The Preparation of Heavy Metal Hydride and Its Catalytic Activity. VIII.* Information on the Mechanism of Iron Hydride Formation**

By Yoshinobu TAKEGAMI, Toru UENO and Kiyoshi KAWAJIRI

Department of Fuel Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received March 26, 1965)

Some information on the mechanism of iron hydride formation in the reaction of iron(III) chloride with phenylmagnesium bromide under a hydrogen atmosphere has been presented. When the molar ratio ($C_6H_5MgBr/FeCl_3$) is larger than 5, 3—4 (mol./mol. $FeCl_3$) of hydrogen is absorbed during the synthesis of hydrides. The amounts of benzene, one of the by-products formed in the synthesis, have also been determined. The treatment of these hydrides with styrene under a nitrogen atmosphere has given ethylbenzene in amounts which correlate well with the amounts of hydrogen absorbed during the hydride synthesis. These observations can be taken as support for the formation of iron hydride. On the other hand, a mixture prepared by the reaction of iron(III) chloride with phenylmagnesium bromide under a nitrogen atmosphere evolved about 0.5 (mol./mol. $FeCl_3$) of hydrogen on hydrolysis. When the hydride prepared under a hydrogen atmosphere was hydrolyzed with dideuterosulfuric acid, D_2 as well as HD was evolved. These results seem to indicate that not only hydride sites but also metallic sites were formed during the iron hydride synthesis. On the basis of these observations, a possible mechanism for the formation of complex hydride containing iron and magnesium has been presented.

The formation of an iron hydride in the reaction of iron(III) chloride with phenylmagnesium bromide under a hydrogen atmosphere has been reported by several workers.[1-3] It was also demonstrated in our own earlier publications[4,5] that the iron hydride and several other transition metal hydrides were of interest for their high catalytic activities in the hydrogenation of olefins. Since the catalytic activity of the hydride is closely dependent on its composition (hydrogen content),[5] we investigated[6] the process of the iron hydride synthesis and found the following facts; 1) no hydrogen was absorbed so long as the ($C_6H_5MgBr/FeCl_3$) molar ratio was lower than 3; 2) a plot of the amounts of hydrogen absorbed during the hydride synthesis vs. the molar ratios was linear when the molar ratios were in the range from 3.5 to 7, and 3) about 4 mol. of hydrogen per mol. of iron(III) chloride was absorbed when the molar ratio was higher than 8. These observations suggested that the reaction scheme involved the following steps: 1) the formation of an intermediate; 2) the interaction of an excess of the Grignard reagent with the intermediate; 3) the replacement of phenyl groups with hydrogen atoms, and 4) the formation of a complex hydride.

$$FeCl_3 + 3C_6H_5MgBr \rightarrow Fe(C_6H_5)_3 + 3MgBrCl \quad (1)$$

$$Fe(C_6H_5)_3(C_6H_5MgBr)_{4/3} + H_2 \rightarrow FeH(C_6H_5)_2(C_6H_5MgBr)_{4/3} + C_6H_6 \quad (2)$$

$$FeH(C_6H_5)_2(C_6H_5MgBr)_{8/3} + H_2 \rightarrow FeH_2(C_6H_5)(C_6H_5MgBr)_{8/3} + C_6H_6 \quad (3)$$

$$FeH_2(C_6H_5)(C_6H_5MgBr)_4 + H_2 \rightarrow FeH_3(C_6H_5MgBr)_4 + C_6H_6 \quad (4)$$

$$FeH_3(C_6H_5MgBr)_{n>4} + C_6H_5MgBr + H_2 \rightarrow 1/2Mg(FeH_4)_2(C_6H_5MgBr)_{n>8} + 1/2MgBr_2 + C_6H_6 \quad (5)$$

However, in view of the instability of organo-iron compounds,[7] it appeared improbable that the $Fe(C_6H_5)_3$ could be an intermediate in the iron hydride synthesis. In this paper, several pieces of

information about the intermediate will be presented, and a probable mechanism based on them will be discussed.

Experimental

Materials.—Phenylmagnesium bromide was prepared under nitrogen by the reaction of freshly-distilled phenylbromide with a 10% excess of magnesium in dry tetrahydrofuran (THF) or diethyl ether. The Grignard reagent was filtered, and the concentration of the stock solution (0.6—0.9 mol./l.) was determined, prior to use, according to Gilman's method.[8] The solvent, tetrahydrofuran or diethyl ether, was dried over sodium and freshly distilled just before use.

The Preparation and Hydrolysis of Iron Hydride.—Since in all cases the hydrides were sensitive to air and moisture, all operations were carried out in a nitrogen or hydrogen atmosphere. The apparatus for the preparation of hydrides consisted of a four-necked flask equipped with a stirrer, a dropping funnel (60 ml.) and a thermometer; this was connected to a gas buret through a silica gel tube. Before the reaction, the apparatus was flushed with hydrogen. A solution of 70 ml. of tetrahydrofuran containing 0.005 mol. of iron(III) chloride was stirred at the reaction temperature for 40 min. To this solution a desired amount of the phenylmagnesium bromide solution (in THF) was then added through the dropping funnel. The solution immediately turned black, and a hydrogen absorption took place. The mixture was then stirred for 5 hr. or more, until the hydrogen absorption ceased. Then the hydride was hydrolyzed by the addition of 20 ml. of 15% aqueous hydrochloric acid, and the amount of hydrogen evolved was measured.

The Reaction of Iron Hydrides with Styrene under a Nitrogen Atomosphere.—The iron hydride was prepared at 0°C. The hydrogen gas in the system was exchanged with nitrogen, and then 5 ml. (0.0435 mol.) of styrene was added to the iron hydride solution. The mixture was stirred for 5 hr. at 0°C (styrene treatment). The mixture was hydrolyzed by the addition of aqueous hydrochloric acid, and the amount of hydrogen evolved was measured. The addition of ether produced two layers. The organic layer was separated, washed with water, concentrated by the evaporation of ether, and analyzed by gas chromatography.

The Determination of the Amounts of Benzene Produced during the Iron Hydride Synthesis.—Two variations of the determination procedure were used. In one method (procedure A), the iron hydride was prepared under hydrogen at 0°C, using ether as the solvent. At the end of the preparation, the stirrer was quickly replaced with a short distilling head, and the solvent, containing a small amount of benzene, was distilled under reduced pressure (10 mmHg) and at room temperature. The distillate collected in a dry ice trap was analyzed by gas chromatography, using cyclohexane as an internal reference. In order to check the validity of this method, another procedure (procedure B) was also employed. To the iron hydride prepared as above, 5 ml. of diethylketone was added, and the solution was stirred for 2 hr. at 0°C. The solution was then hydrolyzed and analyzed by gas chromatography, using cyclohexane as an internal reference. As a small amount of benzene was produced by the same treatment of Grignard reagent alone, it was necessary to correct the observed amount of benzene in gas chromatography in order to determine the true amount of benzene produced by the iron hydride synthesis.

The Hydrolysis of the Iron Hydride with Dideuterosulfuric Acid.—Dideuterosulfuric acid was prepared by the reaction of deuterium oxide with the sulfur trioxide which evolved from warm 30% fuming sulfuric acid. Several iron hydrides were hydrolyzed with dideuterosulfuric acid (30% D_2SO_4 in D_2O). The gas evolved during the hydrolysis was washed with concentrated sulfuric acid and analyzed by mass spectrography.

The Reaction of Iron(III) Chloride with 2, 4, 6-Trideuterophenylmagnesium Bromide.—2,4,6-Trideuterophenylmagnesium bromide was prepared by the reaction of 2,4,6-trideuterophenyl bromide with magnesium in THF. 2,4,6-Trideuterophenyl bromide was prepared by the reaction of phenyl bromide with dideuterosulfuric acid (50 mol.% D_2SO_4 in D_2O) according to Wilson's method.[9] The reaction of iron(III) chloride with the 2, 4, 6-trideuterophenylmagnesium bromide was carried out in THF at 25°C under a nitrogen atomosphere. The reaction mixture was then hydrolyzed by the addition of aqueous hydrochloric acid, and the gas evolved during the hydrolysis was analyzed by mass spectrography.

Results

The Synthesis of Iron Hydrides under a Hydrogen Atmosphere at Various Reaction Temperatures.—In order to elucidate the course of the iron hydride synthesis, reactions of iron(III) chloride with Grignard reagents were carried out at different molar ratios and at several reaction temperatures. The results are given in Tables I.

Others are same in Fig. 1.

and II. The hydrogen absorption curves obatined from the reaction carried out at 0°C are shown in Fig. 1. At the relatively low molar ratios of 3 and 4, the total amount of hydrogen absorbed was small, though the initial rate of the hydrogen absorption was high. At relatively high molar ratios between 6 and 12, the hydrogen absorption proceeded rapidly up to about 3 (mol./mol. iron(III) chloride) but there followed a sluggish hydrogen absorption; the total amount of hydrogen absorbed reached about 4 (mol./mol. iron(III) chloride). This correlation between the hydrogen absorption curves and the molar ratios is almost the same as that observed in the reactions carried out at 35°C.[6]

The experiments performed at lower temperatures (Fig. 2) show that the rates of hydrogen absorption slowed down as the reaction temperature was lowered. At −40°C, the rate was very slow and, therefore, no end point of the hydrogen absorption was detected exactly. At −70°C, no hydrogen absorption was observed, and the reaction mixture did not turn black.

The amount of hydrogen absorbed during the hydride synthesis is closely dependent on the molar ratio. The amounts of hydrogen absorbed plotted

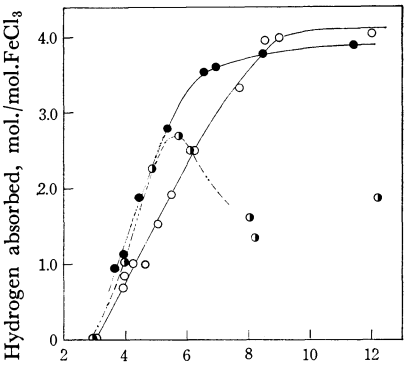

Fig. 3. Molar ratios vs. amounts of hydrogen absorbed.

-●-: At 0°C
-◑-: At −20°C

against the molar ratios (Fig. 3) show that the amounts of hydrogen absorbed at 0°C are more dependent on the molar ratio than those absorbed at 35°C. At −20°C, the amount of hydrogen absorbed reaches a maximum when the molar ratio is 6.10, decreasing with any further increase

in the molar ratio. Evidently, this dependence of the amount of absorbed hydrogen on the molar ratio is different from those observed at 0°C and 35°C. When the iron hydride was prepared at −20°C in the molar ratio of 6, and when phenylmagnesium bromide was added to the reaction mixture at the same temperature, no hydrogen evolution was observed, even though the molar ratio was as high as 12. It now seems impossible to find any probable interpretation for this decrease in the amount of hydrogen absorbed with the increase in the molar ratio.

On the hydrolysis of the hydrides prepared above, a hydrogen evolution was observed. The amounts of hydrogen evolved are given in the last column of Table I. They are somewhat larger than those absorbed during the hydride synthesis.

The Styrene Treatment of the Iron Hydrides.—Ethylbenzene was produced by the reaction of the iron hydride with styrene under a nitrogen atmosphere. The amounts of ethylbenzene produced are given in Table II. They are also shown graphically in Fig. 4 as a function of the amounts of hydrogen absorbed during the hydride synthesis. As may be seen in Fig. 4, a linear relationship is observed between the amounts of ethylbenzene produced during the styrene treatment and the amounts of hydrogen absorbed during the hydride synthesis.

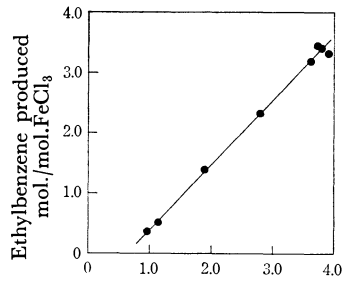

Fig. 4. Amounts of hydrogen absorbed during hydride synthesis vs. amounts of ethylbenzene produced during styrene treatment.

The Determination of the Amounts of Benzene Produced during the Iron Hydride Synthesis.—One mole of benzene should be produced per mole of hydrogen absorbed so long as the iron hydride formation proceeds according to Eqs. 1—5. Therefore, the amounts of benzene produced during the iron hydride synthesis were determined in order to check the scheme. As may be seen in Fig. 5, plots of the amounts of benzene produced against the amounts of hydrogen absorbed during the hydride synthesis gave a straight line, with a slope of 1.0. These results show that one mole of benzene is produced per mole of hydrogen absorbed. However, when the data are extrapolated to zero hydrogen absorbed, about 0.6

(mol./mol. iron(III) chloride) of benzene is to be produced.

The Reaction of Iron(III) Chloride with a Grignard Reagent under a Nitrogen Atmosphere,—Even when the reaction of iron(III) chloride with a Grignard reagent was carried out under a nitrogen atmosphere, a black solution was produced and about 0.5 mol. of hydrogen per mole of iron(III) cholride was evolved on the hydrolysis, as is shown in Table III. The amount of hydrogen evolved increased steadily as the molar ratio increased from 3 to 5, and then it reached a plateau. It was also observed that the amount of hydrogen evolved on the hydrolysis of the nickel (II) chloride - Grignard reagent system was somewhat larger than that evolved from the iron(III) chloride - Grignard reagent system.

the styrene treatment was about 0.5 (mol./mol. iron(III) chloride) when the molar ratio was higher than 5.

Hydrogen Absorption Subsequent to the Reaction Carried Out under a Nitrogen Atmosphere.—The reaction of iron(III) chloride with the Grignard reagent was carried out under a nitrogen atmosphere (the first step), and then under a hydrogen atmosphere (the second step).*1 The amount of hydrogen absorbed was measured in the course of the second step. The hydrogen absorption curves are shown in Fig. 7. A comparison between Fig. 1 and Fig. 7 shows that the hydrogen absorption rate and the amounts of hydrogen absorbed are quite the same as those in the one-step reactions. As is shown in Table IV, the amounts of hydrogen evolved during the hydrolysis subsequent to the hydrogen absorption are larger by 0.3—0.4 than the amounts of hydrogen absorbed in the second step as expressed by the mol. hydrogen/mol. iron(III) cholride ratio. In the cases of the nickel(II) chloride - Grignard reagent system, these increments in the amount of hydrogen evolved on the hydrolysis amounted to 0.6—1.0. The increase in the amount of hydrogen seemingly comes from the hydrogen which the reaction product of the first step evolves in the hydrolysis.

The Hydrolysis of Iron Hydrides with Dideuterosulfuric Acid.—It has been assumed that the hydrogen evolved on the hydrolysis should be attributed to the hydride. However, there is still another possibility, that a metallic compound which evolves hydrogen on the hydrolysis may be included in the reaction system. Therefore, several reaction products of the reaction of iron(III) chloride with phenylmagnesium bromide were hydrolyzed with dideuterosulfuric acid, and the gas evolved, a mixture of D_2, HD and H_2, was analyzed by mass spectrography. Although the mechanism of the evolution of D_2, HD and H_2 has not yet been constructed, we assume that the amount of D_2 evolved can be an index of the amount of the free metal and/or the reaction product not containing hydrogen as a constituent, and that the amount of HD evolved can be an index of the amount of hydride. The results are listed in Table V. The D-purity of the dideuterosulfuric acid was about 92% as determined by the hydrolysis of iron metal (Run 1).

The agreement between the compositions of the

*1 The preparation of hydride which takes two steps (first and second steps) will be described as "two-step reaction," while the preparation carried out under a hydrogen atmosphere from the beginning of the reaction will be described as "one-step reaction" in the discussion below.

TABLE V. HYDROLYSIS OF IRON HYDRIDE WITH DIDEUTEROSULFURIC ACID

3	PhMgBr-$FeCl_3$, $N_2 \rightarrow H_2$*	D_2SO_4	26	45	29
4	PhMgBr-$FeCl_3$ in H_2**	D_2SO_4	20	43	37
5	$C_6H_2D_3MgBr$-$FeCl_3$ in N_2	HCl	>99	<1	—

* Prepared by the two-step reaction: the amount of hydrogen absorbed was 3.2 mol./mol.$FeCl_3$.

** Prepared by the one-step reaction: the amount of hydrogen absorbed was 3.2 mol./mol.$FeCl_3$.

gas evolved in Runs 1 and 2 demonstrates that the major product in the reaction of iron(III) chloride with phenylmagnesium bromide under a nitrogen atmosphere is indeed the free metal and/or the reaction product not containing hydrogen as a constituent. In the cases of the hydrides which absorbed hydrogen, the gas evolved was about 45% (1.6 mol./mol. iron(III) chloride) HD, which can be taken as further support for the presence of the iron hydride. On the other hand, there was about 30% (1.4 mol./mol. iron(III) chloride) D_2; this can not be explained by Eqs. 1—5. About 20% (1.0 mol./mol. iron(III) chloride) of H_2 was also evolved.*2

As may be seen in Run 5, no appreciable D-fraction was detected in the gas evolved during the hydrochloric acid hydrolysis of the product of the reaction of ferric chloride with 2, 4, 6-trideutero phenylmagnesium bromide.

Discussion

The linear relationship between the amounts of hydrogen absorbed during the hydride synthesis and the amounts of ethylbenzene produced during the styrene treatment of the hydrides (Fig. 4) indicates that the hydrogen absorbed during the synthesis was consumed in the formation of the hydride. The evolution of HD during the hydrolysis with dideuterosulfuric acid subsequent to the hydrogen absorption (Table V) is conceivably due to the presence of the hydride.

The facts that one mole of benzene was produced per mole of hydrogen absorbed during the iron hydride synthesis and that plots of the amounts of hydrogen absorbed against the molar ratios were linear in the reaction carried out at 0°C, as well as at 35°C, can be taken as further confirmations of the proposed scheme, Eqs. 1—5.

However, there are several facts that can not be explained by the proposed scheme. About 0.5 mol. of hydrogen per mole of iron(III) chloride was evolved during the hydrolysis of the reaction mixture produced under a nitrogen atmosphere (Table III). Since 0.5 mol. of ethylbenzene per mole iron(III) chloride was produced when this reaction mixture was treated with styrene under a nitrogen atmosphere (Fig. 6), it seems plausible that a small amount of hydride was formed under a nitrogen atmosphere by the elimination of FeH from the intermediate, $Fe(C_6H_5)_3$.*3 This view, however, is discarded by the fact that no appreciable deuterium fraction was detected in the gas evolved on the hydrolysis, with hydrochloric acid, of the reaction mixture prepared by the reaction of iron(III) chloride with 2, 4, 6-trideuterophenylmagnesium bromide under a nitrogen atmosphere. The mass spectral data also show that the reaction mixture produced by the reaction of iron(III) chloride with phenylmagnesium bromide under nitrogen does not contain hydrogen as a constituent. This compound absorbs hydrogen to give the nearly same amount of the hydride as that formed in the one-step reaction under a hydrogen atmosphere. A reasonable scheme must be proposed for the hydrogen absorption in the two-step reaction.

The $Fe(C_6H_5)_3$ intermediate has been considered to be formed in the reaction of iron(III) chloride with phenylmagnesium bromide. This intermediate, however, does not evolve hydrogen in the hydrolysis, and it is improbable that the intermediate is left intact for 2 hr. or more. Therefore, the intermediate in the two-step reaction is considered to be one of the decomposition products of $Fe(C_6H_5)_3$,*4 i. e., $Fe(C_6H_5)_2$, $Fe(C_6H_5)$ or Fe. If Fe is the intermediate, 1.0 mole. of hydrogen should be evolved on the hydrolysis, while no hydrogen evolution should be observed if $Fe(C_6H_5)_2$ is the intermediate. Thus, $Fe(C_6H_5)$

*2 Three points can be considered as the source of this H_2; 1) the H-fraction in the dideuterosulfuric acid used in the hydrolysis; 2) the hydrolysis of iron hydride which contains a relatively large amount of hydrogen (for example, $FeH_3 + 2D_2SO_4 \rightarrow FeSO_4 + 2HD + 1/2\ H_2$), and 3) hydrogen which is adsorbed on the metal surface. We now consider that 1) and 2) contribute greatly to the H_2-evolution.

*3 When cyclohexylmagnesium bromide is used instead of phenylmagnesium bromide, 1.4 mol. of hydrogen per mole of iron(III) chloride is evolved on the hydrolysis of the reaction mixture prepared under a nitrogen atmosphere, presumably indicating the formation of iron hydride through cyclohexene-elimination from the iron-cyclohexyl intermediate; Y. Takegami, T. Ueno, K. Shinoki and T. Sakata, *J. Chem. Soc. Japan, Ind. Chem. Sect.* (*Kogyo Kagaku Zasshi*), **67**, 316 (1964).

*4 Kharasch and his co-workers (*J. Am. Chem. Soc.*, **83**, 3229 (1961)) reported, in their study of the modification of the Grignard reaction in the presence of a small amount of iron(III) chloride serving as a catalyst, that phenylmagnesium bromide combines with iron(III) chloride to produce an unstable organo-iron compound, which then decomposes to give a biphenyl and a reduced iron salt in the following way: $2C_6H_5MgBr + FeCl_3 \rightarrow (C_6H_5)_2FeCl + 2MgBrCl$, $(C_6H_5)_2FeCl \rightarrow FeCl + C_6H_5\text{-}C_6H_5$. Our assumption of $Fe(C_6H_5)_3$ as an unstabe intermediate in place of $Fe(C_6H_6)Cl$ is based on the fact that hydrogen is absorbed only when the molar ratio is higher than 3 (Fig. 3), indicating that 3 mol. of Grignard reagent has been consumed before the hydrogen absorption takes place in the reaction.

appears to be the best choice as the intermediate which evolves 0.5 mol. of hydrogen in the hydrolysis.*5 The fact that the product in the reaction of iron(II) chloride, as well as iron(III) chloride, with the Grignard reagent under a nitrogen atmosphere evolved about 0.5 mol. of hydrogen per mole of iron(III) chloride is also in agreement with the prediction of such an intermediate as $Fe(C_6H_5)$.

As may be seen in Table III, 4—8 mol. of the Grignard reagent per mole of iron(III) chloride is necessary for the hydrogen absorption. The effect of the excess Grignard reagent appears quite similar to that considered in Eqs. 1—5. Therefore, the hydrogen absorption in the two-step reaction is assumed to be initiated by the interaction of the Grignard reagent with $Fe(C_6H_5)$ to form an iron subphenyl-Grignard reagent complex such as II, followed by the replacement of phenyl groups with hydrogen atoms by the attack of hydrogen molecule. Thus, a complex hydride such as III should be produced when 3 mol. of hydrogen per mole of iron(III) chloride is absorbed. On the hydrolysis of III, 3.5 mole. of hydrogen per mole of iron(III) chloride should be evolved. Since this corresponds to the results presented above, the shceme I→II→III can be assumed in the two-step reaction:

$$FeCl_3 + 3\,C_6H_5MgBr \rightarrow Fe(C_6H_5)_3 + 3\,MgBrCl$$

$$\underset{\mathbf{I}}{Fe(C_6H_5)_3} \rightarrow Fe(C_6H_5) + C_6H_5\text{–}C_6H_5{}^{*6} \quad (6)$$

$$Fe(C_6H_5) + 2\,C_6H_5MgBr \rightarrow \underset{\mathbf{II}}{\begin{matrix} & MgBr \\ & \vdots \\ & C_6H_5 \\ & \vdots \\ Fe & \text{–} C_6H_5 \\ & \vdots \\ & C_6H_5 \\ & \vdots \\ & MgBr \end{matrix}} \quad (7)$$

$$II + 3\,H_2 \rightarrow \underset{\mathbf{III}}{\begin{matrix} & MgBr \\ & \vdots \\ & H \\ & \vdots \\ Fe & \text{–} H \\ & \vdots \\ & H \\ & \vdots \\ & MgBr \end{matrix}} \quad (8)$$

Although this new scheme is proposed for the formation of the iron hydride in the two-step reaction, it seems almost certain that this scheme also contributes greatly to the iron hydride formation in the one-step reaction under hydrogen. If this is the case, the following experimental results in the one-step reaction, which can not be explained by the earlier scheme, can be explained: 1) the rate of the absorption and the amount of hydrogen absorbed are nearly the same in the one-tsep reaction as in the two-step reaction (Fig. 1 vs. Fig. 7); 2) the amounts of hydrogen evolved in the hydrolysis are somewhat larger than those absorbed during the hydride synthesis (Table II); 3) the composition of the gas evolved in the hydrolysis with dideuterosulfuric acid is nearly the same as that in the two-step reaction (Table V); 4) about 5 mol. of Grignard reagent per mole of iron(III) chloride is needed to absorb 3 mol. of hydrogen in the iron hydride synthesis (the reaction carried out at 0°C, in Fig. 3), and 5) almost the same results were obtained when iron(III) chloride was used instead of iron(III) chloride (Fig. 1).

It can be reasonably concluded, therefore, that the scheme I→II→III is also valid in the one-step reaction. A more detailed discussion of this hypothesis must, however, await the accumulation of additional data on the composition of the gas evolved by the hydrolysis of hydrides of various hydrogen contents with dideuterosulfuric acid, as well as on other reaction parameters. These data are now being gathered.

The authors wish to express their gratitude to Professor Yoshimasa Takezaki of the Chemical Research Institute, Kyoto University, for his kind mass spectrographic analysis. Thanks are also due to Mr. Takeki Sakata and Mr. Takao Fujii for their skillful assistance in the experiments.

*5 $Fe(C_6H_6) + 2\,HCl \rightarrow FeCl_2 + C_6H_6 + 1/2\,H_2$. This intermediate is being studied by means of electron-spin resonance.

*6 Like Kharasch, we assume a production of one mole of biphenyl. However, a small amount of phenyl radicals may also be produced, which then abstracts the hydrogen atom from the solvent to give benzene. This hypothesis may explain the production of about 0.6 mol. of benzene when the amount of hydrogen absorbed during the iron hydride synthesis is zero (Fig. 5).

Studies of Organic Catalytic Reactions. III.[1] The Hydration Mechanism of Nitriles to Amides with Nickel Catalysts

By Ken-ichi WATANABE and Koji SAKAI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo

(Received March 26, 1965)

Benzonitrile, benzyl cyanide, acetonitrile and 2-cyanopyridine give the corresponding amides by the hydration with nickel catalysts and water. The effect of pyridine and thiophene on the hydration has been investigated. In general, the yield of amides increases upon the addition of a suitable amount of pyridine. On the contrary, the reaction is distinctly suppressed by the addition of thiophene. This fact is in striking contrast to the effect on the hydrogenation of nitriles. The correlation of the catalytic functions in hydration and the hydrogenation of nitriles has been studied, and the hydration mechanism with nickel catalysts has been discussed.

Nitriles are hydrated to the corresponding amides by refluxing them with metal catalysts (a nickel catalyst is the best) in water[1]. In this novel reaction, neither acid nor alkali is necessary, and the reaction is generally stopped at the amide stage, especially in the reaction of aromatic nitriles. However, the reaction of aliphatic nitriles is somewhat complicated because of the side reactions with accompany the hydration. The present paper will deal with the mechanism of this catalytic hydration reaction of nitriles from the points of view of organic reaction and catalytic function.

It has been reported that a nickel catalyst acts in two different ways, exhibiting both acidic and basic functions. In this paper, this conception will be developed further by some experiments and discussed. In the hydration of benzonitrile, benzyl cyanide, benzamide and acetonitrile, when pyridine was used as a basic substance, it accelerated the hydration. While thiophene, when used as an acidic substance, suppressed the hydration. In addition, pyridine also suppressed side reactions. As a result of many facts mentioned below, the hydration mechanism of nitriles to amides with nickel catalysts will be presented.

The Hydration of Benzyl Cyanide, Acetonitrile and 2-Cyanopyridine with Nickel Catalysts.—Though Raney nickel is effective enough for this reaction,[1] Urushibara nickel catalyst-B (U-Ni-B)[1,2] was used in these experiments. Some results of the hydration of three nitriles are shown in Table I and in Figs. 1 and 2. In the hydration of acetonitrile, hydrogen cyanide was generated as well as ammonia. The formation of propionic acid, hydrogen cyanide and formic acid suggests that catalytic cleavages of acetonitrile and

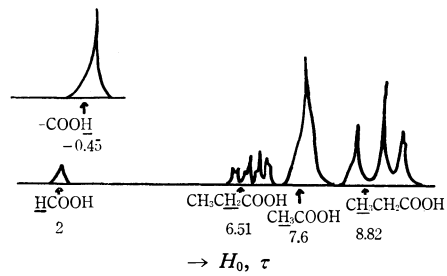

Fig. 2. NMR spectrum chart of acids.

new bond formations take place in addition to the hydration reaction. It is of great interest that such reactions occur in the liquid phase around at 100°C.*1 The effect of the electronegative character of the nitrogen atom in the pyridine nucleus was so predominant in the hydration of cyanopyridines that a remarkably good result was obtained in the case of 3-cyanopyridine (amide yield: 89%),[1] while a nickel complex was obtained in the case of 2-cyanopyridine.

*1 The hydration of adiponitrile gave the corresponding amide in a poor yield (ca. 20%) and was accompanied by various kinds of side reactions. By the gas chromatographic analysis of the oily by-product, five components were detected. It seemed that an acidic substance was included in the oil. It can only be preumed that the reaction was much more complicated than that of acetonitrile.

1) Yield of amides was calculated from the weight of amides obtained.

Studies of Catalysts for the Hydration.—The effect of the nature of many catalysts on this hydration has been examined.[1] It has been found that the usual catalysts for hydrogenation are generally effective in the hydration of nitriles.

For this paper, some other catalysts have also been tested in the hydration of benzonitrile. The catalysts used were U-Ni-B, Stabilized-Ni (F50),*2 zinc oxide, and copper chromium oxide. The results of representative experiments are shown in Table II. The highest yield of benzamide was given with U-Ni-B (Exp. No. 1), the other substances gave poor results as catalysts for the hydration.

The Effect of Ammonia Gas on the Hydration.—During the hydration of any nitrile, a small quantity of ammonia gas is gradually generated. The quantity of ammonia gas generated during the reaction with benzonitrile was examined every hour,*3 this was also tried in the case of the hydrolysis of benzamide with U-Ni-B in water. The

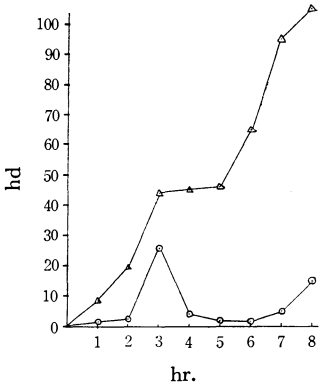

Fig. 3. The relative quantity of ammonia gas generated during the hydration with U-Ni-B.
—△— Benzonitrile —○— Benzamide

results of the measurements are shown in Fig. 3. It may easily be assumed that the ammonia gas generation was caused by the cleavage of the C–N bond of the nitrile groups. The quantitative analysis of all the ammonia gas generated from benzonitrile throughout the eight-hour reaction always gave constant results (ca. 20% yield), while benzamide was obtained in a 77 per cent yield. On the contrary, the hydrolysis of benzamide was much slower than that of benzonitrile, and no constant

results were observed with regard to the ammonia generation. A part of the ammonia generated during the reaction may form an ammonium salt of the acid that is produced by the hydrolysis of nitriles. On the basis of the results of experiments with benzonitrile, however, it may be assumed that the ammonium salts are too unstable under these reaction conditions and that they are likely to decompose and free the ammonia gas. In order to establish whether ammonia gas itself behaves as a catalyst for the hydration of nitriles, some experiments were carried out. Benzonitrile was refluxed with water containing a few drops of concentrated ammonium hydroxide without a nickel catalyst or was refluxed with concentrated ammonium hydroxide without a catalyst.*4 In one case, ammonia gas was introduced constantly throughout the reaction in the absence of a nickel catalyst. The results of the experiments are shown in Table III. It has been proved that ammonia gas itself generally effective to some extent as a catalyst for the hydration.

The Effect of Pyridine and Thiophene on the Hydration of Nitriles.—The effect of pyridine and thiophene on the hydration of some nitriles was studied in detail in the examination of this

*4 Krewson and Couch reported that concentrated ammonium hydroxide was only effective for the hydrolysis of nicotinonitrile in the sealed-tube (at 108°C for twelve hours). C. F. Krewson and J. F. Couch, *J. Am. Chem. Soc.*, **65**, 2256 (1943).

catalytic reaction mechanism. Blank tests with pyridine and thiophene showed that neither of them had any influence upon the hydration of benzonitrile and benzyl cyanide without catalysts (Table IV). In the hydration of benzyl cyanide, benzonitrile and acetonitrile, however, pyridine had favorable effects, while thiophene had unfavorable effects. This effect of pyridine was observed conspicuously in the reactions of benzyl cyanide. As is shown in Table V, the yield of phenylacetamide increased a great deal upon the addition of a suitable amount of pyridine (ca. 20% of a nickel catalyst). Further, it is noteworthy that no by-product could be obtained.

The results of the experiments with benzonitrile are shown in Figs. 4 and 5. Figure 4 shows the amount of the diminution of benzonitrile during the reaction with pyridine. The most desirable amount of pyridine added was ca. 1 g. (ca. 25% of a nickel catalyst). As is shown in Fig. 5,*5 it has been found that thiophene has a distinct effect in suppressing the reaction. The effect of pyridine on the hydration of acetonitrile was somewhat different from that of the other cases. Pyridine did not promote the hydration of acetonitrile, and the yield of acetamide was decreased. However, it was found that no propionic acid or formic acid was obtained, only acetic acid and acetamide were obtained by the addition of pyridine. Therefore, pyridine seemed to suppress the catalytic cleavages of acetonitrile. As for the effect of thiophene, it was as large as in the other cases. When acetamide was refluxed with a newly-prepared catalyst in water, the reaction hardly ever took place suprisingly. The reaction of acetonitrile may be assumed to be as shown in Fig. 6. Benzoic acid was obtained in a poor yield by the hydrolysis of benzamide,*6 a small quantity of ammonia gas was hardly ever generated. The effect of pyridine and thiophene was also observed by the generation of ammonia, a generation which was of the same type as the hydration of benzonitrile.

Discussion

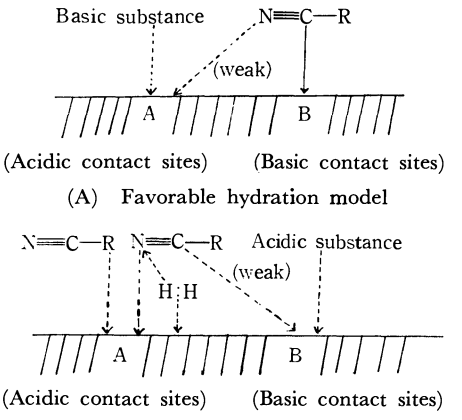
As the result of many experiments, it is apparent, in the hydration of nitriles with nickel catalysts in water, that pyridine and organic bases have favorable effects on the reaction, while that thiophene and organic acids have unfavorable effects. It has previously been shown[1] that nitriles of a basic character afford the corresponding amides in good yields, and that those of an acidic character afford no hydration products. On the other hand, the effects of pyridine and thiophene on the hydrogenation of nitriles with nickel catalysts both

*5 The experimental method with thiophene was that 0.5 g., 1 g. or 1.5 g. of thiophene was added respectively in each run, after the reactions were over, the benzonitrile which remained was analyzed by gas chromatography (Fig. 5).

*6 The same reaction procedure with the hydration of benzonitrile.

in the liquid[3] and the vapor phases[4] have been studied in detail.[5] For instance, an organic base, ammonia or nitriles of a basic character effect an unfavorable hydrogenation. Thiophene does not. Consequently, it is significant that the effect of organic acids and bases on the hydration of nirtiles is in contrast to their effect on the hydrogenation of nitriles. It is of particular interest that *o*-aminobenzamide was obtained by the hydrogenation of *o*-nitrobenzonitrile with a nickel catalyst both in the liquid[6] and the vapor phase[5,7]. It is presumed that the hydrogenating activity of the nickel catalyst is greatly depressed by the nitro group, and also by the amino group produced by the reduction of the nitro group, and that the nitrile group is hydrated with the water produced by the hydrogenolysis of the nitro group. From these facts, it may be inferred that the hydrogenation of nitriles is due to the catalytic action of a kind of active center which may be expressed as acidic contact sites of the nickel catalysts. In this case, the electronegative nitrogen atom of the nitrile group may be first adsorbed on the acidic contact sites and then be activated to cause hydrogenation. So long as other atoms of a more electronegative character cover the acidic contact sites of the catalysts, the nitrogen atom of the nitrile group will hardly ever be adsorbed firmly on the sites, consequently, the hydrogenation of the nitrile group will be depressed. On the other hand, the hydration of the nitrile group with water may occur by means of the activation of the carbon atom of the nitrile group on the other kind of free active-contact sites of the catalysts in spite of the existence of hydrogen. Therefore, the hydration of nitriles is apt to take place instead of hydrogenation when the acidic contact sites of the catalysts are covered with bases or basic substances. From many experimental facts, it may be concluded that the active-contact sites serving to introduce the hydration of nitriles are endowed with a more electronegative character (they are, that is, the basic contact sites of the catalysts). This may be expressed as in Fig. 7 (A). On the contrary, acidic substances may cover the basic contact sites of the catalysts, and interfere with the strong adsorption of nitriles on the same sites, so suppressing the hydration. This may be expressed as in Fig. 7 (B).

The conception that the carbon atom of the nitrile group is adsorbed predominantly on the basic contact sites of the nickel catalysts has been proved



(A) Favorable hydration model

(B) Unfavorable hydration model

Fig. 7

by some other experiments. When benzonitrile was hydrogenated with a nickel catalyst in the vapor phase (250°C), toluene was obtained (87%) by the cleavage of the C–N bond. However, in the reaction at 350°C, about 35% of benzene was formed, and when amine was added to the benzonitrile, the yield of benzene increased to 47%.[5] The formation of benzene is apparently due to the cleavage of the C–CN bond, in this hydrogenolysis, the carbon atom of the nitrile group should be adsorbed on the other kind of active-contact sites of the catalysts (the basic contact sites). It was proved that the cleavage of the C–CN bond occurs before the hydrogenation of the nitrile group.[8] Amine worked on the acidic contact sites to accentuate the function of the basic contact sites of the catalysts. When *o*-nitrobenzonitrile was hydrogenated, 48 per cent of aniline was obtained at a reaction temprature of 300°C.[7] It was about the same with the reaction of *o*-aminobenzonitrile.[5] When benzonitrile mixed with about 35 per cent of water was hydrogenated at 250°C, the yield of toluene was decreased to 60 per cent and amines and unreacted nitrile were obtained.[5] On the other hand, *o*- and *p*-hydroxybenzonitrile afforded no phenols in reactions at 300°C, and only the *o*-compound afforded even 11 per cent of phenol at 350°C.[9] From these results, it can be concluded that the carbon atom of the nitrile group is likely to be adsorbed on the basic contact sites of the nickel catalysts and so cause the hydrogenolysis of the C–CN bond at elevated temperatures. Amine and water relate to the acidic contact sites of the catalysts. The hydroxyl group relates to the basic contact sites and suppreses the hydrogenolysis. As for the cleavage of the C–CN bond in water, it has obviously been shown that hydrogen cyanide, formic acid and propionic

acid are formed in the hydrolysis of acetonitrile with a nickel catalyst. Thus, it may also be assumed that the cleavage of the C–CN bond takes place on the basic contact sites of the catalysts. As was shown in a previous paper,[1] it is of interest that no hydration product was obtained in the reaction of *p*-hydroxybenzonitrile with a nickel catalyst in water. This fact suggests a strong interaction between the hydrogen atom of the hydroxy group and the basic contact sites of the catalysts.

When benzonitrile is hydrogenated with a nickel catalyst in ethanol, amines are obtained as the main products (ordinary hydrogenation). However, it has now been observed that no reaction takes place when water is used as the solvent instead of ethanol at room temperature (the carbylamine test is negative), while, the hydration of the nitrile to benzamide occurs predominantly when the reaction mixture is refluxed with enough hydrogen gas (amide yield; 75%). To examine the effect of thiophene on the reactions mentioned above, 1 g. (25% of the nickel catalyst) and 0.2 g. (5% of the nickel catalyst) of thiophene were added to the catalysts. In the reactions, both at room temperature and at the refluxing temperature (ca. 100°C), even very small quantities of amines were hardly ever obtained. No favorable effect of thiophene on the hydrogenation was observed. On the other hand, the unfavorable effect of thiophene on the hydration of the nitrile was just the same as that shown in Fig. 5 when it was refluxed. Thus, it is evident that water suppresses the hydrogenation of nitriles, causing the hydration in some way. Apparently, the fact that water is the most suitable solvent for this hydration is important. That is, water has two functions, one is to react with nitriles, affording amides, while the other is to suppress other side reactions, especially the hydrogenation of nitriles. It may be assumed, consequently, that the free electron pair of the oxygen atom of the water molecule interacts with the acidic contact sites of the nickel catalysts and interferes with the strong adsorption of the nitrogen atom of the nitrile group on the same sites of the catalysts. The fact that the addition of basic substances to the catalysts does not have an unfavorable effect may mean that the interaction of water and catalysts is fairly strong. From a different point of view, however, if this nickel-catalyzed hydration is essentially due to the ionization or half-ionization of water on the catalysts, the hydrolysis of nitriles to acids should be the main reaction, as is observed in the hydrolysis with acid or base catalysts.

According to the conception of the acidic and basic functions of the nickel catalysts, the nitrile-catalysts-water interaction may be represented as in Fig. 8, while the course of the hydrolysis of nitriles to acids may be represented as in Fig. 9. However, it has not been proved that there are two kinds of active contact sites, A and B, really fixed

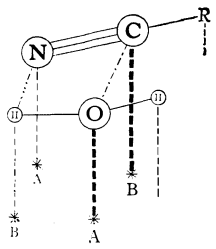

Fig. 8

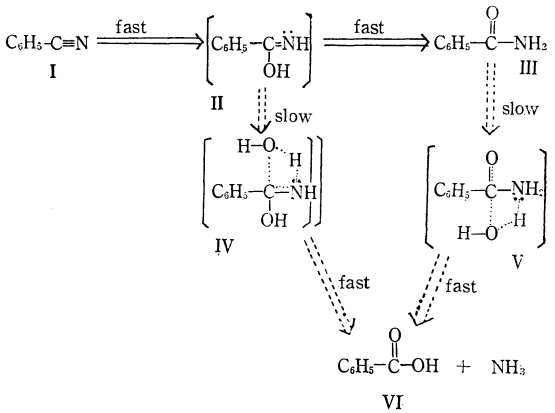

Fig. 9. The hydration of Benzonitrile

⇒ Main reaction

⇛ Hydrolysis

on the surface of the catalysts. This serves only to explain the phenomena and results of the nickel-catalyzed hydration and hydrogenation of nitriles. It is assumed that the hydrolysis of nitriles may arise also by the activation of the carbon atom of the amide group, and that it is less active than the hydration of nitriles. Attention should be focussed on the fact that the hydrolysis of benzamide and acetamide with a nickel catalyst is much more difficult than that of benzonitrile or acetonitrile. This is the reason why two courses, II–IV–VI and II–III–V–VI, have been postulated. The former is expected to be faster than the latter.

In the end, it is noteworthy that the nickel catalysts (U-Ni and Raney nickel) used in this hydration have been prepared somewhat differently from that used for hydrogenation. It does not matter if the catalyst is exposed to air and to common city water during the preparation.[1] This may lead to an assumption that oxygen in the air or in undistilled water attacks the acidic contact sites of the catalysts, but does not have the unfavorable effect on the basic contact sites of causing the hydration of nitriles.

Experimental

According to the common reaction procedure reported previously[1], were refluxed nitriles for eight hours in

water with U-Ni-B. After the reactions, the catalysts were separated by filtration, the filtrates were analyzed by gas chromatography, and the reaction products were obtained by the careful evaporation of the filtrates on a water bath. In general, rather pure amides were thus obtained.

The Hydration of Benzyl Cyanide.—Ten grams of benzyl cyanide and 150 ml. of water were refluxed vigorously with U-Ni-B (containing 4 g. of nickel) for ten hours. During the reaction a small quantity of ammonia was generated as was detected with litmus. After the reaction was over, the catalyst was separated by filtration while hot and washed with hot water. The filtrate, combined with the washings, was extracted with ether. When the aqueous solution (filtrate) was then evaported carefully on a water bath, phenylacetamide was obtained in a 58% yield as the main product, m. p. 153.5—154.2°C. A small quantity of an oily by-product was obtained from the ether extract and was analyzed successfully by gas chromatography.*7 The by-products seemed to be small quantities of phenylacetic acid, phenethylamine and benzaldehyde. However, the presence of benzaldehyde was somewhat doubtful, because the Tollens' test[10] for it varied between being positive and negative; moreover, the detection of benzaldehyde was not always successful by gas chromatography.

The Hydration of Acetonitrile.—Thirty-five grams of acetonitrile and the catalyst (containing 20 g. of nickel) in 500 ml. of water were placed in a 1000-ml., three-necked, round flask and stirred while being refluxed for eight hours. During the reaction, ammonia gas was detected; sometimes hydrogen cyanide was detected as well. The hydrogen cyanide was identified by the method used for picric acid.[11] After the reaction was over, the catalyst was separated by filtration. The filtrates were alkalized with sodium hydroxide and then evaporated to a solid mass on a water bath. When the dried mass was extracted with chloroform in a Soxhlet extractor, crude acetamide was obtained from the extract in rather pure form, m. p. 81.5—81.7°C. The yield was 30.05 g. (ca. 70%). The sodium salt which remained was put into a small quantity of water and acidified with concentrated hydrochloric acid. The free acids were extracted with ether. The total weight of the free acids thus obtained was 6 g. The mixture of the acids was analyzed by means of their NMR spectrum*8 (Fig. 2). On the other hand, they were esterified with diazomethane and the esters were analyzed by gas chromatography*9 (Fig. 1). The acids were propionic acid, acetic acid and a small amount of formic acid. They were identified by NMR and by gas chromatography with three pure acids. Amine was extracted by hydrochloric acid and was identified by carbylamine reaction.

The Hydration of 2-Cyanopyridine.—Seven grams of 2-cyanopyridine and 100 ml. of water were refluxed vigorously with U-Ni-B (containing 4 g. of nickel) for ten hours. During this reaction, the colorless contents turned violet and then blue and the pH value of the contents became 9.4—9.2 and then 8.4—8.2. A small quantity of ammonia gas was generated during the reaction, as could be detected with litmus. The product obtained by the same method as in the other cases was dissolved in ethanol and then separated by column chromatography with active alumina. Thus, pyridine-α-carboxylic acid amide was obtained in ca. 40% yield (m. p. 105°C), along with a blue nickel complex. The weight proportion of pyridine-α-carboxylic acid amide and the nickel complex was about 3 : 1. The nickel complex immediately absorbed moisture in air and had the property of a solid solution. The paramagnetic character was observed. When it was heated with hydrochloric acid, both pyridine-α-carboxylic acid and its amide were obtained. When it was treated with dimethylglyoxime, free pyridine-α-carboxylic acid amide was obtained. As a result of an infrared analysis, it seems that this complex might be formed by an interaction of the nickel and pyridine-α-carboxylic acid amide. By refluxing 2-cyanopyridine with Raney-Ni-W_7 in water, the contents (color and pH) were observed as well as when U–Ni–B was used. However, a small quantity of pyridine was obtained besides pyridine-α-carboxylic acid amide and the nickel complex.

The Hydration of Benzonitrile Accompanied with Hydrogen Gas.—1) Five grams of benzonitrile was refluxed in 80 ml. of water with U-Ni-B (4 g. of nickel) for eight hours. A constant flow of hydrogen gas was introduced into the reaction mixture throughout the refluxing. Benzamide was thus obtained in a 75% yield, along with a very small amount of amine (almost the same reaction and result as were obtained without hydrogen gas; cf. Exp. No 1, Table II).

2) Five grams of benzonitrile, together with U-Ni-B (4 g. of nickel) and 0.2 g. of thiophene (5% of nickel catalyst), was stirred for eight hours at room temperature. A constant flow of hydrogen gas was introduced into the reaction mixture throughout the reaction. Benzamide was thus obtained in a 7% yield, while 80% of the nitrile was recovered. Amine was extracted by hydrochloric acid and was analyzed by means of a study of its infrared spectrum. Benzylamine was obtained in a 2% yield.

3) Five grams of benzonitrile, together with U-Ni-B (4 g. of nickel) and 1 g. of thiophene (25% of nickel catalyst), was refluxed in 80 ml. of water for eight hours. A constant flow of hydrogen gas was introduced into the reaction mixture throughout the refluxing. Benzamide was thus obtained in a 36.5% yield as the main product, while 58% of the nitrile was recovered. A small quantity of amine was obtained as hydrogen chloride-salt, as was detected by carbylamine reaction (almost the same reaction as that with 1 g. of thiophene without hydrogen gas; cf. Fig. 5).

The authors wish to express their hearty thanks to Professor Kazuo Hata for his kind advice.

The Heats of Dilution of Atactic Polystyrene Solutions

By Akihiro KAGEMOTO, Sachio MURAKAMI and Ryoichi FUJISHIRO

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received March 29, 1965)

The heats of dilution of atactic polystyrene ($\bar{P}=244$) - various solvent systems have been measured by using a micro-twin-calorimeter at 25°C. Toluene, anisole, ethyl methyl ketone, dioxane and ethyl acetate were used as the solvents. For the analysis of the experimental data obtained by each dilution process, the simple Van Laar formula has been used, and the apparent enthalpy parameter between the polymer and the solvent has been derived. Since these interaction parameters seemed to depend on the concentration, we tried to analyze the experimental data with a modified Van Laar formula which contained interaction parameters depending on the concentration. The interaction parameters obtained by these analyses are considerably dependent on the concentration in good solvents, while those in poor solvents depend hardly at all on the concentration. This dependence of the interaction parameters on the concentration has been explained by using the dilute solution theory of polymer solutions proposed by Flory and Krigbaum (*J. Chem. phys.*, **18**, 1086 (1951)). The interaction parameters in the dilute region have been compared with those obtained by other methods, and the agreement between our values and those obtained by other methods has been found to be fairly good.

The direct measurement of the heats of dilution of polymer solutions is very important in investigating the interaction parameter between the polymer and the solvent molecules. In spite of the fact that such measurement is accompanied by considerable difficulties, several reports[1-5] have been published in this field. We have now constructed a twin-calorimeter and, by using this apparatus, have attempted thermal measurements in order to study the behavior of atactic polystyrene using such solvents as anisole, toluene, ethyl acetate, dioxane and ethyl methyl ketone.

Experimental

Apparatus and Procedure.—The twin calorimeter which is shown in Fig. 1 was designed to measure the heats of dilution. It consists of two copper cell holders (A), a mixing cell (B_1) and a reference cell (B_2). Around the outside surface of the holders, a thirty-junction copper-constantan thermocouple (C) is wound. The heating coil, with a resistance of about 40 ohm is fixed with araldite cement around the mixing cell (D). The mixing cell is made of glass and consists of an outer cell (E) and an inner cell (F), as is shown in Fig. 2. The outer cell (E) is filled with the polymer solution, and the inner cell (F) is charged with the solvent by using a hypodermic syringe; each cell is then sealed, at G and H, with mercury.

The polymer solution and solvent are mixed by pulling up the lid of the inner cell through the manipulation of the wire (I) from the outside of the calorimeter chamber.

The solution is mixed by being stirred by a synchronous (30 r. p. m.) motor (J). The reference cell (B_2), containing only the solvent, is the same type of cell as the mixing cell and acts as the reference bath for the thermocouple.

The electronic circuit for the measurement of the heat of dilution is the same as that described in a previous

paper[5]. The calorimeter was immersed in a water thermostat kept at 25.00±0.01°C.

Materials.—An atactic polystyrene sample (degree of polymerization: 244) was supplied by Dr. T. Matuo of the Chemical Institute of Kyoto University. This sample was purified by dissolving it in toluene, precipitated with methanol, and then dried under a pressure of 1 mmHg until the solvent has been completely removed. The solvents used were anisole, toluene, dioxane, ethyl acetate and ethyl methyl ketone. These solvents were purified by the ordinary methods described in the literature[6] and finally distilled.

Results and Discussion

The heats of the dilution of atactic polystyrene were measured over the concentration range from a 0.2 to a 0.015 volume fraction of the polymer by the successive addition of 5- or 20-ml. portions of the solvent to a solution of a known concentration. The results obtained are shown in Table I.

Three systems, the solutions of anisole, toluene and ethyl acetate, are exothermic, while the other two systems, those of dioxane and ethyl methyl ketone, are endothermic.

Assuming that the heat of mixing is expressed by the simple Van Laar equation and following the method of treatment by Tompa,[1] the heat of dilution, $\Delta\overline{H}_d$, from the volume fraction ϕ_2 to the volume fraction ϕ_2' can be represented by;

$$\Delta\overline{H}_d = \boldsymbol{R}T\chi_H\phi_2\phi_2'\Delta n_1 \qquad (1)$$

where Δn_1 is the number of moles of solvent added and χ_H is the interaction parameter between the polymer and the solvent. Instead of Eq. 1, we can also obtain the equivalent expression:

$$\Delta\overline{H}_d = \boldsymbol{R}Txn_2(\phi_2-\phi_2')\chi_H \qquad (1')$$

where n_2 is the number of moles of the structure unit and x the degree of the polymerization of the polymer.

By using the experimental data listed in Table I and Eq. 1 or 1', the interaciion parameter, χ_H, can be obtained for each stage of the dilution process of each system; these parameters are given in the last column of the same table.

For the polystyrene-toluene system, we previously measured the heats of dilution in the concentrated solution and so derived the values of the interaction parameter, χ_H, values which were in the vicinity of −0.2. The χ_H values in this experiment are about −0.2 in the concentrated range, which is in good agreement with those obtained in the previous experiment; there is also a decrease in the absolute value in the fairly diluted region. The tendency for the χ_H parameter to depend on the concentration seems to be observed not only in the toluene system but also in other systems. To test this behavior, we plotted the heat of dilution, $\Delta\overline{H}_d$, against $\phi_2\phi_2'\Delta n_1$ or $xn_2(\phi_2-\phi_2')$ in Fig. 3.

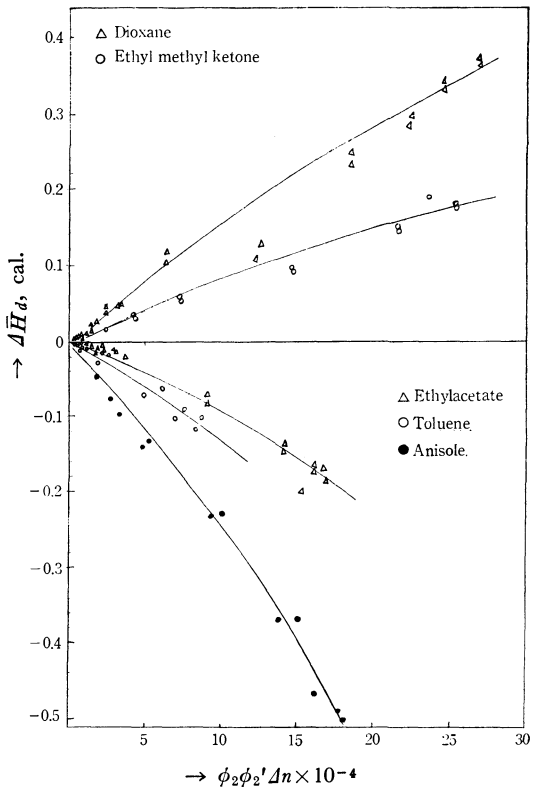

Fig. 3. The plot of the heat of dilution $\Delta\overline{H}_d$ against $\phi_2\phi_2'\Delta n_1$.

According to Eq. 1 a linear plot must be obtained, its slope giving the interaction parameter. However, as may be seen in Fig. 3, this plot is not linear, indicating that the interaction parameter depends on the concentration.

Assuming that the interaction parameter, χ_H, is expressed as:

$$\chi_H=\chi_1+\chi_2\phi_2$$

and making the same derivation as that of Eq. 1 or 1', we can obtain the following equation:

$$\Delta\overline{H}_d=\boldsymbol{R}T\phi_2\phi_2'\Delta n_1[\chi_1+\chi_2(\phi_2+\phi_2')/2] \quad (2)$$

or

$$\Delta\overline{H}_d=\boldsymbol{R}Txn_2(\phi_2-\phi_2')[\chi_1+\chi_2(\phi_2+\phi_2')/2] \quad (2')$$

where $\phi_2=xn_2/(n_1+xn_2)$

and $\phi_2'=xn_2/(n_1+\Delta n_1+xn_2)$.

In order to find χ_1 and χ_2, we tried to plot the $\Delta\overline{H}_d/\boldsymbol{R}T\phi_2\phi_2'\Delta n_1$ against $(\phi_2+\phi'_2)/2$ for each system of Fig. 4.

The experimental data, however, were too scattered for us to obtain accurate values. Therefore,

Toluene, ○ $\overline{P}=244$, △ $\overline{P}=270$

Table II. Values of interaction parameter $\chi_H=\chi_1+\chi_2\phi_2$

Solvent	χ_1	χ_2
Toluene	−0.08	−0.94
Anisole	−0.60	−1.18
Ethyl acetate	−0.05	−0.66
Dioxane	0.16	−0.008
Ethyl methyl ketone	0.10	−0.08
Toluene[5]	−0.27	0.69

we carried out the least-squares treatment of the data according to Eq. 2; this gave the values for χ_1 and χ_2 shown in Table II.

By using the values of χ_1 and χ_2 listed in Table II, a $\Delta\overline{H}_d-\phi_2\phi_2'\Delta n_1$ curve has been calculated for each system; this curve, which is shown by the full line in Fig. 3, is in good agreement with the experimental data for each system.

As may be seen in Table II, the χ_H parameter in good solvents (exothermic systems) are considerable concentration-dependent, while those in poor solvents (endothermic systems) do not depend on the concentration. These tendencies indicate that the absolute values of the χ_H parameter in the dilute solution are considerably lower than those in the moderate concentration range in good solvents, while the values of the χ_H parameter in poor solvents hardly change.

According to the dilution theory of the polymer solution proposed by Flory,[7] the second virial coefficient, A_2, is expressed as:

$$A_2\propto(\psi_1-\kappa_1)F(X)$$

where: $X=2(\alpha^2-1)$,

$$F(X)=1-X/2!\cdot 2^{-3/2}+\cdots$$

An approximate treatment gives the interaction parameter as $\kappa_1F(X)$, which is an apparent interaction parameter in the dilute region. Now we may assume that Flory's formula also applies to the solution of good solvents, though this formula has hitherto been considered to be correct only in poor-solvent systems. Therefore, in good solvents α is greater than 1 and $F(X)$ is considerably less than 1. The apparent interaction parameter, $\kappa_1F(X)$, in the dilute region is, therefore, considerably smaller than that in the moderate concentration in terms of absolute value. On the other hand, in poor solvents the expansion factor α is nearly equal to 1, and $F(X)\simeq 1$, suggesting that the interaction parameter may be independent of the concentration.

The interaction parameter is usually studied by other methods, such as the temperature dependence of the osmotic pressure of the solution. The values for the interaction parameter obtained by various

authors[1,5,8-12] using these methods are listed in Table III. Since these measurements have been carried out in a dilute solution, those of our values of the interaction parameter to be compared with those in Table III must also be in a dilute solution, that is, the χ_1 values, which are the concentration-independent terms in χ_H as determined by our experiment and shown in the last column in Table III.

The agreement between our parameters and those obtained by other methods may be fairly good in terms of absolute value, though there remain some questions concerning their signs.

Summary

We have constructed a twin calorimeter with a thirty-junction thermocouple in order to measure the slight temperature-change of a polymer solution. By using this apparatus, the heats of the dilution of atactic polystyrene ($\overline{P}$=244) have been measured, and from them the interaction parameters have been derived according to Van Laar's simple formula. Since the interaction parameters seemed to depend on the concentration, we tried to analyze the experimental data with a modified Van Laar formula which contained the interaction parameter depending on the concentration.

We found that the interaction parameters are considerably concentration-dependent in good solvents, while those in poor solvents do not depend on the concentration.

The authors wish to thank Dr. T. Matuo of the Chemical Institute of Kyoto University for supplying the sample to them.

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received April 5, 1965)

A DTA apparatus for a polymer solution has been constructed. The heating rate was adjusted to approximately 0.50 or 0.42°C/min., a favorable rate for a polymer solution. From the DTA curves obtained by the use of this apparatus, the temperatures of the end points of the melting or dissolution have been determined; their plots give the solubility curves. The solubility of the isotactic polypropylene in decalin system increases monotonously with the increase in the temperature, except for the abnormality in the region from 30 to 50 wt.% in polymer content. In the case of the isotactic polypropylene-nitrobenzene system, on the other hand, the melting curve has a horizontal part in the region with a polymer content of less than 50 wt.%; above this point lies the phase separation curve, which touches the melting curve at the point with a polymer content of approximately 50 wt.%. The double peaks which appear in the DTA curve of the melting of pure isotactic polypropylene, may be due to the paracrystalline smectic modification of isotactic polypropylene, as has been suggested by Natta (*Makromol. Chem.*, **35,** 93 (1960)). The heat of fusion for isotactic polypropylene has been estimated to be approximately 1000 cal./unit mol. by measuring the area under the melting peak of the DTA curve and the equation for the melting point depression.

It is known that differential thermal analysis (DTA) is very useful in investigating such a thermal change as the phase transition. The applications of the DTA method to polymeric materials, however, have been restricted mainly to the thermal change in a pure polymer or in one with only a small amount of diluents. In this paper we shall use this DTA method in studying the dissolution behavior of isotactic polypropylene-decahydronaphthalene (decalin) and isotactic polypropylene-nitrobenzene mixtures, over the whole concentration range. Decalin and nitrobenzene will be used as a typically good and a typically bad solvent respectively for isotactic polypropylene. Further, the analysis of DTA curves on pure isotactic polypropylene will also be carried out under some pretreatment conditions.

Experimental

Apparatus.—We constructed the DTA apparatus, equipped with a stirrer to secure the smooth dissolution of polymer during heating, illustrated in Fig. 1. A sample cell and a reference cell made of stainless steel were put into the cell holder and fitted with copper-constantan thermocouples at their bottoms.

The e. m. f. representing the temperature difference between the sample cell and the reference cell was amplified by the Okura AM101B amplifier, and the signals for the temperature difference were recorded on a time-base chart recorder (YEW ER1-30). The temperature was determined by measuring the potential difference between the reference substance and the ice point with the potentiometer.

The rate of heating was manually controlled.

Material.—Isotactic polypropylene, Avisun 101117-Q84, was reprecipitated through decalin-methanol, in which the antioxydant had been removed; the precipitate was then washed several times with methanol and dried in a vacuum. The mean molecular weight of the polymer was determined to be 3.7×10^5 by viscometric measurements in decalin.[1]

Decalin was purified by the ordinary method;[2] the ratio of *cis*- to *trans*-decalin was about 3 to 2, as determined by observing the density and the viscosity.

Nitrobenzene was distilled twice in a vacuum.

The urea to be used in calibrating the apparatus for calorimetry was reprecipitated from a methanol solution and dried in a vacuum.

The Pre-treatment of the Sample.—The sample was prepared by putting the weighed solvent and isotactic polypropylene into the sample cell; it was then melted so that the stirrer could be inserted. After the sample cell had been set at the apparatus, the sample was melted once more and then slowly cooled to room temperature at the rate of 0.3—0.5°C/min.; thus a definite condition was given to all samples.

Results and Discussion

The Effect of the Heating Rate.—A sample with an approximately 15% polymer content in a decalin solution was repeatedly run, at the heating rates of approximately 1.25, 0.83, 0.63, 0.50, 0.42 and 0.31°C/min., in order to check the effect of the heating rate on the peak temperature of the dissolution in a highly viscous solution.

We found that the heating rate is not very effective on the dissolution temperature at these rates, while the cooling rate in the pre-treatment is rather effective, as will be discussed later. Therefore, we took the heating rate of 0.50 or 0.42°C/min., in which the reproducibilities of DTA curves seem favorable.

The Isotactic Polypropylene-Decalin System.—The DTA curves obtained for the isotactic polypropylene-decalin system with various proportions of polymer are shown in Fig. 3. The dissolution of a polymer into a solvent is accompanied by each curve reaching a peak which represents the absorption of heat in this experiment. Each curve increases gradually in the low-temperature region,

particularly for the mixture with a small polymer content, reaches the top of the peak, and then rapidly descends. The gradual increase in the low-temperature region suggests that the dissolution may begin at a fairly low temperature. Since the dissolution process is completed at the top of the peak, the corresponding temperature will be assigned to the end point of dissolution.

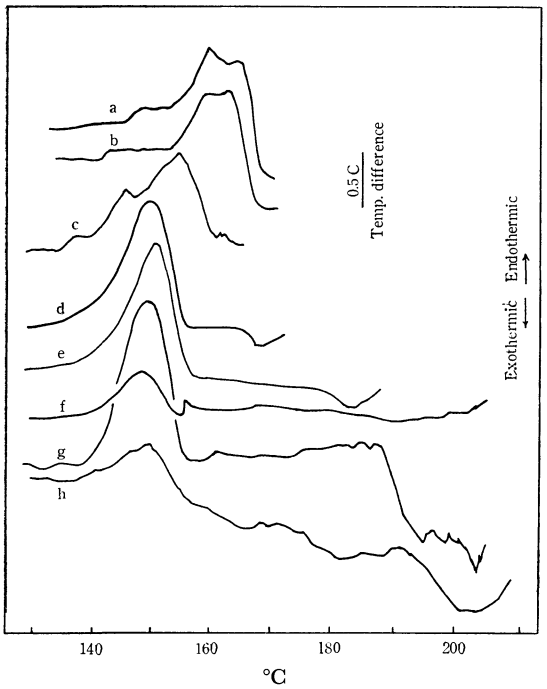

Fig. 4. The DTA curves of isotactic polypropylene-nitrobenzene system.

(a) 98% polymer content
(b) 95% polymer content
(c) 65% polymer content
(d) 41.4% polymer content
(e) 37.5% polymer content
(f) 21.5% polymer content
(g) 25.4% polymer content; stirred
(h) 15.0% polymer content; stirred
The heating rate is 0.5°C/min. for all samples.

By plotting the end points of the dissolution against the polymer content in the mixture, the solubility curve is obtained, as is shown in Fig. 6. Except for the region from 30 to 50% in polymer content, the curve increases smoothly with the polymer content, indicating that decalin is a good solvent for isotactic polypropylene. In the region of the polymer content of from 30 to 50%, the DTA curves are not so reproducible [see Fig. 3. (g) and (h)] and, hence, the end points determined from them are considerably scattered, suggesting that some anomalous states exist in this region. If we connect the curve of a lower polymer content with the other one of a higher content, we must

draw the discontinuous curve with a flection in this region shown by the dotted line in Fig. 6. We can not give a full explanation of this anomalous behavior, but it may be due to the existence of two crystal modifications, such as the usual one crystallized from the melt (or from the concentrated solution) and the other either the one from the dilute solution, as confirmed in polyethylene by Flory,[3] or the metastable paracrystalline smectic one.[4]

The Isotactic Polypropylene-Nitrobenzene System.—The DTA curves obtained for the isotactic polypropylene-nitrobenzene system are shown in Fig. 4. These curves are divided into two types, one appearing in polymer-rich mixtures, and the other in polymer-poor mixtures. The former type contains a main peak the temperature of which decreases with the solvent content, indicating that these peaks may be due to the dissolution of the polymer into nitrobenzene, as in the cases of the decalin system. On the other hand, each curve of the latter type has a peak at almost the same temperature; then it gradually falls until it suddenly shows a small bend at the high-temperature region according to the solvent content, followed by another sharp, upward bend, a bend which is probably due to the beginning of the vaporization of the solvent. In the dilute solutions, the curve after the peak, as a whole, is curved in the endothermic direction as a result of the vaporization of the solvent. When the solution is stirred, as may be seen in Figs. 4. (g) and (h), the curve makes a sharp descent just before the first bend (the cause of this we can not find), and the curve, as a whole, becomes rugged.

By plotting the temperatures of the tops of the peaks and those of the first bends against the polymer contents in the mixtures, the solubility curve shown in Fig. 7 is obtained. "The first bend point-polymer content" curve closely resembles the phase separation curve in the polymer solution, suggesting that two liquid phases may coexist, because nitrobenzene is a bad solvent for isotactic polypropylene.

In order to ascertain if this curve is due to the phase separation, we tried to observe directly the temperature at which the mixture becomes homogeneous or at which the homogeneous solution separates into two phases; we attempted to do this by heating or cooling the polymer-solvent mixture in a test tube immersed in an oil bath. The temperatures obtained by this rough procedure are shown by open triangles in Fig. 7; they are close to the bend point curve, indicating that this curve may be the phase separation curve.

The peak temperature curve is very analogous to the melting curves of the polyethylene - *n*-butyl phthalate and polyethylene - *o*-nitrotoluene systems obtained by Mandelkern and his co-worker[5] with the dilatometric method. These curves show the characteristic feature that each curve contains a slope in the polymer-rich region and a horizontal line at a definite temperature in the polymer-poor region.

In Fig. 7, the extrapolation of the phase separation curve leads to an intersection with the peak temperature curve at an approximately 50% polymer content; this seems to correspond to the furthermost right end of the horizontal part of the peak temperature curve.

When a polymer-poor mixture with a polymer content of less than 50% is heated, the crystallites of the polymer may dissolve into nitrobenzene, forming two polymer solutions in equilibrium with each other at a definite temperature of 150°C, as is indicated by the horizontal line of the dissolution curve. This abrupt dissolution of the polymer shows as a sharp peak in the DTA curves.

The Melting of Pure Isotactic Polypropylene.—The DTA curves of pure isotactic polypropylene show a broad peak, accompanied by a small peak in the low temperature region, and have approximately a 9°C spread, as is illustrated in Fig. 5. The temperature of the top of the main peak, corresponding to the completion of melting, is in the range of 167.7±0.3°C for the samples pre-treated under various conditions.

As may be seen in Fig. 5, the cooling rate in the pre-treatment has a slight effect on the location of the small peak on the low-temperature side. The slower the cooling rate, the more the small peak seems to approach the main peak. The presence of an antioxidant may not produce any effect, showing that the existence of the earlier peak is not due to the thermal degradation and the oxidation of samples.

The double peaks of the melting of isotactic polypropylene have been reported by several authors.[6-8] Ke,[7] one of them, suggests that the double peaks are associated with structural differences, probably different stereospecificities (atactic or syndiotactic) in isotactic polypropylene. Atactic polypropylene has two transitions at 70

and 155°C,[9] but the heats of these transitions, 2.1 and 0.30 cal./g.[9] respectively, are too small in comparison with the heat of the fusion of isotactic polypropylene, 20 cal./g.,[9] to enable one to assign the earlier peak to the two transitions of atactic polypropylene. Syndiotactic polypropylene has been reported to melt at 183°C; this seems inadequate to explain the earlier peak.

Schwenker and his co-worker[8] have observed that the DTA curve of drawn polypropylene shows the double peaks at 158 and 174°C; they also observed that if the melt from the drawn fiber is cooled and rerun, the earlier peak disappears. They have concluded that the earlier peak may be ascribed to the disorientation of the crystallites, as has been confirmed in nylon 66 by White.[10] According to them, our samples crystallized by slow cooling and those crystallized by rapid cooling from the melt consist of disoriented and orientated crystallites respectively; this seems curious, though we can not deny the disorientation of crystallites because we have not carried out measurements of the drawn samples.

As may be seen in Figs. 3 (a), (b) and 4 (a), (b), the earlier peak seems to be enlarged by the addition of solvents; this may confirm that it is not due to disorientation, since, the addition of solvents makes it impossible for the disorientation of crystallites (perhaps perfectly at random in solvents) to occur.

On the other hand, on the bases of the X-ray and infrared spectra of samples rapidly cooled and annealed from the melted isotactic polypropylene, though there has been no information obtained by the thermal method, Natta[4] has reported that a rapid cooling of the melted isotactic polypropylene produces a metastable paracrystalline smectic modification in which right- and left-helices of polymers are placed at random in a psuedo-hexagonal cell, while in the usual samples, produced by slow cooling and annealing, they are regularly disposed facing one another, two by two. Though we can not give an explicit conclusion for the earlier peak, since we have not examined the sample by X-ray, it may be suggested that the earlier peak, produced by rapid cooling, is due to the melting of the metastable paracrystalline smectic modification, and that the location and magnitude of the earlier peak varies with the degree of randomness and with the amount of modification.

The Heat of the Fusion of Isotactic Polypropylene.—The heat of the fusion, ΔH_u, of isotactic polypropylene is easily found by the ratio of the area under the DTA peak of the fusion of isotactic polypropylene to that of a known heat change (e. g., the heat of the fusion of urea), or by Flory's equation of melting point depression:[11]

$$1/T_m - 1/T^\circ_m = (R/\Delta H_u)[(V_{2u}/V_1)v_1 - \chi v_1^2] \quad (1)$$

where T°_m is the melting temperature of a pure polymer; T_m, the melting temperature of a polymer with a diluent; ΔH_u, the heat of the fusion of the polymer per structural-unit mole; χ, the interaction parameter; V_{2u}, the unit molar volume of the polymer; V_1, the molar volume of the diluent, and v_1, the volume fraction of the diluent. The former method gives a value of 1070±100 cal./unit mol. for the heat of fusion, while the latter method gives values of 870±50 cal./unit mol. for a decalin system and 920±50 cal./unit mol. for a nitrobenzene system. These values are in good agreement with each other. The values of the interaction parameter, χ, are estimated to be 0.88 and 2.93 for decalin and nitrobenzene respectively by the above equation. These values may, however, be considered to be a little large.

TABLE I. THE VALUES OF THE HEAT OF FUSION OF ISOTACTIC POLYPROPYLENE

Method	Value of ΔH_u cal./unit mole	Reference
Area of DTA curve	1070±100	This work
Eq. 1		
in decalin	870±50	This work
in nitrobenzene	920±50	This work
Dilatometry	1700	12
Dilatometry	2500	13
Area of DTA curve	650	14
Specific heat	870 (1500)*	9
$dP/dT = \Delta H/T\Delta V$	630	15
$dP/dT = \Delta H/T\Delta V$	2370	16

* Calculated for 100% crystallized.

The above values of the heat of fusion are listed in Table I, together with the values[9,12-16] determined by other authors by using various methods; our values are reasonable, especially considering that Wilkinson and his co-worker,[9] by specific heat measurement, calculated the value to be 1500 cal./unit mol. for the heat of the fusion of the 100% crystallized isotactic polypropylene.

Summary

A DTA apparatus for a polymer solution has been constructed. By using this apparatus, we have investigated the solubility curves of isotactic polypropylene-decalin and isotactic polypropylene-nitrobenzene systems; we have then discussed the DTA curves obtained for these systems, and also

Kinetic Studies of the Solution Polymerization of Trioxane Catalyzed by $BF_3 \cdot O(C_2H_5)_2$. II. The Effect of Catalyst and Water Concentrations of the Molecular Weight of the Polymer

By Toshinobu HIGASHIMURA, Tetsuro MIKI and Seizo OKAMURA

Department of Polymer Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received April 5, 1965)

In the solution polymerization of trioxane catalyzed by $BF_3 \cdot O(C_2H_5)_2$, the dependence of the molecular weight of the polymer formed on the polymerization conditions has been studied. In general, the molecular weight of the polymer formed increases in the course of polymerization, keeps a constant value over a certain range of conversion, and then again incerases remarkably. The molecular weight of the polymers formed decrease with an increase in the catalyst and water concentrations. This phenomenon can be explained qualitatively on the assumptions that the rate of the propagation reaction is smaller than that of the initiation reaction and that the chain breaking occurs through the reaction with water, which is consumed as the polymerization proceeds. This is equal to the assumption that the chain carrier is an oxonium ion in the cationic polymerization of trioxane.

It is neccessary for a study of the characteristics of the polymerization of the cyclic compound to know the molecular weight of the produced polymer as well as the rate of polymerization. None of the papers on the solution polymerization of trioxane has, however, dealt with the relation between the polymerization conditions and the molecular weight of the produced polymer, This relation has been discussed only in connection with the polymerization of molten trioxane.[1,2]

The effect of the concentrations of $BF_3 \cdot O(C_2H_5)_2$ and of water on the rate of polymerization in various solvents was described in previous paper.[3] For the present paper, the molecular weight of the polymer obtained in the previous paper was measured, and its dependence on the concentrations of catalyst and water was studied. The exact relationship between the solution viscosity and the molecular weight for polyoxymethylene has not yet been obtained, so we used the viscosity number instead of the molecular weight of the produced polymer.

The peculiar phenomenon was found that the molecular weight of the produced polymer increased as the polymerization proceeded but decreased as the catalyst concentration increased; no such phenomenon has been found in the cationic polymerization of vinyl monomers.

Experimental

After the polymer obtained in the previous paper[3] had been throughly dried, viscosity number (η_{sp}/C; C=0.6 g./100 ml. solution) was measured in a *p*-chlorophenol solution including 2% α-pinene at 60°C. The polymer was dissoved in *p*-chlorophenol under nitrogen gas by heating it at 120°C for 2—4 min. Under such conditions, it was not clear whether the polymer was decomposed or not during dissolution. The decomposition of the polymer during dissolution was, however, inferred to be negligible since the reproducibility of the measurements of the same sample within 5 min. of heating was very good and since the value of η_{sp}/C varied regularly with the polymerization conditions.

Results

The Effect of the Catslyst Concentration and the Conversion.—The effects of both the

catalyst concentration and the conversion on the molecular weight of the resulting polymer in various solvents were studied. The polymerization conditions were the same as those in the corresponding figures in the previous paper.[3]

The results for the polymers obtained in benzene and ethylene dichloride are shown in Figs. 1 and 2. The molecular weight of both polymers increased with the conversion. Moreover, the molecular weight is the smaller at larger catalyst concentrations.

Although the catalyst concentration did not affect the rate of polymerization at a high-monomer concentration (3.3 mol./l.) in nitrobenzene, the

molecular weight of the produced polymers decreased regularly with an increase in the catalyst concentration and increased remarkably with the conversion, as is shown in Fig. 3. A similar behavior was found in the nitroethane solvent.

The Effect of the Water Concentration— The addition of water also decreased the molecular weight of the produced polymer. The results in *n*-hexane and ethylene dichloride are shown in Figs. 4 and 5, respectively. A similar result was obtained in benzene. In these solvents a small amount of water accelerates the polymerization, but an excessive addition of water decreases the rate. In all these solvents, it may be noted that the molecular weight decreases monotonously with the increase of water, but not with the conversion. In ethylene dichloride, for examlpe, the rate of the increase in molecular weight is remarkably raised at certain conversions.

In nitrobenzene the relation between the molecular weight and the water concentration was also curious. As is shown in Fig 6, when the monomer concentration was equal to 3.3 mol./l., a small amount of water did not affect the molecular weight. However, when the monomer concentration was low, the molecular weight was decreased

by an increase in the water concentration. As the relation between the conversion and the molecular weight at a low-monomer concentration was extraordinary, this matter will be discussed in the next paper.[4]

The Effect of the Addition of Methanol.—The effect of added methanol in ethylene dichloride and nitrobenzene was also studied. As is shown in Figs. 7 and 8, the molecular weight of the polymer decreased with an increase in the concentration of methanol. At a fixed conversion, the rate of the decrease in molecular weight by the addition of methanol in ethylene dichloride was larger than that in nitrobenzene.

Abnormality in Methylene Chloride.—It has been reported that, in the case of the polymerization of trioxane by iron(III) chloride in cyclohexane, the molecular weight of the produced polymer decreased with an increase in the conversion.[5] In our results on the solution polymerization of trioxane, however, the molecular weight of the polymer increased in the course of polymerization. Therefore, we have studied whether the molecular weight of the resultant polymers decreased or not with an increase in the conversion in a $BF_3 \cdot O(C_2H_5)_2$-methylene chloride which is considered to act as a transfer agent.

As is shown in Fig. 9, the rate of the polymerization of trioxane in methylene chloride was smaller than that in ethylene dichloride, but there was no essential difference in the behavior between two solvents. The molecular weight of the produced polymer in methylene chloride, however, was found to exhibit the characteristic behavior as is shown in Fig. 10. In methylene chloride the molecular weight of the polymer increased in the course of polymerization at the initial stage of polymerization, reached a maximum at a certain conversion, and then decreased.

Discussion

Generally in the cationic polymerization of vinyl monomers, the molecular weight of the produced polymers is independent of the catalyst concentration and the conversion. However, in the solution polymerization of trioxane catalyzed by $BF_3 \cdot O(C_2H_5)_2$, the molecular weight of the polymers formed increases in the course of polymerization but decreases with an increase in the catalyst and water concentrations.

The change in the molecular weight in the course of the polymerization of trioxane can be characterized as follows. The molecular weight increases monotonously up to 10—20% conversion; the rate of its increase decreases in the middle stage of the polymerization, and then again increases rapidly at a high conversion. As may be seen from Figs. 4 and 5, the range in which the molecular weight did not increase with the conversion was influenced by the quantity of water. In order

4) T. Higashimura, T. Miki and S. Okamura, ibid., **39**, 31 (1966).
5) V. Jaacks and W. Kern, *Makromol. Chem.*, **62**, 1 (1963).

to clarify the reaction mechanism, we shall first try to explain the relation between the change in molecular weight and the conversion.

Other instances where the moleculat weight of the polymers formed increases in the course of polymerization have been found in the cationic polymerization of such cyclic ethers as ethylene oxide and 1, 3-dioxolane,[6,7] and in the anionic polymerization of the cyclic monomers and vinyl monomers. These results have been summarized[8] and explained by the concept of "successive" polymerization[9] by Kagiya et al.

As for trioxane, this phenomenon was recognized in the cationic polymerization in the molten state.[1] It has been regarded as being caused by the polymerization's proceeding step by step through a living end and by the impurities which act as chain breakers being consumed in the course of polymerization. This suggestion involved the two points that the molecular weight of the polymers formed was independent of the catalyst concentration and that the molecular weight at 0% conversion was not equal to zero.

These proposals[1,8,9] could explain many things, but not the complicated behavior of the solution polymerization of trioxane found in this paper. To explain the observed change in molecular weight, then, the following three elementary reactions are assumed for the solution polymerization of trioxane:

$$\text{Initiation reaction} \quad M + C \xrightarrow{k_i} M_1^* \tag{1}$$

$$\text{Propagation reaction} \quad M_r^* + M \xrightarrow{k_p} M_{r+1}^* \tag{2}$$

$$\text{Transfer reaction} \quad M_r^* + X_{tr} \xrightarrow{k_{tr}} P_n + X'_{tr} \tag{3}$$

Where M, C, and X_{tr} denote a monomer, a catalyst and a chain-transfer reagent like water respectively. If X_{tr} is water, X'_{tr} implies a proton. Consequently, X_{tr} is consumed during the polymerization according to reaction 3. It may be inferred that, in the cationic polymerization of trioxane, the transfer reactions to monomer and solvents used in this paper scarcely ever occur.

According to Kagiya et al.[9] the phenomenon of the molecular weight of the polymers formed increasing in the course of polymerization is found only when the rate of the initiation reaction is larger than those of the propagation and the transfer reaction. In such a system the average degree of polymerization ($\bar{P}$) corresponding to the elementary reactions 1—3 is shown by Eq. 4[9]:

$$\bar{P} = \frac{[M]_0 - [M]}{\alpha[C]_0 + k_{tr}\int [M^*][X_{tr}]dt} \tag{4}$$

where α is a constant which denotes the mole concentration of active center produced per mole of catalyst and where the suffix 0 denotes the initial concentration. If X_{tr} is not consumed during the polymerization (e. g., if $[X_{tr}]$ is a constant), Eq. 5 is obtained by substituting Eq. 2 into Eq. 4:

$$\bar{P} = \frac{[M]_0 - [M]}{\alpha[C]_0 + (k_{tr}/k_p)[X_{tr}]_0 \ln([M]_0/[M])} \tag{5}$$

Equation 5, as derived by Kagiya et al., implies that the degree of polymerization increases with the conversion to the limited value and that after that it again decreases. This behavior is shown schematically in curve c in Fig. 11. This does not agree with our experimental results.

As is shown in Eq. 3, X_{tr} decreases in the course of polymerization. In such a case, the relation between $[X_{tr}]$ and [M] has already been indicated, as is shown in Eq. 6[1]:

$$[X_{tr}] = [X_{tr}]_0([M]/[M]_0)^{k_{tr}/k_p} \tag{6}$$

Equation 7 is obtained by putting Eqs. 2 and 6 into Eq. 4 and integrating;

$$\bar{P} = \frac{[M]_0 - [M]}{\alpha[C]_0 + [X_{tr}]_0\{1 - ([M]/[M]_0)^a\}} \tag{7}$$

$$= \frac{[M]_0 x}{\alpha[C]_0 + [X_{tr}]_0\{1 - (1-x)^a\}} \tag{7'}$$

where $a = k_{tr}/k_p$ and where x denotes the fractional conversion. This is equal to the equation obtained by Kucera[1] except for the first term of the denominator.

In our experiments, η_{sp}/C was measured, but not the molecular weight. There was also the added complexity that the polymer formed precipitated from the reaction system during the polymerization. Therefore, the experimental results will be compared qualitatively.

If the transfer reaction (Eq. 3) does not occur, the second term of the denominator in Eq. 7' may be omitted and $\bar{P}$ increases in proportion to the conversion. This is shown by line a in Fig. 11. If $\bar{P}$, as proposed by Kučera,[1] depends on only the transfer reaction, $\bar{P}$ is indicated by curve b in Fig. 11. If the transfer reagent (X_{tr}) is not consumed during the polymerization, $\bar{P}$ is indicated by Eq. 5 and its change will obey curve c in Fig. 11. These lines do not agree with our experimental results. When a in Eq. 7' is smaller than 1, $\bar{P}$ indicates curve d. However, the rapid increase in the molecular weight at a high conversion cannot be explained. On the other hand, when a is larger than 1, curve e is obtained and the shape of the curve agrees qualitatively with the experimental data. According to this result, it is recognized that, as the water is consumed during the initial

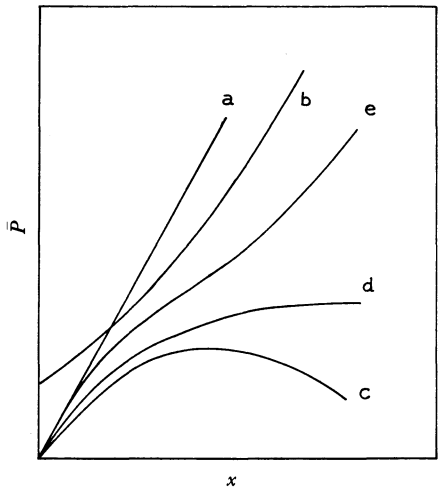

Fig. 11. Schematic diagram of the relationship between the degree of polymerization ($\bar{P}$) and the fractional conversion (x).

stages of polymerization, such a η_{sp}/C-conversion curve is observed. Also, the rate of the transfer reaction may be fairly fast, because k_{tr}/k_p is larger than unity. However, another reason can be given for this phenomenon. Polymer transfer reactions have been reported in the cationic polymerization of trioxane[10] and tetrahydrofuran[11]. Therefore, the transfer reaction of the growing chain to the dead polymer may be considered to exist in this system also.

If α in Eq. 7 is independent of the catalyst concentration,[9] it is recognized that the molecular weight of the polymers decreases with the increase in the catalyst concentration. It is also clear from this equation that an increase in the transfer reagent concentration decreases the molecular weight of the polymers.

In methylene chloride the molecular weight of the polymers decreased at a high conversion. It has also been found that, in the polymerization of trioxane in cyclohexane catalyzed by iron(III) chloride the molecular weight of the polymers decreases in the course of the polymerization.[5] It is considered that these phenomena are caused by the decomposition of the resultant polymers. It is not clear, however, why the decomposition of the polymers takes place only in methylene chloride and cyclohexane.

It has been considered that, in the cationic polymerization of vinyl monomers, the rate of the propagation reaction is larger than that of the other elementary reactions. However, as has been mentioned above, Eq. 7 was derived on the assumption that the rate of the initiation reaction is larger than that of the propagation reaction. This fact is understandable assuming that the growing chain is stable in the cationic polymerization of trioxane. If the active chain end produced from trioxane has the structure shown in Eq. 8, however, this chain end is more unstable than that of vinyl monomers, and the reactivity of the former should be larger than that of the latter;

$$\sim\!\sim CH_2\text{-}O\text{-}\overset{+}{C}H_2\cdots B^- \qquad (8)$$

Nevertheless, the rate of the propagation reaction was smaller than that of the other elementary reaction, according to our results. This may be because the chain carrier is stabilized in a shape of the oxonium ion shown in Eq. 9, as is considered to be the case in the cationic polymerization of many cyclic ethers.

$$\sim\!\sim CH_2\text{-}O\text{-}CH_2\text{-}\overset{+}{O}\begin{matrix}CH_2\text{-}O\\ \vdots\\ B^-\end{matrix}\!\!\diagdown\!\!\diagup\begin{matrix}CH_2\text{-}O\\ CH_2\end{matrix} \qquad (9)$$

Even if the polymerization reaction would proceed through the oxonium ion, there are many cases in which the molecular weight of the polymers formed does not increase in the course of polymerization.[12,13] However, in a system in which the molecular weight of the polymers increases rapidly with the conversion, it may be reasonable to consider the chain carrier to be a stable oxonium ion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 31—36 (1966)

Kinetic Studies of the Solution Polymerization of Trioxane Catalyzed by $BF_3 \cdot O(C_2H_5)_2$. III. The Effect of the Monomer Concentration

By Toshinobu HIGASHIMURA, Tetsuro MIKI and Seizo OKAMURA

Department of Polymer Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received April 5, 1965)

In the solution polymerization of trioxane catalyzed by $BF_3 \cdot O(C_2H_5)_2$, the dependence of the monomer concentration on the polymerization reaction has been studied. The kinetic order of the monomer concentration as determined from the course of polymerization is close to 2 (except in a non-polar solvent). The kinetic order of the initial monomer concentration is extraordinarily large in the polar solvent. On the other hand, the molecular weight of the polymers formed increases with an increase in the initial monomer concentration. In the polymerization of trioxane in a polar solvent such as nitrobenzene at a low monomer concentration, the molecular weight of the polymers does not increase in the course of polymerization, even at the initial stage of polymerization. The reason for this has been discussed in terms of the nature of the chain carrier.

