either hexachlorobutadiene paste or Nujol mull, but the compounds used in this study did not disperse homogeneously in these media; therefore, the measurements of spectra were carried out in a potassium bromide disk which had been carefully prepared in a simple dry box.

Results and Discussion

Several spectra of *S*-alkylisothiouronium salts are illustrated in Fig. 1, while the observed frequencies of the characteristic absorption bands of *S*-alkylisothiouronium salts are shown in Table I. The two characteristic absorption bands of

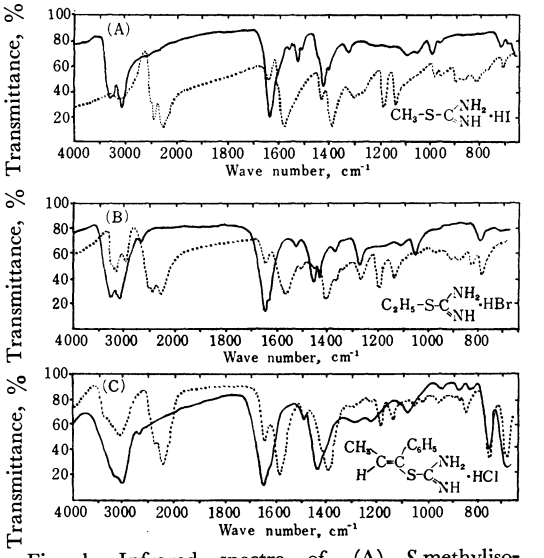

Fig. 1. Infrared spectra of, (A) *S*-methylisothiouronium iodide, (B) *S*-ethylisothiouronium bromide, and (C) 1-phenylpropenylisothiouronium chloride; ——, normal comound, ----, deuterated compound.

S-alkylisothiouronium salts were observed in the 1675—1635 cm^{-1} and 1455—1420 cm^{-1} regions. On deuteration, they shift to the lower frequency regions of 1590—1565 cm^{-1} and 1400—1390 cm^{-1} respectively, as is shown in Table I. The band

8) H. Nishimura, *J. Pharm. Soc. Japan (Yakugaku Zasshi)*, **84**, 930 (1964).

observed at about 1650 cm^{-1} may correspond to the two kinds of NH_2 scissoring vibrations, one of which is coupled with the out-of-phase N–C–N stretching vibration because it is shifted by only 50—90 cm^{-1} on deuteration. The increase in frequency of the out-of-phase N–C–N stretching vibration compared with that (A_2, 1470 cm^{-1}) of thiourea[3] may be explained as resulting from the greater double-bond character of the N–C–N bond; this has been confirmed by X-ray analysis in *S*-methylisothiouronium sulfate.[5] In the metal thiourea complex, the above situation has been reported for the same vibration.[3]

The band observed at about 1440 cm^{-1} may correspond to the band of thiourea at 1417 cm^{-1} (A_1), which has been assigned to the NH_2 rocking vibration coupled with the N–C–N and C=O stretching vibrations. For some compounds, each of the two characteristic absorption bands described above splits into two components, as Table I shows. A quantitative discussion of the nature of these characteristic vibrations could be made possible only by an appropriate normal coordinate treatment. The deuterated compounds give a pair of new bands with a medium intensity at around 1190 cm^{-1} and 1140 cm^{-1}; these bands can be assigned to the ND_2 scissoring vibrations.

Both characteristic absorption bands of *S*-alkylisothiouronium compounds exist in a narrow frequency region when their alkyl groups and their salts are replaced by other groups and salts. *S*-Alkylisothiouronium salt can be distinguished from *O*-alkylisouronium salt, which gives these characteristic absorption bands at slightly higher frequencies. An examination has been made by means of infrared absorption measurements as to whether an interaction of those compounds with alkali halide takes place. However, no change was found in the spectra when those compounds were mixed with alkali halides.

Though only a limited number of compounds were examined, it can be concluded that *S*-alkylisothiouronium salts have their characteristic absorption bands in the 1675—1635 cm^{-1} and 1455—1420 cm^{-1} regions. On deuteration, they shift to 1590—1565 cm^{-1} and 1400—1390 cm^{-1}, and give the two bands in the 1200—1180 cm^{-1} and 1155—1140 cm^{-1} regions. These characteristic absorption bands are expected to be useful for the determination of the *S*-alkylisothiouronium group involved in unknown compounds.

The authors wish to express their gratitude to Drs. Shinsuke Ose, Hideji Takamatsu and Kiyoshi Nakamura of this laboratory for their encouragement. We are also grateful to Dr. Haruki Nishimura for supplying some of the materials.

The Fluorination of Chloromethane, Chlorodifluoromethane and Dichlorofluoromethane*

By Shunji NAGASE, Hajime BABA and Takashi ABE

Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya

(Received January 7, 1966)

The previous papers in this series[1,2] have shown that organic gases which are not very soluble in hydrogen fluoride can be fluorinated controllably by electrochemical fluorination. A good deal has been learned about the electrochemical fluorination of liquid halogenohydrocarbons, including unsaturated ones,[3-8] but no detailed report has yet been made on gaseous compounds.[9]

This paper will deal with the electrochemical fluorination of chloromethane. Such halogenomethanes as chlorodifluoromethane and dichlorofluoromethane were also fluorinated for the sake of comparison.

Chloromethane yielded all the expected fluorinated methanes (tetrafluoromethane, chlorotrifluoromethane, trifluoromethane, chlorodifluoromethane, difluoromethane, chlorofluoromethane and monofluoromethane) in a substantial total yield and with reasonable current efficiency. Chlorination reaction took place to a slight extent during the fluorination, giving traces of dichlorodifluoromethane and dichlorofluoromethane.

Tetrafluoromethane, chlorotrifluoromethane, and trifluoromethane were formed from chlorodifluoromethane, and tetrafluoromethane, chlorotrifluoromethane, trifluoromethane, dichlorodifluoromethane, and chlorodifluoromethane, from dichlorofluoromethane, in reasonable total yields, but with low current efficiencies.

The reaction conditions used for respective samples and the results obtained are summarised

7	13.6	6.7	22.9	22.0	17.6	6.9	10.3

a) All the experiments were carried out with the anodic current density of 2.2 amp./dm^2.
b) Gas volume is expressed in normal condition in this table and in Table II.
c) Calculation of yield of fluorinated product was based on the amount of CH_3Cl fed. A trace of chlorinated by-products, CCl_2F_2 and $CHCl_2F$ was neglected in quantitative calculation.
d) Total current efficiency shown was the sum of the current efficiency of each component based on the following equations, ($n=1, 2$, or 3).

$$CH_3Cl + 2nF = CH_{3-n}F_nCl + nHF \quad (1)$$

$$CH_3Cl + (2n+1)F = CH_{3-n}F_{n+1} + nHF + Cl \quad (2)$$

e) Dilution ratio (CH_3Cl : He) is 1 : 2 by volume.
f) The cell temperature was raised to 6°C at the end of the reaction.

a) All the experiments were carried out with the anodic current density of 2.2 amp./dm^2, with the addition of 10 g. of NaF.
b) Calculation of yield was based on the amount of $CHClF_2$ and $CHCl_2F$ fed, respectively.
c) Calculation of the current efficiency was made with the similar way to that for chloromethane.
d) The cell temperature was raised to 6°C at the end of the reaction.
e) This was introduced together with the carrier of helium (rate at 35 ml./min.) into the cell through the bubbler.

n Tables I and II. It is apparent that the milder fluorination reaction proceeded with an increased sample feed rate, as has also been observed in the fluorination of methane[1] and of ethylene and ethane[2].

Helium appeared to serve satisfactorily as a diluent, and the addition of an increased amount of sodium fluoride resulted in a milder reaction in chloromethane.

The total yield and the current efficiency, as well as the composition of the products, were much affected by the electrolysis temperature.

The order of the facility of replacement between hydrogen and chlorine by fluorine seemed to be indefinite in chloromethane under the fluorination conditions used. In chlorodifluoromethane, the replacement of hydrogen was usually favored over the replacement of chlorine; it yielded a larger amount of chlorotrifluoromethane than that of trifluoromethane.

At lower temperatures, however, this apparent relation was reversed. A similar tendency was observed in dichlorofluoromethane.

Experimental

Apparatus.—Fluorination units, which mainly consisted of an electrolytic cell (1 l. in capacity), a safety tube dipped in mercury, a hydrogen fluoride absorber, an oxygen difluoride absorber, and condensing traps, were virtually identical with those described earlier,[1] but the position of the bubbling arrangement (the bubbler) in the cell and its shape were modified, as is illustrated in Figs. 1 and 2 respectively.

Figure 1 shows a sectional view of the cell with the bubbler, while the plan of the bubbler is shown in Fig. 2. The bubbler consisted of an L-shaped copper tube about 100 mm. in total length and 4 mm. in diameter. At the horizontal portion (about 60 mm. in length) of the tube, a slit-like hole of 2×20 mm. was opened toward the direction of the lower end of the nickel electrodes (the effective surface area of the electrodes was 9.2 dm^2). The hole was wrapped with a filter paper made of polytetrafluoroethylene fiber (Daikin Industries Co.), which was fixed with a copper wire and a polyethylene sheet. The distance between the hole and the lower end of the electrodes was about 8 mm. One end of the copper tube was closed, while the other end was connected to the sample feed tube.

The sample introduced through the sample feed tube was led to the bubbler and came out as a number of minute bubbles in hydrogen fluoride.

Materials and Procedure.—Chloromethane (99.5 %) was obtained from the Matheson Co. Chlorodifluoromethane and dichlorofluoromethane from a commercial cylinder were used after purification by distillation.

The operating procedures used in the fluorination were essentially the same as those described previously.[2] Low-temperature distillation and gas chromatography (a silica gel column was employed) were used for the quantitative analysis of the products. Infrared measurements were frequently carried out in order to identify the components.

A Novel Type of Differential Thermogram Revealed in Potassium Molybdate

By Hiroshi Isozaki and Takeo Ozawa

Electrotechnical Laboratory, Tanashi-machi, Kitatama-gun, Tokyo

(Received January 31, 1966)

Differential thermal analysis experiments have been carried out on anhydrous potassium molybdate, and differential thermograms with novel and interesting features have been obtained. These experiments were conducted in air on a powdered sample packed tightly in a sample cell, by using a new quantitative type apparatus with high sensitivity and resolution.[1] It was previously reported that there are several transition temperatures on anhydrous potassium molybdate;[2-4] 323, 458, 480 and 926°C. In the heating stage, the usual sharp peaks were obtained in our thermograms, as is shown in Fig. 1. The experiments were made up to 500°C; the temperatures and the heats of the transitions were estimated to be 283°C, 8.3±0.1 cal./g. and 457°C, 0.64±0.03 cal./g., respectively, but the third transition, previously reported to occur at 480°C, was not detected. The method of estimating the heats has been described elsewhere.[1]

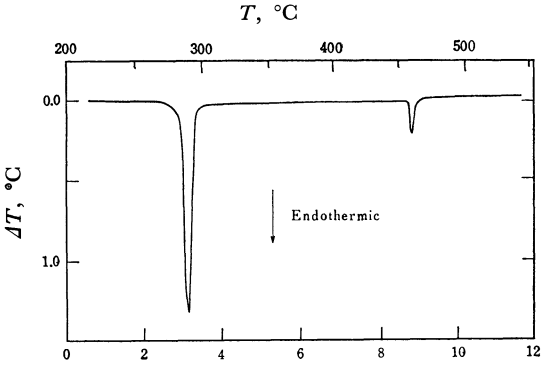

Fig. 1. Differential thermogram of K_2MoO_4 at heating stage in air.
Heating rate, 30°C/hr.

When the sample was heated to about 600°C and then left to be cooled, the transition at 457°C was reversed as a normal peak at the same temperature; however, for the transition at lower temperature, the novel and interesting thermogram which is reproduced in Fig. 2 was obtained. As may be seen in Fig. 2, a saw-tooth-like curve is revealed instead of the usual sharp peak; the transition was supercooled to the temperature range from 152 to 148°C, in comparison with the temperature of the transition, 283°C, in the heating stage. These saw-tooth-like curves are reproducible in nature whenever the sample is cooled after the transition at 283°C, and if one heats the sample up again immediately after the completion of the saw-tooth-like transition, the normal sharp peak is reproduced at 283°C without any change in the peak area. Similar thermograms can be obtained on the same sample by using another type of differential thermal-analysis apparatus with open sample cells.

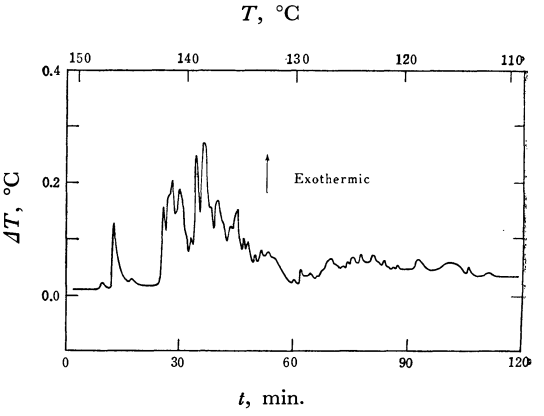

Fig. 2. Differential thermogram of K_2MoO_4 at cooling stage in air.
Cooling rate, about 25°C/hr.

The heats of the transitions in the cooling stage were also estimated. The heat at 457°C was 0.74±0.05 cal./g., somewhat larger than the heats in the heating stage, but the heats of the saw-tooth-like transition were estimated to be about 3.4 cal./g., though the peak area was rather ambiguous and though the recorder did not follow the change exactly because of the long responce time.

Similar thermograms were also obtained in the cooling stage of powdered tin heated to about 450°C. The saw-tooth-like change in the differential temperature began at about 230°C, followed by the usual peak. When the sample was heated again, the usual peak was obtained,

4) G. Petit and J. Mireille, *Compt. rend.*, **244**, 1900 (1957).

and the thermogram was reproduced on the same sample at the second cooling. In this case, oxidation seemed to occur; any oxide would have affected the solidification of the tin.

As may be apparent in its great tendency to supercool, the lower transition is difficult to reverse by cooling, and the transformation could not be propagated beyond the crystalline boundary. Hence, any sample particles would be transformed independently, without influencing each other; this behavior might produce a saw-tooth-like curve. If a differential thermal-analysis apparatus with a high resolution and with a micro amount of a sample were constructed, interesting kinetic aspects of transitions such as this would be elucidated.

The apparatus used has been described elsewhere.[1] Briefly, cylindrical sample cells with threaded lids are inserted in ceramic sample holders set in a metal block, and alumel-chromel thermocouples are inserted between the cells and the cell holders. This arrangement makes the quantitative heat measurement possible.[1] The rates of heating are 60°C/hr. and 30°C/hr.; they are controlled with a PI-type program controller and a SCR regulator. The temperature and the differential temperatures are recorded against the time on a six-point recorder. The sample is of a G. R. grade; it is used without further purification, dried at about 120°C for more than 6 hr., and kept in a desiccator above silica gel. The reference material is calcined alumina.

Studies of Copolymers Containing L-Proline Residue as a Main Constituent. I. The Synthesis of Copolymers of L-Proline with the γ-Ester of L-Glutamic Acid

By Rume SAKAI, Shoichi IKEDA and Toshizo ISEMURA

Department of Biology, Faculty of Science and Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received March 1, 1966)

Polyamino acids are very useful as a model for elucidating the physico-chemical properties of proteins.[1] Many investigators have studied collagen, the major protein component of the connective tissues, which is very specific because of its amino acid composition and structure. The vertebrate collagen contains about 30% glycine residues and more than 20% L-proline residues, inclusive of L-hydroxyproline residues, and its molecular structure is similar to that of poly-L-proline II.[2] Therefore, it is interesting to investigate how the conformation of copolypeptide containing L-proline changes with the L-proline content. We have studied polyamino acids which contain L-proline residue as the main constituent.

In the present communication, the synthesis of copolypeptides with proline will be described. The other constituent is γ-methyl-L-glutamate (γMLG) or γ-benzyl-L-glutamate (γBLG). Some properties of the copolypeptides obtained will also be described briefly. The reason why we have chosen γMLG or γBLG as the other constituent in the copolypeptides is that poly-γ-methyl-L-glutamate (PMLG) and poly-γ-benzyl-L-glutamate (PBLG) have already been thouroghly studied by many investigators.[3] Moreover, the copolypeptides which contain these constituents can be readily converted to water-soluble copolypeptides by the cleavage of γ-ester groups in side chains.

We have carried out the copolymerization in various solvents, including dioxane, pyridine, acetonitrile and nitrobenzene, and have found that nitrobenzene is a solvent suitable for the preparation of copolymers of L-proline with γMLG or γBLG at various molar ratios.

To prepare the copolymers, about 4 g. of *N*-carboxy anhydrides (NCA's) of L-proline and L-glutamate in a desired molar ratio were dissolved or suspended in 100 ml. of a polymerization solvent. Sodium methoxide was used as the initiator for the polymerization. The solution was left standing for about a month. The solution, excepting that in nitrobenzene, became turbid with time, and a precipitate separated out in the course of the reaction. The precipitate thus separated is designated as a precipitate a. After the precipitate had been removed, ethyl ether was added to the solution. Then further precipita-

** Measured in 1,2-dichloroethane - acetic acid (99.5—0.5%).
*** Measured in dichloroacetic acid at 25°C.

tion occurred. This precipitate is designated as the precipitate b. On the other hand, the solution in nitrobenzene remained clear throughout the reaction. When ether was added to the solution, the precipitate separated out as well. The precipitate thus obtained was different in composition from the precipitates a and b. In fact, the specific rotation at 546 mμ in dichloroacetic acid was −376° for the precipitate a and −266° for the precipitate b, when the NCA's of L-proline and γMLG were copolymerized in dioxane at a molar ratio of 4:1. As the specific rotation of PMLG was found to be −37°, and that of poly-L-proline, −510°, in dichloroacetic acid, the precipitate a would contain more proline residues than b. Copoly-1:1-(L-proline, γMLG) which was prepared in nitrobenzene was found to be readily soluble in chloroform, although both poly-L-proline and PMLG were insoluble in it.

Copolymerizations at different L-proline-to-γBLG ratios were performed in nitrobenzene. The amino acid compositions of these copolypeptides were determined by amino acid analysis and by means of studying the ultraviolet absorption at 258 mμ. It was found that the composition is as is shown in Table I.

Poly-L-proline, PBLG and the copolymers obtained above were all soluble in *m*-cresol, dichloroacetic acid and nitrobenzene. In chloroform, PBLG, copoly-1:3-(L-proline, γBLG) and copoly-1:1-(L-proline, γBLG) were soluble, whereas copoly-3:1-(L-proline, γBLG) was soluble in this solvent if the temperature of solution was raised. However, poly-L-proline was not soluble in chloroform. On the other hand, poly-L-proline is the only water-soluble polypeptide among these substances. When copoly-1:1-(L-proline, γBLG) was shaken with a water-chloroform system, no significant amount of the copolymer was found in the water layer. All of these polypeptides excepting poly-L-proline were soluble in 1,2-dichloroethane. Poly-L-proline was soluble in 1,2-dichloroethane containing only 0.5% acetic acid. This solution showed little mutarotation, just as the solutions of other copolymers in 1,2-dichloroethane. The final values of the effective mean residue rotation at 546 mμ are also shown in Table I. As is well known, poly-L-proline can exist in two different forms in solution according to the nature of the solvent.[4] One of these is designated as poly-L-proline I, the specific rotation of which at 546 mμ is about +40°. The other, namely, poly-L-proline II, has its specific rotation of about −500°. Acetic acid is a solvent converting poly-L-proline I to II. Consequently, 1,2-dichloroethane may be a solvent which stabilizes Form I of poly-L-proline. It has already been reported by Katchalski et al.[5] that copolymers can be formed in dioxane with great difficulty. They assumed that the marked tendency of the terminal prolyl residue of a growing chain to react with the NCA of L-proline in preference to the NCA of γBLG was the cause.

However, all the findings reported here support the conception that the true copolypeptides of L-proline with γ-L-glutamate can be formed when nitrobenzene is used as the polymerization solvent.

The authors wish to thank Mr. Keishiro Wada for performing the amino acid analysis.

The Isolation of the Four Isomers of Tris-(L(+)-valinato)cobalt(III)[1]

By Muraji SHIBATA, Hiroaki NISHIKAWA and Yuzo NISHIDA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received March 9, 1966)

Lifschitz[2] isolated α and β forms of tris-(alaninato)cobalt(III) from a reaction mixture of cobalt(III) hydroxide with dextro-alanine, and also separated the α forms into two isomers, α and α'. Recently, Douglas and Yamada[3] found a fourth isomer, β', along with the other three isomers (α, α' and β), in the cobalt(III) complexes of D- and L-alanine. At almost the same time, Dunlop and Gillard[4] reported the isolation of the four isomers of tris-(L(+)-alaninato)-cobalt(III). We have now succeeded in obtaining the analogous four isomers (α, α', β and β') of tris-(L(+)-valinato)cobalt(III).

Following the usual procedure of Ley and Winkler[5] freshly-prepared $Co(OH)_3$ (9.2 g.) was treated with L-valine (34 g.). Red forms (β and β') of the complex precipitated from the reaction mixture as a brown solid containing unreacted $Co(OH)_3$. When the precipitates were extracted with hot water and the solution was evaporated, the more soluble β' isomer crystallized. When the residue from the above was treated with SO_2-water, the β isomer remained as undissolved material. This was then recrystallized from 50% sulfuric acid.

On the other hand, a mother liquor from the reaction mixture was evaporated to dryness, and the resulting solid was treated with ethanol; unreacted L-valine was thereby left. The complex was then taken up in ethanol. The alcohol solution was concentrated under reduced pressure

and then left to stand overnight to precipitate some of the β' isomer. After the β' had been removed, the solution was added to an alumina column previously washed with ethanol. When ethanol was passed through the column, violet forms (α and α') of the complex were eluted out, while a trace amount of the β' remained at the top of the column. The eluted solution was concentrated to a small volume, and then acetone was added to make an ethanol-acetone (1 : 2) solution. The mixed solvent solution was then again chromatographed by using ethanol-acetone (1 : 2) as the eluent. Two violet bands separated completely, and the α and α' were obtained from the first and the second fractions respectively, by evaporation.

Yield: α and α', about 10%; β and β', about 5%.

Found: C, 44.5; H, 7.5; N, 9.4. Calcd. for α-[Co(L-val)$_3$]·1/2H$_2$O: C, 44.5; H, 7.8; N, 10.3%. Found: C, 43.5; H, 7.7; N, 9.4. Calcd. for α'-[Co(L-val)$_3$]·H$_2$O: C, 43.6; H, 7.7; N, 10.2%. Found: C, 39.3; H, 7.5; N, 9.21. Calcd. for β-[Co(L-val)$_3$]·3H$_2$O: C, 40.0; H, 8.0; N, 9.40%. Found: C, 43.2; H, 7.3; N, 10.0. Calcd. for β'-[Co(L-val)$_3$]·H$_2$O: C, 43.6; H, 7.7; N, 10.2%.

The absorption curves are given for only two isomers (α and β) in Fig. 1, since the curves are essentially the same for the others (α' and β'). From these spectra, the α and α' are identified as the 1, 2, 6 (mer) isomer, and the β and β', as the 1, 2, 3 (fac) isomer. The optical rotatory dispersion and circular dichroism curves are given in Figs. 2—3. For the β and β' isomers belonging to the point group C_3, the configurations can be tentatively identified as Λ(D) for the β and Δ (L) for the β' by comparing the C. D. and O. R. D. curves of the present isomers with those of the Λ(D)-tris-(ethylenediamine)cobalt(III) ion.

Optical Resolution and Configuration of *trans*-2, 3-Epoxybutyric Acid[1,2]

By Kaoru HARADA and Jun-ichi OH-HASHI

Institute of Molecular Evolution and Department of Chemistry, University of Miami, Coral Gables, Florida, U.S.A.

(Received March 15, 1966)

The direct epoxidation of the double bond of α, β-unsaturated acids by peroxy acid or by hydrogen peroxide has been known to be generally very slow. (±)-*trans*-2, 3-Epoxybutyric acid (epoxy acid I) was successfully synthesized from crotonic acid (*trans*) by epoxidation with hydrogen peroxide and sodium tungstate.[3] Liwschitz et al.[4] reported the amination of I by treating with benzylamine or ammonia in which they reported the synthesis of (±)-allothreonine.

In the present study, the epoxy acid (I) was resolved by brucine. To determine the configuration of the resolved (−)-*trans*-2, 3-epoxybutyric acid [(−)-epoxy acid] (III), it was treated with benzylamine or ammonia, as was done by Liwschitz et al. The resulting *N*-benzyl allothreonine (IV) was hydrogenolyzed by the use of palladium on charcoal. The isolated amino acid was found to be optically pure (+)-allothreonine (V) and it did not contain any threonine or other amino acid, even in the reaction mixture. This was examined paper chromatographically[5] and also by the automatic amino acid analyzer. This fact suggests that the amination proceeds with a typical S_N2 mechanism and no racemization occurs during the reaction. The configuration of the resulting (+)-allothreonine (V) is known as: 2(s), 3(s). Therefore, the configuration of (−)-*trans*-2, 3-epoxybutyric acid would be 2(R), 3(s). The reaction products of epoxy acid and ammonia showed a large allothreonine peak and a little peak at about the alanine area in the automatic amino acid analyzer, (ratio allo : unknown=99.4 : 0.6). The latter peak might be α-hydroxy β-amino butyric acid (isothreonine) which is a possible ammonolysis product. Attempts to obtain optically active α-hydroxybutyric acid by reduction of (−)-epoxy acid (III) with sodium borohydride and by catalytic hydrogenation were unsuccessful. In each case, mainly β-hydroxybutyric acid was isolated by column chromatography.[6]

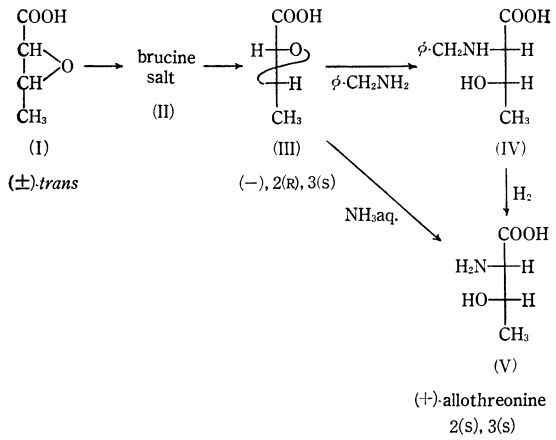

Fig. 1.

Experimental

(±)-*trans*-2, 3-Epoxybutryic Acid (I).—The epoxy acid was prepared by the method of Payne and Williams.[3] M. p. 83°C.

Brucine Salt of (+)-*trans*-2, 3-Epoxybutyric Acid (II).—Epoxy acid (I), 20.4 g. (0.2 mol.), and brucine, 78.8 g. (0.2 mol.), were dissolved in 200 ml. of hot methanol. The solution was filtered and the solvent was evaporated in vacuo. The residual syrup was dissolved in a hot mixture of methanol (20 ml.) and acetone (180 ml.). After cooling, crystallization of brucine salt began by seeding with an authentic specimen which was obtained in another crystallization experiment. After standing overnight at room temperature, the crystals were filtered and were washed with cold acetone. The crystals, 35.0 g., were recrystallized from a hot mixture of methanol (5 ml.) and acetone (95 ml.). Yield, 32.0 g., m. p. 173°C, $[\alpha]_D^{25}=-26.0°$ (*c* 2.1, H_2O).

(−)-*trans*-2, 3-Epoxybutyric Acid (III).—Brucine salt (II), 14.3 g. (0.03 mole), was dissolved in 100 ml. of water. To this solution, 1 N sodium hydroxide solution, 33 ml., was added. The precipitated brucine was separated by filtration. The filtrate was extracted with benzene three times to remove the residual brucine. Concentrated hydrochloric acid was used to bring the pH of the aqueous solution to 2.5. After saturation of the solution with sodium chloride, the epoxy acid was extracted with ether five times (100 ml.×5). The ether solution was dried with anhydrous sodium sulfate. After evaporation of ether, 1.80 g. (60%) of crude III was obtained. This was recrystallized from benzene. 1.20 g. (40%), m. p. 61°C. $[\alpha]_D^{25}=-82.5°$ (*c* 0.59, benzene). Neut. equiv. Found: 102. Calcd. for $C_4H_6O_3$.

(+) *N*-Benzyl-allothreonine (IV).—A mixture of III, 1.53 g., water, 5 ml., and benzylamine, 2 ml., was refluxed for 2 hr. After cooling, the excess benzylamine was removed by ether extraction and the pH of the aqueous solution was brought to 5.5 by the addition of concentrated hydrochloric acid. Precipitated IV was washed with acetone and then with ether. The crude product, 2.2 g. (70%), was recrystallized from *N, N*-dimethylformamide. Yield, 2.0 g. (67%). m. p. 245°C (decomp.), $[\alpha]_D^{25}=+12.2°$ (*c* 1.9, 5 N hydrochloric acid).

Found: C, 63.42; H, 7.20; N, 6.68. Calcd. for $C_{11}H_{15}O_3N$: C, 63.14; H, 7.23; N, 6.69%.

(+)-Allothreonine (V). — (+)-*N*-Benzyl-allothreonine (IV), (2.09 g.), was dissolved in 50 ml. of 50% ethanol. To this solution, 1.0 g. of 5% palladium on charcoal was added and the hydrogenolysis was carried out at room temperature. When the hydrogen uptake ceased, the catalyst was removed by filtration. The filtrate was concentrated in vacuo. The crystalline residue was recrystallized from water and ethanol. Yield, 1.13 g. (95%). This was repurified from water (1) and ethanol (9). Yield, 0.95 g. (80%). M. p. 285°C, $[\alpha]_D^{25}=+32.9°$ (*c* 1.9, N hydrochloric acid).[7]

Found: C, 40.09; H, 7.48; N, 11.57. Calcd. for $C_4H_9O_3N$: C, 40.33; H, 7.62; N, 11.76%.