It has been recognized that, in the cationic, solution polymerization of trioxane catalyzed by $BF_3 \cdot O(C_2H_5)_2$, the molecular weitht of the resultant polymers increases in the course of polymerization, not as in the cationic polymerization of vinyl monomers.[1] This has been explained in terms of the rate of the propagation reaction being smaller than that of the initiation reaction. It has been suggested as the cause of this that the chain carrier in the solution polymerization of trioxane is not a carbonium ion but a stable oxonium ion solvated by monomers. If a condition were selected so that a more reactive carbonium ion than the oxonium ion were easily produced or the reactivity of initiating species were decreased, it might be expected that the relation between the conversion and the molecular weight of polymers would be changed.

Since a decrease in the trioxane concentration corresponds to a decrease in the concentration of the monomeric ether group which solvates the active ends, the behavior of the cationic polymerization of trioxane at a low monomer concentration will be studied in this paper.

It should also be noted that the effect of the catalyst and water concentrations on the polymerization rate is complicated and that the kinetic order of these concentrations varies remarkably with the kind of solvent.[2] Because of this, as well as for the above-mentioned purpose, the effect of the monomer concentration on the polymerization rate has been studied.

As a result, we have found that the kinetic order of the initial monomer concentration to the initial rate is large and that the molecular weight of the polymers produced at a low monomer concentration in a solvent with a high dielectric constant is nearly constant at the initial state of polymerization.

Experimental

The procedures of the polymerization and purification of materials were the same as were used in the first paper.[2] The molecular weights of the polymers formed were compared by the viscosity numbers (η_{sp}/C), which were measured in a *p*-chlorophenol solution.[1]

Results

The Effect of the Monomer Concentration on the Rate of Polymerization.—As non-polar solvents, such as *n*-hexane, do not have a high solubility toward trioxane, ethylene dichloride was used as a polar solvent and nitrobenzene, as a highly-polar solvent.

The time-conversion curves at various monomer concentrations in ethylene dichloride at a fixed catalyst concentration are shown in Fig. 1. With an increase in the initial monomer concentration, the rate of polymerization increased and the induction period decreased. Figure 2 shows the logarithmic plot of the initial monomer concentration against that of the initial rate as determined graphically from Fig. 1. It may be seen that the kinetic order of the initial monomer concentration to the initial rate is approximately 3.

In Fig. 3 is similarly shown the time-conversion curves at various monomer concentrations in nitrobenzene. It may be seen that the effect of the initial monomer concentration on the initial rate was remarkably large. In fact, on plotting the initial rate against the initial monomer concen-

polymers increased in the course of the polymerization, even with a low initial concentration of monomer. The relation between the initial monomer concentration and the value of η_{sp}/C at the fixed conversion as determined graphically from Fig. 5 is shown in Fig. 6. The value of η_{sp}/C was proportional to the initial monomer concentration up to a 10% conversion.

The behavior in nitrobenzene was different. As is shown in Fig. 7, at a low initial concentration of the monomer no increase of the molecular weight with the conversion was seen in the initial state of polymerization. To clarify this unusual behavior at a low monomer concentration, a relation was obtained between the conversion and the molecular weight of polymers formed at various concentrations of catalyst and water when the initial concentration of the monomer was equal

to 1.1 mol./l. The rate of polymerization with respect to this system has already been reported in a previous paper,[2] Figures 8 and 9 show the effects of the concentrations of the catalyst and of water respectively. In both cases the molecular weight was nearly constant, independent of the conversion, up to 30%. Figure 10 was

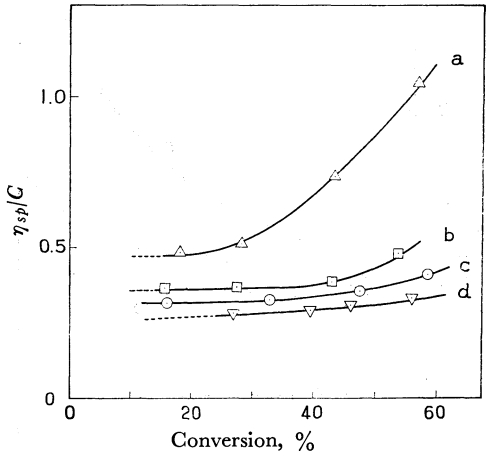

Fig. 9. Effect of the water concentration on the molecular weight of resultant polymers at low monomer concentration in nitrobenzene at 30°C. $[M]_0$; 1.1 mol./l., $[BF_3 \cdot O(C_2H_5)_2]$; 10 mmol./l., $[H_2O]$; a(△): 2.2, b(□): 4.0, c(○): 5.9 and d(▽): 7.8 mmol./l.

obtained upon plotting the initial monomer concentration against η_{sp}/C at a 10% conversion as determined graphically from Fig. 7. It may be suggested that the polymerization behavior at a monomer concentration below about 1 mol./l. differs from that at a monomer concentration larger than 1 mol./l.

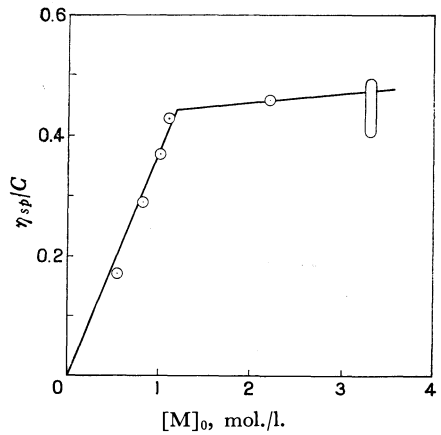

Fig. 10. Relationship between the molecular weight of polymers and the initial concentration of monomer at 10% conversion.

The Kinetic Order of Monomer Concentration as Determined from the Course of Polymerization.—The kinetic order of the monomer concentration to the polymerization rate can be determined from the relation between the polymerization rate and the residual monomer concentration at a settled time in the time-conversion curve.

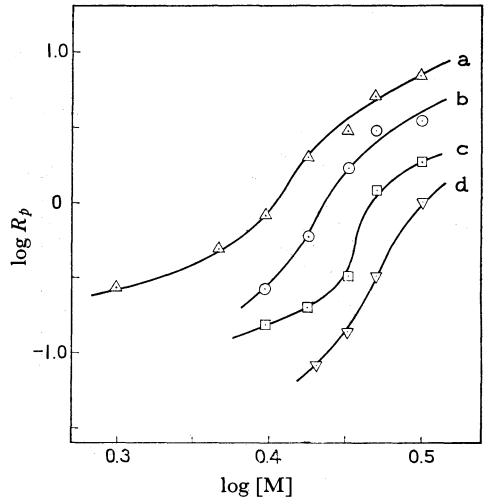

Fig. 11. Relationship between the rate of polymerization and the residual monomer concentration in the course of polymerization in ethylene dichloride at various temperatures.
$[M]_0$; 3.3 mol./l., $[BF_3 \cdot O(C_2H_5)_2]$; 5.0 mmol./l., Polymerization temp.; a(△): 46, b(○): 38.5, c(□): 30 and d(▽): 23°C

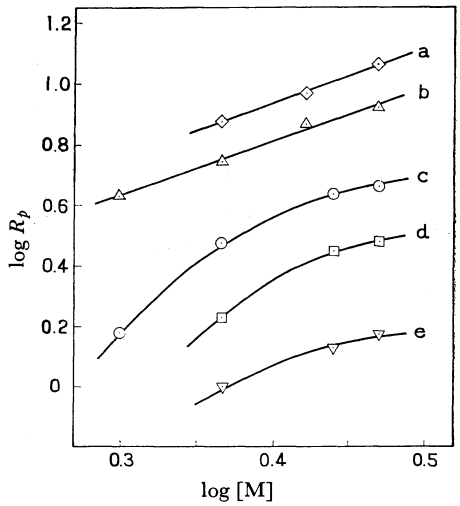

Fig. 12. Relationship between the rate of polymerization and the residual monomer concentration in the course of polymerization in nitroethane at various temperatures.
$[M]_0$; 3.3 mol./l., $[BF_3 \cdot O(C_2H_5)_2]$; 2.5 mmol./l., $[H_2O]$; 2.7 mmol./l., Polymerization temp.; a(◇): 50, b(△): 45, c(○): 38, d(□): 30 and e(▽): 23°C

The results of the analysis of the time-conversion curves of polymerization carried out in the various solvents are shown in Figs. 11, 12 and 13, where the concentrations of the monomer and of the catalyst were fixed and where only the reaction temperature was varied. (All the time-conversion curves will be shown in the fifth paper of this series.)

Excluding the complicated behavior in ethylene dichloride and that at a very low temperature, it may be concluded that the kinetic order of monomer concentration as determined from the course of polymerization is close to 2.

Although an abnormality was found in the relation between the conversion and the molecular weight in nitrobenzene at a low initial monomer concentration, the kinetic order of monomer concentration as determined from the course of polymerization was close to 2 in these systems, much as in systems with a high monomer concentration.

Discussion

The relation between the initial monomer concentration and the polymerization rate is very complicated, as is the relation between the catalyst or water concentration and the polymerization rate. Particularly, it was found that the initial polymerization rate is proportional to the sixth power of the initial monomer concentration in nitrobenzene

On the other hand, the kinetic order of the monomer as determined from the course of the time-conversion curve was close to 2 over a wide range of conversion in a polar solvent such as nitrobenzene, as is shown in Fig. 13. The constant kinetic order of the monomer over the wide range of conversion suggests that, in spite of the heterogeneous polymerization, a kinetic treatment is possible just as in an homogeneous polymerization. In the polymerization at a low temperature and in a less-polar solvent, however, the polymerization rate decreased remarkably in the course of the polymerization reaction. This may be due to the fact that the concentration of the active center was decreased remarkably by the precipitation of the resultant polymers, including catalysts. In a less-polar solvent it may be also considered that the rapid decrease in the polymerization rate in the course of the polymerization reaction is caused by the consumption of water as a co-catalyst.

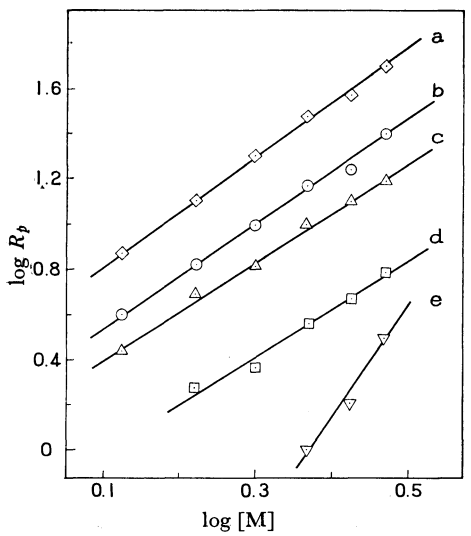

Fig. 13. Relationship between the rate of polymerization and the residual monomer concentration in the course of polymerization in nitrobenzene at various temperatures.
$[M]_0$; 3.3 mol./l., $[BF_3 \cdot O(C_2H_5)_2]$; 2.5 mmol./l., $[H_2O]$; 3.6 mmol./l., Polymerization temp.; a(◇): 30, b(△): 23, c(○): 15, d(□): 8.0 and e(▽): 3.0°C

While the kinetic order of the monomer as determined from the course of polymerization was close to 2, the kinetic order of the initial monomer concentration was extraordinarily large in the polar solvent. This suggests that the monomer or solvents participate in processes other than the propagation reaction. In a previous paper,[1] the relation between the polymerization conditions and the molecular weight of the polymers formed was explained on the assumption of the simple elementary reactions. The expression for the rate of polymerization derived from such simple elementary reactions, however, can not explain the kinetic order of the monomer. An explanation of this will be given in the next paper.[4]

Another remarkable result of the change in the monomer concentration was that, at a low monomer concentration, the molecular weight of the polymers formed was constant, independent of the conversion up to a 20—40% conversion in nitrobenzene.

In a previous paper[1] the increase in the molecular weight of the polymers formed with the conversion at the initial stage of polymerization was considered to be due mainly to the rate of the initiation reaction being larger than that of the propagation and other reactions[5] It has been supposed that, for this reason, in the cationic polymerization of trioxane the chain carrier is not a carbonium ion, but a oxonium ion which is stabilized by the solvation of the former with monomers. The formation of the oxonium ion in the polymerization of cyclic ethers is due to the instability of the corresponding carbonium ion and to the high concentration of ether groups in the reaction system.[3] Therefore, if the carbonium ion is stabilized and if the concentration of ether groups is small, it may be expected that a carbonium ion with a large reactivity exists and that the rate of the propagation reaction will increase. That is, in a solvent with great solvation ability, such as nitrobenzene, the carbonium ion is stabilized and, as the monomer concentration is small (i. e., if

the concentration of the ether groups which solvate the carbonium ion is small), the active end will be able to exist in the form of the carbonium ion. Therefore, in the polymerization of trioxane in nitrobenzene at a low monomer concentration, the molecular weight of the polymers will not vary with the conversion as in the polymerization of vinyl monomers. The increase in the molecular weight in the course of polymerization at a high conversion may be due to the consumption of a chainbreaking or transfer reagent during the polymerization.

Of course, there is another possible explanation of this phenomenon. If the rate of the initiation reaction is decreased in the polymerization at a low monomer concentration in nitrobenzene, we will observe the more usual relationship, in which the molecular weight of the polymer is independent of the conversion.[5] This possibility will be discussed in the next paper.[4]

On the other hand, the cationic polymerization of 3, 3-bis(chloromethyl)oxethane (BCMO) is a typical example of how the reaction proceeds through the oxonium ion. In the polymerization of BCMO the molecular weight of the polymers formed was independent of the conversion.[6,7] From this point of view, it may be unreasonable to conclude that the chain carrier in the polymerization of trioxane in nitrobenzene at a low monomer concentration is not an oxonium ion. However, it could also be concluded that the rate of the initiation reaction is not so large as that of the propagation reaction. To clarify the nature of the chain carrier, a further investigation must be carried out.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 36—41 (1966)

Kinetic Studies of the Solution Polymerization of Trioxane Catalyzed by $BF_3 \cdot O(C_2H_5)_2$. IV. The Change in the Formaldehyde Concentration during Polymerization

By Tetsuro MIKI, Toshinobu HIGASHIMURA and Seizo OKAMURA

Department of Polymer Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received April 5, 1965)

In the solution polymerization of trioxane catalyzed by $BF_3 \cdot O(C_2H_5)_2$ and boron fluoride, the dependence of the yield of CH_2O produced in the induction period on the polymerization conditions has been studied at 30°C. In the case of the $BF_3 \cdot O(C_2H_5)_2$ catalyst, the formation of CH_2O has been recognized in *n*-hexane just after the addition of the catalyst while no induction period of the polymerization was seen. In polar solvents, both the formation of CH_2O and the polymerization were retarded as the water concentration increased. In these systems the concentration of the CH_2O formed changed with time, and no equilibrium or stationary concentration was recognized. In the case of the boron fluoride catalyst, an increase in the water concentration remarkably increased the induction period, also. For either catalyst the induction period was not decreased by the addition of CH_2O to the polymerization system in advance of the catalyst addition. Therefore, it has been deduced that, in the polymerization system catalyzed by $BF_3 \cdot O(C_2H_5)_2$, the polymerization and depolymerization reaction took place simultaneously and that the induction period was caused by water, which inhibits the formation of high polymers.

In the solution polymerization of trioxane by an acidic catalyst, an induction period and the formation of formaldehyde (CH_2O) have been recognized under certain conditions. Kern et al.[1] considered that, during the initial stage of polymerization, a certain concentration of CH_2O was obtained by the depolymerization of CH_2O from the active centers. Monomeric CH_2O must be present in an equilibrium concentration before the polymerization of trioxane can take place; they regarded the induction period as the time during which such a concentration of CH_2O was obtained. Thereafter, kinetic studies of the induction period of the polymerization were carried out by Kučera[2] and by Rakova.[3] While they have agreed that

1) W. Kern and V. Jaacks, *J. Polymer Sci.*, **48**, 399 (1960).

2) M. Kučera and E. Spousta, ibid., **A2**, 3443 (1964).

3) G. V. Rakova, L. M. Ramanov and N. S. Enikolopyan, *Vysokomol. Soed.*, **6**, 2178 (1964).

the free CH_2O produced at the initial stages of polymerization reacts rapidly with the catalyst to form the active centers, they differed on the relationship to the yield of CH_2O during polymerization. Moreover, since they worked under different polymerization conditions, it is impossible to apply their results to our system.

For the present paper, the yield of CH_2O produced during the polymerization of trioxane catalyzed by $BF_3 \cdot O(C_2H_5)_2$ was measured under the same conditions as in the previous papers. For comparison, the polymerization catalyzed by boron fluoride was also carried out. Considering the relation between the induction period and the yield of CH_2O, it may be deduced that the induction period is caused mainly by water in the reaction system.

Experimental

The procedures of the polymerization except for the stopping of the reaction, and of the purification of the materials were the same as in the previous paper.[4] Commercial boron fluoride (Matheson Co., Inc., boron fluride content: 99.5%) was used without purification. In the case of the addition of CH_2O to the polymerization system, the necessary quantity of the formaldehyde solution was prepared by the thermal decomposition of polyoxymethylene at 250—300°C under nitrogen.

The concentration of CH_2O was determined by the sodium sulfite method.[5]

For the measurement of the concentration of CH_2O produced in the polymerization system, the polymerization at a fixed time was stopped by adding a certain quantity of a 1 M sodium sulfite aqueous solution, in which the free sodium hydroxide had previously been neutralized, using thymolphthalein (0.1% alcohol soln.) as an indicator. When necessary, the polymers were separated and CH_2O was measured immediately after the polymerization was stopped. As this solution showed a blue color if CH_2O had been produced, it was quickly titrated by 1/20 N hydrogen chloride until its color disappeared. As the catalyst present in the polymerization system acts as an acid, sodium hydroxide corresponding to the initial catalyst concentration was added before the titration.

Results

The Formation of CH_2O in the Polymerization System Catalyzed by $BF_3 \cdot O(C_2H_5)_2$.—In the polymerization of trioxane catalyzed by $BF_3 \cdot O(C_2H_5)_2$ in various solvents, the relation between the reaction time and the yields of polymer and CH_2O was studied. Here "polymer" is defined as that polyoxymethylene which was insoluble in methanol, and the CH_2O formed means all those CH_2O units which could be measured by the method described in the Experimantal section.

In *n*-hexane, as Fig. 1 shows, the polymerization took place without any induction period. The formation of CH_2O could be detected immediately after the addition of the catalyst (within 6 sec.), and the concentration of CH_2O was almost constant up to a 10% conversion. These results did not change even if the concentrations of catalyst and water were changed.

of water the induction period for the formation of CH_2O was short (CH_2O was found just after the production of polymer), while at a high concentration of water the induction period for the formation of CH_2O was long; here the formation of CH_2O and the polymerization occurred simultaneously.

In nitrobenzene we studied two systems, in one of which the concentration of water was low and, in the other, extremely high. In the former system, as Fig. 3 shows, both the polymer and CH_2O were produced less than one minute after the addition of the catalyst. The maximum concentration of CH_2O was about 15 mmol./l., as in ethylene dichloride. The concentration of the CH_2O formed tended to decrease during the course of the polymerization. However, in a system containing much water, a large quantity of CH_2O was produced during the induction period, the concentration of the CH_2O decreased just before

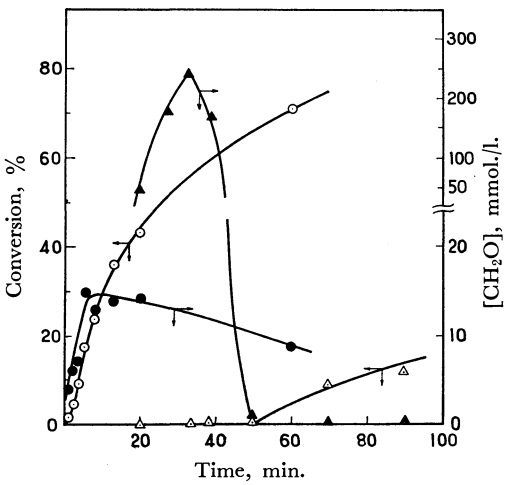

Fig. 3. Effect of water on the rate of polymerization and the concentration of produced CH_2O during polymerization in nitrobenzene catalyzed by $BF_3 \cdot O(C_2H_5)_2$ at 30°C.
$[M]_0$; 1.1 mol./l., [C]; 10 mmol./l., $[H_2O]$; ○ and ●: 2.2, △ and ▲: 18.6 mmol./l.

polymerization occurred, and no CH_2O was found in the system after the polymerization had taken place. So far as Fig. 3 is concerned, no equilibrium concentration of CH_2O was observed.

The Effect of CH_2O Added to the Polymerization System Catalyzed by $BF_3 \cdot O(C_2H_5)_2$.—The effect of the added CH_2O was studied in ethylene dichloride, using $BF_3 \cdot O(C_2H_5)_2$ as a catalyst. When CH_2O was present, the polymerization system became turbid immediately after the addition of the catalyst and the polymerization of trioxane seemed to occur. Nevertheless, the yield of polymers did not increase during a given period, and the true induction period was not changed by

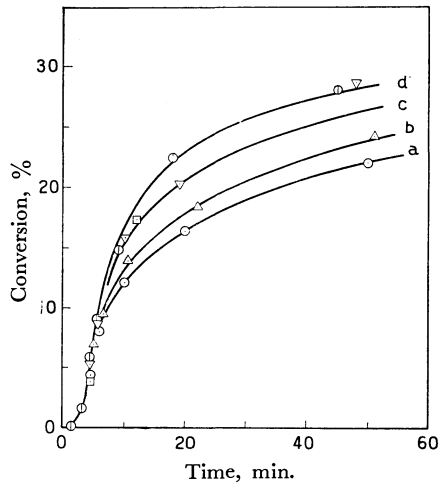

Fig. 4. Effect of addition of CH_2O on the rate of polymerization in ethylene dichloride catalyzed by $BF_3 \cdot O(C_2H_5)_2$ at 30°C. (The exact curve for *e* could not be determined.)

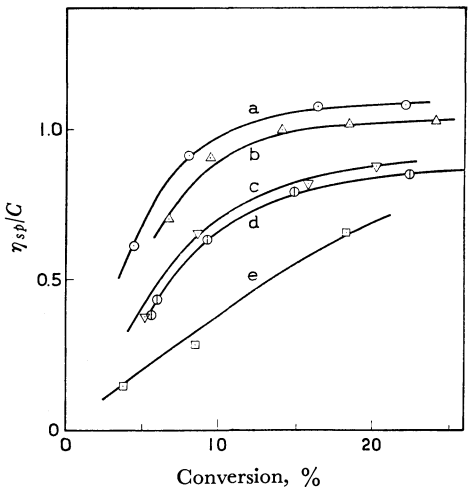

Fig. 5. Effect of addition of CH_2O on the molecular weight of resultant polymers in ethylene dichloride catalyzed by $BF_3 \cdot O(C_2H_5)_2$ at 30°C. Polymerization conditions are the same as in Fig. 4.

the addition of CH_2O, as Fig. 4 shows. These facts indicate that the added CH_2O was polymerized upon the addition of the catalyst, thus giving the observed turbidity. It apparently did not participate in the induction period of the polymerization of trioxane. Increasing the amount of CH_2O added did, however, increase the rate of the polymerization of trioxane and, as Fig. 5 shows, decrease the molecular weight of the resulting polymer. This same tendency was also caused by the increase

in the catalyst concentration.

The Formation of CH_2O in the Polymerization System Catalyzed by Boron Fluoride.— As the CH_2O formation in the polymerization system catalyzed by BF_3, which had been reported earlier,[1] differed from that of the $BF_3 \cdot O(C_2H_5)_2$ catalyst reported in this paper, we again studied the former polymerization system. The effect of the water concentration was studied in ethylene dichloride at a fixed catalyst concentration. As Fig. 6 shows, an increase in the water concentration increased the rate of polymerization and the induction period. When the water concentration was larger than that of the catalyst, the time-conversion curve assumed a typical S-shape, as in the results obtained by Kern et al.[1] in methylene chloride. The saturated yield of the polymer was found to be independent of the water concentration in the case of the BF_3 catalyst. Figure 7 shows that, although the molecular weight of the resulting polymers increased with the conversion (as in $BF_3 \cdot O(C_2H_5)_2$ catalysis), the water concentrations used did not affect the molecular weight of the polymers.

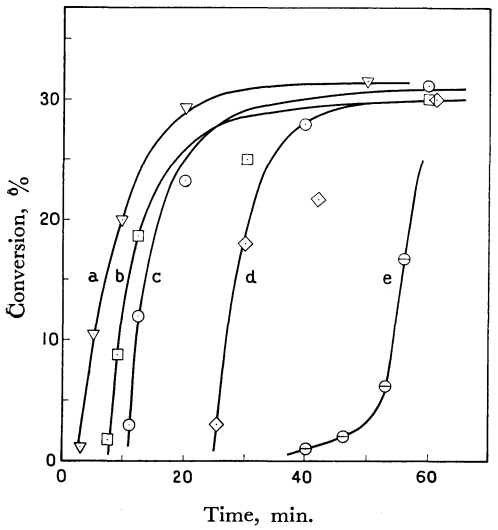

Fig. 6. Effect of water on the rate of polymerization in ethylene dichloride catalyzed by BF_3 at 30°C.
$[M]_0$; 4.4 mol./l., [C]; 3.8 mmol./l., $[H_2O]$; a(▽): 2.7, b(□): 3.6, c(○): 4.0, d(◇): 4.5 and e(⊖): 5.5 mmol./l.

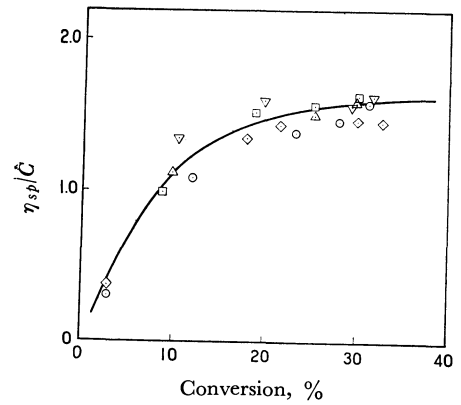

Fig. 7. Effect of water on the molecular weight of resultant polymers in ethylene dichloride catalyzed by BF_3 at 30°C.
$[M]_0$; 4.4 mol./l., [C]; 3.8 mmol./l., $[H_2O]$; ▽: 2.7, △: 3.4, □: 3.6, ○: 4.0 and ◇: 4.5 mmol./l.

In the same system the change in the concentration of CH_2O produced during the induction period of the polymerization was also measured. As Fig. 8 shows, CH_2O was produced during the induction period. When the concentration of CH_2O seemed to reach a maximum, the polymerization of trioxane took place. Thereafter, the concentration of CH_2O suddenly decreased. Here no equilibrium concentration of CH_2O was found, either. The change in the CH_2O concentration was so sudden both before and after the polymerization

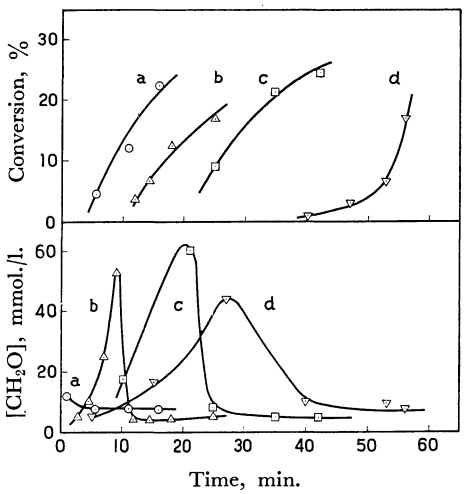

Fig. 8. Effect of water on the rate of polymerization and the concentration of produced CH_2O during polymerization in ethylene dichloride catalyzed by BF_3 at 30°C.
$[M]_0$; 4.4 mol./l., $[BF_3]$; a(○) and d(▽): 3.5 mmol./l., b(△) and c(□): 3.0 mmol./l., $[H_2O]$; a(○): 2.4, b(△): 2.2, c(□) 4.8 and d(▽): 5.5 mmol./l.

that the measurement of the maximum concentration of CH_2O was very difficult.

The Effect of the CH_2O Added to the Polymerization System Catalyzed by Boron Fluoride. — The effect of the added CH_2O on the polymerization reaction was studied in ethylene dichloride, as in the case of the $BF_3 \cdot O(C_2H_5)_2$ catalyst. Similarly to the case of the $BF_3 \cdot O(C_2H_5)_2$ catalyst, when CH_2O was present the reaction system became turbid just after the addition of

the catalyst, but the quantity of polymers was fairly small and did not increase during the settled period. As Fig. 9 shows, a small amount of the added CH_2O did not greatly affect the rate of polymerization and did not decrease the induction period. It was impossible to conclude that these results were caused only by the added CH_2O because of the possibilities that water came into the solvent during the preparation of the CH_2O solution by our method and that CH_2O reacted with water in the polymerization system.

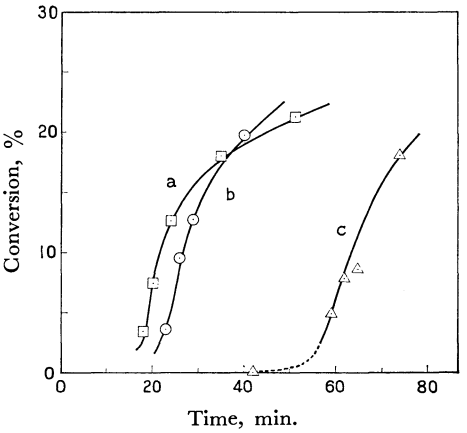

Fig. 9. Effect of addition of CH_2O on the rate of polymerization in ethylene dichloride catalyzed by BF_3 at 30°C.
$[M]_0$; 4.4 mol./l., $[BF_3]$; 2.5 mmol./l., $[H_2O]$; 2.0 mmol./l., $[CH_2O]$; a(□): 0, b(○): 25 and c(△): 71 mmol./l.

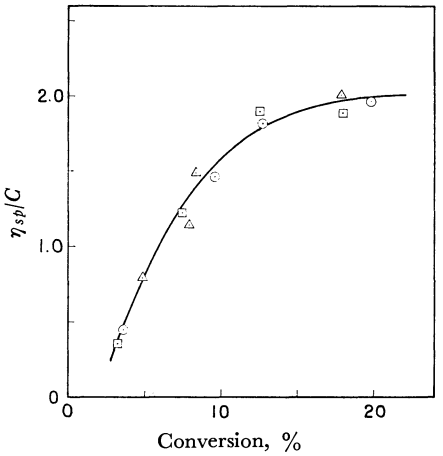

Fig. 10. Effect of addition of CH_2O on the molecular weight of resultant polymers in ethylene dichloride catalyzed by BF_3 at 30°C. (Polymerization conditions are the same as in Fig. 9.)

The molecular weight of the resulting polymers was not affected by the added CH_2O, as Fig. 10. shows. While in the case of the $BF_3{\cdot}O(C_2H_5)_2$ catalyst the addition of water and CH_2O decreased the molecular weight of the polymers, in the case of the BF_3 catalyst the addition of water and CH_2O did not affect the molecular weight of the polymers.

Discussion

In the cationic solution-polymerization of trioxane, the induction period of the polymerization and the formation of CH_2O during the polymerization have often been recognized. In Table I we have summarized our experimental results on the induction period. Here the relation between the induction period and the concentrations of the catalyst and of the monomer was too complicated to be explained quantitatively, as was the relation between the polymerization rate and the concentrations of the catalyst and of the monomer.

In *n*-hexane, no induction period of the polymerization was observed. This agrees with Rakova's result[3] in a non-polar solvent wherein the formation of CH_2O was recognized immediately after the addition of a catalyst. This is probably due to the facile depolymerization of the unsolvated growing-chain end.

On the other hand, our results in polar solvents showed that the factor which most greatly influences the induction period of the polymerization seemed to be the concentration of water. This relation was considered to hold not only in the case of the $BF_3{\cdot}O(C_2H_5)_2$ catalyst, but also in the case of the boron fluoride catalyst, as Fig. 6 shows. In the latter case, when the water concentration was about 1.5 times larger than that of the boron fluoride catalyst, a very long induction period was observed and the time-conversion curve assumed a typical S-shape. In earlier papers, this view has not been dealt with at all.

Kern et al.[1] have indicated that, in the polymerization of trioxane catalyzed by boron fluoride, the active chains were depolymerized, thus liberating free, monomeric CH_2O, whose concentration reached a certain value (i. e., the equilibrium concentration) before the polymerization reaction took place. This conception has been supported by

TABLE I. SUMMARY OF THE RELATIONSHIP BETWEEN INDUCTION PERIOD (t_i) AND REACTION CONDITIONS

* *a* was a very large number, but the value could not be settled.

Kučera in the cationic polymerization of molten trioxane.[2]

In our results concerning the $BF_3 \cdot O(C_2H_5)_2$ catalyst, as long as the water content in the reaction system was not very large, the polymerization reaction and the formation of CH_2O took place simultaneously; we did not observe that the polymerization reaction occurred only when a certain concentration of CH_2O is present. As the change in the induction period was not observed when CH_2O had been added to the polymerization system, the conception of Kern et al.[1] can not be applied to the polymerization catalyzed by $BF_3 \cdot O(C_2H_5)_2$.

Rakova et al.[3] dealt quantitatively with the induction period in the solution-polymerization of trioxane. Considering that, in their results, the stationary concentration of CH_2O varied with the polymerization conditions, and also considering that in our results no stationary or equilibrium concentration was clearly recognized, it is doubtful whether the equilibrium concentration of CH_2O is present.

The behavior of a system containing a large amount of water should be considered, also. In general, an increase in the water concentration increased the induction period during which a high concentration of CH_2O was attained. We have defined "polymer" as the methanol-insoluble polyoxymethylene. Therefore, it seems that the polymerization does not occur if only the methanol-soluble oligomer is formed. Besides, it is well known[6] that, in water, this oligomer decomposes into CH_2O, the decomposition being facilitated by an acid or a base. As the determination of the CH_2O concentration was carried out by using a sodium sulfite aqueous solution, the free monomeric CH_2O could not be distinguished from the CH_2O unit which was decomposed from the oligomer. As water might act as a transfer agent or as an inhibitor and much more oligomer would be produced in the presence of much water, a large quantity of CH_2O might be measured experimentally during the induction period. The decrease in the concentration of CH_2O in the course of polymerization was probably due to the growth of these oligomers to high polymers. Without exact knowledge of the concentration of the free monomeric CH_2O in the polymerization system, however, it will be difficult to discuss the induction period in detail. At any rate, it is clear that the induction period is caused by water, which inhibits the formation of high polymers.

Such aspects of the polymerization catalyzed by $BF_3 \cdot O(C_2H_5)_2$ as the effect of water differed from those of the polymerization catalyzed by boron fluoride; it must be established by future studies whether a consistent mechanism can be applied to both systems.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 41—46 (1966)

Kinetic Studies of the Solution Polymerization of Trioxane Catalyzed by $BF_3 \cdot O(C_2H_5)_2$. V. The Effect of the Solvent and of the Polymerization Temperature

By Tetsuro MIKI, Toshinobu HIGASHIMURA and Seizo OKAMURA

Department of Polymer Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received April 5, 1965)

The effect of the polarity of solvents in the solution polymerization of trioxane catalyzed by $BF_3 \cdot O(C_2H_5)_2$ has been studied. While the molecular weight of the resulting polymer is almost independent of the kind of solvent, the rate of polymerization in a polar solvent is large at a high initial monomer concentration. At a low monomer concentration, however, the rate of polymerization in a non-polar solvent is larger than that in a polar solvent. This fact can probably be explained by observing that, at the low monomer concentration, the initiation species produced from the catalyst is solvated by the solvent molecule rather than by trioxane because of the small basicity of trioxane. The activation energies of the over-all polymerization rate as determined in ethylene dichloride, nitroethane and nitrobenzene are all about 16 kcal./mol. The decrease in the molecular weight of the resulting polymers caused by raising the temperature is very small.

In the cationic polymerization of vinyl monomers, the dielectric constant of the reaction system remarkably affects the rate of polymerization and the molecular weight of the resultant polymers. It is well known that in the polymerization of styrene, the rate of polymerization increases with the dielectric constant.[1] However, the relation between the molecular weight of the polymers and the dielectric constant varies with the kind of solvent. While in the cationic polymerization of the styrene and its derivatives the molecular weight of the resultant polymers increases with the dielectric constant,[1,2] a reverse relation is shown in the polymerization of isobutene[3] and of vinyl ethers.[4] This may be ascribed mainly to the difference between the mechanisms of the monomer transfer reactions.

If, in the cationic polymerization of trioxane, an ionic active species is produced by the interaction between the neutral molecules, as in the cationic polymerization of vinyl monomers, it is to be expected that the increase in the dielectric constant of the reaction system will increases the rate of polymerization.

In the present paper we will try to clarify the effect of the polarity of solvents in the ring-opening polymerization. Therefore, the findings on solvent variation will be summarized from the previous papers in this series and then the temperature dependence in several solvents will be studied. It will be found that the effect of a sovlent in the cationic polymerization of trioxane is not always the same as in the polymerization of vinyl monomers.

Experimental

The procedures of the polymerization and of the purification of the materials were the same as in the previous papers.[5]

Results

The Effect of the Solvent.—As the kinetic orders of the monomer and catalyst to the polymerization rate are changed by the kind of solvent, it was impossible to compare the polymerization rates in various solvents exactly. Figure 1, therefore, compares the polymerization rates in various solvents on the condition that the concentrations of the reagents were selected to be as equal as possible. From this result it can be seen that, at a high monomer concentration (3.3 mol./l.), the polymerization rate increases with the dielectric constant. Nitrobenzene is also found to be a very useful solvent, one in which high polymers can be obtained at high yields.

As *n*-h exane did not have a large solubility of trioxane, the rate of polymerization in *n*-hexane was compared with the rates in polar solvents at only a low monomer concentration. In this case, as the experimental data were not obtained at a very low monomer concentration in the polar solvents, the extrapolated values were used as the rates in the polar solvents. Figure 2 shows the resultant relation between the dielectric constant of the solvent and the rate of polymerization. At a high monomer concentration, as Fig. 1 shows, the rate of polymerization in a polar solvent was larger than that in a non-polar solvent, but the reverse tendency was found at the low monomer concentration. Although it may be difficult to compare these data quantitatively because some of them are extrapolated, this tendency seems to be correct qualitatively.

On the other hand, Fig. 3 shows the molecular weight of the polymers which should be produced under the conditions corresponding to those in Fig. 2. Here the molecular weight was compared at a low conversion (10%). It can be said that the molecular weight of the resultant polymers is independent of the kind of solvent if the other conditions are equal.

Polymerization conditions are the same as in Fig. 2. $[M]_0$; a(○): 3.3 and b(□): 0.4 mol./l.

The Effect of the Polymerization Temperature.—In the polymerization of trioxane at a high monomer concentration, the increase in the polarity of the solvent remarkably increased the rate of polymerization. Therefore, the dependence of the polymerization reaction on the reaction temperature was studied in various solvents.

Figures 4, 5 and 6 show the time-conversion curves at various temperatures in ethylene dichloride, nitroethane and nitrobenzene respectively. The increaes in the reaction temperature increase the

rate of polymerization and decreased the induction period of the polymerization. Except for the polymerization at a low temperature, the reaction order of the monomer as determined from the course of polymerization, as described in the previous paper,[6] was independent of the reaction temperature.

The activation energy determined from the initial

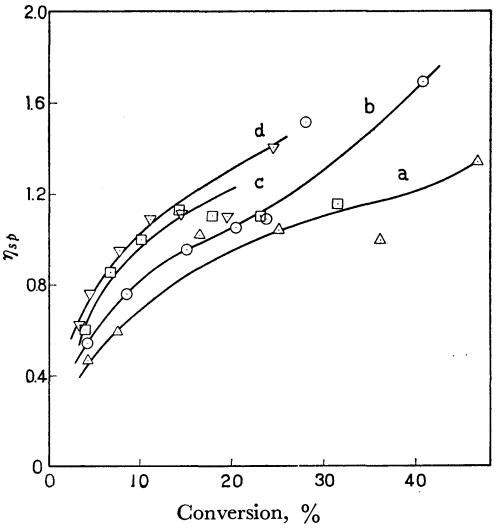

Fig. 9. Effect of temperature on the molecular weight of resultant polymers in ethylene dichloride.
Polymerization conditions are the same as in Fig. 4. Temp.; a(△): 46.0, b(○): 38.5, c(□): 30.0 and d(▽): 23.0°C

rate of these curves was about 16 kcal./mol., as is shown in Fig. 7, in each solvent,

By plotting the logarithms of the induction period against the reciprocal of temperature, the linear correlation was obtained in all the solvents, as Fig. 8 shows. The activation energy with respect to the induction period, as determined from the slope of each line in Fig. 8, was smaller the smaller the dielectric constant of the solvent.

The polymerization temperature also affected the molecular weight of the resultant polymers. Figures 9, 10 and 11 show the relations between the conversion and the molecular weights of the polymers obtained in Figs. 4, 5 and 6 respectively. An increase in the polymerization temperature decreased the molecular weight of the resultant

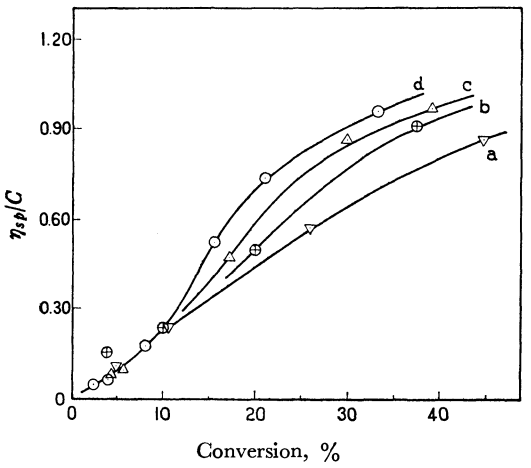

Fig. 10. Effect to temperature on the molecular weight of resultant polymers in nitroethane. Polymerization conditions are the same as in Fig. 5. Temp.; a(▽): 45.0, b(⊕): 38.0, c(△): 30.0 and d(○): 23.0°C

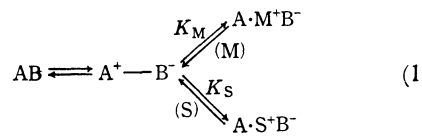
polymers. This tendency has also been found in the polymerization of trioxane in toluene, a non-polar solvent.[7]

Discussion

One of the most remarkable characteristics of the solution polymerization of trioxane is the effect of the polarity of the solvent on the polymerization rate. At a high monomer concentration, an increase in the dielectric constant of the solvent increased the rate of polymerization, as in vinyl polymerization. On the other hand, at a low monomer concentration, an increase in the dielectric constant decreased the rate of polymerization. As the molecular weight of the polymers produced did not greatly depend on the dielectric constant of the solvent, the change in the polymerization rate with the kind of solvent is probably caused by the initiation reaction.

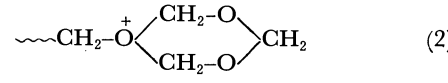
In general, an increase in the dielectric constant of a solvent ought to facilitate a reaction in which the neutral catalyst molecule itself dissociates to produce an ionic species. Therefore, the behavior observed at the high monomer concentration is probably normal. The unusual behavior observed at the low monomer concentration suggests that some reactions which decrease the polymerization rate are present. This postulate is also supported by the large kinetic order of the initial monomer concentration in a olar solvent.[6] It may be considered that the catalyst (AB) dissociates to the ion-pairs ($A^+—B^-$), and that they then are stabilized by solvation with monomer (M) or solvent molecules (S), as is shown in Eq. 1. The solvation of ion-pairs with a monomer implies the



(1)

occurrence of the initiation reaction. As A^+ will be solvated mainly with monomers at a high monomer concentration, the rate-determining step in the initiation reaction is possibly the process in which AB dissociates. In this case, the dissociation constant, K_1, increases with the dielectric constant, and the active centers (AM^+) are rapidly formed as the dielectric constant of the system increases.

At a low monomer concentration the formation of the active centers is in competition with the reaction in which A^+ is solvated with solvent molecules. It has been reported that the trioxane molecule has no great complex-forming ability with the carbonium ion indicated in Eq. 2, i. e., the basicity of trioxane is not very large.[8] In



(2)

fact, in the copolymerization of 3, 3-bis(chloromethyl)oxethane (BCMO) with trioxane, the copolymer was not obtained, was obtained only the

8) S. Iwatsuki, M. Okada, Y. Yamashita and Y. Ishii, ibid., **67**, 1236 (1964).

homopolymer of BCMO.[9] Therefore, it may be expected that, in a polar solvent, K_S will be larger than K_M and that the active center will be produced with difficulty at a low monomer concentration because A^+ will be solvated with the solvent and so become inert. It has been reported that nitro compounds act strongly as transfer agents in the cationic polymerization of styrene.[10] This is one instance in which a polar solvent may stabilize a carbonium ion. On the other hand, in a non-polar solvent such as *n*-hexane, A^+ is not stabilized by solvation with a solvent, but by solvation with a monomer. Such a consideration can explain qualitatively the dependence of the polymeriz ation rate onthe dielectric constant of the solvent.

If the relation indicated in Eq. 1 is valid, the large kinetic order of the initial monomer concentration in the polar solvent is understandable. That is, in the polar solvent, a decrease in the initial monomer concentration implies an increase in the solvent molecule (S), which so stabilizes A^+ that the active centers are not produced. Consequently, a decrease in the initial monomer concentration rapidly decreases the rate of polymerization.

Although the meaning of the induction period is not clear, it must be related to the time during which a certain amount of the active center is produced. It is also clear that the formation of the active centers is hindered by water. This may be explained by the idea which has been described above, the idea that the temperature coefficient is smaller, the smaller the dielectric constant of the solvent. That is, the destruction of the ionic active-center by a water molecule should be easier in a non-polar solvent than in a polar solvent.

The activation energy of the initial rate of polymerization in a polar solvent was independent of the kind of solvent. Although no detailed discussion can be carried out becuase of the obscurity of the elementary reactions in each solvent, it may be inferred that the reaction mechanisms in these halogenated and nitronized solvents is not graetly different. The activation energy in benzene, a non-polar solvent, was reported by Rakova et al.[11] to be 12 kcal./mol.; this value was estimated by a method different from ours.

The activation energy for the decomposition of polyoxymethylene catalyzed by acids has been reported to be about 19 kcal./mol.[12] Since the molecular weight of polymers decreased slightly as the reaction temperature was raised in our work, it is clear that the decomposition of the polymers during polymerization did not greatly affect the molecular weight.

Silent Discharge Reactions in Aqueous Solutions. I. An Acidic Aqueous Solution of Ferrous Sulfate in Atmospheres of Helium and Argon*

By Akira YOKOHATA and Satoru TSUDA

Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received April 6, 1965)

In an atmosphere of helium or argon, the silent discharge reactions of aqueous solutions have been investigated from the point of view of radiation chemistry. A discharge tube with two coaxial glass tubes was used. In a dilute oxygen-free aqueous solution of sulfuric acid, hydrogen peroxide appeared as a result of discharge. Also, the oxidation of ferrous ions to ferric ions has been found. It has been confirmed, first, that neither the effect of metastable excited states of helium and argon nor that of luminescence is serious, and, second, that the reaction may well be interpreted by taking into consideration the actions of slow electrons generated in the gas phase on the liquid water. The yield of hydrogen atoms plus hydroxyl radicals has been estimated from the yields of hydrogen peroxide and ferric ions. The ratios of the yield of hydrogen peroxide to that of radicals show that the silent discharge reaction corresponds to the reaction by ionizing radiation of high LET, the value of which apparently equals 3eV./Å in helium and 8 eV./Å in argon. The $G(Fe^{3+})$

* Presented in part at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964.

value and the absorbed dose (E) estimated were, respectively, as follows: In helium: $G(Fe^{3+})=4.6$, $E=3.8\times10^6$ r./hr.; in argon: $G(Fe^{3+})=4.3$, $E=7.2\times10^6$ r./hr.

In the field of silent discharge reaction, the work has hitherto been chiefly confined to studies of the gas phase; the study of the solutions is, however, currently receiving increasing attention.[1,2] The discharge reactions in the gas phase have been investigated exhaustively,[3-5] and their reaction mechanisms have been elucidated from the point of view of the reactivity of active species. In the studies of liquids,[6-8] the reaction mechanisms have also been interpreted as the reactions of active species generated in an atmosphere to solutes or solvents; the actions on them of low-energy electrons generated in an atmosphere have been neglected or forgotten.

As far as we have been able to determine, few studies of the silent discharge reactions in aqueous solutions from the point of view of radiation chemistry by the low-energy electron generated in an atmosphere have been made. Moreover, their importance has not adequately been explored.

We began our studies with the purpose of rectifying these omissions and so explored the mechanism of the silent discharge reactions, comparing this mechanism with the findings of radiation chemistry. The method we have developed also makes it possible to determine the apparent energy absorbed in a solution by silent discharge if adequate chemical systems are selected.

In the present work the oxidation of ferrous ion in the dilute sulfuric acid solution, well known as a chemical dosimeter, has been studied, using helium or argon as an atmosphere[9]; as has already been pointed out by Davis,[1] the contributions of their metastable-excited states to chemical reactions, to, for example, the oxidation of ferrous ion to ferric ion, seem to be very small.

According to our experimental results, hydrogen peroxide is formed in the dilute sulfuric acid solution; ferrous ion is oxidized to ferric ion, and the yield of ferric ions is always larger than that which would be expected from the oxidation by the hydrogen peroxide formed. Now, assuming that the net effect by the slow electrons is similar to that of the usual ionizing radiation,[10] the yield of hydrogen atoms plus hydroxyl radicals can be estimated from the yields of hydrogen peroxide and ferric ions according to the well-established reaction mechanism. Moreover, the ratio of the yield of hydrogen peroxide to that of radicals shows clearly that the silent discharge reaction[11] in the aqueous solutions corresponds to the reactions by ionizing radiations of high LET. Also, the apparent dose rate in each case of helium and argon under our experimental conditions was estimated by considering carefully our findings on the relations of LET and $G(Fe^{3+})$.

Experimental

Apparatus.—Most of the previous studies of the discharge reaction have been made by means of glow discharge. It is impossible, however, to study the aqueous solution by this method. In this work, a discharge tube of the ozonizer type (Fig. 1) was used;

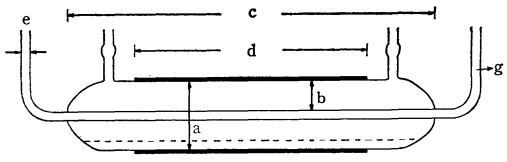

Fig. 1. Schematic diagram of discharge tube.

a	26 mm.	e	10 mm.ϕ
b	8 mm.		
c	300 mm.	---	surface of solution
d	230 mm.	—	tin foil

this makes the study of solutions possible. It is composed of two coaxial, hard-glass tubes; the part consisting of tin foil stuck on the outer tube was used for one electrode, and the part containing the dilute sulfuric acid in the inner tube (g) was used for the other electrode (high-tension side). After the sample solution had been poured into the discharge tube, the discharge was made by applying a high tension between those two electrodes, letting helium or argon flow through the gas space of the discharge tube.

All experiments were made at a constant volume of the solution, 10 ml. The surface of the solution was vibrated gently by the discharge. This may be useful for the renewal of the surface of the solution.

All experiments were made after the dissolved oxygen in the solution had been completely removed by bubbling helium or argon gas into the solution. Sometimes samples were degassed by four successive cycles of freezing, evacuation, and melting on a vacuum line.

9) Even though the effects of such ions as Ar^+ and He^+ have been considered, the effect would probably be very small since their mobility is quite low compared with that of electrons.
10) It is generally accepted that the chemical change produced by a high-energy radiation, such as those of beta-, alpha- and gamma-rays, can be explained as the reaction by secondary electrons with a mean energy of about 100 eV.
11) Since the electron energy is very small, most of the energy might be dissipated by one event. Accordingly, the term "LET", as herein used, may not be adequate, the electron generated by silent discharge being very slow.

For the washing of the discharge tube, a mixed solution of alcohol and a saturated aqueous solution of sodium hydroxide was used, besides the usual cleaning solution. The discharge tube was dried by evacuation.

Sometimes, a quartz discharge tube of the same size was used to test the effect of the light arising from the discharge. In this case. the test was made after the sample had been poured into the inner tube, g in Fig. 1. If the effect were predominant, some contributions would be expected; however, this was not the case.

Another discharge tube (Fig. 2) was also used. This is a vertical one. Samples were tested in the position of A. This experiment makes it possible to estimate the contributions of active species with a long life, such as He^{m*} and Ar^{m*}, and also those of the oxidizing products, such as the trace of ozone formed in the gas phase.

c	300 mm.	h	40 mm.

Electric Circuit.—An electric circuit (Fig. 3) was used for measuring the discharge current running through the discharge tube. In general the wave form shown in Fig. 4 is found, where V and I are the voltage and the current respectively. The phase difference was about 80 degrees.

V Voltage

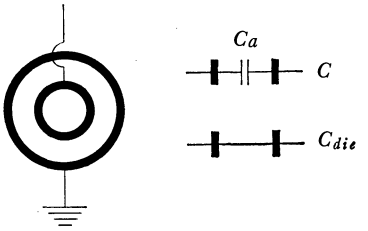

Fig. 5. Cut-away diagram of discharge tube.

The discharge tube is a sort of condenser, the capacitance of which is shown by C and which consists of two parts C_{die} and C_a; the former depends on the thickness of the outer and inner glass tubes, and the latter, on the gap distance of the discharge tube (Fig. 5). The capacitance during discharge may be approximately shown by C_{die}, because it has a short circuit because of the discharge.[12]

Materials.—The water used was purified by the multiple distillation described by Johnson and Allen.[13] Reagent-grade sulfuric acid and ferrous ammonium sulfate were used without further purification. Helium and argon (purity: >99.99%) were also used without further treatment.

Analysis.—The amount of hydrogen peroxide produced in the dilute sulfuric acid solution was determined by the method of Ghormley.[14] The ferric ions in ferrous sulfate solutions were determined by light absorption at 3040 Å.

Results

Figure 6 shows the relation between the applied voltage and the electric current when 10 ml. of solution is contained in the discharge tube, where B or B' shows the firing voltage (V_1) for helium and argon respectively. The AB or AB' part before discharge is expressed by the formula[10] $I=\omega CV$. For BC or B'C' during discharge, $I=\omega CV_1+\omega C_{die}(V-V_1)$: $\omega=2\pi f$; V_1: firing voltage; V: applied voltage; f: frequency. Most of the experiments were made at a constant discharge current, $I=$ 1 mamp. The electric current as measured by the method shown in Fig. 2 shows the low frequency component principally, not the high frequency component. For the latter another method, such as

one using a thermoammeter, seems to be needed. Recently we have made extensive studies of this point,[15] but we will not discuss them here.

The Formation of Hydrogen Peroxide from a Dilute Aqueous Solution of Sulfuric Acid.—In the oxygen-free aqueous solution of sulfuric acid, hydrogen peroxide appeared as a result of discharge in argon or helium. The concentration of sulfuric acid in the range from 2×10^{-2} N to 1.5 N had no effect on the yield of hydrogen peroxide within the range of experimental error (Figs. 7a and 7b). The yield of hydrogen peroxide also showed a good linear correlation with the duration of discharge. A larger amount of hydrogen peroxide was found in argon than in helium. Although the formation of hydrogen peroxide from the water vapor in the gas phase may be expected, it was negligibly small under our experimental conditions, in which the gas passed at a velocity of about 120 ml./min. and the duration time of the discharge (20 min.) was very short.

The formation of hydrogen peroxide, therefore, may be considered to be caused by the actions of low energy electrons generated by discharge on water molecules, just as in radiation chemistry.

The Formation of Ferric Ions.—Ferric ions were found to be formed in an aqueous ferrous sulfate solution acidified with sulfuric acid. Figures 8a and 8b show the relationship between the amount of ferric ions formed and the duration of the discharge in a helium or an argon atmosphere respectively. The yield of ferric ions was independent of the concentration of ferrous ions in the

range from 2×10^{-3} M to 4×10^{-1} M, and of the concentration of sulfuric acid in the range from 2×10^{-2} N to 1.5 N; it also showed a good linear correlation with the duration of discharge. These results suggest that the mechanism of the silent discharge reaction may be interpreted as that of radiolysis by slow electrons.

Discussion

The silent discharge on aqueous solutions in an atmosphere of helium or argon will give many numbers of electrons; excited molecules such as He^{m*} and Ar^{m*}, and atoms or radicals like the H-atom and the OH-radical due to the interaction of the water molecule with an electron or an excited molecule such as He^{m*}; it is also accompanied by a weak luminescence. Accordingly, the effect of the silent discharge may naturally be considered to be the superposed effect caused by those electrons, active species, and luminescence.

It is, however, very important to clarify which of them plays the main role. This is our purpose in the present study.

The Effect of Active Species.—First, let us consider the effect of the excited molecule alone. It is very difficult to clear up this effect quantitatively, but it is possible to do so qualitatively. For this purpose, the discharge tube shown in Fig. 2 was used. 10 ml. samples were tested in the position of A. After the oxygen dissolved in a sample in the A section had been completely excluded by bubbling argon or helium in, a discharge was made. In order to pass the discharged gas rapidly into the sample solution, the gas was sent forth through the capillary tube. The experimental results showed only a very small amount of ferric ions under such these conditions: duration time of discharge =30 min.; flow velocity of gas =120 ml./min., and electric current=1 mamp. If the effect of the excited molecules is predominant, larger amounts of ferric ion may be expected.

Our results are consistent with the work by Davis et al.,[1] in which the oxidation of ferrous ions was checked by introducing argon treated by glow discharge into an aqueous solution. They found only a very slow oxidation. Therefore, the effect of the excited molecule itself may be concluded to be very small. However, when water vapor is present, the situation may be different.

In the study of the total ionization in gases by single alpha-particles, Jesse[16] showed that the number of ion pairs in pure helium or neon is greatly increased by the addition of a small amout of almost any impurity; he then suggested that the additional ionization arose from reactions of the following type:

$$He^* + X \rightarrow He + X^+ + e^- \qquad (1)$$

The metastable-excited states of helium have a sufficiently long life to encounter an impure atom or molecule and ionize it in a collision of the second kind (the Penning effect). With helium, most of the contaminants show this effect. As expected, other ionizing radiations (beta-rays, gamma-rays) show exactly the same effect.

Since the presence of water vapor should be considered in our case, the following reaction may occur in the gas phase:

$$He^* + H_2O \rightarrow He + H_2O^+ + e^- \qquad (2)$$

However, it can, alternatively, result in the "dissociation" of the molecule.[17]

$$He^* + H_2O \rightarrow He + H + OH \qquad (3)$$

One of the reaction products may be electronically excited. If the hydrogen exists in the excited state, reaction 4 may be expected:

$$H^* + H_2O \rightarrow H_2 + OH \qquad (4)$$

In argon also the circumstances are just the same, except that the excitation energy of the metastable state is smaller than that of helium. Since the excitation energy of argon is smaller than the ionization potential of the water vapor molecule, a reaction like 2 may not be expected.

As has already been pointed out,[1] the effect of water vapor cannot be neglected. In the present stage, it is very difficult to estimate separately the effects of H-atoms and OH-radicals arising from the water vapor and those arising from the interaction of liquid water with the slow electrons generated in the gas phase. However, we have already obtained the experimental result that the yield of hydrogen peroxide formed in the gas phase is negligibly small under the experimental conditions. This seems to show that the contribution of the hydroxyl radical from the water vapor is not very great. Also, hydrogen atoms will not naturally make an important contribution.

The Effect of Luminescence.—The silent discharge gives a luminescence, although the intensity is weak. Therefore, photochemical reactions[18] may be expected, although their contribution in this case is thought to be small.

In order to clear up this point, we made an experiment, where a quartz discharge tube was used; the aqueous ferrous sulfate solution to be tested was put in an inner tube (Fig. 1. g). Since quartz is transparent for light of wavelengths of $\lambda>2000$Å, it might be possible to learn the order of contributions due to photons of the wavelengths $\lambda>2000$Å by this experiment. Experimental results showed that this effect was negligibly small.

Evidence that the light below 2000Å is effective in the flash photolysis of aqueous ferrous sulfate

has recently been given by Baxendale and Mansell.[19] They concluded that the observed $Fe^{2+} \rightarrow Fe^{3+}$ oxidation was an indirect effect, the primary one being the photolysis of water to give products which oxidize Fe^{2+}. Although the contribution of ultraviolet rays (<2000Å) may exist in our case, we have not yet performed any experiment to test such effects because of the great difficulty. However, judging from the fact that the effect of luminescence was clearly negligibly small in the case of nitrogen molecule which has $\lambda \fallingdotseq$ 2000Å (E=6.1 eV.) as a resonance line,[20] the resonance lines of helium and argon are also too weak to make contributions.[21]

The Effect of Electrons.—As has been mentioned above, the effects of the metastable-excited state of helium and argon and of the luminescence cannot be serious.

However, the contributions of hydrogen atoms and hydroxyl radicals from the water vapor cannot be neglected, although they might also not be very large. The yield of hydrogen peroxide from the water vapor was very small. On the other hand, our present work shows that the yield of hydrogen peroxide formed in the aqueous solutions is fairly great (Table I). Also, the yield of ferric ions was always larger than that which could be expected from the oxidation by the hydrogen peroxide formed. These phenomena may be interpreted by taking into consideration the actions of the slow electrons generated in the gas phase on the solvent.

About the energy distribution of electrons produced by such silent discharge under an atmospheric pressure, we do not yet have any exact information. The electrons, however, may be considered to have an energy distribution from just above zero to somewhat above the ionization potential for the gas in which the discharge occurs.[22,23] On the other hand, to produce a hydrogen atom and a hydroxyl radical through the excited state of a water molecule, it is well known that the energy 7.4 eV. is necessary.[24] Accordingly, in the silent discharge also, the formation of a hydrogen atom and a hydroxyl radical can be expected. In other words, the effect of electrons may be interpreted in the same way as in radiation chemistry:

$$H_2O \text{ -W-} \rightarrow H, OH, H_2, H_2O_2 \qquad (5)$$

Some part of the hydrogen atoms and the hydroxyl radicals may come from the water vapor. The overall reaction, however, proceeds irrespective of whether they are produced from the water vapor or the liquid water,

Therefore,[25] the following relation is obtained:

$$Y(Fe^{3+}) = 2Y(H_2O_2) + Y(OH) + Y(H) \qquad (6)$$

where Y shows the yield of each product under given conditions.

Table I shows each value of $Y(H_2O_2)$, $Y(Fe^{3+})$, $Y(H+OH)$ estimated by (6), and $Y(H_2O_2)/Y(H+OH)$ in the cases of helium and argon respectively.

Table I. Estimation of $Y(H_2O_2)/Y[(H)+(OH)]$

	$Y(H_2O_2)$ mol./l.	$Y(Fe^{3+})$ mol./l.	$Y[(H)+(OH)]$ mol./l.	$Y(H_2O_2)/Y[(H)+(OH)]$
He	6.5×10^{-4}	3.0×10^{-3}	1.7×10^{-3}	0.38
Ar	1.8×10^{-3}	5.1×10^{-3}	1.5×10^{-3}	1.2

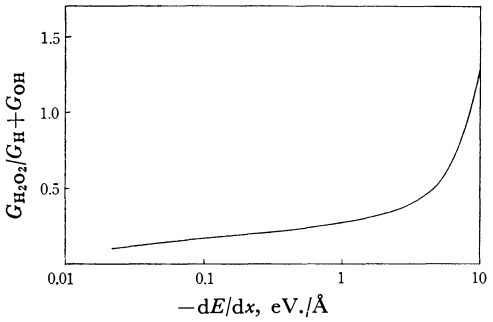

Fig. 9. Relation between $G_{H_2O_2}/G_H+G_{OH}$ and $-dE/dx$.

Figure 9 shows the relations between $G(H_2O_2)/G(H+OH)$ and LET, arranged using the data from Allen, Lefort and Barr.[26-28] The linear energy transfer (LET) in Fig. 9 is expressed by $-dE/dx$ (eV./Å), where ^{60}Co gamma rays: LET 0.02 eV./Å, 40 keV. electron: 0.08 eV./Å, 18 MeV. deuteron: 0.5 eV./Å and 5.5 MeV. alpha-rays: 9 eV./Å, as is already known,[29]

The radical yields decrease with an increase in the LET, and molecular yields increase until the radical yields approach zero at a sufficiently high LET.

By comparing the results in Table I with Fig. 9, the following interesting conclusions can be derived. In an atmosphere of helium, the chemical effect of the silent discharge apparently corresponds to that of the ionizing radiation with a LET of

about 3 eV./Å, while in argon it corresponds to a radiation with a LET of about 8 eV./Å. In argon it seems to be very close to the effect of alpha rays. This is consistent with Hochanadel's finding that, for very low-energy electrons, the radicals are formed in high concentrations along the track in the same way as for alpha particles and low-energy protons.[30]

The slight difference between helium and argon is thought to be due to their different discharge characters; in the former the discharge is very gentle and the high frequency part of the discharge current is very small, while in the latter the discharge is quite vigorous and the high frequency part is relatively large.[15] Also, from the relation between $-dE/dx$ and $G(Fe^{3+})$[31] it becomes possible to estimate the apparent $G(Fe^{3+})$ in helium and in argon. The former is $G(Fe^{3+}) \fallingdotseq 4.6$, and the latter, $G(Fe^{3+}) \fallingdotseq 4.3$.

The Estimation of the Apparent Dose Absorbed.[32]—It is very important to ascertain the absorbed energy or the dose in the silent-discharge chemistry. As a method of measuring the total dissipated energy, the electrical method using a synchroscope has been proposed.[33] In our experience, however, this method was very difficult because the high-frequency component of the electric current fluctuates very vigorously. An approach by theoretical calculations has also been made. The following formula has been proposed for the energy dissipated per second by the silent discharge[34]:

$$A=\frac{f(C_{die}+C_a)(V_i+V_d)\{2E_m-(V_i+V_d)(1+C_a/C_{die})\}}{1+C_a/C_{die}} \qquad (7)$$

A : the energy dissipated per second by the silent discharge
f : the frequency of the electric source used
C_{die} : the total capacitance of the insulator
C_a : the capacitance due to the gap distance in the discharge tube
V_i : the voltage across the gap space at the firing voltage
V_d : the stopping voltage
E_m : the maximum value of the applied voltage

Of couse, this formula is an approximate one, in which the contributions of the high-frequency parts are neglected. Also, V_i means the voltage in the gas space and is correlated by the $V_i=V_1(C_{die}/(C_a+C_{die}))$ formula to the firing voltage, V_1. Now, let us suppose that discharge occurs when the voltage of the gap space attains V_i and stops at V_d. The relation between V_d and V_i is not well known, but the value of V_d/V_i is said to be approximately 0.4—0.2[35]

In our experimental conditions $C_{die}=180$ pF,[36] $C_a=36$ pF, $V_i=1.3$ kV. and $E_m=15.4$kV. in helium, and $V_i=2.4$kV. and $E_m=17.2$ kV. in argon. By putting these values into (7), the ratio of the energy dissipated by the silent discharge in helium and argon can be estimated.[37] Table II shows the results of the calculation for each case of $V_d/V_i=0.2$ and 0.4.

TABLE II. CALCULATION RESULTS OF DISSIPATED ENERGY IN HELIUM AND ARGON (NORMALIZED TO THE CASE OF HELIUM)

Kind of atmosphere	V_d/V_i	Dissipated energy
He	0.2	1
Ar		2.0
He	0.4	1
Ar		2.0

Next, let us estimate approximately in roentgen units the dose absorbed in helium and in argon. By combining $G(Fe^{3+})=4.6$ with $Y(Fe^{3+})=3.0\times10^{-3}$ M in helium and $G(Fe^{3+})=4.3$ with $Y(Fe^{3+})=5.1\times10^{-3}$ M in argon, it becomes possible to estimate them. In helium, the apparent dose rate equals about 3.8×10^6 r./hr. and in argon to 7.2×10^6 r./hr. These values, of course, vary with the value of the electric discharge current. This is the case of 1 mamp. The values also indicate the average integral dose absorbed by the aqueous solution in the apparatus used by the authors, where a solution with a volume of 10 ml. is used. The dose rate in argon is larger than that in helium and its ratio is about 1.9, which is almost consistent with the calculated result.

35) M. Suzuki, *J. Electrochem. Soc. Japan (Denki Kagaku)*, **24**, 354 (1956).
36) This value was estimated approximately from a curve showing the relation between the applied voltage and the discharge current.
37) The value of A means the total energy dissipated per second by the silent discharge. The energy absorbed in a solution occupies only a small amount (x%) of A. Since it is impossible to estimate the value of x, the absolute value of A is not so important. The value of the A_{Ar}/A_{He} ratio, however, would be useful for us as a means to check the value of the absorbed dose as measured by the chemical dosimeter.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 53—55 (1966)

Silent Discharge Reactions in Aqueous Solutions. II. An Acidic Aqueous Solution of Ceric Sulfate in Atmospheres of Helium and Argon*

By Akira YOKOHATA and Satoru TSUDA

Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima

(Received April 6, 1965)

In an atmosphere of helium or argon, the silent discharge reaction of an acidic aqueous solution of ceric sulfate has been investigated from the point of view of radiation chemistry. The results show the reduction of ceric ions to cerous ions. The situation is very similar to that in the case of radiation chemistry. From the known mechanism of the radiolysis of a ceric sulfate solution, the yield of "hydrogen atoms minus hydroxyl radicals" has been determined. Also, combining this yield with that of "hydrogen atoms plus hydroxyl radicals" previously obtained gave the respective yields of hydrogen atoms and hydroxyl radicals. Moreover, on the basis of the value of the dose rate previously determined, the G values of the hydrogen atom, the hydroxyl radical and the cerous ion were determined to be as follows: in helium: $G(H)=1.1$, $G(OH)=1.6$, $G(Ce^{3+})=1.6$; in argon: $G(H)=0.6$, $G(OH)=0.7$, $G(Ce^{3+})=2.9$. On the basis of these results, it may be concluded that the silent discharge reactions in an aqueous solution in inert gas can well be interpreted in terms of the radiolysis caused by the ionizing radiation of high LET.

In the previous report[1] it was pointed out, first, that in the atmospheres of helium and argon, the chemical reaction in an aqueous solution of ferrous sulfate by silent discharge may well be interpreted in terms of the actions of slow electrons generated in the gas phase on the solvent, and, then, that neither the effect of the metastable-excited states of helium and argon nor of the luminescence can be serious.

Using the methods described in that, the present work will deal with a silent discharge reaction, in the atmospheres of helium and argon, on an aqueous solution of ceric sulfate acidified with dilute sulfuric acid.

The reaction mechanism of this system has already been well established in the field of radiation chemistry,[2] in which ceric ions have been reduced to cerous ions.

The silent discharge also showed the reduction of ceric ions. As was established in the previous report, the net effect of slow electrons generated by the silent discharge may be considered to be similar to that of radiation chemistry introduced by alpha- or gamma-ray irradiation. Therefore, combining the yield of cerous ions with that of hydrogen peroxide should give the yield of "hydrogen atoms minus hydroxyl radicals" under given conditions. Accordingly, it may be expected that the yield of hydrogen atoms and hydroxyl radicals can be separately estimated by combining the yield of "hydrogen atoms plus hydroxyl radicals" (described in the previous report) with that of "hydrogen atoms minus hydroxyl radicals."

In this report, the G values of H, OH and Ce^{3+} in the silent discharge will be estimated. Also, it will be pointed out that, in atmospheres of helium and argon, the silent discharge reactions in the aqueous solutions can apparently be interpreted well in terms of the radiolysis caused by a particle of a high LET value.

Experimental

The discharge tube, the electric circuit, and the experimental conditions were the same as have previously been reported.

Merck guaranteed-reagent ceric sulfate was used without further purification. All the other materials were also of a reagent grade. The helium and argon (purity: >99.99%) were used without further treatment.

The ceric-ion concentration was measured directly by spectrophotometry, using the molar extinction coefficient of 5580 at 3200 Å (25°C).

Results

Figures 1a and 1b show the relationship between the amount of cerous ions formed and the duration time of the discharge in the cases of helium and argon respectively. The yield of cerous ions in a ceric sulfate solution acidified with 0.8 N sulfuric acid was independent of the concentration of ceric ions in the range from 1×10^{-3} M to 2×10^{-2}M. The effect of the solute concentration, however, was found at concentrations higher than 5×10^{-2} M (cf. Fig. 1b). The situation is very similar to the

case in radiation chemistry. This point will be discussed later.

Discussion

Harlan and Hart,[3] using a concentrated solution, studied the upper limit of the usefulness of ceric dosimetry; they found that the relation between the change in the ceric-ion molarity and the dose absorbed was not linear. The initial slope corresponded to $G(Ce^{3+})=3.1$, and the final slope to $G=1.7$. Also, the effect of the solute concentration has been determined. For example, in the concentration range from 10^{-4} M to 10^{-3} M, $G(Ce^{3+})$ equals 2.50 and 2.9 at 0.1 M. In a 0.39 M ceric-sulfate solution, $G(Ce^{3+})$ increases to 3.1 because the $H+Ce^{4+}$ reaction now scavenges hydrogen atoms that normally combine to form hydrogen in dilute solutions,

3) J. T. Harlan and E. J. Hart, *Nucleonics*, **17** (No. 8), 102 (1959).

Taimuty et al.[4] irradiated the same system and obtained almost the same results. In the range from 1×10^{-3} M to 5×10^{-2} M, they got $G(Ce^{3+})=2.5$. Also, their results showed no dose-rate dependence; on the other hand a small effect of the temperature was found at temperatures higher than 27°C.

The present work will show that $Y(Ce^{3+})$ is independent of the ceric-ion concentration in the range from 1×10^{-3} M to 2×10^{-2} M within the range of experimental error, but that it is dependent on ceric ions in concentrations higher than 5×10^{-2} M. This point might well be interpreted by taking the $H+Ce^{4+}$ reaction into consideration in the same way as has been described by Harlan and Hart.

Now, in the same manner as was pointed out in the previous report, we may assume a radiolysis by the interaction of slow electrons with the water molecules.

Therefore, in the range of the linear correlation of each yield to the dose, the observed yield of cerous ion may be expressed by (1)[5,6]:

$$Y(Ce^{3+})=2Y(H_2O_2)+Y[(H)-(OH)] \qquad (1)$$

Table I shows $Y[(H)-(OH)]$ as estimated from (1) by combining the $Y(Ce^{3+})$ with the $Y(H_2O_2)$ previously obtained.[1] The cases of both helium and argon give a negative value: $Y(OH)>Y(H)$.

Hochanadel[7] has published the yields of the intermediate H, OH in the decomposition of a 0.4 M sulfuric acid solution as a function of the initial LET (linear energy transfer) value of the incident particle. In the LET range above 10 eV./Å, $G(OH)$ exceeds $G(H)$ and $G(H_2)$ exceeds $G(H_2O_2)$.

TABLE I. YIELD OF "HYDROGEN ATOM MINUS HYDROXYL RADICAL"

	$Y(H_2O_2)$ mol./l.	$Y(Ce^{3+})$ mol./l.	$Y[(H)-(OH)]$ mol./l.
He	6.5×10^{-4}	1.0×10^{-3}	-3×10^{-4}
Ar	1.8×10^{-3}	3.5×10^{-3}	-1×10^{-4}

Our results show that the silent discharge reactions apparently correspond to the reactions induced by particles with values of LET larger than about 10 (eV./Å). In the previous report we showed that the silent discharge reaction in helium

4) S. I. Taimuty, L. H. Towle and D. L. Peterson, ibid., **17** (No. 8), 103 (1959).

5) The following reaction scheme may be expected:

$$H_2O \rightsquigarrow H, OH, H_2O_2, H_2$$
$$H + Ce^{4+} \rightarrow Ce^{3+} + H^+$$
$$H_2O_2 + 2Ce^{4+} \rightarrow 2Ce^{3+} + 2H^+ + O_2$$
$$OH + Ce^{3+} \rightarrow Ce^{4+} + OH^-$$

Accordingly, $G(Ce^{3+}) = 2G(H_2O_2) + G(H) - G(OH)$

6) Y shows the yield of products under these given conditions: discharge current: 1 mamp., and duration time of discharge: 10 min.

7) M. Burton, J. S. Kirby-Smith and J. L. Magee, "Comparative Effects of Radiation," John Willy & Sons, New York (1960), p. 179.

and in argon under given conditions apparently corresponded to that by particles with the LET values of 3 and 8 (eV./Å) respectively. A small discrepancy can be seen in helium. In estimating the value of LET, however, it seems to be more reasonable to take into consideration the ratio of $Y(H_2O_2)$ to $Y[(H)+(OH)]$ than the ratio of $Y(OH)$ to $Y(H)$. Accordingly, the values of 3 (eV./Å) in helium and 8(eV./Å) in argon were used in this work.

Of couse, the yield of hydrogen atoms and hydroxyl radicals from the water vapor may also be present in the case of a silent discharge on an aqueous solution. Our interest, however, was in the net yield of H and OH.

We previously reported the yield of the "hydrogen atom plus the hydroxyl radical":

$$\left.\begin{array}{ll}\text{In helium:} & Y[(H)+(OH)]=1.7\times10^{-3}\ \text{M}\\ \text{In argon:} & Y[(H)+(OH)]=1.5\times10^{-3}\ \text{M}\end{array}\right\} \quad (2)$$

Combining (2) with the results shown in Table I gives these yields of H and OH:

$$\left.\begin{array}{ll}\text{In helum:} & Y(H)=0.7\times10^{-3}\ \text{M}\\ & Y(OH)=1.0\times10^{-3}\ \text{M}\\ \text{In argon:} & Y(H)=0.7\times10^{-3}\ \text{M}\\ & Y(OH)=0.8\times10^{-3}\ \text{M}\end{array}\right\} \quad (3)$$

These values will hereafter be checked further by means of studies of other chemical systems.

Table II shows the relation between G_{obs} and G_{est}. Each G_{obs} indicates a G value obtained by combining $Y(H)$, $Y(OH)$ and $Y(H_2O_2)$ with the dose previously determined. Each G_{est} means a G value estimated from the figure[7] showing the relations of $G(H)$, $G(OH)$ and $G(H_2O_2)$ to LET, using 3 (eV./Å) in helium and 8 (eV./Å) in argon as the LET values. The correspondence of G_{obs} to G_{est} is relatively good, except for $G(OH)$ in helium.

Table II. Relation between G_{est} and G_{obs}

	He		Ar	
	G_{est}	G_{obs}	G_{est}	G_{obs}
H	1.2	1.1	0.7	0.6
OH	1.0	1.6	0.7	0.7
H_2O_2	1.2	1.0	1.4	1.5

Also, the values of $G(Ce^{3+})=1.6$ in helium and $G(Ce^{3+})=2.9$ in argon were obtained. The differences in $G(Ce^{3+})$ in helium and in argon, and also between $G_{obs}(OH)$ and $G_{est}(OH)$ in helium, may be due to the different discharge characters, the locality of the discharge being higher in argon than in helium. Besides, the difference in the formation mode of the hydrogen atom and of the hydroxyl radical from the water vapor may be a reason (cf. part I). These points will be left as a future problem.

It is our conclusion that silent discharge reactions in an aqueous solution in atmospheres of helium and argon may apparently be well interpreted in terms of radiolysis caused by a particle with a high LET value.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 55—57 (1966)

The Color Reaction between Chromium(III) Ion and Potassium Ferrocyanide*

By Yoshio MATSUMOTO and Michiko SHIRAI

Department of Chemistry, Faculty of Hygienic Science, Kitasato University, Minato-ku, Tokyo

(Received April 8, 1965)

The observation of the orange-coloring reaction between potassium ferrocyanide and the chromium(III) ion on filter paper and its application in the paper chromatographical analysis of the chromium(III) ion has been reported on previously by the present authors. The color reaction has now been observed in an aqueous solution as well and studied in relation to the reaction temperature, the reaction time, the characteristic absorption, the species of chromium(III) salts, the chromium(III) ion concentration, the pH level, and the presence of an acetic acid buffer, by measuring the absorption spectra of the reaction solutions. The recommended conditions for getting a satisfactory color reaction and a suitable wavelength for the measurement of this color reaction have been presented.

In continuation of previous work[1] on the color reaction of potassium ferrocyanide with chromium(III) ions on filter paper, the present paper will report on the coloration which takes place in an aqueous solution.

When Cr^{3+} and $K_4[Fe(CN)_6]$ were mixed together in an aqueous solution, the color of the solution gradually changed to reddish orange and its intensity reached near the maximum within 1.5—3 hr. at room temperature; on the other hand, the reaction proceeded more quickly at a higher temperature, a satisfactory coloration being obtained in 15 min. at 50°C.

With regard to the reaction solution described above, the absorption spectra at various Cr^{3+} concentrations for visible light and the variation in the spectra during the reaction were measured. It was thus found that the maximum variation in color intensity was observed at a wavelength between 410 and 420 mμ. It was also found that, in the case of a reaction for 15 min. at 50°C, a strictly linear relationship held between the extinction at 415 mμ and the Cr^{3+} concentration.

The major part of the experiments in this work was done with chrome alum as the representative source salt of Cr^{3+}, and the chromium(III) ion will be referred as having a more general significance in the statement of the experimental results, because of the preliminary experimental proof of the agreement in extinction at 415 mμ of the reaction solutions derived from different chromium(III) salts, such as chromic chloride and chrome alum.

In the course of studying the relation between the pH value and the coloration, interference with the coloration by the acetic acid - sodium acetate buffer was found.

The coloration caused by the present reaction is thought to be due to the formation of a complex anion containing chromium; attempts to isolate such a complex in a crystalline form are now in progress.

Experimental

The Absorption Spectra of Reaction Solutions at Various Cr^{3+} Concentrations.—Solutions of chromium(III) ions from $KCr(SO_4)_2 \cdot 12H_2O$ and potassium ferrocyanide solutions were mixed together in the various ratios shown in Fig. 1, and the absorption spectrum of each solution was measured after 3-hr.'s reaction at room temperature (Fig. 1). The extinction was found to vary widely in accordance with the Cr^{3+} concentration in the wavelength range between 410 and 420 mμ.

The Relation between the Color Intensity and the Reaction Time.—With the Cr^{3+} and $K_4[Fe(CN)_6] \cdot 3H_2O$ used in the final concentrations of 40 μg./cc. and 10 mg./cc. respectively, the absorption spectra were measured after reaction at room temperature for the times of 0, 20, 40, 60, 100, 140 and 180 min. (Fig. 2). In this experiment, the color intensity almost attained its maximum within 100 min. after mixing.

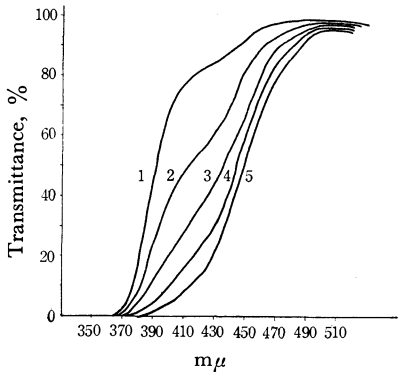

Fig. 1. Absorption curves of the reaction solutions at varying Cr^{3+} concentrations observed after 3-hr.'s reaction at room temperature.
Concentration of $K_4[Fe(CN)_6] \cdot 3H_2O$ after mixing is 10 mg./cc. in each case.

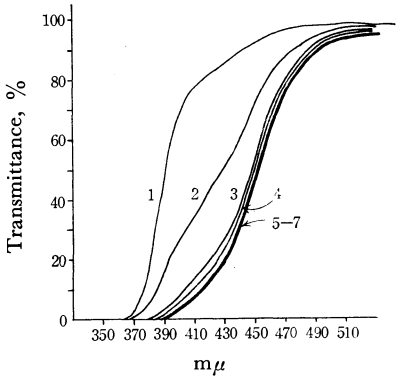

Fig. 2. Absorption curves at varying times after mixing.
Concentrations of Cr^{3+} and $K_4[Fe(CN)_6] \cdot 3H_2O$ after mixing are 40 μg./cc. and 10 mg./cc. respectively.

Curve No.	1	2	3	4	5	6	7
Period of time after mixing, min.	0	20	40	60	100	140	180

Experiments at 50°C.—The reaction time could be shortened with the elevation of the reaction temperature until the temperature attained 50°C, at which point a satisfactory coloration was obtained in only 15 min. A temperature above 50°C, however, was not desirable because the reaction solution became turbid.

The Relation between the Extinction at 415 mμ and the Cr^{3+} Concentration.—The solutions of chromium(III) ions and potassium ferrocyanide were mixed together in the various ratios shown in Fig. 3 and allowed to react together for 15 min. at 50°C;

* A part of this work was orally disclosed at the 11th Annual Meeting of the Japanese Society of Analytical Chemistry, Sapporo, July, 1962.

then the extinction of each reaction solution was measured at 415 mμ (Fig. 3). The results showed a strictly linear relationship between the color intensity and the Cr^{3+} concentration.

A Comparison of the Different Chromium(III) Salts.—A chromic chloride solution in a green color and one in a blue color, considered to contain chiefly the species $[Cr(H_2O)_4Cl_2]^+$ and $[Cr(H_2O)_5Cl]^{2+}$ respectively, were prepared; then the chromium(III) concentration in each solution was determined by the titration method using potassium permanganate and iron(II) sulfate solutions. These chromic chloride solutions were treated with a potassium ferrocyanide solution, and the extinction was measured under the conditions stated in Fig. 3, and compared with the chrome alum solution, which corresponds to $[Cr(H_2O)_6]^{3+}$. The extinctions of the both chromic chloride solutions agreed exactly with each other, and agreed fairly well with that of the chrome alum solution at the same chromium(III) concentrations.

Restriction in pH Value.—This color reaction was not satisfactory at low pH levels, especially below 2, and not an orange but a light blue color was caused at pH levels below 1.5 due to the decomposition of potassium ferrocyanide.

The Effects of Using an Acetic Acid - Sodium Acetate Buffer.—An acetic acid - sodium acetate buffer was found to interfere considerably with this coloration. One evidence responsible for the interference was that the acetic acid itself, reacting with potassium ferrocyanide, gave rise to some coloration during the requisite time for the purposed reaction, which is 1.5—3 hr. in the case of room temperature. At 50°C, however, the purposed reaction proceeded so quickly that the coloration by the reaction between acetic acid and potassium ferrocyanide was found to be negligible. The other interfering factor of acetic acid was its reaction with chromium, which resulted in a considerable decrease in the color intensity of the reaction solution. Thus the presence of acetic acid as a buffering agent is undesirable for this color reaction.

Summary

The color reaction of potassium ferrocyanide with chromium(III) ions in an aqueous solution has been observed. The absorption spectra of the reaction solutions for visible light were measured, and the coloration in relation to the reaction temperature, the reaction time, the characteristic absorption, the species of chromium(III) salts, the Cr^{3+} concentration, the pH level, and the presence of an acetic acid buffer has been studied.

For getting a satisfactory color reaction and for measuring it, a reaction for 15 min. at 50°C and an extinction measurement at 415 mμ were found to be best.

Between the extinction and the Cr^{3+} concentration in the solution of a given chromium(III) salt, a strictly linear relationship held. The same concentration of Cr^{3+} ions from different chromium(III) salts, such as chrome alum and chromic chloride, proved to give almost the same extinction.

This color reaction was not satisfactory at low pH levels. An acetic acid buffer interfered strongly with the coloration.

The authors are grateful to Dr. Konomu Matsumura and Dr. Akiji Fujita for their kind advice and their encouragement of this work, and Dr. Mamoru Mitomi for his kind cooperation in the absorption spectra measurements.

Copper(II) Halide Complexes with Substituted Pyridine *N*-Oxides

By Yoneichiro MUTO* and Hans B. JONASSEN

Department of Chemistry, Tulane University, New Orleans, Luisiana, U. S. A.