(+)-Allothreonine (V) by Ammonolysis of III.—A mixture of 1.53 g. (0.015 mol.) of III and 50 ml. of concentrated ammonia (sp. gr. 0.90) was kept at room temperature. After 4 days the reaction mixture was concentrated in vacuo. A weight of 1.43 g. (80%) of crude V was obtained.[8] This was recrystallized from water. Yield, 0.50 g. (28%). m. p. 285°C (decomp.), $[\alpha]_D^{25}=+33.5°$ (*c* 2.0, N hydrochloric acid).[7]

7) D. F. Elliot, *J. Chem. Soc.*, **1950**, 62. (+)-Allothreonine, $[\alpha]_D^{25}=+32.5°$ (*c* 8.2, N HCl).

8) The crude V contains some impurity which is ninhydrin negative. It decomposes at 238°C and shows specific rotation $[\alpha]_D^{25}=+27.2°$ (*c* 2.1, N HCl).

Triterpenoids from the Leaves of *Ilex latifolia* Thunberg

By Shozo YAMADA

Osaka City Institute of Hygiene, Kita-ku, Osaka

(Received March 31, 1966)

From the leaves of *Ilex latifolia* Thunberg, ursolic acid has been isolated by Kariyone et al.[1] and by Takemoto et al.[2] The present paper will deal with the isolation and identification of β-amyrin, lupeol, taraxerol, uvaol and β-sitosterol, besides that of ursolic acid, and with the isolation of an unknown triterpenoid acid, $C_{30}H_{48}O_3$, m. p. 296—298°C (decomp.), from the leaves of this plant. In this experiment, α-amyrin,[3] which has been isolated from the bird-lime of this plant, was not found. The structure of the triterpenoid acid is now being elucidated.

Experimental*

The Isolation and Identification of β-Amyrin, Lupeol, Teraxerol, Uvaol and β-Sitosterol.—Fresh leaves (6 kg.), collected in Kyoto Prefecture in August of 1963, were cut into chops and percolated with alcohol (55 l.) at room temperature for a week. The evaporation of the alcoholic extract afforded a tarry mass, which was then treated with water. A dark green, oily mass then separated, along with a greenish-white, amorphous material, from a turbid tan brown solution (a). The dark green, oily mass gave, after having been treated with a 50% alcoholic solution, a greenish-white amorphous material. The alcoholic filtrate was again evaporated to dryness and treated with water; the aqueous solution was then combined with the foregoing solution a. Both greenish-white, amorphous materials were continuously extracted with hexane. The unextracted amorphous material was found to be almost pure ursolic acid after purification through its potassium salt. The hexane solution was evaporated to dryness, and the residual resinous matter was divided into neutral and acidic fractions. From the acidic fraction, ursolic acid was isolated. When the crystallized neutral fraction was triturated with hexane and recrystallized from 80% alcohol, it afforded needles, m. p. 220—222°C; the identity of which with uvaol which had been synthesized by the lithium aluminium hydride reduction of methyl ursolate was estabished by a mixed melting point determination and an infrared comparison.

From the mother liquor of uvaol needles, m. p. 258—266°C, were separated. These were purified by silica-gel chromatography, giving needles, m. p. 272—274°C, which were found to be identical with taraxerol by a mixed melting point determination and an infrared comparison.

The mother liquor of taraxerol was mixed with silica gel and was fractionated by silica-gel chromatography, using a *n*-hexane - ethyl acetate mixture as the elution solvent.

Fractions showing R′ values of 0.80—0.82 on TLC were collected and recrystallized from alcohol or acetone to afford fine needles, m. p. 148—167°C. These were then acetylated with acetic anhydride and concentrated sulfuric acid, and the acetate mixture was fractionally recrystallized from ethyl acetate. The less soluble part of acetate in ethyl acetate gave flat rectangular plates, m. p. 293—294°C; undepressed after admixture with an authentic sample of taraxeryl acetate; its identity was confirmed by an infrared comparison.

The more soluble part gave, after tedious recrystallization from ethyl acetate, rods, m. p. 234—236°C, and floculent needles, m. p. 211—213°C. The former and its deacetylated alcohol (m. p. 195—196°C) were shown to be identical with β-amyrin acetate and β-amyrin, respectively, by a mixed melting point determination and an infrared comparison. The deacetylation of the latter gave microneedles, m. p. 210—211°C, from acetone. Its benzoate showed a m. p. of 263°C (from ethyl acetate). The identities of the alcohol and its benzoate were confirmed by a mixed melting point determination and by an infrared comparison with authentic samples of lupeol and its benzoate.

From the fractions showing an R_f value of 0.70, glistening leaflets, m. p. 135—136°C, undepressed after admixture with an authentic sample of β-sitosterol, were obtained.

Uvaol was also obtained from the fractions showing an R_f value of 0.50—0.53.

Some crystalline materials were obtained from the fractions showing lower R_f values, but they were not determined.

The Isolation of a Triterpenoid Acid, $C_{30}H_{48}O_3$.—The aqueous solution a was extracted with ether and, after the ether had been removed, was treated with a neutral lead acetate solution. The precipitated yel-

lowish-white mud was dried and extracted repeatedly with boiling alcohol. The combined alcohol extracts were evaporated under reduced pressure to afford yellowish-white powder upon drying. This powder was crystallized from pyridine when small portions of water were added; then it was recrystallized from a diluted methanol or ethanol solution to give fine needles, m. p. 220—222°C. This compound afforded, on hydrolysis with 6 N hydrochloric acid in methanol, a triterpenoid acid, m. p. 296—298°C (decomp.); $[\alpha]_D^{12}$ +283° (*c* 1.03, chloroform : methanol = 1 : 1), whose R_f value on TLC was 0.32—0.33* (Fig. 1). Liebermann-Burchard reaction: purple; tetranitromethane test: yellow.

Found: C, 79.08, 78.94; H, 10.18, 10.07;. Calcd. for $C_{30}H_{48}O_3$: C, 78.90; H, 10.59%.

The acetylation of the acid with acetic anhydride and pyridine gave a reversible acetate, m. p. 262—264°C (decomp.).

Found: C, 77.12, 77.12; H, 9.66, 9.81. Calcd. for $C_{32}H_{50}O_4$: C, 77.06; H, 10.11%.

When the aqueous solution a (2 l.) stood after acidification with hydrochloric acid, there was precipitated a large amount of a reddish-tan resinous matter which solidified upon being dried (31 g.). This was found to be a mixture of glucosides containing the above-mentioned glucoside, m. p. 220—222°C; on hydrolysis with hydrochloric acid, it gave the above-mentioned triterpenoid acid and several neutral compounds (Fig. 1).

Grateful acknowledgement is hereby made to Dr. Nobumasa Nakayama and Dr. Yoshio Kurayuki of this Institute for their interest and encouragement throughout the progress of this work.

* On the same TLC, ursolic acid showed an R_f value of 0.35—0.36 and oleanolic acid, one of 0.38.

SHORT COMMUNICATIONS

The Formation of Uranium Trioxide by the Oxidation of Uranium Iodides at Low Temperatures

By Muneo HANDA

Division of Fuel Research and Development, Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki

(Received December 6, 1965)

The oxidations of uranium tetraiodide and triiodide by oxygen were studied using a special experimental apparatus, in which the column of a gas chromatograph was replaced with an electric furnace and traps of water vapor, oxygen, and iodine. With this apparatus, studies can be made easily and accurately of chemical reactions between gases and solids, even when such solids cannot be treated in the air. This is because measurements can be made on the gases consumed or released during the reaction. The heating curves (the rate of temperature increase: 2°C/min.) obtained for the reactions between uranium iodides and oxygen are shown in Fig. 1. The peaks appearing in the heating curves correspond to the

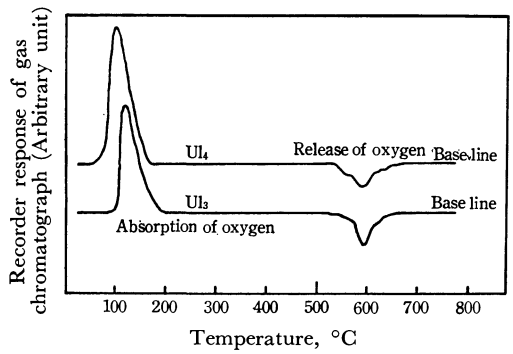

Fig. 1. Heating curves of uranium iodides.
Sample weight UI_4: 0.152 g.
UI_3: 0.141 g.
Partial pressure of oxygen: 1/10 atm.
Rate of temperature increase: 2°C/min.

absorption of oxygen, while the valleys correspond to the release of oxygen during the reaction. The oxidations of uranium tetraiodide and of uranium triiodide by oxygen, whose partial pressure was one-tenth of the atmosphere, started at temperatures of about 60 and 100°C respectively. When the temperatures were raised to about 600°C, the products resulting from the oxidations of uranium iodides released oxygen; the volume of oxygen released was about one-tenth of that absorbed in the oxidation. The colors of the compounds obtained by the oxidations of uranium tetraiodide and triiodide were both brown. When these brown-colored compounds were heated to about 600°C, oxygen was released and they turned black at the same time. The brown and the black compounds were then taken out from the apparatus for chemical and X-ray analyses; these analyses showed that the brown compounds were uranium trioxide and the black compounds, triuranium octoxide. Therefore, the peaks of the absorption of oxygen in the heating curves for uranium iodides appeared when the uranium iodides were oxidized to uranium trioxide; the valleys of the release of oxygen, on the other hand, were caused by the decomposition of uranium trioxide to triuranium octoxide. The reactions involved are as follows:

$$\overset{60°C}{2UI_4 + 3O_2 = 2UO_3 + 4I_2} \quad (1)$$

$$\overset{100°C}{2UI_3 + 3O_2 = 2UO_3 + 3I_2} \quad (2)$$

$$\overset{600\text{—}700°C}{3UI_4 + 4O_2 = U_3O_8 + 6I_2} \quad (3)$$

$$\overset{600\text{—}700°C}{6UI_3 + 8O_2 = 2U_3O_8 + 9I_2} \quad (4)$$

It has been reported by Foster and Tvrzicky[1] that oxygen or dry air converts uranium iodides to triuranium octoxide at elevated temperatures, and to uranyl iodide (UO_2I_2) or uranous oxyiodide (UOI_2) at room temperature. An attempt was therefore made by the present author to obtain the same compounds at various temperatures and at various oxygen partial pressures using the same method; however, his experiments all failed to produce such compounds. In the course of the experiments, however, he observed the reaction in which the oxidation proceeded in two stages as the temperature was raised. The oxidations of uranium iodides at low temperatures, represented by the two chemical equations, 1 and 2, may be useful for the preparation of pure uranium trioxide.

The Proton Magnetic Resonance of Thianaphthenes. IV. The Estimation of the Chemical Shifts of Thianaphthene by Partial Deuteration

By Kensuke TAKAHASHI, Ichi ITO and Yasuo MATSUKI

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

(Received August 1, 1966)

In our previous communications[1-3] we have discussed some long-range coupling constants observed in thianaphthenes. The spectrum of thianaphthene itself is too complex to analyze. Therefore we tried to prepare the 5-, 6- and 7-deuterothianaphthenes and to analyze their proton spectra. Deuteration was done by the reduction of the corresponding bromothianaphthenes. The reduction was carried out by zinc and deuterated acetic acid. Details of the preparation will be published later somewhere. The spectra of the deuterated products are shown in Fig. 1. Spectra were taken in 5 mole per cent solutions in carbon tetrachloride, in cyclohexane and in acetone, with a small amount of tetramethylsilane as an internal reference. The first-order analyses are possible in the cases of 5- and 6-deuterothianaphthenes but not in the case of 7-deuterothianaphthene. The spectrum of 7-deuterothianaphthene is an ABX type which is very close to AA'X type. The results of the chemmical shifts obtained are shown in Table I. Agreement of the chemical shifts given for three deuterated

compounds is good enough to estimate the chemical shifts of thianaphthene, as is shown in the lowest line in Table I. A characteristic point of thianaphthene is that the chemical shifts of the 5- and the 6-hydrogens are almost the same but the former seems to be a little larger than the latter. The difference of the chemical shifts of about 0.5 p. p. m. between the 4- and 5- or between the 6- and 7-hydrogens will be explained by the ring current effect similar to that of natpthalene but it is somewhat larger than that of naphthalene.[4] Therefore the whole part of the difference can not be explained by only the ring current effect. The chemical shift of the 7-hydrogen is larger than that of the 4-hydrogen. This may be due to the magnetic anisotropy or electronic effect of the sulfur atom. Approximate values of the coupling constants between ring hydrogens for deuterothianaphthenes are following: $J_{23}=5._5$, $J_{26}=0.5$, $J_{37}=0.7_5$, $J_{45}=J_{67}=8._0-7._5$, $J_{56}=7._5-7._0$, $J_{46}=J_{57}=1._5-1._0$, $J_{47}=0.7$ c. p. s. respectively. Some of the coupling constants were determined only approximately because of the broadness of the lines caused by the interaction with the deuterium.

The Lifetime of Excimer Fluorescence of Naphthalene

By Tohru AZUMI* and Hiroshi AZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received December 6, 1965)

The radiative lifetimes of the excimer fluorescence of naphthalene are calculated for excimers of various geometrical configurations. The results vary, to a great extent, with the configurations, but with a previously-suggested configuration the calculated lifetime is 6×10^{-6} sec. This is within a factor of 5 of the experimental results.

The lifetime of the excimer fluorescence has been a subject of dispute for a long time. Williams,[1] in an attempt to interpret the delayed fluorescence he observed from the vapor of several aromatic compounds, assumed the production of an excimer, which, after several milliseconds, dissociates into a monomer ground-state molecule and a monomer excited-state molecule. This idea was also incorporated by Stevens, Hutton, and Porter[2] in their interpretation of the delayed fluorescence of phenanthrene species observed from anthracene vapor. These interpretations received some support from the theoretical considerations of Hoijtink,[3] who showed that if the excimer has center of symmetry, excimer luminescence is forbidden and that, hence, apart from radiationless conversion to the ground state, the only way of losing its excess energy is the dissociation to monomers. However, this simple treatment does not satisfactorily explain the fact that excimer fluorescence is indeed observed for a number of molecules. Questions have, therefore, arisen as to whether the excimer fluorescence is a dipole-allowed transition or an environmentally-allowed forbidden transition. Azumi and McGlynn[4] observed delayed excimer fluorescence in rigid glass media, and, in view of their experimental evidence, interpreted this duration as being due to the inherent forbidden character of excimer luminescence. Later work by Smith and McGlynn,[5] however, revealed that the delayed excimer luminescence is due to an excimer produced by triplet-triplet annihilation; namely, the duration of the excimer luminescence is ascribed to the delay in the production of excimer species, and not to the delay in the luminescence itself. In addition to these studies, recent studies of delayed fluorescence have thrown some doubt on the earlier interpretations given by Williams[1] and by Stevens et al.[2] As Azumi and McGlynn[6] suggested, the vapor-delayed fluorescence reported by these researchers might also be interpreted in terms of triplet-triplet annihilation, in which case there is no necessity of assuming any excimer formation. In this way it became questionable whether an excimer of a long duration really exists or not. Things have, however, become clearer since excellent lifetime measurements of excimer fluorescence were reported by Birks, Dyson, and King.[7] The resluts show that the lifetime of excimer fluorescence is quite short—in fact, shorter than the lifetime of normal monomer fluorescence.