(Received April 14, 1965)

Pyridine *N*-oxide copper(II) chloride, the structure of which has recently been elucidated by X-ray analysis [J. C. Morrow and H. L. Schäfer, private communication], has a subnormal magnetic moment (0.85 B. M. [J. V. Quagliano, J. Fujita, G. Franz, D. J. Phillips, J. A. Walmsley and S. Y. Tyree (*J. Am. Chem. Soc.*, **83**, 3770 (1961)]). It consists of a binuclear molecule $[Cu(C_5H_5NO)Cl_2]_2$ in which copper atoms are bridged in pairs by two oxygen atoms. In this work, copper(II) complexes with the empirical formulae of CuX_2L, CuX_2L_2 and CuX_2LY (X=Cl, Br; L=pyridine *N*-oxide, 3-picoline *N*-oxide, 4-picoline *N*-oxide, 4-chloropyridine *N*-oxide, 2, 4-lutidine *N*-oxide, 2, 4, 6-collidine *N*-oxide, 4-nitroquinoline *N*-oxide; Y=*N*, *N'*-dimethylformamide, dimethylsulfoxide) have been prepared, and magnetic and spectral studies of these complexes have been made. The room-temperature magnetic susceptibilities of CuX_2L complexes have been found to be correlated with the pK_a (acid-dissociation constant) values of the attached *N*-oxides. The absorption band in the 735—900 mμ region (the so-called copper band) in the solid-state reflectance spectra of CuX_2L complexes has been found to shift towards a lower frequency as the ligand field strength decreases, and a good parallelism between the frequencies and the magnetic moments has been observed. The effect of the attached ligand on the magnetic interaction has been discussed in terms of the electronic effect of the substituent on the pyridine ring. The infrared spectral data on the N–O stretching frequency indicate the absence of Cu–O–Cu linkage in the CuX_2L_2 complexes with normal magnetic moments.

Quagliano et al.[1] prepared pyridine *N*-oxide copper(II) chloride with an abnormally low magnetic moment of 0.85 B. M. Kubo et al.[2] then suggested that this low magnetic moment is caused by the formation of binuclear oxygen-bridged molecules. Very recently this binuclear structure has been determined by a complete X-ray analysis[3] (Fig. 1.). Harris et al.[4] suggested, in a study of the temperature dependence of the magnetic susceptibility for this complex, that electron exchange demagnetization can occur between pairs of adjacent copper(II) ions via the oxygen atoms. In this case, the following two pathways for the migration of an electron may be set up:

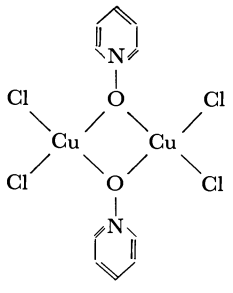

Fig. 1

σ-path: $3d_\sigma(Cu)-2sp_\sigma^2(O)-3d_\sigma(Cu)$

π-path: $3d_\pi(Cu)-2p_\pi(O)-3d_\pi(Cu)$

Either way, via the σ-path or via the π-path, the electron exchange interaction between Cu–O–Cu will become larger as the covalent bond between Cu–O becomes stronger.

The present work was undertaken in an attempt to elucidate the magnetic property in the dihalo copper(II) complexes with pyridine *N*-oxides. First, the complex of the empirical formula CuX_2L (1:1 complex) CuX_2L_2 (1:2 complex) and CuX_2L (1:1 complex) CuX_2L_2 (1:2 complex) and CuX_2LY (X=Cl, Br; L=pyridine *N*-oxide, 3-picoline *N*-oxide, 4-picoline *N*-oxide, 4-chloropyridine *N*-oxide, 2, 6-lutidine *N*-oxide, 2, 4, 6-collidine *N*-oxide, 4-nitroquinoline *N*-oxide; Y=*N*, *N'*-dimethylformamide, dimethylsulfoxide) were prepared. Secondly, the acid-dissociation constants (pK_a) of pyridine *N*-oxides and the magnetic susceptibilities of the copper(II) complexes at room temperature were determined in order to investigate the effect of the nature of the attached ligand on the magnetic interaction. Thirdly, the infrared and visible absorption spectra and the

reflectance spectra were measured for the complexes in order to study the relation between the structure and the magnetic property.

Experimental

Materials.—Pyridine *N*-oxides were obtained commercially. The HCl salts of pyridine *N*-oxides for the pK_a determination were purified by recrystallization from ethanol.

The Preparation of the Copper(II) Complexes. —*1:1 Complexes.*—The complexes were prepared by mixing ethanol solutions of copper(II) halide and pyridine *N*-oxides in a 1:1 molar ratio. In the case of 2,4,6-collidine *N*-oxide, even though ethanol solutions of copper(II) halide and the *N*-oxide in a 1:1 molar ratio were mixed, the 1:2 complexes precipitated immediately. The 1:1 complexes were prepared by refluxing the 1:2 complexes and anhydrous copper(II) halide in a 1:1.5 molar ratio in ethanol for 1 to 2 hr. on a heater plate. However, the 1:1 complexes were rapidly converted to the 1:2 complexes in water, moist air, acetonitril, dioxane, dimethylformamide or dimethylsulfoxide.

1:2 Complexes.—The complexes were prepared by mixing ethanol solutions of copper(II) halide and

f) The reason for the relatively high value seems to be that this sample is contaminated with a very small amount of the 1 : 2 complex; see the Experimental section.
g) These complexes have not been obtained.

pyridine *N*-oxides in a 1:2 molar ratio. Bis-2,4,6-collidine *N*-oxide copper(II) halide was purified by recrystallization from dimethylformamide, while the other complexes were purified by repeatedly washing them with cold ethanol. Except for the collidine *N*-oxide complexes, they all easily lost one mole of the ligand when heated in ethanol. Bis-4-picoline *N*-oxide copper(II) bromide, for instance, gradually lost one mole of 4-picoline *N*-oxide, even in cold ethanol.

The addition compounds of dimethylformamide or dimethylsulfoxide with 1:1 complexes were prepared by the recrystallization of the 1:1 complexes from the respective solvents.

The results of elementary analysis of the complexes are listed in Table I.

Magnetic Susceptibility Determinations.—These were made by the Gouy method at room temperature. The effective magnetic moment, μ, per copper atom was calculated from the expression $\mu=2.83\sqrt{\chi_M \cdot T}$ B. M. where χ_M is the molar susceptibility corrected using Pascal's constants[5] for the diamagnetism of the other atoms in the compounds. The experimental results are presented in detail in Table II, while the correlation between the pK_a values of the ligands and the magnetic moments of the complexes are listed in Table III.

pK_a Determination.—The pK_a values of the various bases were determined by ultraviolet absorption spectroscopy, which was used to measure the concentration of the free and protonated *N*-oxide bases in solutions with measured pH values. The pH measurements were made with a Beckman Zeromatic pH meter which had been calibrated with buffers; the pH values were determined at 20°C 1.07, 2.27, 3.33 and 7.00. The ultraviolet absorption spectra were obtained with a Beckman DB spectrophotometer.

5) G. Foëx, "Constantes Sélectionées Diamagnétisme et Paramagnétisme," Masson & Cie, Paris (1957), p. 222.

Infrared Spectra.—These were recorded on a Beckman IR-8 recording spectrophotometer. The

spectra were taken in both Nujol mulls and KBr disks. The energy of the intense band near 1200 cm^{-1} for each of the complexes and the free ligand are given in Table IV.

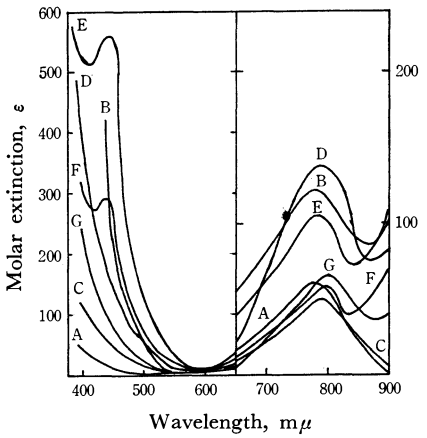

Fig. 2b. Absorption spectra of 2,6-lutidine *N*-oxide $CuCl_2$ in seven different solvents. The letters indicate the solvents noted in Table VI.

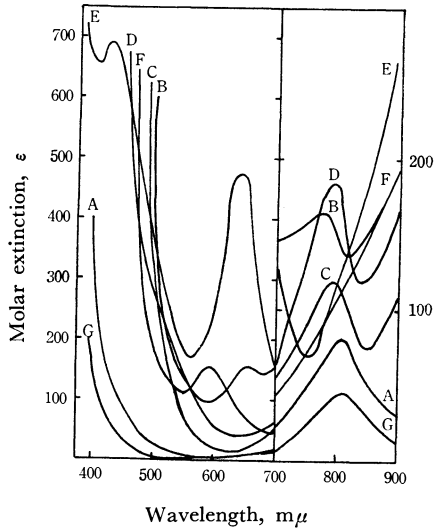

Fig. 2c. Absorption spectra of 2,6-lutidine *N*-oxide $CuBr_2$ in seven different solvents. The letters indicate the solvents noted in Table VI.

Diffuse Reflectance Spectra.—The diffuse reflectance spectra of the 1:1 complexes were measured in the 375—900 mμ region on a Beckman DU spectrophotometer with a reflectance attachment. The band maxima are recorded in Table V. Fig. 2a gives the reflectance spectra for 2,6-lutidine *N*-oxide complexes.

Visible Absorption Spectra.—The visible absorption spectra of the 1:1 complexes in a variety of solvents were determined on a Cary model 14 recording spectrophotometer in the 400—900 mμ region. The absorption maxima are recorded in Table VI, while the absorption curves for 2,6-lutidine *N*-oxide complexes are shown in Figs. 2b and 2c.

Results and Discussion

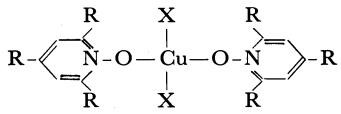
The pK_a Values of Ligands and Magnetic Moments of Complexes.—The 1:1 Complex (CuX_2L).—As is sown in Table II, there is a good correlation between the pK_a values of the *N*-oxides and the magnetic moments of the 1:1 complexes with the oxides, except with 4-chloropyridine *N*-oxide. These data demonstrate that the larger tendency of the *N*-oxide to coordinate with the copper(II) ion results in a larger magnetic interaction.

The introduction of the methyl group on the pyridine ring results in an increase in the pK_a value. Since the pK_a value of the *N*-oxides reflects the σ-electron density on the oxygen atom, such an increase in the value is considered to be caused by the inductive effect of the methyl group. The increase in the electron density on the oxygen atom results in an increase in the Cu-O σ-bond strength, leading to a greater magnetic interaction through the σ-path of the Cu–O–Cu bridge.

The introduction of a chlorine atom on the pyridine ring results in a decrease in the pK_a value as a result of the σ-electron-attracting effect of the chlorine atom. Although the magnetic moment of 4-chloropyridine *N*-oxide copper(II) halide is to be expected in view of the pK_a value of the ligand being smaller than that of the pyridine *N*-oxide complex, just the opposite was observed. However, it is a well-known fact that the chlorine atom conjugated to an aromatic ring has both σ-attracting and π-releasing effects. It seems reasonable, therefore, to conclude that the π-electron on the chlorine atom in the 4-position is conjugated with the π-electron system of pyridine *N*-oxide to increase the π-electron density on the oxygen atom. Consequently, the lowering of the magnetic moment may be interpreted as resulting from the superexchange interaction through the π-path, provided the π-path is more effective for the interaction than the σ-path. The magnetic data for 4-hydroxypyridine *N*-oxide copper(II) chloride (molar magnetic susceptibility: χ_M= 0 at 24.8°C)[6] also suggest the superexchange interaction through the π-path. It is, however, difficult to evaluate the effects of the σ- and π-paths separately at present. Further studies along this line are in progress.

The 1:2 Complex (CuX_2L_2).—No regular correlation between the pK_a value of the ligand and the magnetic interaction in the 1:2 complexes is observed. The observed magnetic moments seem to indicate that the further addition of a ligand to a 1:1 complex produces either a slight or a complete structural change, because the magnetic interaction must be affected by even a slight change in the bond angle in the Cu–O–Cu bridge. The structure shown in Fig. 3 is reasonable for 1:2 complexes with a normal magnetic moment. In the case of complexes with a subnormal magnetic moment, the easy removal of one ligand molecule

6) W. E. Hatfield, Y. Muto, H. B. Jonassen and J. S. Paschal, *Inorg. Chem.*, **4**, 97 (1965).



(R: H, CH_3; X: Cl, Br)

Fig. 3

seems to indicate that one molecule of ligand is weakly bonded to the copper(II) atom, whereas the other forms the Cu–O–Cu linkage with copper atoms. The infrared spectra studies of the N–O stretching frequency support the above conclusion for the 1:2 complexes also, as will be seen in the next section.

Infrared Spectra.—The strong absorption in the 1200—1300 cm^{-1} region in the infrared spectrum of pyridine *N*-oxide and its derivatives has been assigned to their characteristic N–O stretching vibration.[7,8] Kida et al.[9] reported that the coordination of pyridine *N*-oxide with metal ions results in a decrease in the contribution of the mesomeric structure B shown in Fig. 4 and, consequently, in a decrease of the NO double-bond character and in a lowering of the N–O stretching frequency.

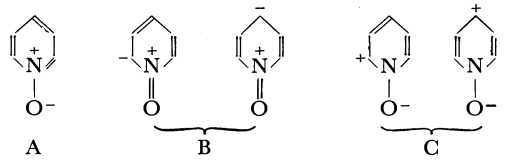


Fig. 4

The NO double-bond character in the 1:1 complexes is expected to be smaller than that in the 1:2 complexes with a normal magnetic moment. This is because a larger electron donation from NO groups is necessary to form the Cu–O–Cu linkage than to form the single coordination shown in Fig. 3 (see also Table IV). The absorption energies of the N–O stretching vibration of the 1:1 complexes were lower than the values for the 1:2 complexes with a normal magnetic moment. This observation is in agreement with our expectation. On the other hand, 1:2 complexes with a subnormal magnetic moment show two N–O stretching frequencies, suggestive of two kinds of NO bonds, for instance, 1223 and 1206 cm^{-1} in bis-pyridine *N*-oxide copper(II) chloride. The assignment of 1223 cm^{-1} to the NO frequency of weakly-bonded pyridine *N*-oxide and 1206 cm^{-1} to the NO frequency of bridged pyridine *N*-oxide are reasonable in view of the chemical property, the magnetic moment and the double-bond character.

Reflectance Spectra.—The spectra which are observed may be conveniently classified into three groups by region: λ_1, 735—940 mμ; λ_2, 400—435 mμ; λ_{Br}505—530 mμ.

λ_1: A band of a relatively low intensity is observed in this region for all the 1:1 complexes studied. From the frequency and the intensity, the band in this region can undoubtedly be attributed to the so-called copper band, a transition within the d shell. This shifts towards lower frequencies as the ligand field strength decreases (cf. Table V). A good parallelism is seen between the frequencies and the magnetic moments. In all the 1:1 complexes the copper atom is combined with two halogen atoms; hence, it may be presumed that the ligand field strength provided by the halogen atoms for the copper atom is almost the same in all the 1:1 complexes.

According to the molecular orbital theory, the splitting of metal d orbitals is essentially attributed to covalent bonding. The greater the overlap of metal d orbitals with the ligand orbitals, the higher in energy will be the antibonding orbital (σd*).[10] Therefore, the frequency of this band may be taken as a measure of the degree of covalency in the Cu–O linkage. The magnetic interaction will become greater as the orbital overlap between the copper and oxygen atoms becomes larger. It may thus be concluded, provided that the ligand-field strength reflects the σ-bond strength of Cu–O linkage, that the superexchange interaction occurs through the σ-path of the Cu–O–Cu bridge.

λ_2: A band of a relatively high intensity is observed in this region for all the 1:1 complexes studied. This corresponds to the band at 350—400 mμ for bivalent metal complexes with picolinic acid *N*-oxide which has been observed and tentatively assigned to a charge transfer, $d_\varepsilon \rightarrow \pi^*$, by Lever et al.[11] A similar band has been observed in solutions, as will be seen in the next section, though this appears at lower frequencies than the band in crystals.

λ_{Br}: In addition to λ_1 and λ_2, a band of a relatively high intensity is observed in this region for all the bromide complexes studied. It is missing, however from the spectra of all the chloride complexes studied. This band has been observed also in solutions of bromide complexes. This band seems to appear by cooperation of copper(II) ion, bromide ion and π-acceptor in a certain environment. However, more work is necessary before we can give it a definite assignment.[12]

Visible Absorption Spectra in a Variety of Solvents.—All the 1:1 complexes are very insoluble in solvents with practically no coordination tendency, such as benzene or chloroform, but they are soluble in organic solvents capable of coordination. The spectra in solutions are somewhat different from the reflectance spectra, as is shown in Table VI and in Figs. 2a, b, and c. This shows that solvation occurs even when the coordination power of the solvent is not high, such as in methanol or nitromethane.

Although the absorption bands for various 1:1 complexes in different solvents differ from one another, they may be classified into three groups just as those of crystals: λ_1, 770—800 mμ; λ_2, 420—460 mμ; λ_{Br}, 590—660 mμ.

λ_1: An absorption band of a low intensity ($\varepsilon \sim 100$) is observed in this region for all the chloride complexes in each solvent. In the case of bromide complexes, an absorption band in this region is observed in weak coordinating solvents, but not in relatively strong coordinating solvents. However, it seems from the shape of the absorption curves that the band peaks in strong coordinating solvents exist at lower frequencies, perhaps near 900 mμ, outside the range of the present measurements.

λ_2: An absorption band is observed in this region for all the complexes in relatively strong coordinating solvents, such as dimethylsulfoxide, *N, N'*-dimethylformamide, acetonitrile and acetone. It is absent, however, from the spectra of the complexes in weak coordinating solvents, such as methanol, nitromethane and dioxane. It has a considerable intensity (ε 300—700) and shifts towards higher frequencies with an increase in the coordination power of the solvents. Recently, a similar band in the near ultraviolet region has been observed for a number of copper(II) complexes; it has been variously ascribed to a d-d transition,[13] a ligand transition,[14] or a charge transfer.[11,15] However, more experimental and theoretical studies are necessary before this band can be assigned definitely.

λ_{Br}: A band in this region is observed for the bromide complexes but not for the chloride complexes, as in crystals. Furthermore, this band is observed in solvents which have a π-electron accepting ability, but not in solvents which do not have an appreciable π-character.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 64—71 (1966)

Molecular Structure Determination by Gas Electron Diffraction at High Temperatures. I. Arsenic

By Yonezo MORINO,† Takeshi UKAJI††,* and Tetsuzo ITO†,**

†*Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo*
††*Department of Chemistry, Ibaraki University, Mito*

(Received April 17, 1965)

A high-temperature nozzle assembly for gas-electron diffraction has been designed and constructed. The molecular structure of gaseous arsenic at 485°C has then been investigated by the use of this nozzle. The regular tetrahedral structure of the molecule has been confirmed from the observed index of resolution; the interatomic distance has been determined to be r_g(As-As)= 2.435±0.004Å, while the mean amplitude has been determined for the first time (l(As-As)= 0.085±0.006Å). The observed amplitude has led to the evaluation of the bond-stretching force constant, f_r(As-As)=1.5±0.3 mdyn./Å.

Recent technical and theoretical developments in the method of gas electron diffraction have made it possible to determine interatomic distances and the mean amplitudes of thermal vibrations in molecules with a precision of a few thousandths of an angstrom. These data are important for elucidating molecular structure. For instance,

* Present address: Ikutoku Kosen, Atsugi, Kanagawa.
** Present address: The Institute of Physical and Chemical Research, Komagome, Tokyo.

the observed interatomic distances reveal various effects of thermal vibrations, and the mean amplitudes afford information on intramolecular forces. However, almost all such high-precision data have been obtained at room temperature; experiments at higher temperatures are usually much more difficult.

About thirty years ago, Maxwell and his co-workers investigated the molecular structure of alkali halides[1] and other molecules[2] at temperatures up to about 1300°C by the visual method. Since then, several investigators have designed and used high temperature nozzles for determining the molecular structure of compounds with low vapor pressures. For example, Kimura and Aoki (1953)[3] investigated acetamide and *N*-methylacetamide at about 250°C by the visual method; Bauer and his co-workers (1960)[4] studied lithium chloride at about 820°C by the same method, and Akishin and his co-workers (1958–) studied alkali halides[5] and other molecules[6,7] in the temperature range up to about 1500°C by the sector-microphotometer method.[8] The uncertainties in the observed interatomic distances ranged from 0.02 to 0.04 Å, and the values of mean amplitudes were only tentative even when they were reported. More recently, Hedberg and Iwasaki (1962)[9] for the first time observed the temperature effects on the interatomic distances and mean amplitudes of phosphorus trichloride by taking diffraction photographs at 27 and 232°C and by applying a least-squares treatment to the molecular intensity curves.

For the present work, a high-temperature nozzle assembly for high-precision studies was designed, constructed, and used for the study of the molecular structure of arsenic in the vapor phase. When the structure of this molecule was studied by Maxwell and his co-workers (1935)[2] at about 500°C by the visual method of gas electron diffraction, they observed one interatomic distance, 2.44 ± 0.03 Å; with the aid of the vapor density data,[10] which indicate that the molecule is predominantly tetratomic below 800°C, they concluded that the molecule has a regular tetrahedral structure. No spectroscopic information has up until now been available on the force field of this molecule.

Experimental

The Construction of the High-Temperature Nozzle Assembly.—After a series of preliminary tests on possible difficulties which were expected to arise in electron-diffraction experiments at high temperatures (the chemical and thermal instability of materials, difficulty in the control of the rate of gas effusion, the fogging of photographic plates due to radiation from the heated assembly, etc.), a nozzle assembly useful for high-precision studies in the temperature range up to 600°C was designed and constructed.

A diagram of the nozzle assembly is shown in Fig. 1. The sample is heated to a required temperature in the oven, 1; the stopcock valve, 2, is then opened, and the vapor is ejected through the capillary nozzle, 3, into the diffraction camera, where it scatters electron beams at about 0.4 mm. above the nozzle outlet. About 2 cm. above the nozzle, there is a brass cold trap cooled with liquid nitrogen designed to condense the ejected vapor. The distinctive features of this nozzle assembly are the material of the nozzle and the construction of the stopcock valve. The oven and the nozzle are made of quartz, which is suitable because of its chemical and thermal stability (the linear expansion coefficient: 4.8×10^{-7}/deg.; the softening temperature: 1300°C). The thermal stability of the nozzle is essential for the accurate determination of the camera length. The nozzle is equipped with a stopcock valve lubricated with a small amount of fine graphite powder in order that the gas can be introduced into the camera chamber for a desired length of time; it also enables a fine control of the rate of sample effusion. Diffraction photographs can be obtained at any fixed temperatures up to 600°C by the use of this valve. The valve is also useful for the study of a reaction system in the vapor phase because it prevents any one of the reactants from evaporating out of the oven through the outlet before the system attains the thermal equilibrium at the desired temperature.

The oven, the capillary nozzle and the cover-framework, 4, are all made of quartz. The oven, about 15 ml. in volume, contains enough sample gas for three successive 4-mmHgl. exposures. The length of the capillary nozzle is about 20 mm., while the inner diameter at the outlet is about 0.2 mm. The edge of the top of the nozzle is cut off lest it should interrupt the scattered electrons. The upper part of the nozzle is covered with gold foil grounded through a fine wire in order to avoid the charging-up of the nozzle, which might cause a drift of the electron beam.

The oven and the nozzle are individually heated with a 10—40 V. a. c. current supplied through coils of nichrome wires, which are supported by a number of small projections of quartz attached to the walls of the oven and the nozzle and which are covered with quartz-wool. The magnetic field produced by the electric current is minimized by a dual winding of nichrome wires in opposite directions. The fluctuation of the electron beam due to the magnetic field is found to be negligible under these working conditions (the electric current up to about 1 amp.). The temperatures of the oven and the nozzle are measured with two alumel-

chromel thermocouples placed in contact with the walls. The difference between the temperature of the ejected gas and that of the nozzle, as measured by the thermocouple, is estimated to be less than 30°C.* The oven and the nozzle can be heated to 600°C in about 15 min. A little degassing from the nozzle assembly during heating does not affect the vacuum of the diffraction camera (ca. 2×10^{-5} mmHg). In the temperature range up to 600°C, the fogging of photographic plates due to radiation from the heated assembly is easily eliminated by means of a radiation shield, 5, which covers the oven and the nozzle. A support, 6, for mounting the gold foil necessary for the calibration of the electron wavelength and the camera distance is attached to the shield.

The oven and the cover-framework are supported by an oven-holder which consists of the following six parts, a to f. Part a is designed for fixing the whole assembly on to the diffraction camera; Part b, for adjusting the position of the nozzle in a plane parallel to the electron beam; Part c, for changing the height of the nozzle, and Part d, for rotating the assembly in such a way that the gold foil is placed in the beam, and also for supporting the cover-framework of the oven. (The framework is cemented to the support with the epoxy adhesive "Araldite.") The vacuum-tightness of the stopcock is assured by Part e, which pushes the oven against the cover-framework, while Part f supports the oven and transmits to the axis of the oven the rotation necessary for opening and shutting the stopcock. A steel spring is inserted between Part f and the axis in order to apply proper pressures on the stopcock and to make allowance for any possible mechanical eccentricity of the male part of the stopcock with respect to the female part. The sample can be easily loaded and unloaded by pulling down the oven, together with Part e and Part f. All parts are made of brass, and Parts a, b, d and f are water-cooled. Various parts of the assembly are made vacuum-tight with O-rings; they are operated independently by means of ball-bearing systems. The whole assembly was processed in the workshop of the Tokyo Shibaura Electric Co.

The Calibration of the Camera Length.—The nozzle assembly was attached to a diffraction camera equipped with an r^3-sector.[11] The cold trap which covered the nozzle was replaced by a glass-window, and the plate-to-gold foil distance, L_g, was adjusted so as to be equal to the camera length, L_c (the distance from the plate to the center of the nozzle outlet) using a comparator. Fine adjustments were made by means of a screw attached to the gold-foil support. The error in the agreement between L_g and L_c was kept to within 0.05 mm., a value which could introduce an error of only about 0.05% in the scale factor, since the camera length was 106 mm. Deviations in the camera length during the heating up to 600°C were also found to be within 0.05 mm.

During the diffraction experiments, however, the rotation of the nozzle assembly necessary for locating the center of the gold foil in the electron beam could not be adjusted using a comparator, since the cold trap obstructed the field of vision. The adjustment was thus made by observing, through a side-window, the images of the electron beam and of the gold-foil support on a fluorescent screen. Another sheet of gold foil was placed in front of the nozzle assembly in order to make the images during the adjustments. An uncertainty in the angle of rotation of the nozzle assembly could be another source of the error in the scale factor.

Figure 2 shows a schematic diagram of the top-view of the nozzle assembly, where R is the radius of the circumference on which the centers of the nozzle outlet

* The temperature measured by the thermocouple was calibrated at 270°C by the following procedure. A small crystal of anthraquinone was placed on top of the nozzle above the outlet while heated iodine gas was ejected through the capillary nozzle. The temperature, as measured by the thermocouple, was 270°C when the crystal began to melt. This temperature was in agreement with the observed melting point of the crystal within a range of experimental error of about ±5°C.

11) Y. Morino, K. Kuchitsu and E. Hirota, "Experimental Chemistry" (Jikken Kagaku Koza), Vol. 3, Maruzen Co., Tokyo (1957), p. 253.

and of the gold foil move, and O is the center of rotation. As is evident from the figure, an error in the angle of rotation, $\Delta\theta$, introduces an error in the camera distance:

$$\Delta Lc = R\Delta\theta\sin\theta$$

In order to assure a 0.1% accuracy in the scale factor, ΔLc must be less than 0.1 mm. If we take the radius of the gold foil, 1 mm., as approtimately the maximum of $R\Delta\theta$, it is necessary to adjust θ to be less than 6°. In the following experiments, care was taken to adjust the center of the rotation of the nozzle assembly to just below the electron beam, as well as to minimize errors in the angle or rotation.

By the use of this nozzle assembly, diffraction photographs of iodine vapor have recently been taken at 80°C, 300°C and 500°C by one of the present authors.[12] A preliminary analysis has shown that the observed interatomic distances r_g(I-I) at these temperatures are in agreement with the values calculated from the spectroscopic data[13,14] within 0.15%. This uncertainty can be regarded as a measure of the total error in the scale factor of this nozzle assembly.

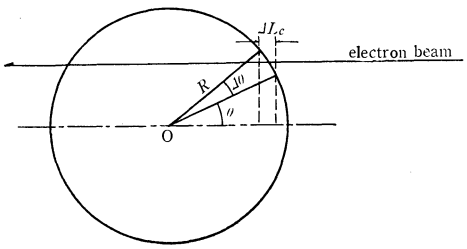

Fig. 2. Error in the camera distance ΔLc caused by the error in the angle of rotation $\Delta\theta$.

Diffraction Photographs of Arsenic. — Solid arsenic was kindly supplied by the Tokyo Shibaura Electric Co. The oxide which had covered the surface of the crystal was easily removed by heating it to about 300°C in a vacuum. The diffraction photographs were taken on Fuji Process-hard plates, with a camera distance of 106 mm., an accelerating voltage of the electron beam of about 43 kV., a beam current of about 0.005 μamp., and exposure times of from two to three minutes. The nozzle temperature was 485±30°C. The photographs were developed for five minutes in a FD-131 developer diluted twice at 20°C. The optical densities of the photographs ranged from 0.1 to 0.4, and the measured range of the scattering angle was from 20 to 100 in the q-scale.

Analytical Procedure

The interatomic distance and the root-mean-square amplitude of arsenic in the vapor phase were determined from the diffraction photographs by a procedure similar to that usually applied.[15] The final results were obtained by a least-squares analysis of the molecular intensity curves, $qM(q)$. All the calculations were carried out by using an electronic computer, PC-2.[16]

Molecular Intensity.—Four diffraction photographs were selected for the analysis; they were traced across the diameter of the diffraction pattern with a Rigaku-Denki MP-3 microphotometer while being rotated rapidly around the center of the pattern. In order to record fine details of the pattern, the transmittancy range corresponding to the undulations of the curve was magnified to about five times the original scale (full scale; 24 cm.) by the use of an electronic amplifier built into the photometer. The magnification ratio was later determined by a least-squares fit of the magnified curve to that of the original scale.

The photometer curves of the magnified and the original scales were measured at intervals of $\Delta q=1$; a value taken from one side of a curve was combined with the corresponding value from the other side, and an average was taken point by point. The distance, $x(q)$, on the abscissa of a photometer chart corresponding to the scattering angle, q, was calculated by using the value of $L_c\lambda$, which was obtained as $L_g\lambda$ from a transmission pattern of gold foil after L_g was corrected for the inclination of the photographic plate by the method of Iijima.[17],* A linear relation between the density and the intensity was assumed, since the densities of all the photographs used for the analysis were less than 0.4.[17]

After the intensity curve was corrected for the deficiency of the sector opening[18] (i. e., for the deviations from the defined opening of cr^3), it was divided by a levelling function, $f(q)$, in order to obtain a levelled intensity curve, $I_L(q)$, which facilitated the drawing of a background line, $I_B(q)$. The $f(q)$ function was derived by a least-squares fit of the intensity curve to a quadratic function. The most probable background line was obtained after two cycles of redrawing the line according to the non-negativity criterion with respect to the radial distribution curve, in which only one peak was observed. The artificial damping factor was so chosen as to reduce the molecular intensity to one-tenth of the original at $q=100$.

The experimental molecular intensity curve, $qM(q)$, was calculated as:

$$qM(q) = q\{I_L(q) - I_B(q)\}/I_B(q) \qquad (1)$$

while the theoretical expression for a tetratomic molecule, As_4, is given by the equation;[15]

* The inclinations of the photographic plates placed in the three positions, A, B and and C, were re-examined because the setting of the disk on which the three plates were mounted had been changed during recent leak tests. The following correction factors, which were not very different from those reported by Iijima, were obtained:
A −0.23±0.02%, B 0.06±0.03%, C 0.01±0.03%.
18) Y. Morino and Y. Murata, ibid., **38**, 104 (1965).

$$qM(q) = k(120/\pi r_a)\{|F_{As}(q)|^2/I'_B(q)\} \cdot\exp(-\pi^2q^2l^2/200) \cdot\sin(\pi q/10)(r_a-\pi^2q^2\kappa/100) \quad (2)$$

where k is the index of resolution; κ is the anharmonicity parameter, and $I_{B'}(q)$ is the sum of the coherent and incoherent atomic scattering.

Least-Squares Analysis.—The experimental intensity curve, Eq. 1, was fitted to the theoretical expression, Eq. 2 (for the tetratomic model), by the least-squares treatment, with the following four variable parameters: the apparent interatomic distance, r_a(As–As); the mean amplitude, l(As–As); the anharmonicity parameter, κ(As–As), and the index of resolution, k. According to the principle of the least-squares method, the weight function, $p(q)$, of the molecular intensity curve should be so chosen as to be inversely proportional to $\sigma^2(q)$, the square of the standard deviation at q. The standard deviation, $\sigma(q)$, was estimated[17] from the standard deviation of the four experimental molecular intensity curves used for the analysis. By this procedure, a discontinuous weight function, $p_d(q)$, was obtained. The elastic scattering factor, $|F_{As}(q)|$, was taken from the table of Ibers and Hoerni,[19] while the inelastic scattering factor, $S_{As}(q)$, was taken from the table of Bewilogua.[20]

The apparent interatomic distance, r_a, determined by the least-squares treatment was converted to r_g by the relation[15]:

$$r_g = r_a + l^2/r_a \quad (3)$$

The distance r_g is the interatomic distance averaged over the anharmonic vibrations of the two end-atoms; it is expressed as[21]:

$$r_g = r_e + \langle\Delta z\rangle + (1/2r_e)(\langle x^2\rangle + \langle\Delta y^2\rangle) + \delta_r \quad (4)$$

where the second and the third terms represent the effects of anharmonic and perpendicular vibrations respectively, and δ_r represents the centrifugal distortion. It should be noted that all the terms except for r_e depend on the temperature.

The Estimation of Errors.—Random and systematic errors in the molecular parameters as determined by gas-electron diffraction have been critically discussed by Kuchitsu,[22] and by Morino, Kuchitsu and Murata.[23] In the present work, the errors were estimated essentially according to their schemes.

Random Errors.—The most probable value, x_m, of a certain molecular parameter, x, was obtained as the arithmetic mean of the most probable values, x_i, derived from N molecular intensity curves (N is the number of plates used for the analysis; it was four in the present case):

$$x_m = \sum x_i/N \quad (5)$$

The random error associated with the most probable value, x_m, was estimated in two different ways[22]: $\sigma_1(x_m)$ and $\sigma_2(x_m)$. They were calculated as:

$$\sigma_1(x_m) = \bar{\sigma}(x)/\sqrt{N} \quad (6)$$

and:

$$\sigma_2(x_m) = \sum\{(x_i - x_m)^2/N(N-1)\}^{1/2} \quad (7)$$

where $\bar{\sigma}(x)$ is the arithmetic mean of N standard deviations of the least-squares treatment. The statistical treatment, Eq. 6, is valid only when the values, x_i, agree with each other within the range of $\bar{\sigma}(x)$. Therefore, σ_2 gives another useful measure of the random error; the larger, σ_1 or σ_2, was taken as the random error.

Systematic Errors.—The following possible sources of important systematic errors were taken into consideration:

i) For the Interatomic Distance:

a) The drift of the wave length of the electron beam, 0.05%.

b) Uncertainty in the lattice constant of the gold foil, 0.05%.

c) Uncertainty in the camera distance, 0.1%. The plate-to-gold foil distance was adjusted to be equal to the camera distance within the range of 0.1% uncertainty.

d) Uncertainty in the corrections for the inclinations of the plates, 0.04%. The camera distance was corrected for the inclination of the photographic plate. The uncertainty in the correction factors, 2.5 σ, was taken as the limit of error.

e) Uncertainty in the anharmonicity parameter. The difference between the most probable value of r_a when κ was taken as a variable parameter and that when κ was fixed at zero was taken as the limit of error.

ii) For the Mean Amplitude:

a) The effect of the finite sample size. The delocalization of the silicon tetrachloride gas near the nozzle outlet was studied by Murata[24] for a needle-type nozzle; it was shown there to be about a half of that for an ordinary drum-type nozzle; the corrections in the mean amplitudes were shown to be about −1.5%. The delocalization was expected to be even smaller for the high-temperature nozzle used in the present work because the inner diameter of the nozzle, 0.2 mm., was less than that of the nozzle used for the silicon tetrachloride, 0.55 mm., while the distance from the outlet to the electron beam was almost the same (about 0.4 mm.). Therefore, no correction was made for the effect of the finite sample size on the mean amplitude; the possible order of magnitude of the correction, which was estimated assuming the same distribution of the sample gas

κ(As-As)	1.46	0.11	0.25	1.78	0.54 10^{-5}Å^3
Index	1.04	0.91	0.98	0.93	0.02

* The arithmetic mean of four standard deviations.

as that of silicon tetrachloride, was regarded as the limit of error.

b) Uncertainty in the weight function. The mean amplitude was found to be influenced slightly by the choice of the weight function. The effect was estimated by using the following smooth-weight function in place of the discontinuous one, and the difference in the most probable value of l was taken as the limit of error;

$$p_s(q)=1 \quad \text{for} \quad q\leq 65$$
$$p_s(q)=\exp\{-0.001(q-65)^2\} \quad \text{for} \quad 65\leq q \qquad (8)$$

c) Uncertainty in the theoretical atomic-scattering factor. The error caused by this uncertainty was estimated by using the values of the atomic-scattering factor taken from different sources in the literature;[25] the largest discrepancy in the most probable value was regarded as the limit of error.

d) The effect of the extraneous scattering. This effect was estimated from a comparison of the results derived from $qM(q)$ with those derived from the molecular intensity curves of a slightly different form, $qN(q)$[26] which were expected to be less influenced by the extraneous scattering; the difference in the most probable value was taken as the limit of error.

Limit of Error.—The limit of error corresponding to the 99 per cent confidence interval was estimated as:

$$\text{Limit of error} = \{(2.5\sigma_r)^2 + \sigma_s^2\}^{1/2} \qquad (9)$$

where σ_r was the random error (the larger of σ_1 and σ_2), and σ_s^2 was the sum of the squares of all the systematic errors discussed above.

Results and Discussion

Molecular Structure.—One of the radial distribution curves is shown in Fig. 3. The results of the least-squares analysis of the molecular intensity curves, $qM(q)$, are listed in Table I, where $\bar{\sigma}$ in the last column denotes the arithmetic mean of the four standard deviations, all of which were found to be nearly equal; for instance, the $\sigma(r_a)$ values of Plates I to IV were 0.0015, 0.0015, 0.0014 and 0.0012 Å respectively. In Fig. 4 one of the experimental molecular intensity curves, $qM(q)$, is compared with the theoretical curve calculated with the parameters obtained above. The correction from the apparent distance, r_a, to the average

r_g(As-As)	l(As-As)	κ(As-As)
2.435±0.004 Å	0.085±0.006 Å	0.9±1.3×10^{-5}Å^3

distance, r_g, was +0.0030 Å. The estimates of the errors in the final values of r_g and l are summarized in Tables II and III respectively. The limit of error in the anharmonicity parameter, $\kappa \times 10^5$ Å^3, was estimated to be 1.3; this comprised the random error, 2.5 σ_2, of 1.05 and the systematic error, 0.74, arising from the choice of the weight function. The final results of the molecular parameters are listed in Table IV.

The index of resolution was found to be 0.96± 0.07. The limit of error was estimated from the random error, 2.5σ_2, of 0.07. Evidence for the tetratomic structure of at least the predominant part of the arsenic molecules at this temperature was given by the small deviation in the observed index from unity. This is evident from the following consideration. The molecular intensity, $qM(q)$, is proportional to the ratio of the number of the atom-pairs to the number of atoms in the molecule. Since the ratios for the diatomic, triatomic, and tetratomic structrues are 1/2, 3/3, and 6/4 respectively, analyses based on the tetratomic model must result in indices of about 0.33, 0.67, and 1, if the molecule has one of the above structures. The observed index of nearly unity clearly eliminates the possibilities of diatomic and triatomic structures.

Force Constants.—The mean amplitude and the anharmonicity parameter obtained above provide information on the intramolecular force field of the arsenic molecule, for which no spectroscopic studies of the vibrational frequencies have been made. The theory of correlating the mean amplitudes to the force constants has been developed by Morino and his co-workers[27] by using Wilson's ***GF*** matrix method, while an X_4 molecule (T_d symmetry) has been treated by Cyvin.[28]

The general quadratic potential function of the As_4 molecule (T_d symmetry) is given by:

$$2V = \sum f_r \Delta r_i^2 + 2\sum f_{rr} \Delta r_i \Delta r_j + 2\sum f_{rr'} \Delta r_i \Delta r_k \quad (10)$$

where Δr_i ($i=1,\cdots,6$) is the change in length of the ith bond, and the interaction constants, f_{rr} and $f_{rr'}$, correspond to the neighboring and the opposite bond pairs respectively. The mean-square amplitude of the As–As bond is given by[28]:

$$l^2 = (\mu/3)\ (2\Delta_1 + \Delta_2 + 3\Delta_3) \quad (11)$$

where μ is the reciprocal mass of the arsenic atom, and Δ_i is the mean square amplitude of the i th normal coordinate:

$$\Delta i = (\hbar/8\pi^2 c\nu_i)\coth(hc\nu_i/2kT) \quad (12)$$

It should be noted that the mean amplitude, l, is a function of the three force constants and of the temperature.

All of the three force constants can not be determined from a single observed value of the mean amplitude. The interaction constants, f_{rr} and $f_{rr'}$, therefore, tentatively assumed to be zero:

$$f_{rr} = f_{rr'} = 0 \quad (13)$$

The relation between the bond-stretching constant, f_r, and the amplitude, l, assuming Eq. 13 is shown in Fig. 5 for the three temperatures: 455°C (the lower limit), 485°C, and 515°C (the upper limit). As is shown in the figure, the observed value of l= 0.085 Å at 485°C corresponds to f_r=1.5 mdyn./Å, while the error caused by the uncertainties in the

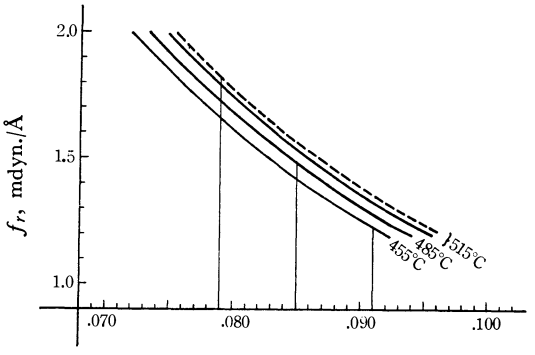

Fig. 5. Relation between the force constant f_r and the mean amplitude l(As-As) of As_4.
—— $f_{rr}=f_{rr'}=0$
---- f_r : f_{rr} : $f_{rr'}$ transferred from P_4

temperature and in the amplitude is ±0.28 mdyn./Å. The error in f_r introduced by the assumption of Eq. 13 was roughly estimated with reference to the P_4 molecule, which has the same T_d structure.[29] The force constants of P_4 have been determined by Pistorius[30] from the Raman spectra: f_r=2.065, f_{rr}=−0.122, and $f_{rr'}$=0.096 mdyn./Å.

27) Y. Morino, K. Kuchitsu and T. Shimanouchi, *J. Chem. Phys.*, **20**, 726 (1952).
28) S. J. Cyvin, *Spectrochim. Acta*, **17**, 1219 (1961).
29) H. J. Bernstein and J. Powling, *J. Chem. Phys.*, **18**, 1018 (1950).
30) C. W. F. T. Pistorius, ibid., **29**, 1421 (1958).

If the $f_r:f_{rr}:f_{rr'}$ ratios of the P_4 molecule are transferred to those of the As_4 molecule, the correlation curves in Fig. 5 are shifted by about 0.05 mdyn./Å, as is shown for the temperature of 515°C. Twice this shift, i. e., 0.1 mdyn./Å, was taken as a measure of the error due to the above assumption. Thus, the bond-stretching constant compatible with the observed mean amplitude was determined to be $f_r=1.5\pm0.3$ mdyn./Å, which is in agreement with the estimate, 1.5 mdyn./Å, from Badger's rule.[31] This shows the covalent nature of the As–As bond of this molecule. The corresponding estimates of the vibrational frequencies are $\nu_1(A_1)=350\pm30$, $\nu_2(E)=180\pm30$ and $\nu_3(F_2)=250\pm30$ cm^{-1}. However, no experimental observation has yet been made because of the difficulty of spectroscopic instrumentation.

The observed value of the anharmonicity parameter of $0.9\pm1.3\times10^{-5}$Å^3 may be compared with the values estimated from other sources. If a Morse-type potential function is assumed for the As–As bond, the anharmonicity parameter, κ, is approximately represented by[14]:

$$\kappa = (\alpha/6)l^4 \qquad (14)$$

where:

$$\alpha = (f_r/2D)^{1/2} \qquad (15)$$

is the asymmetry constant of the Morse function. When we insert the observed values of $l=0.085$Å and $f_r=1.5$ mdyn./Å, together with the binding energy, D, of 34 kcal./mol.,[32] into the above equations, κ is estimated to be 1.5×10^{-5}Å^3. Even though the observed and estimated values are both crude, the orders of magnitude are in essential agreement.

With the force constant obtained above, it is possible to estimate the apparent elongation of the As–As bond due to the perpendicular amplitudes and the elongation caused by the centrifugal force, represented by the third and the fourth terms of Eq. 4 respectively. The former is expressed as $\mu(\Delta_2+\Delta_3)/2r_e$ and is estimated to be 0.0022 Å at 485°C. The centrifugal elongation is estimated by the method of Iwasaki and Hedberg[33] as follows: $\delta_r(\text{As–As})=kT/2F_1r_e=0.0014$Å at 485°C, where $F_1=f_r+f_{rr}+f_{rr'}$. The distance parameter, which is obtained by subtracting the above two terms from r_g, is denoted as r_α[20]; thus, r_α(As–As) is estimated to be 2.431Å at 485°C.

The authors wish to express their sincere gratitude to the Tokyo Shibaura Electric Co. for the constructioh of the nozzle assembly and for the kind gift of the sample. They are also indebted to Mr. Masakatsu Kochi for his assistance.

Molecular Structure Determination by Gas Electron Diffraction at High Temperatures. II. Arsenic Triiodide and Gallium Triiodide

By Yonezo MORINO,† Takeshi UKAJI††,* and Tetsuzo ITO†,**

† *Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo*
†† *Department of Chemistry, Ibaraki University, Mito*

(Received April 17, 1965)

The precise molecular structures of arsenic triiodide and gallium triiodide in the vapor phase have been determined by the sector-microphotometer method of electron diffraction at the nozzle temperatures of 230°C and 255°C respectively. The results of gallium triiodide have confirmed the regular triangle structure of the molecule. The force constants of these molecules have been estimated from the observed mean amplitudes.

In the preceding paper (Part I),[1] a high-temperature nozzle assembly for electron diffraction was reported, together with the results of its application to the determination of the molecular structure of arsenic in the vapor phase. The purpose of the present work is to determine the precise molecular structures of arsenic triiodide and gallium triiodide in the vapor phase, and to obtain information on the force field of these molecules on the basis of the observed mean amplitudes.

1) Y. Morino, T. Ukaji and T. Ito, This Bulletin, **39**, 64 (1966).

The molecular structure of arsenic triiodide has been studied by the visual method of electron diffraction by several investigators; the findings of Finbak and Hassel (1941) (r(As–I)=2.54Å and θ(IAsI)=98.5°) and the preliminary findings of Swingle (1949) (r(As–I)=2.55±0.03Å and θ(IAsI) =101±1.5°) are cited by Sutton.[2] The mean amplitudes have never been observed. The Raman frequencies of the molecule in the $CHBr_3$ and carbon disulfide solutions have been observed by Stammreich and his co-workers.[3] Akishin and his co-workers (1959)[4] investigated the molecular structure of gallium triiodide by the sector-microphotometer method of electron diffraction, with r(Ga–I)=2.44±0.03Å; they concluded that the molecule has a planar, regular triangle structure. They also estimated the mean amplitudes from the radial distribution curve. No spectroscopic data are, however, now available concerning the force field of the molecule.

Experimental

A sample of arsenic triiodide was synthesized by the $AsCl_3+3KI \rightarrow AsI_3+3KCl$ reaction.[5] The melting point of the sample was found to be 140°C, which was lower than the value of 149°C cited in the literature. This was probably due to the potassium chloride remaining in the sample. However, the sample was not further purified, since the melting point of potassium chloride, 776°C, was so much higher than the nozzle temperature that this impurity did not interfere with the present experiment. A sample of gallium triiodide was synthesized by a direct reaction of the gallium and iodine elements.[6] Stoichiometric quantities of gallium and iodine were heated in a vacuum to about 300°C; the resulting gallium triiodide was then purified by sublimation in a vacuum.

The conditions of the diffraction experiments were almost the same as those used in Part I for the arsenic except that the nozzle temperatures were 230±30°C and 255±30°C for the arsenic triiodide and the gallium triiodide respectively. During the exposures for the arsenic triiodide sample, a slight change in the direction of the electron beam was observed at the early stages of the experiments; this was found to be caused by the electronic charge piled up on the sample condensed onto the cold trap. The drift was eliminated by widening the space between the cold trap and the electron beam from the ordinary space of about 2 cm. to about 5 cm. Since the gallium triiodide sample was strongly hygroscopic, it was degassed in the oven of the nozzle assembly in a vacuum for more than an hour at room temperature, and then for a few minutes at about 100°C, immediately before making exposures. The optical densities of the diffraction photographs ranged from 0.15 to 0.5.

Analytical Procedure

The diffraction photographs of the arsenic triiodide and the gallium triiodide were analyzed by almost the same procedure as that described in Part I. The final results were obtained by the least-squares analysis of the molecular intensity curves, $qM(q)$. A least-squares analysis of the molecular intensity curves of a slightly different form, $qN(q)$, was also carried out in order to examine the effects of the extraneous fogging of the photographic plates on the final values of the molecular parameters.

The experimental molecular intensity curve,

$$qM(q)=q(I_L-I_B)/I_B \qquad (1)$$

was fitted by the least-squares method to its theoretical expression:

$$qM(q)=k(10/\pi)\sum\sum(|F_i||F_j|/I_B')\cos \Delta\eta \cdot\exp(-\pi^2q^2l^2/200)(1/r_a')\sin(\pi qr_a'/10) \qquad (2)$$

where r_a' stands for $r_a-\pi^2q^2\kappa/100$, and the subscripts are omitted from $\Delta\eta$, l and r_a' for the sake of simplicity. The parameters to be determined were the interatomic distances, r_a', the root-mean-square amplitudes, l, and the index of resolution, k. The anharmonicity parameters, κ, were fixed to zero because the outputs of the successive cycles did not converge when they were taken as variable parameters. This was because of a strong correlation between r_a and κ, and because the molecular intensity curves could not afford information sufficient to determine r_a and κ separately. The interatomic distances as determined by the leaset-squares procedure are, therefore, not r_a but r_a', i. e., $r_a-\pi^2q^2\kappa/100$ averaged over the observed range of the scattering angle (q=20—100). The values of the elastic scattering factors, $|F_i|$, and of the complex phases, η_i were taken from the tables of Ibers and Hoerni.[7]

When the fogging of the photographic plate is not negligible, as indicated by an appreciable decrease in the index of resolution of gallium triiodide from the ideal value of unity (k=0.8), the experimental molecular intensity, Eq. 1, can not be directly compared with the theoretical expression, Eq. 2, since the experimental background, I_B, in Eq. 1 contains an extraneous scattering which might affect the final values of the molecular parameters, particularly those of the mean amplitudes. As it is difficult to estimate the extraneous scattering, and as the molecular term, I_L-I_B, in Eq. 1 was probably little influenced by the extraneous scattering, an analysis of the molecular intensity curves, $qN(q)$, described below was carried out, and the results compared with those obtained

* The arithmetic mean of four standard deviations.

from $qM(q)$. This type of molecular intensity curve has usually been used by the Norwegian group.[8] The experimental molecular intensity, $qN(q)$, was calculated as:

$$qN(q)=A(q)(I_L-I_B) \tag{3}$$

where $A(q)=f(q)q^2\{1-(\lambda q/40)^2\}^{-3/2}$. The multiplication of the $A(q)$* factor was necessary for a least-squares fit of the curve to the theoretical expression:

$$qN(q)=K\sum\sum|F_i||F_j|\cos\Delta\eta \cdot\exp(-\pi^2q^2l^2/200)(1/r_a')\sin(\pi qr_a'/10) \tag{4}$$

where K is an adjustable constant similar to the index of resolution, k, in Eq. 2 but with less physical importance, since it is difficult to know the absolute intensity of the scattered electrons either from experimental diffraction photographs or from theoretical calculations.

The apparent interatomic distances, r_a', were converted to the average distances, r_g', by the $r_g'=r_a'+l^2/r_a'$ relation, while the bond angles, θ_g'(IMI) (where M denotes arsenic or gallium), were calculated from the average distances by the relation:

$$\sin(\theta_g'/2)=r_g'(\text{I-I})/2r_g'(\text{M-I}) \tag{5}$$

The errors in the observed interatomic distances and the mean amplitudes were estimated by the procedure described in Part I. Although the most probable values of the interatomic distances are, in general, not influenced by the weight functions taken in the course of the least-squares treatment, the effect of the weight function was not negligible in the case of gallium triiodide. The errors were estimated by using the smooth weight function, Eq. 8 of Part I, in place of the discontinuous one. The mean amplitude of a pair of atoms with different atomic numbers is influenced by possible errors in the theoretical phases, η_i, since $\cos\Delta\eta$ has a q-dependence almost the same as that of the exponential damping factor of thermal vibrations. The cosine factor of the As–I ($\Delta Z=20$) or the Ga–I ($\Delta Z=22$) pair, when reduced to the amplitude scale, is about one-tenth of the amplitude. The uncertainties in the values of η_i given by Ibers and Hoerni have been discussed by Karle and Bonham[9] for argon ($Z=18$) and for uranium ($Z=92$); they showed them to be less than 10%. Although uncertainties in the differences, $\Delta\eta$, are expected to be even smaller, 10% was regarded as the limit of error.

The random error in the bond angles was estimated in two ways: as 2.5 σ_2—from the fluctuation among the values derived from the individual plates according to Eq. 7 of Part I, and as 2.5 σ_1—from the errors, σ_1, in the interatomic distances obtained by applying the law of the propagation of errors to Eq. 5:

$$\sigma(\theta)=(360/\pi)\tan(\theta/2)[\{\sigma(r_1)/r_1\}^2+\{\sigma(r_2)/r_2\}^2]^{1/2}$$

where r_1 and r_2 stand for r_g'(M–I) and r_g'(I–I) respectively. The systematic errors in the interatomic distances, other than that introduced by the uncertainty in the weight function, do not influence the bond angles.

Results and Discussion

Arsenic Triiodide.—*Molecular Structure.*—Four diffraction photographs were used for the analysis. One of the radial distribution curves is shown in Fig. 1. The results of the least-squares analysis of the molecular intensity curves, $qM(q)$, are listed in Table I. It should be noted that the mean amplitudes derived from the four plates are in fairly good agreement with one another in spite of the large deviations in the indices of resolution. A typical experimental molecular intensity curve is compared with the best-fit theoretical one in Fig. 2. The corrections from r_a' to r_g' were +0.0022Å and +0.0056Å for the As–I and I–I distances respectively. A deviation of +0.0066Å was observed in the most probable value of l(I–I) when the real atomic scattering factors[10] were used in place of the complex ones. Since there was no suitable way to compare the reliabilities of the scattering factors, the mean of the two values was taken as the final value. The estimates of the errors in the

* $A(q)$ is proportional to $f(q)\{R(q)\}^2q^5/\alpha(q)\cos\theta$, where θ is the scattering angle; $f(q)$ is the levelling function; $R(q)$ is the distance from the nozzle to the point on the plate corresponding to the angle, θ, and $\alpha(q)$ is the sector function and is proportional to $\tan^3\theta$ for the r^3-sector. The cosine term in the denominator comes from the fact that the plate is perpendicular to the incident electron beam.

interatomic distances and the mean amplitudes are summarized in Tables II and III respectively. The index of resolution was found to be 0.94± 0.17. The limit of error, ±0.17, was estimated from the random error of 0.16 ($2.5\,\sigma_2$), plus the systematic error, 0.07, due to the uncertainties in the scattering factors. The final results of the molecular parameters are listed in Table IV. The results of the least-squares analysis of the molecular intensity curves, $qN(q)$, are listed in Table V. They were in good agreement with

Force Constants. — The relations between the mean amplitudes and the force constants of an XY_3 molecule (C_{3v} symmetry) have been discussed by Iwasaki and Hedberg[11] for phosphorus trichloride. The general quadratic potential function of arsenic triiodide is expressed by a set of six force constants, for example, by F_{11}, F_{12}, F_{22}, (A_1 species), F_{33}, F_{34}, and F_{44} (E species), in terms of the ordinary symmetry coordinates as defined in the reference. They are related to the force constants in terms of the internal coordinates:

$$\left.\begin{aligned} F_{11}&=f_r+2f_{rr}, \quad F_{12}=2f_{r\theta}+f_{r\theta'},\\ F_{22}&=f_\theta+2f_{\theta\theta}, \quad F_{33}=f_r-f_{rr},\\ F_{34}&=f_{r\theta}-f_{r\theta'}, \quad F_{44}=f_\theta-f_{\theta\theta} \end{aligned}\right\} \qquad (6)$$

where f_r and f_θ are the stretching and bending force constants respectively, and where f_{rr}, $f_{\theta\theta}$, $f_{r\theta}$ and $f_{r\theta'}$ are the interaction constants corresponding to the neighboring bonds, neighboring angles, neighboring bond and angle, and opposite bond and angle respectively.

The four Raman frequencies, combined with the two observed mean amplitudes, are sufficient for the determination of all the force constants. It should be noted that the values of the force constants are restricted by a set of relations imposed by the four frequencies. This is due to the requirement that force constants be real quantities; it will be shown below for the A_1 species. If the observed

11) M. Iwasaki and K. Hedberg, *J. Chem. Phys.*, **36**, 594 (1962).

frequencies, ν_1 and ν_2, are substituted into the secular equation, $|\boldsymbol{GF}-\lambda_i\boldsymbol{E}|=0$, the following two equations are obtained for the three force constants:

$$\left.\begin{aligned}\lambda_1+\lambda_2&=G_{11}F_{11}+2G_{12}F_{12}+G_{22}F_{22}\\ \lambda_1\lambda_2&=(G_{11}G_{22}-G_{12}^2)(F_{11}F_{22}-F_{12}^2)\end{aligned}\right\} \quad (7)$$

where $\lambda_i=(2\pi c\nu_i)^2$. By eliminating one of the force constants, say, F_{22}, from the above two equations, a quadratic equation for F_{11} and F_{12} is obtained. Then, from the requirement that F_{11} be real, F_{12} is limited to the $-0.03<F_{12}<1.17$ mdyn./Å range. Similarly, F_{34} is limited to the $-0.18<F_{34}<1.03$ mdyn./Å range.

Since the number of unknown force constants is six, a correlation curve (a biquadratic curve) is obtained on the (F_{12}, F_{34}) plane from the four frequencies and one mean amplitude. From the other set of the four frequencies and the remaining

Table VI. Fundamental frequencies of AsI_3[3]

mean amplitude, the other curve is obtained. Thus, the force constants can be determined as the crossing point or points of the two curves. The two correlation curves, as calculated from the Raman frequencies in Table VI and the mean amplitudes in Table IV at the temperature of 230°C, are shown in Fig. 3. The curves corresponding to the limits of error of the mean amplitudes are also shown in the figure. The curve corresponding to the lower limit of l(As–I) of 0.068Å does not exist on the real plane. Contrary to the above expectation, the crossing did not appear for the most probable values. The two curves crossed only for the upper limits of the amplitudes. Thus, the most probable values of the mean amplitudes were found to be hardly compatible with the Raman frequencies. This inconsistency may be ascribed

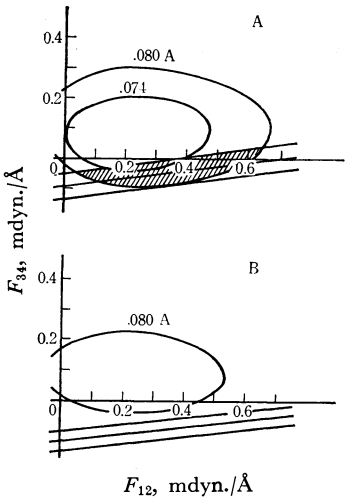

Fig. 4. Correlation curve of F_{34} and F_{12} of AsI_3 (cf. Fig. 3).
A: at 200°C, B: at 260°C

to errors in the Raman frequencies and in the measurement of the temperature in the present experiments. The Raman frequencies were obseved in the solution and not in the gas phase. For the time being, however, the frequencies were assumed to be correct, and the effects of the uncertainty of the temperature were examined. The correlation curves at 200°C and 260°C, corresponding to the lower and the upper limits of the temperature respectively, are shown in Fig. 4. At 200°C, the two curves corresponding to the most probable values of the mean amplitudes came closer, and the overlapped area increased, while at 260°C no crossing of the curves occurred at all.

The force constants, F_{12} and F_{34}, compatible with the observed Raman frequencies and the mean amplitudes were determined from the overlapped areas in Figs. 3 and 4 as follows: $F_{12}=0.3_5\pm0.3_0$ and $F_{34}=-0.0_3\pm0.0_7$ mdyn./Å The six force constants were determined accordingly; they are listed in Table VII, together with the force constants in terms of the internal coordinates. It must be mentioned that these force constants are subject to possible errors in the Raman frequencies used. The observed stretching constant of $1.4_7+0.2_2$ mdyn./Å is in agreement with the estimate, 1.3 mdyn./Å, derived from Badger's rule[12] of $f=1.24/(r_e-d_{ij})^3$, if we define the parameter, d_{ij}, so as to reproduce the force constant of the diatomic molecule, GaI,[13] i. e., if $d_{45}=1.57$Å. This parameter is also consistent with the observed stretching constant, f_r(Ga–I), of gallium triiodide. It should be noted that the interaction constant,

$f_{r\theta}'$, is of the same order of magnitude as f_θ and $f_{r\theta}$, although the associated errors are large; in fact, the assumption of the Urey-Bradley force field, $f_{r\theta}=f_{r\theta}'=0$, is not compatible with the frequencies of Table VI.

Gallium Triiodide. — *Molecular Structure.*— Three diffraction photographs were selected for analysis. The radial distribution curve is shown in Fig. 5. The results of the least-squares analysis are listed in Table VIII. One of the experimental molecular intensity curves is compared in Fig. 6 with the theoretical curve calculated from the parameters as determined by the least-squares treatment. The most probable value of the interatomic distance, r_g'(I-I), was shifted by -0.014 Å (-0.33%) when the smooth weight function, Eq. 8 of Part I, was used in place of the discontinuous one obtained from the fluctuation of the three molecular intensity curves. The discontinuous weight function can not be considered to be more reliable than the smooth one, since it was estimated from only three observations. Therefore, the average of the two values was taken as the final value, and the discrepancy was included in the estimate of the error The estimates of the errors in the interatomic distances and in the mean amplitudes are summarized in Tables IX and X respectively. The corrections from r_a' to r_g' were $+0.0018$ Å and $+0.0060$ Å for the Ga-I and for the I-I distances respectively. As was the case for arsenic triiodide, the mean amplitude, l(I-I), was influenced by the choice of the atomic scattering factors and was corrected by $+0.0033$ Å. The final results of the molecular parameters are listed in Table XI.

TABLE XI. FINAL RESULTS OF THE MOLECULAR PARAMETERS OF GaI_3 AT 255°C

	r_g'	l	θ_g'(IGaI)
Ga-I	2.458 ± 0.005Å	0.067 ± 0.004Å	$120.0°\pm0.7°$
I-I	4.256 ± 0.018	0.163 ± 0.010	

The observed bond angle of 120.0°±0.7° has confirmed the planar regular triangle structure of the molecule. It is also consistent with the results of the vapor-pressure measurement[14] and the mass-spectroscopic analysis[15], which indicate that the molecule is predominantly (about 97%[14]) monomeric at 255°C. The r_g'-structure determined above is different from the equilibrium structure (see Eq. 4 of Part I). Aside from the anharmonic contribution, the average distance, r_g', contains additional contributions due to the centrifugal distortion and the perpendicular amplitudes. The centrifugal distortion of the gallium triiodide molecule was estimated, using the force constant obtained from the observed mean amplitudes, to be $\delta_r = kT/(f_r+2f_{rr})r_e(\text{Ga-I}) = 0.0017$ Å for the Ga-I bond. The distortion does not change the bond angle of the molecule, since it is totally symmetric. The effects of the perpendicular amplitudes were estimated as follows: $(L^2_{22}\Delta_2+2L^2_{43}\Delta_3+2L^2_{44}\Delta_4)/18r_e(\text{Ga-I}) = 0.0074$ Å for the Ga-I bond, and $\{(\sqrt{3}L_{33}-L_{43})^2\Delta_3+(\sqrt{3}L_{34}-L_{44})^2\Delta_4\}/12r_e(\text{I-I}) = 0.0026$ Å for the I-I bond. (As for the notations, see the definitions following Eq. 9.) In the above estimate, ν_2 was assumed to be equal to ν_1. If the average distances, r_g', are corrected for the perpendicular amplitudes, the bond angle is 120.4°; this is different from the planar angle of 120°, but the discrepancy is within the range of experimental error.

The index of resolution was found to be 0.80± 0.06. The limit of error was estimated from the random error of 0.03 (2.5 σ_2) plus the systematic error, 0.05, due to the uncertainty in the scattering factors. Since the rather large deviation of the observed index from unity was considered to be due to extraneous scattering, $qN(q)$ was analyzed in order to examine the effect of the extraneous scattering on the molecular parameters. The results of the least-squares analysis of $qN(q)$ are listed in Table XII. In spite of the small index of resolution, the results were in fairly good agreement with those obtained from $qM(q)$. The discrepancies in the mean amplitudes were less than those due to the uncertainties in the theoretical scattering factors. In Fig. 7 the experimental background line, which was obtained as the average of the three lines, is compared with the two theoretical lines; the theoretical background lines, denoted as C and R, were calculated from the complex and from the real[10] atomic scattering factors respectively. The lines are normalized to unity at $q=48$. The experimental background line lies between the theoretical lines, C and R. Therefore, it can be concluded that the extraneous scattering raised the background uniformly, and hence decreased the index of resolution; fortunately, however, it did not seriously affect the values of the mean amplitudes.

Table XII. Results of the least squares analysis of $qN(q)$ of GaI_3 at 255°C

	r_g'	l	θ_g'(IGaI)
Ga-I	2.456±0.005Å	0.066±0.004Å	120.2°±0.8°
I-I	4.258±0.020	0.162±0.011

— Calcd. -- Obs.

Force Constants.—Since spectroscopic data regarding the force field of gallium triiodide are not available, we must resort to the approximation of the valence forces in order to estimate the stretching and bending force constants, f_r and f_θ, from the two observed mean amplitudes. The general quadratic potential function of a GaI_3 molecule (D_{3h} symmetry) in terms of the internal coordinates is given by:

$$\begin{aligned}2V = &\sum f_r \Delta r_i^2 + 2\sum f_{rr}\Delta r_i \Delta r_j + 2\sum f_{r\theta}\Delta r_i (R\Delta\theta_j) \\ &+ 2\sum f_{r\theta}'\Delta r_i (R\Delta\theta_i) + \sum f_\theta (R\Delta\theta_i)^2 \\ &+ 2\sum f_{\theta\theta}(R\Delta\theta_i)(R\Delta\theta_j) + f_\tau (R\Delta\gamma)^2 \end{aligned} \quad (8)$$

where Δr_i and $\Delta\theta_i$ are the changes in the ith bond and in the bond angle respectively; R is the Ga-I distance, and the $R\Delta\gamma$ coordinate is the distance of the central gallium atom from the plane of the three iodine atoms. The number of independent force constants is reduced from seven to five when the potential function is expressed in terms of symmetry coordinates. By an ordinary procedure,[16] the mean-square amplitudes, l^2(Ga-I) and l^2(I-I), are expressed as:

$$\begin{aligned} l^2(\text{Ga-I}) &= (1/3)L^2_{11}\Delta_1 + (2/3)(L^2_{33}\Delta_3 + L^2_{34}\Delta_4) \\ l^2(\text{I-I}) &= L^2_{11}\Delta_1 + (1/6)(\sqrt{3}L_{33}-L_{43})^2\Delta_3 \\ &\quad + (1/6)(\sqrt{3}L_{34}-L_{44})^2\Delta_4 \end{aligned} \quad (9)$$

14) W. Fischer and O. Jübermann, *Z. anorg. u. allgem. Chem.*, **227**, 227 (1936).
15) T. Tsuchiya, private communication.
16) Y. Morino, K. Kuchitsu and T. Shimanouchi, *J. Chem. Phys.*, **20**, 726 (1952).

where L_{ij} is the element of the $\boldsymbol{L}$ matrix connecting the symmetry coordinates to the normal coordinates, and Δ_i is the mean-square amplitudes of the ith normal coordinate. The subscripts 1, 3 and 4 specify the symmetric stretching (A_1') and the degenerate stretching and bending (E_1') vibrations respectively. It should be noted that the out-of-plane vibration (A_2') has no influence on either of the amplitudes in this order of approximation.

When the approximation of the valence force field is introduced, i. e., when all the cross terms are assumed to be zero, the number of the force constants is reduced to two besides f_r, and a correlation diagram similar to those used for arsenic triiodide is obtained on the (f_r, f_θ) plane by using the values of the mean amplitudes as parameters. Figure 8 shows a diagram for the gallium triiodide at the temperature of 255°C. The correlation curves for the observed mean amplitudes and those corresponding to the limits of error are also shown in the figure. From the shaded area of the figure, the force constants were estimated as follows: $f_r=1.7\pm0.2$ mdyn./Å, $f_\theta=0.06\pm0.02$ mdyn./Å. The corresponding estimates of the vibrational frequencies are $\nu_1(A'_1)=150\pm10$, $\nu_2(E')=300\pm20$ and $\nu_4(E')=65\pm10$ cm^{-1}. The uncertainty in the temperature (±30°C) was taken into consideration in the estimates of the errors, while the uncertainty due to the approximation of the valence force field was not included.

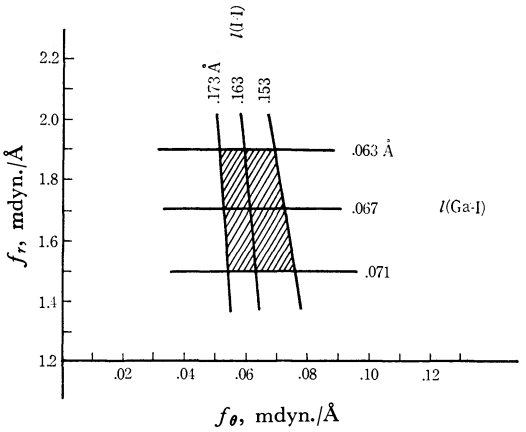

Fig. 8. Correlation curve of f_r and f_θ of GaI_3 at 255°C.

The authors wish to express their gratitude to the Tokyo Shibaura Electric Co. for the supply of gallium. They are also indebted to Dr. Toshikazu Tsuchiya of the Government Chemical Industrial Research Institute, Tokyo, for his mass-spectroscopic analysis of gallium triiodide.

The Formation Conditions and the Properties of Copper, Zinc, Ammonium Sulfites*

By Keiichi OMORI

Department of Mineralogy, Faculty of Science, Tokyo University

and

Akitsugu OKUWAKI, Takahiro SUZUKI, Hiroshi ITO and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Katahira-cho, Sendai

(Received April 19, 1965)

On the reaction of an ammonium sulfite solution with a mixed solution of cupric sulfate and zinc sulfate, ten or more complex sulfite salts have been identified by chemical analysis and X-ray diffraction, and their formation regions have been shown with equilateral triangle coordinates. Their crystallographic properties have been examined through optical observation and X-ray diffraction. Usually some of them are formed simultaneously, but sometimes only one of them is formed, depending on the reaction conditions. The newly-found compounds are as follows:

$Cu_2SO_3 \cdot 7(NH_4)_2SO_3 \cdot 9H_2O$	Tetragonal
$Cu_2SO_3 \cdot ZnSO_3 \cdot 6(NH_4)_2SO_3 \cdot 10H_2O$	Tetragonal
$Cu_2SO_3 \cdot 2ZnSO_3 \cdot 5(NH_4)_2SO_3 \cdot 12H_2O$	Monoclinic
$Cu_2SO_3 \cdot 4ZnSO_3 \cdot 3(NH_4)_2SO_3 \cdot 12H_2O$	Hexagonal

* Presented at the 17th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1964.

The authors have already proposed a new hydrometallurgical process for copper, a process includes the sulfatizing roasting of copper sulfide ores, the extraction of cupric sulfate, the reduction of cupric sulfate with ammonium sulfite, the separation of metallic copper, and the recovery of ammonium sulfate.[1] In the case of simple sulfide ores, there is no technical problem in the process, but in the case of complex sulfide ores containing zinc, lead and other heavy metals besides copper, the reduction of cupric sulfate proceeds unsatisfactorily. The reason for this trouble seems to be due to the formation of inactive complex copper-zinc-ammonium sulfites, which are easily produced with both metal sulfates and ammonium sulfite in an aqueous solution.

In the present paper, an effort will be made to determine the composition, the properties, and the formation conditions of the complex sulfites.

Experimental

Procedure.—A mixed solution of cupric sulfate and zinc sulfate, prepared by the dissolution of an E. P. reagnt, was placed in a 200-ml. Erlenmeyer flask; then a freshly-prepared ammonium sulfite solution was added drop by drop to the sulfate solution until the three component salts reach a desirable mole fractions. The mixture was vigorously shaken, sealed tightly and allowed to stand for 1—20 days. The crystals which formed were separated from the solution, washed with water and then with methyl alchohl, and dried for 30 min. in a vacuum.

Analysis.—The complex salts formed in the reaction were dissolved by treatment with bromine water. The solution was then boiled on a sand bath until the bromine was completely expelled. The copper and zinc contents were determined by iodometry and by chelatometry respectively. The ammonia content was determined by alkalimetry after distillation, and sulfurous acid, as barium sulfate by oxidation.

Results and Discussion

Complex Sulfite Salts and the Conditions of Their Formation.—When an ammonium sulfite solution is added to a mixed solution of the two metal sulfates, an amorphous, yellowish-brown precipitate is immediately formed, this then gradually changes into transparent crystals. When the mixture is vigorously stirred, the amorphous precipitate tends to coagulate into a plastic mass, one which seems very stretchable without any trace of recovery. If more than a 0.78 mol. fraction of the ammonium sulfite solution is added, the amorphous precipitate is dissolved again, and a wine-red solution is obtained.

The complex salts formed in the reaction are listed in Table I, among which the compounds from III to VI have not been previously reported in the literature; their analytical values are shown in Table II. Besides, the existence of other complex sulfites, XII, XIII, XIV and XV, were recognized by means of X-ray diffraction, but regrettably, these compounds could not be isolated or identified.

Table I. The complex salts formed in the reaction

Compd. No.	Chemical formula
I	$7Cu_2SO_3 \cdot 2CuSO_3 \cdot 3(NH_4)_2SO_3 \cdot 24H_2O$
II	$Cu_2SO_3 \cdot 7(NH_4)_2SO_3 \cdot 10H_2O$
III	$Cu_2SO_3 \cdot 7(NH_4)_2SO_3 \cdot 9H_2O$
IV	$Cu_2SO_3 \cdot ZnSO_3 \cdot 6(NH_4)_2SO_3 \cdot 10H_2O$
V	$Cu_2SO_3 \cdot 2ZnSO_3 \cdot 5(NH_4)_2SO_3 \cdot 12H_2O$
VI	$Cu_2SO_3 \cdot 4ZnSO_3 \cdot 3(NH_4)_2SO_3 \cdot 12H_2O$
VII	$ZnSO_3 \cdot (NH_4)_2SO_3$
VIII	$Cu_2SO_3 \cdot (NH_4)_2SO_3$
IX	$Cu_2SO_3 \cdot CuSO_3 \cdot 2H_2O$ (Chevreul's salt)
X	$ZnSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$ (Tutton's salt)
XI	$ZnSO_3 \cdot 2.5H_2O$
XII	Unknown (Cotton-like crystal)
XIII	Unknown (Calcite-like crystal)
XIV	$Cu_2SO_3 \cdot 5ZnSO_3 \cdot (NH_4)_2SO_3 \cdot 18H_2O$
XV	Unknown (Chevreul's salt-like crystal)
XVI	Non-recoverable plastic mass

The region where the complex salts are formed is shown in Figs. 1(a) and (b). The three component salts are placed at the vertexes of the coordinates, while the mole fractions of their salts in the original mixture are indicated on the internal points. The regions where the complex salts are formed are regularly distributed in the order of II, III, IV, V and VI, from the region rich in ammonium sulfite to the region of little ammonium sulfite.

Properties and Methods of Preparation.—Since some of the above salts contain copper as cuprous sulfite, they are easily oxidized with atmospheric oxygen.

Compound I: $7Cu_2SO_3 \cdot 2CuSO_3 \cdot 3(NH_4)_2SO_3 \cdot 24H_2O$.[2] — Colorless, transparent, square, thin plates, or an aggregate of spherical microcrystals observed as a yellowish-green powder by the naked eye. This salt is easily formed in a very wide region, together with other salts, and it is slowly converted into Chevreul's salt in a low-mole fraction of copper ion. That is, in the region where the mole fraction of cupric sulfate is less than 0.1, the formation of this salt takes place first with an extreme decrease in the quantity of copper ions; consequently, both ramentum-like crystals of compound XIII and Tutton's salt of zinc, $ZnSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$, appear. Besides, in the region where the mole fraction of ammonium sulfite is about 0.65, compound VI appears, as a result of the change in the

composition of the solution, in the zinc-rich region after the formation of the compound I.

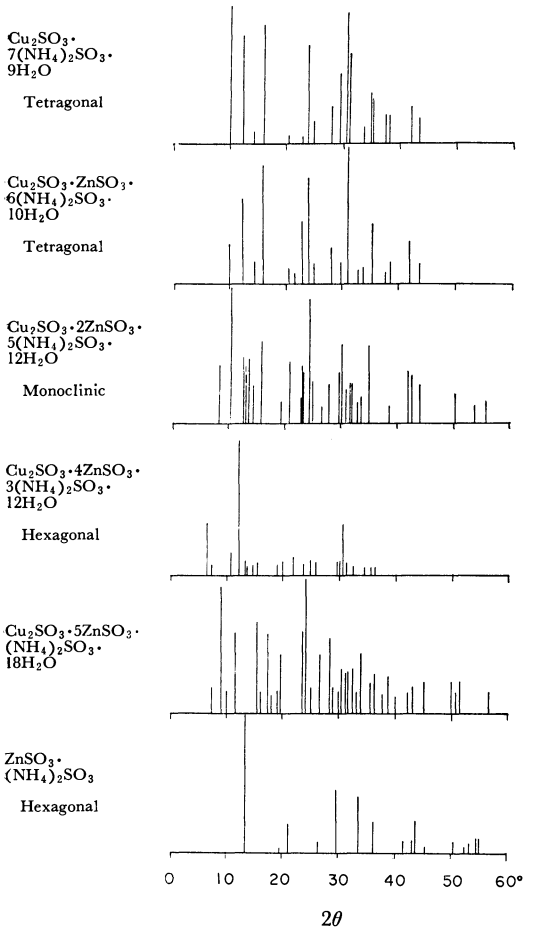

Fig. 2. The X-ray diffraction patterns of some complex sulfites.

Compound II: $Cu_2SO_3 \cdot 7(NH_4)_2SO_3 \cdot 10H_2O$.[2]—Transparent, colorless needles. Very soluble in water. This salt is prepared easily by the drop-by-drop addition of a cupric sulfate solution to a 3-mol./l. or a more concentrated solution of ammonium sulfite in the region where the mole fraction of cupric sulfate is less than 0.06.

Compound III: $Cu_2SO_3 \cdot 7(NH_4)_2SO_3 \cdot 9H_2O$.—Tetragonal (4/m 2/m 2/m). $c=0.3223$. Soluble in water. This salt is formed in a pale wine-red solution at about a 0.9 in mole fraction of ammonium sulfite. When zinc ions are absent in the solution, this salt is obtained as transparent, colorless plates as a result of the good development of the (110) face, and also occasionally as large crystals with a sandglass structure of a wine-red color, while in the presence of a few zinc ions in the solution, this salt is obtained as prisms, as is shown in Fig. 3. This salt bears a resemblance to the compound II and to the $Cu_2SO_3 \cdot 7(NH_4)_2SO_3 \cdot 14H_2O$ reported by Svensson[3] in composition; apparently, however, these salts are not the same, for their chemical properties, X-ray diffraction patterns and formation regions are different.

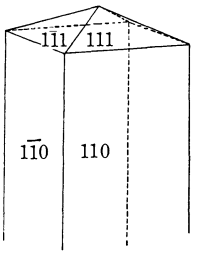

Fig. 3. Cuprous, ammonium sulfite, III.

Compound IV: $Cu_2SO_3 \cdot ZnSO_3 \cdot 6(NH_4)_2SO_3 \cdot 10H_2O$.—Tetragonal, transparent, colorless prisms. Soluble in water. When this salt is oxidized in moist air, it gradually turns yellow. The X-ray diffraction pattern is almost equal to that of the compound III except for the peak corresponding to d: 2.88 Å. This salt is obtained in the region where the amount of zinc ions is larger than that in the formation region of the compound III. This salt is obtained as transparent prisms, for example, in a mixed solution of metal sulfates to which 2—2.5 mol./l. ammonium sulfite solution is added until the mole fractions of cupric sulfate zinc sulfate and ammonium sulfite reach 0.08, 0.06 and 0.86 respectively, and which has stood for several days.

Compound V: $Cu_2SO_3 \cdot 2ZnSO_3 \cdot 5(NH_4)_2SO_3 \cdot 12H_2O$.—Monoclinic prisms, as are shown in Fig. 4 and in Photograph 1. $a : b : c=0.9325 : 1 : 0.4557$, $\beta=93°$ or 87°. Easily soluble in water. The solution of this salt is yellowish green. This salt is formed slowly as large crystals, together with the plastic mass in the region where the mole fraction of cupric sulfate is nearly equal

3) N. Svensson, *Ber.*, **4**, 713 (1871).

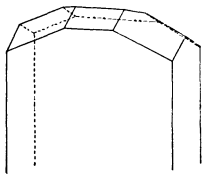

Fig. 4. Cuprous, zinc, ammonium sulfite, V.

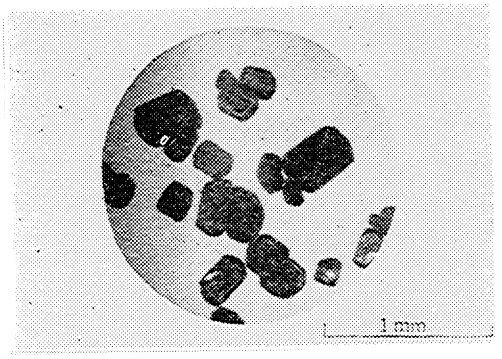
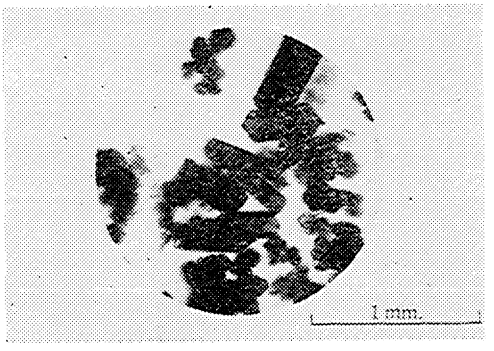
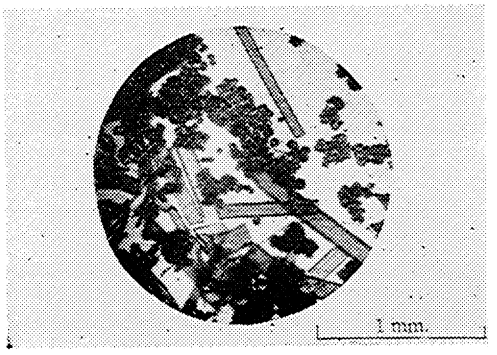


Photograph 1.

to that of zinc sulfate and where the mole fraction of ammonium sulfite is 0.75—0.83. When the number of zinc ions is large, the compound VII, $ZnSO_3 \cdot (NH_4)_2SO_3$, is formed, while when the number of copper ions is large, the compound VIII, $Cu_2SO_3 \cdot (NH_4)_2SO_3$, is formed.



Photograph 2.



Photograph 3.

Compound VI: $Cu_2SO_3 \cdot 4ZnSO_3 \cdot 3(NH_4)_2SO_3 \cdot 12H_2O$. — Hexagonal crystals, as are shown in Photographs 2 and 3. Insoluble in water and stable in the air. This salt is formed as plates since the $(10\bar{1}0)$ face grows well in the region where the mole fraction of ammonium sulfite is 0.63—0.73. This salt is prepared by adding a 2 mol./l. ammonium sulfite solution to a mixed solution of metal sulfates until the mole fractions of cupric sulfate, zinc sulfate and ammonium sulfite become 0.15, 0.20 and 0.65 respectively. At this state, the mixture must be shaken sufficiently to dissolve the plastic mass and then allowed to stand for a few days, isolated from the atomsphere.

Compound VII: $ZnSO_3 \cdot (NH_4)_2SO_3$.[4]—Hexagonal, transparent and colorless crystals. Slightly soluble in water and relatively stable in the air. The X-ray diffraction pattern and the Miller indices of this salt resemble those of the monohydrate registered on the ASTM X-ray Card 7-0426, but the results of the chemical analysis are apparently different from that of the monohydrate. This salt is formed easily at a 0.25 molar ratio between zinc sulfate and ammonium sulfite. Hexagonal plates are formed in the presence of copper ions, and bipyramidal plates, in the absence of copper ions or at a low concentration of ammonium sulfite. The primary formation of this salt is usually followed by that of the compound V or VI. (Found: NH_4, 13.19; Zn, 25.19; SO_3, 61.55%).

Compound VIII: $Cu_2SO_3 \cdot (NH_4)_2SO_3$.[5]—Rhombohedral, $c=9.0139$. Insoluble in water and stable in the air. Bipyramidal crystals are formed in the presence of zinc ions, and hexagonal plates, in the absence of zinc ions. This salt is obtained over a wide region by adding cupric sulfate to an ammonium sulfite solution until the molar ratio of cupric sulfate to ammonium sulfite becomes nearly 0.25.

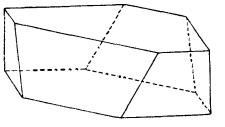


Fig. 5. Cuprous, ammonium sulfite, VIII.

Compound IX: $Cu_2SO_3 \cdot CuSO_3 \cdot 2H_2O$.[6]—Pseudo orthorhombic.

$a=8.34$ Å
$b=7.64$ Å
$c=5.56$ Å

Insoluble in water, but slightly soluble in sulfurous acid. This salt is always formed easily in a

5) A. Rosenheim and S. Steinhauser, ibid., **25**, 98 (1900).
6) G. Brauer and M. Eichner, *Z. anorg. u. allgem. Chem.*, **287**, 95 (1956).

small mole fraction of ammonium sulfite, or in a relatively large one through the conversion of the compound I.

Compound X: $ZnSO_4 \cdot (NH_4)_2SO_4 \cdot 6H_2O$.—This salt is formed slowly in the zinc-rich region as large crystals after the formation of zinc sulfite.

Compound XI: $ZnSO_3 \cdot 2.5H_2O$.[7]—This salt is formed when the mole fraction of ammonium sulfite is smaller than 0.55. Below a 0.4 mol. fraction of ammonium sulfite, only this salt is formed, but at about 0.45 it is accompanied by Tutton's salt.

The following compounds have also been obtained, but their properties have not been identified.

Unknown Compound XII.—This salt is obtained as a cotton-like aggregate of needles, together with a plastic mass, when a 3 mol./l. or more concentrated solution of ammonium sulfite is added to a mixed solution of the two metal sulfates. The X-ray diffraction pattern of this salt resembles that of the compound II, but the peak at d: 11.7 Å disappears and the intensity of the peak at d: 2.12 Å decreases compared with that of the compound II.

Unknown Compound XIII.—Transparent, colorless and calcite-like crystals. This salt is obtained in the same region as the compound XII is formed. However, the conditions under which only this salt is obtained could not be discovered.

Compound XIV: $Cu_2SO_3 \cdot 5ZnSO_3 \cdot (NH_4)_2SO_3 \cdot 18H_2O$.—This salt is formed as transparent and ink crystals in the clear solution after the dissolution of the plastic mass first formed. Besides, several salts with X-ray diffraction patterns similar to that of the compound II are formed in the region where the mole fraction of copper is below 0.1. (Found: NH_4, 2.56; Zn, 23.00; Cu, 8.96; SO_3, 42.18; H_2O, 23.30%).

Unknown Compound XV.—In the presence of zinc sulfate the color of the Chevreul salt formed in the reaction varies from a reddish brown through orange to yellow with the increase in the amount of zinc sulfate. The change in color may be due to the partial replacement of copper by zinc. The X-ray diffraction pattern varies with the color change until the formation of a certain pattern of this salt is established.

The Non-recoverable Plastic Mass. — Upon the drop-by-drop addition of an ammonium sulfite solution to a mixed solution of metal sulfates in the region where the molar ratio of zinc to copper is 1—2.5 and where the mole fraction of ammonium sulfite is 0.63—0.78, yellowish brown amorphous precipitates are rapidly formed at first; when stirred, these turn into a paste-like material which has no elasticity but which does have a good plasticity; this is named the "non-recoverable plastic mass."

The mass gradually hardens when the occluded water is released, and it is partly converted into the compounds I and VI within a few days or weeks.

Summary

In the reaction of an ammonium sulfite solution with a mixed solution of cupric sulfate and zinc sulfate, ten or more of the complex salts formed have been identified, and their formation regions and properties have been examined. Usually some of them are formed simultaneously, but sometimes only one is formed, depending on the reaction conditions. The newly-found compounds are as follows;

$Cu_2SO_3 \cdot 7(NH_4)_2SO_3 \cdot 9H_2O$
$Cu_2SO_3 \cdot ZnSO_3 \cdot 6(NH_4)_2SO_3 \cdot 10H_2O$
$Cu_2SO_3 \cdot 2ZnSO_3 \cdot 5(NH_4)_2SO_3 \cdot 12H_2O$
$Cu_2SO_3 \cdot 4ZnSO_3 \cdot 3(NH_4)_2SO_3 \cdot 12H_2O$

Among these salts, some may be represented by the general formula of $Cu_2SO_3 \cdot mZnSO_3 \cdot n(NH_4)_2SO_3 \cdot xH_2O$, in which $(m+n)=7$. Possibly, ammonium ions may be replaced by zinc ions to a certain extent.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 84—88 (1966)

The Solvent Effect on the Equilibrium of a Chemical Reaction in a Non-electrolyte Solution: Application to the Keto-enol Tautomerism and Dimerization of Nitrogen Dioxide

By Satohiro TANAKA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received April 27, 1965)

A simple lattice theory of a non-electrolyte solution in which the equilibrium of chemical reaction is reached has been presented and compared with the data of the enolization of ethyl acetoacetate in various solvents and with those of the dimerization of nitrogen dioxide in chloroform. Predicted linear relationships has been obtained for the data of the enolization in non-polar solvents, but they could not be obtained for the reaction in ethyl alcohol or for the dimerization of nitrogen oxide in chloroform. The van't Hoff-Dimroth relation has been derived by the present theory.

It is generally found that the equilibrium of a chemical reaction in a liquid solution is influenced by its medium; this is usually known as the solvent effect. The equilibria in electrolyte solutions has been discussed from the point of view of molecular theory, but those in non-electrolyte solutions have usually been treated only in terms of macroscopic thermodynamic quantities, such as activity and activity coefficient[1-3]; they have hardly been discussed at all from the standpoint of molecular theory.

Recently, the idea[4-6] of accounting for the behavior of associated solutions, in which hydrogen bonding and other weak bonding can occur between the molecules, by considering the system as an ideal mixture of the pure component and the associated complexes has been presented. In this case it is assumed that a chemical equilibrium between the monomers and the associated complexes occurs, and that the equilibrium ratio, as represented in terms of their mole fractions, is independent of the concentrations. However, this idea and its assumptions are very doubtful in the case of real mixtures.

Therefore, some further consideration of the non-electrolyte solution in which the equilibrium of the chemical reaction occurs is desirable in order to account for the medium effect. Such a consideration would contribute to a clearer interpretation of the behavior of associated solutions.

The A⇄B Type Reaction in a Solvent.— The system of a non-electrolyte solution in which a simple equilibrium of the chemical reaction, A⇄B, such as keto-enol tautomerism, occurs in an inert solvent, S, will be considered first. Then the lattice model may be applied to this system, the components of which are A, B and S. Although the lattice model does not describe the behavior of real liquid mixtures exactly,[7] it is convenient for calculating any thermodynamic quantity in the case of a multi-component system, and it can be used as one of approximations for real liquid mixtures.

In addition to the usual assumptions[8] of the lattice theory, these further assumptions were made:

1) All molecules are similar in size.

2) There is no long-range molecular interaction.

Then, using a simple zeroth approximation[9] for the sake of simplicity in calculation, one obtains the partition function (PF) of this system as:

$$(\mathrm{PF}) = \mathrm{e}^{-N_{\mathrm{B}}\varepsilon_0/kT} f_{\mathrm{A}}^{N_{\mathrm{A}}} f_{\mathrm{B}}^{N_{\mathrm{B}}} f_{\mathrm{S}}^{N_{\mathrm{S}}} \frac{N!}{N_{\mathrm{A}}!\, N_{\mathrm{B}}!\, N_{\mathrm{S}}!} \times \exp\left\{-\frac{z}{kT}\left(\frac{N_{\mathrm{A}}N_{\mathrm{B}}}{N} w_{\mathrm{AB}} + \frac{N_{\mathrm{B}}N_{\mathrm{S}}}{N} w_{\mathrm{BS}} + \frac{N_{\mathrm{S}}N_{\mathrm{A}}}{N} w_{\mathrm{SA}}\right)\right\} \quad (1)$$

where N_{A}, N_{B}, and N_{S} are the numbers of A, B, and C molecules respectively; N is the total number of molecules, $N_{\mathrm{A}}+N_{\mathrm{B}}+N_{\mathrm{S}}$; f_{A}, f_{B}, and f_{S} are the partition functions of A, B, and C

respectively: ε_0 is the energy change in the $A \rightleftarrows B$ reaction in the gaseous phase; and w_{AB}, w_{BS}, and w_{SA} are molecular interchange energies between the species identified in the subscript.

The Helmholtz free energy of the system is, then, given by:

$$\frac{F}{kT} = -\ln(PF) = \frac{N_B\varepsilon_0}{kT} - N_A \ln f_A - N_B \ln f_B - N_S \ln f_S + N_A \ln \frac{N_A}{N} + N_B \ln \frac{N_B}{N} + N_S \ln \frac{N_S}{N} + \frac{z}{kT}\left(\frac{N_A N_B}{N} w_{AB} + \frac{N_B N_S}{N} w_{BS} + \frac{N_S N_A}{N} w_{SA}\right) \quad (2)$$

Differentiating with respect to N_A and N_B, one obtains for the chemical potential μ_A and μ_B;

$$\frac{\mu_A}{kT} = -\ln f_A + \ln x_A + \frac{z}{kT}\{x_B(1-x_A)w_{AB} - x_B x_S w_{BS} + x_S(1-x_A)w_{SA}\} \quad (3)$$

$$\frac{\mu_B}{kT} = \frac{\varepsilon_0}{kT} - \ln f_B + \ln x_B + \{x_A(1-x_B)w_{AB} - x_S x_A w_{SA} + x_S(1-x_B)w_{BS}\}\frac{z}{kT} \quad (4)$$

where x_A, x_B, and x_S are the mole fractions of A, B, and S respectively.

$$x_A + x_B + x_S = 1 \quad (5)$$

As in the equilibrium,

$$\mu_A = \mu_B \quad (6)$$

the following expressions can be obtained:

$$\ln K = \ln \frac{x_B}{x_A} = -\frac{\varepsilon_0}{kT} + \ln \frac{f_B}{f_A} + \frac{z}{kT}\{(x_B - x_A)w_{AB} + x_S(w_{SA} - w_{BS})\} \quad (7)$$

$$K = \frac{x_B}{x_A} = e^{-\varepsilon_0/kT}\frac{f_B}{f_A}\exp\left[\frac{z}{kT}\{(x_B - x_A)w_{AB} + x_S(w_{SA} - w_{SB})\}\right] \quad (8)$$

From Eqs. 7 and 8, it may easily be seen that the equilibrium ratio, $K = x_B/x_A$, where x_A and x_B are the mole fractions of A and B, contains a factor which represents the solvent effect in terms of x_S, w_{SA}, w_{SB}. A similar formula was also obtained by Moelwyn-Hughes,[10] but he did not develop his formula further or apply it to any experimental data.

For the convenience of analyzing the experimental data, formula 7 is transformed as follows. By substituting $x_S = 1 - x_A - x_B$ into 7, one obtains:

$$\ln K = -\frac{\varepsilon_0}{kT} + \ln \frac{f_B}{f_A} + \frac{z}{kT}(w_{SA} - w_{SB}) + \frac{z}{kT}(w_{AB} - w_{SA} + w_{SB})x_B + \frac{z}{kT}(w_{SB} - w_{SA} - w_{AB})x_A \quad (9)$$

$$= \gamma + \beta x_B + \alpha x_A \quad (10)$$

with:

$$\alpha = \frac{z}{kT}(w_{SB} - w_{SA} - w_{AB})$$

$$\beta = \frac{z}{kT}(w_{AB} + w_{BS} - w_{SA})$$

$$\gamma = \frac{\varepsilon_0}{kT} + \ln \frac{f_B}{f_A} + \frac{z}{kT}(w_{SA} - w_{SB})$$

For $x_S = 0$, formula 10 becomes:

$$\ln K^0 = \gamma + \beta x_B^0 + \alpha x_A^0 \quad (11)$$

where K^0, x_A^0, and x_B^0 are the values of K, x_A, and x_B respectively in the absence of a solvent. When 11 is subtracted from 10, the following equation is obtained:

$$\frac{\ln K - \ln K^0}{x_A - x_A^0} = \alpha + \beta \frac{x_B - x_B^0}{x_A - x_A^0} \quad (12)$$

The $2A \rightleftarrows B$ Type Reaction in a Solvent.—This is also a non-electrolyte solution system containing three components, A, B, and S.

In equilibrium,

$$2\mu_A = \mu_B \quad (13)$$

Then, using a procedure similar to that previously used, the following formula can be obtained:

$$\ln K = \ln \frac{x_B}{x_A^2} = -\frac{\varepsilon^0}{kT} + \ln \frac{f_B}{f_A^2} + \{2x_B - x_A x_B - x_A)w_{AB} + x_S(2 - x_A)w_{SA} - x_S(1 + x_B)w_{SB}\}\frac{z}{kT} \quad (14)$$

This formula will be tested later on the dimerization reaction of nitrogen dioxide.

A Comparison with the Experimental Data of the Keto-enol Isomerization of Ethyl Acetoacetate.—Any adequate comparison of the present formula with the experimental data requires the experimental determination of the mole fractions of the reacting species in non-electrolyte solutions over a wide range of composition. Unfortunately, there are only a few reactions for which such measurements have been made.

As an example of older measurements, the keto-enol isomerizations of ethyl acetoacetate in *n*-hexane, carbon disulfide, benzene and ethyl alcohol were studied by Meyer and Kappelmeier[11] over the whole concentration range. Figure 1

10) E. A. Moelwyn-Hughes, "Physical Chemistry," 2nd Ed., Pergamon, Oxford (1961), p. 1031.

11) K. H. Meyer and P. Kappelmeier, *Ber.*, **44**, 2718 (1911).

shows the variations in the equilibrium ratio with the solvent concentration, which was recalculated from their data. These recalculated equilibrium ratios, $K=x_B/x_A$, where A and B represent keto and enol forms respectively, were used to test formula 12; the results are shown in Fig. 2. In these tests, the equilibrium ratio, K^0, for a pure reactant was chosen as the standard of comparison because the K^0 ratio was measured most accurately in their measurements. Despite scattering in the original data and a wide variation in

Carbon disulfide	−1.3	−0.9
Benzene	−0.8	−0.6
Ethyl alcohol	—	—

the solvent concentration, the plots describe a fairly satisfactory straight line, with a reasonable slope for each solvent except for ethyl alcohol. Alcohol is known as a polar-associated liquid, and the usual simple lattice theory cannot describe the equilibrium behavior of solution; therefore, a straight line perpendicular to the abscissa, which is not in accordance with the prediction of formula 12, might be obtained.

From Fig. 2 the values of α and β can be read. The value of w_{AB}, the molecular interchange energy between A and B, can also be calculated; they are given in Table I for all the solvents. The values of w_{AB} should be independent of the solvent, but the values for the carbon disulfide solvent differ from the values for *n*-hexane and benzene, and the differences exceed the range of experimental error. The difference may be due to the simplicity of the present model and approximation. However, the three values of w_{AB} are in fairly good accordance with each other in spite of the large difference in the influences of the solvents.

The Derivation of the van't Hoff-Dimroth Relation.—For the $A \rightleftarrows B$ reaction, the value of the equilibrium constant, K, given by the $K=C_B/C_A$ equation at a high dilution, varies from solvent to solvent if the concentrations, C_A and C_B respectively, of A and B are expressed either in moles per liter or in any other conventional unit. However, the constant, G (characteristic of the particular reaction), defined by the equation;

$$G = \frac{C_B/S_B}{C_A/S_A} \tag{15}$$

should be more or less independent of the solvent if the solubilities, S_A and S_B respectively, of A and B in the solvent of interest are not too great. This Eq. 15 is called the van't Hoff-Dimroth relation; it was derived by van't Hoff[12] from thermodynamic considerations and was tested by Dimroth[13] for the isomerism of 1-phenyl-5-aminotriazole carboxylic acid esters in various solvents. The relation has been shown to hold also for the equilibrium between tautomeric forms in various solvents in which the solubilities of the reactants are not too great.

It may easily be shown that the relation can be

12) J. H. van't Hoff, *Lectures on Theoret. Chem.*, **1**, 221 (1898).
13) O. Dimroth, *Ann.*, **377**, 127 (1910).

deduced from the present theory. Let us first obtain the solubility, x_A^*, of A in a solvent, S. In a saturated solution of A in S, we have:

$$\mu_A(s) = \mu_A(l) \tag{16}$$

where $\mu_A(s)$ and $\mu_A(l)$ are the chemical potentials of A in its solid and solution states respectively. By substituting 3 into 16, we obtain:

$$\ln x_A^* = \ln\frac{f_A^l}{f_A^s} - \frac{z}{kT}(1-x_A^*)^2 w_{AB} \tag{17}$$

where f_A^s and f_A^l are the partition functions of A in the solid and liquid states respectively. Similarly, the solubility, x_B^*, of B in S can be obtained:

$$\ln x_B^* = \ln\frac{f_B^l}{f_B^s} - \frac{z}{kT}(1-x_B^*)^2 w_{BS} \tag{18}$$

On the basis of, 17, and 18, the right-hand side of Eq. 15 can be expressed in this form:

$$\ln\frac{x_B/x_B^*}{x_A/x_A^*} = -\frac{\varepsilon_0}{kT} + \ln\frac{f_A^s}{f_B^s} + \frac{z}{kT}\{(w_{AB}+w_{BS}-w_{AS})(x_B-x_A) + w_{BS}(x_B^*-2)x_B^* - w_{AS}(x_A^*-2)x_A^*\} \tag{19}$$

The conditions under which the van't Hoff-Dimroth relation holds, when the equilibrium is at a high dilution and the solubilities of the reactants are not too great, are:

$$x_A,\ x_B,\ x_A^*,\ x_B^* \ll 1 \tag{20}$$

Therefore, x_A^{*2} and x_B^{*2} can be neglected compared with x_A^* and x_B^*, and 19 becomes:

$$\ln\frac{x_B/x_B^*}{x_A/x_A^*} \simeq -\frac{\varepsilon_0}{kT} + \ln\frac{f_B^s}{f_A^s} + \frac{z}{kT}\{(w_{AB}+w_{BS}-w_{AS})(x_B-x_A) - 2(w_{BS}x_B^* - w_{AS}x_A^*)\} \tag{21}$$

The third term on the right-hand side of 21, containing solvent parameters, is consisted of differences of small values if the conditions 20 are taken into consideration, and it may become appreciably small compared with the other terms. Therefore, the quantity on the left-hand side of 21 becomes hardly dependent at all on the solvent; it can thus easily be seen that 21 is equivalent to the van't Hoff-Dimroth relation 15.

A Comparison with the Experimental Data of the $2NO_2 \rightleftarrows N_2O_4$ Reaction in Chloroform.— Cundall[14] investigated the dimerization of nitrogen dioxide in chloroform at 0°C over the full range of concentration, and Lewis et al.[15] calculated the equilibrium ratio, $K=x_B/x_A^2$, at various values of x_S from Cundall's data; x_A, x_B, and x_S are the mole fractions of nitrogen dioxide, nitrogen tetraoxide and chloroform respectively.

14) J. T. Cundall, *J. Chem. Soc.*, **59**, 1076 (1895).
15) Reference 2, p. 273.

According to their results, the condition,

$$x_A \ll x_B,\ x_S$$

held over nearly the entire range of the concent ration. Therefore, formula 14 becomes:

$$\ln K \simeq -\frac{\varepsilon_0}{kT} + \ln\frac{f_B}{f_A^2} - \frac{2zw_{AB}}{kT}x_B + \frac{2z}{kT}(w_{SA}-w_{SB}-w_{AB})x_S + \frac{z}{kT}w_{BS}x_S^2 \tag{22}$$

In the absence of a solvent, i. e. when $x_S=0$, a similar condition,

$$x_A \ll x_B,$$

holds; then 14 becomes:

$$\ln K^0 = -\frac{\varepsilon_0}{kT} + \ln\frac{f_B}{f_A^2} - \frac{2zw_{AB}}{kT}x_B \simeq -\frac{\varepsilon_0}{kT} + \ln\frac{f_B}{f_A^2} - \frac{2zw_{AB}}{kT} \tag{23}$$

By subtracting 23 from 22, one obtains the following equation:

$$\frac{\ln K - \ln K^0}{x_S} = \frac{2z}{kT}(w_{SA}-w_{AB}-w_{SB}) + \frac{z}{kT}w_{BS}x_S \tag{24}$$

Again the ratio, K^0, for pure a reactant is chosen as a standard because it can be measured more accurately than at a high dilution.

The $(\ln K - \ln K^0)/x_S$ values obtained from Cundall's data are plotted in Fig. 3 against the

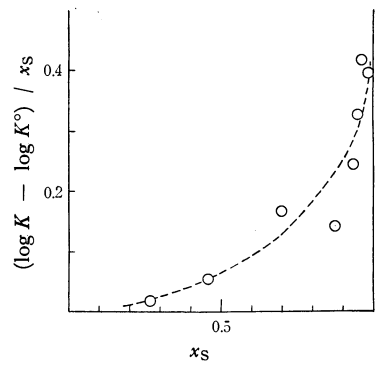

Fig. 3. A test of Eq. 23 for dimerization of nitrogen dioxide in chloroform.

x_S values, but the predicted linear plot cannot be obtained. This failure may be due to the simplicity of the present lattice model and the rough approximation, to the assumption that the dimers are the same size as the monomer; the long-range molecular interaction is neglected although a considerable change in dipole moment occurs in the dimerization in the polar solvent.

The author wishes to thank Dr. Kazuo Amaya for his interest and advice. He also wishes to thank Mrs. Kazuko Sasaki for her interest and encouragement.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 88—91 (1966)

The Flocculation of Kaolin and Precipitated Calcium Carbonate by Polymers

By Kahei SAKAGUCHI and Kunihiko NAGASE

Industrial Research Laboratories, Kao Soap Co., Ltd., Wakayama-shi

(Received May 7, 1965)

The subsidence rate of a suspension of kaolin or precipitated calcium carbonate flocculated by polyacrylamide increases with an increase in the intrinsic viscosity of the polymer, and it shows a marked acceleration above an intrinsic viscosity of 5—6. However, in the case of the flocculation of the precipitated calcium carbonate flocculated by sodium polyacrylate, the subsidence rate depends linearly upon the intrinsic viscosity of the polymer. The results have been discussed in terms of Verwey and Overbeek's theory. The real unperturbed dimension of polyacrylamide has been calculated from the equations proposed by Kurata, Stockmayer and Fixman. As a consequence, it has been suggested that the dimension of a polymer has a close relationship with its flocculation behavior.

It has been suggested by Michaels[1,2] and by other authors[3-5] that the flocculation of the suspension brought about by water-soluble high polymers is caused by the cross-linking of the solid particles with the adsorbed polymer molecules. In the case of the flocculation of a clay suspension by polyacrylamide, it has been reported by Toyoshima[5] that the subsidence rate depends linearly upon the molecular weight of the polymer. However, his observations were confined to the region where the intrinsic viscosity of the polymer solution was less than 6.

In the present work we have investigated the dependence of the molecular weight of polyacrylamide and sodium polyacrylate on the subsidence rate of kaolin or of precipitated calcium carbonate in suspensions. The results will be discussed in terms of Verwey and Overbeek's theory[6]; the conclusion that the flocculation is closely related to the dimension of a polymer will be obtained.

Experimental

Materials.—Both the polyacrylamides and the sodium polyacrylates used in this experiment were prepared by the aqueous polymerization of the corresponding monomers, using ammonium persulfate as an initiator. The viscosities of the resultant polymer solution were measured at 30°C with an Ubbelohde viscometer.

Kaolin was supplied by the Sanko Seiyaku Kogyo Co., Ltd.; its composition and particle-size distribution are shown in Table I and Fig. 1 respectively. The PH of a 5% suspension of this kaolin in water is 4.0.

The precipitated calcium carbonate was supplied by the Shiseido Seiyaku Co., Ltd.; its particle-size distribution is shown in Fig. 2. The PH of a 5% suspension of this carbonate is 9.5.

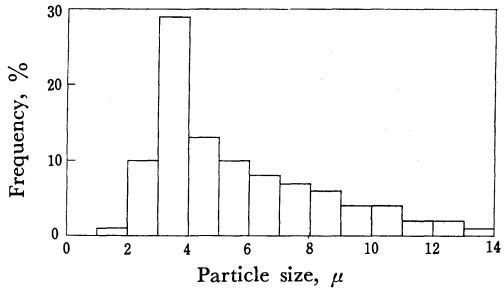

Fig. 2. Particle size distribution of precipitated calcium carbonate.

Methods.—The subsidence data were obtained at room temperature using 25-ml., graduated cylinders 1.2 cm. in inner diameter and 19.4 cm. long. After 1.25 g. of kaolin or calcium carbonate had been weighed into the cylinder, 20 ml. of water was added. The cylinder was then shaken vigorously in order to obtain a suspension. An aqueous solution of a polymer was added to make a total of 25 ml. The amount of the polymer was 0.01% of the solid. The content was mixed by inverting the cylinder 20 times a minute; then it was allowed to settle. The subsidence rates were determined by plotting the height of the solid-liquid boundary as a function of the time.

Results

Figure 3 shows the subsidence rate of a kaolin suspension flocculated by polyacrylamide as a function of the intrinsic viscosity of the polymer. Figure 4 shows the results of the flocculation of the precipitated calcium carbonate suspension by polyacrylamide. In each case, the subsidence rate increases with an increase in the intrinsic viscosity and shows a marked acceleration above an intrinsic viscosity of 5—6. Upon the sedimentation of precipitated calcium carbonate flocculated by sodium polyacrylate, as is shown in Fig. 5, the subsidence rate depends linearly upon the intrinsic viscosity of the polymer.

In the flocculation of a kaolin or precipitated calcium carbonate suspension by polyacrylamide, it appears that a polymer with an intrinsic viscosity

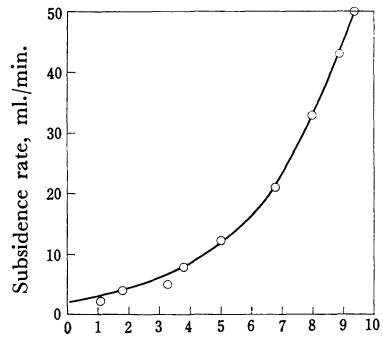

Fig. 4. The relation between the subsidence rate and the intrinsic viscosity of polyacrylamide at the flocculation of calcium carbonate suspension.

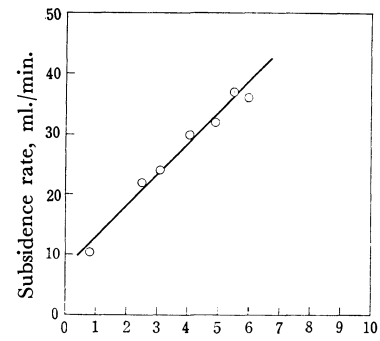

Fig. 5. The relation between the subsidence rate and the intrinsic viscosity (in 2 N NaOH aqueous solution) of sodium polyacrylate in the flocculation of precipitated calcium carbonate.

of 5 or more has a special property to facilitate the crosslinking of the suspended particles with each other. On the other hand, sodium polyacrylate, in contrast to polyacrylamide, shows a moderate flocculating power, even at a low intrinsic viscosity, and it shows a typical linear relationship between the subsidence rate and the intrinsic viscosity. Some of these results have been discussed in another paper.[7]

Discussion

These results seem to suggest that the dimensions of a polymer in an aqueous medium are closely related to the flocculating power. In a dilute aqueous solution of sodium polyacrylate, the configuration of the polymer chain may be greatly expanded by the electrostatic repulsion between carboxyl groups. The intrinsic viscosities of sodium polyacrylates were determined in 2 N sodium hydroxide. Consequently, the actual

7) K. Sakaguchi and K. Nagase, *J. Chem. Soc. Japan, Ind. Chem. Sect.* (*Kogyo Kagaku Zasshi*), to be published.

dimensions of the polymer chain in an aqueous solution may be much larger than that of polyacrylamide, even if the intrinsic viscosity is same. Polyacrylamide is essentially nonionic, and it is not believed that the configuration of the polymer chain is as expanded as in the case of a polyelectrolyte.

On the stability of lyophobic sols, Verwey and Overbeek[6] and Derjaguin and Landau[8-10] have proposed a theory that a flocculation occurs when the London - van der Waals' force exceeds the repulsion force. For coarser particles of polystyrene in dilute salt solutions, Schenkel and Kitchener[11] showed that flocculation takes place at the "secondary minimum" in the potential energy curves, at which the interparticle distance is 500—1000 Å. Hachisu and Furusawa[12] reported that, at low concentrations of sodium chloride, a loose flocculation of "tungustic acid sol" occurs at an interparticular distance of 800—1000 Å; this flocculation at the "secondary minimum" is explained as a balance between the London - van der Waals' force and the repulsion force. The bond combining the particles is easily broken by a mild shock, for the "secondary minimum" is in any case rather shallow. This state of flocculation is a "pseudo flocculation," in which flocculation-deflocculation is reversible.

In order to flocculate the suspension irreversibly, it is necessary to reduce the repulsion force (or the ζ-potential) between the particles by adding larger amounts of electrolytes. Then the interparticular distance becomes narrower than 100 Å, and the aggregate can not be destroyed easily by a mild shock.

The size of the kaolin or of the precipitated calcium carbonate used in the present study was rather coarse; its average diameter was 2—6μ. When these particles were suspended in water in the absence of a polyacrylamide flocculating agent, a loose flocculation of suspensions occurred spontaneously, and the suspensions were deflocculated easily by a mere mechanical shock. The interparticular distance under these conditions could be assumed to be around 1000 Å.

In order to obtain a stable aggregate, one in which the particles are combined stronlgy with each other, the dimensions of a polymer which is to be adsorbed onto the solid surface to facilitate the crosslinking of the particles should be at least larger than 1000 Å. As is demonstrated in Figs. 3 and 4, the polyacrylamides with intrinsic viscosities higher than 5—6 are very effective flocculants. Moreover, as the polyacrylamides used in this study were essentially nonionic, it can be assumed that the adsorption of this polymer causes little change in the repulsion force between particles. In this connection, it would be very interesting to calculate the dimensions of polyacrylamide molecules in water and to examine the relationship between these dimensions and its flocculating behavior.

Recent theoretical investigations by Stockmayer and Fixman[13-15] into the expansion factor of a coiled-chain molecule and its role in the viscosity give these simple intrinsic viscosity equations:

$$[\eta]=[\eta]_\theta \alpha_\eta{}^3 \tag{1}$$

$$[\eta]=KM^{1/2} \tag{2}$$

$$K=\Phi_0 A^3 \tag{3}$$

$$\alpha_\eta{}^3=1+1.55\,Z \tag{4}$$

where $[\eta]$ and $[\eta]_\theta$ represent the intrinsic viscosities in ordinary and theta solvents respectively. M is the molecular weight of the polymer; Φ_0 is an universal constant, 2.87×10^{23} (c. g. s.); α_η is the viscosity expansion factor, and A and Z are shown in Eqs. 5 and 6 respectively:

$$A^2=\langle R_0{}^2\rangle M^{-1} \tag{5}$$

$$Z=\left(\frac{3}{2\pi}\right)^{3/2} BA^{-3}M \tag{6}$$

where $\langle R_0{}^2\rangle$ is the mean-square dimension of the polymer chain and where B is a parameter measuring the polymer-solvent interactions. By combining these equations, we obtain:

$$[\eta]=KM^{1/2}+0.51\Phi_0 BM \tag{7}$$

Rewriting Eq. 7 gives:

$$[\eta]M^{-1/2}=K+0.51\Phi_0 BM^{1/2} \tag{8}$$

On plotting $[\eta]M^{-1/2}$ against $M^{1/2}$, the intercept is equal to K and the slope of the straight line is $0.51\Phi_0 B$. By substituting K in Eq. 3, $\langle R_0{}^2\rangle$ can be determined from Eq. 5. By then substituting B into Eq. 6, Z is determined. Then α_η can be calculated from Eq. 4. The relationship between the mean-square dimension of the polymer chain, $\langle R_0{}^2\rangle$, and the unperturbed mean-square radius of gyration, $\langle S_0{}^2\rangle$, is :

$$\langle S_0{}^2\rangle=(1/6)\langle R_0{}^2\rangle \tag{9}$$

The real unperturbed mean-square radius of gyration, $\langle S^2\rangle$, is :

$$\frac{\langle S^2\rangle}{\langle S_0{}^2\rangle}=\alpha_s \tag{10}$$

where

$$\alpha_s{}^3=\alpha_\eta{}^{2.43} \tag{11}$$

The relationship between the intrinsic viscosity

and the molecular weight for polyacrylamide has been reported by Dainton et al.[16] to be:

$$[\eta]=6.8\times10^{-4}M^{0.66} \quad (12)$$

where $[\eta]$ is the intrinsic viscosity in an aqueous solution at 30°C, dl./g., and where M is the number-average molecular weight. By plotting $[\eta]M^{-1/2}$ against $M^{1/2}$, values which were calculated from Eq. 12, the curve shown in Fig. 6 was obtained.

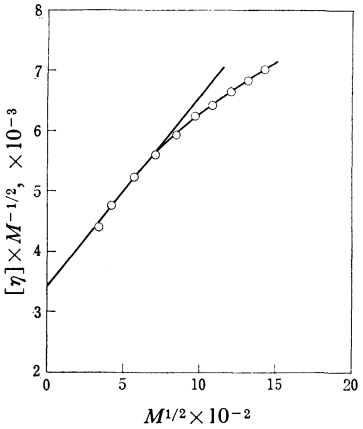

Fig. 6. Plots of $[\eta]M^{-1/2}$ versus $M^{1/2}$.

K and B were determined from the intercept and from the slope of a straight line in the lower molecular weight region respectively:

$$K=3.40\times10^{-3} \quad (13)$$

$$B=2.10\times10^{-27} \quad (14)$$

From Eq. 12, when $[\eta]$ is 6, M is 942000. Substituting K and M values into Eqs. 3 and 5 gives:

$$\langle R_0^2\rangle=1.047\times10^{-10} \quad (15)$$

$$\langle R_0^2\rangle^{1/2}=1.024\times10^{-5} \quad (15')$$

Consequently, the dimension of the polymer chain in a theta solvent is 1024 Å. Using a B value of 2.10×10^{-27}, the Z, α_η and α_s values were calculated successively:

$$Z=0.573 \quad (16)$$

$$\alpha_\eta=1.236 \quad (17)$$

$$\alpha_s=1.187 \quad (18)$$

Subsequently, $\langle S^2\rangle$, $\langle S^2\rangle^{1/2}$ and $\langle R^2\rangle^{1/2}$ were obtained:

$$\langle S^2\rangle=2.07\times10^{-9} \quad (19)$$

$$\langle S^2\rangle^{1/2}=4.55\times10^{-6} \quad (20)$$

$$\langle R^2\rangle^{1/2}=6^{1/2}\langle S^2\rangle^{1/2}=1.114\times10^{-5} \quad (21)$$

Thus, the "real dimension" (the root mean-square end-to-end distance of the chain, $\langle R^2\rangle^{1/2}$) of the polyacrylamide molecules with the intrinsic viscosity of 6 was calculated to be 1114 Å.

Figure 7 shows the relationship between $\langle R^2\rangle^{1/2}$ and the intrinsic viscosity of polyacrylamide. When $[\eta]$ is 5.3, $\langle R^2\rangle^{1/2}$ equals 1000 Å.

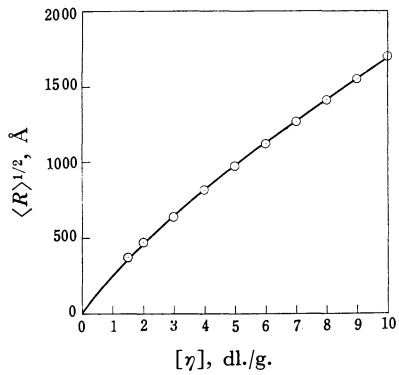

Fig. 7. Plots of $\langle R^2\rangle^{1/2}$ versus $[\eta]$.

This is in good accord with the value of 1000 Å which had been predicted.

Conclusion

At the "secondary minimum" in the potential curve of the Verwey and Overbeek theory, the particles can approach each other up to an inter-particular distance of 1000 Å. However, in this state, the flocculation is not complete. When a polymer with a dimension of 1000 Å or more is added to this suspension, the particles are bound together to give a stable aggregate. Thus, by the addition of polyacrylamide with a dimension larger than 1000 Å, which corresponds to the intrinsic viscosity of 5—6, the suspension is effectively flocculated. Sodium polyacrylate, on the other hand, because of its chain expansion in solution due to the repulsion between carboxyl groups, shows a moderate flocculating power even at a lower intrinsic viscosity. Thus, it gives a linear intrinsic viscosity - subsidence rate relation.

The authors wish to express their thanks to Dr. Eiichi Wada of the Institute of Physical and Chemical Research, Tokyo, for his valuable suggestions.

The Crystal Structure of Tris(*l*-propylenediamine)cobalt(III) Bromide and the Absolute Configuration of the Complex Ion, [Co *l*-pn_3]$^{3+}$ *1

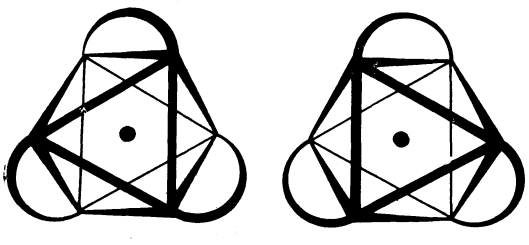
By Hitoshi IWASAKI and Yoshihiko SAITO

Institute for Solid State Physics, The University of Tokyo, Azabu, Tokyo

(Received May 13, 1965)

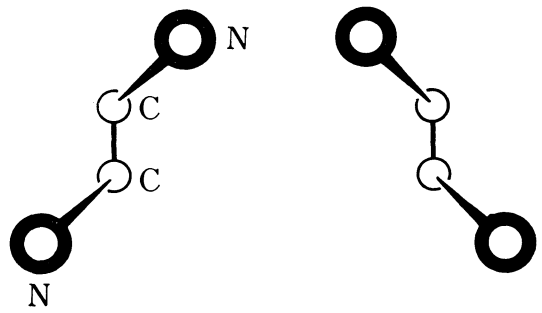
Crystals of L-[Co *l*-pn_3]Br_3 (pn: propylenediamine) were prepared and their crystal structure was completely determined by means of X-rays. They are hexagonal, with the space group $P6_3$; $a=11.08\pm0.03$, $c=8.59\pm0.02$Å and $Z=2$. The structure is essentially ionic, consisting of complex ions and bromide anions. A complex ion has a three-fold axis of symmetry through the central cobalt atom. Five-membered Co-pn rings are puckered, and the C–C bonds in these rings are nearly parallel to the threefold axis. The methyl carbon bonds are equatorial with respect to the plane of the ring. The absolute configuration of the complex ion has been determined by using the absorption-edge technique. The L*lll*-type complex ion has been found to be laevorotatory with respect to the NaD lines. By the introduction of an asymmetric carbon atom into the ligands, the absolute configuration of a series of tris(bidentate)-complexes could be successfully correlated to the configurational series in organic compounds.

In the study of the optical properties of complex compounds, tris(bidentate)-metal complexes are most frequently taken up since they have relatively simple structures and exhibit typical optical isomerism. When three bidentate ligands are coordinated to the central atom in an octahedral fashion, it is possible for two optically active isomers, D and L, to occur (Fig. 1). Niekerk et al. have shown that a [Cr ox_3]$^{3-}$ ion (ox=oxalate ion) essentially possesses the structure shown in Fig. 1.[1] When the chelating molecules are not planar, another kind of isomer appears. For example, when ethylenediamine molecules (usually denoted as "en") are chelated to a metal atom, they assume the "gauche" configuration, and the five-membered ring, consisting of metal and an ethylenediamine molecule, is puckered. If we denote the two possible and enantiomorphous conformations of ethylenediamine as *d* and *l*[*2]



D L

Fig. 1. Two possible configurations of a tris-(bidentate)-complex ion.



d *l*

Fig. 2. Two possible gauche forms of an ethylenediamine molecule.

(Fig. 2), there will be eight isomers of the [M en_3], such as D*ddd*, L*ddl*, etc.[3] Kuroya et al. found that the most stable form of the [Co en_3]$^{3+}$ ion has a three-fold symmetry and takes either the D*ddd* or the L*lll* form,[*3,3-5] forms which correspond to the "lel" type according to Corey and Bailar's notation.[2] The determination of the absolute configuration proved that the D-type complex is dextrorotatory with respect to the NaD lines.[4]

Now it is widely recognized that the optical rotatory dispersion (ORD) curve is diagnostic of the absolute configuration. In attempting to

verify this convention of correlating the configurations of various complex ions, the tris(l-propylenediamine)cobalt(III) ion, [Co l-pn$_3$]$^{3+}$, has been chosen and its absolute configuration determined by means of X-rays; the ORD curve of this ion bears a close resemblance to that of [Co en$_3$]$^{3+}$, whose absolute configuration had already been established. Moreover, by the introduction of the methyl groups in the ethylenediamine ring in [Co en$_3$]$^{3+}$ ion, the ligands themselves are optically activated, actually being the l-forms in the present case. The absolute configuration of the l-pn has been chemically correlated to that of D-alanine.[6,7] Accordingly, we may expect to find a correlation between the configurational series in organic chemistry and that of the complex compounds.

Experimental

Commercial racemic propylenediamine was resolved with d-tartaric acid according to the method described by O'Brien and Toole.[8] 5.5 g. of the l-pn was heated with 5.0 g. of chloropurpureo-salt, [CoCl(NH$_3$)$_5$]Cl$_2$. The reaction mixture was then dissolved in a small amount of water. When concentrated hydrobromic acid was added to the solution, crystals of the bromide of the aimed complex were precipitated. By recrystallization from an aqueous solution, single crystals of suitable sizes for X-ray works were obtained.

The crystals are reported to have two moles of water of crystallization.[9] However, no weight loss was observed after the specimen had been kept in an air bath at 123°C for 80 min. The results of the chemical analysis*4 also showed that the specimen was anhydrous. (Found: N, 16.18%; calcd. for [Co l-pn$_3$]Br$_3$: N, 16.15%; calcd. for [Co l-pn$_3$]Br$_3$·2H$_2$O: N, 14.61%). This was supported by the present X-ray structure analysis.

The crystals are deep orange-red in color and transparent. They are hexagonal prismatic, and stable in air at room temperature. An X-ray examination showed the prismatic axis of the crystal to be coincident with the c-axis of the hexagonal system, and the well-developed prismatic faces are indexed as $\{11\bar{2}0\}$. Since the crystals contain only the l-isomer of the propylenediamine, they are optically active. In fact, the crystal was found to be laevorotatory with respect to the NaD lines under a polarizing microscope.

Oscillation photographs were taken around the c-axis. When one uses the Cu$K\alpha$ radiation ($\lambda=1.542$ Å), the intensity distribution on the films was approximately of a mirror symmetry with respect to the equatorial line; i. e.,

$$I(hkl) \fallingdotseq I(hk\bar{l})$$

Detailed examination, however, revealed that this was not exactly true for many weak reflections, though the deviation from the strict mirror symmetry was generally quite small. The photographs taken with the Fe$K\alpha$ radiation ($\lambda=1.937$ Å), for which the effect of the anomalous scattering is expected to be smaller than in the case of Cu$K\alpha$, had a nearly perfect mirror symmetry with respect to the equatorial line. Therefore, it may safely be concluded that the deviation from the symmetry is attributable to the anomalous dispersion occurring in the acentric crystals. The equatorial and upper-level Weissenberg photographs showed the existence of a sixfold symmetry in each reciprocal plane perpendicular to the c-axis. Thus the Laue symmetry group to which the intensity distribution from this crystal belongs is 6 (C_6). The space group was uniquely determined from the systematic absences to be No. 173, $P6_3$ (C_6^6).

The lattice constants were determined from the Weissenberg photographs of crystals rotating about tha a and c axes. The following values were obtained:

$$a=11.08\pm0.03, \qquad c=8.59\pm0.02 \text{ Å}$$

A unit cell contains two formula units of [Co l-pn$_3$]Br$_3$ (Density: observed 1.91 g. cm^{-3}, calcd. 1.90 g. cm^{-3}).

The specimen used for the collection of the final intensity data was polished by emery paper into a cylindrical form with a diameter of 0.012 cm. Equi-inclination Weissenberg photographs were taken around the c-axis up to the seventh layer with the filtered Cu$K\alpha$ radiation. The $0kl$ reflections were also collected by the a-axis rotation. Intensities were estimated visually with a standard film strip. 541 independent reflections were observed. The usual Lorentz, polarization, spot-shape and absorption corrections were then applied. For the a-axis data it was found that the standard deviations of the intensities among the equivalent reflections were larger than those for the c-axis data, probably due to the irregular shape of the specimen. Therefore, these data were not used for the final refinement.

The Determination of the Crystal Structure

Since a unit cell contains only two cobalt atoms, they must be located at one of the two kinds of two-fold special positions: 2a and 2b. However, the former was decidedly ruled out on the basis of the packing consideration. The z-parameter of the cobalt atom was chosen to be zero without any loss of generality.

Thus the cobalt atoms are located on the threefold axis. Consequently, the complex ion [Co l-pn$_3$]$^{3+}$ must possess the symmetry 3 (C_3). The positions of the bromine atoms were easily deduced from the Patterson functions projected along the a- and c-axes. By making use of the results of the structure analyses of the related complex compounds,[3,10] a structural model of the complex ion [Co l-pn$_3$]$^{3+}$ could be easily set up. The positions of the cobalt and bromine atoms being already fixed, only the azimuthal orientation of the complex ion around the threefold axis was left to be determined. After several trials, an optimum

condition was obtained in which the discrepancy factor, $R=\sum||F_o|-|F_c||/\sum|F_o|$, became 0.26, where the summation was taken over all the observed $hk0$ data. Starting with this plausible position, the usual difference Fourier method was repeatedly applied to the (001) projection until the structure projected on this plane was completely established. An a-axis projection was also worked out at the same time. Using the results of the c-axis projection, together with the structural model quoted above, the R-factor for the $0kl$ reflections was only 0.25 for the first trial of the z-parametres, where the position of the bromine atoms was chosen so that it gave the N-Br contact of about 3.5 Å. Thus, these parameters were thought to be reasonable and essentially correct.

By the several Fourier refinements described below, the R factors were reduced to 0.12 for $hk0$ and 0.16 for $0kl$. The final refinement was performed on the full-matrix least-squares program, ORFLS, originally written by Busing, Martin and Levy, and slightly modified by Nakatsu and Sakurai to take the effect of the anomalous scattering into account. Anisotropic temperature factors were not used since the three-dimensional electron density map and the difference Fourier map did not indicate the existence of any large anisotropic thermal motions of the atoms. After three cycles of this refinement, the R value dropped and converged to 0.100. All the reflections were given the weight of 1. The extinction effect was corrected for the strongest 17 reflections. Atomic scattering curves were taken from the International Tables.[11]

In the calculations of the structure factors, the effect of the anomalous dispersion was strictly considered. The correction factors for the f-values were assumed as follows:[12]

$$\text{for Co, } \Delta f'=-2.2, \quad \Delta f''=3.9$$

and

$$\text{for Br, } \Delta f'=-0.9, \quad \Delta f''=1.5$$

In the final refinement alone was the angular dependence of these quantities[13] also taken into account.

In the calculations of the Fourier syntheses, the contributions from the anomalous scattering to the structure factors were directly subtracted from F_{obs}, whose phases were given those of F_c. The remainder was used as the Fourier coefficients; i. e.,

$$F(\text{coef.})=|F_o|\exp(i\alpha)-F_c''$$

Here α is the calculated phase factor, and F_c'' is the contribution of the correction terms of the atomic scattering factors to the structure factor. F_c'' contains only the contribution from the cobalt and bromine atoms whose positional parameters are easily fixed. At each step of the refinement, this quantity may take a different value, which is in line with the improvement of the temperature factors and also with a slight change in the position of the bromine atoms. Moreover, the scale factor of F_o may be slightly changed at each step. Therefore, these Fourier coefficients had to be re-calculated at each step of the Fourier refinement. This was made possible by successive approximation. Though such a procedure seems to be rather complicated, it takes the effect of the anomalous dispersion strictly into account, and probably it is one of the best ways to solve the problem when the correction of the anomalous scattering is necessary. A computer program was written for the entire course of calculating both the structure factors and the electron densities. The shifts of the atomic parameters were read from a Fourier map, and the results were used as the next input data for the calculation of the structure factors and electron densities.

In order to obtain the Fourier coefficients by such a procedure, it is necessary to fix the absolute sign of the z-parameters so as to calculate F_c''. Thus, the absolute structure of the crystal had also to be determined during the course of the Fourier refinement.

On oscillation photographs taken around the c-axis, the diffraction spots corresponding to hkl and $hk\bar{l}$, the latter being equivalent to $\overline{hkl}$ due to the symmetry of the space group, are recorded at the symmetrical positions on each side of the equatorial line. These two spots are not equal in intensity as a result of the breakdown of Friedel's law. If the proper indices are given to these spots, including the correct sign of l, inequality

relations between $I(khl)$ and $I(hk\bar{l})$ will be established. The sense of the c^* direction could be easily determined with the help of a Weissenberg photograph. The differences between $I(hkl)$ and $I(hk\bar{l})$ were observed by several people independently at first, and later the intensities were estimated visually by the authors. Under the present conditions, the Lorentz, polarization and absorption factors take the same value for hkl and $hk\bar{l}$ reflections. Hence, the $\sqrt{I(hkl)/I(hk\bar{l})}$ ratio is equal to the ratio of the two structure factors, i. e., $|F(hkl)|/|F(hk\bar{l})|$. Some of the observed ratios, together with the calculated ratios, are listed in Table I. The latter are based on the parameters listed in Table II. Considering the general agreement in Table I, it may be concluded that these atomic parameters correspond to the absolute structure of the (−)-[Co *l*-pn$_3$]Br$_3$ crystal. A complex ion based on these parameters is illustrated in Fig. 3. Therefore, the complex ion shown in this figure must correspond to the (−)-[Co *l*-pn$_3$]$^{3+}$ ion.

The trial model with the reversed z-parameters was checked several times during the course of the Fourier refinement in order to justify the assumption of the absolute configuration of the complex ion. The calculations of the structure factor ratios were repeated at each cycle in these refinements. After the final refinement, the R values for all the hkl reflections became 0.100. If one takes a set of parameters in which the signs of the z-parameters of all the atoms are reversed, the R value becomes 0.123. Though the difference is small in terms of the values of the R-factors, a detailed examination of individual reflections clearly excludes the possibility of the reversal of the z-parameters.

The final set of the atomic parameters, together

with their standard deviations, is shown in Table II. The standard deviations are calculated from the usual treatment of the errors, using the disagreement of the structure factors.[14] This corresponds to the standard errors of the positions of an average of about 0.007 Å for Br, 0.027 Å for N and 0.046 Å for C.

The observed and calculated structure factors are listed in Table III. In the table the asterisk * denotes those reflections which have already been corrected for the extinction effects.

A composite electron density diagram made from the sections of the three-dimensional Fourier synthesis is shown in Fig. 4. The structure projected along the a-axis is illustrated in Fig. 5.

The Description of the Structure and Discussion

The atomic arrangement in the crystal is shown in Figs. 4 and 5. The interatomic distances and bond angles are given in Table IV.

The structure is essentially ionic and consists of the positively-charged [Co l-pn_3]$^{3+}$ ions and Br^- ions. The Br–Br separation is 4.11$_2$ Å, corresponding to twice the ionic radius of Br^-. The cobalt and bromine atoms lie in approximately one

* Distances between layers.
** Distances within one layer.

14) D. W. J. Cruickshank, *Acta Cryst.*, **2**, 65 (1949).

layer, perpendicular to the *c*-axis. The whole structure can be obtained if exactly similar layers are placed on the first in such a way that they are all related by the operation of 6_3. A complex ion is surrounded by three Br^- ions within the same layer at a distance of 4.49_9 Å and by six anions at the apices of a trigonal prism. The Co atom lies approximately at the center of this prism, the Co–Br distances being 4.98_5 and 4.83_0 Å. The atomic group composed of three Br^- ions is surrounded by the complex ions in just the same way as the latter is surrounded by the anions.

There are some possibilities of the formation of weak hydrogen bonds between the Br^- and the nitrogen atoms in the propylenediamine rings. Two of the closest N–Br approaches occur at the distances of 3.36 and 3.43 Å. The directions of these close N–Br contacts are almost parallel to the *c*-axis. By these hydrogen bonds each layer seems to be held together. These distances are of the same order as those found in isoleucine hydrobromide[15] and 11-aminoundecanonic acid. $HBr \cdot 1/2H_2O$[16]. The existence of any water molecules is evidently excluded.

The complex ion has a three-fold symmetry because of the requirements of the space group. The three chelate rings must, therefore, be completely identical with each other. The CH–CH_2 bond in the chelate rings is nearly parallel to the three-fold axis of the complex ion, corresponding to the "lel" form. The shape and size of the five-membered ring, composed of Co and pn except for the methyl group, closely resembles that found in [Co en$_3$]$^{3+}$,[3-5] [$CoCl_2$en$_2$]$^+$[17] and [$CoBr_2$-en$_2$]$^+$[18]. The substituted methyl group does not disturb the overall features of the Co-en ring. The C–CH_3 bond lies in an approximately equatorial plane of the five-membered ring, in agreement with the prediction of Corey and Bailar that the equatorial orientation is of a lower energy than the axial one.[2] The shape and size of the Co-pn rings are essentially the same as those found in [$CoCl_2$ *l*-pn$_2$]$^+$.[10]

All the distances and angles within the chelate rings are normal. The Co–N separation is 2.00_0 Å, compared with 1.98—2.03 Å in [Co en$_3$]$^{3+}$ [3,5] and 1.94—2.02 Å in [$CoCl_2$*l*-pn$_2$]$^+$ [10]. Six nitrogen atoms form a slightly distorted octahedron around the central cobalt atom, the N–Co–N angle being 86.5°. The ligand molecule assumes a gauche configuration with an azimuthal angle of 51° between the planes determined by the C–C and C–N bonds.

The complex ion [Co *l*-pn$_3$]$^{3+}$ shown in Fig. 3 corresponds to the laevorotatory form with respect to the NaD lines. This form can be denoted as the L*lll* configuration.

If three methyl groups of L-(−)-[Co *l*-pn$_3$]$^{3+}$ are replaced by hydrogen atoms, the absolute configuration of the complex ion L-[Co en$_3$]$^{3+}$ is obtained. The latter is known also to be laevorotatory with respect to the NaD lines.[3,4] Smirnoff found that the ORD curves of (−)-[Co en$_3$]$^{3+}$ and (−)-[Co *l*-pn$_3$]$^{3+}$ correspond well to one another.[9] From this fact it has been deduced, without verification, that these two ions would possess the same absolute configuration; that is, the latter would also take the L-form. The present investigation has revealed that this is actually the case. Thus, the conventional method of correlating the absolute configurations with the ORD curves has been proved for the first time to be useful and reliable.

The absolute configuration of the propylenediamine, which has an asymmetric carbon atom in the molecule, could be determined at the same time. The result corresponds to the configuration correlated to D-alanine, which is in agreement with the previous conclusion about [$CoCl_2$ *l*-pn$_2$]$^+$ [10] and also with the chemical convention[6,7].

One of the most important conclusions of this study is that the absolute configuration of a series of tris(bidentate)-complexes can be successfully correlated to the configurational series in organic compounds. The complex ion [Co en$_3$]$^{3+}$, which is the simplest and the most familiar of the tris-(bidentate)-complexes, has been correlated to the *l*-pn and, consequently, to the whole system of the organic compounds through the intermediation of the absolute configuration of [Co *l*-pn$_3$]$^{3+}$. This was possible because the complex ion possesses a remarkable stereospecificity.[2] When three bidentates, en or pn, are co-ordinated to the cobalt atom, the central C–C bonds prefer the "lel" configuration to the oblique one. In the five-membered chelate rings, the C–CH_3 bond has a tendency to take the equatorial configuration rather than the axial one. Furthermore, the complex ion seems to favor the highest attainable symmetry, so that the three bidentates become identical with each other, as was pointed out by Jaeger et al.[19] If one accepts these three conditions, there is only one way in which three molecules of the *l*-pn can be co-ordinated to the cobalt atom. It may readily be seen that the resultant complex ion must assume the L-form shown in Fig. 1. These results are expected to be applied to the whole series of tris-(bidentate)-complexes. Investigations along these lines are now in progress for crystals of [Co cptn$_3$]$X_3 \cdot 4H_2O$ and [Co chxn$_3$]$X_3 \cdot 4H_2O$.

The calculations of the structure factors and electron densities were carried out on the PC 2

The Alkaline Sulfide Reduction of Aromatic Nitro Compounds. VII. The Induction Period of the Sodium Monosulfide Reduction of Sodium *m*-Nitrobenzene Sulfonate*

By Shizunobu HASHIMOTO and Junzo SUNAMOTO

Department of Applied Chemistry, Doshisha University, Karasuma-imadegawa, Kamikyo-ku, Kyoto

(Received May 15, 1965)

In the sodium monosulfide reduction of sodium *m*-nitrobenzene sulfonate, an induction period appears. The present investigation was undertaken in order to determine the causes of this induction period. The induction period is due not to the nitro compound, but to the reducing agent. The induction period is shortened by means of irradiation by ultraviolet light, the addition of potassium persulfate, ferric chloride, and α,α'-azobisisobutyronitrile, or under atmospheric conditions. On the other hand, the addition of phenol or alcohol lengthens the induction period. Further, on the basis of polarographic and spectroscopic studies of the induction period, it has been suggested that soduim disulfide is produced during this induction period. On the basis of these data, it seems reasonable to assume that, in the reduction of aromatic nitro compounds by sodium monosulfide, the reducing power of monosulfide is very small in itself, and that the nitro group is reduced by the disulfide produced by the radical oxidation of monosulfide. The formation of the sulfide ion radical and its dimerization appear to be responsible for the induction period of this reaction.

In an earlier presentation dealing with the kinetic studies of the alkaline sulfide reduction of sodium *m*-nitrobenzene sulfonate,[1] we reported that an induction period appeared in the sodium monosulfide reduction.

Although the alkaline sulfide reduction of aromatic nitro compounds is of much preparative significance, very little work has been carried out on it from the standpoint of reaction kinetics. One of the few available publications, with the exception of our own studies, is that of Goldschmidt and Larsen,[2] who measured the electric conductivity of the medium and followed the disappearance of sodium *m*-nitrobenzene sulfonate. However, they mistook the hydrosulfide for the monosulfide; when the aqueous monosulfide was prepared, gaseous hydrogen sulfide was introduced into the aqueous sodium hydroxide solution until the color of phenolphtalein disappeared. As sodium monosulfide undergoes hydrolysis, as is shown in Eq. 1, the sulfide which was prepared by Goldschmidt and Larsen is, then, hydrosulfide.

$$S^{2-} + H_2O \rightleftarrows SH^- + OH^- \qquad (1)$$

Another publication is that of Hojyo et al.,[3] who reported that the rate of the sodium monosulfide reduction of nitrobenzene in a 70 vol.% aqueous methanolic solution was too slow for the reaction to be followed kinetically. It may be supposed that they here observed the induction period which we later established.

The present investigation was undertaken in order to determine the causes of the appearance of the induction period in the sodium monosulfide reduction.

Experimental

Materials.—All the reactants and solvents were obtained commercially or by standard methods of preparation and were used after careful purification, either by distillation or by recrystallization. Sodium disulfide was freshly prepared by the method described in a previous paper.[4]

* Presented at the 18th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1965.

Typical Procedure for Rate Measurements.—Appropriate amounts of a solvent, a nitro compound, and additives were placed in a 1000-ml. three-necked flask equipped with a reflux condenser, an outlet tube, and a nitrogen inlet tube with a trap containing the same solvent as the reaction flask. The flask was then immersed in a thermostat regulated and flushed by nitrogen at given temperatures for half an hour. The reaction was commenced by introducing a definite amount of an aqueous solution of sodium monosulfide which had previously been warmed to the reaction temperature. At appropriate time intervals aliquots (20 ml.) were withdrawn, poured into 20 ml. of a hydrochloric acid aqueous solution (1 : 2), and then warmed on a steam bath for half an hour.

Procedures for Irradiation.—In order to irradiate with ultraviolet light, a low-pressure mercury vapor lamp (2537 Å, 15 W.) was placed in the reaction flask; on the other hand, in order to irradiate with visible light, a National FCL-30D-SDL fluorescence lamp (4000—4500 Å, 20 W.) was set up at a distance of ca. 3 cm. from the reaction flask.

Analytical Procedures.—The above-mentioned acidic solutions were cooled below 10°C with ice, and the quantities of amine produced were determined by diazotizing titration according to the usual method.

Irradiation on an Aqueous Sodium Monosulfide Solution.—About 1000 ml. of a 1.33 mol./l. sodium monosulfide aqueous solution was placed in a flask equipped with a high-pressure mercury vapor lamp (3500—4000 Å, 100 W.), a reflux condenser, and an outlet tube. The flask was immersed in a thermostat regulated at 37—38°C, and then the internal atmosphere was substituted for nitrogen sufficiently. At appropriate time intervals samples were pressed out by nitrogen. The reaction was followed by the usual methods of acidimetry and iodometry and by polarography, as has previously been described.[4] The ultraviolet absorption spectra were run on a SHIMADZU Beckmann-type Model-DU spectrophotometer, while the visible absorption spectra were run on a SHIMADZU BAUSCH & LOMB Spectronic 20 photometer. Both absorption spectra were compared with that of an authentic solution of sodium disulfide. The coincidence was satisfactory.

Results and Discussion

The first investigation was undertaken in order to examine which species, the nitro compound or the reducing agent, exhibits an induction period in the reduction with sodium monosulfide. The results when the initial concentrations of the nitro compound and sodium monosulfide were changed with a varying molar ratio of the two reactants are shown in Figs. 1 and 2. The initial concentration of the reducing agent had an effect on both terms, the induction-period intervals and the rate of the main reaction. However, the initial concentration of the nitro compound had an effect only on the main reaction. It may, therefore, be concluded that the induction period is due not to the nitro compound, but to the reducing agent. Further, when nitrobenzene was used instead of sodium *m*-nitrobenzene sulfonate in the sodium monosulfide reduction, though the rate of the main reaction became slower, the induction period was certainly observed.

The rate of the main reaction is given by runs in which the initial concentrations of the nitro compound and sodium monosulfide were interchanged; it is certain that the rates can be expressed by Eq. 2:

$$d(Ar\text{–}NH_2)/dt = k_3(Ar\text{–}NO_2)(Na_2S)^2 \qquad (2)$$

This equation is the same as that given for the sodium hydrosulfide reduction in a previous presentation.[1]

Some complementary data on the induction-period intervals and the calculated apparent

third-order rate constants are shown in Table I.

The Effect of Light.—The effect of light on the induction period was also investigated. As is shown in Fig. 3, the induction periods were shortened by means of the inside irradiation of ultraviolet light and the outside irradiation of visible light, compared with the dark reaction. Of course, the effect was far better in the former, In neither case, however, was any effect on the main reaction observed.

On the basis of these data, it is reasonable to assume that the induction period contains a radical reaction, but the main reaction perhaps contains an ionic reaction.

Barret and his co-workers presented evidence that the sulfate ion radical was formed by the irradiation by ultraviolet light of an aqueous or methanolic sulfate solution.[5] It may be similarly

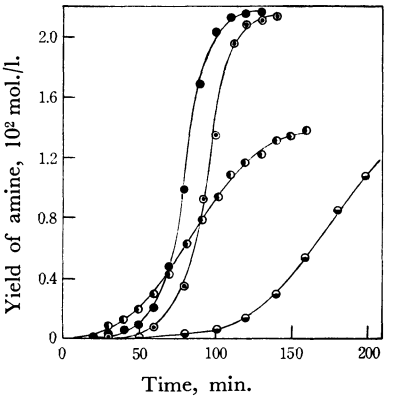

Fig. 3. Effect of light.

⊙ : Exp. No. 17
● : Exp. No. 18

5) J. Barret, M. F. Fox and A. L. Mansell, *Nature*, **200**, 257 (1963).

reasonable to assume the following processes for the formation of the sulfide ion radical:

$$(S^{2-}H_2O) \xrightarrow{h\nu} (S\cdot^{-}H_2O^{-})^{*}$$
$$\rightarrow S\cdot^{-} + H\cdot + OH^{-} \quad (3)$$

The disulfide ion is immediately produced by the coupling of two sulfide ion radicals:

$$2S\cdot^{-} \rightarrow (S\text{-}S)^{2-} \quad (4)$$

Therefore, it was supposed that the reduction of the nitro group was proceeded by that of the disulfide ion produced.

The Effect of the Solvent.—Figure 4 shows that the induction-period intervals are longer in an aqueous alcoholic solution than in an aqueous solution. It can be considered that the sulfide ion radical was deactivated by the solvent.

$$S\cdot^{-} + \text{Solvent} \rightarrow \text{Deactivated species} \quad (5)$$

It is well known that the α-hydrogen of alcohol is more easily abstracted by the radical than is the hydrogen of water.[6] Also, the rate of the main reaction became a little solwer in an aqueous alcoholic solution than in an aqueous solution. This observation may be reasonable since the solubility of sodium *m*-nitrobenzene sulfonate is decreased, and the diminished solvent polarity may also be responsible.

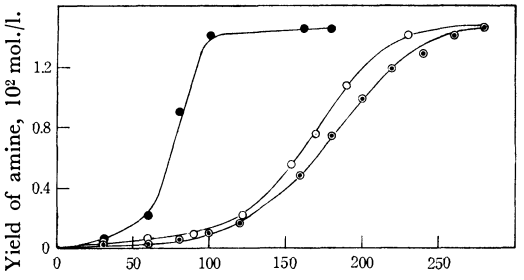

Fig. 4. Effect of solvent.
● : Exp. No. 8 in Table I
⊙ : Exp. No. 9
○ : Exp. No. 10

The Effect of Air.—Figure 5 shows that the induction period was only a little, though obvioulsy, shortened under the atmospheric conditions than a nitrogen atmosphere. It was earlier known that the oxidation of aqueous sodium sulfite is an auto-oxidation,[7] and that it is very sensitive to light and air in a chain oxidation process.[8] It may be reasonable to assume that the effect of air on the auto-oxidation of a sodium monosulfide solution is the same as on the auto-oxidation of a sodium sulfite solution; it may also be reasonable to suggest that the processes is as follows, for example:

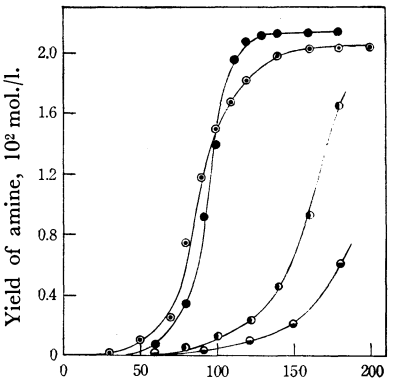

Fig. 5. Effect of air.
⊙ : Exp. No. 17 in Table I
● : Exp. No. 19
◒ : Exp. No. 21
◐ : Exp. No. 22

$$S\cdot^{-} + 3O \rightarrow SO_3\cdot^{-} \quad (6)$$

$$SO_3\cdot^{-} + S^{2-} \rightarrow SO_4^{2-} + S\cdot^{-} \quad (7)$$

In this case, however, it is necessary to reduce the rate of the main reaction with the air oxidation of the sodium disulfide produced.

The Effect of Sodium Disulfide and Sodium Thiosulfate.—The effects of the oxidation products of sodium monosulfide were also investigated. The addition of a catalytical amount of sodium disulfide made the induction period disappear. It may be reasonable to assume that the disulfide ion will make up for the sulfide ion radical, as in Eq. 8, and may be useful as an initiator:

$$(S\text{-}S)^{2-} \rightarrow S\cdot^{-} + S\cdot^{-} \quad (8)$$

However, the addition of sodium thiosulfate had scarcely any effect on the induction period or on the main reaction.

The Effect of ABIN and Phenol.—The addition of ABIN (α,α'-azobisisobutyronitrile) shortened the induction period, but it had scarcely any effect on the rate of the main reaction. On the other hand, the addition of phenol, which is often used as an inhibitor or a retarder for a radical reaction,[9] made the rate of the over-all reaction much slower.

The Effect of Potassium Persulfate and Ferric Chloride.—The salt of some metals of a variable valency is used as a radical source for a polymerization in an aqueous solution, such as a redox polymerization or an emulsion polymerization. If the induction period is due to the radical oxidation of sodium monosulfide to sodium disulfide,

6) C. F. Wells, *Trans. Faraday Soc.*, **57**, 1703 (1961).
7) N. N. Semenov, "Some Problems of Chemical Kinetics and Reactivity," translated by J. E. S. Bradley, Vol. I, Pergamon Press, New York (1958), p. 178.

9) P. G. Ashmore, "Catalysts and Inhibition of Chemical Reactions," Butterworth, London (1963), p. 266.

as was previously assumed, it may naturally be supposed that these salts have an effect on the induction period. In fact, the addition of a catalytical amount of potassium persulfate or ferric chloride shortened the induction period, as is shown in Fig. 6. When both salts were used together, it shortened it greatly.

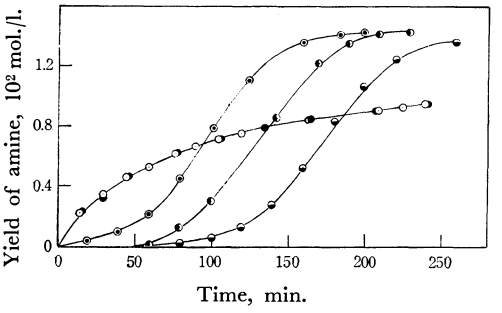

Fig. 6. Effect of ferric chloride.
◒ : Exp. No. 1 in Table I
◐ : Exp. No. 3
⊙ : Exp. No. 4
○ : Exp. No. 6
● : Exp. No. 7

At the present time, the sulfide ion radical is believed to be formed as follows:

$$Fe^{3+} + 2S^{2-} \rightarrow Fe^{2+} + 2S\cdot^{-} \quad (9)$$

$$S_2O_8^{2-} + S^{2-} \rightarrow SO_4^{2-} + SO_4\cdot^{-} + S\cdot^{-} \quad (10)$$

$$SO_4\cdot^{-} + S^{2-} \rightarrow SO_4^{2-} + S\cdot^{-} \quad (11)$$

In a system containing potassium persulfate and ferrous chloride, the formation of the ion radical is believed to start as follows[10]:

$$Fe^{2+} + S_2O_8^{2-} \rightarrow Fe^{3+} + SO_4^{2-} + SO_4\cdot^{-} \quad (12)$$

Ion radicals derived from the salts of these metals of a variable valency may exchange electrons with stable species and thereby form active-ion radicals in, e. g., the reaction of a sulfide with a salt of a trivalent iron. In this case an electron is transferred from the monosulfide ion to the ferric ion, producing the highly-active radical ion; this active-ion radical immediately dimerizes to disulfide, as in Eq. 4.

These reduction-oxidation systems, then, shortened the induction period due to the auto-oxidation of monosulfide to disulfide; the oxidation appeared to proceed even in the dark if traces of these salts were present.

On the other hand, in no case did the addition of these catalysts have any effect on the main reaction. The addition of ferric chloride in the sodium disulfide reduction, in fact, had no effect at all on its reduction rate.

When persulfate is used as a catalyst for a usual reaction, thiosulfate, as well as ferrous or ferric ion, is used as a promoter.[11] In the alkaline sulfide reduction of aromatic nitro compounds, thiosulfate, which is an oxidation product of sulfide, is certainly produced; therefore, it may be reasonable to assume that the reduction of persulfate by thiosulfate occurs. However, as disulfide or monosulfide has a far larger reducing power than thiosulfate,* there is no need to consider the effect of thiosulfate.

The Effect of pH.—In an aqueous solution the monosulfide undergoes hydrolysis, as Eq. 1 shows. Therefore, it may be considered that the pH will also have a large effect on the induction period. As is shown in Fig. 7, the addition of neither sodium hydroxide nor sodium hydrogen carbonate had, in fact, any effect on the induction period; rather, each had a large effect on the main reaction. Between the monosulfide ion and the hydrosulfide ion, we could not determine which species is more rapidly oxidized to the disulfide ion.

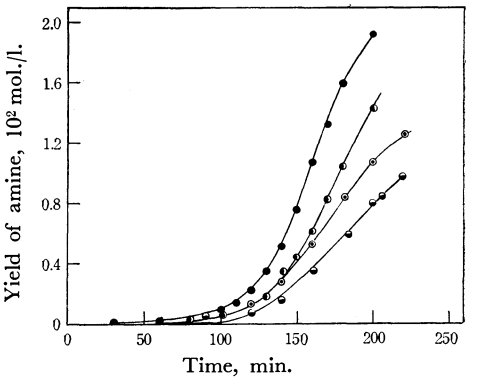

Fig. 7. Effect of pH.

● : Exp. No. 14

Hojyo et al.,[3] stated that, in the reduction of nitrobenzene by sodium disulfide in a 70% aqueous methanolic solution, the rate of reaction shows a first-order dependence on the hydroxide ion concentration. They also stated that the reaction mechanism involved an attack by the disulfide ion, which is the kinetically effective species, on the positive nitrogen of the nitro group in conjunction with the hydrolytic equilibrium of the disulfide ion:

$$S_2^{2-} + H_2O \rightleftarrows S_2H^{-} + OH^{-} \quad (13)$$

10) J. W. L. Fordham and H. L. Williams, *J. Am. Chem. Soc.*, **73**, 4855 (1951).

11) D. Dunn, *Trans. Faraday Soc.*, **42**, 190 (1946).

* Their mercury anodic oxidation potentials clearly show this difference in reducing power.

The effect of the pH on the main reaction in our experiments may be similarly analyzed.

The Irradiation of an Aqueous Sodium Monosulfide Solution.—In order to examine the above hypothesis in detail, the irradiation of an aqueous sodium monosulfide solution was investigated. An aqueous solution of pure sodium monosulfide is colorless, but an aqueous disulfide solution is yellow.[12] When the monosulfide solution was irradiated, it turned yellow. Figure 8 shows that the absorption at 360 mμ, which is not observed before irradiation, appears upon irradiation and thereafter gradually increases in intensity. After a long irradiation its position and the intensity of the maximum absorption of irradiated monosulfide were essentialy identical with those of disulfide which had not been irradiated. The polarograms of the irradiated monosulfide solution support the discussion of the results of spectrophotometry.

Conclusion

In view of the above facts, the most reasonable conclusion to be drawn from the available data is as follows. In the reduction of aromatic nitro compounds by sodium monosulfide, the reducing power of monosulfide is very small in itself, and the reduction of the nitro compound hardly proceeds at all. However, after the formation of disulfide by the radical oxidation of monosulfide, which involves the dimerization of the sulfide ion radical, the reduction of the nitro group is furthered by the disulfide produced. This step, containing of the formation of the sulfide ion radical and its dimerization, appears as the induction period in the sodium monosulfide reduction of aromatic nitro compounds.

Thanks are due to Mr. Takao Shima for his assistance in some of the experimental work. The authors are also indebted to the Daiwa Dyestuff Co., Ltd., for its gift of materials.

Studies on Long Chain Alkyl Amides of Water-soluble Poly-α-amino Acids. III. The Association of Poly-DL-alanine Dodecylamides in Aqueous Solution

By Shoichi IKEDA, Masakazu MAEKAWA* and Toshizo ISEMURA

Department of Biology, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received May 15, 1965)

Poly-DL-alanine dodecylamide, prepared by the polymerization of *N*-carboxy-DL-alanine anhydride with dodecylamine initiation at different anhydride-to-initiator ratios, ([A]/[I]), is soluble in aqueous hydrochloric acid solutions to form micelles. Its micellar properties at pH 2.0 have been investigated by means of hydrodynamic methods. The material prepared at [A]/[I] 5 has a critical micelle concentration around 0.2—0.3 g. dl^{-1}, which can be detected by Archibald sedimentation measurements. The micelle has been determined by the Archibald method to consist of about 13 monomer molecules. The molecules in the micelle are hydrogen bonded intermolecularly to form a structure similar to the β-conformation. Hydrogen bonding

* Present address: Mitsubishi Paper Mills, Inc., Takasago, Hyogo.

between peptide groups is more important for the micelle formation than hydrophobic bonds between dodecyl groups. The materials prepared at [A]/[I] 15 and 20 associate into large micelles, consisting of about 320 and 240 monomers respectively, as deduced from the sedimentation and viscosity measurements. The micelles exhibit even a flow birefringence. The structure of micelles seems to be a disordered one composed of randomly coiled monomer molecules; intermolecular hydrogen bonding and hydrophobic bonding are cooperative in its stabilization.

A series of amphipathic polypeptides, poly-DL-alanine dodecylamide (PADA) with degrees of polymerization from 5 to 30, has been synthesized by the polymerization of *N*-carboxy-DL-alanine anhydride with dodecylamine initiation, and their physical chemical properties have been investigated in relation to the degree of polymerization.[1,2] PADA is soluble in aqueous hydrochloric acid solution of pH below 5.5, and the surface tension of its aqueous solution decreases considerably with the concentration. The surface activity of PADA decreases with increasing the degree of polymerization, but the lowest molecular weight PADA behaves like a typical amphipathic substance or a surface active agent. It is then expected that PADA molecules will be associated in aqueous solution to form micelles.

It has been accepted that intermolecular hydrophobic bonds, which should be strong between long chain alkyl groups, are important as a cohesive force for micelle formation. In the case of PADA, an additional cohesion, i. e., intermolecular hydrogen bonds between peptide groups, will also contribute to the stability of its micelle. Therefore, the effect of hydrogen bonding should be reflected in the associated states of PADA molecules such as the size of micelle. While PADA has a constitution somewhat similar to that of polyoxyethylene dodecyl ether, the latter being unable to form intermolecular hydrogen bond, it would be of interest to examine the micellar properties of PADA in comparison with those of polyoxyethylene dodecyl ether.

In the present work, the micellar properties of PADA in aqueous hydrochloric acid solutions have been investigated by means of measurements of viscosity, sedimentation and flow birefringence. It was found that the association of PADA is specifically dependent on its degree of polymerization. Since it has been confirmed[3] that poly-DL-alanine is molecularly dispersed in an aqueous solution, the hydrophobic force between dodecyl groups is operative and important in the association of PADA as in the other amphipathic substances; here evidence was also obtained that intermolecular hydrogen bonding between peptide groups also exerts a profound effect on the micellar association. The size and structure of the micelles were discussed in the light of the intermolecular forces and the molecular conformation.

Experimental

Materials.—PADA was synthesized by the polymerization of *N*-carboxy-DL-alanine anhydride by dodecylamine initiation in dioxane.[1] The anhydride-to-initiator molar ratio, [A]/[I], was varied from 5 to 20, to obtain PADA samples with different degrees of polymerization.

Titration of Terminal Amino Groups.—To obtain the number-average degree of polymerization of PADA, the anhydrous titration of terminal amino groups were carried out.[4] About 3 mg. of PADA were dissolved in 1 ml. of a formic acid - acetic acid (1 : 9 v/v) mixture, and the solution was titrated to a blue point of crystal violet with 0.05 N perchloric acid dissolved in acetic acid. The blank titer was then subtracted from the solution titer. The mixed solvent was used, because the indicator color was blue in formic acid even without any titer, and also because PADA was insoluble in acetic acid alone.

Preparation of Aqueous Solutions.—Almost all the experiments were made with PADA solutions in aqueous hydrochloric acid at pH 2.0. The pH's of the solutions were adjusted by the addition of hydrochloric acid a day after solutions were made. Solutions of different concentrations were prepared by diluting a ca. 1 g. dl^{-1} stock solution with water and by readjusting the pH's with hydrochloric acid. The pH values were measured by a Horiba Model H pH-meter. Each solution was filtered through a No. 4 glass filter before use.

Electric Conductivity.—The specific conductances were measured at 25°C with a Yanagimoto MT-7 Conductivity Bridge. The electrodes of a conductivity cell were made of white platinum, since platinized platinum electrodes blocked the electric current completely because of the adsorption of PADA on their surfaces. The cell constant was 0.450, as calibrated by 0.01 M potassium chloride.

Density.—The densities of the solutions were determined at 25°C by an Ostwald type pycnometer with a volume of 3 ml. The partial specific volume of PADA, $\bar{v}$ (ml. g^{-1}), was calculated from the equation

$$\rho = \rho_0 + (1 - \bar{v}\rho_0)c$$

where ρ (g. ml^{-1}) is the density of the solution at a given concentration, c (g. ml^{-1}), and ρ_0 (g. ml^{-1}) is the density of the solvent, i. e., of 0.01 N hydrochloric acid.

Viscosity.—An Ubbelohde type viscometer with a flow time 140 sec. for water was used for the viscosity measurements. The relative viscosities were referred to 0.01 N hydrochloric acid at 25°C.

Sedimentation. — *The Archibald Method.* — The Archibald method[5-7] was adapted to the determination of the micellar molecular weight of PADA [A]/[I] 5. The measurements were performed in a Hitachi UCA-1 Analytical Ultracentrifuge using a schlieren optical system. A piece of stretched human hair was drawn in place of a schlieren diaphragm. The rotor speed read by an odometer was 41000 r. p. m., and the temperature measured by a radiation thermocouple was 30±1°C. The solutions were centrifuged in a standard cell, putting a thin layer of Dow-Corning Silicone 555 at the cell bottom.[8] Photographic films were enlarged tenfold on an Olympus Model CP-20 Precision Contour Projector and traced on graphic paper. For the calibration of the schlieren pattern to the concentration scale, a synthetic boundary cell of the Pickels type was utilized.

Sedimentation Velocity.—The sedimentation coefficients of PADA [A]/[I] 15 and 20 were determined in a Spinco Model E Analytical Ultracentrifuge using a schlieren optical system. The rotor speed was 44770 r.p.m. The sedimentation coefficients were reduced to those at 25°C by the correction of the solvent viscosity coefficients.

Flow Birefringence.—Both the extinction angles and the birefringences were measured in a Rao Flow Birefringence Instrument, Model 7-B. The birefringence was determined at 517 mμ of a zirconium lamp. The rotor speed was read by counting the speed of the driving motor with a tachometer.

Refractive Index Increment.—The refractive index increments at 547 mμ were measured in a Shimadzu Differential Refractometer of the Debye type against 0.01 M hydrochloric acid at 25°C.

Results

Characterization.—PADA is soluble in formic acid, dichloroacetic acid, phenol and *m*-cresol, in which it will be molecularly dispersed without association. The determination of the molecular weight of PADA in these solvents, however, involves numerous difficulties.* Therefore, the number of terminal amino groups was determined by the anhydrous titration to estimate an approximate number-average degree of polymerization. As is shown in Table I, the degree of polymerization, x_{NH_2}, derived from the number of amino groups is almost equal to the [A]/[I] value, indicating that the synthetic procedure can be well controlled in obtaining PADA of desired molecular weight. The number-average degree of polymerization, x_n, was thus assumed to be equal to the [A]/[I] value. The weight-average degree of polymerization, x_w, was estimated from the number-average one, assuming that the molecular weight distribution follows the Poisson distribution.[12] The results are summarized in Table I.

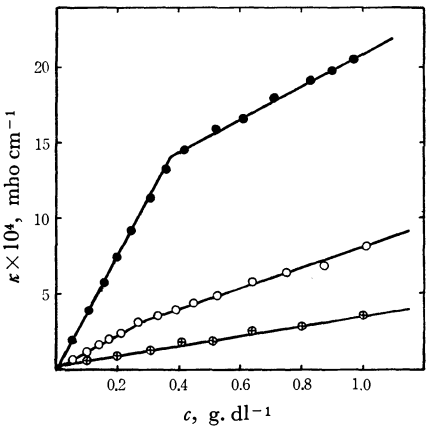

Fig. 1. Specific conductances of PADA solutions at pH 5.0.
○, [A]/[I] 5; ⊕, [A]/[I] 15; ●, dodecylammonium chloride in water

The specific conductances of PADA solutions at pH 5.0 are shown in Fig. 1, together with those of dodecylammonium chloride in water. The latter data are in accord with the published ones.[13] On the conductance curve of PADA [A]/[I] 5, a break similar to the critical micelle concentration (CMC) for dodecylammonium chloride appeared. The CMC of PADA [A]/[I] 5 was found to be 0.295 g. dl^{-1} or 5.4×10^{-3} M. A similar break was observed in the surface tension curve.[1] The CMC was somewhat lower as the pH was lowered.

The [A]/[I] 10 preparation was unstable in an aqueous solution. Its relative viscosity markedly increased with the time elapsed after the solution

* The application of the Archibald method was limited by such factors as the negative value of the $1-\bar{v}\rho_0$ term in organic acids, as has been observed elsewhere,[9] the corrosive nature of these acids against the available cell materials and the high viscosity of *m*-cresol. The freezing point depression in formic acid or phenol was much larger than that to be expected from the [A]/[I] value and it was also strongly dependent on the concentration in a dilute region, probably because PADA is ionized at its terminal amino groups or at each peptide group, as has been noted in polyamides.[10,11]

was made up, and it did not settle within several days. The sedimentation pattern of the same solution consisted of many discrete peaks. Thus this preparation was not investigated further.

The reduced viscosities of PADA of solutions at pH 2.0 are shown in Fig. 2. The values of the intrinsic viscosities, $[\eta]$, are given in Table II together with those of the partial specific volumes. The latter was also calculated from the partial molar volumes of the constituent atoms.[14] Assuming the micelles to be unhydrated ellipsoids of revolution, the axial ratios of the PADA micelles were estimated from the intrinsic viscosities and partial specific volumes by means of the Simha's equation.[15]

* Values in parentheses were calculated from molar volumes of constituent atoms.[14]
** Data in distilled water.

The electrostatic effect of ionized terminal groups has not been taken into account in all cases, since it seems likely that a good amount of hydrochloric acid exists to suppress the effect, at least, at pH 2.0.

The Association of PADA [A]/[I] 5.—The Archibald method of sedimentation is based on the fact that the equation for sedimentation equilibrium is formally satisfied at both the meniscus and the bottom of a solution in a sedimentation cell, irrespective of the time of centrifugation. If a solution is centrifuged in a cell with an angular velocity, ω (sec^{-1}), and if the concentration at a distance, r (cm.), from the rotor axis is given by c (g. ml^{-1}) at time t, the apparent molecular weight at the meniscus or the bottom can be obtained by the equation[5-7,16,17]:

$$M_{app}(t)=\frac{\boldsymbol{R}T}{\omega^2(1-\bar{v}\rho)}\left(\frac{dc/dr}{rc}\right)_{m \text{ or } b}$$

where T is the temperature and $\boldsymbol{R}$ is the gas constant. The suffix m or b denotes the meniscus or the bottom. For a given initial concentration, c_0 (g. ml^{-1}), $M_{app}(t)$ can be evaluated from the schlieren pattern at any time, t, and then extrapolated to zero time to obtain $M_{app}(0)$ for c_0. The extrapolation is usually performed by postulating a linear relation of $M_{app}(t)$ with t. The apparent molecular weight, $M_{app}(0)$, obtained in this way should be equal at both the meniscus and the bottom; it can be related to the weight-average molecular weight, M_w, of the solute by

$$M_{app}{}^{-1}(0)=M_w{}^{-1}+2Bc_0+\cdots$$

where B is the second virial coefficient.

The determination of the micellar molecular weight of PADA [A]/[I] 5 is somewhat complicated, since it has the CMC. The validity of the Archibald method has been demonstrated even for association-dissociation systems, whether the conversion velocity is fast or slow.[18] However, as far as monomers and micelles coexist in a solution, the usual procedure of the Archibald method, as described above, can not be applied; an extrapolation must be made to the CMC rather than that to an infinite dilution. A similar procedure has been widely adopted in the case of light scattering in micellar solutions.[19-21] In the Archibald method the values of CMC and $\{(dc/dr)/r\}_{CMC}$ must be first determined from the plots such as those of $\{(dc/dr)/r\}_{m \text{ or } b}$ against c_m or c_b, in order to obtain the micellar molecular weight. However, these values could not be determined very accurately for the present system, probably because the rates of the mutual conversion between monomers and micelles were not sufficiently fast as compared with the sedimentation velocities, so that the values $M_{app}(t)$ were not independent of the initial concentration.

Consequently, the usual procedure was first adopted for the determination of the molecular weight. Nevertheless, it gave an approximate

value for the CMC. The plots of $M_{app}(t)$ against t were drawn for different initial concentrations and the curves were extrapolated to zero time of centrifugation to obtain $M_{app}(0)$. They are shown in Fig. 3. Linear extrapolation was always possible at the cell bottoms, but the slopes of the straight lines varied from negative to positive as the inital concentrations were lowered. On the other hand, some of the plots at the menisci were not linear but upward convex: they initially rise up and then fall gradually with time. Then the intercept at zero time at the meniscus can be made coincident with that at the bottom, thus giving an identical value of $M_{app}(0)$ for a given initial concentration. Such anomalous behavior may be qualitatively explained in the following way.

In general, the fractionation effect of a polydisperse system under centrifugal field results in a decrease in $M_{app}(t)$ with time at the meniscus and in its increase at the bottom. On the contrary, the non-ideality of the system has an opposite effect on the change in $M_{app}(t)$ with time.[16,17] In the present system, however, the micelle formation at the bottom or the dissociation of micelles into monomers at the meniscus seems to be more important than the fractionation effect. At the bottoms for high initial concentrations, the decrease in $M_{app}(t)$ with time can be ascribed to the non-ideality of the micellar solutions. For the lowest initial concentration investigated, the concentration at the bottom increases with time, reaching and then exceeding the CMC after some time of centrifugation; micelles are formed and accumulate there to increase the $M_{app}(t)$ value with time. At the intermediate initial concentration, the micelle-forming effect compensates for the non-ideality of the micellar solution, and $M_{app}(t)$ becomes practically independent of the time.

The initial rise in $M_{app}(t)$ at the meniscus can also be attributed to the non-ideality of the micellar solution. The decrease in $M_{app}(t)$ after some time reflects the dissociation of micelle into monomers through the CMC region. At the lowest initial concentration, the curve monotonously decreases with time, suggesting the dissociation of micelle into monomers. Near the CMC or even above it, micelles leaves the meniscus faster than monomers, and the dilution at the meniscus brings about the dissociation of the remaining micelles; thus $M_{app}(t)$ decreases with time. These results indicate the presence of rather a broad concentration region for micelle formation.

After such a justification for the non-linear relation of $M_{app}(t)$ with t, the same intercept, $M_{app}(0)$, can be derived from both the meniscus and the bottom.* Then the intercept, $M_{app}(0)$, was plotted against c_0, as is shown in Fig. 4. The curve clearly indicates[22] that the CMC locates around 0.3 g. dl^{-1}. The linear part of the curve is extrapolated to the CMC The intercept gives

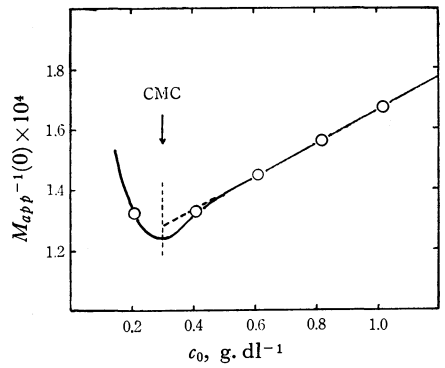

Fig. 4. The $M_{app}^{-1}(0)$ versus c_0 curve of PADA [A]/[I] 5 solutions at pH 2.0.

* There is no reason, however, to have an identical value for $M_{app}(0)$ at the meniscus and at the bottom, epecially for the present system. Solute molecules adsorbed at the meniscus, i. e., at the air-water interface, need not necessarily have an identical apparent molecular weight with that in solution or at the bottom, for they may have different conformations or different associated states.

TABLE III. MICELLAR PROPERTIES OF PADA [A]/[I] 5 (B4201)

CMC g. dl^{-1}	M_w	m (Number of association)	B mol. ml. g^{-1}
0.3	7700	13	2.5×10^{-3}

the weight-average molecular weight of the micelle, while the slope gives its second virial coefficient, omitting some contribution of the monomers present. The micellar molecular weight and the second virial coefficient of PADA [A]/[I] 5 obtained in this way are listed in Table III. The molecular weight, 7700, or the number of association, 13, is very small as compared with that of the corresponding derivatives of polyoxyethylene.[23-25]

A method similar to that described above was applied to a solution of 1.0 g. dl^{-1} at pH 5.0; it gave a value of $M_{app}(0)$ 3300. The micellar molecular weight would be lower than that at pH 2.0, even if the second virial coefficient is taken into account. Hence, lowering the pH serves merely to promote the association of PADA; free hydrochloric acid would act to suppress the electrostatic interaction.