In a previous paper[8] the present authors calculated the energy of the excimer luminescence of naphthalene with a variety of geometrical configurations. Starting from the excimer of such a configuration that one of the molecules which constitute an excimer is exactly superposed, at some distance, over the other, the authors examined the effect of the rotation of one molecule with respect to the other on the energy of the excimer luminescence. The principal axes of the two molecules were kept common, and the intermolecular distance was chosen as 3 Å. The excimer configuration for which the calculations were carried out is schematically represented in Fig. 1. It was shown that excimer is stable when the angle, α, of rotation is 75 degrees; this configuration was proposed as the one responsible for excimer fluorescence.

In this paper, the radiative lifetime of naphthalene excimer fluorescence will be calculated for excimers of the same geometrical configurations as in the previous paper[8] (i. e., those represented in Fig. 1). It will also aim to check if the previously-developed

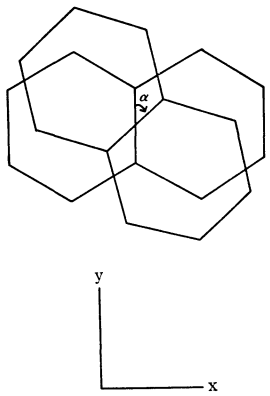

Fig. 1

model of an excimer, which gives satisfactory energy data, also gives reasonable lifetime data.

The Method of Calculation

The general scheme of calculation is identical to that developed in previous papers.[8,9] The highest-occupied and the lowest-vacant molecular orbitals of one ground state molecule (say, molecule A) are designated, respectively, as ϕ_1 and ϕ_2, and the corresponding orbitals of the other molecule (say, molecule B), as θ_1 and θ_2. ϕ_1 and ϕ_2 are orthogonal, as are also θ_1 and θ_2. It is assumed that an orthogonality exists between ϕ_1 and θ_2 and between θ_1 and ϕ_2. The overlap integral between ϕ_1 and θ_1 is designated by S_1.

Wave Functions.—The dimeric wave function for the ground state is:

$$|G\rangle = (1 - 2S_1^2 + S_1^4)^{-1/2}|\phi_1\bar{\phi}_1\theta_1\bar{\theta}_1| \quad (1)$$

The wave function for the excimer state is expressed as a linear combination of four zeroth-order wave functions:

$$|E\rangle = a\psi_A + b\psi_B + c\psi_C + d\psi_D \quad (2)$$

where:

$$\psi_A = \{2(1-S_1^2)\}^{-1/2}\{|\phi_1\bar{\phi}_1\theta_1\bar{\theta}_2| + |\phi_1\bar{\phi}_1\theta_2\bar{\theta}_1|\} \quad (3)$$

$$\psi_B = \{2(1-S_1^2)\}^{-1/2}\{|\phi_1\bar{\phi}_2\theta_1\bar{\theta}_1| + |\phi_2\bar{\phi}_1\theta_1\bar{\theta}_1|\} \quad (4)$$

$$\psi_C = \{2(1-S_1^2)\}^{-1/2}\{|\phi_1\bar{\theta}_2\theta_1\bar{\theta}_1| + |\theta_2\bar{\phi}_1\theta_1\bar{\theta}_1|\} \quad (5)$$

$$\psi_D = \{2(1-S_1^2)\}^{-1/2}\{|\phi_1\bar{\phi}_1\phi_2\bar{\theta}_1| + |\phi_1\bar{\phi}_1\theta_1\bar{\phi}_2|\} \quad (6)$$

The mixing coefficients, a, b, c, and d, at different α values were evaluated in a previous paper[8]; they are tabulated in Table I of Ref. 8.

9) T. Azumi, A. T. Armstrong and S. P. McGlynn, *J. Chem. Phys.*, **41**, 3839 (1964).

Transition Moment.—The transition moment length for the excimer luminescence is expressed as:

$$\begin{aligned}\mu_E &= \langle G|\boldsymbol{R}|E\rangle \\ &= \{2(1 - S_1^2)/(1 - 2S_1^2 + S_1^4)\}^{1/2} \\ &\quad \times [\langle\phi_1|\boldsymbol{R}|\phi_2\rangle\{(a + b) - S_1(c + d)\} \\ &\quad + \langle\phi_1|\boldsymbol{R}|\theta_2\rangle\{(c + d) - S_1(a + b)\}]\end{aligned} \quad (7)$$

μ_E is calibrated by taking the experimental transition moment length for the monomer ^{1}A-^{1}L$_a$ transition, μ_M, as a standard, so that the correct transition moment be obtained at an infinite separation of the two molecules. A theoretical evaluation of μ_M yields:

$$\mu_M = \sqrt{2}\,\langle\phi_1|\boldsymbol{R}|\phi_2\rangle \quad (8)$$

μ_E is then calculated by the equation:

$$\begin{aligned}\mu_E = \mu_M^{exp}&\{(1-S_1^2)/(1-2S_1^2+S_1^4)\}^{1/2} \\ &\times[(a+b)-S_1(c+d)+\{(c+d)- \\ &S_1(a+b)\}\langle\phi_1|\boldsymbol{R}|\theta_2\rangle/\langle\phi_1|\boldsymbol{R}|\phi_2\rangle]\end{aligned} \quad (9)$$

where μ_M^{exp} is the experimental transition moment length for the monomer ^{1}A-^{1}L$_a$ absorption and has the value:

$$\mu_M^{exp} = 0.6923\,\text{Å} \quad (10)$$

The lifetime of the excimer luminescence is then evaluated by the equation:

$$\tau_E = \frac{3h}{64\pi^4\tilde{\nu}^3e^2\mu_E^2} \quad (11)$$

MO Integrals in Terms of AO Integrals.—The MO overlap integral, S_1, is evaluated by:

$$S_1 = \sum_r\sum_s C_{r1}C_{s1}\langle r_A \mid s_B\rangle \quad (12)$$

where C_{r1} is the Hückel coefficient of the atomic orbital, r, in ϕ_1, $\langle r_A|s_B\rangle$ is the overlap integral between the atomic orbital, r, in the A molecule and the atomic orbital, s, in the B molecule, it is evaluated by the formulas given by Parr and Crawford.[10]

The intermolecular transition moment length $\langle\phi_1|\boldsymbol{R}|\theta_2\rangle$ is expressed as:

$$\langle\phi_1|\boldsymbol{R}|\theta_2\rangle = [\langle\phi_1|\boldsymbol{x}|\theta_2\rangle^2+\langle\phi_1|\boldsymbol{y}|\theta_2\rangle^2]^{1/2} \quad (13)$$

where x and y axes are along the long and short axes of one molecule, as are shown in Fig. 1. The z axes component need not be considered, since the group theoretical treatment[11] shows that the excimer fluorescence is invariably polarized in-plane when the principal axes of the two molecules which constitute an excimer are common. The x component is further expressed in the following way:

10) R. G. Parr and B. L. Crawford, ibid., **16**, 1049 (1948).

11) T. Azumi and S. P. McGlynn, ibid., **42**, 1675 (1965).

$$\langle\phi_1|\boldsymbol{x}|\theta_2\rangle = \sum_r\sum_s C_{r1}C_{s2}\langle r_A|\boldsymbol{x}|s_B\rangle$$
$$= (1/2)\sum_r\sum_s C_{r1}C_{s2}\langle r_A|s_B\rangle$$
$$\times\{x(r_A) + x(s_B)\} \quad (14)$$

where C_{s2} is the Hückel coefficient of atomic orbitals in ϕ_2 (or θ_2), and where $x(r_A)$ and $x(s_B)$ are the x coordinates of r_A and s_B respectively. Here, the center of the naphthalene molecule is taken as the origin of the coordinate, and axes are chosen along the molecular axes of the A molecule (Fig. 1). Then,

$$x(s_B) = \cos\alpha\, x(s_A) + \sin\alpha\, y(s_A) \quad (15)$$

Consequently,

$$\langle\phi_1|\boldsymbol{x}|\theta_2\rangle = (1/2)\sum_r\sum_s C_{r1}C_{s2}\langle r_A|s_B\rangle$$
$$\times\{x(r_A)+\cos\alpha x(s_A)+\sin\alpha y(s_A)\} \quad (16)$$

The y component is obtained similarly:

$$\langle\phi_1|\boldsymbol{y}|\theta_2\rangle = (1/2)\sum_r\sum_s C_{r1}C_{s2}\langle r_A|s_B\rangle$$
$$\times\{y(r_A)-\sin\alpha x(s_A)+\cos\alpha y(s_A)\} \quad (17)$$

The intramolecular transition moment, $\langle\phi_1|\boldsymbol{R}|\phi_2\rangle$, in Eq. 9 is similarly obtained; the result is:

$$\langle\phi_1|\boldsymbol{R}|\phi_2\rangle = 0.8137\,\text{Å} \quad (18)$$

Results and Discussion

The calculated lifetimes at different configurations are shown in Table I. The only results of any physical significance are those around the stable configurations, $\alpha=75°$ and $\alpha=0°$. The excimer is most unstable around $30°<\alpha<50°$ (see Fig. 4 of the previous paper[8]); the calculated values in Table I for such unstable configurations are those of virtual states and are thus, in fact, meaningless. The fact that quite unreasonable data are obtained around $30°<\alpha<50°$ configurations of the excimer is consistent with the potential energy diagram obtained in the previous paper. At the previously suggested stable configuration, $\alpha=75°$, the calculated lifetime is 6.3×10^{-6} sec.

The lifetimes of the naphthalene excimer fluorescence recently observed by Mataga, Tomura, and Nishimura[12] are $\sim10^{-7}$ sec, but the contribution of the radiative decay is unknown and a direct comparison with the calculated result is impossible. There are, unfortunately, no other experimental data on the lifetime of the naphthalene excimer. However, lifetime data for 1, 6-dimethylnaphthalene were obtained by Birks and King.[13]

Table I. Lifetimes of excimer fluorescence at variety of geometrical configurations

α	μ_E, Å	Lifetime, sec.
0	0	—
5	-2.69×10^{-2}	2.84×10^{-5}
10	-2.54×10^{-2}	3.18×10^{-5}
15	-2.29×10^{-2}	3.92×10^{-5}
20	-1.89×10^{-2}	5.75×10^{-5}
25	-1.31×10^{-2}	1.20×10^{-4}
30	-5.57×10^{-3}	6.61×10^{-4}
35	-1.57×10^{-5}	8.30×10
40	-8.63×10^{-3}	2.76×10^{-4}
45	-1.53×10^{-3}	8.77×10^{-3}
50	-5.88×10^{-3}	5.94×10^{-4}
55	2.83×10^{-3}	2.57×10^{-3}
60	1.58×10^{-2}	8.25×10^{-5}
65	2.97×10^{-2}	2.33×10^{-5}
70	4.35×10^{-2}	1.08×10^{-5}
75	5.71×10^{-2}	6.30×10^{-6}
80	7.17×10^{-2}	4.00×10^{-6}
85	9.49×10^{-2}	2.28×10^{-6}
90	5.91×10^{-1}	5.89×10^{-8}

Since the excimer fluorescence of dimethyl derivatives of naphthalene behaves quite like that of naphthalene,[14] it is reasonable to assume that the lifetime also does not differ much. Radiative rate parameters for the excimer fluorescence of 1, 6-dimethylnaphthalene[13] is $1.4\times10^6\,\text{sec}^{-1}$ in an n-heptane solution and $2.2\times10^6\,\text{sec}^{-1}$ in pure liquid. When calibration is made to a medium whose reflactive index is unity, the rate parameters are $0.73\times10^6\,\text{sec}^{-1}$ for the former, and $0.85\times10^6\,\text{sec}^{-1}$ for the latter. These data correspond to radiative excimer lifetimes in vacuo of $1.2-1.4\times10^{-6}$ sec. Hence, the lifetime calculated in this paper, 6.3×10^{-6} sec., is within a factor of 5 of the experimental value. The fairly good agreement with the experimental value is another support of the excimer configuration suggested in a previous paper.[8]

The above consideration is confined to the lifetime at one of the two stable configurations, i. e., $\alpha=75°$. We have disregarded the lifetime at the other stable configuration, i. e., at $\alpha=0°$, since excimer luminescence is forbidden there. It might be argued that the allowed component may arise by the thermal motion of the two molecules of the excimer. In order to check this, let the thermal motion be confined to the thermal vibration needed to change the angle, α. It may then be seen, from the energy data given in the previous paper, that the α which can be changed by the energy of the thermal motion, $1.5kT=0.04$eV., is approximately 5°. Even though there is a considerable increase in the transition probability for this change of α, the calculated lifetime

at $\alpha=5°$ of 3×10^{-5} sec., which is 20 times larger than the experimental value, still can not account for the observed lifetime of the excimer fluorescence.

The present calculations were carried out for excimers in which the two molecular planes are parallel and which have principal axes in common. This is, in fact, rather a freakish situation. To treat the excimers of random orientations, however, is quite difficult, if not impossible, and, at any rate, beyond the range of the present paper. The present treatment may, therefore, only be considered as a prototype calculation. Our suggestion that the excimer of $\alpha=75°$ is responsible for the excimer fluorescence is valid only within the framework of the above specified model. The only conclusion of any general validity may be that the geometrical configuration of the excimer which is responsible for excimer fluorescence is definitely different from the one of the highest symmetry.

The numerical calculations were carried out on the NEAC 2230 at the Computation Center, Tohoku University.

The authors wish to express their appreciation to Dr. John B. Birks of Manchester University for valuable discussions and for supplying them his lifetime data prior to publication. They are also indebted to Dr. Yoshito Amako for fruitful discussions.

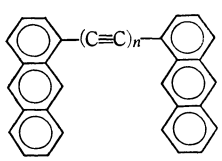
(Received January 18, 1966)

The electronic spectra of 1, 1'-dianthrylpoly-ynes have been studied by Hückel MO theory on the basis on various approximations for resonance integrals. A good agreement between theoretical and experimental values is obtained from a modified bond-alternation approximation. This result shows that the contribution of a cumulene-type ionic structure to the ground state of the molecule increases with an increase in the number of the triple bonds.

Recently, two of the present authors (S. A. and M. N.)[2)] found a peculiar spectral shift in the electronic absorption spectra of 1, 1'-dianthryl-poly-ynes (I). In this series, the maxima of the longest wave length absorptions increase linearly with the square of the number of the triple bonds. This fact forms a striking contrast to a well-known spectral shift in the series of linear polyenes or linear poly-ynes, in which the square of the absorption maxima, λ^2_{max}, varies linearly with the number of the conjugated multiple bonds.[3,4)] In order to elucidate this interesting spectral shift, we have carried out some MO calculations of the electronic structure of 1, 1'-dianthrylpoly-ynes.



(I)

Calculation

The calculations were carried out in the framework of the Hückel MO theory. All interpretations of the spectra of polyenes by the wave-mechanical method have hitherto required that there should be an alternation of double and single

bonds along the polyene chain.[5-9] This requirement is most important for the interpretation of the spectra of poly-ynes. It is, however, desirable to carry out calculations on the basis on the following approximations: All conventional Coulomb integrals are assigned the same value, α. According to the study by Hinze and Jaffe,[10] the valence-state electronegativity of the carbon π-orbital is practically independent of its hybridization, so the constant Coulomb integral approximation is reasonable. The resonance integral associated with the aromatic carbon-carbon bond is assigned a constant value, β. On the other hand, there is at present no definite method for the estimation of the resonance integrals associated with a triple and a single bond of the polyacetylene system. In this paper, the following approximations will tentatively be used;

I Constant β approximation

$$\beta_{C\equiv C} = \beta_{C-C} = 1.0\,\beta$$

II Bond alternation 1

$$\beta_{C\equiv C} = 1.1\,\beta,\ \beta_{C-C} = 0.9\,\beta$$

III Bond alternation 2

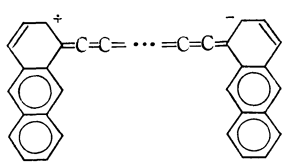
$$\beta_{C\equiv C} = 1.2\,\beta,\ \beta_{C-C} = 0.8\,\beta$$

IV Modified bond alternation

$$\beta_{C\equiv C} = (1 + 1/(n+4))\beta$$

$$\beta_{C-C} = (1 - 1/(n+4))\beta$$

Approximation I is most usual. Approximation II is suitable for polyenes.[11] The value of 1.2β in Approximation III was estimated for acetylene from an empirical relation.[12] Approximation IV is proposed with the following points in mind; for 1, 1'-dianthrylpoly-yne, we can write down twenty-five cumulene-type ionic structures (II), in which the formal charges move in the anthracene nuclei:



(II)

In structure I, the bond alternation in poly-yne chain might be present. However, a rather uniform electron distribution may be expected in the cumulene chain in structure II. Therefore, the energy difference between the structure I and a given cumulene-type ionic structure may be given by;

$$\Delta E = I_C - A_C - n\Delta\gamma + C$$

where I_C and A_C are the ionization potential and the electron affinity of the carbon atom respectively. The core energy difference between the two structures is included in the correction term, C. $\Delta\gamma$ measures the energy difference between the electron repulsions in a classical triple bond, γ_t, and those in a cumulene-type bond, γ_c. It is natural that γ_t should be larger than γ_c, because in the classical triple bond the four electrons are packed in a small space. Therefore, the contributions of the cumulene-type ionic structures to the ground state of the molecule would increase with the number of the triple bonds, n, because the energy difference between the ionic and the non-ionic structures decreases with n. This situation might be characteristic of a poly-yne system. In order to take this situation into account, the values of $\beta_{C\equiv C}$ and β_{C-C} are varied with n, The longest-wavelength absorption in anthracene is polarized in the direction of the molecular short axis (^1L_a species).[13] Similarly, the absorptions of poly-ynes are also polarized in this direction. It is, therefore, reasonable to assign the longest-wavelength absorption of 1, 1'-dianthrylpoly-yne to the ^1L_a species. The absorption wavelengths of a conjugated system can be calculated by the Hückel MO theory, using very simple correlation equations.[12] The equation for the ^1L_a species is expressed by;

$$\lambda(^1L_a) = 474(\Delta m)^{-1/2} - 145\ m\mu$$

where $\lambda(^1L_a)$ is the absorption wavelength. Δm is the energy difference expressed in β between the highest-occupied and the lowest-vacant orbitals of the molecule. The calculated $\lambda(^1L_a)$'s for the various approximations are given in Table I and in Fig. 1, together with the experimental values.

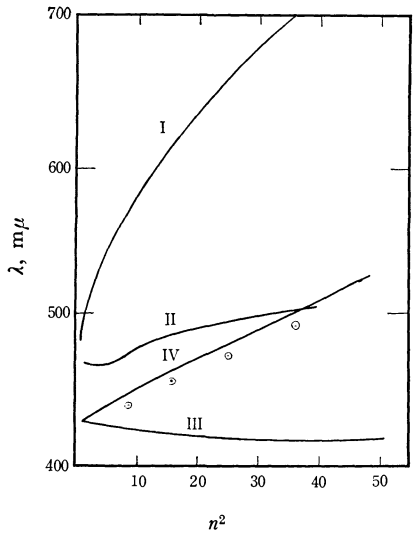

Fig. 1. The predicted and observed absorption wavelengths in the 1-1'-dianthrylpoly-ynes.

As Fig. 1 shows, the calculated results based on Approximation IV and the experimental data agree well. It should be noted that Approximation III leads to the very strange result that the $\lambda(^1L_a)$ value should decrease with n.

Conclusion

The present study has shown that the interpretation of the peculiar spectral shift in a series of 1, 1'-dianthrylpoly-ynes in the visible region requires a modified bond-alternation approximation which assumes that the contribution of cumulene-type ionic structures to the ground state of the molecule increases with an increase in the number of triple bonds. All other approximations give unsatisfactory results.

We are grateful to Professor Kenzo Jo of Osaka University for providing machine time of the NEAC 2203 there. One of authors (K. N.) wishes also to acknowledge the most generous financial support of the Mellon Institute.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 2322—2331 (1966)

The Crystal and Molecular Structure of 8, 8-Dicyanoheptafulvene

By Hirotaka SHIMANOUCHI,* Tamaichi ASHIDA, Yoshio SASADA and Masao KAKUDO

Institute for Protein Research, Osaka University, Kita-ku, Osaka

and Ichiro MURATA and Yoshio KITAHARA

Department of Chemistry, Faculty of Science, Tokoku University, Katahira-cho, Sendai

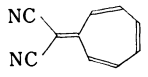
(Received February 3, 1966)

Crystals of 8, 8-dicyanoheptafulvene, $C_{10}H_6N_2$, are monoclinic, with two molecules in a unit cell with the dimensions $a=7.84$, $b=13.14$, $c=3.99$ Å, and $\beta=97.9°$; the space group is $P2_1/m$. The intensities were recorded on multiple-film equi-inclination Weissenberg photographs and measured visually against a standard scale. A trial structure was constructed from the Patterson projections, $P(u, v)$ and $P(u, w)$, and a Harker section, $P(u, 1/2, w)$. The atomic coordinates and anisotropic temperature factors were refined by the least-squares method. The final R factor for (hkl) reflections is 0.107. A considerable bond alternation in the conjugated seven-membered ring has been observed. The average long and short bond lengths in the ring are 1.44 and 1.34 Å respectively. The shortest C=C bond measures 1.31 Å, which is shorter than that in ethylene. The exocyclic C=C bond length is 1.42 Å, suggesting a considerable dipolar resonance structure, one which may be responsible for the stability of the compound. The C≡N bond length is 1.13 Å. The molecule deviates slightly from being planar; it lies nearly parallel to the (101) plane. All the intermolecular separations correspond to normal van der Waals interactions; the perpendicular distance between the molecular planes is 3.4 Å. The thermal motion was interpreted in terms of rigid body vibrations, and the bond lengths and angles were corrected for the rotational oscillations.

Recently 8, 8-dicyanoheptafulvene $C_{10}H_6N_2$ (I), a derivative of the non-alternant hydrocarbon

* On leave from Department of Chemistry, Faculty of Science, Tohoku University.

heptafulvene, has been synthesized in several laboratories.[1-3]



I

While heptafulvene itself decomposes at room temperature and cannot be isolated,[4] this derivative is very stable at temperatures up to 300°C, and reacts neither with dienophiles nor with electrophilic reagents. It will be interesting to ascertain the structural basis of this high stability. The present work has been underatken out of our general concern with the molecular geometry of aromatic seven-membered ring compounds, which should give fundamental information for investigating quantitatively the physical and chemical properties of such systems.

A preliminary report on the structure has already been published.[5]

Experimental

8, 8-Dicyanoheptafulvene (I) was prepared by the method given by Kitahara and Doi (1959).[6] It crystallizes from a methanol solution in the form of red needles elongated along the c axis.

The crystallographic and physical data obtained are: 8, 8-Dicyanoheptafulvene $C_{10}H_6N_2$, m. p. 199—200°C; Monoclinic, $a=7.84$ Å, $b=13.14$ Å, $c=3.99$ Å, and $\beta=97.9°$. Absent spectra, $(0k0)$ when k is odd. Space group, $P2_1$ or $P2_1/m$. Two molecules per unit cell. Volume of the unit cell; 407.1 Å^3 Density (by flotation); 1.27_2 g. cm^{-3}. Density (calculated); 1.26_4 g. cm^{-3}. Linear absorption coefficient for Cu$K\alpha$ radiation; $\mu=6.31$ cm^{-1}. Total number of electrons per unit cell; $F(000)=160$.

Equi-inclination Weissenberg photographs for 0—3 layers were taken around the c axis, using Cu$K\alpha$ radiartion at room temperature. Precession photographs for $(h0l)$ zone were also taken, using Cu$K\alpha$ and Mo$K\alpha$ radiations, in order to determine the relative scales among the layers. The crystal used was square in cross-section, with rectangular dimensions: 0.02×0.01 cm.

Intensities were estimated by visual comparison with a standard scale prepared with the same crystal. The multiple-film technique was applied to correlate strong and weak reflections, ranging in relative intensity from 10000 to 1. Reflections from 514 planes were observed out of 930 accessible (hkl)'s. The corrections for Lorentz and polarization factors were made in the usual way, while that for absorption was omitted. Tentative scale and temperature factors were obtained by Wilson statistics,[7] the latter being $B=2.0$ Å.^{2}

Structure Determination

The sharpened Patterson projection, $P(u, v)$, shown in Fig. 1, was calculated with the relative intensities of 100 observed $(hk0)$ reflections. A planar molecular model was set up by assuming plausible bond distances and angles, the hydrogen atoms being ignored. The molecular orientation was obtained by seeking the best fit of the intramolecular vector sets with the Patterson function. The long axis of the molecule is perpendicular to the b axis, and the molecule lies nearly parallel to the (101) plane. Vector sets at the best fit are indicated by the spots in Fig. 1. This orientation was also supported by another Patterson projection, $P(u, w)$, shown in Fig. 2.

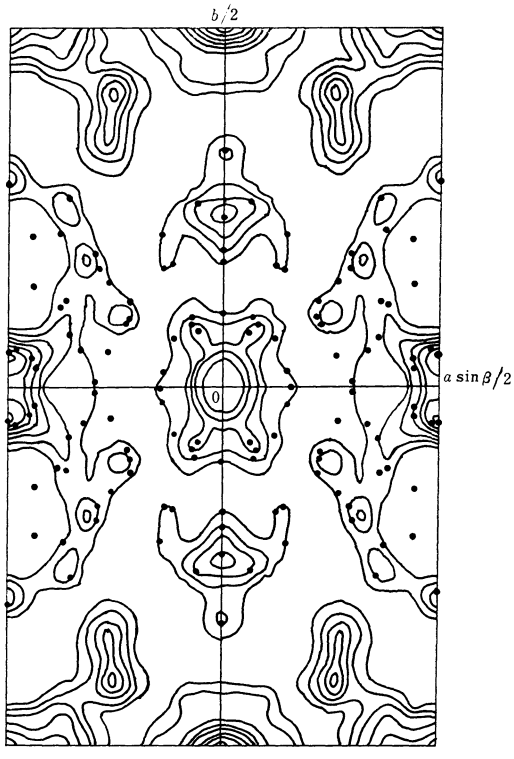


Fig. 1. Patterson projection $P(u, v)$. The contours are at equal arbitrary intervals and those at the origin are omitted. The spots show the intramolecular vector sets at the best fit.

If the space group is $P2_1$, the y coordinate of an atom can be arbitrarily chosen. Therefore, approximate y coordinates of the other atoms were

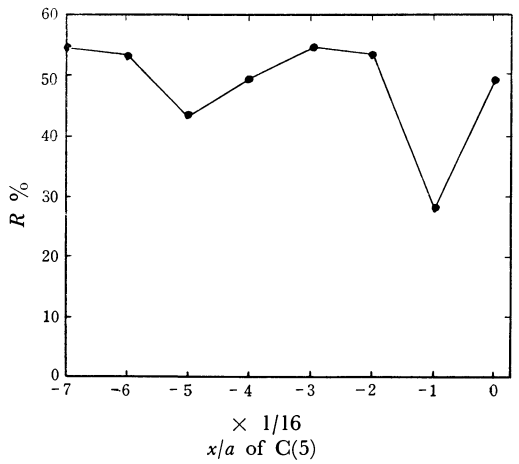

Fig. 3. One dimensional R map computed with all $(hk0)$ reflections.

given by the model. The x coordinates were obtained by a one-dimensional minimum residual calculation,[8] where the discrepancy factor, $R=\Sigma||F_o|-|F_c||/\Sigma|F_o|$, was computed for all $(hk0)$ reflections. Figure 3 shows the variation of R against the x coordinate of the reference atom, C(5). The first electron density projection, $\rho(x, y)$, was computed with phases based on these parameters. It clearly showed a definite molecular shape, without any ghost peaks. The atomic coordinates read off from the Fourier synthesis were refined by the block-diagonal matrix least-squares method. After five cycles of the refinement, the R factor reached 0.078 for the observed reflections. The atomic arrangement in the unit cell thus obtained suggested the existence of a mirror plane perpendicular to the b axis, within the limits of error. Moreover, the pyroelectricity test and the statistical investigation of the intensity data,[9] $|F_o(hk0)|^2$'s and $|F_o(hk1)|^2$'s respectively, showed that the crystal should be centrosymmetrical. Therefore, the space group of this crystal was chosen to be $P2_1/m$ for the subsequent studies.

9) E. R. Howells, D. C. Phillips and D. Rogers, ibid., **3**, 210 (1950).

In order to obtain the z coordinates, a sharpened Harker section, $P(u, 1/2, w)$, was calculated, as is shown in Fig. 4. There were two rows of peaks parallel to the (101) plane. The high peaks near the c axis were interpreted as follows. If the y coordinates of the two atoms are euqal, the non-Harker peak due to these atoms should be placed at the midpoint of their Harker peaks and be doubly weighted.[10] In the tentative structure of 8, 8-

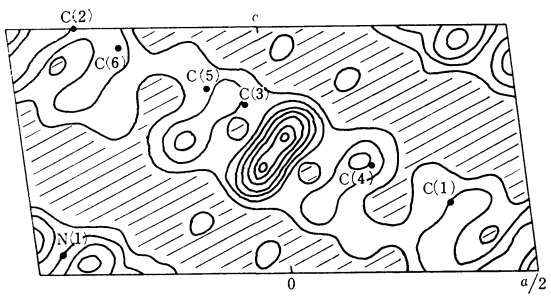

Fig. 4. Harker section $P(u, 1/2, w)$. The contours are at equal arbitrary intervals. The region lower than the starting contour is indicated by oblique lines. The spot shows the position of the expected Harker peak of each atom.

dicyanoheptafulvene, there were three pairs of atoms at the same y level; i. e., C(4) and C(5), C(1) and C(6), and C(1′) and C(6′), their corresponding Harker peaks being indicated by the spots in Fig. 4. The non-Harker peaks due to these atoms pairs were situated at nearly the same position and gave the considerably high peaks mentioned above.