The Association of PADA [A]/[I] 15 and 20. —The sedimentation velocities of PADA [A]/[I] 15 and 20 in solution were both sufficiently high, even at low rotor speeds. The sedimentation pattern of PADA [A]/[I] 15 consisted of two components, one amounting to about 95% and the other appearing as a faster shoulder. The shoulder is probably a remnant of discretely heterogeneous aggregates, as was observed in the [A]/[I] 10 preparation. PADA [A]/[I] 20 gave a symmetrical peak. The sedimentation coefficients of the main peaks are plotted against the concentration in Fig. 5. From the extrapolation to infinite dilution,

TABLE IV. MICELLAR PROPERTIES OF PADA [A]/[I] 15 AND 20

[A]/[I]	$s^0_{25°}$ / S	Simha-Perrin	M	m	Scheraga-Mandelkern M	Scheraga-Mandelkern m
15 (B4203)	12.5	Prolate	509000	340	477000	320
		Oblate	599000	400		
20 (B4204)	12.1	Prolate	468000	250	447000	240
		Oblate	576000	310		

the sedimentation constants, $s°$, were obtained; they are given in Table IV.

Assuming the micelles to be unhydrated ellipsoids of revolution, and omitting the contribution of minor components in the [A]/[I] 15 preparation, the micellar molecular weights were estimated by means of the Simha-Perrin tretament.[15,26,27] The values for both prolate and oblate ellipsoids are listed in Table IV. They may be limits of the micellar molecular weights. Alternatively, assuming the micelles to have a structure similar to random coils, the Scheraga-Mandelkern equation[28]

$$M^{2/3}=\frac{N s^0[\eta]^{1/3}\eta_0}{\beta(1-\bar{v}\rho_0)}$$

can give another estimate of the micellar molecular weights, as is also given in Table IV. Here η_0 is the viscosity coefficient of the solvent, N the Avogadro number and β is a shape factor having a value of 2.5×10^6 for random coils.

The micellar molecular weights obtained by the Scheraga-Mandelkern treatment are rather in better agreement with those obtained by the Simha-Perrin treatment for the prolate ellipsoidal model, although the latters are extreme cases without hydration. PADA might have the micellar molecular weights of 480000 and 450000 for [A]/[I] 15 and 20, respectively. Their numbers of association are 320 and 240, respectively. Therefore, the PADA micelles are much larger than those of the corresponding polyoxyethylene derivatives.[23-25] Since poly-DL-alanine does not associate in an aqueous solution,[3] it seems likely that the number of association of PADA micelle decreases with increasing the degree of polymerization, as far as the latter exceeds about ten.

At pH 5.0 the sedimentation experiments were performed on solutions of about 1 g. dl^{-1}. The sedimentation coefficients were 5.6 S and 5.4 S for [A]/[I] 15 and 20, respectively. They are lower than those at pH 2.0, This again indicates that the micelles at higher pH's consist of a smaller number of molecules than those at lower pH's, and that the excess hydrochloric acid merely suppresses the electrostatic effect.

Discussion

It may be supposed that the instability of the solution of the [A]/[I] 10 preparation that there are two kinds of PADA micelles, depending on the degree of polymerization. In fact, the low molecular weight PADA forms a micelle consisting of only 13 monomer molecules, while the higher molecular weight PADA forms a micelle the number of association of which amounts to a few hundred for [A]/[I] 15 and 20.

Structure of the Small Micelle.—It has been shown from infrared spectral studies[1,2] that PADA [A]/[I] 5 assumes the β-conformation in the solid state. In the β-conformation the polypeptide chains are extended and arranged in an antiparallel way, and hydrogen bonds are formed between peptide groups of different chains. A similar structure may be expected to exist in the micelle. In solutions of acid pH's, however, the intermolecular hydrogen bonds would compete with the electric repulsion between ionized amino groups. If the solution is not dilute enough, ionized amino groups would be shielded electrically by other ionized molecules and the PADA molecules would associate into a micelle through the intermolecular hydrogen bonds: PADA has a structure similar to the β-conformation. If the solution is so dilute that the electric repulsion is not sufficiently suppressed, the intermolecular hydrogen bonds would be disrupted and the PADA molecules would assume a random coil conformation without associating with one another. Therefore, a sharp change in solution properties should occur at some intermediate concentration. The CMC would correspond to this concentration, where the association-dissociation of molecules and the coil-β transition of conformation take place simultaneously.

If the micelle has a structure similar to the β-conformation in the solid, dodecyl groups are directed outwards within the plane of polypeptide chains alternately. The micellar dimension can be roughly estimated for this model. This axial ratio of an oblate ellipsoid approximating this model was about 9, which is comparable with that derived from the intrinsic viscosity. Alternatively, by converting the model into an equivalent disk, the second virial coefficient may be evaluated by means of an excluded volume equation.[29] It was found to be $1—2\times10^{-3}$ c. g. s., which was of the same order of magnitude as the observed value, 2.5×10^{-3} c. g. s. The correction for polydispersity and intermolecular interaction may explain the discrepancy between the calculated and observed values.

From these considerations regarding the micellar size and shape in relation to the conformation of PADA in solid, it may be concluded that the micelle of PADA [A]/[I] 5 has a structure similar to the β-conformation.

Structure of the Large Micelles.—The micelles of high molecular weight PADA are different from the small micelle of the [A]/[I] 5 preparation. The micellar size decreases with the degree of polymerization, and poly-DL-alanine does not associate in an aqueous solution. Such a dependence of the micellar size on the monomer size is similar to that of polyoxyethylene derivatives.[25] Hydrophobic bonds between dodecyl groups are certainly an important factor in the cohesion of the micelles. However, intermolecular hydrogen bonding between peptide groups is also effective in the association, since the micellar size of PADA is much larger than that of polyoxyethylene derivatives. In connection with the conformation in the solid state and the hydrodynamic behavior of the micelles, it can be concluded that the large micelles of PADA [A]/[I] 15 and 20 have a structure similar to that of random coils; the conformation of each molecule is randomly coiled in these micelles.

It may be expected that the large PADA molecule can be oriented by shear flow to exhibit flow birefringence. Preliminary experiments on flow birefringence were made with the two preparations, [A]/[I] 15 and 20. The results concerning PADA [A]/[I] 20 are shown in Fig. 6. A slight dependence of the extinction angle, χ, and of the birefrigence increment, $\Delta n/c$ on the concentration was observed. Since the micellar structure and its rigidness are not known accurately, no definite conclusion on the micellar size and shape can be derived from these results. If the micellar shape is assumed to be a hydrodynamically

equivalent ellipsoid derived by the Simha treatment, the rotary diffusion coefficient, Θ, and the optical anisotropy factor, g_1-g_2, can be obtained by the use of the equations of Peterlin and Stuart.[30] These values are listed in Table V. The rotary diffusion coefficients, however, lead to too large micellar dimensions when they are compared with those derived from the sedimentation experiments. This may be due to the polydispersity of the micelles and to the concentration dependence of the extinction angle.

If the data on birefringence increment, $\Delta n/c$, and refractive index increment, dn/dc, are combined, the principal refractive indices, n_1 and n_2, for the ellipsoids of revolution can be obtained; these values are also given in Table V. It was found that the principal refractive indices of the micelles are equal to each other for the two preparations, [A]/[I] 15 and 20, whether a prolate or an oblate ellipsoid is postulated. This suggests that the micelles formed from these two preparations have similar structures.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 112—117 (1966)

The Vibrational Assignment and Rotational Isomerism of *n*-Propyl Mercaptan

By Michiro HAYASHI, Yuji SHIRO and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received May 17, 1965)

The infrared and Raman spectra of *n*-propyl mercaptan have been measured and vibrational assignments made with relation to the rotational isomerism. The normal vibration calculation has been carried out in a modified Urey-Bradley force field. In the gaseous and liquid states, TT and GT molecular forms have been confirmed to exist. An appreciable energy difference in the isomers has been found even in the liquid state. The TT form has a lower energy than the GT form. The CH_2 hydrogen deformation frequencies of CH_2CH_2 groups in molecules similar to *n*-propyl mercatpan have been listed and discussed in relation to their molecular forms.

In a series of studies[1,2] we have studied the Raman and infrared spectra of molecules containing sulfur atoms in relation to the rotational isomerism. As a continuation of this reseach, we shall now report on the vibrational spectra of *n*-propyl mercaptan. This is the third of this series of papers.

For this substance, Scott et al.[3] pointed out the possibility of rotational isomers and gave a brief assignment of the observed spectra as a mixture of the trans and the gauche isomers around the C–C bond. This assignment, unfortunately, requires many improvements when a comparison is made with other members of the series of molecules we have studied.

In the previous papers, we pointed out a tendency toward hydrogen deformation frequencies in molecules containing sulfur atoms. In this paper, we will summarize the results of all the studies of this series of molecules.

Experimental

The sample used for the measurements was commercial *n*-propyl mercaptan which had been carefully redistilled. B. p. 67°C; n_D^{20} 1.4351.

The spectra were obtained by the same apparatus and under the same conditions as we have described in the previous papers. We attempted to measure the infrared spectra in the crystalline state for a sample cooled by liquid nitrogen at about −120°C. However, we could not make the sample in the crystalline state, though we could measure the spectra in a very viscous liquid state. The observed spectra in the liquid state were in a good agreement with those reported by Scott et al.

Rotational Isomerism

Though the spectra in the crystalline state are not available, the infrared spectra recorded at about −120°C have shown large changes in their relative absorption intensities.

Around 800 cm^{-1}, we have three bands, at 815, 793 and 779 cm^{-1}, of which the one at 779 cm^{-1} appears as a shoulder of the strongest band at 793 cm^{-1} at room temperature, while at a low temperature, the one at 815 cm^{-1} becomes the

c) Not measured.

strongest band, and the band at 793 cm^{-1} appears as a shoulder of a weak band at 779 cm^{-1}.

Around 900 cm^{-1}, three bands are seen at room temperature, at 925, 892 and 880 cm^{-1}, with weak, strong and medium intensities respectively, while at a low temperature, the band at 892 cm^{-1} becomes much more intense, that at 925 cm^{-1} shifts to 918 cm^{-1} and that at 880 cm^{-1} appears as a shoulder of 892 cm^{-1}. At 1225 cm^{-1}, we have a shoulder of a strong band at 1246 cm^{-1} at room temperature, while at a low temperature, this shoulder gains in intensity and appears as a doublet with that at 1246 cm^{-1}.

There are too many observed spectra for unique molecular form, and, as Scott et al. have pointed out, we may also conclude that for this substance rotational isomers exist which have different energies even in the liquid state. The skeletal deformation frequencies have been calculated as a four-body problem using the reported values[1,4] of the force constants in the Urey-Bradley force field. The calculations have been carried out for seven different isomers around the C–C bond. It has been found that a Raman line observed at 363 cm^{-1} belongs to the trans isomer, while the lines at 233 and 417 cm^{-1} belong to the gauche isomer around the C–C bond.

When the molecular form around the C–S bond is taken into consideration, we would expect five different isomers, TT, TG, GT, GG and GG′ in the notation described in the previous papers, where the first symbol refers to the molecular form around the C–C bond, and the second, to those around the C–S bond. In the second paper of this series, we mentioned that the molecular form of the CH_2CH_2SH part of the molecule affects strongly only the CSH deformation frequencies, while its influence is negligible for the other vibrational modes. For β-chloroethyl mercaptan, a refinement of the normal vibration calculation has shown that CSH deformation frequencies for five different isomers would be arrayed in the sequence

4) S. Mizushima, T. Shimanouchi, I. Nakagawa and A. Miyake, *J. Chem. Phys.*, **21**, 215 (1953).

of GG', TG, TT and GT ranging from the higher frequencies to the lower frequencies. The highest frequency for β-chloroethyl mercaptan is 928 cm^{-1}, whie the lowest is 860 cm^{-1}.

For *n*-propyl mercaptan CSH deformation mode would be expected at a frequency region lower than those of β-chloroethyl mercaptan for two reasons; (1) the lack of C–Cl stretching modes in the lower frequency region, and (2) the introduction of the CH_3 rocking modes at the frequency region higher than the region where the CSH deformations would be expected.

We have five infrared bands, at 925, 892, 880, 815 and 793 cm^{-1}, of which those at 925, 880 and 793 cm^{-1} may be attributed to the gauche bands around the C–C bond on the basis of intensity measurements at different temperatures. The bands at 925, 892 and 880 cm^{-1} are assigned to the CH_3 rocking modes on the basis of a comparison of the spectra with those of propane which Takahashi[5] reported. The bands at 815 and 793cm^{-1} might be the CSH deformation frequencies, of which that at 815 cm^{-1} arises from the trans isomer around the C–C bond. A refinement of the normal vibration calculation, which will be described below, indicates that these should be attributed to TT and GT molecular forms. As for the other three isomers (GG', GG and TG), since the CH_3 rocking modes might overlap in the region expected, we could not confirm their existence.

A Refinement of the Normal Vibration Calculation

In the previous papers we attempted to test the set of force constants in a modified Urey-Bradley force field, considering all the vibrational freedoms which we obtained from the observed frequencies of 1, 2-ethanedithiol in the first paper of this series. (The details of the modifications of the Urey-Bradley force field were described in that paper.) For *n*-propyl mercaptan, we have also attempted to find the transferability of the set of force constants. All the force constants are listed in Table II. To make the treatment simple, the C–H and S–H stretching modes were split out from the $\boldsymbol{G}$ and $\boldsymbol{F}$ matrices by the high-frequency splitting technique. Thirty force constants are required, of which twenty can be transferred from the set obtained from 1, 2-ethanedithiol, while ten can be transferred from propane, for which Takahashi reported the force constants.[5] The calculation has been carried out on the assumption that the molecular forms are TT and GT. The results are shown in Table III, with forty-one observed frequencies. The assignments have been found to be very satisfactory (average error, 1.9%). In the table we have also added brief descriptions of the potential energy distributions. For the other molecules of this series, we found that all the vibrational modes have relatively well-localized potential energy distributions. However, we found,

as special features of *n*-propyl mercaptan, that some of the vibrational modes are largely mixing and that their potential energy distributions are not localized in special internal coordinates.

The Energy Difference between the Isomers

We determined the change in the absorption intensities of the spectra at a lower temperature and used it as one of the most important data for the assignment of the observed spectra to different rotational isomers.

Since these changes were observed in the liquid state, the rotational isomers are shown to have different energies, even in the liquid state. For this molecule we would think the electrostatic interaction might not depend on the molecular forms so strongly. Therefore, it seems natural to expect that the energy difference is not large in either the liquid or the gaseous state, as in the works by Mizushima and his co-workers.[6] However, Scott et al. reported that, in the gaseous state, the trans isomer around the C–C bond has an energy about 400 cal./mol. lower than the gauche isomer. We also found that there is some energy difference in the liquid state, and that the trans has a lower energy than the gauche isomer. We have no idea at present how to explain this fact.

The Assignment of the Spectra

As we have mentioned above, a mixing of the vibrational modes sometimes makes the assignments of the observed spectra difficult. For example, the band at 880 cm^{-1} has almost equal contributions from the CH_3 and CH_2 rocking modes of the gauche isomer. However, we will call this band a CH_2 rocking mode, since we can find the bands at 1060 and 925 cm^{-1} for two CH_3 rocking modes, and since this band corresponds well to a CH_2 rocking mode for the other molecules of the

6) S. Mizushima "Structure of Molecules and Internal Rotation," Academic Press, New York (1964).

series which we previously reported on. In the table, the underlining indicates the names of vibrations given in this way.

Scott et al. did not report the spectra at a lower temperature, and they did not notice that the spectra show appreciable changes in their absorption intensities. Furthermore, they took *n*-propyl bromide as the sample for comparison, while we have taken 1, 2-ethanedithiol and β-halogenoethyl mercaptan, in assigning the observed spectra. When we compare the infrared spectra of these substances, we immediately find that the spectra of *n*-propyl mercaptan resemble those of 1, 2-ethanedithiol and β-halogenoethyl mercaptan, but that they are different from those of *n*-propyl bromide both in the shapes of the bands and in their frequency values. Therefore, our choice of the sample for comparison would be much better than theirs. Therefore, we believe that our assignments are better than theirs.

Actually, we have the sum rule of $\sum\nu^2(TT)=8.949\times10^7$ and $\sum\nu^2(GT)=8.925\times10^7$ (0.3% difference), in which the CH and SH stretching frequencies are excluded from the calculation, while they reported a 1.25% difference between the sums. The most appreciable difference in the assignments between ours and theris may be those of the CH_2 rocking frequencies, which would have a great influence on the assignments of the other spectra. They took 767 and 1105 cm^{-1} for the trans isomer and 793 and 1105 cm^{-1} for the gauche isomer. It seems to us, according to this assignment, that the frequency differences between the two CH_2 rockings are too large, and also that the frequency differences between different isomers are too small. As we will discuss again below, when we take the ratio of the frequencies of different isomers, we would expect that it would be around 0.65, while it is 0.89 according to their assignments. Therefore, we think their assignments are not acceptable.

CH_2 Hydrogen Deformation Frequencies in Relation to Molecular Forms

It is well known that the CH_2 hydrogen deformation frequencies for molecules with the $-CH_2CH_2-$ structures are strongly influenced by molecular forms around the C–C bond. Especially, the frequency difference between two CH_2 rocking frequencies for the trans isomer is found, in general, to be much larger than those for the gauche isomer. In Table IV we have listed the CH_2 rocking frequencies of the molecules with rotational isomers. In the tenth column of Table IV, we have added the ratio of the frequency differences for the trans and the gauche isomers in order to make the above tendencies clear. From the table, it can be seen that this ratio is less than unity; we always have a larger ratio for the molecules containing sulfur atoms than for the typical example, 1, 2-dichloroethane. Larger ratios are also obtained for molecules which do not contain sulfur atoms. For example, it is 0.62 for succinonitrile.[7] The averages

8) M. Hayashi, Y. Shiro, T. Kawakita and H. Murata, to be published.
9) M. Hayashi, Y. Shiro, T. Oshima and H. Murata, This Bulletin, **39**, 118 (1966).

of two CH_2 rocking frequencies for the trans isomers of molecules containing sulfur atoms are found to be nearly 872 $cm^{-1}\pm10$ cm^{-1}, except for *n*-propyl mercaptan, while for the other molecules the averages are far from the above range.

If we arrange the molecules in the sequence of X, which stands for SH, CH_3, SCH_3, Br and Cl, we find that the ratio is strongly influenced by the exchange of X, as is shown in Table V.

For $HSCH_2CH_2X$, the ratio decreases slightly as X changes. For four other series of molecules, that is, for the $CH_3CH_2CH_2X$, $CH_3SCH_2CH_2X$, $BrCH_2CH_2X$ and $ClCH_2CH_2X$ series, the ratio decreases appreciably. In general, this ratio is largest when X is SH, becomes smaller as X changes to CH_3, SCH_3 Br and Cl successively, and is smallest when X is Cl.

Table V. Ratio of frequency differences in two CH_2 rocking frequencies

Y=	SH	CH_3	SCH_3	Br	Cl
$HSCH_2CH_2Y$	0.66	0.65	0.64	0.64	0.64
$CH_3CH_2CH_2Y$	0.65	—	—	0.54	0.51
$CH_3SCH_2CH_2Y$	0.64	—	0.43	0.43	0.43
$BrCH_2CH_2Y$	0.64	0.54	0.43	0.32	0.31
$ClCH_2CH_2Y$	0.64	0.51	0.43	0.31	0.28

Table VI is a similar table given for the CH_2 wagging frequencies. The frequency differences in two wagging frequencies are, in general, much smaller than those of the CH_2 rocking frequencies. Therefore, a large uncertainty is introduced into the ratio of the frequency differences of isomers. However, when X and Y stand for one of the groups, SH, CH_3, Br or Cl, the ratio of the frequency diffrences for the XCH_2CH_2Y molecule always takes a value between those of the XCH_2CH_2X and YCH_2CH_2Y molecules.

We believe, then, that the above tendencies for the CH_2 rocking and wagging frequencies will be useful in the assignment of the observed spectra.

Table VI. CH_2 wagging frequencies of the molecules (XCH_2CH_2Y) (cm^{-1})

a) The ratio of the frequency differences for the trans and the gauche isomers.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 118—121 (1966)

The Vibrational Assignment and Rotational Isomerism of 1, 2-Dithiamethyl Ethane

By Michiro HAYASHI, Yuji SHIRO, Toshiyuki OSHIMA and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received May 17, 1965)

The infrared and Raman spectra of 1, 2-dithiamethyl ethane have been measured in gaseous, liquid and solid states. Vibrational assignments have been made in relation to the rotational isomerism. The normal vibration calculation has been carried out in a modified Urey-Bradley force field. In the gaseous and liquid states, GTG' and GGG molecular forms exist, while in the solid state the GTG' form alone persists. The energy difference between GTG' and GGG molecular forms has been found to be 1.1 kcal./mol. in the gaseous state and very small in the liquid state. The GTG' form is more stable than the GGG form, in both the gaseous and liquid states.

In previous papers, we have dealt with the vibrational spectra of 1, 2-ethanedithiol,[1] β-halogenoethyl mercaptan[2] and *n*-propyl mercaptan[3] in relation to the rotational isomerism. The present work, the fourth of a series of papers, will deal with the vibrational spectra of 1, 2-dithiamethyl ethane. For this substance Sweeny et al.[4] discussed the possibility of rotational isomers in relation to its metal complex. However, they did not mention details of the vibrational assignments of the observed spectra, and they also did not consider the molecular forms around two C–S bonds.

In the present work, we will attempt assignments of the spectra and will consider the molecular forms around two C–S bonds as well as the C–C bond. The energy differences between the isomers will also be measured.

Experimental

1, 2-Dithiamethyl ethane was prepared by the reaction of 1, 2-dichloroethane with sodium methyl mercaptide in absolute alcohol. B. p. 84°C/20 mmHg; n_D^{20} 1.5297.

The spectra were obtained by the same apparatus and under the same conditions as we have described in the previous papers.

The infrared spectra in the crystalline state were recorded for a sample cooled with liquid nitrogen at about −120°C.

Rotational Isomerism

From a comparison of the observed spectra in the gaseous and the liquid states with those in the crystalline state, and also from a comparison of the spectra with those of 1,2-ethanedithiol which we reported in a previous paper, the following evidence of rotational isomers has been obtained.

The CH_2 wagging frequencies found for 1, 2-ethanedithiol at 1220, 1273 and 1292 cm^{-1} are also seen at 1202, 1273 and 1292 cm^{-1}, of which only 1202 cm^{-1} persists in the crystalline state. One C–C stretching frequency is seen at 1008 cm^{-1}; it disappears in the crystalline state. These are similar to those found for 1, 2-ethanedithiol. As Sweeny et al. pointed out, we may conclude that the isomer persisting in the crystalline state has the center of symmetry, which is the trans form around the C–C bond, while the other, which disappears in the crystalline state, might be the gauche form around the C–C bond.

The assignments of the observed spectra are easy from a comparison with those of 1, 2-ethanedithiol and β-halogenoethyl mercaptan. The assignments of the spectra are shown in Table I. It is important to note that there are no unassigned spectra over the spectral region obtained.

When we take the molecular forms around the two C–S bonds into consideration, ten different isomers may be expected for this substance. Four of them have the trans form, and six have the gauche form, around the C–C bond. We will use the symbols G and T for the molecular forms around each internal-rotation axis, as we did in the previous papers.

The actual molecular form in the crystalline state should be either TTT or GTG' in this notation, because the observed spectra demonstrate the mutual exclusion rule between the infrared and the Raman spectra.

To get information on the detailed molecular form, the skeletal deformation frequencies have been calculated in the Urey-Bradley force field for

skeletal def.

a) Molecular forms around the C-C bond have been given in parentheses.

six different molecular forms as a four-body problem, using the reported values[1,5] of the six necessary force constants; these values are $K(CH_2\text{-}S)=2.60$, $K(CH_2\text{-}CH_2)=3.70$, $H(CH_2CH_2S)=0.15$, $H(CH_2SCH_3)=0.157$, $F(CH_2CH_2S)=0.50$ and $F(CH_2SCH_3)=0.211$ md./Å.

The results are shown in Fig. 1, where we have also added the observed Raman lines below 500 cm^{-1}. There are five observed Raman lines below 500 cm^{-1}, where the skeletal deformation frequencies are expected, while four skeletal deformation frequencies are calculated for a unique molecular form. If the form has the center of symmetry, two of the four frequencies become inactive in the Raman effect.

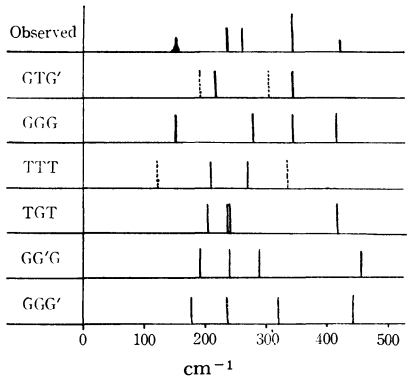

Fig. 1. Observed and calculated skeletal vibration frequencies below 500 cm^{-1}.
(·····Raman inactive)

The calculated frequencies of the skeletal deformation modes show a strong dependance on the molecular forms, as we expected. The results suggest that the gauche forms for two C–S bonds are more favorable than the trans form for predicting the observed lines. Especially, the strong Raman line at 340 cm^{-1} should only belong to the frequencies for either GTG' or GGG, while the weak Raman line at 143 cm^{-1} should also only belong to the frequency for GGG. It may be noted that GTG' has the center of symmetry; this could be the molecular form in the crystalline state.

In general, the above treatment of normal vibrations is relatively uncertain, and there is difficulty in measuring weak Raman lines. Therefore, we could not determine whether GTG' is a unique molecular form in the crystalline state, and whether the other form exists in the gaseous and the

5) M. Hayashi, *J. Chem. Soc. Japan, Pure Chem. Sect.* (*Nippon Kagaku Zassi*), **78**, 627 (1957).

liquid states in addition GTG' and GGG. However, we believe that GTG' and GGG are the main molecular forms for this substance.

The absorption intensity of the spectra were measured at ten different temperatures in the range from 50 to 140°C in the gaseous state, and at five different temperatures in the range from −20 to 50°C in the liquid state.

Three wagging frequencies around 1250 cm^{-1} were used in the measurements. From the observed optical densities, the energy difference of the isomers around the C–C bond has been computed to be 1.1 kcal./mol. in the gaseous state. In the liquid state, it has been found to be very small (<0.1 kcal./mol.).

A Refined Treatment of Normal Vibration Calculations

In the previous papers, we attempted to determine the force constants in a modified Urey-Bradley force field, considering all the vibrational freedoms. The purpose of this attempt was to determine a set of transferrable force constants which we could apply to every molecule with the $-SCH_2CH_2S-$ structure and, finally, to polyalkyl polysulfides.

In the first paper of this series, we determined a set from the observed spectra of 1, 2-ethanedithiol. In the second and the third papers, we tested it for the cases of β-halogenoethyl mercaptan and *n*-propyl mercaptan and found that the agreement between the observed and the calculated frequencies is quite satisfactory. In the present work, we have tried to apply the set to 1, 2-dithiamethyl ethane.

The force field adopted in the calculation is a modified Urey-Bradley force field, which has been described fully in the first paper of this series; it will also be described separately in a paper in which we will use dimethyl sulfide as an example.[6] All the force constants used are listed in Table II. To simplify the treatment, the C–H stretching modes were split from the $\boldsymbol{G}$ and $\boldsymbol{F}$ matrices by the high-frequency splitting technique.

Twenty-seven force constants are required, of which sixteen can be transferred from the set obtained from 1, 2-ethanedithiol, while eleven can be transferred from the set obtained from dimethyl sulfide. The calculations have been carried out on the assumption of two pairs of molecular forms. One of them is a pair (TTT and TGT) which have the trans form around two C–S bonds, while the other is a pair (GTG' and GGG) which have the gauche form around two C–S bonds. The results are shown in Table III for fifty-one observed frequencies.

From the table, it may be seen that the influence of the molecular forms around two C–S bonds makes no essential difference in the calculated frequencies except in the frequencies of skeletal deformation modes. This indicates that we will have no chance to confirm the molecular forms around the C–S bond unless we examine the skeletal deformation modes. Though the observed Raman lines for the skeletal deformation frequencies are all relatively weak, the five observed Raman lines assigned to skeletal deformation modes can be much better predicted on the assumption of one pair (GTG' and GGG) than on that of the other pair (TTT and TGT).

Therefore, we have concluded that GTG' and GGG are the actual molecular forms for this substance; of these, GTG' persists in the crystalline state.

The agreement between the calculated and the observed frequencies, assuming that the molecular forms are GTG' and GGG, is quite satisfactory; the transferability of the set of force constants has also been proved for this substance.

The Assignment of CH_2 Rocking Frequencies

As is shown in Table I, there are several differences in the assignments of the observed spectra between ours and those reported by Sweeny et al. They reported that 840 and 900 cm^{-1} were two CH_2 rocking vibrations for the gauche isomer. We found a very weak band at 890 cm^{-1} at first. However, this disappeared after careful distillation, while that at 840 cm^{-1} remained unchanged.

a) Molecular form around the C-C bond.

Therefore, the band at 900 cm^{-1} may be caused by an impurity.

We regarded one of the CH_2 rocking modes as overlapping with a CH_3 rocking frequency at 960 cm^{-1}. For the trans isomer, since in the crystalline state the band at 739 cm^{-1} exists as a doublet, this band has two components, that is, one of the CH_2 rocking modes and one of the C–S stretching modes, as Sweeny et al. pointed out. The other CH_2 rocking modes for the trans isomer might be at 1020 cm^{-1}.

The frequency differences in the two CH_2 rocking modes are found to be 281 and 120 cm^{-1} for the trans and the gauche isomers respectively, while 221 and 62 cm^{-1} are found for 1, 2-dichloroethane, which Sweeny et al. chose as the standard. If the band at 900 cm^{-1} actually existed, the frequency differences for this substance could be close to those for 1, 2-dichloroethane. Since the band at 900 cm^{-1} does not exist, we have a large difference between these substances. However, when all the CH_2 rocking frequencies of the series of molecules which we studied are taken into consideration, the assignment of the two CH_2 rocking modes to 840 and 960 cm^{-1} for the gauche isomer is not only reasonable but inevitable.

The results of normal vibration calculations support the present assignment.

As we pointed out in the third paper of this series, we believe that this is a characteristic difference for the series of molecules containing sulfur atoms. It is worth noting that this improvement in the assignment does not have any influence on the discussions of the metal complex which Sweeny et al. reported on.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 122—127 (1966)

Influence of Metal Ions and of Metal Chelates on the Hydrolysis of α-D-Glucose 1-Phosphate*

By Yukito MURAKAMI and Michio TANAKA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received May 18, 1965)

The hydrolysis reaction of α-D-glucose 1-phosphate has been studied in the presence of several metal ions and metal chelates at 40.0 and 60.0°C, in the pH range of 1.69—2.71, and at an ionic strength of 0.10 M (KNO_3). The reaction rate was followed by the colorimetric method using a combination of the amidol reagent and 8.3% molybdate solution. Among the metal ions employed in this work, dipositive ions, such as manganese(II), cobalt(II), nickel(II), copper(II), zinc(II) and uranyl ions, were observed to be nearly without effect on the rate of hydrolysis, while iron(III) and thorium(IV) ions demonstrated a negative catalytic effect. On the other hand, all the chelating agents employed tend to restore the reaction rate in reference to the corresponding metal-ion-effected reactions. With the 1:1 thorium(IV)-EDTA and the 1:1 iron(III)-EDTA chelate system, the rate was completely restored. Both iron(III)-kojate and thorium(IV)-Tiron chelate systems restored the reaction rate to a lesser extent. The roles of the chelating agents were discussed. The reaction mechanism in the presence of the catalyst species has been considered, and two possible mechanisms have been put forward for the present reactions.

The hydrolysis of organic orthophosphates are in general complicated by several factors[1] even in the absence of metal ions and of metal chelates. Firstly, an organic phosphate exists in various ionic forms in aqueous media, the composition of which depends on the nature of the medium, the structure of the alcohol substituent, and the acid dissociation constants of the phosphate. Secondly, each ionic species of the substrate undergoes either carbon-oxygen or phosphorus-oxygen bond fission, or both simultaneously in the course of hydrolysis. Thirdly, the reactivity of each ionic species is controlled by the structure and the physical properties of the alcohol substituent, and by the nature of the medium. The reactivity is also affected by a reaction process through which hydrolysis of a substrate proceeds.

Among the organic phosphates of biological interest, α-D-glucose 1-phosphate is known to form as an intermediate in biological system during the course of degradation of sugars. The hydrolysis of this phosphate has been extensively studied by Bunton and co-workers[2] and the neutral species was found to be the most reactive one among the neutral, monoionic and diionic species. A unimolecular mechanism was assigned to the hydrolysis of both the neutral and the monoionic species.

Present research has been carried out to investigate the participation of metal ions and metal chelates in the hydrolysis of α-D-glucose 1-phosphate. Since a series of studies on the hydrolysis of salicyl phosphate analogs have been carried out previously[3-5] to investigate the catalytic roles of metal ions and of metal chelates, this work may provide some additional information on the role of metals in such reactions.

Experimental

Reagents.—The dihydrate form of dipotassium α-D-glucose 1-phosphate was purchased from Sigma Chemical Company, St. Louis, Mo., U. S. A. The purity of this compound, which was established by phosphorus analysis and potentiometric titration, was sufficiently high, so that further purification was not necessary.

The disodium salt of ethylenediaminetetraacetic acid and Tiron (sodium pyrocatechol-3, 5-disulfonate) were the products of the Research Laboratories of Dojindo & Co., Ltd.; both were used without further purification. Kojic acid was purchased from Tokyo Kasei Kogyo Co., Ltd. and was purified by sublimation in vacuo.

The nitrates of divalent metals, $Co(NO_3)_2 \cdot 6H_2O$, $Ni(NO_3)_2 \cdot 6H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$, and $Zn(NO_3)_2 \cdot 6H_2O$; and manganese sulfate, $MnSO_4 \cdot nH_2O$, of an analytical grade were purchased from Wako Pure Chemical Industries, Ltd. The nitrates of actinide metals, $UO_2(NO_3)_2 \cdot 6H_2O$ and $Th(NO_3)_4 \cdot 4H_2O$, of an analytical

grade are the products of the British Drug Houses Ltd. and Wako Pure Chemical Industries, Ltd. respectively. The ferric nitrate nonahydrate was a pure grade reagent of the latter company. Standardization of aqueous stock solutions of these metal salts was established by the usual method of chelatometric titration.

Potentiometric Measurements.—The apparatus and procedures for potentiometric titrations have been mentioned elsewhere.[6] Potentiometric titrations of α-D-glucose 1-phosphate were carried out at temperatures of 34.8, 39.8, 45.0 and 60.0°C, and at an ionic strength of 0.10 M with added potassium nitrate. In order to avoid any perturbation of the data which may be caused by hydrolysis of the phosphate during the course of titrations, the reliability of titration data was confirmed by repeated titration runs and by the detection of any liberated inorganic phosphate.

Kinetic Measurements.—The pH value of an experimental solution was maintained constant during each run without adding any base or acid, since each solution was sufficiently acidic that the chemical reactions occurring did not cause any significant change in its acidity. Nevertheless, the pH value of each experimental solution was checked from time to time with an HRL Model P pH meter of the Horiba Instruments Inc. fitted with extension glass and calomel electrodes. The ionic strength of the experimental solutions was maintained at 0.10 M with potassium nitrate. Two reaction temperatures were selected; 40.0±0.1 and 60.0±0.1°C. The rate of hydrolysis was determined by measuring the amount of phosphoric acid liberated in the course of hydrolysis.

The analytical method for the liberated inorganic orthophosphate, employed in this work, essentially followed the procedure established by Allen.[7] The two kinds of solutions were prepared: Amidol reagent was prepared by dissolving 2.5 g. of amidol (product of Naniwa Chemical Co., Ltd.) recrystallized from water-methanol and 50 g. of sodium bisulfite (Wako analytical grade) in mineral-free water, and diluting to 250 ml. This mixed solution was allowed to stand overnight in a refrigerator after a small amount of active charcoal being added, and then filtered to remove active charcoal and any other precipitates. The activity of this reagent was checked from time to time to assure the accurate analysis of orthophosphate. The second reagent is the 8.3% molybdate solution. To prepare this solution, 22.035 g. of ammonium molybdate $(NH_4)_6(Mo_7O_{24})\cdot 4H_2O$ (Wako analytical grade) was dissolved in 228 ml. of mineral-free water.

The following analytical procedure was employed in this study. A 2.0 ml. sample was pipetted from the experimental solution and was transferred to a 25 ml. volumetric flask containing 10 ml. of water, which had been cooled in an ice bath. The reaction stopped immediately because of low temperature. Two milliliters of 60% perchloric acid (Wako analytical grade), 2.0 ml. of the amidol reagent, and 1.0 ml. of the 8.3% molybdate solution were added in this order, and the mixture was diluted to 25 ml. with mineral-free water. The volumetric flask was then placed in a constant temperature bath at 15.0±0.5°C for 5 min. to develop the violet color. The absorbance was measured at 720 mμ with a Shimadzu-Bausch & Lomb Spectronic 20 Colorimeter immediately after the development of the color. The amount of inorganic phosphate was determined by reference to a calibration curve obtained with the use of a standard potassium dihydrogen phosphate (Wako analytical grade) solution.

Results

Determination of Acid Dissociation Constants.—The evaluated acid dissociation constants of α-D-glucose 1-phosphate are summarized in Table I. Some different values of pK_{HA} were reported by Ashby and co-workers,[8] and the discrepancy can be ascribed to the difference in experimental ionic strength among this work and theirs. Another set of pK values reported by Cori and co-workers[9] are in a rather close agreement with the present data.

Kinetics of Spontaneous Hydrolysis.—Hydrolysis of α-D-glucose 1-phosphate has been studied at 40 and 60°C in the lower pH region ranging from 1.72 to 3.38. This hydrolysis reaction was found to follow the apparent first order kinetics, rate constants obtained at various pH's being summarized in Table II. The reaction rate is seen to increase as the pH of the solution decreases.

a) Not first order

Kinetics of Hydrolysis in the Presence of Metal Ions.—In order to investigate effects and roles of metal ions in the hydrolysis reaction of α-D-glucose 1-phosphate, several metal ions of the first transition series and of the actinide series have been employed in this study. The hydrolysis reaction has been studied at a 1:1 molar ratio of substrate to metal ion and the reaction was observed to proceed homogeneously in all cases. The experimental data obtained at 60.0 and 40.0°C indicate an apparent first order rate with respect to the total concentration of unreacted organic phosphate species in most instances. All the rate data obtained for the metal-ion-effected hydrolysis reactions are listed in Table III. In most cases where the hydrolysis reaction followed first order kinetics, the divalent metal ions and uranyl ion did not cause any significant change in reaction rate in reference to the spontaneous rate. As can be seen, those metal ions which caused a significant change in reaction rate acted as negative catalysts. Although the thorium ion provided a first order rate constant at $-\log[H^+]=1.72$ and 60°C, the hydrolysis did not follow first order kinetics under other experimental conditions with this metal ion present. Moreover, the apparent reaction rate increases as pH value is raised in the presence of the thorium ion, while the rate of spontaneous hydrolysis and of other metal ion-effected reactions decreases. The rate profiles at various pH's for the thorium-effected reaction are shown in Fig. 1 along with those for the spontaneous reaction.

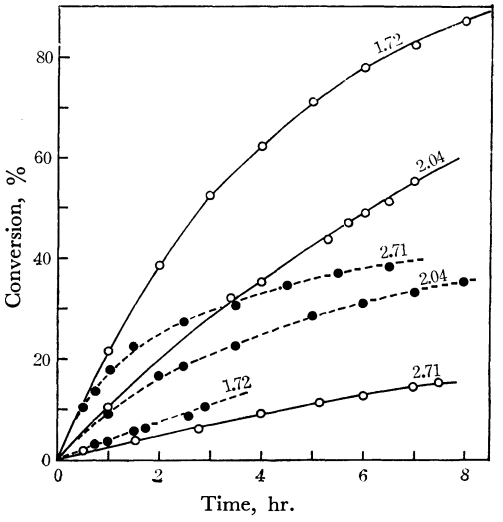

Fig. 1. Hydrolysis of α-D-glucose 1-phosphate at 60.0°C in 0.10 M KNO_3, with the total substrate concentration of 1.00×10^{-3} M; ○, spontaneous reaction; ●, thorium(IV)-ion-effected reaction ($T_S/T_M=1.0$). Numbers refer to the hydrogen ion concentration in $-\log[H^+]$. T_M=total concentration of the thorium ion; T_S=total concentration of the phosphate species.

Kinetics of Hydrolysis in the Presence of Metal Chelates.—Four different chelate systems have been employed in the present work to investigate the interaction of each chelate system with α-D-glucose 1-phosphate in the course of

hydrolysis reaction of the latter. These chelate systems are iron(III)-kojate, iron(III)-EDTA, thorium(IV)-Tiron, and thorium(IV)-EDTA. The hydrolysis reaction was studied at 60.0°C and was observed to follow first order kinetics in all instances; all the experimental solutions contained a 1:1:1 molar ratio of metal ion, ligand, and substrate. The specific rate constants determined experimentally are listed in Table IV.

Table IV. Hydrolysis rates of α-D-glucose 1-phosphate in the presence of metal chelates
60.0±0.1°C; μ=0.10 M (KNO_3); T_M/T_S=1.0; $T_S=1.00\times10^{-3}$ M; T_M/T_L=1.0

c) Not first order.

As shown in Table IV, at both pH's the interaction of metal ion alone with the phosphate resulted in a much slower rate of hydrolysis than the spontaneous hydrolysis rate. The presence of a ligand capable of coordinating to metal ion, however, tends to restore the rate to the spontaneous one. With the two chelate systems, Fe(III)-EDTA and Th(IV)-EDTA, the rate is recovered completely. The concentration effect of the Fe(III)-kojate chelate system was studied at a selected hydrogen ion concentration ($-\log[H^+]=2.07$), and the rate-concentration profile is shown in Fig. 2. The reaction rate is seen to decrease with an increase of the chelate concentration.

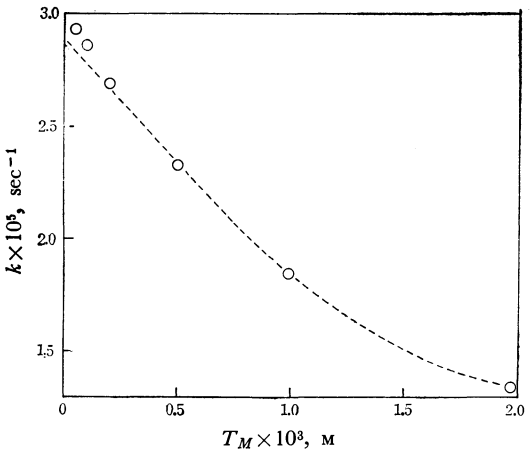

Fig. 2. Variation of the first order rate constant of the hydrolysis of α-D-glucose 1-phosphate with the concentration of Fe(III)-kojate chelate species at $-\log[H^+]=2.07$; μ=0.10 M (KNO_3); 60.0°C; T_M=total concentration of the Fe(III) species (free metal ion and chelate species).

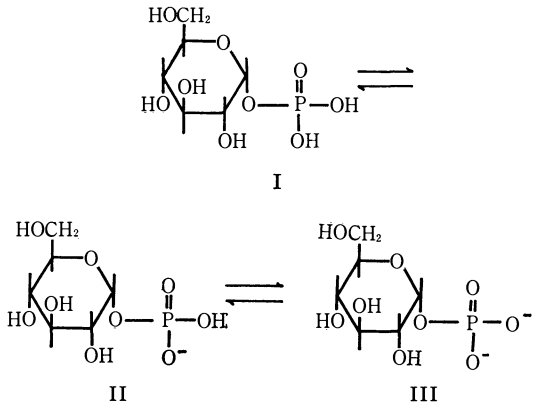
Discussion

Spontaneous Hydrolysis.—The substrate, α-D-glucose 1-phosphate, is considered as a dibasic acid and exists in three different forms, I, II, and III, the composition of which is dependent on the pH value of a solution.



The mole fractions of these three substrate species at various hydrogen ion concentrations are shown in Table V together with the hydrolysis rate constant at each hydrogen ion concentration. A plot of

a mole fraction of the neutral species against corresponding spontaneous rate constant resulted in a straight line in the region lying below a mole fraction 0.18, as is seen in Fig. 3.

Therefore, the main active species existing in this pH region may be assumed to be the neutral phosphate species. In the higher mole fraction range, the specific rate constant plot deviates from linearity. Thus, an acid catalyzed reaction is considered to be superimposed upon the spontaneous hydrolysis of the neutral species. These considerations are in agreement with and in support of the results obtained by Bunton et al.[2]

Effects of Metal Ions.—In this investigation the pH value of experimental solutions was maintained in the range, 1.72—2.71. Therefore, the acid catalyzed reaction may not be significant under present experimental conditions. The effect of metal ions on the hydrolysis reaction is obviously dependent on the positive charge that these metal ions possess, as illustrated in Table III. Thus, all the divalent metal ions and even the uranyl ion do not cause any significant change in reaction rate. As the mechanism in which metal ions can show any profound effect in the hydrolysis reaction, four cases illustrated in Chart 1 may be considered probable. The four mechanisms proposed are based upon two principal concepts: firstly, that a proton-transfer process plays a vital role in the transition state, and secondly, that the spontaneous hydrolysis mechanism, which results in the formation of a carbonium cation, is not disturbed to

a significant extent so that an S_N1 process still holds in the presence of metal ions. Mechanisms 1 and 4 would be favored if the reaction were accelerated in the presence of metal ions. A mechanism similar to the first one involving metal ion attack at the site of the phosphate group was given previously for the hydrolysis of salicyl phosphate and its derivatives.[3-5] In the activated complex of structure IV, the metal ion may act to accelerate the transfer of a phosphate proton to the ester oxygen. This proton-transfer results in the formation of structure IV', which undergoes degradation to yield the carbonium cation. On the other hand, a proton of a hydrated water in structure VII may be transferred to the ester oxygen by the help of the electron-withdrawing effect of the metal ion, with the C–O bond being subsequently cleaved to give the carbonium ion.

A different situation is expected for mechanisms 2 and 3. The proton-accepting capacity of the ester oxygen would be reduced by the presence of metal ion where the metal ion acts on the ester oxygen as shown in structure V. The coordination of the metal ion to the ether oxygen of the glycoside ring and to the phosphate oxygen, as illustrated in structure VI, acts to reduce the electron-donating power of the ether oxygen on one hand, and to diminish the proton accepting tendency of the ester oxygen on the other. The former effect would be unfavorable for the formation of the carbonium ion and the latter unfavorable for C–O bond cleavage. Therefore, from the above consideration, mechanisms 2 and 3 may be reasonable for the cases where a diminished rate of hydrolysis was observed.

Effects of Metal Chelates.—With the thorium-EDTA chelate system, the hydrolysis rate was found to be comparable with the spontaneous one. The predominant species present in the experimental solutions is the 1:1 chelate species even in the low pH region used in this investigation due to an extremely high stability of the chelate.[10] Since only two coordination sites are left on the nuclear metal of the Th(IV)-EDTA chelate[11] and the thorium ion is well-shielded with the ligand from the substrate species, the steric interaction of the substrate with this thorium chelate may prohibit the formation of the activated complexes mentioned above with the exception of IV. A similar explanation can be given for the effect of the Fe(III)-EDTA chelate system on the hydrolysis reaction. The presence of both Fe(III)-kojate and Th(IV)-Tiron chelate systems resulted in an increased rate of hydrolysis in comparison with the corresponding free metal ions. However, there still remains a negative catalytic effect with these chelates. Under these conditions of hydrogen ion concentration, the 1:1 Fe(III)-kojate[12] and Th(IV)-Tiron[13] chelate systems consist primarily of two components, free metal ion and the 1:1 chelate species. Therefore, these two chelating agents seem to demonstrate their roles in two aspects in the course of hydrolysis:

(1) the reduction of the concentration of the free metal ion, which is the most active negative catalyst;

(2) the reduction of the affinity of metal toward the substrate species through the chelation.

In conclusion, the catalytic hydrolysis reaction of organic phosphates may be explained in terms of the proton-transfer mechanism, whenever the substrate species involve any active protons. When metal ions and metal chelates showed any catalytic effect in this work, they acted to reduce the reaction rate in contrast to the hydrolysis of salicyl phosphate analogs.[3-5] Thus, whether the catalytic effect is positive or negative seems to be controlled by the three factors; ionic forms of a substrate, structure of an alcoholic residue, and hydrolytic reaction mechanism. Some further studies on the roles of metal ions and of metal chelates in the hydrolysis of organic phosphates are under progress in these laboratories.

The Direct Iodination of Polyalkylbenzenes Bearing Bulky Groups[1)]

By Hitomi SUZUKI,* Kiyomi NAKAMURA and Ryozo GOTO

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received May 20, 1965)

The following polyalkylbenzenes bearing bulky groups have been subjected to direct iodination using iodine and periodic acid, and the corresponding mono-iodinated products have been obtained in fairly high yields: 4-*t*-butyl-1, 2-dimethylbenzene, 5-*t*-butyl-1, 3-dimethylbenzene, 5-*t*-butyl-1, 2, 3-trimethylbenzene, 1, 2, 4, 5-tetraisopropylbenzene and *p*-di-*t*-butylbenzene. The polyiodination of polymethylbenzenes has also proceeded smoothly, giving polyiodo compounds in high yields. A comparison of various direct methods has proved the above reagent to be the best iodinating agent for a variety of polyalkylbenzenes.

Because of our interest in the disproportionation of aromatic iodo compounds in sulfuric acid, some attempts to prepare the iodo derivatives of some polyalkylbenzenes bearing bulky groups by ordinary direct methods have been made. Up to the present, however, little attempt has been made to introduce an iodine atom into the rings of such polyalkylbenzenes. As the polyalkylbenzenes are unreactive towards molecular iodine, it is necessary to use some oxidizing agents for a successful direct iodination. In order to determine the best oxidizing agent for the reaction, we carried out a series of preliminary tests, using 5-*t*-butyl-1, 3-dimethylbenzene as a common substrate. Seven reagents have been tested as oxidizing agents or iodinium cation sources: silver sulfate,[2)] silver perchlorate,[3)] mercuric oxide,[4)] potassium persulfate,[5)] iodic acid,[6)] periodic acid, and *o*-iodoanisole.[7)] The experimental procedures employed for the tests were nearly the same as those described in the original papers. The results are shown in Table I. As is apparent from the table, *iodine used with periodic acid* was found to be the best iodinating agent for polyalkylbenzenes possessing bulky groups.

The following five polyalkylbenzenes have been subjected to the direct iodination: 4-*t*-butyl-1, 2-dimethylbenzene, 5-*t*-butyl-1, 3-dimethylbenzene, 5-*t*-butyl-1, 2, 3-trimethylbenzene, 1, 2, 4, 5-tetraisopropylbenzene and *p*-di-*t*-butylbenzene. All five polyalkylbenzenes underwent the iodination and afforded new iodo derivatives. Even 1, 2, 4, 5-tetraisopropylbenzene, which was almost completely inert towards the other iodinating agents, gave the iodo product in an acceptable yield. It is interesting that 5-*t*-butyl-1, 2, 3-trimethylbenzene was, in spite of its apparently highly-crowded structure, readily iodinated to give 5-*t*-butyl-4-iodo-1, 2, 3-trimethylbenzene. This is probably because the steric aversion towards the entry of the bulky iodine atom is in part surmounted by the combined inductive effects of the four alkyl groups. In sharp contrast to the iodo derivatives of lightly-alkylated benzenes,[8)] these iodinated products were relatively stable towards sulfuric acid and did not liberate iodine until they were heated with sulfuric acid at a moderately high temperature. Nor did they undergo disproportionation under ordinary conditions of the Jacobsen reaction.

As an extension of this work, the polyiodination of some polymethylbenzenes was also carried out. Subjected to the reaction were *o*-xylene, *p*-xylene, durene and prehnitene. The reaction occurred fairly smoothly and afforded polyiodo products in high yields. The increased introduction of the iodine atoms into the ring usually diminishes the reactivity of the compound, so the tri- or tetra-iodination of xylenes was difficult to effect. For the purpose of synthesizing highly-iodinated compounds, therefore, the disproportionation of diiodo compounds by the action of sulfuric acid (Jacobsen reaction) is preferable.[9)]

Although no exhaustive investigation to find the optimum conditions was carried out, the excellent results in the present experiments showed the superiority of this reagent. The ready availability and convenience of the agent, the simple reaction conditions, the complete absence of

Table I. Direct iodination of 5-*t*-butyl-1, 3-dimethylbenzene by various methods

Reagent, g.		Solvent, ml.		Hydrocarbon g.	Temp. °C	Time hr.	Yield %	Remark
Iodine	3.39	Acetic acid	17	5.40	60—65	4	91	All iodine disappeared within 4 hr. On cooling, the product separated out as white crystals. No by-product. The use of iodic acid gave similar result (86%), except that the reaction needed much longer time for completion.
Periodic acid dihydrate	1.54	Water Sulfuric acid	3 0.6					
Iodine	10.77	Cyclohexane	10	3.32	10—15	4	46	Removal of silver iodide from the product was troublesome. At elevated temperature (35—40°C), resinous materials and an oil with a camphor-like odor were formed.
Silver sulfate	4.13	Sulfuric acid Water	20 2					
Iodine	5.10	Chloroform	30	3.58	10—15	3	43	Resinous materials always accompanied the reaction. In one experiment, a violent explosion occurred.*
Silver perchlorate	4.14							
Iodine	8.50	Cyclohexane	30	5.40	40—43	3	26	Resinous materials were always formed.
Silver perchlorate	6.91							
Magnesium oxide	1.30						50**	
Iodine	10.86	Cyclohexane	20	3.25	45—50	35	55	Reactions were slow and incomplete. Mercuric oxide became pasty and greatly disturbed the smooth agitation.
Mercuric oxide	4.38							
Iodine	2.78	Acetic acid	20	3.62	60—65	6	62	Reactions proceeded slowly. Persulfate was in part consumed for the formation of iodic acid.
Potassium persulfate	2.64	Water	5					
o-Iodoanisole	4.68	Cyclohexane	10	3.25	25—30	4	83**	Small amounts of 2, 4-diiodoanisole tenaciously clinged to the product were difficult to remove.
		Sulfuric acid	10					

* The reaction had been being carried out at sunny window side, magnetically stirring with a plastic-covered stirrer, when the explosion suddenly occurred.

** Yields based on unrecovered hydrocarbon.

polymeric by-products in the final reaction mixtures, and the excellent yields of iodo derivatives recommend this method for a wide variety of polyalkylbenzenes.

Experimental

Materials.—Commercially-available *o*- and *p-xylene* were used. *Durene* and *prehnitene* were prepared according to the literature.[10,11] *4-t-Butyl-1, 2-dimethylbenzene* (I; b. p. 101—103°C/22—23 mmHg), *5-t-butyl-1, 3-dimethylbenzene* (II; b. p. 95—96°C/22—23 mmHg), and *p-di-t-butylbenzene* (III; m. p. 78—79°C) were prepared by the *t*-butylation of *o*-xylene, *m*-xylene and *t*-butylbenzene respectively.

1, 2, 4, 5-Tetraisopropylbenzene (VI) was prepared by the direct isopropylation of cumene using propylene and small amounts of 98% sulfuric acid as the catalyst. A white, oily, crystalline cake which formed in the flask was scraped out and filtered by suction until no more oil could be removed. Several recrystallizations from hot 2-propanol yielded large white needles; m. p. 118—119°C.[12]

5-t-Butyl-1, 2, 3-trimethylbenzene was prepared by the lithium hydride reduction[13] of 4-*t*-butyl-2, 6-dimethylbenzyl chloride, which had been prepared by the chloromethylation of 5-*t*-butyl-1, 3-dimethylbenzene.

4-t-Butyl-2, 6-dimethylbenzyl Chloride (V).—A mixture of II (160 g.), 37% formalin (180 g.) and concentrated hydrochloric acid (500 ml.) was stirred and heated to 65—70°C over a 7 hr. period, while a stream of hydrogen chloride was being bubbled through this mixture. After it had stood overnight, the upper organic phase was extracted with ether, washed with a saturated aqueous sodium bicarbonate solution, dried over calcium chloride, and fractionated. Colorless, rather thick oil distilled at 151—152°C/24 mmHg.[14,15] Yield, 171 g. (82%).

5-t-Butyl-1, 2, 3-trimethylbenzene (VI).—In a 500-ml. four-necked flask, fitted with a thermometer, a reflux

condenser and a dropping funnel containing 125 g. of V dissolved in a small amount of tetrahydrofuran, lithium hydride (10 g.), lithium aluminum hydride (4 g.) and tetrahydrofuran (300 ml.) were placed and rapidly stirred with a mechanical stirrer. Then a solution of V was added drop by drop at such a rate that a gentle refluxing was maintained in the system. After the completion of dropping, the flask was immersed in a water bath and warmed at 50—60°C for several hours in order to complete the reaction. The reaction mixture was then carefully poured into large amounts of water, and the crystalline solid which precipitated was extracted with ether. Drying over calcium chloride, followed by fractional distillation, gave 96 g. (92%) of colorless oil, b. p. 115—116°C/19 mmHg, which readily solidifieds to large plates and which melted at 30—31°C.[14,15]

The use of magnesium ribbon or zinc dust as reducing agents leads to a remarkable formation of the coupling product, 4, 4'-di-*t*-butyl-2, 2', 6, 6'-tetramethyl-1, 2-diphenylethane, m. p. 215—217°C.[14]

Solvent.—The solvent used for the reaction was aqueous acetic acid, with small amounts of sulfuric acid added as a catalyst ($CH_3COOH : H_2O : H_2SO_4 = 100 : 20 : 3$).

Monoiodinated Products.—*4-t-Butyl-2, 6-dimethyliodobenzene.*—A mixture of II (5.40 g.), periodic acid dihydrate (1.54 g.), iodine (3.39 g.) and the solvent (20 ml.) was magnetically stirred and warmed at 60—65°C. After 4 hr., the elementary iodine had almost entirely disappeared and a heavy oil had precipitated. Upon cooling, the solidified product was collected by filtration and recrystallized from petroleum ether to give large plates, m. p. 59—60°C. The yield was 8.7 g. (90%). Because of its great tendency to avoid the hindered position, the iodine atom is supposed to be present at a position para to the *t*-butyl group.

Found: C, 49.73; H, 5.74. Calcd. for $C_{12}H_{17}I$: C, 50.00; H, 5.95%.

I was iodinated in a similar manner. This reaction, however, needed a little more time (6—7 hr.). The oil which precipitated was extracted with ether, and the ethereal solution was distilled after being washed with a dilute aqueous sodium bisulfite solution. There was obtained *5-t-butyl-2, 3-dimethyl-iodobenzene,* boiling at 146—147°C/14 mmHg, in a 81% yield. The unsymmetrical structure was confirmed by the aromatic substitution pattern of an infrared spectrum.

Found: C, 50.27; H, 6.07. Calcd. for $C_{12}H_{17}I$: C, 50.00; H, 5.95%.

6-t-Butyl-2, 3, 4-trimethyliodobenzene.—This was obtained, using a similar procedure, from VI (5.86 g.), periodic acid dihydrate (1.56 g.), iodine (3.39 g.) and the solvent (20 ml.). The crude product was chromatographed with an alumina column (1.7×35 cm.) using petroleum ether as an eluant; it was then recrystallized from hot ethanol to afford 8.9 g. of colorless plates melting at 74—75°C.

Found: C, 51.54; H, 6.41. Calcd. for $C_{13}H_{19}I$: C, 51.77, H, 6.35%.

2, 3, 5, 6-Tetraisopropyliodobenzene.—A mixture of IV (8.25 g.), periodic acid (1.54 g.), iodine (3.30 g.) and the solvent (35 ml.) was stirred and heated in such a manner that the temperature of the reaction mixture was held in the 75—80°C range. The iodine which sublimed on the upper part of the reaction vessel was scraped off by an occasional shaking. After 30 hr.'s heating, the hot mixture was poured into water, and the crystalline mass which precipitated was collected by filtration. Direct chromatography on an alumina column (1.7×65 cm.), using petroleum ether as an eluant, gave the unchanged hydrocarbon (7.0 g.), followed by the monoiodo product (1.9 g.). The latter compound was recrystallized several times from hot ethanol to obtain about 1.6 g. of white needles, m. p. 161—163°C.

Found: C, 58.35; H, 7.93. Calcd. for $C_{18}H_{29}I$: C, 58.07; H, 7.85%.

2, 5-Di-t-butyliodobenzene. — To a solution of III (6.38 g.) and iodine (3.38 g.) in the solvent (30 ml.), periodic acid dihydrate (1.60 g.) was added. The mixture was then agitated and heated at 75—80°C for about 30 hr. The reaction proceeded so slowly that the frequent shaking of the reaction vessel was necessary to scrape off the iodine which sublimed. After it had cooled, the solidified material was collected by filtration and washed with a dilute aqueous sodium bisulfite solution. As an attempted separation of the iodinated product from the unchanged hydrocarbon by alumina chromatography was found to be unsuccessful, the white crystalline cake was subjected to fractional distillation. There was obtained, after the removal of the low-boiling, unchanged hydrocarbon, 2.2 g. of a colorless oil boiling at 156—157°C/13—14 mmHg.

Found: C, 54.11; H, 6.96. Calcd. for $C_{14}H_{21}I$: C, 54.11, H, 6.70%.

Polyiodinated Products. — *4, 5-Diiodo-1, 2-dimethylbenzene.*—A mixture of *o*-xylene (3.54 g.), periodic acid dihydrate (3.04 g.), iodine (6.8 g.) and the solvent (20 ml.) was heated to 70°C and stirred until the purple color of the elementary iodine had almost disappeared (3—4 hr.). Then the mixture was poured into a dilute sodium bisulfite solution in order to remove the unreacted iodine. The tan solid which precipitated was then collected and chromatographed over a short alumina column (1.7×20 cm.). Recrystallization from ethanol gave 10.2 g. (85%) of colorless plates, m. p. 93—94°C. Raman and Varma reported a m. p. of 74—76°C.[16] Since they used nitric acid as an oxidizing agent, their product was necessarily contaminated with a small amount of nitro compounds. The symmetrical structure of the product was confirmed by the substitution pattern of an infrared spectrum.

Found: C, 26.69; H, 2.03. Calcd. for $C_8H_8I_2$: C, 26.84; H, 2.26%.

By a similar procedure, *2, 5-diiodo-1, 4-dimethylbenzene* was obtained from *p*-xylene. The product, recrystallized from benzene-ethanol, melted at 104—105°C. (Reported, m. p. 104°C).[16]

Found: C, 26.90; H, 2.31. Calcd. for $C_8H_8I_2$: C, 26.85; H, 2.26%.

The use of double the amounts of iodine and periodic acid has proved to have no effect. The reaction stopped at the stage of diiodination, and no tri- or tetra-iodo compounds were formed.

Diiodoprehnitene.—Prehnitene (4.47 g.) dissolved in the solvent (20 ml.) was iodinated with iodine (6.8 g.) and periodic acid (3.04 g.) in the manner described above. The reaction was completed within 1.5 hr,

16) P. S. Varma and K. S. V. Raman, *J. Indian Chem. Soc.*, **12**, 343 (1935).

and a pink-colored solid was precipitated. The product was collected and recrystallized from hot benzene. White needles; m. p. 190—191°C. Sparingly soluble in ethanol and petroleum ether. The yield was 10.8 g. (84%).

Found: C, 30.99; H, 3.38. Calcd. for $C_{10}H_{12}I_2$: C, 31.11; H, 3.13%.

Durene was converted by the same procedure to diiododurene, m. p. 140—141°C. Slightly soluble in hot ethanol and readily soluble in hot benzene, but nearly insoluble in petroleum ether.

Found: C, 31.00; H, 3.26. Calcd. for $C_{10}H_{12}I_2$: C, 31.11; H, 3.13%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 131—137 (1966)

The Simultaneous First- and Second-Order Esterifications of *l*-Menthol by Acyl Chlorides: Autocatalyses by Menthol in Acetonitrile and in Liquid Sulfur Dioxide*

By Fuminori AKIYAMA and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Higashinoda, Osaka

(Received May 21, 1965)

The propionylation and *p*-methoxybenzoylation of *l*-menthol in various solvents have been studied. In chloroform, benzene, ethyl methyl ketone and carbon tetrachloride, the reaction follows the second-order rate law. However, in acetonitrile or in liquid sulfur dioxide, the rate follows the second-order rate law only at the initial stage of the reaction; thereafter it gradually deviates from the second-order type to the first-order one. Moreover, the first-order rate equations both in acetonitrile and liquid sulfur dioxide are dependent on the initial concentration of the alcohol; the over-all rates being expressed as:

$$\text{Rate} = k_1^{\circ}\,(\text{AcCl})\,(\text{ROH})_0 + k_2\,(\text{AcCl})\,(\text{ROH})$$

where $(\text{ROH})_0$, (ROH), (AcCl), k_1° and k_2 are the concentrations of the alcohol at time zero and t, that of the acyl chloride at time t, the first-order rate constant and the second-order rate constant respectively.

It has been reported in a preceding paper[1] that the initial rates of the esterifications between *l*-menthol and acetyl chloride in various solvents obey the second-order and the first-order rate laws with the alcohol and the acetyl chloride respectively and that the rates depend neither upon the dielectric constants nor upon the Z values[2] of the solvents. The rate constant in liquid sulfur dioxide is the largest, the reason for this has also been discussed.

However, the inspection of the conversion vs. time curve in liquid sulfur dioxide revealed that the order of the reaction varies gradually and that the reaction obeys the first-order rate law after the middle stage of the reaction has passed.

Since the reaction rate of acetyl chloride with menthol in liquid sulfur dioxide is so rapid, the rate constant has only been determined by an extrapolation method. In the present paper, a further investigation of the esterification has been undertaken on slower rate systems, the propionylation and *p*-methoxybenzoylation of *l*-menthol in various solvents, thus we hope to make an unambiguous scrutiny of the reaction mechanism.

The reaction processes in various solvents, from the initial stages through the completion of the reactions, have been examined and analyzed; we found that the first-and second-order esterifications take place simultaneously in some of the solvents used, such as acetonitrile, liquid sulfur dioxide and nitromethane. When nitromethane is used as the solvent, another phenomenon in addition to the simultaneous reactions has also been observed; this finding will be published elsewhere in the near future.

The simultaneous nucleophilic substitutions (S_N1 and S_N2), the so-called border-line cases, in liquid sulfur dioxide have already been reported by Ingold et al.[3], and the possibility of such a phenomenon has been discussed by Tokura and Kondo[4] in connection with the Menschutkin reaction in liquid sulfur dioxide. Moreover, the first-order reaction rates in acetonitrile and in liquid sulfur dioxide have been found to be enhanced by the initial concentration of the *l*-menthol

employed. This means that the autocatalyses by the alcohol and/or the material produced from the alcohol are taking place in the esterification in these solvents.

Experimental

Solvents.—The following materials were purified by the methods described in the preceding paper[1] and were used as the solvents; liquid sulfur dioxide, chloroform, acetonitrile, benzene, ethyl methyl ketone, nitromethane and carbon tetrachloride.

Materials.—Commercial extra-pure-grade *l*-menthol was used without further purification; m. p. 41.5—43°C, $[\alpha]_D^{25}$ −47.6° (benzene). Preliminary examinations in liquid sulfur dioxide and in other solvents verified that the optical rotations of the solutions of *l*-menthol were stable over all the reaction times employed. Propionyl chloride was distilled, and the fraction boiling from 76.6 to 78.2°C was used. *p*-Methoxybenzoic acid and thionyl chloride (1 : 1.5 molar ratio) were heated together on a water bath for a half hour; the chloride produced was then distilled, the fraction with a b. p. of 132—133°C/11 mmHg being used.

The Identification of the Esters Obtained.—The reaction mixture after the esterification was concentrated in vacuo, and the residual oil was fractionated. The yield was almost quantitative. *l*-Menthyl propionate: b. p. 116°C/8 mmHg, $[\alpha]_D^{25}$ −82.18°, (benzene);

Found: C, 73.63; H, 11.64. Calcd. for $C_{13}H_{24}O_2$: C, 73.53; H, 11.39%.

l-Menthyl *p*-methoxybenzoate: b. p. 197°C/7 mmHg $[\alpha]_D^{25}=-80.0°$ (benzene);

Found: C, 74.87; H, 8.83. Calcd. for $C_{18}H_{26}O_3$: C, 74.44; H, 9.02%.

The specific rotations of *l*-menthyl propionate in various solvents are listed in the following table.

Table I. The specific rotations of *l*-menthyl propionate in solvents

Solvent	$-[\alpha]_D^{25}$ degree·dm^{-1}·g^{-1}·ml.
Liq.SO_2	79.04
Chloroform	84.19
Acetonitrile	77.25
Ethyl methyl ketone	78.86
Benzene	82.18
Nitromethane	80.44

The Kinetic Procedure.—The polarimetric procedure used for the kinetic followings was described earlier,[1] a graphic representation of the apparatus (a polarimeter equipped with a pressure-cell for use in the reaction in liquid sulfur dioxide) will also be found therein. *l*-Menthol dissolved in a solvent was placed in the cell. An acyl chloride in an ampoule was deposited in a cell situated in a polarimeter before a menthol solution was introduced. After the temperature equilibration of the apparatus containing the menthol solution in the thermostat had been attained, the ampoule in the cell was broken by a vigorous shaking and the solution was mixed. Then the kinetic following by means of polarimetry was began.

The Estimation of the Rate Constant.—The second-order rate constant, k_2, may be obtained from the slope of the linear plot:

$$\log\frac{(ROH)_0\{l([R]^\circ_E-[R]^\circ_A)(AcCl)_0-(\alpha-\alpha_0)\}}{(AcCl)_0(\alpha_\infty-\alpha)} \text{ vs. } t,$$

since

$$\frac{1}{(AcCl)-(ROH)_0}\times \ln\frac{(ROH)_0\{l([R]^\circ_E-[R]^\circ_A)(AcCl)_0-(\alpha-\alpha_0)\}}{(AcCl)_0(\alpha_\infty-\alpha)}=k_2\cdot t \quad (1)$$

where $(ROH)_0$ and $(AcCl)_0$ are the initial concentrations of the alcohol and the acyl chloride and $(R)^\circ_A$ and $(R)^\circ_E$ are the specific rotations of the alcohol and the ester in the solvents in degree·dm^{-1}·mol^{-1}·l. respectively. l, α, α_0 and α_∞ are the length of the cell, dm., and the rotations of the solution at time t, zero and infinity.

When equimolar concentrations of menthol and acyl chloride were used, the rate constant, k_2, was given by the slope of the linear plot of :

$$\frac{1}{\alpha_\infty-\alpha} \text{ vs. the time, } t,$$

since:

$$\frac{1}{\alpha_\infty-\alpha}-\frac{1}{\alpha_\infty-\alpha_0}=\frac{k_2\cdot t}{l[(R)^\circ_E-(R)^\circ_A]} \quad (2)$$

First-order Rate Constant.—The first-order rate constant, k_1, will be expressed as;

$$\ln\frac{\alpha_\infty-\alpha_0}{\alpha_\infty-\alpha}=k_1\cdot t \quad (3)$$

Therefore, the $-\log(\alpha_\infty-\alpha)$ vs. t plot will give a straight line, whose slope will be the value of k_1.

Typical Runs.—The second-order plots of the esterifications in chloroform, ethyl methyl ketone and benzene are visualized in Fig. 1. The second-order plots of the reactions in acetonitrile and in liquid sulfur dioxide are shown in Figs. 2 and 5, which show the deviations from linearity as the reactions proceed.

The first-order plots of the same esterifications are seen in Figs. 3 and 6, which again exhibit the deviations from linearity in the initial periods of the reactions.

Results

The Propionylation of *l*-Menthol.—In chloroform, ethyl methyl ketone, benzene and carbon tetrachloride, the esterification reactions strictly obey the second-order rate law throughout the reaction (Fig. 1). These results, together with the second-order rate constants in acetonitrile, in liquid sulfur dioxide and in nitromethane, are listed in Table II.

That the second-order rate law consists of the first order with both the alcohol and the acyl chloride has already been established[5]; evidence for this was also given in the previous paper.[1]

On the contrary, in acetonitrile, liquid sulfur dioxide or nitromethane, the apparent kinetic order of the reaction varies as the reaction proceeds.

TABLE II. THE SECOND-ORDER RATE CONSTANTS (k_2, $sec^{-1} \cdot mol^{-1} \cdot l.$) OF THE PROPIONYLATION OF *l*-MENTHOL IN VARIOUS SOLVENTS

Solvent	Reaction temp., °C				
	5	15	25	30	35
Liq.SO_2	2.11×10^{-2}	3.12×10^{-2}	4.70×10^{-2}		
Nitromethane			1.50×10^{-3}		
Chloroform		8.99×10^{-4}	1.35×10^{-3}		2.17×10^{-3}
Benzene		2.39×10^{-4}	4.40×10^{-4}	5.70×10^{-4}	
Carbon Tetrachloride			8.13×10^{-4}		
Acetonitrile		2.12×10^{-4}	3.33×10^{-4}		5.70×10^{-4}
Ethyl methyl ketone		4.21×10^{-5}	9.18×10^{-5}		2.29×10^{-4}

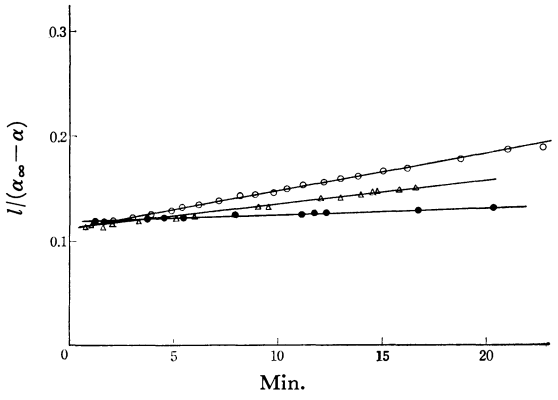

Fig. 1. Propionylation of *l*-menthol at 25°C.
-○- Chloroform
-△- Benzene
-●- Ethyl methyl ketone

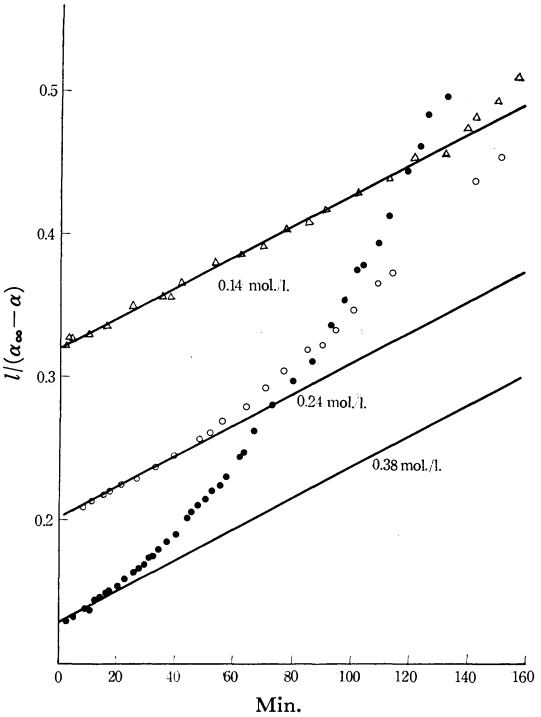

Fig. 2. Second-order plots in acetonitrile. 25°C

During the initial stage of the reaction, a second-order law was directive, this was followed by a gradual transition to an apparent first-order rate law, first order in acyl chloride and zero order in the alcohol. In the present paper, the findings and the discussion of the esterification in nitromethane are omitted, since another interesting feature has been found in nitromethane.

Propionylation in Acetonitrile.—As may be seen in Fig. 2, the second-order plot of the reaction deviates from linearity as the reaction proceeds. Figure 3 is the first-order plot of the esterification in the middle and the final periods of the reaction, following the first-order rate law.

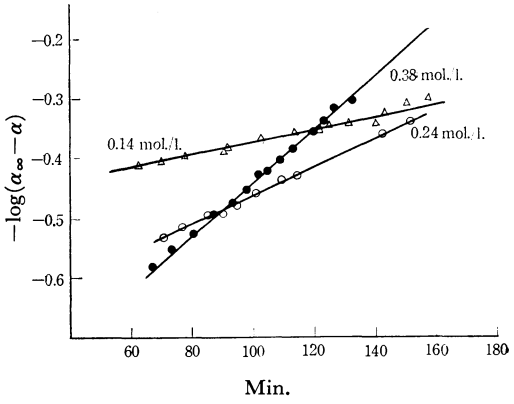

Fig. 3. First-order plots in acetonitrile. 25°C

The deviation from the second-order law is greatly affected by the initial concentration of the alcohol. Also, the rate constant of the first-order reaction is affected by the initial concentration of the alcohol, although the rate law is zero-th order in the alcohol concentration. The transition or the deviation points which are shown by the conversions from the second law, may be seen in Fig. 2 and are listed in Table III.

The larger the initial concentration, the earlier the transition point appears, as may be seen in Table III. The dependency of the rate constant, k_1 on the initial concentration is visualized in Fig. 4, which shows a linear correlation between k_1 and $(ROH)_0$.

Table III. First-order rate constants of the esterification in acetonitrile, 25°C
The dependence of thf rate constants on the initial concentrations

$(ROH)_0$ mol./l.	$(AcCl)_0$ mol./l.	k_1, sec^{-1}	Conversion at the transition point, %
0.14	0.14	3.85×10^{-5}	35
0.24	0.24	9.19×10^{-5}	18
0.36	0.24	1.43×10^{-4}	
0.38	0.38	1.63×10^{-4}	11
0.38	0.19	1.53×10^{-4}	
0.48	0.24	2.28×10^{-4}	
0.67	0.38	3.11×10^{-4}	

The rate expression, then, will be

$$\text{Rate} = k_1^\circ(\text{ROH})_0(\text{AcCl}) \quad (4)$$

since

$$k_1 = k_1^\circ(\text{ROH})_0 \quad (5)$$

while k_1° is estimated to be $k_1^\circ = 5.14 + 10^{-4}\ sec^{-1}\cdot mol^{-1}\cdot l.$ at 25°C.

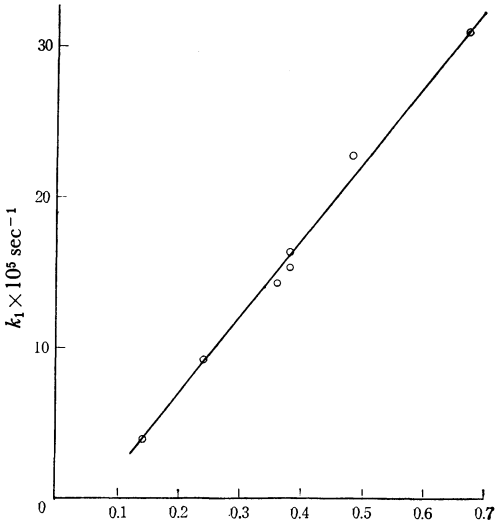

Fig. 4. Dependency of k_1 on $(ROH)_0$ in acetonitrile at 25°C.

Propionylation in Liquid Sulfur Dioxide.—The results resemble those in acetonitrile, but the transition to the first order occurs at a later period of the reaction, as may be seen in Fig. 5 and in Table IV. The first-order plots are also visualized in Fig. 6, which confirms a linear dependency on the initial concentration of menthol, as in the case of acetonitrile.

Table IV. The transition from the second-order law at 25°C in $Liq.SO_2$

Initial concn. mol./l.	Transition point conversion, %
0.27	76
0.13	78
0.11	81

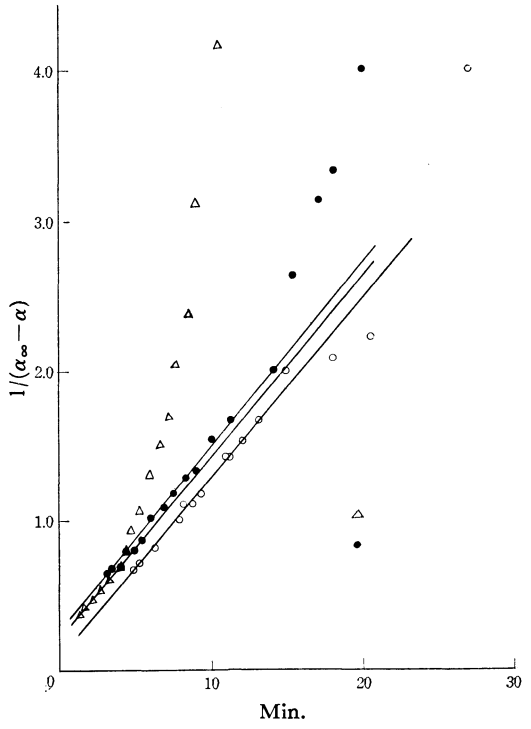

Fig. 5. Second-order plots in liquid sulfur dioxide. 25°C
△ 0.27 mol./l. ● 0.13 mol./l. ○ 0.11 mol./l.

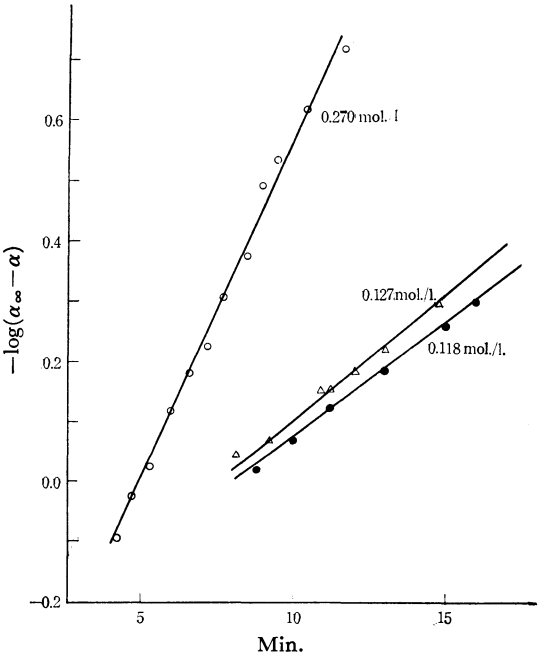

Fig. 6. First-order plots in liquid sulfur dioxide. 25°C

The higher the initial concentrations, the earlier

the deviations from the second-order rate law; however, in liquid sulfur dioxide the deviation occurs at a later stage, at over a 76% conversion, as is shown in Fig. 5.

Table V. First-order rate constants, k_1 in various initial concentrations of $(ROH)_0$ at 25°C

$(ROH)_0$, mol./l.	k_1, sec^{-1}
0.27	4.15×10^{-3}
0.133	1.72×10^{-3}
0.127	1.63×10^{-3}
0.120	1.46×10^{-3}

As is illustrated in Fig. 7 and Table V, the dependency of k_1 on $(ROH)_0$ in liquid sulfur dioxide is linear and the $k_1°$ value is given as;

$$\text{Rate}=k_1(\text{AcCl})$$
$$=k_1°(ROH)_0(\text{AcCl}) \quad (6)$$

since $$k_1=k_1°(ROH)_0 \quad (7)$$

$$k_1°=1.77\times10^{-2}\,sec^{-1}\cdot mol^{-1}\cdot l. \text{ at } 25°C$$

The Kinetic Parameter of the Second-order Reaction.— The activation parameters for the second-order reaction in various solvents as estimated from the

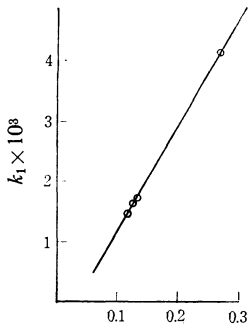

Fig. 7. Dependency of k_1 on $(ROH)_0$ in liquid sulfur dioxide at 25°C.

Table VI. The activation parameters of the esterification of *l*-menthol with propionly chloride in solvents

Solvent	$\Delta E^{\ddagger}$ kcal./mol.	$\Delta H^{\ddagger}$ kcal./mol.	$\Delta S^{\ddagger}$, e. u.
Liq. SO_2	6.57	5.98	−44.55
Chloroform	7.75	7.16	−47.6
Acetonitrile	8.53	7.94	−47.7
Benzene	11.40	10.81	−37.6
Ethyl methyl ketone	15.00	14.41	−28.52

Table VII. The activation parameters of the esterification of *l*-menthol with *p*-methoxybenzoyl chloride in Liq. SO_2 and $CHCl_3$

Solvent	$\Delta E^{\ddagger}$	$\Delta H^{\ddagger}$	$\Delta S^{\ddagger}$
liq. SO_2	10.07	9.48	−35.3
$CHCl_3$	17.96	17.37	−23.4

results in Table II are listed in Tables VI and VII.

Discussion

The results may be summarized as follows. The reactions, the propionylations and the *p*-methoxybenzoylations of *l*-menthol follow the second-order rate law in chloroform, benzene, ethyl methyl ketone and carbon tetrachloride at 25°C, as they do in the acetylations of *l*-menthol, which were reported on earlier.[1]

However, in acetonitrile or in liquid sulfur dioxide, the rate obeys the second-order rate law at the initial stage of the reaction, the second-order plot, deviates from linearity as the reaction proceeds, and gradually changes into a first-order rate reaction. The apparent transition or the deviation from the second-order rate law is prompted when the initial concentration of the alcohol is increased and acetonitrile is used as the solvent.

The inversion of the rate laws during an acylation in a solvent has not hitherto been reported, although the change in the rate orders in the acylation of an alcohol by solvents has been reported by Brown and Hudson.[6] The change in the reaction orders during a reaction course in a solvent, as is reported in the present paper, may be plausibly explained as the results of simultaneous reactions consisting of a first-order type and a second-order type reaction, such as have been frequently encountered and discussed in nucleophilic substitutions in various solvents[7] including liquid sulfur dioxide.[3] Thus, it may be shown by the following expression:

$$\text{Rate}=k_1(\text{AcCl})+k_2(\text{AcCl})(ROH) \quad (8)$$

or, for equimolar initial concentrations of the alcohol and the acyl chloride:

$$\text{Rate}=dx/dt=k_1(a-x)+k_2(a-x)^2 \quad (9)$$

where a and x are the concentrations of the alcohol initially added and of the ester formed respectively.

The integration of Eq. 9 gives this relation:

$$\log\frac{a-x}{a-x+k_1/k_2}=\frac{-k_1}{2.303}t+\log\frac{a}{a+k_1/k_2} \quad (10)$$

By substituting the values, k_1 and k_2, obtained experimentally into the left term of Eq. 10, the plots of $\log\frac{a-x}{a-x+k_1/k_2}$ vs. time t are linear, as is shown in Figs. 8 and 9, in both acetonitrile and liquid sulfur dioxide. The slopes of the respective plots are fairly coincident with the experimentally-attained values of k_1's in the range of experimental error.

7) a) W. G. Young and L. J. Keefer, *J. Am. Chem. Soc.*, **66**, 421 (1944). b) V. Gold, ibid., **78**, 4633 (1956). c) Y. Pocker, *J. Chem. Soc.*, **1954**, 3939, 3943. d) P. Casapieri and R. E. Swart, ibid., **1961**, 4342.

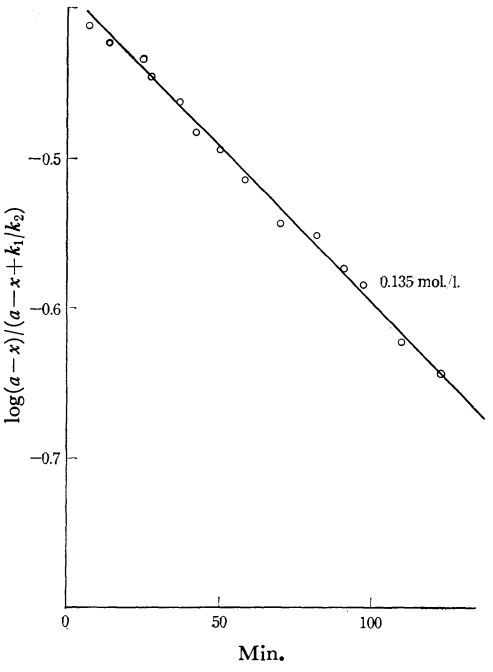

Fig. 8. Plots of the simultaneous reactions in acetonitrile at 35°C.