The coordinates thus obtained were then refined by the block-diagonal matrix least-squares method with anisotropic temperature factors, all (hkl) reflections being used. The parameters of the hydrogen atoms were also refined; they were first located at a distance of 1.0 Å outward radially

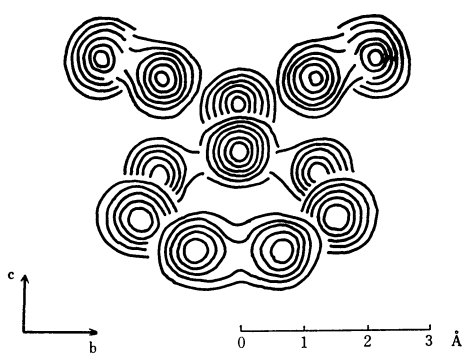

Fig. 5. Composite electron density diagram of sections parallel to (100). The contours are at intervals of 1.0 e.Å^{-3} starting with 2.0 e.Å^{-3}.

from each carbon atom in the ring, with an isotropic temperature factor of 3.5 Å.[2] After five cycles of the refinement, the decreasing rate of the R factor seemed to slow down and no significant shifts in the parameters were observed. The final R factor reached 0.107 for the observed reflections. The atomic scattering factors for carbon and nitrogen given by Berghuis, Haanappel, Potters, Loopstra, MacGillavry and Veenendaal,[11] and for hydrogen given by McWeeny,[12] were used

throughout this structure determination. The observed and calculated structure factors are listed in Table I. The final atomic coordinates and the temperature factors are given in Table II, and their standard deviations, in Table III. The final three-dimensional electron-density distribution, calculated with signs based on these atomic coordinates, is shown in Fig. 5.

The computations were done on a NEAC 2101 computer in the Institute, with programs written by Takano and Nishi, and on an IBM 7090 computer through "UNICON" project, with programs written by one of the present authors (T. A.).

Discussion

Molecular Geometry.—The intramolecular bond lengths and angles are illustrated in Fig. 6 and are listed in Table IV.

All the bond distances in the dicyanomethylene group are nearly equal to those of the corresponding bonds in 7, 7, 8, 8-tetracyanoquinodimethane[13] (TCNQ) (C≡N=1.140 Å and C-C=1.441 Å). They slightly differ from those in pyridinium dicyanomethylide[14] (C≡N=1.13 Å and C-C=1.41Å), and TCNQ in a 1 : 1 complex of TCNQ

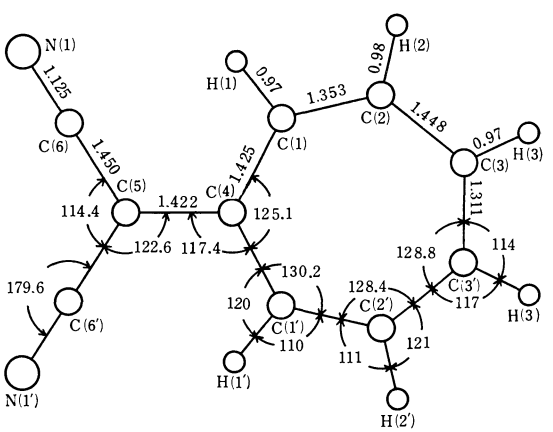

Fig. 6. Bond length (Å) and angles (degrees), without libration corrections.

and *N, N, N', N'*-tetramethyl-*p*-phenylenediamine (TMPD)[15] (C≡N=1.160 Å and C–C=1.412 Å). On the other hand, the length between C(4) and C(5), 1.422 Å, is significantly longer than that of TCNQ, and slightly longer than that of TCNQ in a 1 : 1 complex with TMPD. A comparison of these values with the normal C–C bond lengths seems to suggest a considerable contribution of

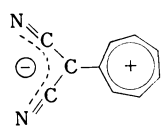
1, 2, 3, 4-Tetrachlorobenzo[g]sesquifulvalene	1.45	1.37	1.41	19
1, 2, 3-Tribromo-6-(*o*-methoxyphenyl)fulvene	1.48**	1.31**	1.40**	20
8, 8-Dicyanoheptafulvene	1.437	1.339	1.388	

* These values were obtained from the trans-chain parts.
** These values were obtained from the five-membered ring.

the following dipolar resonance form to the structure:



Thus, the present analysis supports the idea that this dipolar structure must be responsible for the stability of the molecule.[1-3,16,17]

The bond alternation, as suggested by its Kekule formula, is observed in the seven-membered ring. Similar bond alternation has been reported in other non-benzenoid aromatic compounds, dimethylfulvene,[18] 1, 2, 3, 4-tetrachlorobenzo[g]sesquifulvalene,[19] and 1, 2, 3-tribromo-6-(*o*-methoxyphenyl)fulvene.[20] To investigate the extent of bond alternation, average single and double bond lengths in the conjugated cyclic molecules were compared with those in molecules with an all-trans conjugated polyene chain (cf. Table V). The average lengths of single bonds and those of double bonds are approximately constant in the various linear polyenes. On the other hand, these values spread out over a wider range in the cyclic molecules. This may occur as a result of intramolecular strain. However, it may be pointed out that the mean values between the average single and double bond lengths show nearly the same value, 1.40 Å, throughout all the compounds given in Table V.

Even after the rotational corrections, as will be shown later, the C(3)-C(3′) distance is apparently shorter than the C=C distance in ethylene (1.337±0.003 Å).[26] Similar situations have been observed elsewhere; a C=C bond distance in *p*-benzoquinone[24] is 1.322±0.008 Å, the shortest bond distance in pyrene[27] is 1.315±0.020 Å without rotational corrections and 1.320±0.020 Å with the corrections, and the shortest double bond distance in cyclooctatetraenecarboxylic acid[25] is 1.310±0.007 Å, while its average double bond distance is 1.322 Å. These values suggest that the C=C distance in ethylene can not be taken as the normal double bond distance in the molecules of this type.[28]

Planarity.—The 8, 8-dicyanoheptafulvene molecule is approximately planar, as may be expected from the chemical formula. The detailed analysis of the atomic coordinates shows, however, a slight but significant deviation from this planarity. The equation for the best plane of the molecule, calculated with all twelve heavy atoms equally weighted, is:

$$Z = -0.6048X + 1.2571$$

where $X=ax\sin\beta$, $Y=by$, and $Z=cz+ax\cos\beta$. The large deviations from this plane are 0.059 Å for C(5), −0.040 Å for N(1), and 0.024 Å for C(1). On the other hand, the eight atoms, C(1)-C(5), all lie, within the range of 0.014 Å, on the plane:

$$Z = -0.5834X + 1.2081$$

as is illustrated in Fig. 7. The linear C(5)-C(6)-N(1) unit thus makes an angle of about 2° with this plane. A similar non-planarity has also been

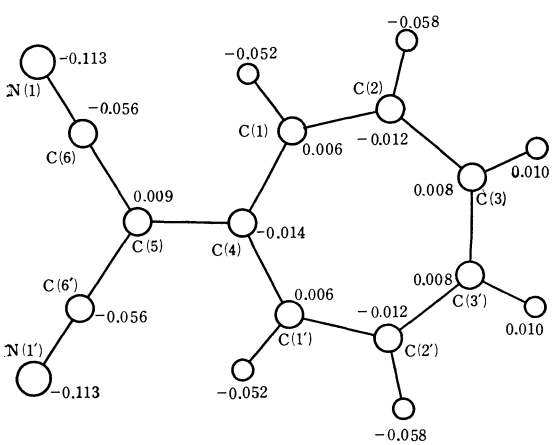

Fig. 7. The deviations (Å) of the atoms from the least-squares plane through atoms C(1)—C(5).

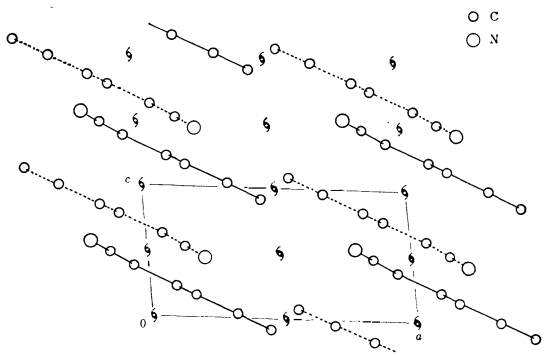

Fig. 8. The crystal structure projected along the b axis. The molecules drawn with brokn lines lie down half-period of the b axis.

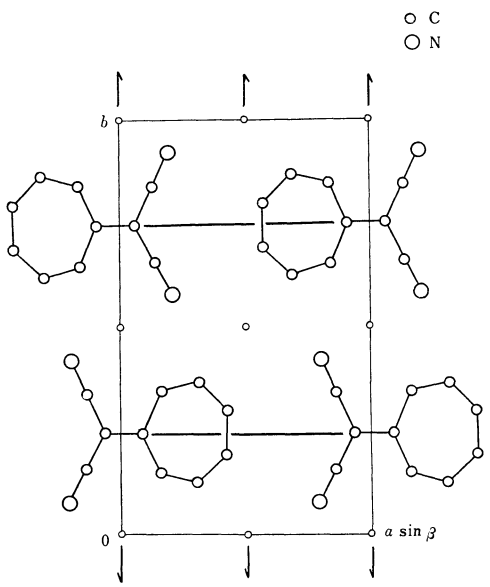

Fig. 9. The crystal structure projected along the c axis.

TABLE VI. SHORT INTERMOLECULAR DISTANCES (Å)

TMPD[15]. In TCNQ,[13] however, the molecule is planar within the limit of errors. It may be anticipated that, because of the dipolar resonance structure, the electronic state of the C(5) significantly deviates from the sp^2 hybridization.

Crystal Structure.—The packing diagrams of the crystal of 8, 8-dicyanoheptafulvene viewed along the b and c axes are shown in Figs. 8 and 9 respectively. Short intermolecular distances are listed in Table VI. There are no abnormal intermolecular approaches displayed in the crystal. This compound has the high dipole moment of 7.49 D (in dioxane at 25°C).[17] The arrangement of the molecules appears to be favorable enough to compensate for this high dipole moment.

The molecule lies nearly parallel to the (101) plane at an intermolecular spacing of 3.41 Å, which corresponds to the normal van der Waals contact between the benzenoid rings.

Anisotropic Thermal Motion.—The anisotropic thermal parameters, B_{ij}, were transformed to U tensors referred to the molecular axes, 1, 2 and 3, shown in Fig. 10, the origin of the coordinate system lay at the center of gravity of the molecule. The direction cosines of the molecular axes referred to the orthogonal axes (a*, b, c) are:

axis 2 : 0, 1, 0
axis 3 : +0.5175, 0, +0.8557

The values of the six independent U_{ij}'s for each atom are shown in Table VII in the columns headed 'Obs.' The values of the mean-square oscillation, $\bar{u}^2$, in the directions radial and tangential to the center, and perpendicular to the molecular plane were derived from the U_{ij}'s,[29] as is shown in Fig. 10.

If a molecule is rigid-body, the molecular vibration can be expressed in terms of two symmetric tensors, T and ω, the former giving the translational vibrations of the mass center, and the latter the angular oscillations about the axes through the center.[30] Given the U tensors for a number of atoms, the T and ω tensors may be determined by the method of least-squares. The resulting T and ω tensors for 8, 8-dicyanoheptafulvene are given in Table VIII. The r. m. s. amplitudes of translational oscillation in the directions of the molecular axes, obtained from the square roots of the diagonal elements of T, are 0.21, 0.23 and 0.19 Å respectively. The corresponding r. m. s. amplitudes of angular oscillation obtained from ω are 6.5°, 3.0° and 2.5°.

While the r. m. s. amplitudes of translational oscillation are nearly equal to each other, those of angular oscillation are different for the three axes. This may be interpreted as indicating a

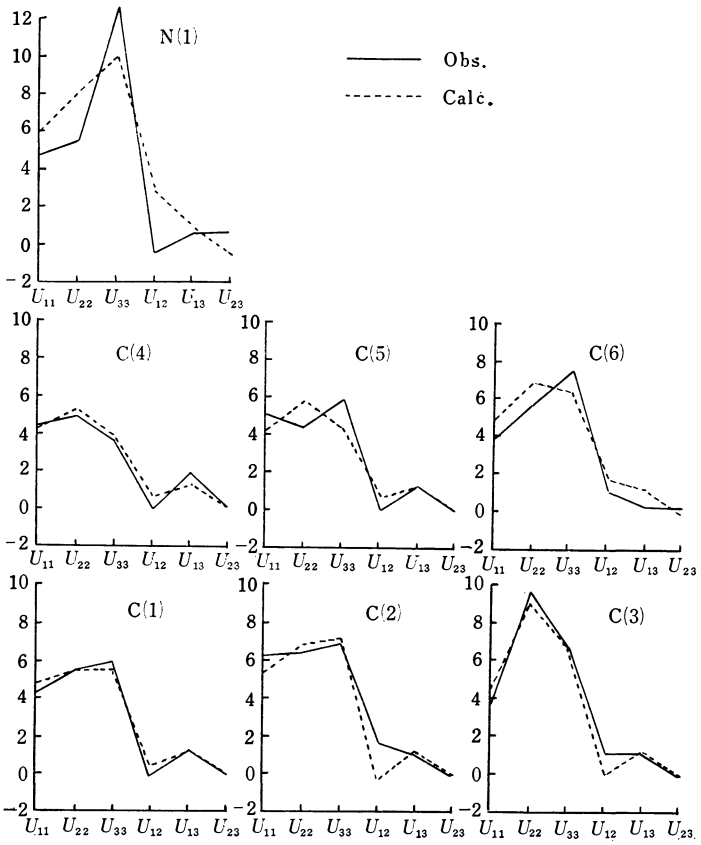

Fig. 12. Comparison between observed and calculated U_{ij}, the latter being evaluated with T and w in Table IX.

difference in the moments of inertia of the molecule around the three axes. The moments of inertia are $I_1=274$, $I_2=698$ and $I_3=972$ g.Å^2/mol. around the 1, 2 and 3 axes respectively. The larger the moment, the smaller the amplitude becomes.

In order to examine the validity of the rigid-body approximation, the U_{ij} values calculated with T and ω are listed in Table VIII in the column headed 'Calcd.' while the observed and calculated U_{ij}'s are compared in Fig. 11. Considerable discrepancies are observed for C(2), C(3) and C(5), which may be due to equal weights for all the atoms in the evaluation. T and ω tensors were, therefore, calculated with only seven atoms in the ring weighted equally, as is shown in Table IX, and the U_{ij}'s were then calculated using these values, as is shown in Table X. The observed and calculated U_{ij}'s are compared in Fig. 12. Good agreements are observed within the seven-membered ring, but in the dicyanomethylene group there are large discrepancies. This may be due to the twisting and scissoring of the exocyclic group.

It is necessary to allow for the angular oscillations causing the atoms to appear too close to the center of the molecule.[31] The radial error in the position of an atom is given by:

$$1/2r\{s^2/(1+s^2/q^2)+t^2/(1+t^2/q^2)\},$$

where s^2 and t^2 are the mean-square amplitudes of the angular oscillation in the molecular plane and in the direction perpendicular to it respectively, where q^2 is the Gaussian peak-width parameter for an atomic peak without the angular oscillations, and where r is the distance from the point of origin. The two mean-square amplitudes, s^2 and t^2, were calculated from ω_{ij}'s by Cruickshank's equation.[30] Using a value of q^2, 0.112 Å^2, the corrected bond distances and angles were calculated to be as shown in parentheses in Table IV. The corrected C(3)-C(3′) distance is still shorter than the C=C distance in ethylene, as has been stated above.

The authors wish to express their deep thanks to Mrs. Yoriko Nishi and Dr. Tsunehiro Takano for their assistance in the use of the electronic computer. The computing time of IBM 7090 was made available to the authors through the "UNICON" project.