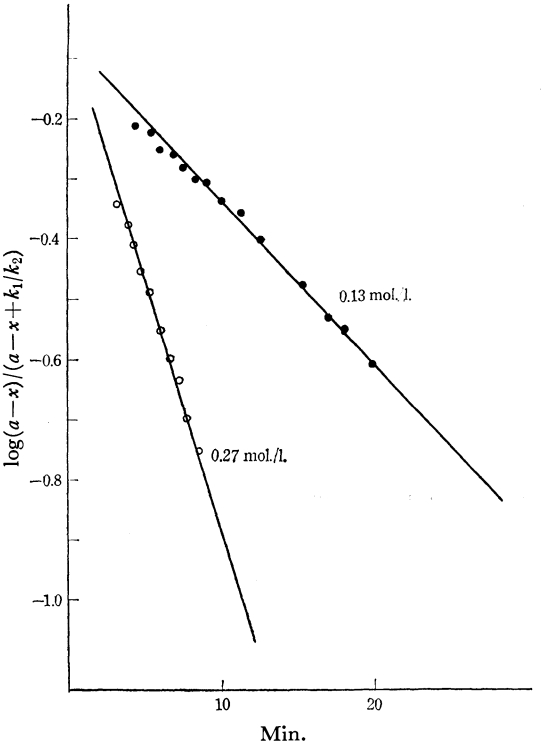

Fig. 9. Plots of the simultaneous reactions in liquid sulfur dioxide at 25°C.

These results satisfactorily confirm the assumption of the simultaneous nature of the reaction in two solvents.

Moreover, in both solvents the first-order rate constants, the k_1 values, are dependent upon the initial concentrations of the alcohol; the higher the initial concentration, the larger the first-order rate constant, as is shown in Figs. 4 and 7. This suggests that the alcohol and/or a compound produced from the alcohol (perhaps the ester or HCl) might be responsible for the apparent autocatalysis in the propionylation of the alcohol, and that the over-all kinetics of the reaction may be expressed as;

$$\text{Rate}=k_1^{\circ}(\text{AcCl})(\text{ROH})_0+k_2(\text{AcCl})(\text{ROH}) \quad (11)$$

	k_1°, $\text{sec}^{-1}\cdot\text{mol}^{-1}\cdot\text{l}.$	k_2, $\text{sec}^{-1}\cdot\text{mol}^{-1}\cdot\text{l}.$ at 25°C
Acetonitrile	5.14×10^{-4}	3.33×10^{-4}
Liq. SO_2	1.77×10^{-2}	4.70×10^{-2}

The multimolecularity of alcohol in the rate law of the esterification was first recognized by Ashdown[8] as early as in 1930 in his study of the ethanolysis of *p*-nitrobenzoyl chloride, where the reaction followed a third-order rate law, while it followed a second order in ethanol and a first order in the acyl chloride.

Ingold et al.[9] have also observed, in a nucleophilic substitution by ethanol in nitromethane, that the first-order rate constant is dependent on the initial concentration of the alcohol. The dependency of k_1 on the initial concentration of menthol $(\text{ROH})_0$ can be most adequately elucidated in terms of the solvation of the alcohol to enhance the rate-determining ionization of the acyl chloride.

The rate constants, both k_1 and k_2, are largest in liquid sulfur dioxide, as may be seen in Tables II, III and IV.

One might suspect that the expression 11 could be replaced by a simpler equation, such as;

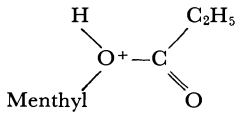
$$\text{Rate} = k(\text{AcCl})(\text{ROH})_0 \quad (12)$$

since Eq. 12 is also consistent with the experimental fact that the reaction is second-order at the initial stage but soon changes to a first-order rate law. However, this rate equation is not adequate to explain the reaction in liquid sulfur dioxide where the second-order rate law predominates until a 80% conversion or so.

$(\text{ROH})_0$ can be explained in terms of the alcohol present in the reaction mixture and/or the compound produced as the result of the reaction of the alcohol in an equivalent molarity, such as that of the ester or of HCl.

An inspection of Table II will reveal that the second-order esterifications are more reactive in the electrophilic solvent than in the electrodonative solvent, suggesting that the rate-determining step is the formation of an ionic compound such as:

8) A. A. Ashdown, *J. Am. Chem. Soc.*, **52**, 269 (1930).
9) E. Gilles, E. D. Hughes and C. K. Ingold, *J. Chem. Soc.*, **1954**, 2918.



It is interesting to note that, in both acetonitrile and liquid sulfur dioxide, which are the two extreme solvents (viz., a Lewis base and a Lewis acid), the reactions are simultaneous. One explanation for this is that acylium ions (RCO^+) are formed in an appreciable amount in these dipolar aprotic solvents with large polarities:

$$RCOCl \rightleftarrows RC^+O+Cl^-$$

Summary

The propionylation and *p*-methoxybenzoylation of *l*-menthol in various solvents have been studied. In chloroform, benzene, ethyl methyl ketone and carbon tetrachloride, and at the initial stages of the reaction courses in acetonitrile and in liquid sulfur dioxide, the reactions follow the second-order rate law. However, in acetonitrile or liquid sulfur dioxide, the rate gradually varies from the second-order type to the first-order type apparently as the reaction proceeds.

The phenomena in both solvents have been elucidated as resulting from simultaneous unimolecular and bimolecular reactions. Moreover, the first-order rate constants in both acetonitrile and liquid sulfur dioxide, are dependent on the initial concentration of the alcohol.

The over-all rates in the two solvents are expressed as:

$$\text{Rate}=k_1^\circ(\text{AcCl})(\text{ROH})_0+k_2(\text{AcCl})(\text{ROH})$$

The rate constants in liquid sulfur dioxide, both k_1 and k_2, are the largest among those in the solvents used.

The authors are indebted to the Seitetsu Kagaku Co., Ltd., for its donation of liquid sulfur dioxide.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 137—140 (1966)

The Adsorption Equilibria of DL-Mandelic Acid on Starch in an Aqueous Phase

By Masaaki OHARA, Chau-Yang CHEN and Takao KWAN

Division of Physicochemical Technology, Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Tokyo

(Received May 25, 1965)

The selective adsorption of D- or L-mandelic acid on starch from an aqueous solution of racemate has been quantitatively investigated. L-Mandelic acid has been judged from the distinct negative value of the optical rotation in the solution to be adsorbed preferentially over the D-isomer. The separation factor for the adsorption of the two enantiomers was 1.06 ± 0.02 at 0°C. From the saturation value estimated by the Langmuir equation for adsorption, the ratio of the glucose residue to the DL-mandelic acid adsorbed has been calculated as 5, indicating that not all the glucose residues in the starch constitute adsorption sites for mandelic acid.

The asymmetric adsorption of racemate on optically active adsorbents has so far been studied by the batch adsorption or the chromatographic technique.[1] Despite the effort devoted to this subject, however, little progress has been made in the quantitative estimation of the stereospecific adsorption of optical antipodes. The lack of the observation of large rotation angles and the absence of a distinct difference in adsorption between enantiomers in the systems investigated have hampered any further clarification of this subject, although several reliable and somewhat systematic attempts using the batch method have been reported for such systems as wool - DL-mandelic acid,[2] and silica-gel - DL-*s*-butanol.[3]

It has been investigated by several authors,[4] and well established in this laboratory,[1] that starch, when used as an optically active column packing, takes up the L-(+)-isomer selectively

through the passage of DL-mandelic acid from an aqueous solution. The selective adsorption of this kind has now been further investigated by utilizing a batch technique. In this paper, we will report on the first quantitative investigation on the adsorption equilibria of DL-mandelic acid on starch, in which the separation factor of the isomers is evaluated as 1.06 ± 0.02 at the temperature of 0°C.

Experimental

Materials.—Commercial DL-mandelic acid of a high grade was used (m. p. 118°C). The elementary analysis showed:

Found: C, 63.28; H, 5.32; O, 31.40. Calcd. for $C_6H_8O_3$: C, 63.15; H, 5.30; O, 31.55%.

Potato starch of a reagent grade was used without special pretreatment. It contained 18 ± 0.1% moisture.

General Procedure.—Samples of starch, weighing 18 g., 13.5 g., 9 g. and 4.5 g., were immersed in a 50 ml. Erlenmeyer flask equipped with a stopper. The closed flask was then kept at 0°C for 48 hr. with occasional agitation until equilibrium was attained. After the starch had been allowed to settle, the supernatant liquid equilibrated was withdrawn; the optical rotation of the solution α_D^{15} was then determined in a 10 cm. tube in a Yanagimoto Model OR-20-type photomagnetic polarimeter within a ±0.002 accuracy. The concentration of the acid was determined by means of the optical absorption at 257 mμ.

Results

First, the adsorption of DL-mandelic acid on starch was studied by means of the optical rotatory dispersion. The results were compared with those of the two control experiments. Hence the systems studied were:

1) 10 w/v% DL-mandelic acid aqueous solution (30 ml.) - untreated starch (18 g.)
2) water (30 ml.) - starch (18 g.)
3) 14.3 w/v% glycolic acid aqueous solution* (30 ml.) - starch (18 g.).

The optical rotatory dispersion was determined in a 5 cm. tube on a Nippon Bunko Model ORD/UV-5-type recording spectrophotometer. In Fig. 1

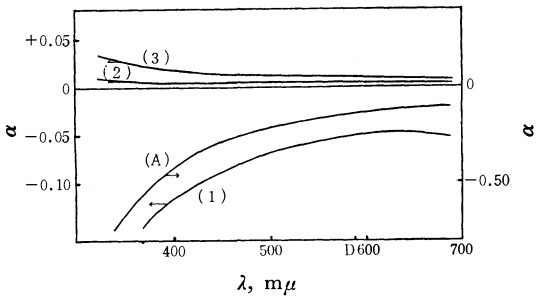

Fig. 1. The optical rotatory dispersion curves of DL-mandelic acid solution (1), water (2) and glycolic acid solution (3) in contact with starch as compared with that of D-(−)-mandelic acid (A).
Cell length: 5 cm.
Temp. : 12—14.5°C
D : Sodium D line

the observed curves are compared with that of authentic D-(−)-mandelic acid.

The curve 3 bends slightly to the (+) side, while the curve 2 indicates no definite rotation, suggesting that glycolic acid slightly decomposes or extracts the optically active starch component. On the other hand, the curve 1 bends on a large scale to the (−) side, as does that of the authentic sample. The difference between 1 and 3 gives a (−) sign of rotation; this may be ascribed to the net rotation value of mandelic acid in a solution. It is apparent, therefore, that L-(+)-mandelic acid is preferentially adsorbed from the racemate solution. This finding is consistent with those revealed by the column chromatography.[1]

Let us proceed to the principal subject. It was previously confirmed that the adsorption of DL-mandelic acid on starch reaches an equilibrium within 8 hr. at 0°C. However, the equilibrium data were recorded after the solution had been left standing over 2 days. By carying the amount of DL-mandelic acid, on the one hand, and the amount of starch on the other, the adsorption isotherm was determined as usual at the temperature of 0°C. Table I lists some of the adsorption data,

TABLE I. ADSORPTION EQUILIBRIUM DATA OF DL-MANDELIC ACID ON STARCH (T=0°C)

Sample No.	C_i	C_e	Amount adsorbed	Optical rotation of solution		$\Delta W/W$	f
	mg./ml.	mg./ml.	mg.	α_D^{15}	$[\alpha]_D^{15}$	%	
B1	25.05	21.8	137	−0.017	−0.78	2.2	1.05
B2	50.0	43.8	265	−0.036	−0.82	2.4	1.06
B3	74.5	66.5	360	−0.045	−0.68	2.2	1.05
B4	100.3	91.8	420	−0.060	−0.66	2.6	1.06
D1	25.05	19.7	232	−0.035	−1.8	2.5	1.07
D2	50.0	39.4	461	−0.061	−1.6	2.2	1.07
D3	74.5	61.4	614	−0.082	−1.3	2.2	1.06
D4	100.3	84.2	785	−0.103	−1.2	2.2	1.06

* Glycolic acid was chosen as the control sample, since (1) it is of almost the same acidity as mandelic acid; (2) it has a chemical structure similar to that of mandelic acid, and (3) it is an optically-inactive organic acid.

obtained along with parameters estimated therefrom.

In Table I, the signs B and D stand for the amount of starch used, 9 g. and 18 g. respectively, while C_i and C_e are the initial and equilibrium concentrations of the acid respectively. To determine the amount of mandelic acid adsorbed, W, the usual method would be to measure the change in the concentration of the solution after equilibrium. However, this method was thought to be inadequate for the present investigation, as the untreated starch, which contains 18% moisture, sorbs addition water, Consequently, W was estimated from the following revised equation:

$$W=30C_i-(30-Gw)C_e$$

where G is the amount of the untreated starch and w, the volume of the additionally sorbed water (ml.) per gram of the untreated starch. It was estimated at about 0.2 ml. from the difference between the amount of moisture in the untreated starch and that of water bound to potato starch suspended in an aqueous solution. The amount of bound water, about 33%, was based upon the data in the literature.[5] ΔW is the difference between enantiomers in the amount of mandelic acid adsorbed, and f is the separation factor, which will be defined later.

The net angle of rotation of mandelic acid in the solution is indicated in the 5 th column of Table I. These values were corrected for the rotation due to the optically active starch component produced by the interaction of the acid with starch. In Table II typical data are given on the interaction of an acid with starch.

Table II. α_D^{15} of the glycolic acid solution in contact with starch (T=0°C)

Concn. of glycolic acid mg./ml.	Weight of starch g.	Reaction time hr.	α_D^{15} of the solution after reaction
143	4.5	48	+0.001
143	9.0	48	+0.003
143	13.5	48	+0.006
143	18.0	48	+0.009

It was recognized that the α_D^{15} of the solution was little dependent on the concentration of the glycolic acid, but very dependent on the amount of starch used.

Using the data of Table I, the adsorption isotherm of DL-mandelic acid on starch is plotted in Fig. 2. The equilibrium concentration of the acid was in the range from 3.1 to 95 mg./ml.

The limited solubility of the acid did not permit the observation of the adsorption over the higher equilibrium concentrations. However, the Langmuir equation, $W=W_m bC_e/(1+bC_e)$, seemed to apply to the observed data. The Langmuir

5) F. Schierbaum and K. Täufel, *Die Stärke*, **15**, 161 (1963).

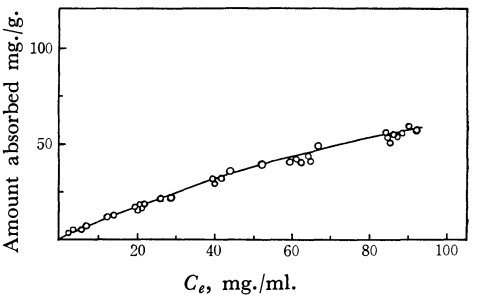

Fig. 2. Adsorption isotherm of DL-mandelic acid on starch at 0°C.

equation may be tested by arranging it in the form:

$$C_e/W=C_e/W_m+1/bW_m$$

In Fig. 3 plots of C_e vs. C_e/W are shown. They yield approximately a straight line. From the slope $1/W_m$, a reciprocal of the saturated amount of adsorption can be calculated. It was found to be W_m=188 mg.

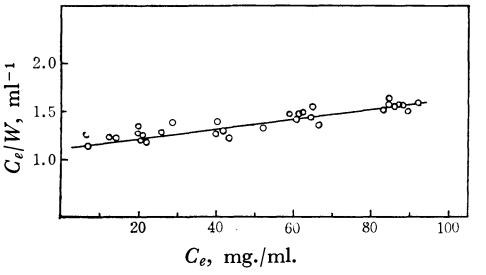

Fig. 3. Adsorption isotherm of DL-mandelic acid plotted according to the Langmuir equation.

The amounts of D- or L-isomers adsorbed on the surface of the starch were computed from the data of the specific rotation in the solution. The concentration of each isomer in the solution may be calculated by assuming that the additivity rule holds between $[\alpha]_D$ and the composition of each isomer, and that the $[\alpha]_{DP}$ of the acid is independent of the concentration. Here, $[\alpha]_{DP}$ is the specific rotation of optically pure mandelic acid. The difference between enantiomers in the amount adsorbed may be expressed as:

$$\Delta W=W_d-W_l=(30-Gw)C_e \mid [\alpha]_D/[\alpha]_{DP} \mid$$

where W_d and W_l are, respectively, the amount of the L- or D-isomer adsorbed. Consequently, $\Delta W/W$ may be obtained as:

$$\Delta W/W=(30-Gw) \mid [\alpha]_D/[\alpha]_{DP} \mid C_e/W$$

The substitution of 0.2 and $\pm$157 for w and $[\alpha]_{DP}$ respectively in the above equation yields a $\Delta W/W$ value for each G, values which range between 2.1% and 2.6%. These values are shown in the 7 th column of Table I.

Finally, the separation factor, f, as defined by the ratio of the adsorption equilibrium constants of the isomers, is expressed as:

$$f=\frac{W_d/C_{ed}}{W_l/C_{el}}=\frac{1+|[\alpha]_D/[\alpha]_{DP}|}{1-|[\alpha]_D/[\alpha]_{DP}|}\times\frac{1+\Delta W/W}{1-\Delta W/W}$$

where C_{ed} and C_{el} are the concentrations of L- and D-isomers respectively in the liquid phase at equilibrium.

On the basis of this equation, f may be estimated to be 1.06 ± 0.02. The values of f are presented in the last column of Table I.

Discussion

It is interesting to note that the adsorption of mandelic acid on starch obeys the Langmuir equation. This would mean that the surface of starch is rather homogeneous for the adsorption of mandelic acid, and that no interaction between the adsorbed molecules is present. The saturation value for the adsorption was found, according to the Langmuir equation, to be 188 mg./g. starch. This value corresponds to 7.4×10^{20} molecules. Since one gram of starch consists of about 3.7×10^{21} glucose residues, the following stoichiometric relation may hold at saturation:

Glucose residue: Mandelic acid $\approx$ 5 : 1

Let us discuss the problem in connection with bound water. In a series of investigations bearing the title of "The Hydration of Starch," Schierbaum and Täufel have definitely shown that bound water in the starch may be distinguished from free water. The literature[5] estimates the amount of bound water to be 32.5—33.8% for potato starch. This value corresponds to:

Glucose residue : Water molecule $\approx$ 1 : 4

The logical sites for the adsorption of mandelic acid or water seem to be the hydroxyl groups of the starch. If so, three available sites are found in each glucose residue. It may be suggested, therefore, that not all glucose residue are effective in the adsorption of mandelic acid, and that bound water occupies almost all the active sites.

The surface area of starch effective in the adsorption of mandelic acid may be evaluated from the saturation value.

Assuming that the molecular shape of mandelic acid is a sphere, the molecular area, σ_m, of acid is estimated to be:

$$\sigma_m=34 \text{ sq. Å}$$

Consequently, the surface area is given by $S=250$ m^2/g.

The surface area of potato starch was determined by Hellman and Melvin[6] by the BET method, using nitrogen as the adsorbate at -195°C. Accordingly, the area was 0.11 m^2/g. The same author found that the surface area of the same starch was about 300 m^2/g. when the adsorption of water vapor was applied to the BET plot at 25°C.

The amount of water adsorbed at the monolayer, according to these authors, corresponded to:

Glucose residue : Water molecule $\approx$ 1 : 1

Therefore, the amount of bound water is about four times as great as that of the monolayer.

The discrepancy between the BET area obtained by the nitrogen adsorption at -195°C and that due to the water adsorption at room temperature is well known in the surface area of organic high polymers, such as cellulosic fibers and proteins[7] and coal[8]. In Table III the surface areas of some organic polymers as determined by the nitrogen adsorption method and by the water (methanol) adsorption method are compared, using those of titanium dioxide (anatase) as a reference sample.

TABLE III. THE SURFACE AREA OF SOME ORGANIC HIGH POLYMERS AS DETERMINED BY DIFFERENT METHODS

Material	Area Determined by nitrogen at -195°C m^2/g.	Area Determined by water at 25°C m^2/g.	Lit.
Potato starch	0.11	296	6
Wool	0.96	206	7
Cotton	0.76	108	7
Nylon	0.31	45.0	7
Coal	0.1—10	20—200**	8
Titanium dioxide	7.90	7.0	7

Obviously, the nitrogen adsorption method at -195°C would be inadequate for the measurement of the surface area of organic polymers. On the other hand, the surface area of starch, estimated from the saturation of the mandelic acid adsorption, is not very different from that of water adsorption as determined by Hellman and Melvin. The adsorption of mandelic acid on starch is probably to be considered as a kind of inclusion of the adsorbate molecule on the internal surface of starch.

The difference in the adsorption of D- and L-mandelic acid, established in this paper, must be investigated further with regard to the structural correlation of the adsorbate molecule with starch.

The authors wish to express their gratitude to Professor Syun-ichi Yamada and Dr. Kazuo Achiwa of The University of Tokyo for letting them use both the ORD spectrophotometer and the polarimeter.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 141—145 (1966)

Organic Syntheses by Means of Noble Metal Compounds. XIV. The Carbonylation of Cyclooctadienes

By Jiro Tsuji, Shuntaro Hosaka, Jitsuo Kiji and Tosaku Susuki

Basic Research Laboratories, Toyo Rayon Company, Kamakura

(Received May 27, 1965)

The 1, 5-cyclooctadiene - palladium chloride complex and carbon monoxide react in ethanol to form ethyl 4-cyclooctenecarboxylate. The carbonylation of 1, 5-cyclooctadiene catalyzed by palladium chloride has given ethyl 4-cyclooctenecarboxylate and cyclooctanedicarboxylate. It has been found that the monoester can be obtained selectively under certain conditions; the further carbonylation of the monoester gives the diester. Under the same reaction conditions, 1, 3-cyclooctadiene gives ethyl 2-cyclooctenecarboxylate in a low yield. Metallic palladium has been found to be the true catalyst and the presence of hydrogen chloride has been found to be essential for the catalysis. It has also been found that the 1, 5-cyclooctadiene - palladium chloride complex can be formed from 1, 5-cyclooctadiene, metallic palladium and hydrogen chloride by heating them in an autoclave under nitrogen. It seems likely that the catalytic carbonylation of 1,5-cyclooctadiene proceeds through the formation of the 1,5-cyclooctadiene - palladium chloride complex.

Previous work in this series has shown that palladium chloride complexes of simple olefins,[1] allylic compounds,[2,3] and conjugated dienes[4] can be carbonylated easily to form saturated or unsaturated esters in an alcoholic solution, and acid chlorides in a benzene solution. In the present paper, we wish to report the carbonylation of the 1, 5-cyclooctadiene (1, 5-COD) - palladium chloride complex (I). It was of special interest to study the carbonylation of 1, 5-COD complex in view of the fact that the complex is unusually stable and has a monomeric structure which is different from halogen-bridged olefinic and π-allylic complexes of palladium chloride.[5] In addition, the direct carbonylation of 1, 5-COD to form a mono- or a di-ester in the presence of a catalytic amount of palladium chloride seemed to be worthy of study.

Experimental

The NMR spectra were determined with high-resolution spectrometer, models DP 60 and HR 100, using tetramethylsilane as an internal standard; the peak positions are expressed in terms of τ values. Gas chromatographic analyses were carried out on a Thermol-3 column, 2 m. long, at 220°C for higher-boiling products, or on a Silicone DC 550 columm, 2 m. long, at 180°C for lower-boiling products. All boiling points are uncorrected. The molecular weights were determined in benzene using a Mechrolab vapor-pressure osmometer, or by mass spectroscopy.

Materials. — Commercially available anhydrous palladium chloride was used without further purification. Carbon monoxide (99.5% pure) was purchased from the Matheson Co., U.S.A. 1, 5-COD was also a commercial product (99% pure). 1, 3-COD was prepared from 1, 5-COD by Devaprabhakara's method.[6]

3-Bromocyclooctene was prepared by refluxing a mixture of cyclooctene (80 g.), N-bromosuccinimide (110 g.), benzoyl peroxide (0.2 g.), and carbon tetrachloride (400 ml.) for 1 hr. The product (b. p. 73—75°C/ 7mmHg) was obtained in a 69% (96 g.) yield.

The Carbonylation of 1, 5-COD in Ethanol.— The reaction conditions are given in Table I. The general procedure is as follows. To avoid the effect of the metal surface of a stainless steel autoclave, the reaction was carried out in a glass vessel with a gas-inlet capillary. In the glass vessel, a mixture of ethanol (or an ethanolic solution of hydrogen chloride), 1, 5-COD, and palladium chloride (or metallic palladium, or palladium acetylacetonate) was placed; the vessel was then set in the autoclave. Then carbon monoxide was introduced (100 kg./cm^2), and the mixture was shaken at 100°C for a certain period of time. After the reaction, the reaction mixture was poured into five times its volume of water, and the solution was extracted several times with ether. The ethereal solution was dried over anhydrous magnesium sulfate. Distillation under reduced pressure gave COD (40°C/14 mmHg), the monoester (102°C/15 mmHg), and the diesters (143°C/4 mmHg). The recovered COD consisted of 1, 5- and 1, 3-isomers. Their relative amounts varied

with the reaction conditions. Ethyl 4-cyclooctenecarboxylate was converted into crystalline amide by heating it with excess concentrated ammonia in a sealed tube at 100° for 10 hr; m. p. 203°C[7] (from ethanol). When the ester was hydrogenated in ethanol in the presence of palladium on carbon, ethyl cyclooctanecarboxylate was obtained (b. p. 120°C/20 mmHg.). On hydrolysis with 15% alcoholic potassium hydroxide, cyclooctane-carboxylic acid was obtained (b. p. 110—120°C/1 mmHg). The acid was converted into acid chloride by treatment with oxalyl chloride in benzene. The crude acid chloride was converted into amide by treatment with ammonia; m. p. 194—196°C (from ethanol) reported m. p. 195.8°C),[8] hydrazide, m. p, 67—68°C.

The Carbonylation of Cyclooctene.—To a mixtrue of 30 ml. of ethanol, 3g. of palladium chloride, and 17 g. of cyclooctene in a glass vessel set in the autoclave, carbon monoxide was introduced (97 kg./cm^2); this mixture was then shaken at 100°C for 25 hr, After the usual work-up, 8.4 g. of cyclooctanecarboxylate was collected by distillation (108—115°C/14 mmHg). The ester was converted into crystalline amide in the manner described above.

The Carbonylation of 1, 3-COD.—A mixture of 1, 3-COD (16 g.), ethanol (30 ml.), and palladium chloride (5 g.) was allowed to react under 155 kg./cm^2 of carbon monoxide at 100°C for 23 hr. After the usual work-up, distillation gave 1, 3-COD (4.3 g., 50—75°C/46 mmHg) and crude ester (5.0 g., 75—145°C/46 mmHg). The purification of the crude ester by preparative gas chromatography gave ethyl 2-cyclooctenecarboxylate and a small amount of 3-ethoxycyclooctene. Analytical results of the monoester;

Found: C, 72.21; H, 9.89; mol. wt., 184. Calcd. for $C_{11}H_{18}O_2$; C, 72.49; H, 9.96%; mol. wt., 182.

NMR spectrum: 8.77 (triplet, 3 methyl protons), 8.44 (multiplet, ring methylenes), 7.92 (multiplet, 2 allylic protons), 6.70 (multiplet, 1 proton at the carbethoxy-bearing carbon), 5.95 (diffuse quartet, 2 protons $-O-CH_2-$), and 4.34 (multiplet, 2 vinyl protons). Ethyl 2-cyclooctenecarboxylate was converted into amide by treating it with ammonia in a sealed tube at 100°C for 10 hr; m. p. 185—186°C (from ethanol).

Found: C, 70.50; H, 9.87; N, 9.11. Calcd. for $C_9H_{15}O_1N$; C, 70.55; H, 9.87; N, 9.14%.

3-Ethoxycyclooctene was identified, by means of its NMR and infrared spectra, with an authentic sample prepared by refluxing 3-bromocyclooctene with sodium ethoxide in ethanol. Mol. wt., Found: 154 (mass spectroscopy). Calcd. for $C_{10}H_{18}O_1$: 154.

The ether had the following NMR peaks; 8.87 (triplet, 3 methyl protons), 8.51 (diffuse multiplet, ring methylenes), 7.87 (multiplet, 2 allylic protons), 6.65 (multiplet, 2 protons $-O-CH_2-$), 5.91 (multiplet, 1 proton $-CH-O-$), and 4.52 (multiplet, 2 vinyl protons). Two protons of the ethoxy (5.91) and carbethoxr groups (5.95) do not show a clear quartet, because of the effect of the neighboring asymmetric carbon (the carbethoxy- or ethoxy-bearing carbon). A similar observation has been reported with cortisone acetate.[9]

In addition, 1.5 g. of unidentified diester (mol. wt., 240) was obtained.

The Carbonylation of 3-Bromocyclooctene.—A mixture of 3-bromocyclooctene (8 g.) and palladium chloride (1.8 g.) in ethanol (60 ml.) was allowed to react under 92 kg./cm^2 of carbon monoxide at 100°C for 14 hr. The crude product then obtained by distillation (62—94°C/5 mmHg) was purified by preparative gas chromatography; 3-ethoxycyclooctene (yield based on 3-bromocyclooctene 16.9%) and ethyl 2-cyclooctenecarboxylate (yield 36.4%) were thus obtained.

The Carbonylation of the 1, 5-COD Complex.—The complex (15 g.) was suspended in 30 ml. of ethanol in a glass vessel. Carbon monoxide was then introduced (100 kg./cm^2), and the mixture was shaken for 24 hr. at 110°C. After the usual work-up, 2.4 g. of crude monoester (100—120°C/21 mmHg), together with a small amount of 1, 5-COD, was obtained. Further distillation gave 0.3 g. of the diesters (140°C/5 mmHg).

The Formation of the 1, 5-COD Complex from Metallic Palladium.—In a glass vessel, 20 ml. of a 15% alcoholic solution of hydrogen chloride, 0.2 g. of palladium black, and 8 ml. of 1, 5-COD were mixed. The mixture was then shaken in the autoclave at 110°C under a nitrogen atmosphere (40 kg./cm^2). After 18 hr., a yellow precipitate contaminated with palladium black was collected by filtration and recrystallized from acetic acid to give 0.12 g. of the 1, 5-COD palladium chloride complex. The complex was identified by a comparison of its infrared spectrum with that of an authentic sample.

Found: C, 33.76; H, 4.28; Cl, 24.62. Calcd. for $C_8H_{12}Pd_1Cl_2$: C, 33.62; H, 4.23; Cl, 24.80%.

The recovered COD consisted of a 1 : 2.3 muxture of 1, 5- and 1, 3-isomers.

The Carbonylation of Di-μ-chloro-bis(8-methoxycyclooct-4-enyl)-dipalladium.—This complex was prepared by the treatment of the 1, 5-COD complex with sodium carbonate in methanol following the method of Chatt et al.[10] To a suspension in the autoclave of the complex (5.5 g.) in 50 ml. of benzene, carbon monoxide was introduced (50 kg./cm^2). The mixture was then stirred at 60°C for 20 hr. After the reaction, the palladium which had precipitated was removed. An infrared spectrum of the crude solution showed an absorption band at 1735 cm^{-1} due to an ester. No absorption at 1800 cm^{-1} due to an acid chloride was observed. To ensure the conversion of an acid chloride, if present, into an ester, the solution was then refluxed with 10 ml. of methanol for 30 min. When the solvent was removed, 1.2 g. of an oily residue was obtained. Gas chromatographic analysis showed the presence of two main products, which were separated by preparative gas chromatography. The first fraction was identified as 1, 5-COD. The second fraction was determined to be methyl 8-methoxy-4-cyclooctenecarboxylate.

Found: C, 66.39; H, 9.03 mol. wt. 198. Calcd. for $C_{11}H_{18}O_3$: C, 66.64; H, 9.15%; mol. wt. 198.3.

The NMR spectrum had the following peaks; 4.43τ (multiplet, 2 vinyl protons), 6.43τ (singlet, methyl protons of the ester,), 6.79τ (singlet methoxy protons),

7) G. Stork and H. K. Landesman, *J. Am. Chem. Soc.*, **78**, 5129 (1956).

10) J. Chatt, L. M. Vallarino and L. M. Venanzi, *J. Chem. Soc.*, **1957**, 3413.

7.28τ (multiplet, proton at the carbomethoxy-bearing carbon), 6.5τ (multiplet, 1 proton at the methoxy-bearing carbon), broad multiplets centered at 7.8 (4 allylic protons), and 8.24 (4 ring methylene protons). Furthermore, a small amount of methyl 4-cyclooctene-carboxylate was detected.

The Conversion of Ethyl 4-Cyclooctenecarboxylate (II) into Ethyl 3-Carbethoxyl-2-oxocyclopentanepropionate.—Fourteen grams of II were oxidized by the drop-by-drop addition of 220 ml. of a sodium permanganate solution (12%) for 3 hr., with the occasional addition of small pieces of dry ice. After the oxidation, sulfur dioxide gas was passed through until the solution became clear. Then the product was extracted with ether. The ether was then evaporated, and the residue was esterified in a mixture of benzene and ethanol by the azeotropic method. The benzene and ethanol were then evaportaed; the distillation of the residue gave 9 g. of ethyl 1, 3, 6-hexanetricarboxylate (b. p. 145—152°C/2 mmHg. Found: mol. wt., 293, Calcd. for $C_{15}H_{26}O_6$: 302).

The triester (5 g.) in 50 ml. of benzene was refluxed overnight with 1.2 g. of sodium hydride. The reaction mixture was washed with aqueous acetic acid and then with water. Distillation gave 2.1 g. of ethyl 3-carbethoxy-2-oxocyclopentanepropionate (b. p. 130—140°C (bath temp.)/ 1 mmHg). The ester gave a positive test with ferric chloride.

The ester (2 g.) was dissolved in a mixture of concentrated hydrocholric acid (8 ml.) and acetic acid (8 ml.); the mixture was then refluxed for 5 hr. The reaction mixture was concentrated under reduced pressure, and the residue was treated with 2, 4-dinitrophenylhydrazine to give the hydrazone of 2-oxocyclopentanepropionic acid; m. p. 171—172°C (reported m. p. 170°C[11]).

Found: C, 49.57; H, 4.69; N, 16.60. Calcd. for $C_{14}H_{16}O_6N_8$: C, 50.00: H, 4.76; N, 16.66%. Furthermore, the residue was esterified in a mixture of benzene and ethanol by the azeotropic method. After the solvents had been evaporated, the residue was treated with 2, 4-dinitrophenylhydrazine. The hydrazone of ethyl 2-oxocyclopentanepropionate thus obtained was recrystallized from ethanol; m. p. 87.5—88.5°C.

Found: C, 52.61; H, 5.56; N, 15.08. Calcd. for $C_{16}H_{20}O_6N_4$: C, 52.74; H, 5.53; N, 15.38%.

The Synthesis of Ethyl 2-Oxocyclopentanepropionate.—An enamine (30 g.) was prepared from cyclopentanone (21 g.) and pyrrolidine (30 g.) by the usual azeotropic method.[12]

The enamine (7 g.) was dissolved in 30 ml. of ethanol. To the solution 7 g. of ethyl 3-bromopropionate was added; then the mixture was refluxed for 5 hr. The enamine was hydrolyzed by warming it with excess dilute hydrochloric acid. After most of the ethanol had been evaporated, the residue was dissolved in ether. The ethereal solution was washed successively with a sodium bicarbonate solution and with water. The distillation of the solution gave 2 g. of ethyl 2-oxocyclopentanepropionate (b. p. 114—115°C/5 mmHg). 2, 4-Dinitrophenylhydrazone was prepared; its melting point was undepressed on admixture with the 2, 4-dinitrophenylhydrazone obtained above. (Found: C, 52.87; H, 5.61; N, 15.50%).

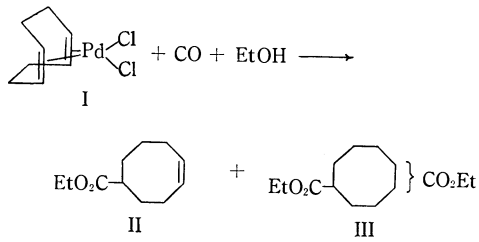
Results and Discussion

The Carbonylation of the 1, 5-COD Complex.—It was found that, unlike the other olefinic complexes previously studied,[1,2] the 1, 5-COD complex did not react with carbon monoxide in benzene, even at 100°C, under a carbon monoxide pressure of 100 kg./cm^2; unchanged complex was recovered. The complex, however, reacted smoothly with carbon monoxide in ethanol at about 100°C; an unsaturated monoester was the main product, along with a small amount of saturated diesters. The infrared and NMR spectra, the gas chromatography and the crystalline amide of the monoester were identical with those of ethyl 4-cyclooctenecarboxylate (II) as synthesized by Stork's method.[7] II was converted into ethyl cyclooctanecarboxylate by hydrogenation and identified with the ester obtained by the carbonylation of cyclooctene catalyzed by palladium chloride. The diesters were considered to be a mixture of 1, 4- and 1, 5-cyclooctane dicarboxylates (III). Their separation was not possible, and they did not give sharp melting points after hydrolysis. The interesting reactions of the mixed esters will be described later in a separate paper.



The Carbonylation of 1, 5-COD.—Considering that the complex can easily be formed from palladium chloride and 1, 5-COD, we attempted the direct carbonylation of 1, 5-COD without the prior formation of the complex. When 1, 5-COD in ethanol was smoothly carbonylated in the presence of palladium chloride, the monoester (II), accompanied by the mixed diesters (III), was obtained. As is shown in Table I, it was confirmed that only a catalytic amount of palladium chloride is necessary. Interestingly, it was found that a metallic palladium such as palladium on carbon or palladium black can be used as an active catalyst when the reaction is carried out in ethanol containing hydrogen chloride. Palladium acetylacetonate was found effective only when hydrogen chloride was added to the reaction medium. The concentration of hydrogen chloride has a marked effect on the reaction products. When the concentration was high, the yield of the diesters increased. When palladium iodide, instead of chloride, was used,

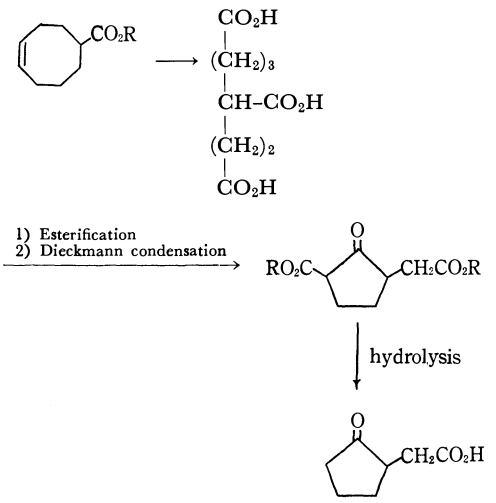
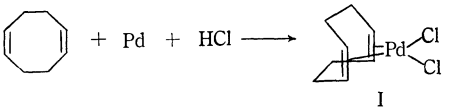
c) 10% hydrogen chloride in absolute ethanol
d) Carbon monoxide pressure was 100 kg./cm² in all cases.

an almost exclusive formation of the diesters was observed. The catalytic action of the hydrogen chloride - palladium system in the carbonylation of olefins,[13] allylic compounds[2] and acetylene[14] has already been reported.

It is known that 1, 5-COD can be easily isomerized to 1, 3-COD by the catalytic action of palladium chloride.[15] Therefore, we should consider the possibility of the double bond migration during the carbonylation reaction to give isomers of ethyl cyclooctenecarboxylate. The position of the double bond in the monoester II was determined in the following way. The oxidation of II with sodium permanganate gave 1, 3, 6-hexanetricarboxylic acid, which was then esterified. The Dieckmann condensation of the ester gave ethyl 3-carbethoxy-2-oxocyclopentanepropionate, which in turn gave a low melting 2, 4-dinitrophenylhydrazone. The ketoester was converted into 2-oxocyclopentanepropionic acid and then to ethyl 2-oxocyclopentanepropionate, both of which gave 2, 4-dinitrophenylhydrazones as crystalline substances with sharp melting points. An authentic sample of ethyl 2-oxocyclopentanepropionate was synthesized by the reaction of cyclopentanone with ethyl 3-bromopropionate by the enamine method. Its identity was confirmed by a mixed melting point determination. Thus, the reaction sequences described above give convincing evidence for the structure of ethyl 4-cyclooctenecarboxylate. It can be concluded that the double bond of the monocarbonylation product remained at the original position, at least in the major portion, though not necessarily all, even in the presence of palladium; this suggests that the rate of carbonylation is larger than that of the double bond migration.



The first step in the carbonylation reaction of 1, 5-COD catalyzed by palladium - hydrogen chloride is evidently the formation of the 1, 5-COD complex. The complex is known to be formed by the direct contact of 1, 5-COD with palladium chloride or its complex.[10] Interestingly, we have confirmed that the complex can be prepared by the reaction of metallic palladium, not palladium chloride, with 1, 5-COD in ethanol containing hydrogen chloride (15%) at 100°C.



I

In connection with our observation, it should be mentioned that π-allylpalladium bromide can be prepared from metallic palladium and allyl bromide.[16]

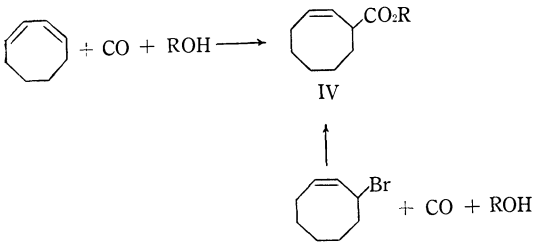
Table II. Comparative studies of carbonylation of dienes

CO pressure: 100 kg./cm²; reaction temp.: 100°C

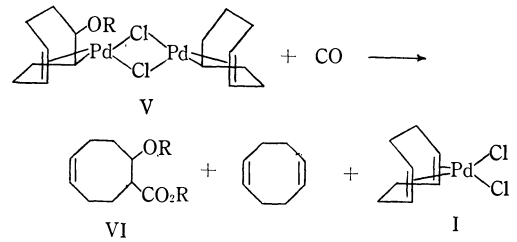
Diene ml.	EtOH ml.	$PdCl_2$ g.	Time hr.	Yield of monoester %	By-product %
1,3-COD 20	30	3	23	2-Cyclooctene-carboxylate (IV) 9.5	3-Ethoxycyclooctene 1.3
1,5-COD 20	30	3	3	4-Cyclooctene-carboxylate (II) 58.4	1,4- and 1,5-Cyclo-octanedicarboxylate 19.8
1,3-Cyclohexa-diene 5	12	1.2	24	2-Cyclohexene-carboxylate 79.8	

The second step in the carbonylation is the coordination of carbon monoxide on the palladium of the complex. When the 1, 5-COD complex in ethanol was shaken under 100 kg./cm² of carbon monoxide at room temperature, the complex changed into another yellow complex, while absorbing carbon monoxide. The new complex was quite unstable and decomposed when exposed to the air. Although no further elucidation of the new complex has been undertaken because of its instability, it is reasonable to expect that the complex is an intermediate in the carbonylation.

The Carbonylation of 1, 3-COD.—As has been mentioned, the COD recovered from the carbonylation was a mixture of 1, 5- and 1, 3-isomers. Therefore, the carbonylation of pure 1, 3-COD was studied. Ethyl 2-cyclooctenecarboxylate (IV) was obtained in a low yield. As is shown in Table II, the carbonylation of 1, 3-COD is much slower than that of 1, 5-COD. Under comparable conditions, 1, 3-cyclohexadiene gave 2-cyclohexenecarboxylate in a higher yield. In general, conjugated dienes such as butadiene can be carbonylated easily to form β, γ-unsaturated esters,[4] the steric factors of 1, 3-COD seem to be responsible for this difference in reactivity. The same ester was obtained by the carbonylation of 3-bromocyclooctene. The formation of the β, γ-unsaturated ester by a carbonylation of the allylic halogen catalyzed by palladium is a general reaction.[2]



The Carbonylation of Di-μ-chloro-bis (8-methoxycyclooct-4-enyl)-dipalladium. — The 1, 5-COD complex can be converted into a halogen-bridged alkoxy-substituted complex (V) by means of the action of sodium carbonate on the complex in alcohol.[10] The complex involves σ-bonds, which may be expected to be carbonylated more easily than the original 1, 5-COD complex. Actually the complex was carbonylated in benzene at 60°C to form an alkoxycyclooctenecarboxylate. Although no identification with an authentic sample has been made, it is highly probable that the product is methyl 8-methoxy-4-cyclooctenecarboxylate (IV); this suggestion is based on its NMR spectrum. In addition, 1, 5-COD and its palladium chloride complex were detected in the reaction mixture.



Although the reaction was carried out in a benzene solution, a methyl ester was obtained, instead of the expected acid chloride.[1] Undoubtedly the methoxy group is supplied by the decomposition of the methoxysubstituted complex.

Summary

1, 5-Cyclooctadiene - palladium chloride complex and carbon monoxide react in ethanol to form ethyl 4-cyclooctenecarboxylate. The carbonylation of the 1, 5-cyclooctadiene catalyzed by palladium chloride has given 4-cyclooctenecarboxylate and cyclooctanedicarboxylate. Under the same conditions, 1, 3-cyclooctadiene has given 2-cyclooctenecarboxylate in a low yield.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 146—149 (1966)

Organic Syntheses by Means of Noble Metal Compounds. XV. The Carbonylation of 1, 5, 9-Cyclododecatriene Catalyzed by Palladium

By Jiro Tsuji and Tatsuo Nogi

Basic Research Laboratories, Toyo Rayon Company, Kamakura

(Received May 27, 1965)

The carbonylation of 1, 5, 9-cyclododecatriene has been carried out in ethanol in the presence of palladium chloride; mono- and diesters have thus been obtained without ring contraction. It has been observed, by means of a study of the NMR and infrared spectra, that the first attack of carbon monoxide occurred at the trans double bond, giving ethyl cyclododecadienecarboxylate. The second attack of carbon monoxide occurred randomly, giving an isomeric mixture of ethyl cyclododecenedicarboxylate. No triester was obtained even under prolonged carbonylation. The true catalyst has been found to be metallic palladium, and the presence of hydrogen chloride has been found to be essential for the catalysis. The oxidation of ethyl cyclododecadienecarboxylate, followed by esterification, has given ethyl succinate and 1, 3, 6-hexanetricarboxylate. This result indicates that the double bonds of ethyl cyclododecadienecarboxylate remain at the original positions.

We have reported that pallaium chloride or metallic palladium, in the presence of hydrogen chloride, is an active catalyst for the carbonylation of olefins in alcohol, thus forming carboxylic esters.[1] The reaction proceeds quite smoothly under rather mild conditions. The palladium-catalyzed carbonylation reaction was then extended to various allylic compounds[2] and conjugated dienes[3] to form β, γ-unsaturated esters. Furthermore, it was found that 1, 5-cyclooctadiene (1, 5-COD) can be carbonylated smoothly to form mono- or diester, depending on the reaction conditions.[4] The above-mentioned olefinic compounds are known to form π- or π-allylic complexes with palladium chloride,[5] and certainly their carbonylations proceed through the formation of these complexes.

Like 1, 5-COD, 1, 5, 9-cyclododecatriene (1, 5, 9-CDT) can be easily prepared from butadiene by the catalytic action of several transition metal complexes. However, unlike 1, 5-COD, which is known to form a stable palladium chloride complex, 1, 5, 9-CDT does not easily form a complex with palladium chloride. Only recently it was reported that a complex can be prepared after the prolonged contact of 1, 5, 9-CDT with palladium chloride - benzonitrile complex, but its structure is not yet known.[6] It seems likely that the three double bonds of 1, 5, 9-CDT are not orientated in a way suitable for forming a stable complex with palladium chloride. From these considerations, it seemed worthwhile investigating the carbonylation of 1, 5, 9-CDT by the catalytic action of palladium. The carbonylation of 1, 5, 9-CDT has been reported by Rull,[7] who obtained methyl cyclododecanecarboxylate by the catalytic action of cobalt carbonyl in methanol. In this case, two double bonds were hydrogenated. In addition, the carbonylation of 1, 5, 9-CDT by the catalytic action of Lewis acids to give carboxylic acids is known, but in this case ring contractions due to transannular reaction have occurred, giving a variety of carboxylic acids.[8a,b] In contrast, the carbonylation reaction reported in this paper gives mono- and dicarbonylation products without ring contraction or the reduction of the double bonds.

Experimental

The gas chromatographic analyses were carried out on a Thermol-3 column, 2 m. long, at 220°C. All the boiling points are uncorrected. The molecular weights were determined in benzene by the ebullioscopic method, using a Mechrolab vapor pressure osmometer. The NMR spectra were recorded on a high resolution spectrometer, model DP 60, and the peak positions are expressed in τ values. The infrared spectra were recorded on a Hitachi infrared spectrometer, model EPI-S2.

Materials. — Commercially - available palladium chloride was used without further purification. *cis, trans, trans*-1, 5, 9-CDT was prepared in the Central Research Laboratories, Toyo Rayon Company, and distilled before use.

The Carbonylation of 1, 5, 9-CDT—The reaction conditions and the amounts of the reactants used are shown in Table I. A typical example of the carbonylation is as follows. One gram of palladium chloride, 20 ml. of ethanol containing a certain amount of hydrogen chloride, and 10 g. of 1, 5, 9-CDT were introduced into a glass vessel with a gas-inlet capillary. The vessel was then set in a stainless steel autoclave (made by Sakashita Seisakusho), and carbon monoxide was introduced (100 kg./cm^2). After the autoclave had been set in an electrical furnace preheated to 100°C, the furnace was shaken. After a certain period of time, the autoclave was quenched in a water bath. The catalyst was removed by filtration, and the solution was distilled. The 1, 5, 9-CDT recovered was collected at 90—95°C/8 mmHg. Ethyl cyclododecadiencarboxylate (140—145°C/5 mmHg) and ethyl cyclododecenedicarboxylate (165—175°C/4 mmHg) were easily separated by fractional distillation.

The presence of four olefinic protons was confirmed by a study of the NMR spectrum of ethyl cyclododecadienecarboxylate (Fig. 1). Also, the monoester was hydrogenated in ethanol in the presence of an Adams platinum catalyst, with the absorption of 2 mol. of hydrogen; it gave ethyl cyclododecanecarboxylate.

Found: C, 74.57; H, 11.60; mol. wt., 240. Calcd. for $C_{15}H_{28}O_2$: C, 74.95; H, 11.74%; mol. wt., 240.

The hydrolysis of ethyl cyclododecanecarboxylate was carried out by refluxing it in a 10% alcoholic potassium hydroxide solution for 5 hr. After the usual work-up, cyclododecanecarboxylic acid was recrystallized from hexane, m. p. 97—98°C (reported m. p. 99.5°C[7]).

Found: C, 73.45; H, 11.39%. Calcd. for $C_{13}H_{24}O_2$: C, 73.53; H, 11.39%.

An NMR spectrum of ethyl cyclododecenedicarboxylate showed the presence of 2 olefinic protons (Fig. 2), and the hydrogenation of the diester consumed 1 mol. of hydrogen. The hydrolysis of the hydrogenated diester with 10% ethanolic potassium hydroxide gave the corresponding solid acid, which did not show a sharp melting point, even after chromatographic purfication.

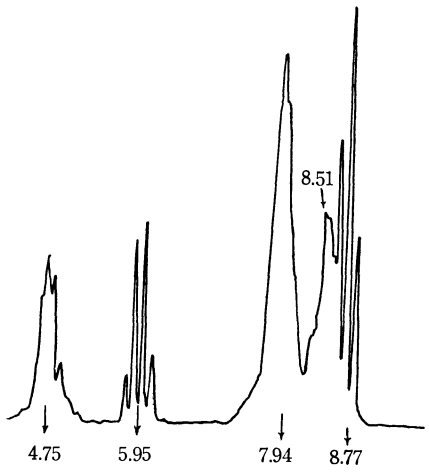

Fig. 1. NMR spectrum of ethyl cyclododecadienecarboxylate.

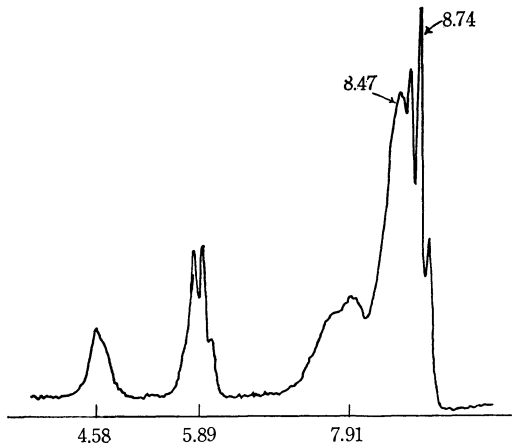

Fig. 2. NMR spectrum of ethyl cyclododecenedicarboxylate.

Found: C, 65.41; H, 9.41. Calcd. for $C_{14}H_{24}O_4$: C, 65.59; H, 9.44%.

The Carbonylation of Cyclododecene.—A mixture of 1 g. of palladium chloride, 20 ml. of ethanol containing hydrogen chloride (7.5%), and 6 g. of cyclododecene was placed in a glass vessel; the reaction was then carried out at 120°C for 20 hr. under a pressure of carbon monoxide (100 kg./cm^2). After the usual work-up, 8.0 g. (93%) of ethyl cyclododecanecarboxylate was obtained by distillation (148—150°C/10 mmHg). The ester was then hydrolyzed to crystalline cyclododecanecarboxylic acid.

The Oxidation of Ethyl Cyclododecadienecarboxylate.—The ester (10 g.) was mixed with 20 ml. of cyclohexane and 20 ml. of water in a 1-l. round-bottomed flask. To the mixture there was then vigorously stirred 250 ml. of a sodium permanganate solution (12.5%) over a 3-hr. period, with the occasional addition of small pieces of dry ice. The oxidation product was then esterified in a manner described before,[4] and distilled. A lower-boiling fraction was confirmed to be ethyl succinate by gas chromatography and infrared spectrum; then it was hydrolyzed to succinic acid, m. p. 186—188°C. A higher-boiling fraction (b. p. ca. 150°C/2 mmHg, mol. wt., 300; yield 4 g.) was identified by infrared and NMR spectra, with the ethyl 1, 3, 6-hexanetricarboxylate obtained from ethyl cyclooctenecarboxylate, and by converting it into ethyl 2-oxocyclopentanepropionate.

Results and Discussion

There are three isomers of 1, 5, 9-CDT, namely, cis-trans-trans, cis-cis-trans and trans-trans-trans. In this study, the most easily obtainable cis-trans-trans isomer was used. The carbonylation proceeded smoothly, and mono- and di-carbonylation were observed, giving ethyl cyclododecadienecarboxylate and ethyl cyclododecenedicarboxylate respectively. The presence of, respectively, two and one double bonds in these esters was confirmed clearly by the

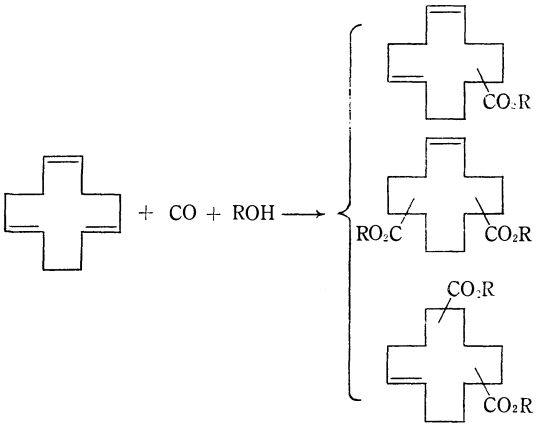
NMR spectra (Fig. 1 and 2) and hydrogenation, showing that no ring contraction occurs during the carbonylation reaction.



When 1, 5-COD was carbonylated, it was rather easy to control the reaction so that mono- and diester were selectively obtained,[4] because the double bonds of 1, 5-COD behave as a bidentate ligand, forming a stable complex with palladium. Although the trans double bond was attacked first, as will be described later, there was not much difference in the reaction rate between mono- and dicarbonylation, as is shown in Table I, and it seemed likely that the double bonds of 1, 5, 9-CDT behaved almost independently. The only way to obtain the monoester as a main product was to stop the reaction after a comparatively short period. A longer reaction time gave rise to the diester exclusively. The reaction stopped at the dicarbonylation stage and the further carbonylation of the remaining double bond to form a saturated triester was almost impossible. It is supposed that the two ester groups of cyclododecenedicarboxylate inhibit the access of palladium to the remaining double bond, thus making the carbonylation almost impossible. On the other hand, cyclododecene, which has no such steric hindrance, was carbonylated easily to give ethyl cyclododecanecarboxylate.

It is known that there is considerable diffrence in reactivity between the cis and trans double bonds of *cis, trans, trans*-1, 5, 9-CDT.[9] In general, one of the trans double bonds is attacked first. In this carbonylation reaction, as was expected, it was found, by comparing the changes of intensities of the infrared bands at 968 cm^{-1} (trans) and 707 cm^{-1} (cis), that the first attack of carbon monoxide occurred at the trans double bond. As is shown in Figs. 3, 4 and 5, the intensity ratio of the cis and trans bonds of 1, 5, 9-CDT is about 1 : 2, while those of the monoester and diester are nearly equal. Therefore, it is apparent that the second attsck is not selective and that both the cis and trans double bonds are randomly attacked.

By mono- and dicarbonylation, considerable numbers of isomers can be formed on the basis

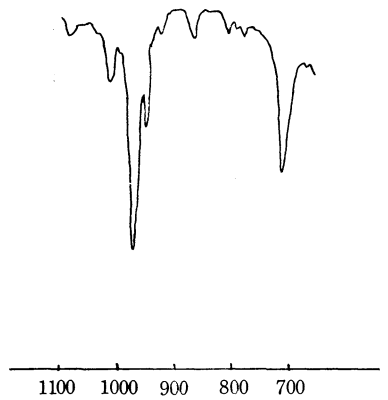


Fig. 3. Infrared spectrum of 1,5,9-cyclododecatriene (in CCl_4).

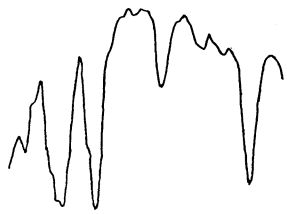

Fig. 4. Infrared spectrum of ethyl cyclododecadienecarboxylate (in CCl_4).

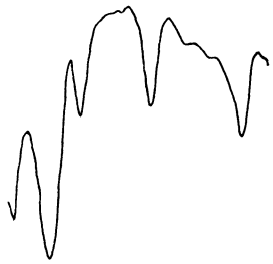

Fig. 5. Infrared spectrum of ethyl cyclododecenedicarboxylate (in CCl_4).

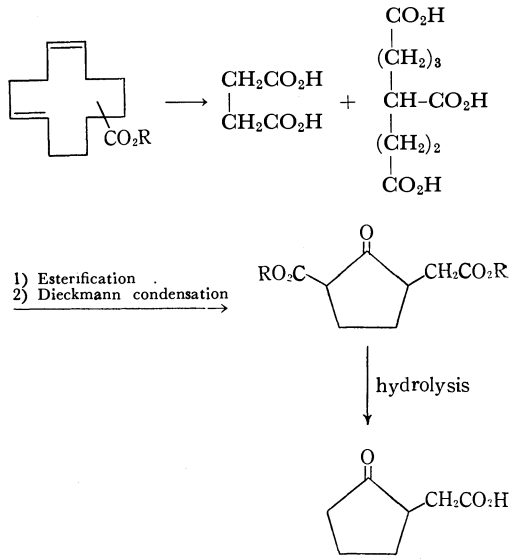
of the relative position of the carbethoxy groups. There are two possible sites of the carbethoxy group in ethyl cyclododecadienecarboxylate relative to the remaning cis and trans double bonds. Actually, two peaks were observed closely by gas chromatography, but it was impossible to separate them by any means. By hydrogenation, a single peak was observed; this was identified with the ethyl cyclododecanecarboxylate obtained by the carbonylation of cyclododecene catalyzed by palladium chloride. The hydrolysis of the hydrogenated ester gave cyclododecanecarboxylic acid as a crystal.

It is known that palladium chloride is an active catalyst for double bonds migration. For example, 1, 5-COD can be isomerized to 1, 3-COD by the action of palladium chloride.[10] In view of this the possibility of the double bond migration after the monocarbonylation was investigated by the oxidation of the monoester with sodium permanganate. When the oxidation product was esterified, the presence of ethyl succinate was detected by gas chromatography. The ester was isolated by distillation. Ethyl 1, 3, 6-hexanetricarboxylate was also isolated. This ester's identity with the ester isolated from the oxidation product of ethyl 4-cyclooctenecarboxylate was confirmed by means of a study of their infrared and NMR spectra. Furthermore, the structure of ethyl 1, 3, 6-hexanetricarboxylate was confirmed by its conversion into ethyl 2-oxocyclopentanepropionate, as has been described in the structural determination of ethyl 4-cyclooctenecarboxylate.[4] Thus, the oxidation studies have confirmed that the double bonds of ethyl cyclododecadienecarboxylate remain at the original positions, at least usually, even in the presence of palladium chloride.



For ethyl cyclododecenedicarboxylate, there exist six possible isomers without considering optical isomerism, and their differentation and separation were impossible by any means. By hydrogenation, the number of the isomers decreased to three, and after hydrolysis the product did not give a sharp melting point, even after an attempted chromatographic separation.

In this carbonylation, as has been described before,[4] metallic palladium and hydrogen chloride are essential for the catalysis. Palladium on carbon alone was inactive. The concentration of hydrogen chloride in the reaction medium has a marked influence on the reaction rate, as can be seen in Table I.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 150—155 (1966)

A Mass Spectrometric Study of Phosphorus Oxide

By Akio HASHIZUME, Nobuhide WASADA and Toshikazu TSUCHIYA

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received May 28, 1965)

Phosphorus pentoxide has been investigated with a mass spectrometer over the temperature range from 60°C to 650°C. A Knudsen cell has been installed in the source of the mass spectrometer. Two samples were used in the experiment. One was commercially-available phosphorus pentoxide, while the other had been purified from the commercial phosphorus pentoxide by Finch's method. The ionization efficiency curves near the appearance potential of $P_4O_9^+$ and $P_4O_{10}^+$, and the fractional yield of each ion versus the ionizing voltage have been investigated and interpreted as evidence for the presence of the P_4O_9 molecule. Three curves representing the intensity of the mass 284 ($P_4O_{10}^+$) peak as a function of the temperature have been obtained. Two of them, which set on at about 250°C and 450°C respectively, are related to the known vapor pressure curves of phosphorus pentoxide. The curve with the lowest onset temperature, about 100°C, may be interpreted as a vapor pressure of a new low temperature phase of phosphorus pentoxide.

The nature of phosphorus oxides has been investigated by various authors,[1-3] since the oxides have a great significance in the chemistry of fertilizer manufacture, and an accurate knowledge of their behavior in the pure state is a prequisite to a complete understanding of complex systems of a more practical importance. Especially, phosphorus pentoxide is known to be a component of several phase systems. This has not, however, been determined unequivocally, because the oxides cannot be handled conveniently, as they absorb moisture from air immediately and attack glass at elevated temperatures.

Some people believe that "phosphorus pentoxide" is not as a very favorable drying agent for a vacuum system, as lower oxides of phosphorus sublime.

Several works have been published studying the sublimation products from solid state compounds by mass spectrometry.[4,5] Manometric investigations based upon various principles have been reported and used; these studies have measured a quantity which is proportional, in some sense, to the total pressure of the gas under investigation, whereas mass spectrometry gives information about the partial pressure of each species of molecules contained in the gas phase. Such being the case, the present study was undertaken in order to investigate the properties of phosphorus oxides with a mass spectrometer.

Experimental

The phosphorus oxides used in this investigation were obtained from two sources. One was an extra pure phosphorus pentoxide available commercially (hereafter referred to as commercial phosphorus pentoxide) and obtained from Miyazaki Shōten, while the other was prepared from the commercial product by sublimation in a current of oxygen in an iron tube at about 800°C, according to the method of Finch and Frazer.[6] The iron tube was heated electrically instead of by gas. In this process the lower oxides of the phosphorus are reported to be oxidized completely. After sublimation, the oxidized product (hereafter referred to as purified phosphorus pentoxide) was handled carefully so as to prevent it from absorbing moisture.

Most of the work was carried out with a 60° Nier-type mass spectrometer of our own construction.[7] The median radius of the stainless-steel analyzer of this instrument was 20 cm., and the resolving power was about 150. The ion current was amplified by an Applied Physics Corporation, model 36, vibrating reed amplifier. The other electronic circuits and the construction of the ion source were much the same as those reported by Nier.[8] Figure 1 shows the mass spectrometer mounting, containing a Knudsen effusion cell similar to that of Porter, Schissel and Inghram.[4] The cell consisted of two crucibles, an outer stainless-steel crucible and an inner crucible made of aluminum oxide; the latter contained the phosphorus oxide to be

investigated. The stainless-steel cover of the outer crucible had an effusion hole (0.15 mm. in diameter). As the ratio of the total vaporizing area of the phosphorus oxide to the effusion area was approximately 1000, a true equilibrium partial pressure of each gaseous species with the charged oxide can exist inside the Knudsen cell. The stainless-steel crucible was heated directly by means of a surrounding tungsten filament coated with aluminum oxide or by electron bombardment from the filament. The Knudsen cell and the heating filament were enclosed by a stainless-steel radiation shielding, which had an effusion hole 2 mm. in diameter. The distance between the holes of the outer crucible and the radiation shielding was about 5 mm. The temperature was measured with a platinum-platinum-rhodium thermocouple attached to the bottom of the stainless-steel crucible. Gases effusing out of the Knudsen cell pass through the hole in the top of the radiation shielding and enter the ionization chamber of the ion source, where they are ionized.

As soon as the compound to be investigated was loaded in the inner crucible, the stainless-steel cover was placed on; then, in about 5 min., the ion source system, including the crucible, was mounted on the analyzer of the mass spectrometer and evacuated.

Since thr resolving power of the mass spectrometer described above was insufficient, a CEC 21-103C mass spectrometer was used to determine the mass numbers of those ions which have mass numbers higher than 150. In this case the material to be investigated was charged in an ampoule. The ampoule was then positioned at the necessary depth in a flask of liquid nitrogen just prior to the evacuation and during the sealing. The ampoule was attached directly to the

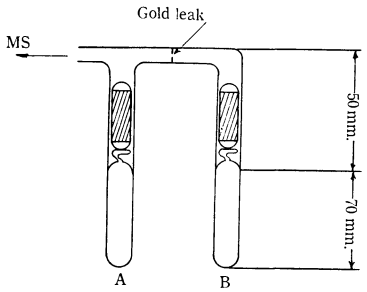

Fig. 2. Mounting of ampoules containing sample.
(A) Phosphorus pentoxide, (B) *n*-eicosane

sample manifold of the mass spectrometer, as is shown in Fig. 2. Such ampoules were fabricated from pyrex and in the approximate dimensions shown.

In order to determine the mass numbers of the ion peaks, *n*-eicosane was introduced simultaneously with phosphorus oxide as a reference. The location of the ampoule containing *n*-eicosane is shown in Fig. 2. The vapor of the sample was extracted from the ampoule by breaking the breakable seal and by then heating the ampoule to an appropriate temperature with an electric furnace. The vapor was introduced into the ion source of the mass spectrometer directly or through the gold leak. The mass numbers of the spectral peaks of phosphorus oxides were determined by comparing them with those of *n*-eicosane. In some cases, the intensity of the isotope peak contributed by ^{18}O was calculated[9] and used to indentify the mass number.

A Pirani-type manometer was constructed, and the vapor pressure of phosphorus pentoxide was checked through the temperature range from 90°C to 260°C. The manometer, which had a platinum filament 30 μ in diameter, was of an ordinary type and was calibrated with reference to a thermocouple gauge obtained from the Showa Rikagakukikai Co. At a constant wall temperature of the manometer, the calibration curve was a straight line, the tangent of which was a function of the temperature. A glass tube containing the phosphorus pentoxide was connected directly with the manometer. After the interior was pumped down to 10^{-4} mm Hg or lower, the glass tube with the manometer was closed off, with the vacuum still applied. Then it was immersed in a thermostat and the pressure was measured.

Results

Pattern Coefficient.—Table I shows the pattern coefficients of the mass spectra of the phosphorus oxides corresponding to *m/e* values greater than 47. No peak of an *m/e* value greater than

that at 288, which is due to an isotope peak of $P_4O_{10}^+$, was observed. Under the present experimental conditions, the pattern coefficients corresponding to $P_4O_6^+$ or $P_2O_3^+$ were smaller than 1. The pattern coefficients of the commercial phosphorus pentoxide varied with the time. The variation in the pattern coefficients of the $P_4O_9^+$ is shown in Table II. The pattern coefficient of the *m/e* 47 ion was found to have a poor reproducibility, the reason for this was not studied.

TABLE II. VARIATION OF THE PATTERN COEFFICIENTS OF P_4O_9 WITH TIME

Measurement was made at about every 10 min.
Temperature of the crucible was at 100°C during the measurements.
Phosphorus pentoxide used in this measurement was extra pure.

The Intensity of the Peaks as a Function of the Electron Accelerating Voltage.—Figures 3 and 4 show the fractional yields (the percentage ratio of a peak height to the sum of all peaks in a mass spectrum of a substance) of several main peaks in the spectra of the commercial phosphorus pentoxide and in the purified phosphorus pentoxide respectively; the yields are shown as a function of the electron-accelerating voltage above the appearance potential. The voltage scale is not corrected for contact potentials or any other conditions.

Commercial phosphorus pentoxide. Curve 1, *m/e* 268; Curve 2, *m/e* 284; Curve 3, *m/e* 47

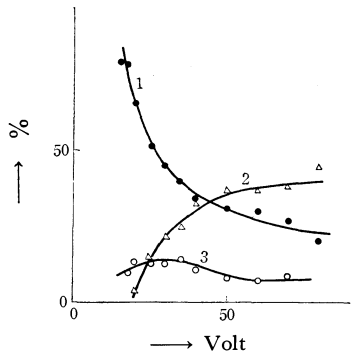

Fig. 4. Fractional yield of ions.
Purified phosphorus pentoxide. Curve 1, *m/e* 284; Curve 2, *m/e* 47; Curve 3, *m/e* 268

The ionization efficiency curves near the appearance potentials of the *m/e* 268 and *m/e* 284 ions from the commercial phosphorus pentoxide are shown in Fig. 5. Though the energy scale was not corrected and though the absolute values of the appearance potentials of the ions were not estimated, it is clear that the *m/e* 268 ion, $P_4O_9^+$, appears at an ionizing voltage about 0.5 eV. lower than that of the *m/e* 284 ion, $P_4O_{10}^+$.

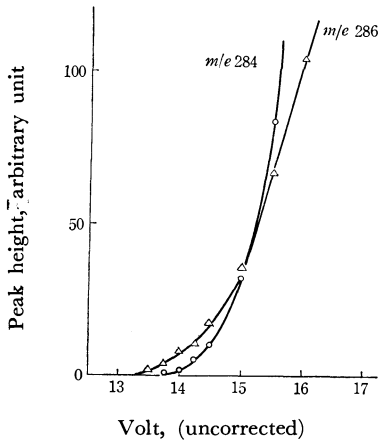

Fig. 5. Ionization efficiency curves. Commercial phosphorus pentoxide.

The Variation in *m/e* 284 Ion Intensity with the Temperature.—Figure 6 shows the relation between the *m/e* 284, $P_4O_{10}^+$, ion intensity and the temperature of phosphorus pentoxide. In the intermediate temperature ranges between curves 1, 2 and 3 of Figure 6, which had onset points at about 100°C, 250°C and 500°C respectively, the ion intensity was found to be zero. After the sample had been heated at about 200°C for a while, the intensity of the ion corresponding to curve 1 gradually dropped; after the temperature had been maintained for a few hours, the ion disappeared completely. Then when the temperature was raised, the ion began to appear again at about 250°C and curve 2 could be traced. A phosphorus pentoxide sample, previously heated to a temperature higher than 250°C in the crucible, gave almost no *m/e* 284 ions at about 200°C.

While vapor pressure curves which are very similar in shape and onset point to curves 2 and 3 have been reported by other authors[1,2,10,11] (curves

4 and 5 in Fig. 6[2]), the one which sets on at about 100°C has not yet been reported. A Pirani gauge was used in order to check the vapor pressure in this temperature range by a means other than mass spectrometry. The determination of the absolute value of the pressure was not carried out, however, as the sample material may corrode the filament of the gauge during the measurement. However, as in the case of determination with the mass spectrometer, the pressure rise was observed to begin at about 100°C. The pressure was roughly estimated to be at least of an order of magnitude higher than the value estimated by the extrapolation of curve 4 in Fig. 6, which was obtained by Southard and Nelson.[2]

Discussion

Previous Works on Phosphorus Pentoxide.—The vapor pressures of phosphorus pentoxide have been investigated, either with a Jackson-type manometer or with a platinum bulb gauge, by many authors.[1-3,10,11] From these vapor pressure data, together with their microscopic observation of the crystalline form of the compound, Hill, Faust and Hendricks[3] have concluded that phosphorus pentoxide exists in three crystalline modifications. The low-temperautre polymorph belongs to the rhombohedral division of the hexagonal system (referred to as the H-form). A high-temperature form obtained by heating the hexagonal crystals below 420°C for an appropriate period belongs to the orthorhombic system (referred to as the O-form). When the aggregate of the O-form is heated at 450°C for twenty-four hours, it is converted into a stable crystalline modifications, which is thought to be tetragonal (designated as the T-form). The H-form is metastable with respect to the O-form. This change takes place very slowly at 70°C, but it is completed in one hour at 378°C. Alternatively, the O-form is metastable with respect to the T-form. The H-, the O- and the T-forms exist, respectively, in the three temperature ranges bounded by curve 4 and curve 5 in Fig. 5. While various papers have since been published discussing the higher temperature forms, the H- and the O-forms have been considered to be corroborated. Curve 6 has been reported by Southard and Nelson to be a vapor pressure curve on a liquid phase.

According to Southard and Nelson, the vapor pressure curves, 4, 5, and 6, are represented by the following equations respectively:
Low temperature form:

$$\log p = -(50000/T) + 9.792 \quad (1)$$

High temperature form:

$$\log p = -(7930/T) + 11.113 \quad (2)$$

Liquid:

$$\log p = -(4320/T) + 6.809 \quad (3)$$

They determined the heats of vaporization per gram of the molecule from Eqs. 1, 2 and 3 for the low-temperature form (the H-form according to Hill et al.), the high-temperature form (the O-form) and the liquid respectively. The data are listed in the last column of Table III.

Table III. Heats of vaporization
L (kcal./mol.) of P_4O_{10}

Curve	*L*	Crystalline form	*L**
1	19.2		
2	23.8	H	22.8
		O	36.3
3	20.6	liq.	19.7

* J. C. Southard and R. A. Nelson, *J. Am. Chem. Soc.*, **59**, 911 (1937).

The only available calorimetric work on the heat of vaporization is that of Frandsen[12] on the low-temperature form. He obtained the value of 8800+1300 cal. per gram formula weight of phosphorus pentoxide. On the basis of the assumption that the molecular formula P_4O_{10} is nearly correct, the heat of vaporization was calculated to be 17600 +2600 cal. par gram mole, which deviates considerably from the value of 22800 obtained by Southard and Nelson and from the 22600 calculated from the data of Hoeflake and Scheffer.[13]

Heats of Vaporization.—The curves 1, 2 and 3 obtained in the present experiment are represented by Eqs. 4, 5 and 6 respectively:

$$\log p = -(42 \times 10^2/T) + 13.06 \quad (4)$$

$$\log p = -(52 \times 10^2/T) + 11.06 \quad (5)$$

12) M. Frandsen, *Bur. Standards J. Res.*, **10**, 54 (1933).
13) J. M. A. Hoeflake and F. E. C. Scheffer, *Rec. trav. chim.*, **45**, 191 (1926).

$$\log p = -(45 \times 10^2/T) + 7.55 \quad (6)$$

The constants in Eqs. 1—6 are functions of the sensitivity of the manometer used and of the unit of pressure. The heats of vaporization calculated from Eqs. 4—6 are listed in column two, Table III. When we compare these values with those of Southard and Nelson given in column four, and when we take the temperautre range of each curve into account, we see that curve 2 and curve 3 of the intensity correspond to curve 4 and curve 6 of the vapor pressure respectively.

As has been shown in the present study, no polymer of P_4O_{10} was observed in the gas phase. This shows that Frandsen's assumption is correct. As may be seen in Table III, Frandsen's value, 17600±2600 cal. per gram mole, is in agreement with the one calculated from curve 1 within the tolerance of experimental error.

A New Modification of Phosphorus Pentoxide.—In mass spectrometry, a measured ion-peak height is proportional to the pressure, in the ionization chamber, of the parent compound of the ion, as long as an ion peak of a certain mass number is concerned. In the present instance, although the pressure coefficient of the peak height may be a function of the temperature of the parent molecules, the peak height was assumed to be approximately proportional to the pressure, since the temperature range was not very wide. From the arrangements of the Knudsen cell and the ionization chamber, the pressure in the chamber was properly assumed to be proportional to the P_4O_{10} vapor pressure, which is in equilibrium, at that temperature, with the charged phosphorus pentoxide in the cell.

While curves 2 and 3 of the intensity obtained in the present study are considered to correspond to curves 4 and 6 of the vapor pressure respectively, given by Southard and Nelson, no vapor pressure curve which corresponds to the curve 1 of the intensity obtained in the present study is yet known. One of the significant differences in the experimental conditions between those of Southard and Nelson and ours is the treatment of the sample materials. Whereas they distilled the sample directly into a measuring manifold, we exposed the sample to air for a short time in a room kept at a low humidity. This procedure has been mentioned previoulsy. Under these circumstances, the possible amount of water absorbed by the sample is estimated to be of the order of a 10^{-2} weight percentage of the sample.[13] Nothing is known about the pressure of P_4O_{10} vapor on a phosphorus pentoxide containing a minute quantity of water. The pressure of P_4O_{10} vapor on a phosphorus pentoxide containing a minute quantity of water cannot be considered to exceed that on a pure phosphorus pentoxide by an order of magnitude. As has been mentioned already, the evaporation of P_4O_{10} vapor near 200°C lasts for a few hours and the heat of evaporation coincides with the calorimetric value. Taking these circumstances into consideration, we infer that curve 1 in Fig. 6 is a vapor pressure curve attributable to a phase of pure phosphorus pentoxide, and that there exists a new phase (which we shall refer to as the α-form phosphorus pentoxide), which has not yet been reported on, corresponding to the curve. The behavior of the *m/e* 284 ion in the temperature range between 100°C and 250°C may be understood if we assume that the α-form substance changes readily into a higher temperature form, presumably into the H-form. One possible explanation of the fact that the α-form or curve 1 has not been reported by previous investigators may be that from the outset they investigated phosphorus pentoxide in a form other than the α-form. If the distilled phosphorus pentoxide condenses on a wall at a temperature higher than about 250°C, the prepared substance may be in a form other than the α-form.

P_4O_9—King and Long[14], in a study of the mass spectrum of some simple esters, showed that the curves representing the fractional yield of each ion versus the ionizing voltage fall into three distinct types. According to these authors, the first group of curves, designated by them as Type I, is for those ions whose fractional yields vary inversely with the electron energy. Type I curves are observed only for parent ions and for primary ions with a low activation energy. Type II curves are for those ions whose relative yields rise rapidly to a maximum at about 10 V. above the ionization potential, and then drop off slightly at higher voltages. This type of curve arises from primary products with a slightly higher energy; the slight drop in yield observed at the higher electron voltages probably arises from competition with primary processes with still higher activation energies or from a slight secondary decomposition. Type III curves are for those ions whose relative yields rise slowly and do not level off until at much higher voltages. Type III ions result from high energy processes; they are either primary ions with a high activation energy, or secondary or further fragmentation products which require a high energy for their formation.

Their conclusion is for a pure substance, but according to circumstances it may furnish useful information on a composite system. Curve 1 in Fig. 3 and curve 1 in Fig. 4; curve 2 in Fig. 3 and curve 3 in Fig. 4; and curve 3 in Fig. 3 and curve 2 in Fig. 4 of the present investigation assume forms typical of curves of types I, II and III respectively.

In the spectrum of commercial phosphorus pentoxide, the appearance potential of the $P_4O_9^+$ ion is lower than that of the $P_4O_{10}^+$ ion, as may be

14) A. B. King and F. A. Long, *J. Chem. Phys.*, **29**, 374 (1958).

seen in Fig. 5, and no ion peak of a mass greater than the *m/e* 284 ion, $P_4O_{10}^+$, is observed, as has been mentioned previously. Table II shows that the peak height of the $P_4O_9^+$ ion, at a constant temperature, decreased with time. These results suggest that some part of the $P_4O_9^+$ may not be produced by electron bombardment from the P_4O_{10} molecule by the loss of an oxygen atom and an electron, but that the P_4O_9 itself is a parent molecule. Curve 1 in Fig. 3, indeed, assumes a typical parent ion type, i. e., type I. In the oxidation process of commercial phosphorus pentoxide, lower oxides of phosphorus are reported to be oxidized completely. Curve 3 in Fig. 4, which represents the behavior of the *m/e* 268 ion, $P_4O_9^+$, of purified phosphorus pentoxide, shows that the ion current is far less intense at lower electron energies, where further fragmentations of the P_4O_9 are of minor importance, than that of commercial phosphorus pentoxide. The finding that curve 2 in Fig. 3, the $P_4O_{10}^+$ ion curve from commercial phosphorus pentoxide, is not of the parent ion type, i. e., type I of King and Long, can be accepted if we consider that the oxide contanis a P_4O_9 molecule, the appearance potential of its parent ion, $P_4O_9^+$, being lower than that of $P_4O_{10}^+$ from the P_4O_{10} molecule. In fact, curve 1 in Fig. 4, for $P_4O_{10}^+$ from purified phosphorus pentoxide which contains no P_4O_9 molecule at all, is of the typical parent ion type. A graph similar to Fig. 3 was also obtained from a commercial phosphorus pentoxide at 295°C.

From the standpoint of mass spectrometry, we may conclude that a vapor equilibrium with a commercial phosphorus pentoxide, which is oxidized incompletely, contains the P_4O_9 molecule as well as the P_4O_{10} molecule, and no stable polymers heavier than P_4O_{10}. The molecular structrues of P_4O_{10} and P_4O_6 have been well established by electron diffraction studies.[15] In P_4O_6 the four phosphorus atoms are at the corners of a tetrahedron, each bonded to three oxygen atoms along the tetrahedron edges. The P_4O_{10} molecule is very similar to the P_4O_6 molecule in structure, with the addition of an oxygen atom to each phosphorus atom completing the PO_4 tetrahedra. The structure of P_4O_9 might be much the same as the P_4O_{10} molecule, with the exception of the loss of an unshared oxygen atom from a phosphorus atom. This phosphorus will be trivalent, while the other three atoms are pentavalent. Recently, Thilo, Heinz and Host[16] and Heinz[17] have reported on a mixed crystal consisting of P_4O_9 and P_4O_8 molecules.

From the difference in pattern coefficients between purified phosphorus pentoxide and the commercially-available guaranteed reagent phosphorus pentoxide, the amount of P_4O_9 contained in the latter is estimated to be of an order of a percentage points.

Summary

Phosphorus oxides have been investigated by means of mass spectrometers. The mass spectrometers used were a Nier-type spectrometer equipped with a Knudsen cell and a CEC 21-103C type. From the ionization efficiency curves, P_4O_9 molecules have been found to be contained in vapor equilibrium with a commercially available phosphorus pentoxide. From the relation between the vapor pressure and the temperature of phosphorus pentoxide, the existence of a new low-temperature phase of the oxide has been inferred.

The authors wish to thank Dr. Kazuo Someno and Dr. Etsuro Kobayashi for their helpful discussions. We are also indebted to Miss Hiroko Hoshino for her cooperation in constructing the mass spectrometer, and to Mr. Toshio Nishikawa, Mr. Ichiro Kuga and Mr. Kazuo Maruyama for their help in the measurements. We are also indebted to Mr. Ryuzo Shiota for reading and discussing this manuscript prior to publication.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 156—160 (1966)

Nitrous Oxide as an Electron Scavenger in the Radiolysis of Hydrocarbons

By Shin SATO, Rei YUGETA, Kyoji SHINSAKA and Terumi TERAO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 4, 1965)

Nitrous oxide has been used as an electron scavenger in the radiolysis of hydrocarbons: cyclohexane, cyclohexene, benzene, and their mixtures. Considering that the energy for the formation of an ion pair is about 25 eV. in hydrocarbons, 0.4 mol.l^{-1} of nitrous oxide is not enough to capture all the electrons ejected from irradiated hydrocarbons. In the case of cyclohexane, 70% of the ejected electrons seem to be captured by 0.4 mol.l^{-1} of nitrous oxide. In the case of benzene, $G(N_2)$ is about a half of that for cyclohexane. This has been explained tentatively in terms of the ability of benzene to capture electrons. The $G(H_2)$'s in the cases of cyclohexene and benzene have not shown any noticeable dependence on the concentration of nitrous oxide. This shows that hydrogen does not result from the neutralization in these systems. In order to clarify them, the primary processes in the radiolysis of cyclohexane have been further considered using the data previously obtained.

In an attempt to investigate the charge separation in the radiolysis of liquid hydrocarbons, various electron scavengers, such as iodine, methyl iodide and tetrachloromethane, have been used as solutes.[1,2] However, these compounds are known to be reactive to the free radicals as well as to the electrons produced in the radiolysis, so they are not quite suitable for discriminating the reactions of free radicals and charged species, both of which are believed to participate in the radiolysis of hydrocarbons.

Recently it has become clear that nitrous oxide is highly reactive to electrons, but not to free radicals.[3] The compound has been used as an additive in the radiolysis of water[4,5] and its reaction with hydrated electrons has been interpreted in terms of the following dissociative mechanism:

$$e_{aq} + N_2O \rightarrow N_2 + O^-$$

In the radiolysis of hydrocarbons, it is possible that nitrous oxide are capable of capturing the electrons ejected from irradiated hydrocarbons if its concentration is high enough. In fact, Scholes and Simic suggested in a preliminary report that such a reaction occurs in the radiolysis of cyclohexane.[6]

The present paper will report the results of an independently-undertaken study of the applicability of this technique to the radiolysis of cyclohexane, cyclohexene, and benzene, and mixtures of these hydrocarbons.

Experimental

Guaranteed-grade cyclohexane, cyclohexene and benzene, supplied by the Tooa-gosei Co., have been purified by the conventional method described elsewhere.[7] The final step in the purification was to pass the liquids separately through 1-m. silica gel columns. Impurities of less than 0.1% were detected in the purified cyclohexene by gas chromatography; such small impurities are believed to have no appreciable effect on the radiolysis studied. In the case of cyclohexane, special precaution was taken to eliminate olefin contamination.[7] Nitrous oxide supplied by the Takachiho-shoji Co. was used as supplied; no impurities were detected by gas chromatography.

Samples consisting of 5 ml. of each liquid were irradiated with ^{60}Co-γ rays at room temperature, at a does rate of 1.60×10^{17} eV. ml^{-1} min^{-1}. In estimating the dose, $G(Fe^{3+})=15.6$ was used in the Fricke dosimetry.

The products not condensable at the temperature of liquid nitrogen were measured by a Toepler pump attached to a gas burette and a cuprous oxide furnace kept at 240°C. In this furnace, hydrogen is combusted into water, which is then trapped at the temperature of liquid nitrogen. In the cyclohexane radiolysis, a fair amount of water was detected as a product in some cases, although the amounts measured by gas chromatography were not quantitatively reliable.

Since the solubilities of nitrous oxide in cyclohexane and cyclohexene were not known, they were determined at room temperature using the technique reported by Loprest.[8] The Ostwald absorption coefficients obtained are shown in Table I. The value obtained for

benzene is in good agreement with the value 3.668 at 20°C listed in the International Critical Tables.

Table I. Ostwald absorption coefficients of nitrous oxide (22.9°C)

Solvent	Benzene	Cyclohexane	Cyclohexene
Coefficient	3.45	2.62	3.10

Results

Figure 1 shows the dose dependence of products in the radiolysis of cyclohexane containing 0.05 mol.l^{-1} of nitrous oxide. Hydrogen and nitrogen increase linearly with the dose up to 3×10^{20} eV.ml^{-1}, while cyclohexene shows a non-linear dependence on the dose. The initial G-value of

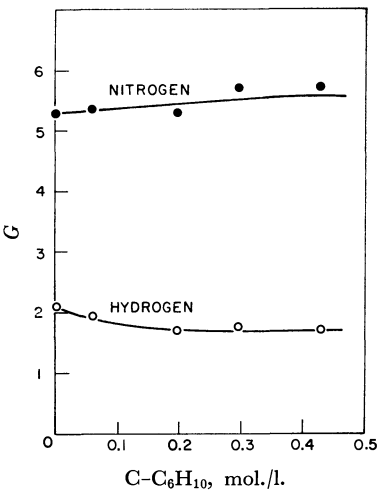

Fig. 5. The effect of cyclohexene on the radiolysis of cyclohexane containing 0.39 mol. l^{-1} N_2O.

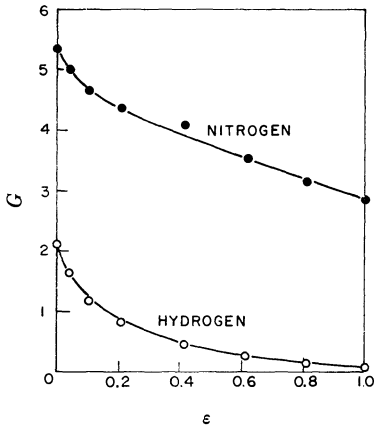

Fig. 6. The effect of N_2O on the radiolysis of mixtures of cyclohexane and benzene. ε is the electron fraction of benzene.

cyclohexene is about twice as large as that in pure cyclohexane.

When the concentration of nitrous oxide is increased, the nitrogen yield increases and the hydrogen yield decreases, though both tend to level-off at high N_2O concentrations, as is shown in Fig. 2. At any N_2O concentration in Fig. 2, the following relationship is found to hold exactly:

$$G(N_2) = 2\Delta G(H_2)$$

where $\Delta G(H_2)$ is the decrease in the G-value of hydrogen. Although quantitative measurements could not be made, the yields of water and cyclohexene were observed to increase with an increase in the concentration of nitrous oxide.

Similar experiments were carried out using cyclohexene and benzene as solvents; the results are shown in Figs. 3 and 4. In these cases water was not detected in the products.

Since olefins are known to act as radical scavengers in the radiolysis of cyclohexane, the effect of the presence of cyclohexene has also been investigated. The results are shown in Fig. 5, where the nitrous oxide concentration is 0.39 mol.l^{-1}. As can be seen from Fig. 2, this concentration is not high enough for $G(N_2)$ and $G(H_2)$ to reach their limiting values. However, in order to obtain a concentration higher than 0.39 mol.l^{-1}, the pressure of N_2O gas inside the cell would have to be in excess of 3 atm., which was the limiting value in the apparatus used.

Figure 6 shows the effect of nitrous oxide on the radiolysis of mixtures of cyclohexane and benzene. The dependence of the nitrogen and hydrogen yields on the electron fraction of benzene evidently indicates an interaction between the two solvents.

Discussion

Nitrous Oxide as an Electron Scavenger.— The initial processes in the radiolysis of cyclohexane may be represented as follows:

$$C_6H_{12} \rightsquigarrow C_6H_{12}^+ + e \quad (1)$$
$$C_6H_{12} \rightsquigarrow C_6H_{12}^* \quad (2)$$

Reaction 1 corresponds to the ionization, and reaction 2 to the excitation, while $C_6H_{12}^*$ does not necessarily mean an excited state of cyclohexane but a precursor of the decomposition into neutral fragments. The nitrous oxide is known to react with electrons as follows:[9]

$$N_2O + e \rightarrow N_2 + O^- \quad (3)$$

Therefore, if electrons ejected from irradiated cyclohexane are captured by nitrous oxide according to this reaction, the succeeding reactions may be represented as follows:

$$O^- + C_6H_{12}^+ \rightarrow C_6H_{11} + OH \quad (4)$$
$$OH + C_6H_{12} \rightarrow H_2O + C_6H_{11} \quad (5)$$

These reactions explain the formation of water and the increase in the G-value of cyclohexene in the radiolysis of a cyclohexane solution.

If reaction 3 is the only source of nitrogen, $G(N_2)$ should be equal to the G-value of the electrons captured by nitrous oxide. At the highest concentration of nitrous oxide used, $G(N_2)$ reaches 5.3, which means that the energy for the formation of an ion pair should be lower than 20 eV. in this system, while the value observed in the gas phase of many hydrocarbons ranges from 20 to 30 eV.,[10] although the value for cyclohexane has not been reported. Another possible source of nitrogen is the reaction of O^- with nitrous oxide; this has been suggested by Johnson and Warman[11] in the gas phase radiolysis of propane:

$$O^- + N_2O \rightarrow N_2 + O_2^- \quad (6)$$

According to Adams et al.,[12] the rate of the reaction of O^- with the oxygen molecule in an alkaline solution is 2.6×10^9 l. mol^{-1} sec^{-1}. If we take this value for the rate of reaction 6 and assume the rate of reaction of O^- with cyclohexane to be equal to that of a hydrogen atom with cyclohexane, which is lower than 10^7 l.mol^{-1} sec^{-1}, a concentration of 0.1 mol. l^{-1} of nitrous oxide is large enough for the reaction between O^- and cyclohexane to become negligible. However, it is not certain that even a concentration of 0.5 mol.l^{-1} of nitrous oxide is high enough to capture all the electrons ejected from the irradiated cyclohexane.

The highest value of $G(N_2)$ obtained in the radiolysis of cyclohexene solution is 4.3, which is

11) G. R. A. Johnson and J. M. Warman, *Nature*, **203**, 73 (1964).
12) G. E. Adams, J. W. Boag and B. D. Michael, ibid., **205**, 898 (1965).

lower than that for cyclohexane by 1.0. The difference may be explained by the higher reactivity of cyclohexene with O^- than that of cyclohexane.

As is shown in Fig. 5, $G(N_2)$ from a 0.39 mol. l^{-1} N_2O cyclohexane solution slightly increases upon the addition of cyclohexene. The addition of cyclohexene may be considered to assist nitrous oxide in scavenging electrons as follows:

$$e + C_6H_{10} \rightarrow C_6H_{10}^- \quad (7)$$

$$C_6H_{10}^- + N_2O \rightarrow C_6H_{10} + N_2 + O^- \quad (8)$$

where $C_6H_{10}^-$ does not necessarily represent a real ion. In other words, cyclohexene provides a shallow trap for electrons. However, this suggestion seems to contradict the observation that $G(N_2)$ from cyclohexene is lower than that from cyclohexane. Evidently, this matter requires further investigation.

Benzene as an Electron Scavenger.—It has recently been established, from studies of the absorption spectra, that aromatic compounds capture electrons to form negative ions; for example, negative naphthalene ions have been observed in the radiolysis at the temperature of liquid nitrogen[13] and diphenyl ions, in the pulsed radiolysis at room temperature.[14] Similarly, benzene may be expected to capture electrons in the radiolysis, although its ability to do so may be weaker. As is shown in Fig. 4, the $G(N_2)$ from a benzene solution of nitrous oxide is about a half of that from a cyclohexane solution at the same concentration of nitrous oxide. This difference may be explained in terms of the competition between nitrous oxide and benzene for electrons. The reactions of benzene may be represented as follows:

$$C_6H_6 + e \rightarrow C_6H_6^- \quad (9)$$

$$C_6H_6^- + C_6H_6^+ \rightarrow 2C_6H_6 \quad (10)$$

i. e., some of the electrons ejected from the molecules are captured by benzene to form negative ions, and these ions are then neutralized by their parent ions without decomposing. The ratio of the rates of the competitive reactions, 3 and 9, is estimated to be 20 to 1 from the plots of $G(N_2)$'s in Figs. 4 and 6. The reported value for this ratio is about 100 to 1.[6]

The dependence of $G(H_2)$ on the electron fraction of benzene in Fig. 6 may be tentatively explained by the following charge transfer reaction:

$$C_6H_{12}^+ + C_6H_6 \rightarrow C_6H_{12} + C_6H_6^+ \quad (11)$$

The possibility of this reaction has already been suggested.[7]

Initial Processes in the Radiolysis of Cyclohexane.—All the important initial steps which can be envisaged in the radiolysis of cyclohexane may be written as follows:

Initial ionization and excitation:

$$C_6H_{12} \begin{cases} \rightsquigarrow C_6H_{12}^+ + e \\ \rightsquigarrow C_6H_{12}^* \\ \rightsquigarrow C_6H_{12}^{*+} + e \end{cases}$$

Neutralization:

$$C_6H_{12}^+ + e \begin{cases} \rightarrow C_6H_{12} & (a) \\ \rightarrow H + C_6H_{11} & (b) \\ \rightarrow H_2 + C_6H_{10} & (c) \end{cases}$$

Neutral decomposition:

$$C_6H_{12}^* \begin{cases} \rightarrow C_6H_{12} & (d) \\ \rightarrow H + C_6H_{11} & (e) \\ \rightarrow H_2 + C_6H_{10} & (f) \end{cases}$$

The decomposition of the excited ion:

$$C_6H_{12}^{*+} \begin{cases} \rightarrow H + C_6H_{11}^+ & (g) \\ \rightarrow H_2 + C_6H_{10}^+ & (h) \end{cases}$$

where $C_6H_{12}^{*+}$ stands for a precursor ion decomposing before neutralization, if this ever occurs. Reaction h does not necessarily mean a unimolecular decomposition; it can stand for an ion-molecule reaction, such as:

$$C_6H_{12}^+ + C_6H_{12} \rightarrow H_2 + \text{residue} \quad (12)$$

If we now take the letters $a, b, \ldots$, etc. to represent the G-values for the respective reactions, we can obtain the following simultaneous equations (I to V):

For the case of the radiolysis of pure cyclohexane:

$$G(H_2) = b + c + e + f + g + h = 5.6 \quad (I)$$

because hydrogen atoms from reactions b, e and g react as follows:

$$H + C_6H_{12} \rightarrow H_2 + C_6H_{11} \quad (13)$$

and because the observed initial G-value of hydrogen is 5.6.[7]

In the gas phase, the energy needed for the formation of an ion pair of many hydrocarbons is observed to be around 25 eV.; i. e., the G-value of the electron may be assumed to be 4, even in the liquid phase. Therefore:

$$a + b + c + g + h = 4 \quad (II)$$

The relation observed above, $G(N_2) = 2\Delta G(H_2)$, gives:

$$e + f + g + h = 5.6 - G_e = 1.6 \quad (III)$$

When cyclohexene is present in sufficient amounts, the reactions involving hydrogen atoms may be omitted; i. e.,

$$G(H_2) = c + f + h = 2.8 \quad (IV)$$

This value has been estimated to be 2.8 in a previous paper.[7]

When both nitrous oxide and cyclohexene are

13) M. R. Ronayne, J. P. Guarino and W. H. Hamill, *J. Am. Chem. Soc.*, **84**, 4230 (1962).

14) S. Arai and L. M. Dorfman, *J. Chem. Phys.*, **41**, 2190 (1964).

present in sufficient concentrations, the G-value of hydrogen should be given by:

$$G(H_2)=f+h \qquad (V)$$

the observed value of which is 1.7, very close to the 1.6 in III. We will now adopt the latter value.

These simultaneous equations give the following solutions:

$$a=e=g=h=0,\ b=2.8,\ c=1.2 \text{ and } f=1.6$$

If this reasoning is correct, the main primary processes in the radiolysis of cyclohexane can be simply expressed as follows, with their approximate G-values as indicated:

$$C_6H_{12} \begin{cases} \rightsquigarrow C_6H_{12}^{+} + e \\ \rightsquigarrow C_6H_{12}^{*} \end{cases}$$

$$C_6H_{12}^{+}+e \begin{cases} \rightarrow H + C_6H_{11} & G \sim 2.8 \\ \rightarrow H_2 + C_6H_{10} & G \sim 1.2 \end{cases}$$

$$C_6H_{12}^{*} \rightarrow H_2 + C_6H_{10} \qquad G \sim 1.6$$

The last reaction does not necessarily represent only a unimolecular reaction; it may also include a bimolecular reaction. Deuterium labeling can discriminate between these two possibilities.

The authors wish to express their deep thanks to Professor Shoji Shida (Tokyo Institute of Technology) for his interest in and encouragement of the present work. They are also indebted to Dr. R. J. Cvetanovic (National Research Council, Canada) for reading the present manuscript.

Perchloro-(dimethylene-1, 2-cyclobutanedione) and Its Solvolytic Degradation*

By Akira FUJINO, Kousuke KUSUDA and Takeo SAKAN

Organic Chemistry Division, Research Institute for Atomic Energy, Osaka City University, Kita-ku, Osaka

(Received June 5, 1965)

Perchloro-(3, 4-dimethylenecyclobutene) has been converted to 1, 3', 3', 4', 4'-pentachloro-2-methoxy-3, 4-dimethylenecyclobutene; in some solutions exposed to the air, this then gradually decomposed to perchloro-(dimethylene-1, 2-cyclobutanedione). The further spontaneous degradation of the last compound in an aqueous ethanol solution has also been investigated in order to elucidate the structures of an unstable intermediate (an adduct of ethanol to the carbonyl) and the end product (the hemi-ketal lactone ester). The physical and chemical properties of these compounds have been given and discussed. A possible bicyclic intermediate caused by the interaction between the hydroxyl group and the diagonally-positioned dichloromethylene group in above unstable ethanol adduct has been suggested in the process from the latter compound to the end product.

In a preceding paper,[1] which reported on some chemical properties of perchloro-(3, 4-dimethylenecyclobutene) (I), it was demonstrated that the double bond at the C_{1-2} position of this chlorocarbon is readily cleaved by the attack of various oxidizing agents. Although the extremely high reactivity of the corresponding hydrocarbon,[2,3] which rapidly polymerizes upon being exposed to the air, placed it beyond direct comparison, the expectation of valuable information about the hitherto little mentioned complicated triene system in chlorocarbon led us to initiate this study of the chemical behavior of I. Perchloro-substitution positively effects a retardation of the polymerization tendency of the triene, as in the case of open-chain compounds.[4] Another reason for examining the chemical properties of I as well as of the related compounds is that the reactivity would be closely connected with both the electronic and the steric characters of the chlorine substituents in the molecule. This paper will deal with the action of some bases on I, the subsequent air oxidation of the product to a four-membered α-diketone, and the ethanolysis of the latter, which involves unique type of ring cleavage, to a lactone ester.

Results and Discussion

Compound II (m. p. 124°C), in which one of the chlorine atoms in I is replaced by a methoxy-group, was obtained almost quantitatively when I was treated for a short period with a methanolic sodium or potassium hydroxide solution containing a total of 2.5 equivalents base to I. Similar results were observed with the use of a sodium methoxide solution. Both the infrared spectrum ($\nu_{C=C}$ 1705 s and 1605 vs cm^{-1}, and 935 cm^{-1} assigned to the $-\underset{|}{C}=CCl_2$ group[5]) and the ultraviolet absorption (in Fig. 1, along with that of I) of II indicate that no remarkable change either in its skelton or in the double system has occurred in the transformation of I.

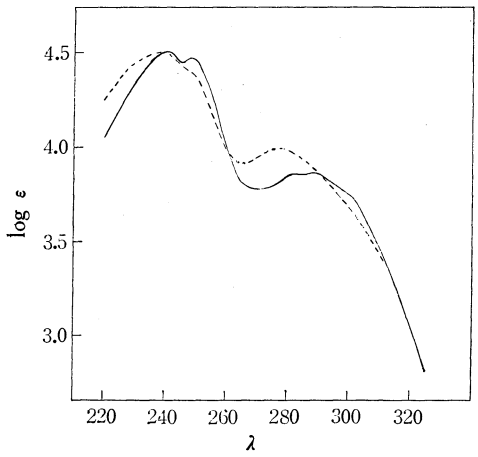

Fig. 1.
---- Perchloro-(3, 4-dimethylenecyclobutene) (I)
—— 1, 3', 3', 4', 4'-Pentachloro-2-methoxy-3, 4-dimethylenecyclobutene (II)

The 1605 cm^{-1} band is the most intense one over the whole absorption range; it is approximately twice as strong as the 1705 cm^{-1} band. This suggests that two bands with the same wave number coincide in the former. In addition, the data are also in accord with the reported observation that the replacement of a chlorine substituent by a methoxy-group in some polychloro-cyclopentadiene[6] and cyclobutene[7] derivatives has caused a shift of their $\nu_{C=C}$ frequencies to a higher region. The oxidation of II with hydrogen peroxide in ether gave perchloro-(dimethylenesuccinic acid).[1] (III) (m. p. 215°C (decomp.)), revealing that the location of the methoxy-group is on the ring carbon. The structural proof for III has been established by the catalytic reduction of III to a chlorine-free dicarboxylic acid (m. p. 211°C), an acid which is identical with the *meso*-dimethylsuccinic acid synthesized from 2-bromopropionic acid. Therefore, the structure shown in Chart I may, without doubt, be given to II.

II was gradually decomposed in benzene or in carbon tetrachloride, while hydrogen chloride was evolved, when the solution was exposed to the air for a long period. The product was a red oil from which scarlet crystals of $C_6Cl_4O_2$ (IV) (m. p. 167°C) were obtained. The structural evidence for its giving the four-membered α-diketone may be enumerated as follows: 1) infrared absorption: $\nu_{C=O}$ 1805 m, 1755 s; $\nu_{C=C}$ 1595 s, 1515 m cm^{-1}; 935cm^{-1} ($-\underset{|}{C}=CCl_2$).[5] 2) IV was oxidized with 30% hydrogen peroxide to the anhydride (V)[1] (m. p. 119—120°C) of III. A similar type of oxidation has been reported by several authors[8-11] for members of the substituted cyclobutadienoquinone series, sometimes as a diagnostic method for α-diketone. 3) IV was normally condensed with *o*-phenylenediamine in acetic acid to give a quinoxaline derivative (IV) (m. p. 197.5—198°C), the ultraviolet spectrum of which is shown, along with that of IV, in Fig. 2. No ring opening as in the reaction of mono-[11] or diphenylcyclobutadienoquinone[12] with the diamine has been observed in this case.

IV may be sublimed under a vacuum and recrystallized from ether. Most interestingly, however, IV was spontaneously decomposed in a solution

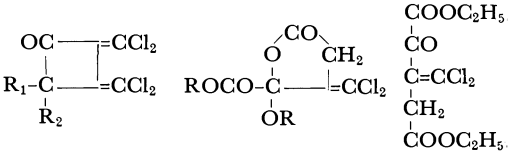
---- Quinoxaline derivative (VI) from IV

in the presence of ethanol and water. It has been observed that, when a small amount of 99% ethanol was added to the system, the peak heights at 234, 280, 383 and 400 (mμ) in the ultraviolet absorption of IV in cyclohexane began to lower at a markedly rapid rate, and then went on to produce, less rapidly, a new absorption peak at 335 mμ. This new peak also started to decay, after reaching a certain height, and finally became a complete transparency. In ethanol alone the original spectral features of IV disappeared too quickly for it to be precisely followed. A more detailed plot of the slower decay at 335 mμ against the time with a highly-diluted, freshly-prepared ethanol solution revealed its half life period to be ca. 30 min. This observation suggests that some unstable reaction intermediate is formed from IV and ethanol, and that the intermediate collapses a little more slowly than IV itself. The isolation of this intermediate has not been successful; the attempted procedures have resulted only in the regeneration of IV as a sublimate. It is highly probable that ethanol has first been added to one of the carbonyls, thus establishing an equilibrium between the adduct (VIIa) and the components, as has been suggested by Mallory and Roberts[13] in the thermal methanolysis of phenylcyclobutadienoquinone. Blomquist and LaLancette[9] reported a smooth ethanolysis of diphenylcyclobutadienoquinone at 25°C; it then proceeds to diethyl α, α'-diphenylsuccinate, probably via bisphenylketene. In the case of IV, however, there can be no transformation like this, for the bis-ketene formation is structurally disallowed. Uhler, Shechter and Tiers[14] also observed the instability of 3, 4-bis(diphenylmethylene)-1, 2-cyclobutanedione in ethanol near room temperature, but they provided no other information on its degradation process. The speculation about the mono-hemiketal intermediate VIIa is further supported by the observation that perchloro-(2, 3-dimethylenecyclobutanone)[15] (VIIb) absorbs the ultraviolet light at 344 mμ in cyclohexane.

IV was refluxed with 99% ethanol in order to examine the decomposition product. The reaction mixture soon turned strongly acidic, and the evolution of hydrogen chloride was observed. The chromatographically-fractionated neutral product was an oily material, $C_{10}Cl_2H_{12}O_5$ (b. p. 170°C (bath temp.)/3.5 mmHg), in a 70% yield. The hemi-ketal lactone ester formula VIIIa is the only one which rigorously accounts for its infrared ($\nu_{C=O}$ 1780m and 1730 s cm^{-1}, $\nu_{C=C}$ 1580 m cm^{-1} and 920 s cm^{-1} for $-C=CCl_2$ group[5]), ultraviolet (λ_{max}^{EtOH} 260 mμ, ε 4500) and NMR (5.64, 5.86, 8.60 and 8.73 τ for the protons in the ethoxy-group and 6.41 τ for the two protons in the $-CH_2CO-$ group) spectral properties. The chain structure (IX), the most possible alternative, may be ruled out in view of the observed high value of the first $\nu_{C=O}$ frequency. The ultraviolet absorption was drastically changed by the addition of alkali;



VII a: R_1=OH, R_2=OC_2H_5 b: R_1=R_2=Cl
VIII a: R=C_2H_5 b: R=H
IX

it did not reproduce the original curve on acidification. Further, the 2, 4-dinitrophenylhydrazine test proved the existence of a ketonic group in VIIIa. Both the Tollens' reagent and phosphomolybdic acid in aqueous ammonia normally reacted with VIIIa, whereas the fuchsin-sulfurous acid did not bring about a parallel result. This irregularity in the aldehyde test can well be interpreted as what may reasonably be expected if it is assumed that the dichloromethylene group in VIIIa is a potential aldehyde which, in effect, functions only in the alkaline medium. The alkaline hydrolysis converted VIIIa to a carboxylic acid, $C_6Cl_2H_4O_5$ (VIIIb) (m. p. 131°C). The evidence for the structure included: 1) neutralization equivalent: 114; 2) pK_a value: 1.65 and 4.08; 3) ultraviolet (λ_{max}^{EtOH} 254.5, ε 2100), infrared (ν_{OH} 3200, $\nu_{C=O}$ 1770, 1730; $\nu_{C=C}$ 1670 cm^{-1}) and NMR (5. 79 τ in D_2O) spectra; 4) an indication of a potential aldehyde in the test similar to those for VIIIa. An additional confirmation of the structure has been achieved by the hydrogenation of the dichloromethylene group to a methyl group, followed by an alkaline

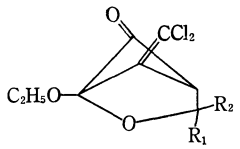
15) This compound will be reported in detail in the succeeding paper.

hydrolysis, presumably to β-methyl α-ketoglutaric acid (X) (the 2, 4-dinitrophenylhydrazone of its monoethyl ester: m. p. 171°C).

In the process VIIa→VIIIa, the initial hydrolysis of the dichloromethylene group β-positioned to the residual carbonyl in VIIa appears to have occurred by way of an acid chloride or its analog. It should be noted here, however, that there is is an another possibility, that the initial participation of the hydroxyl group in VIIa to the diagonally-positioned dichloromethylene moiety is more important in this degradation. Because of the enhanced puckering of the four-membered ring in VIIa due to the two severely-interacting chlorine atoms on each exocyclic methylene carbon, the hydroxyl group is made so closely accessable to the diagonal dichloromethylene or chloroethoxymethylene group as to cause the subsequent formation of a potential lactone, such as XIa or XIb. At the present stage it seems fairly difficult to conclude which one is the true transformation process. However, one piece of evidence which favors the speculation that the ring puckering makes the vinylogical chlorine substituent less reactive toward hydrolysis has been experimentally observed; the fading rate of the red color of IV in dioxan-water (9 : 1 by vol.) was much slower than in an alcoholic system. Even when the solution was heated at 100°C, the hydrolytic degradation took place very gradually. This suggests that the chlorine-substituent hydrolysis of either one or of both, in VIIa will also be slow and will not precede the formation of XI.



XI a: $R_1=R_2=Cl$
b: $R_1=Cl$, $R_2=OC_2H_5$

An inspection of the model also supports this speculation about the stereospecific approach. Perhaps, as the following step, the hydrolysis of the geminated dichloromethylene or chloro-hemiketal group and the alcoholytic cleavage of the ketone would take place almost concertedly because of its highly-strained bicyclic structure.

Other alcohols, such as methanol (1), propanol (2), isopropyl alcohol (3), *n*-butanol (4), *t*-butanol (5), *n*-hexanol (6), cyclohexanol (7) and benzyl alcohol (8), were preliminarily examined in terms of the ketone degradation. It was found that, except for 3, 5 and 8, they react with IV much like ethanol. IV was decomposed very slowly in the isopropyl alcohol solution, while no noticeable change was observed in *t*-butanol and benzyl alcohol. These definite differences in the reactivity of alcohols may be well interpreted by assuming a difference in the ease of their initial addition to the carbonyl group in IV.

Experimental[16]

1,3',3',4',4'-Pentachloro-2-methoxy-3, 4-dimethylenecyclobutene (II). — A mixture of perchloro-(3, 4-dimethylenecyclobutene) (I) (10 g.) dissolved in benzene (80 ml.) and methanolic potassium hydroxide (4.8 g. of potassum hydroxide in 50 ml. of anhydrous methanol) was stirred at room temperature for 3 hr. The solution was then repeatedly washed with water, and the neutral fraction was separated. The crystalline product was collected after the evaporation of the solvent as white needles, which were recrystallized from methanol to give a material with a melting point of 118—120°C. 5.3 g. (55%). The pure sample for analysis melted at 124°C.

Found: C, 30.11; H, 1.48; Cl, 63.25. Calcd, for $C_7Cl_5H_3O$: C, 29.98; H, 1.08; Cl, 63.23%. UV: λ_{max}^{EtOH} 238(30200), 277(10000); λ_{sh} 233(28200); λ_{min} 264—267(9100), mμ(ε).

The Oxidation of II with Hydrogen Peroxide. —A reagent solution was first prepared by shaking an aqueous hydrogen peroxide solution (30%, 30 ml.) twice with ether (each 25 ml.). II (327 mg.) was dissolved in the ether containing the peroxide, after which the entire solution was allowed to stand at room temperature for 17 days. A part of the acidic fraction (37 mg.) crystallized to give a material which is, in a comparison of their infrared charts, identical with the perchloro-(dimethylenesuccinic acid) (III) previously reported.[1]

The Reduction of III to *meso*-Dimethylsuccinic Acid.—III (266 mg.) dissolved in ethanol (5 ml.) was hydrogenated with 5% palladium chloride on charcoal (200 mg.). After the absorption of the calculated amount of hydrogen, the separated acidic fraction was vacuum-sublimed (120—130°C (bath temp.)/5 mmHg) to give 34 mg. of the material with a melting point of 211°C.

Found: C, 49.44; H, 6.91. Calcd. for $C_6H_{10}O_4$: C, 49.31; H, 6.90%.

meso-Dimethylsuccinic acid was synthesized by heating a mixture of 5 g. each of 2-bromopropionic acid and of silver powder at 150—160°C in a sealed tube for 3 hr. The crystalline product was then collected from a viscous acidic oil after the solution had been kept in a refrigerator. The crystals were purified by sublimation, after being pressed between a folded filter paper, a to material with a melting point of 204—208°C. The infrared absorption of this acid was identical with that of that obtained above by the reduction of III.

Perchloro-(dimethylene-1, 2-cyclobutanedione) (IV).—The benzene (10 ml.) solution of II (2.77 g.) was shaken with oxygen gas at room temperature. A little more than one equimolar amount of oxygen was absorbed in 3 hr. While it was being kept in the open air, the solution gradually turned red and there was a slow evolution of hydrogen chloride, and the solid material crystallized out as red leaflets. The filtered crystals, after being washed with a small amount of carbon tetrachloride, weighed 1.02 g. (42%). Recrystallization from ether afforded a pure sample of diketone IV (m. p. 167°C). The yield of IV was lower when the run was carried out in carbon tetrachloride.

16) All meltng points given are uncorrected.

Found: C, 29.52; H, 0.44; Cl, 57.31. Calcd. for $C_6Cl_4O_2$: C, 29.31; H, 0.00; Cl, 57.68%. UV: $\lambda_{max}^{cyclohexane}$ 233—234(14700), 280(2900), 383(11500), 402—403(11500), 550—560(400); λ_{min} 270(2800), 320(600), 395(10700), mμ(ε).

The Oxidation of IV to Perchloro-(dimethylenesuccinic) Anhydride.—A mixture of a chloroform (4 ml.) solution of IV (100 mg.) and 30% aqueous hydrogen peroxide (1 ml.) was efficiently shaken and allowed to stand at room temperature for 48 hr. The neutral solid mass was then collected and recrystallized from petroleum ether to give a sample of V with a melting point of 119—120°C. 14 mg. The infrared absorption is identical with that previously reported.[15]

1, 2 - Bis (dichloromethylene) cyclobuta [b] quinoxaline (VI).—A mixture of IV (105 mg.) and *o*-phenylenediamine (46 mg.) was heated in acetic acid at 100°C for one hour. After it had been cooled, the solid product was filtered under reduced pressure and recrystallized from ethanol as long yellow needles (m. p. 197.5—198°C). 79 mg.

Found: C, 45.56; H, 1.57; N, 8.75. Calcd. for $C_{12}Cl_4H_4N_2$: C, 45.32, H, 1.27; N, 8.81%. UV: λ_{max}^{EtOH} 270—271(23700), 279(23300), 335—337(5400), 378(10500), 400—402(12200), mμ(ε). IR: $\nu_{C=C}^{Nujol}$ 1665 s, 1640 m, 1610 s, 1583 m cm.$^{-1}$

The Ethyanolytic Degradation of IV to the Hemiketal Lactone Ester (VIIIa).—IV (4.79 g.) was, after the addition of ethanol (40 ml.), heated on a water bath for 10 min. The neutral fraction was then separated and chromatographed on silica gel (10 g.) with benzene. The light yellow main fraction (4.64 g.) was vacuum-distilled at 170°C (bath temp.)/3.5 mmHg to give a colorless oil of VIIIa.

Found: C, 42.35; H, 4.49. Calcd. for $C_{10}Cl_2H_{12}O_5$: C, 42.42; H, 4.27%.

The Hydrolysis of VIIIa to the Hydroxylactone Acid (VIIIb).—To VIIIa (381 mg.) an aqueous sodium hydroxide solution (N, 2.8 ml.) was added; the mixture was then shaken for 10 min. at room temperature. The acidic fraction, when separated in the usual manner, furnished a viscous oil (207 mg.) which gradually solidified to give colorless fine crystals, (m. p. 128—131°C). Repeated recrystallization from chloroform afforded a sample of VIIIb with a melting point of 131—133°C.

Found: C, 31.88; H, 2.04. Calcd. for $C_6Cl_2H_4O_5$: C, 31.74; H, 1.78%.

The Hydrogenation of VIIIb and the Subsequent Hydrolysis to β-Methyl-α-ketoglutaric Acid (X).—The ethanol (5 ml.) solution of VIIIb (1.72 g.) was shaken with hydrogen under atmospheric pressure in the presence of 5% palladium chloride on charcoal. After the calculated amount of hydrogen had been absorbed, the catalyst was filtered off and the filtrate was passed through a column packed with aluminum oxide (5 g.). After the solvent had been removed, the residual oil was vacuum-distilled at 100—120°C (bath temp.)/5 mmHg.

Found: C, 54.96; H, 7.58. Calcd. for $C_{10}H_{16}O_5$: C, 55.54; H, 7.46%. IR: $\nu_{C=C}$ 1800, 1725 cm.$^{-1}$

The distillate above (230 mg.) was heated with an aqueous sodium hydroxide solution (0.1 N, 20 ml.) for 10 min. on a water bath; the acidic product was then continuously extracted with ether. After the ether had been removed After the solution had been dried, the hygroscopic residue remained oily and its infrared spectrum showed a very intense and broad ν_{OH} band.[17] This material (70 mg.) was heated with 2, 4-dinitrophenylhydrazine (60 mg.) in ethanol, the quantity of which was enough to dissolve both of them. A small amount of water (2 ml.) was added, and the whole solution was then strongly heated under refluxing for one hour. The acidic fraction was separated and chromatographed on silica gel, with a developing solvent of benzene - methanol - acetic acid (25: 8 : 4 by vol.), to acid crystals with a melting point of 167—171°C.

Found: C, 45.67; H, 4.33; N, 15.23. Calcd. for $C_{14}H_{16}N_4O_8$: C, 45.65; H, 4.38; N, 15.21%.

We wish to express our thanks to Mr. Junichi Goda and Miss Hiromi Tokuda of Osaka City University for his elemental analyses and her infrared spectra measurement, and also to Dr. Kazuo Tori of Shionogi Research Laboratory for NMR spectra data.

17) Although G. Cauquil reported the melting point of 167°C for X (*Compt. rend.*, **208**, 1156 (1939)), it is doubtful whether the precursory compound (m. p. 186°C), obtained by the oxidation of pulegon with selenium oxide, really has a triketone structure. Our infrared datum indicated the presence of alcoholic group in this compound.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 165—169 (1966)

The Solvent Extraction of Europium Ions with Benzoyltrifluoroacetone. The Synergistic Effect of Oxygen- and Nitrogen-containing Solvents

By Tsunenobu SHIGEMATSU, Masayuki TABUSHI, Masakazu MATSUI and Takaharu HONJYO

Institute for Chemical Research, Kyoto University, Sakyo-ku, Kyoto

(Received June 7, 1965)

The synergistic effect of many kinds of oxygen- and nitrogen-containing solvents on the extraction of europium ions with benzoyltrifluoroacetone in *n*-hexane has been studied. The addition of alcohols, esters, ketones, amines and heterocyclic compounds enhances the extraction, and in general, the solvents with longer carbon chain, especially alcohols and amines, have the larger synergistic effects. At a constant benzoyltrifluoroacetone concentration, the logarithm of the distribution coefficient is linear with pH. The slope of the log D vs. pH plot is about 1.5 in the extraction with 0.05 M benzoyltrifluoroacetone in *n*-hexane, but it is 2 in the presence of 0.04 M oxygen-containing compound and 3 in the presence of 0.04 M nitrogen-containing compound. It may be considered that europium benzoyltrifluoroacetonate forms some adducts with these oxygen- or nitrogen-containing Lewis bases, and that the coordination of nitrogen-containing Lewis bases to the chelates is stronger than that of oxygen-containing ones. Since the solvent extraction of neodymium and lutetium ions with β-diketones is performed as well as that of europium ions, it seems to be a favorable procedure for the extraction of rare earth ions with β-diketones to utilize the adduct formation between β-diketonates and active oxygen- or nitrogen-containing Lewis bases.

The nature of the organic solvent is important in the extraction of metal ions with a suitable chelating reagent.[1] Here the neutral chelate compounds may be extracted into the organic phase, there forming addition compounds with some molecules of water, a solvent and/or an uncoordinated chelating reagent.

In the case of the extraction with such an inert solvent as benzene, chloroform, carbon tetrachloride, *n*-hexane and cyclohexane, the addition of an active oxygen- or nitrogen-containing solvent to the extraction system often increases the extraction. This phenomenon, the synergistic effect of the solvent, may be attributed to the formation of adducts or solvates between the metal chelates and the polar oxygen- or nitrogen-containing solvents. This synergistic effect of the solvent has been observed in the solvent extractions of thorium TTA chelates in the presence of tri-*n*-octylamine[2] and acetic acid[3]; in the solvent extractions of copper(II) and zinc(II) TTA or β-isopropyltropolone chelates in the presence of TBP or hexone,[4] and in the solvent extraction of alkali earth oxinates in the presence of *n*-butyl amine.[5] The synergistic effect has also appeared in the thorium TTA and phosphate ester systems,[2,6] the uranyl DBP-TBP system,[7] and the actinide TTA, TBP and TBPO systems.[8] The chelating reagent also reacts as a donor molecule in the case of a UO_2R_2HR-type complex with uranium(VI) and TTA.[9-11]

On the other hand, there have been severa-investigations of the adduct or solvate formation by the crystallization of chelates, such as the halomethane solvates of tervalent metal acetylacetonates[12]; the solvates of the rare earth acetylacetonates with water and methanol[12,13]; the adducts of copper(II) β-diketonates with heterocyclic bases[14]; the adducts between UO_2 β-diketonates and amine, ammonia, water, ketones or alcohols,[15-17] and europium(III) dibenzoylmethide

adducts with a number of oxygen- and nitrogen-containing Lewis bases.[18]

During the course of the authors investigations of the extraction of many metal ions with β-diketones,[11,19-23] it has been found that rare earth and uranyl β-diketonates are extracted better with a polar oxygen-containing solvent, such as butyl acetate, than with chloroform or benzene. It may be inferred that rare earth β-diketonates form adducts with the active solvents as well as uranyl chelates do.

In this paper, the synergistic effect of a number of oxygen- and nitrogen-containing solvents on the extraction of europium ions with a fluorinated β-diketone, benzoyltrifluoroacetone in *n*-hexane, will be studied, and the usefulness of this effect in the extraction of rare earth(III) ions with β-diketones will be discussed.

Experimental

Apparatus.—Radioactivity countings were made with a Kobe Kogyo NaI(Tl) (4.45 cm.×5.08 cm.) well-type scintillation counter, model PS-300, connected to a transistorized scaler, model SA-230. A Hitach-Horiba glass electrode pH meter, model M-3, was used for the pH measurements.

Materials.—The radioisotopes of neodyminum-147, europium-152, 154 and lutetium-177 were supplied from ORNL, U. S. A. or from The Radiochemical Center, Amersham, England.

The benzoyltrifluoroacetone was obtained from the Dojindo Co., Ltd., Research Laboratories.

The chloroform was purified by washing it with a diluted sodium hydroxide solution, water, a diluted hydrochloric acid solution and three portions of water, followed by distillation. The butyl acetate was washed with water and distilled. The ethers were shaken with an aqueous ferrous sulphate solution. The furan was refluxed with cuprous chloride and then distilled. All the other reagents were reagent-grade materials and were used without further purification.

Procedure.—The extractions are made by shaking 10 ml. of the aqueous sample solution with 10 ml. of the organic solvent. The aqueous sample solution, adjusted to a desired pH, contains europium ions in the concentration of about 1 p. p. m. (^{152,154}Eu 2—3×10^4 c. p. m.), sodium chloride and acetic acid in each 0.1 molar concentration respectively. When the effect of the nitrogen-containing solvent is investigated, the material is added to the aqueous solution to make a 0.04 M solution. The organic solvent phase is composed of 0.05 M benzoyltrifluoroacetone and a 0.04 M oxygen-containing compound in the studies of the effect of an oxygen-containing solvent.

The aqueous and the organic phase are taken into a 50 ml. separating funnel and then shaken for 15 to 30 min. Two milliliters of each of the two phases are then pipetted into test tubes (14 mm. in diameter); the gamma activities are measured with the NaI scintillation counter, and the pH values of the aqueous phase after the extraction are obtained with the pH meter.

Results

The distribution ratio, D, and the per cent of extraction, $\%E$, were calculated by the following equations;

$$D=\frac{\gamma\text{-count rate per 2 ml. of the org. phase}}{\gamma\text{-count rate per 2 ml. of the aq. phase}}$$

$$\%E=(D/(1+D))\cdot 100$$

The extraction curves for neodymium-, europium- and lutetium-benzoyltrifluoroacetonates with butyl acetate, chloroform and benzene are shown in Fig. 1. From the figure, it may be seen that the extraction of rare earth benzoyltrifluoroacetonates is performed better with butyl acetate than with chloroform or benzene. Figure 2 represents the extraction behavior of the europium chelate in mixed solvents which are prepared by changing the concentration of butyl acetate using *n*-hexane as the diluent. The extraction is much enhanced, even at a low concentration of butyl acetate such as 0.06 M.

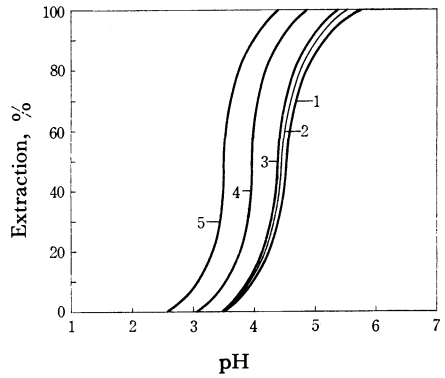

Fig. 3. Extraction of europium benzoyltrifluoroacetonate.

1 None, furan or pyrrole
2 Pyrrolidine
3 Tetrahydrofuran
4 Pyridine or piperidine

The effects of alcohols, esters, ketones and ethers have also been investigated according to the above-described procedure; the extraction curves obtained in the presence of 0.04 M oxygen-containing compounds are shown in Fig. 3 (alcohols), Fig. 4 (esters) and Fig. 5 (ketones). Figure 3 indicates that the higher alcohols have the larger solvent effects. Esters and ketones show effects similar to those of alcohols, although the effect of the latter is much greater than that of the former. Ethers do not have such an influence. The effect of heterocyclic bases has also been studied; the results are shown in Fig. 6. Furan and pyrrole do not exert any effects,

whereas tetrahydrofuran, pyrrolidine, pyridine and piperidine increase the extraction. As is shown in Fig. 7, amines have the same effect as alcohols, and the presence of amines and other nitrogen-containing Lewis bases causes a steeper rise in the extraction curves than does that of oxygen-containing compounds.

This fact becomes more evident from the results in Fig. 8, which presents the slope of the log-D vs. pH plot obtained at 0.05 M benzoyltrifluoroacetone. When the extraction is carried out using n-hexane as the extracting solvent, the slope of the log D vs. pH plot is about 1.5. This slope is 2 in the extraction using n-hexane containing 0.04 M oxygen-containing compounds as the extracting solvents, and 3 in the presence of 0.04 M nitrogen-containing Lewis bases.

Discussion

The extraction of rare earth benzoyltrifluoroacetonates improves in the order of lutetium, europium, and neodymium, as is shown in Fig. 1. Generally, the stability of rare earth β-diketonates increases with the decrease in the ionic size, that is, with the decrease in basicity,[24-26] while their extraction is enhanced with the decreasing basicity of the central metal ions.[27] The results in Fig. 1 are in agreement with these facts.

Table I shows the shifts of the $pH_{1/2}$s of the extraction caused by the addition of several sorts of oxygen- or nitrogen-containing compounds (Lewis base). In general, the $pH_{1/2}$ shifts seem to enlarge with the increase in the length of the carbon chain of the base. These effects of the carbon cahin length could be ascribed to the decreasing solubility of the higher base in water.

The role of these Lewis bases in the extraction behavior of the chelate can be explained as follows. If a neutral metal chelate extracted reacts with a Lewis base to form the adduct compound, the concentration of the chelate in the organic phase decreases. Then the overall extraction equilibrium of the metal chelate shifts in the direction that favors the rise of the distribution ratio (organic/aqueous) of the metal.

Table I suggests an attractive technique for the solvent extraction of rare earth ions. By utilizing the adduct formation between rare earth benzoyltrifluoroacetone chelate and Lewis bases, the extraction can be undertaken at a lower pH region.

The differences found among the solvent effects of alcohols, esters, ketones and ethers are probably due to the basicity of the oxygen atoms in the solvent molecules. Figure 6 suggests that lone-pair electrons of furan and pyrrole participate in the resonance stabilization of the molecule, whereas lone-pair electrons of tetrahydrofuran, pyrrolidine, pyridine and piperidine are utilized in the adduct formation.

The difference observed between the solvent effect of oxygen- and nitrogen-containing Lewis bases may be attributed to the differences in the donating power of the active oxygen and nitrogen atoms in the molecules, indicating that the bonding of the former to the metal chelates is weaker than that of the latter.

Acetone	0		

The bondings of the donor molecules (including water molecules) to the metal chelates have been widely studied by various methods; they have generally been classified into two groups; (1) donor molecules bond to the coordinated chelating reagents by dipole-dipole interaction or hydrogen bonding,[12] and (2) donor molecules coordinate directly to the central metal ions.[17,18] Both monomers and dimers of the chelates also exist in a non-aqueous solution.[13,28,29] There are several pieces of evidence that rare earth β-diketonates have coordination numbers greater than six,[30] and the coordination number of seven may be expected from the fact that one water molecule is always tightly held on the crystal of rare earth β-diketonates.[12,13,31] From the results in Fig. 6 and Fig. 7, it might be considered that nitrogen-containing Lewis bases substitute with the water molecule directly coordinated to central metal ions, although more detailed experiments must be undertaken before a definite conclusion can be reached.

At any rate, it is evident that the adduct formation with Lewis bases is favorable for the solvent extraction of rare earths as the benzoyltrifluoroacetone chelates; it is also probable that a similar advantage can be expected in some other cases of the extraction of metal β-diketonates, which show a poor extractability in the absence of adduct-forming materials.

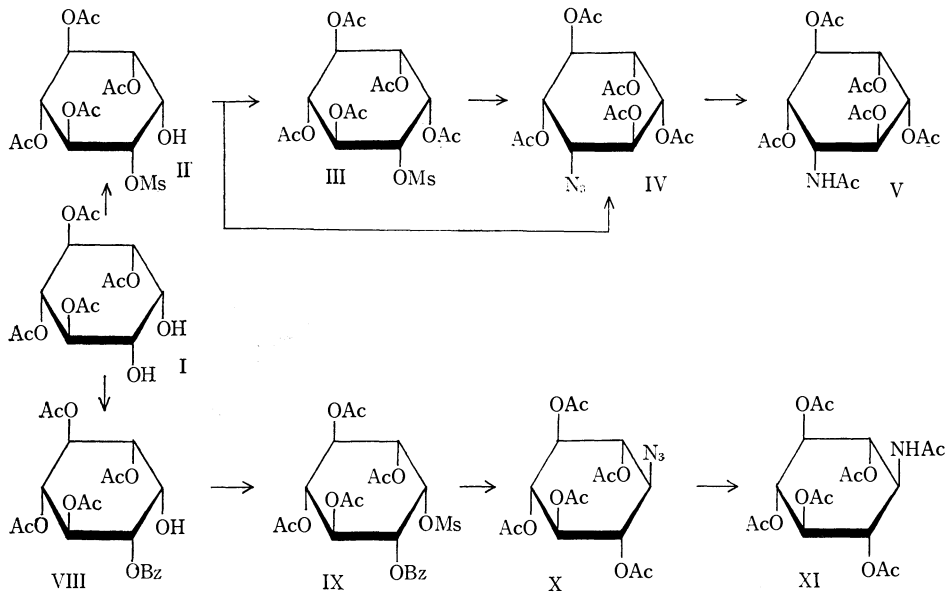
(Received June 8, 1965; in revised form July 23, 1965)

muco-Inosamine-1, *scyllo*-inosamine, *muco*-inosadiamine-1, 5 and *myo*-inosadiamine-1, 2 have been synthesized from *myo*-inositol. Their structures have also been established by a study of the NMR spectra of their acetyl derivatives. When 1, 4, 5, 6-tetra-*O*-acetyl-3-*O*-mesyl-*myo*-inositol is treated with sodium azide in boiling aqueous 2-methoxyethanol, an azido derivative is obtained. The azido compound is hydrogenated in the presence of a catalyst and subsequently acetylated to give muco-inosamine-1. The stereochemical course of the reaction has been proposed to be an anchimeric reaction. When the analogous reaction is carried out with 2, 3-di-*O*-mesyl-*myo*-inositol tetraacetate, *myo*-inosadiamine-1, 2 or *muco*-inosadiamine-1, 5 is obtained as the main product, depending on the solvent applied.

In connection with a previous communication,[1] a new synthesis of *muco*-inosamine-1,[4] *scyllo*-inosamine,[8] *muco*-inosadiamine-1, 5 and *myo*-inosadiamine-1, 2, and their structures as established by means of the NMR spectra, will be described in the present paper.

scyllo- and *muco*-1-Inosamine

1, 4, 5, 6-Tetra-*O*-acetyl-*myo*-inositol (I)[2] has been used as the starting material. By treating I with one mole of methanesulfonyl chloride in pyridine, 1, 4, 5, 6-tetra-*O*-acetyl-3-*O*-mesyl-*myo*-inositol (II) is obtained in a fairly good yield. Then the acetylation of II gives 3-*O*-mesyl-*myo*-inositol pentaacetate (III).[3] The sturctures of II and III have been established by means of the NMR spectra, along with chemical evidence.[1] The spectrum of III in chloroform (Fig. 1) reveals a sharp signal at 7.00 τ, which is assigned to the protons of an equatorial mesyloxy group.[3] The signal at 7.78 τ corresponds to an axial acetoxy group, and the



* A part of this research has been presented at the 18th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1965.

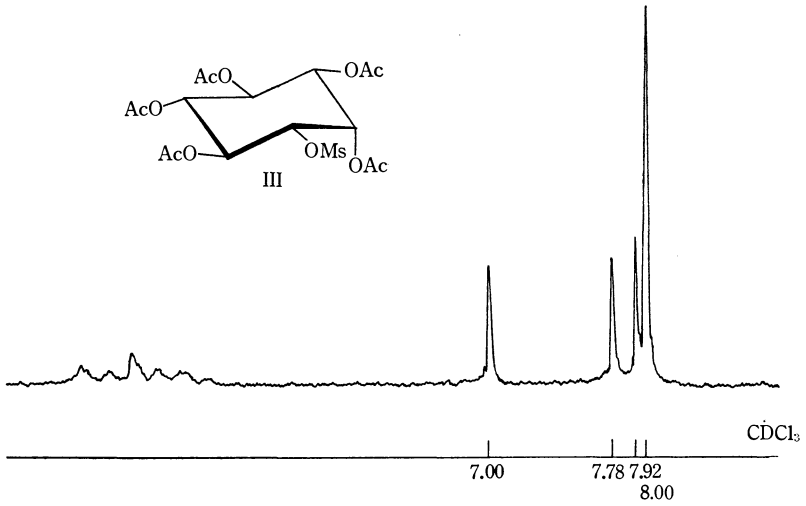

Fig. 1

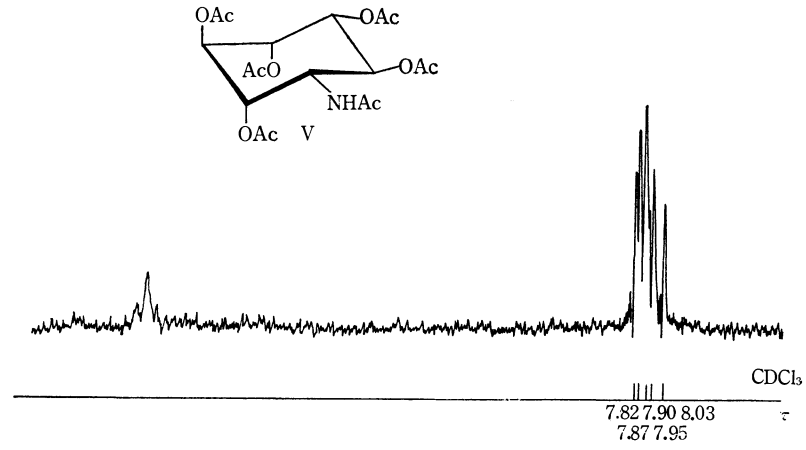

Fig. 2

signals at 7.92 and 8.00 τ with a 1 : 3-intensity are expected from four equatorial acetoxy groups.

When III is treated with sodium azide in boiling aqueous 2-methoxyethanol and subsequently acetylated, an azido acetate (IV) is obtained. Upon the catalytic reduction of IV, followed by acetylation, hexaacetyl-*muco*-inosamine-1 (V) is obtained in 32% yield; it has been identified by a mixed melting point determination.[4] V can also be prepared from II by an analogous reaction sequence.

Considering the configuration of the product obtained, the demesylation of III seems to proceed through an intermediate formation of a dioxolane-ring by participation of the vicinal, trans-orientated acetoxy group, which is then cleaved by a nucleophilic attack of the azide ion in the manner of a diaxial opening.[3]

V can also be prepared in 40% yield from II by treatment with ammonia in methanol under pressure and by subsequent acetylation. Since the first step of this reaction is a de-*O*-acetylation, the formation of V must proceed via an oxirane ring between C-3 and C-4, a ring which is diaxially opened.[5]

The stereochemical courses of these reactions are analogous to an attack of the acetate ion on

4) M. Nakajima, A. Hasegawa and N. Kurihara, *Chem. Ber.*, **95**, 2708 (1962): The melting point determination has kindly been carried out by Professor Minoru Nakajima of Kyoto University.

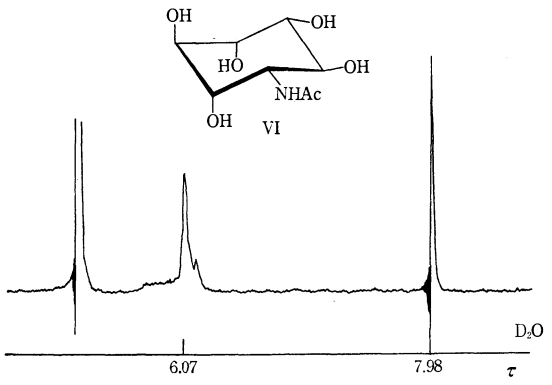
the anchimeric intermediate acetoxonium ion[6] and to an opening of a highly-strained oxirane ring by a nucleophile.[7]

NMR-spectroscopical data support the muco-configuration: the hexaacetate V shows sharp signals at 8.03 τ, as is to be expected from an equatorial acetamido group, and at 7.82, 7.87, 7.90 and 7.95 τ (1 : 1 : 1 : 2), arising from three axial and two equatorial acetoxy groups.

The NMR spectrum of *N*-acetyl-*muco*-inosamine-1 (VI), prepared by the de-*O*-acetylation of V, in D_2O (Fig. 3) reveals one sharp signal at 7.98 τ due to the acetamido group in an equatorial orientation.

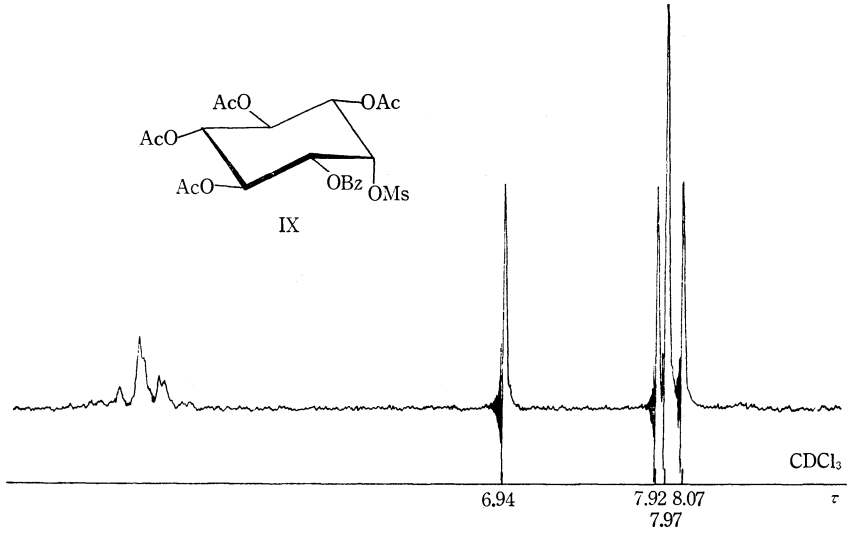


p. p. m., $H \rightarrow$

Fig. 3

When the demesylation of III with sodium azide is carried out in dimethylformamide instead of in 2-methoxyethanol, an as-yet-unidentified hexaacetyl-inosamine (VII) is obtained besides V, and this substance shows a remarkable depression in a mixed melting point determination with hexaacetyl-*rac*-inosamine-2.[8]

In analogy to the monomesylation of tetraacetyl-*myo*-inositol (I→II), a selective monobenzoylation to the 3-*O*-benzoyl derivative should also be possible by treating I with benzoyl chloride under appropriate conditions. When one mole of benzoyl chloride is added to I in pyridine at 5°C, a tetra-*O*-acetyl-3-*O*-benzoyl derivative (VIII) is obtained in a good yield. It can easily be mesylated with methanesulfonyl chloride to 3-*O*-benzoyl-2-*O*-mesyl-*myo*-inositol tetraacetate (IX). This product IX is quite different in its physical properties from the 2-*O*-benzoyl-3-*O*-mesyl-*myo*-inositol tetraacetate (XIX) prepared by the benzoylation of II. Also, their NMR spectra are distinctly different (cf. Figs. 4 and 5 respectively). The spectrum of IX reveals a sharp signal at 6.94 τ corresponding to an axial mesyloxy group, while in the case of XIX the signal of the mesyl protons is shifted to a higher field (6.98 τ), as is to be expected from an equatorial mesyloxy group. Therefore, it is reasonable to conclude that IX is 3-*O*-benzoyl-2-*O*-mesyl-*myo*-inositol tetraacetate. It must be noticed that benzoyl chloride attacks an equatorial hydroxyl group rather than an axial one, as does *p*-toluenesulfonyl chloride[9] or methanesulfonyl chloride[1].



p. p. m., $H \rightarrow$

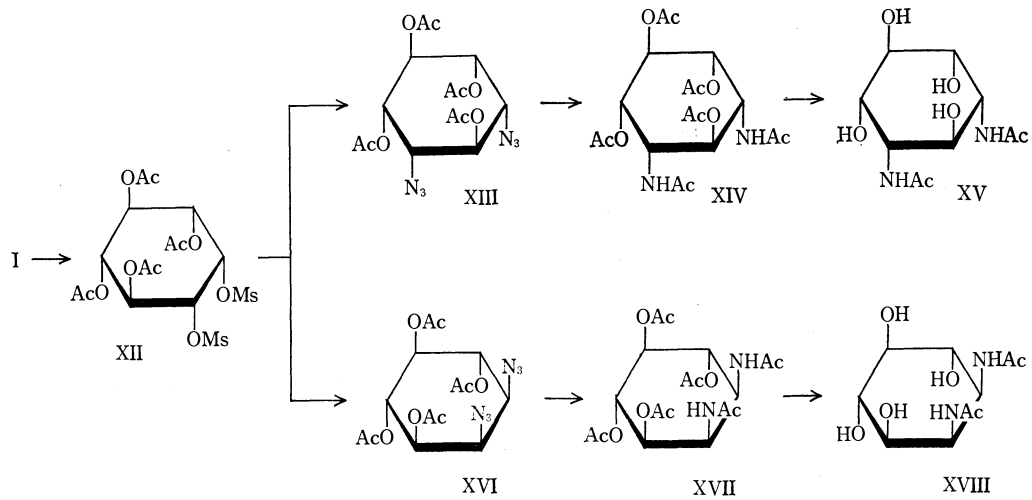
Fig. 5



When IX is treated with sodium azide in boiling aqueous 2-methoxyethanol, an azido compound (X) is obtained; upon hydrogenation and subsequent acetylation, this compound yields hexaacetyl-*scyllo*-inosamine (XI).[10]

In the case of compound IX, the two vicinal acyloxy groups are located in an anchimerically-unassisted cis configuration to the mesyloxy group. Thus a neighboring group participation is improbable, and a direct S_N2 mechanism[11] must be proposed for the demesylation of IX with sodium azide.

myo-1, 2 and *muco*-1, 5-Inosadiamine

Upon the treatment of tetraacetyl-*myo*-inositol (I) with two moles of methanesulfonyl chloride in pyridine, 2,3-di-*O*-mesyl-*myo*-inositol tetraacetate (XII) is obtained in a good yield. Its NMR spectrum (Fig. 6) reveals two sharp signals at 6.80 and 6.89 τ, corresponding to an axial and an equatorial mesyloxy group respectively.

By treating XII with sodium azide in aqueous 2-methoxyethanol, a diazido derivative (XIII) is obtained; this is converted to hexaacetyl-*muco*-inosadiamine-1, 5 (XIV) by hydrogenation and by subsequent acetylation.

The structure of XIV as a *m*-inosadiamine and its *muco*-1, 5-configuration is established on the basis of the following data: 1) The hexaacetate XIV is easily de-*O*-acetylated with methanolic ammonia to its di-*N*-acetate (XV), which, upon periodation, consumes 2.2 mol. of periodate in 43 hr. Thus the two acetamido groups must be located in a 1, 3-position. 2) Since the hexaacetate XIV is insoluble in chloroform, the NMR spectrum was measured in pyridine and in d_6-dimethylsulfoxide (DMSO). In pyridine, signals

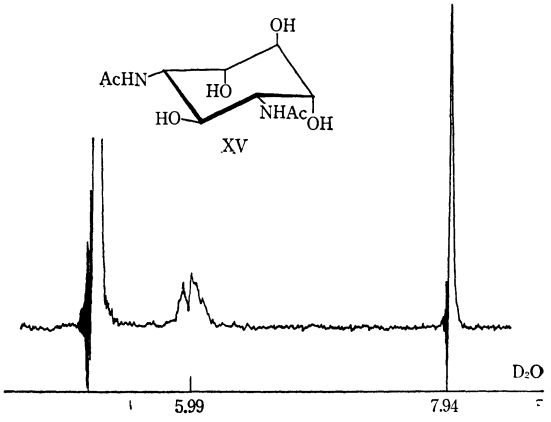
Fig. 7



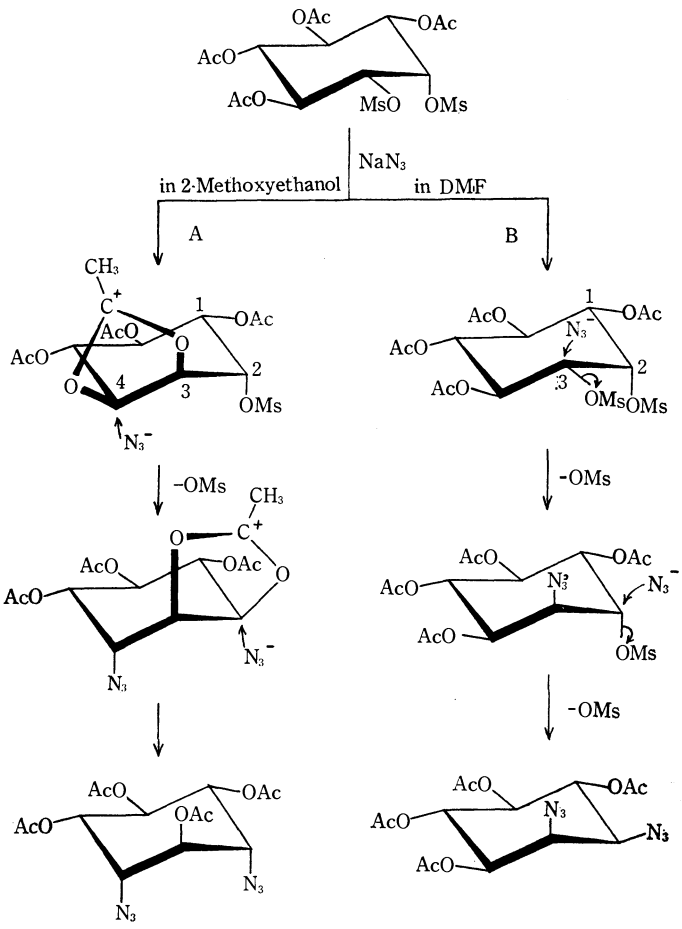
p. p. m., $H \rightarrow$

Fig. 8

were obtained in the 8 τ-region; however, when compared with the signals in similar compounds, these signals showed no apparent correlation with the configuration. In d_6-DMSO however, nicely-resolved signals for the acetyl groups were obtained in the 8 τ-region (Fig. 7): a four signal pattern with a 1 : 2 : 1 : 2-intensity. Since the absorption ranges obtained for axial and equatorial acetoxy or acetamido-groups in chloroform solution[12] cannot be applied for other solvents, a series of compounds have been measured in d_6-DMSO; on the basis of these measurements the following ranges could be established: a) acetoxy-groups, axial 7.86—7.91 τ; equatorial 8.05—8.11 τ; b) equatorial acetamido-groups 8.19—8.30 τ.[13] Subsequently, the NMR-signals of XIV in d_6-DMSO can be convincingly assigned to three axial acetoxy groups, 7.87 τ (1) and 7.90 τ (2), one equatorial acetoxy group (8.08 τ), and two equatorial acetamido groups (8.21 τ), thus establishing the *muco*-1, 5-configuration for XIV.

The di-*N*-acetate (XV) has, in its NMR-spectrum in D_2O (Fig. 8), one sharp signal at 7.94 τ, showing the presence of two sterically-equivalent

12) F. W. Lichtenthaler, *Chem. Ber.*, **96**, 2047 (1963).
13) F. W. Lichtenthaler, H. Leinert and H. P. Albrecht, *Tetrahedron Letters*, in press.



(equatorial) acetamido-groups, thus supporting the *muco*-1, 5-configuration.

The course of the reaction can be explained by assuming the formation of an acetoxonium ion in an anchimeric mechanism with the displacement of the mesyloxy group on C-3. Then an nucleophilic attack by an azide ion can occur in the manner of a trans-diaxial opening of a dioxolane ring.[6] Now again, a mesyloxy group and an acetoxy group are in a trans orientation, resulting in the formation of another acetoxonium ion and subsequent clevage by the azide ion. This reaction sequence is shown in the following chart (course A).

When XII is treated with ammonia under pressure, the same *muco*-inosadiamine-1, 5 is obtained. In this reaction, de-*O*-acetylation takes place at first and an oxirane ring may be formed;[5] this ring is then cleaved by the nucleophilic attack of ammonia in the manner described above.

When XII is reacted with sodium azide in aqueous dimethylformamide instead of 2-methoxyethanol and subsequently treated in a manner analogous to that in which XIV is obtained, hexaacetyl-*myo*-inosadiamine-1, 2 (XVII) is obtained.

The structural and configurational proof was obtained from the following data; the NMR spectrum of XVII in d_6-DMSO (Fig. 9) gives two sharp signals, with an equal intensity, at 8.14 and 8.23 τ; these signals are to be assigned to an axial and an equatorial acetamido group respectively. The four equatorial acetoxy groups give two signals with a 1 : 3-intensity at 8.05 and 8.08 τ. The NMR spectrum of the di-*N*-acetate (XVIII), obtained by the de-*O*-acetylation of XVII with methanolic ammonia is shown in Fig. 10: two sharp signals, with an intensity of 1 : 1, at 7.96 and 8.07 τ, corresponding to an axial and an equatorial acetamido group respectively. Furthermore, it shows a triplet at 5.47 τ (J= 3.5 c. p. s.), as i expected[14] for the C-2-hydrogen in XVIII. Also, XVIII consumes 3.3 mol. of periodate in 43 hr., showing that the two acetamido groups are in a vicinal position, thus establishing unequivocally the *myo*-1, 2-configuration. Considering the structure and configuration of the product obtained, a quite different mechanism must operate in the course of this reaction; the

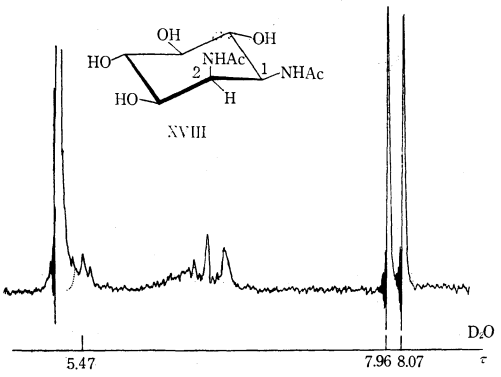
Fig. 9



p. p. m., $H \rightarrow$

Fig. 10

replacement of the mesyloxy groups on C-2 and C-3 must proceed predominantly through a direct S_N2 mechanism and, hence, Walden inversions must occur on C-2 and C-3 (course B).

The different reaction mechanisms caused by a change in solvent in the displacement of a mesyloxy group have been reported in previous communications;[3,15] this is another valid example of a solvent effect on a stereochemical course of the reaction. That is, in 2-methoxyethanol an anchimeric reaction is predominant, while a direct S_N2 reaction is dominant in dimethylformamide.

Experimental

The melting points reported were determined on a Mitamura Riken micro hot stage. The melting points marked with asterisks were measured in a liquid bath and are uncorrected. The infrared spectra were determined by pressed potassium bromide disks. The NMR spectra of the samples were determined at a frequency of 60 Mc. p. s. in deuteriochloroform, deuterium oxide or deuteriodimethylsulfoxide with tetramethylsilane, sodium trimethylsilylpropanesulfonate or tetramethylsilane respectively as an internal standard. The peak positions are given in τ-values.

1, 4, 5, 6-Tetra-*O*-acetyl-3-*O*-mesyl-*myo*-inositol (II).—To a stirred solution of 3.45 g. of 1, 4, 5, 6-tetra-*O*-acetyl-*myo*-inositol (I) in 40 ml. of pyridine, 1.5 g. of methanesulfonyl chloride was added at 5°C. The mixture was kept at room temperature overnight and then poured into ice and water, after which the solution was evaporated under reduced pressure to dryness. The residue was digested with cold water, and the product was collected by filtration. The crude product (3.9 g.) was recrystallized from methanol to give 2.7 g. (72%) of colorless crystals at *210—213°C. Further recrystallization afforded an analytical sample of II, m. p. *210.5—212°C.

Found: C, 41.86; H, 5.31; S, 7.83. Calcd. for $C_{15}H_{22}O_{12}S$: C, 42.25; H, 5.20; S, 7.52%.

3-*O*-Mesyl-*myo*-inositol Pentaacetate (III).—A 200 mg. portion of II was treated with 3 ml. of acetic anhydride in pyridine at 90°C. The mixture was then evaporated under reduced pressure to dryness, and the residue was crystallized from a mixtrue of methanol and petroleum ether to give 220 mg, of white crystals melting at 158—160°C. Recrystallization from ethanol furnished 193 mg. (87.7%) of colorless needles, m. p. 159—161°C.

Found: C, 43.42; H, 5.34; S, 6.58. Calcd. for $C_{17}H_{24}O_{13}S$: C, 43.59; H, 5.17; S, 6.85%.

2-*O*-Mesyl-*myo*-inositol Pentaacetate.—To a stirred mixture of 37 mg. of 1, 3, 4, 5, 6-penta-*O*-acetyl-*myo*-inositol[16] and 0.5 ml. of pyridine, 0.1 g. of methanesulfonyl chloride was added. After it had stood overnight at room temperature, the mixture was poured into 1 ml. of cold water. The solution was then evaporated to dryness, and the residue was crystallized from ethanol to give 15 mg. of colorless needles melting at 190—192°C.

Found: C, 43.45; H, 5.35. Calcd. for $C_{17}H_{24}O_{13}S$: C, 43.59; H, 5.17%.

Hexaacetyl-*muco*-inosamine-1 (V).—a) A mixture of III (0.907 g.), sodium azide (0.255 g.) and 90% aqueous 2-methoxyethanol was refluxed for 16 hr. A brown mixture was evaporated under reduced pressure to dryness. The residue was dissolved in 10 ml. of ethanol, and an insoluble material was removed by filtration. The filtrate was then evaporated to give a brown oil, which showed an infrared absorption characteristic of an azide group at 2100 cm^{-1}. Then the oil was acetylated with acetic anhydride in pyridine to give an oily product (IV).

IV was hydrogenated in 20 ml. of ethanol over Raney nickel T4[17] under 50 p.s.i.g. of initial hydrogen pressure for 6 hr. After the catalyst had been removed,

16) E. L. May, ibid., **17**, 286 (1952).
17) S. Nishimura, This Bulletin, **32**, 61 (1959).

the filtrate was evaporated and the residue was acetylated with acetic anhydride in pyridine to yield 0.273 g. (32.3%) of crystals melting at 204°C after sintering at 190°C. Recrystallizations from methanol gave rhombic crystals of V melting at 205—205.5°C.

Found: C, 50.08; H, 5.97; N, 3.30. Calcd. for $C_{18}H_{25}NO_{11}$: C, 50.11; H, 5.84; N, 3.23%.

b) A mixture of II (1.02 g.), sodium azide (0.32 g.) and 90% aqueous 2-methoxyethanol was heated under reflux for 15 hr. The reaction mixture was then treated in the manner described above, giving 0.409 g. (39.2%) of crystals melting at 204—205°C after sintering at 197°C. Recrystallization from ethanol afforded crystals melting at 205—205.5°C.

c) A mixture of II (1.00 g.), sodium azide (1.00 g.) and 90% aqueous dimethylformamide was heated under reflux for 40 hr. The mixture was treated in the manner described above to give 0.26 g. (25%) of crude hexaacetyl-inosamine, m. p. 170—190°C. Fractional recrystallizations from a mixture of ethanol and ether gave 0.10 g. (9.6%) of V, m. p. 197—199°C. and 0.03 g. of an unidentified product (VII), m. p. *175—178°C.

When VII was mixed with an authentic sample of hexaacetyl-*rac*-inosamine-2, a remarkable depression of the melting point was observed.

IR: 3260, 1685, 1655, 1550 (amide), 1750 cm^{-1} (OAc).

Found: C, 49.95; H, 6.59; N, 3.43%.

After hydrolysis with 6 N hydrochloric acid, VII gave a single spot of R_f 0.26 in ascending paper chromatography in an ethyl acetate - pyridine - acetic acid - water (5 : 5 : 1 : 3) system[18] at 20°C (R_f of D-glucosamine hydrochloride: 0.35).

d) A mixture of III (7.08 g.) and 350ml. of methanol. saturated with ammonia was heated at 110°C for 24 hr. in an autoclave. After it had then been cooled, the mixture was evaporated in vacuo and the residue was acetylated with acetic anhydride (10 ml.) and sodium acetate (0.5 g.) at 100°C for 2 hr. to give a crude product. The product was recrystallized from ethanol to yield colorless crystals of V (2.52 g., 40.5%), m. p. 204.5—205°C. From the mother liquor, an unidentified product (0.22 g.), m. p. 192—218°C, was obtained.

N-Acetyl-*muco*-inosamine-1 (VI).—A 297 mg. portion of V was added to 25 ml. of methanol saturated with ammonia. The mixture was kept at room temperature overnight and evaporated under reduced pressure; a colorless oil was thus obtained. The product was washed with 5 ml. of ethyl acetate and crystallized from 90% ethanol to yield 118 mg. (77.7%) of colorless plate melting at 222—224°C. The second crop, m. p. 221.5—224°C (14 mg., 86.5%), was recovered from the mother liquor. Recrystallization from ethanol gave fine plates melting at 223—225°C.

Found: C, 43.55; H, 6.96; N, 6.37. Calcd. for $C_8H_{15}O_6N$: C, 43.43; H, 6.84; N, 6.33%.

1, 4, 5, 6-Tetra-*O*-acetyl-3-*O*-benzoyl-*myo*-inositol (VIII).—To a solution of 9.4 g. of I in 60 ml. of pyridine there was added, portion by portion, 3.5 ml. of benzoyl chloride at 5°C. The mixture was kept at room temperature for 20 hr. and then poured into 100 ml. of ice and water. The solution was extracted four times with chloroform (50 ml.), and the extracts were washed with water. After it had been dried over anhydrous sodium sulfate, the chloroform was evaporated in vacuo to give a crystalline residue. The crystals were washed with ethanol. The crude product (8.9 g., 73%) melted at *201.5—203°C. A second crop (1.3 g., 84%) was obtained from the washings. Recrystallization from ethanol afforded fine needles which melted at *202—203°C.

Found: C, 55.81; H, 5.26; Calcd. for $C_{21}H_{24}O_{11}$: C, 55.76; H, 5.35%.

1, 4, 5, 6-Tetra-*O*-acetyl-2-*O*-mesyl-3-*O*-benzoyl-*myo*-inositol (IX).—To a solution of 8.0 g. of VIII in 80 ml. of pyridine, 3.5 g. of methanesulfonyl chloride was added. The mixture was kept at room temperature for 2 days, and then poured into 300 ml. of ice and water. The precipitate was collected and washed with ethanol. The crude product weighed 8.0 g. (85%). Recrystallization from 2-methoxyethanol gave colorless rhombics (6.34 g., 67%) which melted at 240.5—242°C.

Found: C, 50.08; H, 5.07; S, 5.78. Calcd. for $C_{22}H_{26}O_{13}S$: C, 49.80; H, 4.94; S, 6.04%.

1-Azido-1-deoxy-*scyllo*-inositol Pentaacetate (X).—A mixture of 5.0 g. of IX, 2.0 g. of sodium azide and 170 ml. of 90% aqueous 2-methoxyethanol was refluxed for 20 hr. The brown mixture was evaporated under reduced pressure, and the residue was acetylated by heating it with acetic anhydride and pyridine at 100°C for 1 hr. After the solution had cooled, the insoluble material was removed and the filtrate was evaporated under reduced pressure to give a partly-crystallized residue. The residue was triturated with ethanol and filtered to yield 3.02 g. (77%) of crystals melting at *200—203°C. Recrystallization from ethanol gave colorless needles (2.04 g.) melting at *205—205.5°C.

Found: C, 46.57; H, 5.05; N, 9.78. Calcd. for $C_{16}H_{21}N_3O_{10}$: C, 46.26; H, 5.10; N, 10.12%.

Hexaacetyl-*scyllo*-inosamine (XI).—X (0.547 g.) was dissolved in glacial acetic acid (30 ml.) and hydrogenated at room temperature in a Parr shaker type apparatus at an initial pressure of 50 p.s.i.g. of hydrogen over Adams platinum oxide (33 mg.) for 13 hr. The catalyst was then removed, and the filtrate was evaporated in vacuo. The residual oil was treated with 10 ml. of pyridine - acetic anhydride (1 : 1) to give crude hexaacetyl-*scyllo*-inosamine (0.518 g., 91.3%) melting at *269—272°C with decomposition after sintering at 230°C. Recrystallization from 2-methoxyethanol gave colorless needles (0.397 g.) melting at *271—272°C with decomposition after coloring at 240°C. (Lit.[8,10] m. p. 275—276 and 288°C)

Found: C, 50.56; H, 5.79; N, 3.22. Calcd. for $C_{18}H_{22}NO_{11}$: C, 50.11; H, 5.84; N, 3.23%.

The NMR spectrum was superimposable upon that of an authentic sample.

N-Acetyl-*scyllo*-inosamine, m. p. *285—286°C (decomp), was prepared by an ordinary method of selective deacetylation [Lit.[10] m. p. 289—301°C (decomp.)].

1, 4, 5, 6-Tetra-*O*-acetyl-2, 3-di-*O*-benzoyl-*myo*-inositol.—A mixture of I (1 g.), benzoyl chloride (1 ml.) and pyridine (5 ml.) was heated on a boiling-water bath for 30 min. After it had been cooled, the mixture was diluted with cold water and the precipitate was collected and washed with water. The crude

18) F. G. Fischer and H. Dorfel, *Hoppe-Seyler's Z. physiol. Chem.*, **301**, 224 (1955).

product weighed 1.46 g. (91%) and melted at 157—163°C. The analytical sample was obtained by recrystallizations from methanol; it melted at 180.5—182°C.

Found: C, 60.31; H, 4.89. Calcd. for $C_{28}H_{28}O_{12}$: C, 60.43; H, 5.07%.

1, 4, 5, 6-Tetra-*O*-acetyl-2-*O*-benzoyl-3-*O*-mesyl-*myo*-inositol.—A mixture of II (0.408 g.), benzoyl chloride (0.5 ml.) and pyridine (5 ml.) was treated similarly to give 0.285 g. (56%) of crystals melting at 150—153°C. The analytical sample was obtained by recrystallization from ethanol m. p. *152—154.5°C, 154—155.5°C.

Found: C, 49.66; H, 5.00; S, 6.17. Calcd. for $C_{22}H_{26}O_{13}S$: C, 49.80; H, 4.94; S, 6.04%.

2, 3-Di-*O*-mesyl-*myo*-inositol Tetraacetate (XII).—To a solution of 1.0 g. of I in 10 ml. of pyridine, 1.3 g. of methanesulfonyl chloride was added under ice cooling. The mixture was treated in the manner described for II to give 1.25 g. (87.5%) of the product, m. p. *205.5—209°C. Recrystallizations from ethanol afforded 1.12 g. (78.5%) of needles, m. p. *211—213°C.

Found: C, 38.34; H, 4.98; S, 12.48. Calcd. for $C_{16}H_{24}O_{14}S_2$: C, 38.10; H, 4.80; S, 12.72%.

A mixed melting point determination with II showed a remarkable depression.

Hexaacetyl-*muco*-inosadiamine-1, 5 (XIV). — a) A mixture of XII (2.06 g.), sodium azide (1.05 g.) and 95% aqeous 2-methoxyethanol (75 ml.) was refluxed for 19 hr. The mixture was then treated in the manner described for V a) to give 193 mg. of the crude product, m. p. *282—283°C (decomp.). Recrystallizations from ethanol afforded 134 mg. (7.6%) of the crystals, m. p. *305—306°C.

Found: C, 50.14; H, 6.22; N, 6.50. Calcd. for $C_{18}H_{26}N_2O_{10}$: C, 50.23; H, 6.09; N, 6.51%.

No other crystalline isomer could be obtained from the mother liquor.

b) A mixture of XII (3.0 g.) and methanol (180 ml.) which had previously been saturated with ammonia was heated in an autoclave at 110°C for 20 hr. Then the reaction mixture was treated in the manner described for V c) to give 646 mg. (25.0%) of the crude XIV, m. p. *292.5—294.5°C (decomp.). Recrystallizations from ethanol gave 438 mg. (16.9%) of colorless needles, which melted at *306.5—307°C.

Di-*N*-acetyl-*muco*-inosadiamine-1, 5 (XV).—XIV (100 mg.) was selectively deacetylated by the ordinary method described for VI to give 66 mg. of the crude product of XV, m. p. 235—237°C. Recrystallization from aqueous alcohol gave 43 mg. (71%) of colorless plates, m. p. 238.5—239°C.

Found: C, 45.25; H, 7.09; N, 10.38. Calcd. for $C_{10}H_{18}N_2O_6$: C, 45.79; H, 6.92; N, 10.68%.

Periodate Oxidation.—A 21.9 mg. portion of XV was treated with 25 ml. of a 0.0301 M sodium metaperiodate solution at 15°C. Iodometric titrations with sodium arsenite[19] showed that 2.18 mol. of periodate was consumed per mole of XV in 43 hr.

***muco*-Inosadiamine-1, 5 Dihydrochloride.**—XIV (300 mg.) was heated in 6 N hydrochloric acid on a boiling water bath for 1.5 hr. The solution was then evaporated under reduced pressure to give a crystalline residue. The residue was recrystallized from a mixture of methanol and ethanol to give 175 mg. (60.6%) of crystals melting at *300°C (decomp.) after coloring at 260°C.

Found: C, 29.24; H, 6.28; N, 10.74; Cl, 27.83. Calcd. for $C_6H_{14}N_2O_4 \cdot 2HCl$: C, 28.70; H, 6.42; N, 11.15; Cl, 28.24%.

Hexaacetyl-*myo*-inosadiamine-1, 2 (XVII). — A mixture of XII (5.0 g.), sodium azide (3.0 g.) and 80% aqueous dimethylformamide (120 ml.) was refluxed for 18 hr. The reaction mixture was then evaporated under reduced pressure and extracted with ethanol (30 ml. × 3). The extracts were evaporated in vacuo to dryness, pyridine - acetic anhydride (1 : 1) (50 ml.) was added, and the mitture was kept at room temperature overnight. The insoluble material was removed, and the solution was evaporated under reduced pressure to give an oil. This oil was dissolved in ethanol (20 ml.) and kept in a refrigerator overnight. The precipitate (the starting material) was filtered off and treated again with toluene (20 ml.) in a similar manner. The filtrate was evaporated, and the residual oil was dissolved in ethanol (20 ml.) containing Adams platinum oxide (100 mg.). The mixture was hydrogenated at room temperature in a Parr shaker-type apparatus at an initial pressure of 50 p.s.i.g. of hydrogen for 20 hr. The catalyst was filtered off, and the filtrate was evaporated. The residual oil was treated again with pyridine-acetic anhydride (1 : 1) (10 ml.) and crystallized from ethanol/ether to give the crude product (152 mg.), which melted at *270—274°C with decomposition after sintering at 260°C. The second crop was obtained from the mother liquor, 123 mg., melting at *250—262°C with decomposition after sintering at 245°C. The total yield was 6.4%. The crude product was recrystallized from ethanol with carbon to give colorless needles (151 mg.) which melted at *275—277°C with decomposition after sintering at 267°C.

Found: C, 50.14; H, 6.18; N 6.67. Calcd. for $C_{18}H_{26}N_2O_{10}$: C. 50.23; H, 60.9; N, 6.51%.

Di-*N*-acetyl-*myo*-inosadiamine-1, 2 (XVIII). — XVII (150 mg.) was treated in the manner described for XV to give 85.9 mg. (94.1%) of crystals, m. p. 262—264°C The analytical sample was obtained, by recrystallization from a mixture of ethanol, ether and water, as plates melting at 270—271°C.

Found: C, 45 62; H, 6.85; N, 10.47. Calcd. for $C_{10}H_{18}N_2O_6$: C, 45.79; H, 6.92; N, 10.68%.

Periodate Oxidation. — A 25.1 mg. portion of XVIII was dissolved in 50 ml. of a 0.0301 M sodium metaperiodate solution at 15°C. Iodometric titrations with sodium arsenite[17] showed that 3.30 mol. of periodate was consumed per mole of XVIII in 43 hr.

The authors are grateful to Professor Sumio Umezawa for his helpful advice and to Mr. Saburo Nakada for his elementary analyses. The authors are also indebted to Mr. Hiroyasu Suzuki for his assistance in the measurements, and to the Japan Electron Optics Co., Ltd., for the NMR spectra. This research has been financially supported in part by a grant of the Ministry of Education and by the Deutsche Forschungsgemeinschaft, to which the authors' thanks are due.

The Interaction between a Polysoap and a Monosoap

By Fumikatsu TOKIWA

Kao-Atlas Laboratory, Kao Soap Co., Ltd., Minato-Yakushubata, Wakayama

(Received June 10, 1965)

The way in which a cationic polysoap, prepared by quaternizing the nitrogen of poly-2-vinylpyridine with *n*-dodecyl bromide, interacts with additives, such as a cationic monosoap (*n*-dodecyl-α-picolinium bromide), a non-ionic surfactant (polyoxyethylene dodecyl ether) and potassium bromide, has been studied in aqueous solutions in terms of the viscosity and solubilizing power for oil-soluble dyes of the mixed solutions of the polysoap and the additives. An experiment on the effects of these additives on the behavior of a polyelectrolyte (poly-2-vinyl-*N*-ethylpyridinium bromide), prepared from the same parent polymer as the polysoap, has also been included for the purpose of comparison. The hydrophobic hydrocarbon chains in the polysoap and additive molecules play an important role in the interaction of the polysoap with the additives. Co-micellization or mixed micellization occurs between the polysoap and the monosoap or the non-ionic surfactant in aqueous solutions.

In previous papers[1,2] the solubilization behavior of cationic polysoap and monosoap was compared in terms of the spectra of some oil-soluble dyes solubilized by both soaps,[1] as well as in terms of the solubilizing power, the viscosity and the electrical conductivity of the soap solutions.[2] In general, a polysoap molecule has been regarded as a model of a micelle of ordinary soaps in the sense that the molecule acts as a prefabricated soap micelle.[3] However, this is not necessarily true. It has, for instance, been pointed out by the present author that the polysoap, *n*-dodecyl bromide addition compound of poly-2-vinylpyridine, differs considerably in its behavior, such as in the solubilization of oil-soluble dyes, from the monosoap, *n*-dodecyl-α-picolinium bromide, which is considered to be very similar in its chemical structure to the polymeric unit of the polysoap.[1,2] It will also be of interest to study the properties of mixed solutions of the polysoap, which is a long flexible chain of a macroion with a great number of hydrocarbon side chains, with the monosoap.

With respect to the properties of aqueous solutions of the mixtures of a cationic polysoap and a monosoap, Narasaki and Ito[4,5] have reported that whether the addition of the monosoap to the polysoap solutions leads to a synergistic or to an antigistic effect on some physicochemical property varies from case to case.

The present paper is a study of mixed solutions of a polysoap and a monosoap in terms of viscosity and solubilization; this study leads to an understanding of the way in which the polysoap and the monosoap interact in aqueous solutions. The effects of a simple electrolyte and a non-ionic surfactant upon the behavior of the polysoap are also included. An experiment in which the polysoap was replaced by the polyelectrolyte prepared from the same parent polymer as the polysoap is also included for purposes of comparison.

Experimental

Materials.—The polysoap, *n*-dodecyl bromide addition compound of poly-2-vinylpyridine, was prepared and purified by a method previously described.[1] The molecular weight of the parent polymer, poly-2-vinylpyridine, was 1.16×10^5, as estimated from its intrinsic viscosity in 92% ethanol by weight[6]; this value corresponds to a degree of polymerization of 1.10×10^3. The analysis of the polysoap revealed that 32.5% of the nitrogen was quaternized with *n*-dodecyl bromide, while 9.6% carried hydrogen bromide.

The monosoap, *n*-dodecyl-α-picolinium bromide, was prepared by the quaternization of α-picoline with *n*-dodecyl bromide according to the ordinary method. The soap was then purified by repeated recrystallizations from acetone.

The polyelectrolyte, poly-2-vinyl-*N*-ethylpyridinium bromide, was prepared from ethyl bromide and the poly-2-vinylpyridine described above. The method of Strauss et al.[7] was employed from preparing poly-4-vinyl-*N*-ethylpyridinium bromide. Analysis gave nitrogen 7.57% bromine 32.3%.

The non-ionic surfactant, polyoxyethylene dodecyl ether (abbreviated hereafter as PODE), was the same sample as that used in a previous investigation[8]. The

average degrees of the polymerization of polyoxyethylene chain, p, of the two samples used were 7.6 and 15.8, the number written after PODE representing the value of p.

The potassium bromide was a special-grade product obtained from the Wako Pure Chemicals Co. Solubilizates, the 1-benzeneazo-2-naphthol and 1-*p*-nitrobenzeneazo-2-naphthol (abbreviated hereafter as BAN and *p*-nitro-BAN respectively) were the same samples as those described in a previous paper.[1] The details of these samples were reported in that paper

Procedure.—The solubilizations were run in a water bath at 30±0.1°C for 40 hr. in order to attain equilibrium, the method described in a previous paper[8] being employed. The amount of solubilized dyes was determined by optical density measurements using a spectrophotometer, Shimadzu Model B60.

The viscosities were measured in a water bath at 30±0.01°C with Ostwald-type viscometers, the flow times for pure water at 30°C being 102.8 and 128.3 sec.

Results

The viscometric behavior of the polysoap in pure water and in aqueous solutions of additives, i. e., monosoap, potassium bromide and PODE, is shown in Figs. 1 and 2, where the reduced viscosity, η_{sp}/c of the polysoap is plotted against the concentration, c. In this paper the aqueous solution with the same concentration of one of the above additives was taken to be the solvent for the polysoap.