Studies of the Aqueous Solution of a Surface Active Substance by Means of an Ultrasonic Interferometer. II. The Effects of Added Electrolytes on the Dissolved State of Sodium Alkyl Sulfate

By Koji SHIGEHARA*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received February 8, 1966)

The sound velocity (U) and the density of aqueous solutions of sodium dodecyl (SDS) and octyl (SOS) sulfates with inorganic electrolyte have been measured by using a differential ultrasonic interferometer and a float balance respectively, and the compressibility (β) has then been calculated from these results. The CMC's of SDS solutions of various concentrations of sodium salts have been determined from U-vs.-SDS and β-vs.-SDS concentration (C_2) diagrams. The results show a linear relationship between the logarithm of CMC and the logarithm of the concentration of sodium ions. The values of $d\beta/dC_2$ below CMC are affected by the addition of electrolytes, while the values above CMC are almost not affected at all by the addition of electrolytes. The diagrams of $d\beta/dC_2$ of alkyl sulfate vs. the number of carbon atoms in alkyl sulfate molecules with varying concentrations of added electrolytes showed straight lines which all passed through the same point when extrapolated to a zero number of carbon atoms. These results have been explained by taking account of the dissolved state of a surface active substance under the builder action of added inorganic electrolytes, which action decreases not only the mutual repulsion of the ionized-head group of a surface active substance but also the non-ionic hydration of the CH_2-chain of the surface active substance.

In previous papers,[1] it has been shown that differential ultrasonic interferometry is one of the most useful methods for the study of aqueous solutions of surface active substances. The sound velocity measurements by this method, together with the density measurements, has made possible the calculation of the compressibility and the critical micelle concentrations (CMC) of aqueous solutions of several alkyl sulfates, and from these data the compressibility, the molar volume, and the hydration number of the ionic micelle were determined. It was concluded therefrom that the hydrocarbon interior of an ionic micelle assumes a liquid-like structure rather than a solid-like one.

It has been well known that the addition of some inorganic salts, often called the "builders," enhances the surface activity. This effect can also be well studied by hydration measurements using differential ultrasonic interferometry. Hitherto little has been known experimentally, however, about the hydration of surface active substances in connection with the builder action. The present paper will describe the results of measurements of the sound velocity, the density, and the compressibility of aqueous solutions of sodium alkyl sulfates containing inorganic electrolytes. The CMC, the hydration, and the compressibility of single molecules and micelles of alkyl sulfates in the presence of the added electrolytes will also be discussed.

Experimental

Sodium *n*-dodecyl (SDS) and *n*-octyl (SOS) sulfate were prepared from the respective alcohols and purified as usual. The sodium chloride, sodium sulfate, and magnesium chloride used to study the builder action were purified from commercial products by recrystallization.

The method of measuring the small changes in the sound velocity (ΔU) due to the small changes in the concentrations (C_2) of the alkyl sulfates by the differential ultrasonic interferometer was the same as that reported in previous papers.[1] The concentration of the added inorganic electrolytes was kept constant during the measurements. The sound velocity of an aqueous solution containing the inorganic electrolyte alone was also measured. The measurements were carried out in a thermostat at 30.00 ± 0.003°C. The frequency of the ultrasonic wave was 1.432 Mc./sec., and the error in the measurement of ΔU was ±3 cm./sec.

The density of the solution at 30°C was determined by the float-balance method.[2] As the standard,[3]

the aqueous solution of the inorganic electrolyte was used, and the change in density ($\Delta\rho$) caused by the addition of alkyl sulfates was measured. The thermostat used was controlled to ± 0.001°C. The accuracy of the measurements was $\pm 10^{-6}$ g./cc.

The compressibility (β) of the solution was calculated from the sound velocity (U) and the density (ρ) by using the Laplace equation:

$$\beta = 1/U^2\rho$$

Results and Discussion

In Figs. 1 and 2, the change in sound velocity (ΔU) is plotted against the concentration of alkyl sulfates (C_2), while in Figs. 3 and 4, the change in compressibility ($\Delta\beta$) is plotted against the concentration of aqueous solutions of SOS and SDS, with and without the addition of inorganic electrolytes. As may be seen in Figs. 2 and 4, the diagrams for SDS solutions consist of two linear portions with a sharp break point between them; this break point may reasonably be ascribed to the CMC of SDS, as will be mentioned later. The change in density ($\Delta\rho$)-vs.-SDS concentration diagrams show similar break points corresponding to CMC, but they are not shown in this paper.

The change in the value of CMC with the concentration of sodium chloride and sulfate is shown in Fig. 5. As may be seen in Fig. 5, the logarithm of CMC changes linearly with the logarithm of the concentration of sodium ions; a similar linear relationship has been reported by Corrin and

Harkins[4] and by Matuura et al.[5]

In the diagrams of $\Delta\rho$ vs. C_2, the slopes were not affected by the addition of inorganic electrolytes. This shows that the molar volume of alkyl sulfate in the dissolved state is not affected by the addition of inorganic electrolytes. This fact is consistent with the findings of Hutchinson and Mosher[6] on the partial molal volume of sodium decyl sulfate above CMC.

The increase in $\Delta\beta$ with C_2 ($d\Delta\beta/dC_2$ or $d\beta/dC_2$) for solutions of SOS and SDS is plotted against the concentration of the added electrolyte in Fig. 6. In this figure, the $d\beta/dC_2$ increases with the concentration of the electrolyte up to CMC. This result may be ascribed to the dehydration of SOS and SDS by the added electrolytes. After the CMC, the value of $d\beta/dC_2$ is almost independent of the concentration of inorganic electrolytes.

Figure 7 shows the plots of $d\beta/dC_2$ vs. the number of carbon atoms (N) in the solute molecule. As may be seen in Fig. 7, the values of $d\beta/dC_2$ change linearly with N when sodium chloride is added to the solution. The values without the addition of sodium chloride reported in previous papers[1] also fall on straight lines. From this figure, the values of $d\beta/dC_2$ for the solutions of various NaCl contents at the zero carbon number were estimated by extrapolation below and above CMC. These values all fall at the same point. This suggests that the hydration characteristics of the SO_4Na radical of alkyl sulfates are independent of the carbon number as well as of the presence of the builder and of the micellization. The contribution of each CH_2-chain in the solute molecule to the value of $d\beta/dC_2$ is independent of the total number of

carbon atoms in its molecule, but it is changed by the addition of electrolytes. As has been pointed out in the previous papers,[1] the value of $d\beta/dC_2$ obtained by the extrapolation to $N=0$ shows a compressibility decrease due to the introduction of one mole of Na^+ and $-SO_4^-$ each in water. The decrease in this value with respect to N for the solution below CMC, namely, the vertical difference between the dotted horizonatal line and the straight line for the solution below CMC in Fig. 7, shows an additional decrease in compressibility due to the dissolution of one mole of alkyl chains of the respective carbon numbers in a molecule in the state of molecular dispersion in water; the increase for the solutions above CMC, namely, the vertical difference between the dotted horizontal line and the upper straight line, shows a similar increase in compressibility due to the introduction of one mole of alkyl chains in micelles. Therefore, the fact that the $d\beta/dC_2$ value above CMC was almost unchanged by the addition of the electrolyte indicates that the compressibility of micelles is presumably not affected by the addition of an inorganic electrolyte.

It may be inferred from these results that the non-ionic hydration of the CH_2-chain, together with ionic hydration, is one of the important factors in the dissolution of surface active substance into water, and that the builder action of inorganic electrolytes is due not only to the decrease in the mutual repulsion of the ionized head group of the surface active substance by the gegen-ion attachment, as may be understood from Fig. 5, but also to the decrease in the non-ionic hydration of the CH_2-chain of the surface active substance.

The author wishes to express his deep gratitude to Professor Tsunetaka Sasaki of our University for his kind direction and valuable criticism. The cost of this research has been defrayed by a grant of the Ministry of Education given to Professor Sasaki.

Properties of Dilute Solutions of Polyurethanes. I. Linear Polymers

By Hiroshi SATO

Research Laboratory, Mitsubishi Rayon Co., Ltd., Otake, Hiroshima

(Received February 10, 1966)

Polyurethanes were prepared from polycaprolactone, 4, 4'-diphenylmethane diisocyanate, and ethylene diamine. Two kinds of polymers were used for the present experiments. One contained polycaprolactone with the number-average molecular weight, $\overline{M}_n$, of 1.30×10^3, while the other contained polycaprolactone with an $\overline{M}_n$ value of 2.80×10^3. Each polymer was fractionated from a dimethyl acetamide solution by progressive precipitation with a mixture of *n*-heptane and ethyl ether, and the fractions were characterized in terms of viscosity and sedimentation. The relations between the intrinsic viscosity and the molecular weight were found in DMF at 25°C to be:

$$[\eta] = 5.52\times10^{-4}M^{0.66}$$

for the polymer containing polycaprolactone ($\overline{M}_n=1.30\times10^3$) and

$$[\eta] = 7.71\times10^{-4}M^{0.62}$$

for the polymer containing polycaprolactone ($\overline{M}_n=2.80\times10^3$). The viscosities of the solutions of the polymers were measured in several solvents at different temperatures, and the polymer-solvent interaction parameters were obtained by using the Fixman theory for the expansion factor. The molecular-weight distribution of the polymer containing polycaprolactone ($\overline{M}_n=1.30\times10^3$) was obtained from the distribution of the sedimentation coefficient, while the value of $\overline{M}_w/\overline{M}_n$ was calculated from the distribution curve to be 1.95.

Recently a number of studies have reported on the elastic properties of polyurethanes. As is well known, the elastic properties of polymers depend on their polymer characteristics, such as their molecular weight and its distribution. As polyurethane used for fiber-forming has no cross-link in the molecule, the characteristics of the polymer exert a great influence on its behavior in the fiber-forming process and on the elastic properties of the fiber. Little information[1] has,

1) J. Moacanin, *J. Appl. Polymer Sci.*, **1**, 272 (1959); M. Nishide and M. Sera, *J. Chem. Soc. Japan, Ind. Chem. Sect. (Kogyo Kagaku Zasshi)*, **63**, 189 (1960).

however, been found about the characteristics of the polymer.

On the other hand, it is of great interest from the point of view of physical chemistry to study polyurethane as a kind of block copolymer.

The present investigation has, therefore, been carried out in an attempt to establish the relation between the intrinsic viscosity and the molecular weight and to obtain knowledge of the molecular-weight distribution and the thermodynamic properties of solutions of polyurethane consisting of polycaprolactone, diphenylmethane diisocyanate, and ethylene diamine.

Experimental

Polymer.—One mole of polycaprolactone (PCL) was treated with 2 moles of 4, 4'-diphenylmethane diisocyanate (MDI) in bulk for 110 min. at 75°C in order to prepare the prepolymer. The prepolymer thus obtained was then dissolved in dimethyl acetamide and was extended into polyurethane by reaction with the equivalent moles of ethylene diamine (ED) at 40°C.

The solution thus obtained was spun into water in order to obtain the coagulated polymer, which was then dried in a vacuum at room temperature.

In this manner, two kinds of polyurethanes were prepared. One contained PCL with a number-average molecular weight, $\overline{M}_n$, of 1.30×10^3; it was designated as the polymer B. The other contained PCL with an $\overline{M}_n$ value of 2.80×10^3; it was designated as the polymer C.

The polymer may be symbolized as follows:

$$-(-\text{MDI}-\text{PCL}-\text{MDI}-\text{ED}-)_{\overline{n}}$$

Solvents.—Dimethyl formamide (DMF), dimethyl acetamide (DMAA), and dimethyl sulfoxide (DMSO) were purified by the usual method.

Fractionation.—Each polymer was fractionated from a 1% solution in DMAA by precipitation fractionation, using a mixture of *n*-heptane and ethyl ether as the precipitant at 25°C. The gel-like precipitate was then dissolved in a small amount of DMAA, and the resulting solution was added, drop by drop, into an excess of water. Thus, the polymer B was divided into 13 fractions, which were designated as UB(1300), and the polymer C, into 12 fractions, designated as UC(2800). Each fraction was dried in a vacuum at room temperature.

In the other runs of fractionation, both of the polymers B and C were divided into 3 fractions; the middle fractions were designated UB-T(1300) and UC-T(2800) respectively.

Viscosity.—A modified Ubellohde viscometer was used to measure the viscosity of polymer solutions.

Partial Specific Volume.—The density of solutions was determined over the concentration range from 0.5 to 3.0 wt. % by using a 10-cc. Ostwald picnometer at 25°C; the partial specific volume was then calculated from the density data.

Ultracentrifugation.—The sedimentation velocity was measured with a Hitachi analytical ultracentrifuge, Model UCA-1, equipped with Schlieren optics and a phase plate. The rotor temperature was maintained at 25°C, and the rotor speed was 55430 r. p. m. throughout the experiments.

Results and Discussion

The Constitution of the Polymer. — The nitrogen content of the original polymer, as determined by the micro-Kjeldahl method, was less than the calculated value for both polymers B and C. This may mean that a small amount of water reacted with isocyanate groups in the polymerization process, resulting in the inhomogeniety in the composition (cf. Tables I and II).

The Relation between the Intrinsic Viscosity and the Molecular Weight.—From the plots of the reduced viscosity (η_{sp}/C) against the concentration (expressed in g./100 cc.), as is shown in Fig. 1, the intrinsic viscosity and the Huggins constant, k', were obtained by using the following equation:

$$(\eta_{sp}/C) = [\eta] + k'[\eta]^2C \qquad (1)$$

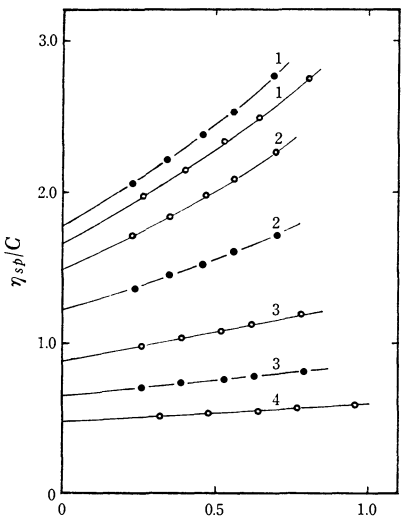

Fig. 1. (η_{sp}/C) vs. C of polymer fractions in DMF at 25°C.
Open circles, 1: UB-3, 2: UB-5, 3: UB-10, 4: UB-12
Solid circles, 1: UC-3, 2: UC-4, 3: UC-10

As the plots became curved in the higher-molecular weight fractions, the values of $[\eta]$ and k' for these fractions were estimated from the straight lines obtained from the plots of the inherent viscosity ($\ln \eta_r/C$) against the concentration by applying the following equation:

$$(\ln \eta_r/C) = [\eta] - (0.5 - k')[\eta]^2C \qquad (2)$$

The results are given in Tables I and II for the UB(1300) and UC(2800) polymer fractions respectively.

The Huggins constant, k', slightly decreases with an increase in the molecular weight of PCL.

The reciprocals of the sedimentation coefficients, $1/S$, were plotted against the concentration (expressed in g./100 cc.), as is shown in Fig. 2. The sedimentation coefficient at the infinite dilution, S_0, and the constant, k_s, were obtained from the empirical equation:

$$1/S = (1/S_0)(1 + k_sC) \qquad (3)$$

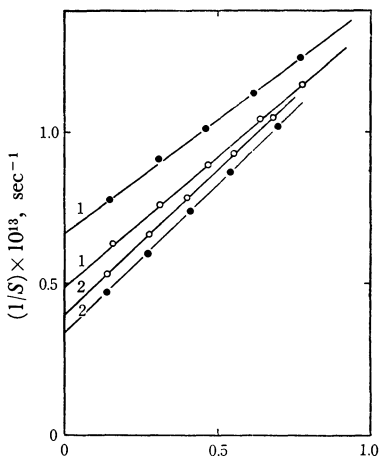

Fig. 2. ($1/S$) vs. C of polymer fractions in DMF at 25°C.
Open circles, 1: UB-9, 2: UB-5
Solid circles, 1: UC-10, 2: UB-5

Wales[2] has proposed this relation between the constant, k_s, and the intrinsic viscosity:

$$k_s/[\eta] = 1.66 \qquad (4)$$

Yamakawa[3] has theoretically estimated the ($k_s/[\eta]$) ratio to be about 1.7 in good solvent systems. The ratio obtained in the present study is also about 1.7, as may be seen in column 6 of Tables I and II. Wales' equation can, therefore, be applied to the case of these block copolymer solutions.

The molecular weight of each fraction, M, was calculated from the intrinsic viscosity and the sedimentation coefficient by using the Mandelkern-Flory equation[4]:

$$S_0[\eta]^{1/3}/M^{2/3} = (\boldsymbol{\Phi}^{1/3}\boldsymbol{P}^{-1})(1-\bar{v}\rho)/\eta_0\boldsymbol{N}_A \qquad (5)$$

where $\boldsymbol{\Phi}$ and $\boldsymbol{P}$ are universal constants; $(\boldsymbol{\Phi}^{1/3}\boldsymbol{P}^{-1})$ takes the value of 2.5×10^6; $\bar{v}$ is the partial specific volume of the polymer in solution; ρ and η_0 are the density and the viscosity of solvent respectively, and $\boldsymbol{N}_A$ is Avogadro's number.

The partial specific volumes of the polymers in DMF at 25°C were calculated from the data of density to be as follows:

2) M. Wales and K. E. Van Holde, *J. Polymer Sci.*, **14**, 81 (1964).
3) H. Yamakawa, *J. Chem. Phys.*, **36**, 2995 (1962).
4) L. Mandelkern, W. R. Krigbaum, H. A. Scharaga and P. J. Flory, ibid., **20**, 1392 (1952).

$\bar{v} = 0.8480$ for the polymer B

$\bar{v} = 0.8745$ for the polymer C

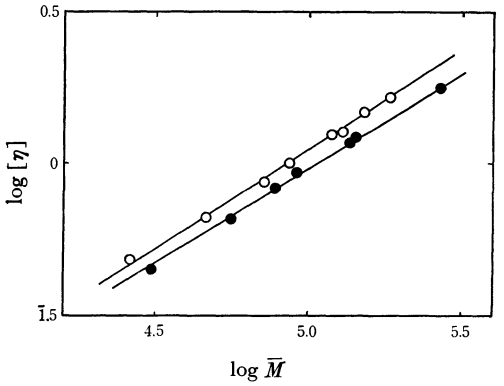

Fig. 3. Log $[\eta]$ vs. log $\bar{M}$ of polymer fractions in DMF at 25°C.
Open circles: UB(1300), Solid circles: UC(2800)

The intrinsic viscosities are plotted logarithmically against the molecular weight in Fig. 3. From this figure, the following two equations, 6 and 7, are obtained for the UB(1300) and UC(2800) polymer fractions respectively in DMF at 25°C:

$$[\eta] = 5.52 \times 10^{-4} M^{0.66} \quad (6)$$

$$[\eta] = 7.71 \times 10^{-4} M^{0.62} \quad (7)$$

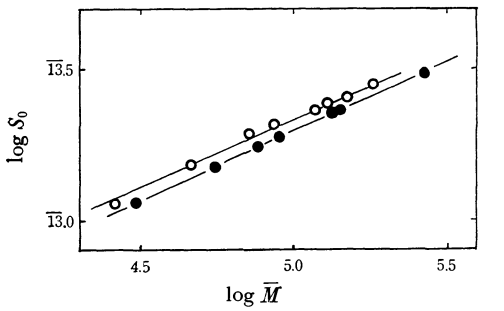

Fig. 4. Log S_0 vs. log $\bar{M}$ of polymer fractions in DMF at 25°C.
Open circles: UB(1300), Solid circles: UC(2300)

The relation between the sedimentation coefficient and the molecular weight was derived from the double logarithmic plots in Fig. 4; it was found in DMF at 25°C to be:

$$S_0 = 1.36 \times 10^{-15} M^{0.44} \quad (8)$$

for the UB(1300) polymer fractions and

$$S_0 = 9.86 \times 10^{-16} M^{0.46} \quad (9)$$

for the UC(2800) polymer fractions.

Polymer-Solvent Interaction Parameters.— The intrinsic viscosity depends on the molecular weight of the polymer in accordance with the relationship:

$$[\eta] = KM^{1/2}\alpha^3 \quad (10)$$

where $K = \Phi(\bar{r}_0^2/M)^{3/2}$, $\bar{r}_0^2$ is the mean square end-to-end distance for an unperturbed chain and α, the viscosity expansion factor.

Stockmayer and Fixman[5] have proposed the simple relation:

$$[\eta] = KM^{1/2} + 0.66\Phi BM \quad (11)$$

by combining Eq. 10 with the following Fixman equation[6] for the excluded volume effect:

$$\alpha^3 = 1 + 2z \quad (12)$$

where $z = (3/2\pi)^{3/2}(\bar{r}_0^2/M)^{-3/2}BM^{1/2}$;
$B = 2(\bar{v}^2/V_1N_A)\psi_1(1-\Theta/T)$; V_1 is the molar volume of the solvent; ψ_1, the entropy term of Flory's polymer-solvent interaction parameter, and Θ, Flory's temperature.

Hence, a plot of $[\eta]/M^{1/2}$ vs. $M^{1/2}$ will be linear in a given solvent at a particular temperature. The value of K is determined by the intercept. Thus, the value of α^3 can be evaluated by putting the value of K into Eq. 10. $(\alpha^3-1)M^{-1/2}$ should give a straight line when plotted against $1/T$, and both Θ and ψ_1 for any given solvent can be evaluated.

The values of K were obtained by using Eq. 11 in DMF at 25° and 70°C for UB(1300) and UC-(2800) fractions respectively; a small decrease in K with an increase in the temperature was observed for both polymers. The decrease in K with the temperature was, then, assumed to be linear between 25°C and 70°C, and the α for each polymer-solvent-temperature combination was calculated from the intrinsic viscosity by using Eq. 10 and the interpolated value of K at the temperature, T.

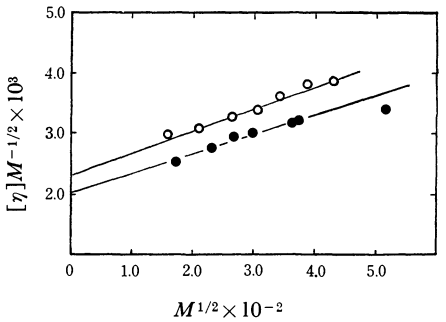

Fig. 5. $([\eta]/M^{1/2})$ vs. $M^{1/2}$ of polymer fractions in DMF at 25°C.
Open circles: UB(1300), Solid circles: UC(2800)

Figure 5 shows the Stockmayer-Fixman plots. The relations obtained from the straight lines are as follows:

$$[\eta] = 2.29 \times 10^{-3} M^{1/2} + 3.64 \times 10^{-6} M \quad (13)$$

for UB(1300), and

5) W. H. Stockmayer and M. Fixman, *J. Polymer Sci.*, Part C, No. 1, 137 (1963).
6) M. Fixman, *J. Chem. Phys.*, **36**, 3123 (1962).

$$[\eta] = 2.02\times10^{-3} M^{1/2} + 3.20\times10^{-6} M \quad (14)$$

for UC(2800), both being measured in DMF at 25°C.

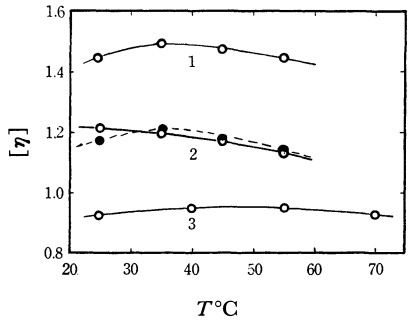

Fig. 6. Dependence of $[\eta]$ on temperature in various solvents.
Open circles: UB-T (solvent 1: DMAA, 2: DMF, 3: DMSO)
Solid circles: UC-T (solvent: DMF)

Figure 6 shows the temperature dependence of the intrinsic viscosities of the UB-T(1300) and UC-T(2800) polymers plotted against the temperature in several solvents.

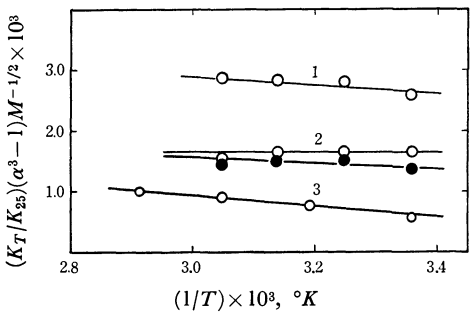

Fig. 7. Plots of $(K_T/K_{25})(\alpha^3-1)M^{-1/2}$ vs. $(1/T)$ for polymer fractions in various solvents.
Open circles: UB-T (solvent 1: DMAA, 2: DMF, 3: DMSO)
Solid circles: UC-T (solvent: DMF)

The plots of $(K_T/K_{25})(\alpha^3-1)M^{-1/2}$ against $1/T$ are given in Fig. 7. K_T/K_{25}, the ratio of K at T to K at the reference temperature, 25°C, was introduced in view of the temperature dependence of $(\bar{r}_0^2/M)^{3/2}$.

The results are given in Table III, where the heat term, κ_1, at 25°C was calculated by the relation:

Table III. Thermodynamic parameters

Polymer	Solvent	ψ_1	Θ°K	κ_1^{25}	χ_1^{25}
UB-T(1300)	DMAA	0.35	141	0.17	0.32
UB-T(1300)	DMF	0.10	0	0	0.40
UB-T(1300)	DMSO	0.21	235	0.16	0.45
UC-T(2800)	DMF	0.17	158	0.09	0.42

$$\kappa_1 = \psi_1\Theta/T \quad (15)$$

and where the polymer-solvent interaction parameter, χ_1, at 25°C was evaluated from the following relation:

$$(1/2) - \chi_1 = \psi_1 - \kappa_1 \quad (16)$$

For the solutions of UB-T(1300), the heat of dilution behaves athermally in DMF and endothermally in DMAA and DMSO. The cohesive energy densities (CED) of these solvents are 123, 147 and 170 cal./cc. for DMAA, DMF and DMSO respectively. The value of κ_1 is related to the solubility parameter, δ, which is the square root of CED, through the following Hildebrand equation:

$$\kappa_1 = (V_1/\boldsymbol{R}T)(\delta_1-\delta_2)^2 \quad (17)$$

where $\boldsymbol{R}$ is the gas constant and where the suffixes 1 and 2 represent the solvent and the polymer respectively. Consequently, the value of CED for the polymer B lies between those for DMAA and DMSO, and is nearly the same as that for DMF.

The constant, a, of the Mark-Houwink equation and the long-range interaction term of the Stockmayer-Fixman equation decrease in DMF solutions with an increase in the molecular weight of PCL, as has been shown above. When the long-range interaction term is separated into two terms, the heat and the entropy of dilution, the heat term, κ_1, increases with the molecular weight of PCL.

These results lead us to the conclusion that the PCL segments may mix endothermally with such a polar solvent as DMF, although the value of CED for the copolymer may be obtained as the average of the values of two sorts of segments and although the values of CED have not been obtained for each segment of the polymers used in the present study.

Molecular-weight Distribution.—The distribution of the limiting sedimentation coefficient, S_0, for the polymer B was evaluated by making corrections for both diffusion and concentration, and the transformation from the distribution of the sedimentation coefficient to the molecular-weight distribution was made by using Eq. 8. The results are given in Fig. 8.

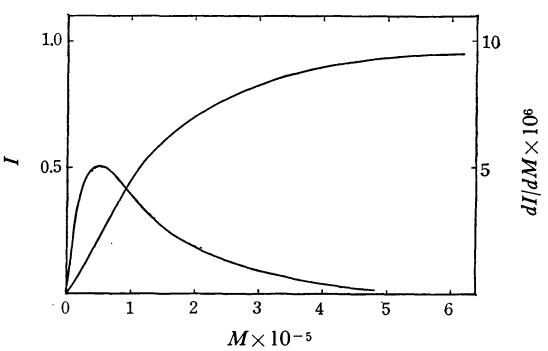

Fig. 8. Molecular weight distribution of polymer B.

The ratio of the weight-average molecular weight, $\overline{M}_w$, to the number-average, $\overline{M}_n$, was calculated from the distribution curve. The value of 1.95 for the $\overline{M}_w/\overline{M}_n$ ratio agrees fairly well with the value of 2.0 for the "*most probable distribution*" which can be expected in the addition polymerization.

On the other hand, the distribution estimated from the data of precipitation fractionation seems to be narrower than that obtained by the sedimentation method. This may be caused by insufficient effectiveness of fractionation.

The author wishes to express his hearty thanks to Professor Masaji Miura of Hiroshima University and to Dr. Toshizo Isoshima and Dr. Nobuo Yamada of this laboratory for their encouragement and useful discussions throughout this work.

Properties of Dilute Solutions of Polyurethanes. II. Branched Polymers

By Hiroshi SATO

Research Laboratory, Mitsubishi Rayon Co., Ltd., Otake, Hiroshima

(Received February 10, 1966)

Linear and branched polyurethanes, both of which contained polycaprolactone ($\overline{M}_n = 1.80 \times 10^3$), were prepared. Each polymer was fractionated from a dimethyl acetamide solution by precipitation with a mixture of *n*-heptane and ethyl ether, and the fractions were characterized by viscosity and sedimentation. The degree of branching for the fractions of the branched polymer was estimated by using the relation between viscosity and branching, derived by Flory. The ratio of the concentration dependence of the sedimentation coefficient k_s to $[\eta]$ was about 1.7 for the linear polymer, but the $k_s/[\eta]$ value increased with an increase in the degree of branching for the branched polymer. The Huggins constant, k', seems to be independent of the degree of branching.

In a previous paper,[1] the properties of dilute solutions of polyurethanes were investigated in an attempt to establish the relation between the intrinsic viscosity and the molecular weight and to obtain knowledge of the molecular weight distribution and the thermodynamic properties of solutions.

As linear polyurethane is usually prepared from a long chain diol, a diisocyanate, and a so-called chain-extender, such as diamine, a rather well-characterized branched polymer can easily be obtained by substituting triol for a part of the diol.

The purpose of the present paper is to estimate the degree of branching for branched polymers and to investigate the dependence of the properties of polymer solutions on the degree of branching.

The degree of branching can be estimated by several measurements, such as of the "*radius of gyration*" of the polymer chain,[2] the osmotic second virial coefficient,[3] the intrinsic viscosity, and the sedimentation.[4,5] The methods used here consist of measuring the viscosity and the sedimentation, as these measurements are rather more accurate than the others.