Figure 1 shows the η_{sp}/c - c curves of the polysoap at a constant concentration of the additives. The

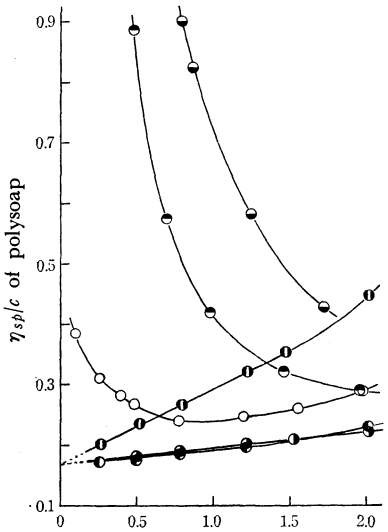

Fig. 1. The reduced viscosity vs. concentration of polysoap curves at a constant concentration of 0.77×10^{-2} M monosoap (◐), 2.26×10^{-2} M monosoap (◑), 2.05×10^{-2} M PODE-7.6 (◓), 2.11×10^{-2} M PODE-15.8 (◒) or 2.03×10^{-2} M KBr (◐); polysoap alone (○) at 30°C.

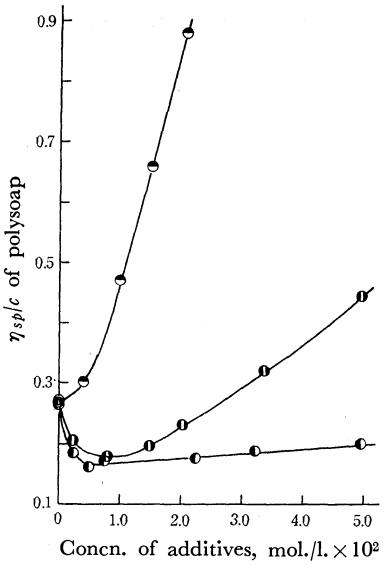

Fig. 2. The effect of additive concentrations on the reduced viscosity of polysoap of a constant concentration at 30°C: ◐, monosoap (polysoap concn. 0.407 g./100 ml.); ◓, PODE-7.6 (polysoap concn. 0.498 g./100 ml.); ◐, KBr (polysoap concn. 0.497 g./100 ml.).

η_{sp}/c of the polysoap in the monosoap solution is lower than that in water, and the η_{sp}/c - c curve runs linearly with c, giving an intrinsic viscosity, $[\eta]$, of 0.17. The curve in the potassium bromide solution is also linear and $[\eta]=0.17$. On the other hand, the η_{sp}/c in the PODE solution becomes abnormally higher as the concentration of the polysoap decreases. Figure 2 illustrates the effect of the concentration of the additives on the η_{sp}/c of the polysoap. Each additive influences the polysoap viscosity in a different way. The viscosity in the PODE solution increases abruptly with the increase in the PODE concentration. The viscosity rise of the polysoap in the PODE solution became more striking with the increase in the polyoxyethylene chain-length of PODE.

The results of the solubilzation of BAN by the mixed solutions of the polysoap with the monosoap, potassium bromide or PODE are shown in Figs. 3 and 4. Figure 3 shows the amounts of BAN solubilized by that mixed solution in which the concentration of the polysoap is varied while that of the additive remains constant. Since the monosoap and PODE have a solubilizing power above their critical micelle concentration (CMC), the amount of BAN solubilized by the mixed solutions is greater than that solubilized by the polysoap solution alone. However, the effect of the monosoap on the solubilization differs from that of PODE. Figure 4 illustrates the effect of the additive concentrations on the solubilizing power of that mixed solution in which the concentration

of the polysoap remains constant while that of the additive is varied. For comparison, the solubilizing power of the solution of the monosoap or PODE without the polysoap is also given in Fig. 4. The presence of potassium bromide slightly lowers the solubilizing power of the polysoap.

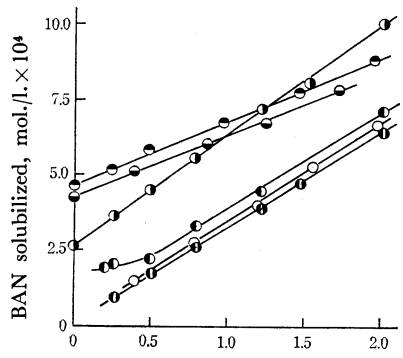

Fig. 3. The solubilization of BAN vs. concentration of polysoap curves at a constant concentration of 0.77×10^{-2} M monosoap (◐), 2.26×10^{-2} M monosoap (◑), 2.05×10^{-2} M PODE-7.6 (◓), 2.11×10^{-2} M PODE-15.8 (◒) or 2.03×10^{-2} M KBr (◐); polysoap alone (○) at 30°C.

The results of the solubilization of *p*-nitro-BAN by the same solutions are shown in Fig. 5. *p*-Nitro-BAN showed a more characteristic solubilization behavior than the two other nitro substituents studied in a previous experiment.[2] The amount of *p*-nitro-BAN solubilized by the mixed solution of the polysoap with the monosoap or PODE is considerably smaller than that solubilized by the polyaoap solution alone, in spite of the presence of the monosoap or PODE with solubilizing power.

For comparison, the viscosities of the polyelectrolyte with no dodecyl side chain, in the absence of and in the presence of the additives, are shown in Fig. 6. The η_{sp}/c - c curve of the polyelectrolyte

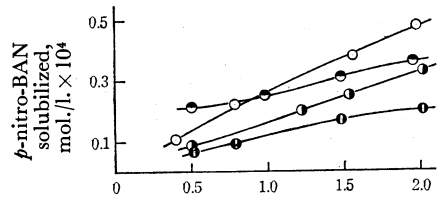

Fig. 5. The solubilization of *p*-nitro-BAN vs. concentration of polysoap curves at a constant concentration of 2.26×10^{-2} M monosoap (◑), 2.05×10^{-2} M PODE-7.6 (◓) or 2.03×10^{-2} M KBr (◐); polysoap alone (○) at 30°C.

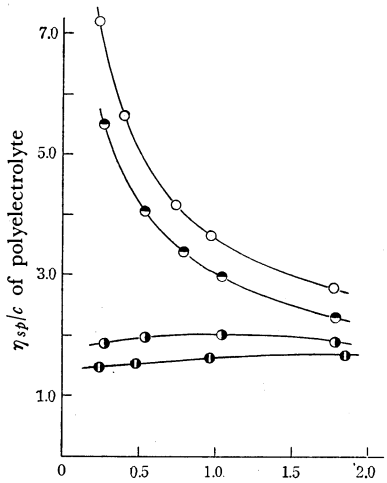

Fig. 6. The reduced viscosity vs. concentration of polyelectrolyte curves at a contant concentration of 2.03×10^{-2} M monosoap (◑), 2.06×10^{-2} M PODE-7.6 (◓) or 2.00×10^{-2} M KBr (◐); polyelectrolyte alone (○) at 30°C.

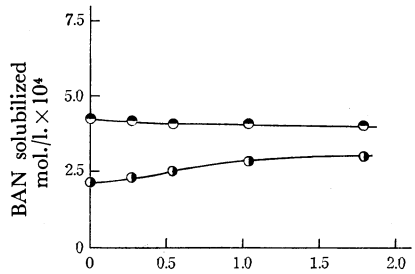

Fig. 7. The effect of poly electrolyte concentration on the solubilization of BAN by 2.03×10^{-2} M monosoap (◑) or 2.06×10^{-2} M PODE-7.6 (◓) at 30°C; the polyelectrolyte alone has no solubilizing power.

in water shows a familiar pattern. In the monosoap or potassium bromide solution, the reduced viscosity depression at the lower concentrations is remarkable. However, the polyelectrolyte molecule in a PODE solution behaves similarly to that in water.

Figure 7 shows the effect of polyelectrolyte concentrations on the solubilizing power of the monosoap and PODE for BAN. The polyelectrolyte makes the solubilizing power of the monosoap slightly higher, while it leaves that of PODE almost unchanged.

Discussion

Interaction between the Polysoap and the Monosoap.—The effect of potassium bromide on the viscosity of the polysoap has already been investigated by Strauss et al.[9] While at first the reduced viscosity of the polysoap decreases with an increase in the potassium bromide concentration, in time it reaches a minimum and then rises sharply, as may be seen in Fig. 2. They ascribed the initial viscosity decrease to the contraction of the polysoap molecule, and the viscosity rise with the added potassium bromide to interaction between the molecules. It the monosoap, which is a kind of electrolyte although it has a long hydrocarbon chain, would act on the polysoap only like potassium bromide, it might be expected to show a viscosity behavior similar to that in a potassium bromide solution. However, the results obtained in the monosoap solution are different from those obtained in the potassium bromide solution, as is shown in Figs. 1 and 2. This difference in viscosity behavior can be considered to arise from the long hydrocarbon chain in the monosoap molecule.

It is known that such polar materials with long hydrocarbon chain as higher alcohols are solubilized, with their polar groups located in the polar region near the polymer backbone and with their hydrocarbon chains penetrating into the hydrocarbon region of the polysoap molecule, in a way similar to their penetration into micelle. The solubilized hydrocarbon which supplies additional van der Waals' force to the hydrocarbon atomsphere inside the polysoap molecule causes the molecule to contract further.[3,7]

If the hydrocarbon chains of the monosoap cations penetrate into the interior of the polysoap molecule in the similar manner described above, this penetration will cause a contraction of the polysoap molecule. At the same time the surface of the polysoap molecule will be covered for the most part with hydrophilic ionized groups of the monosoap cations. An increase in the electrical charge on the surface leads to an enhancement of the electrostatic repulsion between different polysoap molecules, which will simultanously diminish the interaction between them. Although this will cause a swelling of the polysoap molecule, the van der Waals' attraction between hydrocarbon chains compensates for the ionic repulsion, so the resulting polysoap molecule is more compact than the initial molecule. This interaction between the polysoap and the monosoap may be regarded as a type of "co-micellization" or" mixed micellization." If the above argument is reasonable, the interaction may not be involved in the micelle formation of the monosoap. In fact, an insignificant change in viscosity could be found below and above the CMC of the monosoap (1.02×10^{-2} mol./l.), as may be seen in Fig. 1. After the penetration of the monosoap reaches the saturation point, the free monosoaps, which do not contribute directly to the co-micellization with the polysoap, will act on the polysoap in a way similar to potassium bromide.

On the other hand, in the case of the polyelectrolyte, there is no significant difference between the monosoap and potassium bromide in their effects on the reduced viscosity, as Fig. 6 shows. The hydrocarbon chain of the monosoap cation, which plays an important role in the interaction with the polysoap, can not act effectively with regard to the interaction with the polyelectrolyte having no long hydrocarbon side chains. In this case the monosoap cation seems to act on the polyelectrolyte as an electrolyte. This indicates the importance of the hydrocarbon chains of the polysoap, and supports the mechanism described above. However, the action of the monosoap cations on the polyelectrolyte is not completely negligible. The monosoap cations seem to interact slightly with the polyelectrolyte between the hydrocarbon chain of the cation and the hydrophobic portion in the backbone of the polyelectrolyte. The slight increase in the solubilizing power of the monosoap in a polyelectrolyte solution to be seen in Fig. 7 may be attributed to this interaction.

It is instructive to consider the intrinsic viscosity of the polysoap in the monosoap solution in the light of the general principle developed by Flory et al.[10] The Θ-solvent intrinsic viscosity, $[\eta]_\theta$, of poly-4-vinylpyridine[7] is:

$$[\eta]_\theta = 8.1 \times 10^{-4} M^{1/2}$$

Assuming that the $[\eta]_\theta$ of poly-2-vinylpyridine is equal to that of poly-4-vinylpyridine, the $[\eta]_\theta$ of the parent polymer used in this experiment, whose molecular wieght is 1.16×10^5, equals 0.276. From this value, according to Strauss' assumption,[7] one can calculate the expected value for the $[\eta]_\theta$ of the quaternization product, i. e., the polysoap, by the relation:

9) U. P. Strauss, N. L. Gershfeld and E. H. Crook, *J. Phys. Chem.*, **60**, 577 (1956).

10) P. J. Flory, "Principles of Polymer Chemistry," Cornell University Press, Ithaca, N. Y. (1953), Chap. 12—14.

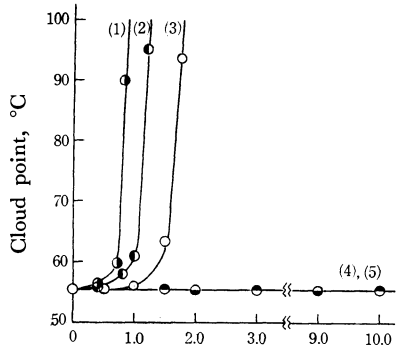

Fig. 8. The effect of polysoap and polyelectrolyte on the cloud point of PODE-7.6 solution of 10 ml.; PODE concn. (1) 0.82, (2) 1.13, (3) 1.63, (4) 0.80, (5) 1.60 g./100 ml. (1), (2) and (3) refer to the polysoap, and (4) and (5) refer to the polyelectrolyte.

$$[\eta]_{\theta,Q} = [\eta]_{\theta,P} (M_P/M_Q)$$

where the subscripts P and Q refer to the parent polymer and the quaternization product respectively. The resulting estimate of $[\eta]_{\theta,Q}$ is 0.15, slightly lower than the observed intrinsic viscosity of 0.17 shown in Fig. 1. It has been reported[9] that polysoaps can dissolve in aqueous media without phase separation, even when the intrinsic viscosity, $[\eta]$, is lower than the value of $[\eta]_\theta$. Further, the Einstein figure for a compact sphere is 0.025. Thus there is considerable room left inside the polysoap molecule for the solubilization for oil-soluble materials, even when the polysoap molecule is contracted by the penetration of monosoap cations.

The oil-soluble dye, BAN, would be mainly solubilized in an interior of a micelle, i. e., a dense hydrocarbon region of a micelle.[2] Therefore, it may be expected that an increase in the hydrocarbon region in the interior of the polysoap molecule, as a result of its co-micellization with monosoap molecules, will enhance the solubilizing power of the polysoap similarly to the effect of alcohols with a long hydrocarbon chain on the solubilizing power of ordinary soaps.[11] As may be seen in Figs. 3 and 4, the amount of BAN solubilized by the mixed solution of the polysoap and the monosoap is greater than the total amount solubilized by the respective solution of the corresponding concentration. This is an indication of the synergistic effect of the mixed micelle of the polysoap and the monosoap. It is noteworthy that an increase in solubilizing power is appreciable in the mixed solution in which the concentration of the monosoap is lower than the CMC. On the other hand, the addition of potassium bromide slightly lowers the solubilizing power of the polysoap, because potassium bromide acts as only a simple electrolyte.

The results of the solubilization of *p*-nitro-BAN are very interesting in contrast with that of BAN. The amount of *p*-nitro-BAN solubilized by the mixed solution of the polysoap and the monosoap is considerably smaller than that solubilized by the polysoap solution alone. Essentially, *p*-nitro-BAN is not so solubilized by soaps as is BAN.[2] The present author has previously pointed out that the loci of the solubilization of oil-soluble dyes in the polysoap molecule are not only in the dense hydrocarbon region in the interior but also in the polar region near the polymer backbone. In the case of the solubilization of *p*-nitro-BAN especially, the polar region of the polysoap molecule acts as a strong solubilizing locus.[1,2] With this picture in mind, the electrical charge on the surface of the polysoap molecule appears to be more correlated with the solubilization of *p*-nitro-BAN than the interior of the polysoap molecule. The addition of the monosoap or potassium bromide may change the electrical charge on the surface and at the same time change the atomosphere of the polar region. These changes, which may be disadvantageous for the solubilization of *p*-nitro-BAN, will lead to a lowering of the solubilizing power of the polysoap.

The Effect of a Non-ionic surfactant on the Behavior of the Polysoap.—Since PODE has no ionized group in its molecule, at first it may be expected to be able to show only the hydrocarbon effect on the polysoap. However, unexpected results for the viscosity were obtained. That is, the polysoap exhibited an extraordinary viscosity rise in the presence of PODE. In Figs. 1 and 2 we can see that the viscosity rise of the polysoap becomes higher with an increase in the ratio of PODE to the polysoap. A similar result was obtained by Narasaki when non-ionic surfactants, such as polyoxyethylene compounds, were added to the aqueous solution of the cationic polysoap prepared by quaternizing the nitrogen of poly-α-vinyl-β-ethylpyridine with *n*-dodecyl bromide and ethyl bromide.[5] The steep rise in the viscosity curves may be an indication of either an anomalous extension of the polysoap molecules or of an anomalous interaction between different polysoap molecules. The effect of the length of the polyoxyethylene tail on the viscosity of the polysoap —the longer the tail, the higher the viscosity— suggests that the polyoxyehtylene tail is responsible for the viscosity rise. Furthermore, the fact that the viscosity of the polyelectrolyte with no long hydrocarbon chain is almost not affected at all by PODE, as may be seen in Fig. 6, suggests the importance of the interaction by van der Waals'

11) M. E. L. McBain and E. Hutchinson, "Solubilization and Related Phenomena," Academic Press, New York (1955), pp. 45, 147.

force between the hydrocarbon chain of the polysoap and that of PODE. The two following mechanisms seem possible ways by which the polysoap interacts with PODE:

1) The PODE molecules penetrate into the hydrocarbon-water interface of the polysoap molecule in such a way that the polyoxyethylene tails are in the water, while the hydrocarbon chains are anchored in the hydrocharbon region of the polysoap molecule. The polyoxyethylene tails thus exposed on the surface of the polysoap molecule will interact with similarly-exposed polyoxyethylene tails belonging to other polysoap molecules, with the result that the viscosity of the poysoap will tend to increase. This interaction between polyoxyethylene tails may occur through the hydrogen bonding between the tails, probably by the medium of the water.

2) It is well-known that ordinary soap micelles swell as a result of hydrocarbon solubilization,[11] and that sometimes polysoap molecules also swell under certain conditions of solubilization.[9] The swelling of the polysoap molecules may be another type of mechanism to explain the reduced viscosity increase. When the PODE molecules penetrate into the polysoap molecule, the bulky polyoxyethylene tails may reduce the van der Waals' force between different parts of the same polysoap molecule as a result of a steric effect. As a result, the polysoap molecules will swell and extend beyond their original size, resulting in the viscosity rise.

Of course, it is difficult, on the basis of only the present experiment, to say which type of the mechanism is the more probable. The clear resolution of this problem will have to await further study. At any rate, however, the importance of polyoxyethylene tails in this interaction may easily be understood from the effect of the tail length.

In contrast to the synergistic effect of the solubilization exhibited by the polysoap and the monosoap, the amount of BAN solubilized by the mixed solution consisting of the polysoap and PODE is smaller than the total amount solubilized by the respective solution of the corresponding concentration. Namely, the PODE exerts an antigistic effect with regard to the solubilization of BAN. A similar effect has been observed when ethyl alcohol is added to some soaps.[11] Whether the presence of additives leads to a greater or a lesser solubilizing power varies from case to case; no valid generalization is possible at this stage.

Evidence for the existence of the interaction between the polysoap and PODE is also provided by the disappearance of the "clouding phenomenon" which is observed in the aqueous PODE-7.6 solution. As Fig. 8 shows, the addition of a very small amount of the polysoap to the PODE solution raises the "cloud point." A further addition makes the cloud point disappear. This may be an indication of the formation of the co-micelle or mixed micelle of the polysoap and PODE.[12] The amount of the polysoap required to make the clouding disppear increases in proportional to the concentration of PODE, the value being 5.4×10^{-2} g. polysoap/1 g. PODE. The clouding phenomenon is generally considered to be a phase separation resulting from the breaking of the hydrogen-bonding between the polyoxyehtylene portion of PODE and the water at a high temperature.[13] Therefore, the disappearance of the clouding means that the polysoap makes the PODE, which is insoluble in water at an elevated temperature, soluble in water in terms of interaction or co-micellization.[12]

On the other hand, the polyelectrolyte has no influence upon the cloud point of the PODE-7.6 solution, even when a fairly large amount of the polyelectrolyte is added to the solution, as may be seen in Fig. 8. This indicates that no interaction occurs between the polyelectrolyte and PODE.[14] The absence of interaction must be due to the lack of long hydrophobic side chains in the polyelectrolyte molecule, for it is only in this respect that the two types of polymers, i. e., the polysoap and the polyelectrolyte, are chemically distinct. The interaction between the polysoap and PODE is, therefore, characterized by the presence of the dodecyl side chains in the polysoap molecules.

Summary

The viscosity and solubilizing power of a polysoap (the *n*-dodecyl bromide addition compound of poly-2-vinylpyridine) in aqueous solutions of a monosoap (*n*-dodecyl-α-picolinium bromide), a non-ionic surfactant (polyoxyethylene dodecyl ether, PODE) or potassium bromide have been measured. A similar experiment with a polyelectrolyte (poly-2-vinyl-*N*-ethylpyridinium bromide) has also been carried out for purposes of comparison. The effect of the polysoap on the cloud point of PODE has also been included.

The presence of the monosoap in the polysoap solution lowers the reduced viscosity, η_{sp}/c, of the polysoap. Potassium bromide has a similar effect at lower concentrations, while it causes the η_{sp}/c of the polysoap to rise at higher concentrations. The η_{sp}/c in the PODE solution is markedly high, and it becomes even higher as the PODE/polysoap-ratio increases. In the case of the polyelectrolyte, on the other hand, the monosoap and potassium bromide show a similar effect on the η_{sp}/c of the

polyelectrolyte, and the PODE deos not affect the η_{sp}/c significantly. The addition of the monosoap to the polysoap solution promotes the solubilization for 1-benzeneazo-2-naphthol, while that of PODE lowers the solubilization. 1-*p*-Nitrobenzeneazo-2-naphthol exhibits an interesting behavior with regard to solubilization, and it is less solubilized by the mixed solution of the polysoap with the monosoap or PODE than by the polysoap solution alone. The cloud point of the aqueous PODE solution disappears when a very small amount of the polysoap is added.

From these results, the way in which the polysoap interacts with the monosoap or the non-ionic surfactant has been discussed. The interaction can be explained by the co-micellization or the mixed micellization of the polysoap and the nonosoap or the non-ionic surfactant.

The author wishes to express his hearty thanks to Professor Toshizo Isemura of Osaka University for his helpful discussion. He also wishes to express his appreciation to Kao Soap Co., Ltd. for permission to publish this paper.

Studies on Amino-hexoses. IX. The *N*-Deacetylation of Methyl *N*-Acetyl-β-D-glucosaminide, Methyl *N*-Acetyl-3-*O*-methyl-α- and β-D-glucosaminide, and Methyl *N*-Acetyl-4, 6-*O*-ethylidene-α-D-glcosaminide

By Mamoru FUJINAGA and Yoshio MATSUSHIMA

Department of Chemistry, College of Science, Osaka University, Nakanoshima, Osaka

(Received June 11, 1965)

The efficiency of hydrazine as a mild *N*-deacetylating reagent has been studied in the reaction of hydrazine with four *N*-acetylaminosugars. This reagent has been shown to be of great use in the *N*-deacetylation of methyl *N*-acetyl-β-D-glucosaminide and methyl *N*-acetyl-4, 6-*O*-ethylidene-α-D-glucosaminide. It may be noted that the 3-*O*-substitution of the sugars makes the deacetylation reaction reluctant. The synthesis of methyl *N*-acetyl-4, 6-*O*-ethylidene-α-D-glucosaminide and the isolation of crystalline methyl β-D-glucosaminide and methyl 4, 6-*O*-ethylidene-α-D-glucosaminide in the free-base form have been described.

The hydrazine treatment of methyl *N*-acetyl-α D-glucosaminide (Ia) was described in a previous paper of this series.[1] The *N*-acetyl group in Ia was there shown to be well removed by the hydrazine treatment, and methyl α-D-glucosaminide (IVa) was isolated in a fairly good yield as the deacetylated product. It was also shown that both anhydrous and hydrated hydrazine had a minimal influence on the glycosidic linkage of Ia.

The present paper will describe the hydrazine treatment of four glucosamine derivatives: methyl *N*-acetyl-β-D-glucosaminide (Ib), methyl *N*-acetyl-3-*O*-methyl-α-D-glucosaminide (IIa), methyl *N*-acetyl-3-*O*-methyl-β-D-glucosaminide (IIb) and methyl *N*-acetyl-4, 6-*O*-ethylidene-α-D-glucosaminide (III). Anomerically-pure Ib was obtained, together with pure Ia by the chromatography on Dowex 1×3 (OH^- form), as has been described by Matsushima, Miyazaki and Park.[3] A pure 3-*O*-methyl α-compound (IIa) was prepared from Ia according to the method of Neuberger.[3] The β-anomer (IIb) was prepared from Ib by the known methods.[2-5] In the preparation of IIb, the physical data of the intermediate compounds were in good agreement with those described by Roth and Pigman,[5] whose data were different from those of Masamune, Okuyama and Sinohara.[4] The ethylidene compound (III) was newly synthesized by a slight modification of the method of Helferich and Appel.[6] The structure of III was verified by leading it to methyl *N*-carbobenzyloxy-4, 6-*O*-ethylidene-α-D-glucosaminide (VII), which had been prepared by Akiya and Osawa,[7] and by the periodate oxidation of the *N*-deacetylated product of III, methyl 4, 6-*O*-ethylidene-α-D-glucosaminide (VI). The deacetylation yield was assayed by the Van Slyke method in the case of Ib and by the micro

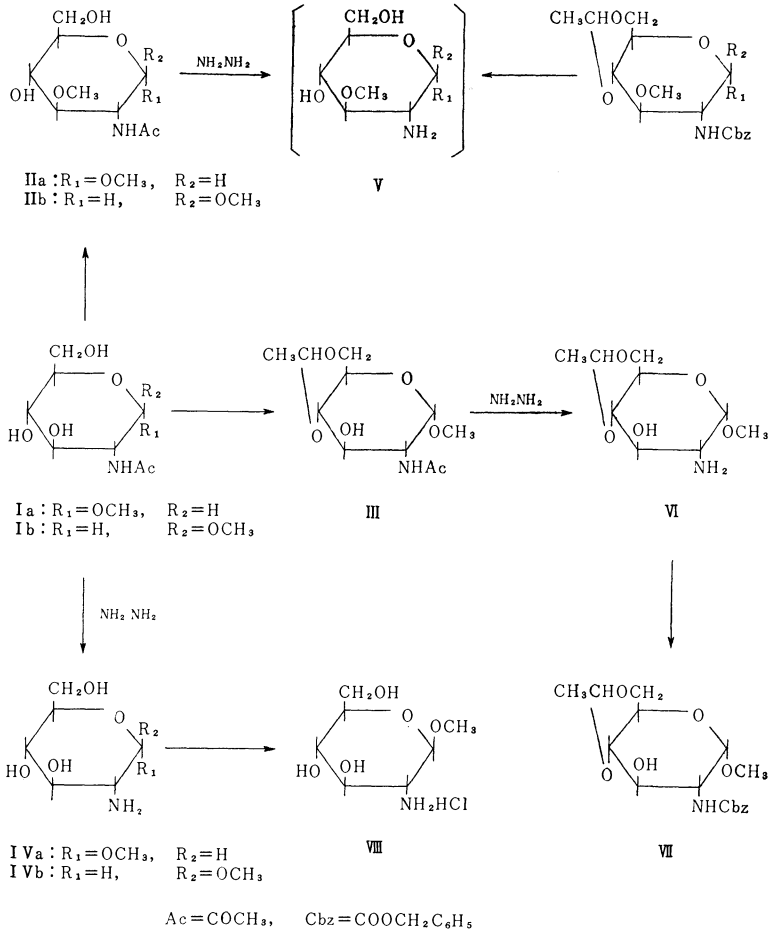

Chart 1.

Kjeldahl method in the case of IIa, IIb and III. A Hitachi amino acid autoanalyzer was also used to determine the deacetylation yield in the case of III. The starting compound which remained was assayed by isolation in every case. The results are shown in Tables I-IV. Methyl N-acetyl-β-D-glucosaminide (Ib) was well deacetylated, as in the case of the α-anomer (Ia);[1] the ethylidene compound (III) was also well deacetylated by the treatment with hydrated hydrazine, while the 3-*O*-methyl compounds (IIa and IIb) were both deacetylated in an unexpectedly low yield. These findings may give some suggestions about the reaction mechanism.

The reaction courses followed in this investigation are shown in Chart 1.

Experimental

Methyl β-D-Glucosaminide (IVb).—The starting methyl *N*-acetyl-β-D-glucosaminide (Ib)[2] (Chart 2) had a m. p. of 202—203°C and $[\alpha]_D^{29}$ −39.7° (*c* 2.890, water). A mixture of Ib (1 g.) and hydrazine (3 ml.) was kept in a sealed tube at 100°C for 20 hr.; it was then treated in a manner similar to that described in a previous paper.[1] The colorless crystals obtained from ethanol had a m. p. of 132—133°C and $[\alpha]_D^{14}$ −41.2° (*c* 1.608, water). Yield, 0.45 g. (55%).

Found: C, 43.56; H, 7.93, N, 7.26. Calcd. for $C_7H_{15}O_5N$: C, 43.52; H, 7.83; N, 7.25%.

The infrared spectrum of IVb is shown in Chart 2.

Methyl β-D-Glucosaminide Hydrochloride (VIII).—The treatment of IVb with 1 N hydrochloric acid gave a hydrochloride which ahd a m. p. of 187—188°C and $[\alpha]_D^{14}$ −23.6° (*c* 1.824, water) after recrystallization from ethanol.

Found: C, 35.81; H, 7.00; N, 6.04; Cl, 15.49. Calcd. for $C_7H_{16}O_5NCl$: C, 36.61; H, 7.02; N, 6.10; Cl, 15.44%.

Methyl *N*-Acetyl-4, 6-*O*-Benzylidene-β-D-glucosaminide.—A mixture of Ib, benzaldehyde and zinc chloride was shaken for 16 hr. The resulting benzylidene compound was then isolated by the usual method. Recrystallization from methanol gave the pure substance. Yield, 80%. M. p. 270—274°C. $[\alpha]_D^{18}$ −17.4° (*c* 0.432, dimethylsulfoxide).

Found: C, 59.39; H, 6.54; N, 4.28. Calcd. for $C_{16}H_{21}O_6N$: C, 59.43; H, 6.55; N, 4.33%.

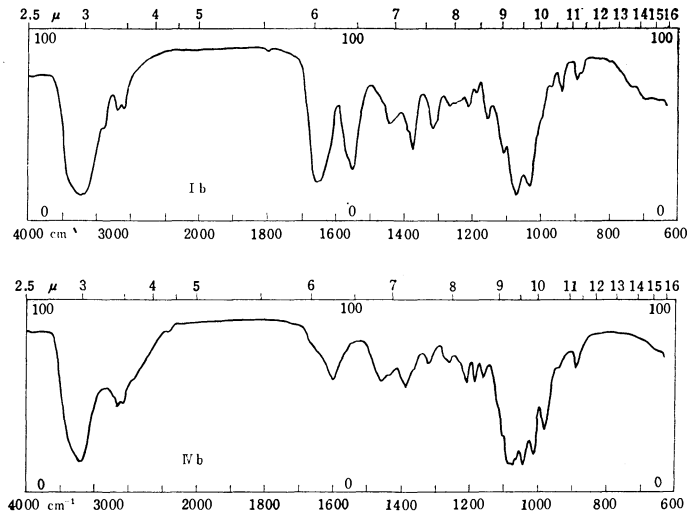

Chart 2. Infrared spectra of methyl *N*-acetyl-β-D-glucosaminide (Ib) and methyl β-D-glucosaminide (IVb).

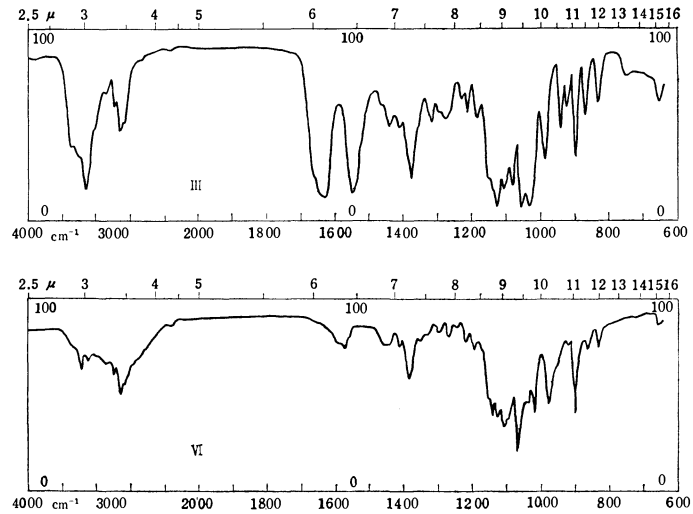

Chart 3. Infrared spectra of methyl *N*-acetyl-4,6-*O*-ethylidene-α-D-glucosaminide (III) and methyl 4,6-*O*-ethylidene-α-D-glucosaminide (VI).

Methyl *N*-Acetyl-4, 6-*O*-benzylidene-3-*O*-methyl-β-D-glucosami-nide.—Methyl *N*-acetyl-4, 6-*O*-benzylidene-β-D-glucosaminide was treated with dimethylsulfate and 30% sodium hydroxide in a large amount of dioxane. The reaction mixture was then poured into water, and the precipitates were collected and recrystallized from methanol. Yield, 57%. M. p. 276—280°C; $[\alpha]_D^{18}$ −64.8 (*c* 0.432, dimethylsulfoxide).

Found: C, 60.45; H, 6.70; N, 4.13. Calcd. for $C_{17}H_{23}O_6N$: C, 60.52; H, 6.87; N, 4.15%.

Methyl *N*-Acetyl-3-*O*-Methyl-β-D-Glucosaminide (IIb).—Methyl *N*-acetyl-4, 6-*O*-benzylidene-3-*O*-methyl-β-D-glucosaminide was heated with 60% acetic acid for 15 min. The clear solution was then evaporated in vacuo, and the residue was recrystallized from ethanol. Yield, 55%. M. p. 220—22°C; $[\alpha]_D^{14}$ −50.1 (*c* 2.176, water).

Found: C, 48.40; H, 7.71; N, 5.65. Calcd. for $C_{10}H_{19}O_6N$: C, 48.18; H, 7.68; N, 5.62%.

Methyl *N*-Acetyl-4, 6-*O*-ethylidene-α-D-glucosaminide (III).—Into a cooled suspension of Ia (4g.) in freshly-distilled paraldehyde (80 ml.), two drops of concentrated sulfuric acid were mechanically stirred. After the mixtrue had then been warmed at 60°C for 4 hr., a large amount of chloroform was added. The insoluble materials were then filtered off, and the filtrate was treated with solid potassium carbonate and then evaporated in vacuo. The crystalline residue was recrystallized twice from ethyl acetate. Yield, 3.6 g. (80%). M. p. 237—238°C; $[\alpha]_D^{12}$ +118.9° (*c* 1.968, ethanol).

Found: C, 50.31; H, 7.33; N, 5.34. Calcd. for $C_{11}H_{19}O_6N$: C. 50.56; H, 7.33; N, 5.36%.

The infrared spectrum of III is shown in Chart 3.

TABLE I. HYDRAZINOLYSIS OF METHYL *N*-ACETYL-β-D-GLUCOSAMINIDE (Ib)

Reagent	Starting compound mg.	Yield of the deacetylated product, %	Recovery of the starting compound			Total recovery %
			mg.	%	m. p.,* °C

TABLE II. HYDRAZINOLYSIS OF METHYL *N*-ACETYL-3-*O*-METHYL-α-D-GLUCOSAMINIDE (IIa)

Reagent	Starting compound mg.	Yield of the deacetylation product, %	Recovery of the starting compound			Total recovery %
			mg.	%	m. p.,* °C	
Hydrazine hydrate (90%)	1001.2	27.0	716.6	71.6	205—207	98.6
Anhydrous hydrazine	1000.4	10.4	869.7	86.6	210—211	97.0

* Before recrystallization

Methyl 4, 6-*O*-Ethylidene-α-D-glucosaminide (VI).—A mixture of III (1.0 g.) and hydrazine hydrate (6 ml.) was kept, with occasional shaking, in a sealed tube at 100°C for 20 hr. The crystalline residue obtained by the evaporation of the reaction mixture was dissolved in hot cyclohexane, and then the solution was cooled gradually. The soft colorless needles thus obtained had a m. p. of 134—135°C ($[\alpha]_D^{18}$ +110.8° (*c* 2.048, water)) and 6.49% nitrogen. Yield, 0.7 g. (83%). Recrystallization from cyclohexane gave a pure VI, m. p. 135—136°C, $[\alpha]_D^{18}$ +111.1° (*c* 1.980, water).

Found: C, 49.13; H, 7.69; N, 6.34. Calcd. for $C_9H_{17}O_5N$: C, 49.30; H, 7.82; N, 6.39%.

The infrared spectrum of VI is given in Chart 3.

Methyl *N*-Carbobenzyloxy-4, 6-*O*-ethylidene-α-D-glucosaminide (VII).—Sodium bicarbonate (0.5 g.) and carbobenzyloxychloride (1 ml.) were stirred into an aqueous solution of VI (0.5 g.) at room temperature. After the stirring had been continued for an hour, the precipitates were filtered and washed with water. Recrystallization from ethanol gave fine needles; m. p. 176—177°C, $[\alpha]_D^{18}$ +67.5° (*c* 2.058, chloroform). Yield, 0.42 g. (52%).

Found: C, 57.69; H, 6.39; N, 3.96. Calcd. for $C_{17}H_{23}O_7N$: C, 57.78; H, 6.56; N, 3.96%.

No depression of the melting point was observed when VII was mixed with an authentic specimen which has been prepared according to the method of Akiya and Osawa,[7] and it had a m. p. of 176—177°C; $[\alpha]_D^{17}$ +67.4° (*c* 1.720, chloroform).

The Hydrazine Treatment of Methyl *N*-Acetyl-β-D-glucosaminide (Ib).—An about 500 mg. portion of Ib was treated with hydrazine (1.5 ml.) at 100°C for 20 hr. in a sealed tube, and then it was treated in a manner similar to that described in the previous paper.[1] The recovered substance obtained by passing the reaction mixture through a column of Dowex 50×4 (H^+ form) was characterized as the starting compound, Ib, by chromatographic examination and by a study of the infrared spectra, though a slight difference in melting point was observed. The results are shown in Table I.

The Hydrazine Treatment of Methyl *N*-Acetyl-3-*O*-methyl-α-D-glucosaminide (IIa).—The starting methyl *N*-acetyl-3-*O*-methyl-α-D-glucosaminide (IIa)[8] had a m. p. of 212—213°C; $[\alpha]_D^{12}$ +113.6° (*c* 1.690, water). In a sealed tube, IIa (1 g.) and hydrazine (3 ml.) were kept at 100°C for 20 hr. After it had then cooled, the reaction mixture was dissolved in absolute ethanol and concentrated in vacuo on a boiling water bath. An aqueous solution of the crystalline residue was passed through a column of Dowex 50×4 (2×18 cm., H^+ form), and then washed with water (300 ml.). The effluent and washings were combined and concentrated in vacuo to dryness, and the final crystalline residue was weighed. The compound thus recovered was identified as the starting compound, IIa, by a melting point determination, a study of its infrared spectra, and thin-layer chromatography.

The column of Dowex 50×4 was eluted with 0.5 N hydrochloric acid. The effluent solution was collected in about 6 ml. fractions, which were then checked with ninhydrin and *p*-dimethylaminobenzaldehyde - hydrochloric acid reagents. Hydrazine and hydrazide react with the latter reagent to form an intensely-yellow to orange-colored substance and a yellow fluorescent product respectively.[8,9] The fractions which were positive with the ninhydrin and negative with the *p*-dimethylaminobenzaldehyde reagent were collected, passed through a column of Dowex 1×4 (2.2×25 cm., OH^- form), and then washed with water. The effluent, combined with washings, was concentrated in vacuo to a syrup, which was then dissolvend in an appropriate amount of water. The aqueous solution thus obtained was subjected to micro Kjeldahl nitrogen determination, from which the yield of the deacetylated product was calculated. The results are shown in Table II.

The Hydrazine Treatment of Methyl *N*-Acetyl-3-*O*-methyl-β-D-glucosaminide (IIb).—One gram of IIb was treated with hydrazine as in the case of IIa. The results are shown in Table III.

The Hydrazine Treatment of Methyl *N*-Acetyl-4, 6-*O*-ethylidene-α-D-glucosaminide (III).—A two-hundred-mg. portion of III was treated with hydrazine (1.2 ml.) and then treated in a manner similar to that

** Determined by an amino acid autoanalyzer

used in the case of IIa, except that a column of Dowex 50×4 cooled with ice-water was used to avoid the splitting of the ethylidene group. The Hitachi amino acid autoanalyzedr was used to determine the yield of the deacetylated product. An aqueous solution (1 ml.) containing about 0.5 μmol. of the deacetylated product, from which hydrazine and hydrazide had been removed as thoroughly as possible by repeated evaporation, was introduced into an amino acid analyzer (0.9×7 cm. column, pH 5.28, 0.2 N citrate buffer). A small peak due to acthydrazide, a low broad peak due to hydrazine, and a main peak of methyl 4, 6-*O*-ethylidene-α-D-glucosaminide (VI) were observed. The results are shown in Table IV.

The Periodate Oxidation of Methyl 4, 6-*O*-Ethylidene-α-D-Glucosaminide (VI). — One milliliter of a 0.05 M potassium periodate solution was added to 9 ml. of a 10^{-3} M aqueous solution of VI at 25°C in a dark place, and the optical density at 290 mμ was read at several intervals against the reagent blank.[10] The decrease in the optical density at this wave lengh: after 72 hr. was 0.194, which corresponded to the consumption of one mole of periodate per mole of VI.

Discussion

Methyl β-D-glucosaminide (IVb) has also been obtained, by a different method, by Matsushima and Miyazaki,[11] who gave a m. p. of 130—132°C, $[\alpha]_D^{18}$ −40.7°. As has been described above, the compound isolated from the reaction mixture gave identical physical constants. The hydrochloride of IVb had melting point and optical rotation values consistent with those described by Foster, Horton and Stacey,[12] who prepared the compound via methyl *N*-carbobenzyloxy-β-D-glucosaminide and gave a m. p. of 189—190°C, $[\alpha]_D^{20}$ −24°. The infrared spectrum of IVb (Chart 2) shows the existence of the free amino group. Thin-layer chromatography using a moving phase of buthanol: acetic acid: water=4 : 1 : 5 (upper layer) revealed that the reaction mixture contained only two components, Ib and IVb. These findings together with the data in Table I, show that Ib was well deacetylated by the hydrazine treatment and gave IVb as the sole deacetylated product. The glycosidic linkage in Ib was stable under the hydrazine treatment.

While methyl 3-*O*-methyl-D-glucosaminides (V) have not been reported yet, their 4, 6-*O*-ethylidene and 4, 6-*O*-benzylidene compounds have been prepared by Akiya and Osawa.[7] By the method of these authors, 4, 6-*O*-ethylidene compounds of IIa and IIb were prepared and the ethylidene group was split with 60% acetic acid. The resultant amorphous substances (both of which we tried to crystallize, but all in vain), were used as the standard methyl 3-*O*-methyl-D-glucosaminides in the chromatographic examinations. The hydrazinolyzed products of IIa and IIb were thus characterized without isolating them.

Tables II and III show that the greater part of the starting compounds, IIa and IIb, were recovered, the *N*-deacetylation occurring in an unexpectedly low yield.

As has been mentioned above, the hydrazinolyzed product of III was characterized as a *N*-carbobenzyloxy derivative, one with a melting point and optical rotation data consistent with those of an authentic specimen prepared by the method of Akiya and Osawa.[7] A thin-layer chromatogram and its infrared spectra showed that VII was identical with the authentic specimen.[7] The infrared spectrum (Chart 3) and the elemental analyses support the structure of VI. These results and the

periodate oxidation of VI show definitely that an ethylidene group in III or VI is in the 4, 6-position.

Hydrazine hydrate seems to have a greater power to deacetylate than does anhydrous hydrazine (Tables I—IV). Another trait observed is that the compounds with a free hydroxyl group vicinal to the *N*-acetyl group undergo deacetylation more easily. The results obtained in the case of IIa and IIb are consistent with the fact that the hydrazine treatment of *N*-acetylaminopolysaccharides with a substituent of C-3, such as chondroitin sulfate,[13-15] hyaluronic acid[15] and the cell wall mucopolysaccharide of Micrococcus lysodeikticus,[16] resulted in low yields.

The total recovery (Table I—IV) and the chromatographic examinations show that hydrazine treatment caused little cleavage of glycosidic likages. These findings are consistent with the reported fact that the hydrazine treatment of a simple polysaccharide such as soluble starch and glycogen[17] does not cause any extensive cleavage of glycosidic linkages. As regards the hydrazinolysis of mucopolysaccharides,[13-15] which ended in a considerable degradation of the molecule, some specific interpretations will be required.

Summary

Methyl *N*-acetyl-β-D-glucosaminide, methyl *N*-acetyl-3-*O*-methyl-α- and β-D-glucosaminide and methyl *N*-acetyl-4, 6-*O*-ethylidene-α-D-glucosaminide have been deacetylated using anhydrous and hydrated hydrazine. It has been found that the 3-*O*-substitution slowed the deacetylation reaction considerably.

Crystalline methyl β-D-glucosaminide (IVb) and methyl 4, 6-*O*-ethylidene-α-D-glucosaminide (VI) have been newly obtained in the free base form from the corresponding *N*-acetyl compounds.

This investigation was supported by U. S. Public Health Service Grant No. AI-04586-03.

(Received April 17, 1965)

The growth of single crystals from a vapor phase has become an important technique in the preparation of single crystals of such semiconducting compounds as GaAs. It has recently been discovered[1] that, when a small quantity of iodine is added as a carrier to polycrystals of GaAs, the starting material, the growth takes place at relatively low temperatures of about 700°C, although GaAs itself has only a negligible vapor pressure at such temperatures. It is, therefore, important to identify the reacting species in the vapor phase in order to understand the mechanism of the crystal growth. After we had started the high-temperature diffraction work for this purpose, Silvestri and Lyons[2] published their work on this system by vapor-pressure measurements; they showed that the vapor phase of this system consists mainly of GaI_3 and As_4 and established the $2GaAs(s)+GaI_3(v)\leftrightarrow 3GaI(v)+(1/2)As_4(v)$ reaction in the 560—850°C temperature range.

In the present work, in pursuit of a possible change in the species present in the mixture at different temperatures, a vapor-phase equilibrium of the GaAs-I_2 system at a lower temperature of 440°C has been studied by the sector-microphotometer method of electron diffraction. The above temperature was also selected because the operation of the present high-temperature nozzle was easier below 500°C.

Experimental

Polycrystals of GaAs of a high purity were kindly supplied by the Tokyo Shibaura Electric Co. The sample of iodine was purified by sublimation. About 0.1 g. of the iodine and an excess amount (about 1 g.) of the crystals were placed in the oven of the nozzle at the same time. After the mixture had been degassed for about ten minutes in a vacuum, it was slowly heated to 440°C in about 30 min. The diffraction photographs were taken under conditions almost the same as those described in a preceding paper.[3]

Results and Discussion

One diffraction photograph of the GaAs-I_2 reaction system was analyzed. The molecular intensity curve, $qM(q)$, which was obtained by the drawing of a smooth background line across the experimental total intensity curve was found to be similar to those of the GaI_3 described in a preceding paper.[4] The molecular intensity curve thus obtained is compared with the theoretical curve of the GaI_3 in Fig. 1.

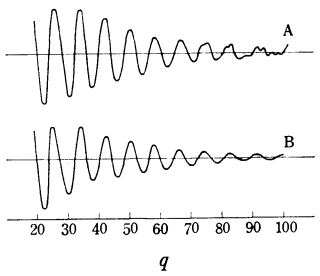

Fig. 1. Molecular intensity curve of GaAs-I_2 at 440°C.
A: Observed $qM(q)$ of GaAs-I_2
B: Calculated $qMq(q)$ for the GaI_3 model

Since the intensity of a small-angle region is sensitive to the specimen, it seemed desirable to examine the $q<20$ region in order to confirm that the system was indeed GaI_3. The photograph taken by the usual procedure was not suitable for this study, since the beam trap of the sector interfered with the observation of the diffraction pattern in this region. Moreover, the nozzle

2) V. J. Silvestri and V. J. Lyons, ibid., **109**, 963 (1962).
3) Y. Morino, T. Ukaji and T. Ito, This Bulletin, **39**, 64 (1965).
4) Y. Morino, T. Ukaji and T. Ito, ibid., **39**, 71 (1965).

assembly was not designed for use at a longer camera distance. The features of the diffraction pattern in that range of the scattering angles were, therefore, examined qualitatively by the following procedure. The sector was removed, and the photographs were taken with two different exposure times: about one second, and one and a half seconds. The photographs were then traced with a microphotometer across the diameter of the pattern, and the two intensity curves corresponding to the above exposure times were joined together at the q of about 13, and the curve thus obtained was converted to the molecular intensity curve, $qM(q)$. In Fig. 2 this curve is compared with the theoretical molecular intensity curve calculated with the molecular parameters of the GaI_3 (r_a'(Ga-I)=2.456, r_a'(I-I)=4.250 Å. The mean amplitudes were corrected for the change in temperature as follows: l(Ga-I)=0.076 and l(I-I)=0.185 Å).

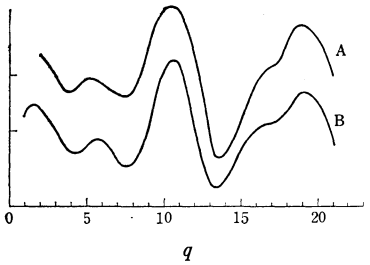

Fig. 2. Small-angle intensity curve of $GaAs\text{-}I_2$ at 440°C.
A: Observed $qM(q)$ of $GaAs\text{-}I_2$
B: Calculated $qM(q)$ for the GaI_3 model

The features of the experimental intensity curve are in qualitative agreement with the theoretical curve. The radial distribution curve was, therefore, obtained from the experimental molecular intensity curve spliced in the range of the scattering angles q less than 20 by a theoretical curve calculated with the molecular parameters of the GaI_3. The curve is shown in Fig. 3A; it is essentially similar to that of the GaI_3. It should be mentioned, however, that in this curve two fairly large negative areas between the two main peaks are observed, as is an appreciable distortion from the Gaussian form for the I-I peak.

Synthetic radial distribution curve for the GaI_3 model mentioned above was then calculated and subtracted from the experimental curve of Fig. 3A. The curve obtained as the difference between the two curves is shown in Fig. 3B. Three peaks are observed in this curve. Although the peak at about 2.5 Å might correspond to the As—As distance of As_4 (r_a=2.432Å)[3] and the As—I distance of AsI_3 (r_a'=2.554 Å)[4], and the peak at about 3.9 Å, to the I—I distance of AsI_3 (r_a'=3.915 Å), no quantitative discussions can be made, since the heights of these peaks are of the same orders of magnitude as those of ghosts (the negative peaks). The peak at about 3.1 Å has not been assigned to any, possible interatomic distance; it may be a ghost.

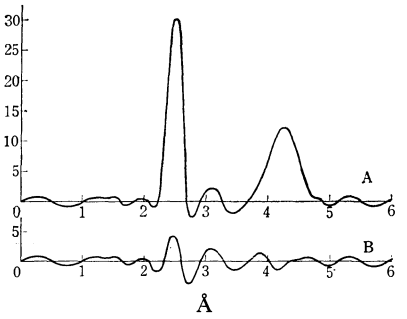

Fig. 3.
A: Radial distribution curve of $GaAs\text{-}I_2$ at 440°C
B: Difference between the RD curve of $GaAs\text{-}I_2$ and that of the GaI_3 model

In conclusion, the present study has shown that the predominant species in the vapor phase of the $GaAs\text{-}I_2$ reaction system at 440°C is GaI_3. It may, therefore, be inferred that a reaction similar to that reported by Silvestri and Lyons takes place at this temperature. The vapor pressure of the GaI_3 is about 700 mmHg (estimated from the amount of the starting iodine), while the arsenic which results from the reaction is expected to remain mainly in the solid phase (the vapor pressure of arsenic is about 10 mmHg at 440°C); it has, therefore, only a little influence on the diffraction photograph.

The authors wish to express their deep gratitude to the Tokyo Shibaura Electric Co. for kindly supplying the sample of GaAs.

SHORT COMMUNICATIONS

A New Spectrophotometric Method for the Determination of Tungsten with Stilbazogall I

By Hajime ISHII and Hisahiko EINAGA

Central Research Laboratory, Onoda Cement Co., Ltd., Koto-ku, Tokyo

(Received October 20, 1965)

A new spectrophotometric method for the determination of a trace of tungsten has been developed. It is based upon the formation of a red tungsten(VI) complex of Stilbazogall I, stilbene-4, 4' - bis [(1-azo)-2, 3, 4-trihydroxybenzene] - 2, 2'-disulfonic acid (I), which was synthesized by Cherkesov et al.[1] and which has recently been reported to be a reagent for the determination of zirconium.

The absorption spectra of the complex at various pH values are shown in Fig. 1, from which it may be seen that tungsten(VI) froms more than one type of complex. In detailed experiments, two types of complexes were found. One of them was a 1 : 1 metal-to-reagent complex formed at about pH 2, while the other was a 1 : 2 complex

formed at about pH 5. The composition of the complex was found to change continuously from 1 : 1 to 1 : 2 with an increase in the pH value. Figure 2 shows the results obtained by the mole ratio method as an example. A linear relationship was found between the concentration of tungsten(VI) and the absorbance. The molar extinction coefficients of 1 : 1 and 1 : 2 complexes were about 2.1×10^4 and 3.7×10^4, and the sensitivities were 8.7×10^{-3} and 4.9×10^{-3} μg.W/cm^2 respectively, corresponding to log $(I_0/I)=0.001$. The proposed procedure for the determination is as follows. To a sample solution containing tungsten(VI) in a 25-ml. volumetric flask, 5.0 ml. of a Stilbazogall I solution (10^{-4} mol./l.) and 5 ml. of a sodium acetate - acetic acid buffer solution (pH=4.9) are added. The solution is then diluted to the mark with distilled water. The absorbance of the solution is measured at 520 mμ against a reagent blank solution between 5 and 15 min. after the addition of the reagent solution. Some metals, such as aluminum(III) copper(II), molybdenum(VI), titanium(IV), and zirconium(IV), interfere under the conditions proposed.

The details of this study will be reported elsewhere.

A New Colorimetric Method for the Determination of Beryllium with Sodium *p*-Chlorophenol-azo-1, 8-dihydroxynaphthalene-3, 6-disulfonate

By Katsuya UESUGI and Yukiteru KATSUBE

Himeji Institute of Technology, Idei 600, Himeji

(Received October, 21, 1965)

A new colorimetric method for the determination of traces of beryllium has been developed. It is based upon the stable blue beryllium complex of sodium *p*-chlorophenol-azo-1, 8-dihydroxynaphthalene-3,6-disulfonate in an aqueous solution. This compound has been used for the colorimetric determinations of calcium and magnesium in serum,[1] urin[2] and cast iron[3].

The absorption spectra of the beryllium complex are shown in Fig. 1. At pH 6.5, the maximum absorbance is found at 610 mμ. The complex is formed by adding a small amount of beryllium to the mixture of 10 ml. of a sodium acetate - acetic acid buffer solution and 2.0 ml. of a 0.1% reagent solution in a 25 ml. volumetric flask. The solution is diluted to the mark with distilled water and thoroughly mixed. The beryllium complex has a maximum absorbance in the pH range from 6.2 to 6.8. The color under these conditions develops completely within 10 min. and is stable for at least 30 min. There is no variation in the absorbance of the color over the temperature range of 10 to 30°C. When the color is measured spectrophotometrically at its absorption peak, 610 mμ, the beryllium complex obeys Beer's law within the range from 0.02 to 0.3 p.p.m. of beryllium (Fig. 2).

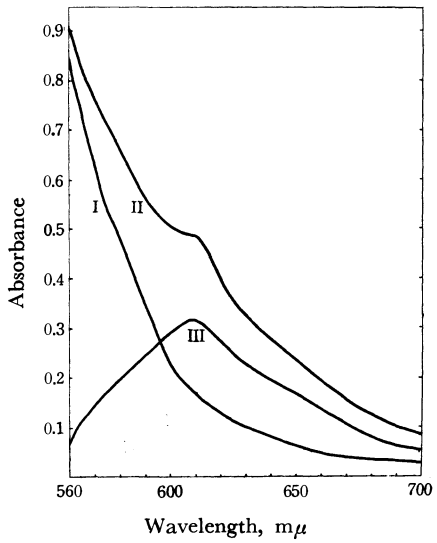

Fig. 1. Absorption spectra. pH 6.5

I. Reagent (40 p.p.m.), against water
II. Reagent (40 p.p.m.) + Be (0.28 p.p.m.), against water
III. Reagent (40 p.p.m.) + Be (0.28 p.p.m.), against reagent blank

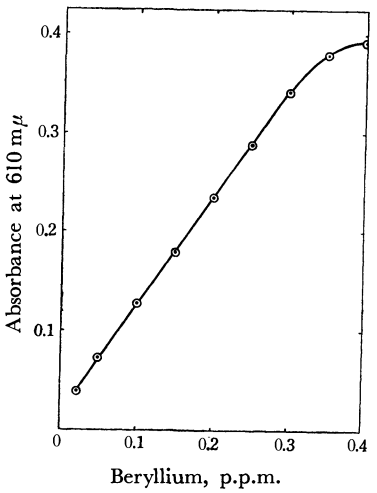

Fig. 2. Beer's law curve. pH 6.5

At 610 mμ, the molar extinction coefficient is about 11000, the sensitivity being 0.0008 μg. Be/cm^2, corresponding to log I_0/I=0.001.

5 μg. of beryllium can be determined satisfactorily in the presence of 50 μg. of iron (II, III), manganese(II), calcium and magnesium. Copper-(II), aluminum, zinc, cobalt and nickel interfere.

Further, detailed studies are now in progress.

A Novel Direct Synthesis of the *N*-Oxides of Quinoline Derivatives

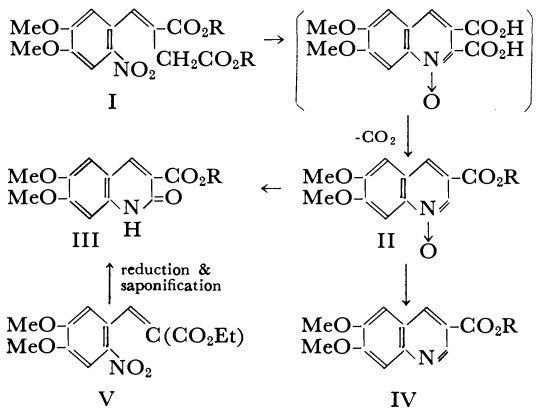
By Yusuf AHMAD and Shamim Ahmad SHAMSI

Chemical Research Division, Central Laboratories, Pakistan Council of Scientific and Industrial Research Karachi, West Pakistan

(Received October 27, 1965)

The *N*-oxides of quinoline compounds are usually obtained by the oxidation of corresponding quinoline derivatives. No synthesis resulting in the direct formation of the *N*-oxide of quinoline derivatives seems to have been recorded so far. Perhaps the only exception is the report of Loudon et al.[1] regarding the syntheses of some 1, 4-dihydro-1-hydroxy-4-oxoquinolines, which in their tautomeric form can be regarded as 4-hydroxyquinoline *N*-oxide derivatives.

We record below a novel quinoline synthesis, in which the nitro group of a benzene derivative interacts with the side chain in the ortho position, in the presence of a base, and results in the direct formation of the *N*-oxide of a quinoline derivative.



a) R=H, b) R=Et, c) R=Me

Veratraldehyde was condensed with ethyl succinate to obtain veratrylidenesuccinic acid,[2] m. p. 174—175°C, which on nitration gave *o*-nitroveratrylidenesuccinic acid[3] (Ia) as yellow needles, m. p. 214—415°C. Ia, on being warmed with 20% aqueous potassium hydroxide, gave an acid (m. p. 282—283°C decomp.) which was then purified by precipitation with acid from its sodium bicarbonate solution. The constitution of this acid was confirmed to be 6,7-dimethoxyquinoline-1-oxide-3-carboxylic acid (IIa), as it underwent the known rearrangement[4] of the *N*-oxides of quinoline to carbostyrils on being heated with acetic anhydride, and gave 2-hydroxy-6, 7-dimethoxyquinoline-3-carboxylic acid (IIIa) as yellow needles (m. p. 310°C decomp.), an acid which was identical (delete infrared spectrum and mixed melting point) with an authentic sample[5], synthesised through a previously-reported unambiguous route, involving the reduction of the intermediate (V) and its simultaneous cyclisation, followed by the saponification of the resulting ester. IIIa obtained by either of the routes, on sublimation in vacuo, decarboxylated to the same 6, 7-dimethoxycarbostyril (III, H for CO_2R) (m. p. 232—234°C); the two samples had identical infrared spectra, and their melting point and mixed melting point were the same. On esterification, 6, 7-dimethoxyquinoline-1-oxide-3-carboxylic acid (IIa) gave the ethyl ester (IIb), as white needles (m. p. 214—215°C) and the methyl ester (IIc), as white needles (m. p. 211—212°C). The ethyl ester, on deoxygenation[6] with PCl_3, gave ethyl 6, 7-dimethoxyquinoline-3-carboxylate (IVb) as white needles, m. p. 140—141°C; on saponification this gave 6, 7-dimethoxyquinoline-3-carboxylic acid (IVa), as white micro-needles (m. p. 267—268°C). All the compounds reported above gave satisfactory C, H and N analyses.

Similar work in an analogous series has been completed; it will be described in detail in a subsequent publication.

The Electron Spin Resonance of Sodium Polyphosphate Glass Irradiated with γ-Rays

By Masaji MIURA and Akinori HASEGAWA

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima

(Received October 29, 1965)

Phosphate glass is easily colored upon irradiation with γ-rays. Krapetyan and Yudin have reported that the red color of phosphate glass induced by the irradiation of γ-rays is to be attributed to the electron trapped by phosphorus atoms.[1] By taking the g values and the coupling constant into account, however, it has recently been concluded that the color is caused by the hole trapped by the oxygen atom rather than by the electron trapped by the phosphorus atom.[2]

These authors have used phosphate glasses, but the degrees of polymerization were not determined. No relationship between the effect of γ-rays on the glass and its degree of polymerization, $\bar{n}$, has yet been established. The purpose of the present work is to investigate this relationship by using sodium polyphosphate, which is so-called Graham's salt. Samples of sodium polyphosphate glass with various values of $\bar{n}$ were prepared and irradiated with γ-rays from a ^{60}Co source at room temperature. The ESR and optical-absorption measurements were then carried out on these glasses.

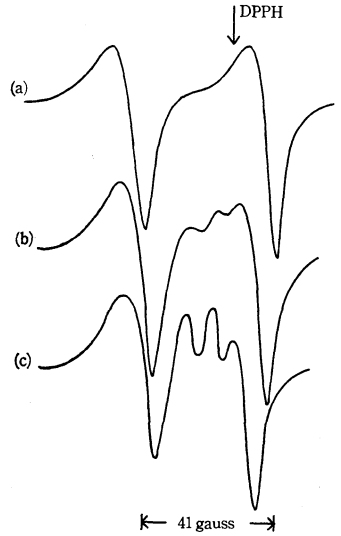

Fig. 1. The ESR spectra of γ-irradiated sodium polyphosphate glasses with (a) $\bar{n}=86$, (b) $\bar{n}=11$ and (c) $\bar{n}=4.8$.

The glass with a higher value of $\bar{n}$, as is shown in Fig. 1a, gave two asymmetric ESR absorptions which are hyperfine structures originating from the interaction between the ^{31}P nucleus and the hole trapped in the non-bonding orbital of the oxygen atom. The coupling constant between these two absorptions became smaller and, at the same time, a new doublet appeared more definitely with a decrease in the $\bar{n}$ value (Figs. 1b and 1c). The latter doublet may be attributed to the hole trapped in the oxygen ion of the end group, PO_4^{2-}, because it has a much smaller coupling constant than that of the former doublet and becomes more evident with an increase in the content of the end groups.

After the irradiation of 5×10^5 r., the ESR measurement on each glass was carried out at room temperature. The intensity of the larger doublet decreases rapidly as the value of $\bar{n}$ decreases.

Each transparent sheet of these glasses showed an intrinsic absorption band in the ultraviolet region. After the irradiation with γ-rays, however, each gave two additional bands, one in the visible, and the other in the ultraviolet region. The wavelengths of the maximum absorption of these bands depend upon the value of $\bar{n}$. The visible absorption band may be due to the electronic transition between the excited level of the non-bonding orbital, where the trapped hole is mainly localized, and the lower levels of the bonding orbital. On the other hand, the ultraviolet absorption may be caused by the charge transfer of the trapped electron to the neighbors.

Thus, from the ESR spectra of γ-irradiated sodium polyphosphate glasses, two doublets were found; the larger doublet is due to the hole trapped by the main chain of polyphosphate, while the smaller doublet is due to the hole trapped by the end group. The ESR of the larger doublet and the optical absorption of the glass may be modified by the change in the distortion of the P-O-P bond caused by the variation in the degree of polymerization.

Stable *trans*-Isomers of Bis(acetato)-triethylenetetramine-cobalt(III) and Bis(propionato)-triethylenetetramine-cobalt(III) Complexes

By Kashiro KURODA and Motoko GOTO

Department of Chemistry, Kyoto-Gakugei University, Fushimi-ku, Kyoto

(Received November 4, 1965)

Although a diacido-triethylenetetramine-cobalt-(III) complex may exist in three stereoisomeric forms, two *cis*- and one *trans*-isomers, all of the complexes prepared so far have been *cis*-isomers except for *trans*-[$CoBr_2$trien]X.[1] Concerning the complex, however, the absorption spectrum has not been measured because of its instability in solution. In our previous studies of [Co(halac)$_2$-$(NH_3)_4$]X and [Co(halac)$_2$(en)$_2$]X,[2] where halac= acetato and halogenoacetato ligands, we have noticed that *trans*-isomers occur when the reaction mixture of a carbonato-complex and a halogeno-acetic acid is evaporated at a high temperature and that they are apt to arise in the cases of halac ligands with low halogen contents. In the light of this knowledge, two compounds, [Co$(CH_3CO_2)_2$-trien]ClO_4·$HClO_4$ and [Co$(C_2H_5CO_2)_2$]trienClO_4·$HClO_4$, have been obtained which must be *trans*-isomers judging from their preparation procedures[3] and absorption spectra.

Figure 1 and Table I show the absorption spectra of the complexes prepared, together with those of some related complexes. It has been well-established that, in a [Coa_4b_2]-type complex, the first band of the *trans*-isomer splits much more significantly than that of the *cis*-isomer.[4,5] As may be seen in Fig. 1, the absorption curves of the prepared complexes obviously exhibit the features of a *trans*-isomer. In addition, the absorption maxima are in good correspondence with those of *trans*-[Co$(CH_3CO_2)_2$-$(en)_2$]ClO_4. The identification is also reasonable in view of the preparation procedures. Much as in the procedures for some *trans*-[Co(halac)$_2$$(en)_2$]-$ClO_4$,[2] the reaction mixture of [$CoCO_3$trien]ClO_4 and CH_3CO_2H (or $C_2H_5CO_2H$) was boiled for a few minutes at the final period of the evaporation. Moreover, just as *trans*-[Co(halac)$_2$$(en)_2$]$^+$ precipitate as acidic salts upon the addition of perchloric acid,[2] so do the present complexes.

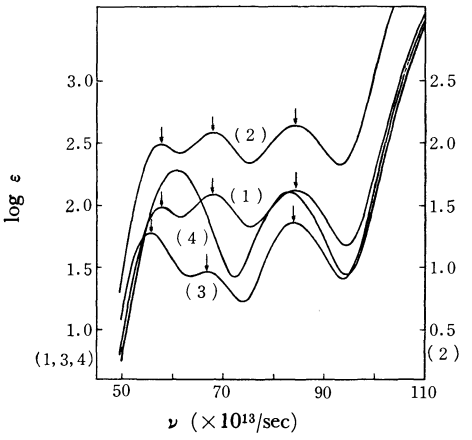

Fig. 1. Absorption spectra of *trans*-[Co$(CH_3CO_2)_2$-trien]ClO_4 and some related complexes.
1 : *trans*-[Co$(CH_3CO_2)_2$ trien]ClO_4
2 : *trans*-[Co$(C_2H_5CO_2)_2$ trien]ClO_4
3 : *trans*-[Co$(CH_3CO_2)_2$ $(en)_2$]ClO_4
4 : *cis*-[Co$(CHCl_2CO_2)_2$ trien]ClO_4

The intensity is the most significant difference between the spectra of *trans*-[Co$(CH_3CO_2)_2(en)_2$]$^+$ and of *trans*-[Co$(CH_3CO_2)_2$ trien]$^+$. The high intensity of the latter is probably due to the low symmetry of the complex. Because the trien molecule is constrained by the square planar coordination and because there is no chelation at one side of the square, the square is necessalily distorted to some extent. That is, the symmetry of the complex is much lower than those of the $(NH_3)_4$- and $(en)_2$- analogues. This may effect the increase in the transition moment and, hence, the high extinction coefficients.

TABLE I. ABSORPTION SPECTRA OF *trans*-[Co$(CH_3CO_2)_2$ trien]ClO_4

	ν_{1a} (10^{13}/sec.)	log ε_{1a}	ν_{1b} (10^{13}/sec.)	log ε_{1b}	ν_2 (10^{13}/sec.)	log ε_2
trans-[Co$(CH_3CO_2)_2$trien]$^+$	57.7	1.981	67.8	2.083	84.3	2.122
trans-[Co$(C_2H_5CO_2)_2$trien]$^+$	57.7	1.989	67.8	2.082	84.2	2.139

Photooxidation with Cupric Ions. A Novel Dimethoxylation and Diacetoxylation of Styrene

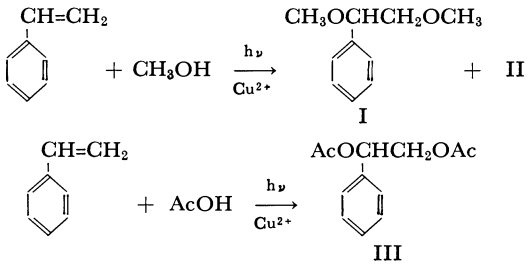
By Shinji MURAI and Shigeru TSUTSUMI

Department of Chemical Technology, Faculty of Engineering, Osaka University, Miyakojima-ku, Osaka

(Received November 4, 1965)

Previous investigations of photooxidation with transition metal ions have dealt almost exclusively with aqeuous solutions.[1] The hydroxylation of benzene[2] and benzoic acid[3,4] to the corresponding phenols by irradiation with ultraviolet light in an aqeuous ferric ion solution have been reported. Recently Kochi has reported the photochemical chlorination of organic compounds in organic media.[5]

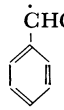
We wish now to report some novel photooxidations in nonaqeuous solutions: the photochemical reactions of styrene with methanol or with acetic acid in the presence of cupric ions. The over-all reactions are shown below:



A homogeneous solution of styrene (0.1 mol.) and cupric perchlorate hexahydrate (0.1 mol.) in methanol (200 mol.) was irradiated by 2537Å light for 24 hr. The reaction mixture was then diluted with water and extracted with ether.[6] The ether extract was dried and distilled to give 2.4 g. of styrene glycol dimethyl ether (I), b. p. 90—95°C/11 mmHg, and 1.7 g. of an almost colorless oil, b. p. 110—120°C/0.5 mmHg, which was partially crystallized on standing and which was separated by filtration into 0.2 g. of crystalline *meso*-1, 4-dimethoxy-2, 3-diphenylbutane (II) and an oil. This oil, obtained also in the absence of cupric perchlorate, was presumably a mixture of styrene dimers (infrared). When compound I was purified by preparative gas chromatography, it showed an infrared spectrum identical with that of an authentic sample.[7] Found: C, 72.29; H, 8.77. Calcd. for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%. II was recrystallyzed from methanol, m. p. 129—130°C, underpessed on admixture with an authentic sample.[7] When the reaction of styrene with methanol was carried out, under irradiation, using cupric sulfate pentahydrate in place of cupric perchlorate, I (0.3 g.) and II (0.2 g.) were also obtained.

In the same manner, a homogeneous solution of styrene (0.1 mol.) and cupric perchlorate hexahydrate (0.1 mo.l) in acetic acid (400 ml.) was irradiated by 2537Å light for 24 hr. No gas evolution was observed during the reaction. On working up as has been described above, 1.5 g. of styrene diacetate (III), b. p. 102—105°C/0.3 mmHg was obtained. III was identified by gas chromatography on a polyester-DA column at 185°C. III also showed an infrared spectrum identical with that of an authentic sample.[8] III gave styrene glycol upon hydrolysis, m. p. and m. m. p. 65—66°C (ligroin).

Upon irradiation in the absence of styrene, a solution of cupric perchlorate in methanol gave formaldehyde, while in acetic acid the products were mainly CH_4 and CO_2, with small amounts of H_2 and C_2H_6. Therefore, in these reactions the methoxy radical or the acetoxy radical are probably formed initially by the photooxidation of methanol or acetic acid with cupric ions. Then addition of these radicals to styrene probably takes place, thus yielding intermediate radicals such as IV.



IV R=CH_3, Ac

Finally, IV gives I or III by the usual cupric ion oxidation of free radicals.[9] Small amounts of fine precipitates of metallic copper were obtained throughout these reactions. Cupric ions might be reduced to cuprous ions, which might then disproportionate to cupric ions and metallic copper. However, the possibility of the initial formation of the styrene cation radical by a photochemical one-electron oxidation of styrene with cupric ions and the trapping of the cation radical by solvents, thus yielding IV, has not been eliminated.

The Determination of Singlet-Triplet Separation from the Anomalous Hyperfine Structure Observed with a Radical Pair

By Hisaharu HAYASHI, Koichi ITOH and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Azabu, Tokyo

(Received November 12, 1965)

It has recently been found by ESR studies that radical pairs are stably trapped in the single crystals of several oximes X-irradiated at 77°K.[1-3] In particular, the radical pair, "K", of dimethylglyoxime shows an anomalous hyperfine structure; i. e., the observed central three lines among the nine hyperfine lines corresponding to the $\Delta m=\pm 1$ transitions of the radical pair are not equally spaced.[1] This can not be explained by a first-order treatment which considers only the nonequivalence of the hyperfine tensors of two interacting radicals.[1] We have attempted to interpret the anomaly by considering the mixing between the singlet and triplet states through the hyperfine interaction and the electronic Zeeman term.

The Hamiltonian for the system under consideration consists of the electronic Coulomb, electronic Zeeman, electron spin-spin interaction, hyperfine interaction and nuclear Zeeman terms. The effective energy difference due to the first term between the singlet and triplet states is expressed by the exchange term, $-2J\mathbf{s}_1\mathbf{s}_2$, where J is the exchange integral. On the assumptions that the second term is much larger than the third and fourth terms, and that the fourth term is much larger than the fifth term, the energy level, $E(m, M^a, M^b)$, of the triplet state can easily be evaluated by the aid of the second-order perturbation. In this case, the interacting nucleus is only one nitrogen ($I=1$) for each radical.[1,4] The two radical sites are designated as a and b, and m and M^p are the z-components of the electron spin of the triplet state and of the nitrogen nuclear spin on the p site respectively. Only the allowed transitions of $\Delta m=\pm 1$ and $\Delta M^a=\Delta M^b=0$ are considered.

Since the anomaly is noticeable for the hyperfine lines due to $M^a+M^b=0$, the deviation, $\delta_\pm$, defined below should be considered,

$$\delta_\pm=\{\Delta E_\pm(1,\ -1)-\Delta E_\pm(-1,\ 1)\}/2-\Delta E_\pm(0,\ 0) \qquad (1)$$

where the transition energies, $\Delta E_+(M^a, M^b)$ and $\Delta E_-(M^a,M^b)$, are represented by $E(1, M^a, M^b)-E(0, M^a, M^b)$ and $E(0, M^a, M^b)-E(-1, M^a, M^b)$ respectively. When the perturbation is applied to the second order, $\delta_\pm$ is given as follows:

$$\delta_\pm=\pm A/(2J\mp g\beta H-d/6)\pm B/(2J+d/3)-C_\pm \qquad (2)$$

where:

$$A=\{A^a{}_{xx}{}^2+2A^a{}_{xy}{}^2+A^a{}_{yy}{}^2+A^b{}_{xx}{}^2+2A^b{}_{xy}{}^2+A^b{}_{yy}{}^2-2(A^a{}_{xz}+A^b{}_{xz})^2-2(A^a{}_{yz}+A^b{}_{yz})^2\}/16 \qquad (3)$$

$$B=\{2(A^a{}_{zz}+A^b{}_{zz})^2-A^a{}_{zx}{}^2-A^a{}_{zy}{}^2-A^b{}_{zx}{}^2-A^b{}_{zy}{}^2\}/8 \qquad (4)$$

$$C_\pm=(A+A^a{}_{xz}A^b{}_{zx}/2+A^a{}_{yz}A^b{}_{yz}/2)\times\{2/(g\beta H\pm d/2)-1/(g\beta H\mp d/2)\} \qquad (5)$$

The laboratory coordinates are taken as x, y and z, and the external magnetic field is parallel to the z-axis. $A^p{}_{ij}$ is the ij-element of the hyperfine tensor for the p site, g is equal to $(g^a{}_{zz}+g^b{}_{zz})/2$, and d is represented by $D(3\cos^2\Theta-1)/3$, where Θ is the angle between the axis of symmetry and the external magnetic field. D may be of the negative sign, since the odd electron is localized on the =N–O· group of the oxime[1,4] and the distance between the groups of the interactng radicals is very large (5.6 Å).[1] E is negligibly small in this case[1]. The first and second terms of Eq. 2 arise from the mixing of the singlet state with the $m=\pm 1$ and $m=0$ states of the triplet state respectively. On the other hand, the third term is brought about by the mixing within the triplet state.

From the $\delta_\pm$ values measured with four crystal orientations at the X-band, J was evaluated as $-(1.24\pm 0.12)\times 10^{-5}$ eV. In this case the second term of Eq. 2 was found to be predominant. Thus, the system is proved to be a ground-state singlet.

It may be emphasized that magnitudes and signs of J as small as 10^{-5} eV. can be determined by the present method. Details will be published elsewhere.

The Base-catalyzed Oxidation of Friedelin with Molecular Oxygen

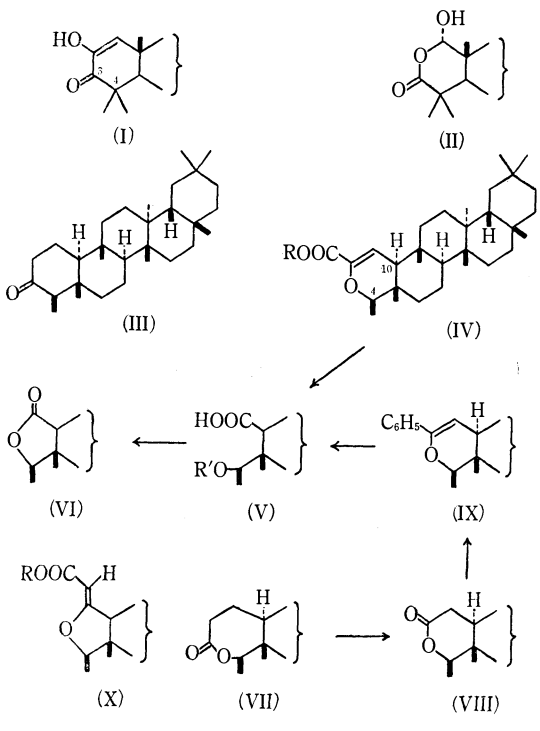
By Tadaaki NISHIHAMA and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received December 2, 1965)

The autoxidation of 3-ketotriterpenes and 3-keto-4,4-dimethylsteroids in the presence of potassium *t*-butoxide has been reported by Hanna and Ourisson, who also recorded the isolation of the corresponding 2,3-dione (I) together with lactol (II).[1)]

We now wish to report the oxidation of friedelin (III) under the same conditions, this oxidation leads to a product of a different type. Oxygen was passed into a solution of friedelin in *t*-butyl alcohol in the presence of a ten-molar excess of potassium *t*-butoxide at room temperature for 40 hr. The residue obtained, when methylated with diazomethane, gave, after separation by chromatography, an unsaturated ester (IV, R=CH_3), m. p. 214.5—215°C, λ_{max}^{EtOH} 253 mμ (ε, 8900), IR: $\nu_{C=O}$ 1720 (ester), $\nu_{C=C}$ 1640 cm^{-1}, NMR: τ 7.92 (doublet, J=2 c. p. s., 1 H, C=CH-CH), τ 6.21 (singlet, 3 H, $COOCH_3$), τ 6.08 (quartet, J=7 c. p. s., 1 H, -O-CH-CH_3) and τ 3.99 (doublet, J=2 c. p. s., 1 H, C=CH-CH), $C_{31}H_{50}O_3$ (Found: C, 78.70; H, 10.79. Calcd.: C, 79.10; H, 10.71%), whose mass spectrum shows a peak at *m/e* 470 (M^+), together with other peaks due to skeletal fragmentations.



The oxidation of IV (R=CH_3) with ozone and hydrogen peroxide gave V (not isolated); on partial reduction with lithium aluminum hydride, followed by treatment with hydrochloric acid, this afforded a lactone (VI), m. p. 269°C, $\nu_{C=O}$ 1765 cm^{-1}. The same γ-lactone was also obtained by an alternative route. 3-Keto-3a-oxa-A-homo-friedelane (VII) was, by the Barbier-Wieland procedure, converted into 2-keto-3-oxa-friedelane (VIII), m. p. 263—266°C, $\nu_{C=O}$ 1735 cm^{-1}. VIII was, then, submitted to a Grignard reaction using phenylmagnesium bromide; it yielded 2-phenyl-3-oxa-1-friedelene (IX), m. p. 223—225°C, $\nu_{C=C}$ 1640 cm^{-1}, NMR: τ 7.88 (doublet, J=2 c. p. s., 1 H, C=CH-CH), τ 6.03 (quartet, J=7 c. p. s., 1 H, -O-CH-CH_3) and τ 4.79 (doublet, J=2 c. p. s., 1 H, C=CH-CH), $C_{35}H_{52}O$ (Found: C, 86.22; H, 10.71. Calcd.: C, 86.00; H, 10.72%). The oxidation of IX with chromium trioxide afforded V (R'=COC_6H_5); on partial reduction with lithium aluminum hydride and subsequent treatment with dilute hydrochloric acid, this gave a lactone, m. p. 273—273.5°C, $\nu_{C=O}$ 1765 cm^{-1}, $C_{28}H_{46}O_2$ (Found: C, 81.40; H, 11.17. Calcd.: C, 81.10; H, 11.18%), identical (IR, m. p. and mixed m. p.) with γ-lactone (VI).

The γ-lactone (VI) obtained by either procedure described above gave one spot on a thin-layer chromatogram, while an alkaline saponification of V (R'=COC_6H_5), followed by acidification, afforded γ-lactone which showed one more spot on the same chromatogram. This indicates that the configuration at C_{10} in VI is the same as that of friedelin, and that a partial isomerization at C_{10} has taken place under alkaline conditions. On the other hand, in a conversion of VII into VI, the configuration at C_4 is untouched. Along with the information obtained from the NMR data, these results established the constitution and stereochemistry of the unsaturated ester (IV, R=CH_3). As no γ-lactone was isolated on the normal ozonolysis of the unsaturated ester, the alternative structure (X, R=CH_3) for this unsaturated ester could be eliminated. Thus the structure of IV (R=H) for the unsaturated acid initially formed was established.

Vibrational Analysis of Substituted and Perturbed Molecules. III. Green's Function Determination of Force Constants for XY_3 Planar Molecules

By Thomas WOLFRAM, C. D. BASS, Roger E. DEWAMES and L. LYNDS

North American Aviation Science Center, Thousand Oaks, California, U. S. A.

(Received Junary 26, 1965)

Using the Green's function formulae for isotopic frequencies of the XY_3 molecule together with the spectral theorem, explicit formulae for the molecular force constants directly in terms of the vibrational frequencies have been obtained. The relationship between the Wilson force constants and the cartesian force constants is discussed and leads to the above formulae. The procedure is applied to the BCl_3 and BBr_3 molecules and force constants are obtained. A simple procedure for calculating the variations in the force constants with variations in vibrational frequencies is suggested.

In previous papers[1,2] (hereafter referred to as VAI and VAII), it was shown that the vibrational frequencies of isotopically substituted molecules can be calculated using a Green's function procedure, thereby avoiding the construction of a force constant model. It was pointed out in VAI that a unique set of force constants for the molecule can be generated directly from the vibrational frequencies once the mixing parameters were known. This procedure leads to explicit expressions for the force constants in terms of the vibrational frequencies. These formulae are the inverted relationships between the force constants and frequencies. One customarily obtains by the FG procedure explicit expressions for the frequencies involving non-linear combinations of the force constants. For example, the procedure employed recently by Ladd, Orville-Thomas, and Cox[3] in the treatment of the boron trihalides involves the solution of two simultaneous non-linear equations with the three unknown force constants (for the two doubly degenerate frequencies). By assuming value for one force constant, the corresponding values of the other two are calculated. When the sets of values of the three are plotted graphically, the resulting figure is an ellipse. The isotopic frequencies yield another, intersecting ellipse. One of the intersection points corresponds to a physically acceptable set of force constants. In this paper we illustrate a quite different approach which makes use of the spectral theorem together with the Green's function isotopic formulae and leads to exact, explicit formulae for the force constants. The procedure is easily applied to the BX_3 molecules, however it is clear that the solution of the isotopic Green's function equations can become a sizable task for larger molecules with lower symmetry. Determination of the mixing parameters may approach in more complex cases the difficulty associated with a standard force constant analysis. On the other hand, once the mixing parameters are known the Green's function procedure is extremely convenient for the analysis of related or perturbed molecular systems as discussed in previous papers[1,2] and in the companion paper.

In section I the relationships between the cartesian coordinate force constants and the Wilson internal coordinate force constants are reviewed. The spectral theorem for the force constants in the Wilson FG representation is derived. Explicit formulae for force constants of XY_3 planar molecules are derived in terms of the vibrational frequencies and the mixing parameter. The discussion in section I is given in some detail because it serves as the theoretical foundation for the development of the Green's function procedure in the internal coordinate system which is presented in the companion paper. In section II the explicit formulae developed in I are used to calculate the force constants for $^{10}BCl_3$, $^{11}BCl_3$, $^{10}BBr_3$, and $^{11}BBr_3$. The mixing parameters necessary for these calculations were obtained by application of the Green's function isotopic formulae discussed in VAII. The results of the calculations are presented in section III. A simple procedure of calculating the variation of the force constants with variations in the input data (frequencies) is discussed.

I. Valence and Cartesian Molecular Force Constants

A. General Formalism.—Consider a molecule with n atoms numbered 1 through n and label

1) R. E. DeWames and T. Wolfram, *J. Chem. Phys.*, **40**, 853 (1964).
2) C. D. Bass, L. Lynds, T. Wolfram and R. E. DeWames, ibid., **40**, 3611 (1964).
3) J. A. Ladd, W. J. Orville-Thomas and B. C. Cox, *Spectrochem. Acta*, **19**, 1911 (1963).

the cartesian coordinates x_i $(i=1,2,...,3n)$ so that, for example, the three cartesian coordinates of atom 1 are x_1, x_2, x_3, and those of atom 2 are x_4, x_5, and x_6. The internal coordinates are designated by α_i $[i=1,2,...,(3n-6+r)]$ where r is the number of redundant coordinates. An arbitrary motion of the entire molecule may be represented by a supervector, $\boldsymbol{X}$ in the cartesian system

$$\boldsymbol{X}=\begin{pmatrix} x_1 \\ x_2 \\ \vdots \\ x_{3n} \end{pmatrix} \tag{1}$$

The internal symmetry coordinates do not span the entire vector space, but excluding translation and rotation, a vibratory motion of the molecule can be represented by a supervector, $\boldsymbol{\alpha}$, in the internal coordinate system

$$\boldsymbol{\alpha}=\begin{pmatrix} \alpha_1 \\ \alpha_2 \\ \vdots \\ \alpha_{3n-6+r} \end{pmatrix} \tag{2}$$

Because the cartesian coordinates span a larger vector space than the internal coordinates it is not possible to define transformation from the external to the internal coordinate system. In order to relate the two systems we must eliminate the redundant coordinates from the internal system and rotations and translations from the external system. This task is conveniently accomplished by transforming to symmetry coordinates. Let $\boldsymbol{X}_t$ $[t=(\Gamma, \nu_i)]$ be a supervector in the cartesian coordinate representation which transforms according to the νth row of the Γth irreducible representation of the group of the molecule.[4] (The subscript i on ν indexes different coordinates with identical transformation properties.) A new set of orthogonal symmetry coordinates, $\boldsymbol{S}_t$, may be constructed from the $\boldsymbol{X}_t$ as follows: The $\boldsymbol{X}_t$ corresponding to translations and rotations (about the center of mass) are mass weighted. The mass weighted vibrational type motions with identical transformation properties are then orthogonalized to the translation and rotation vectors and to each other. The symmetry coordinates, $\boldsymbol{S}_t$, then consist of orthogonalized mass weighted, translations, rotations and vibrational type motions which tranform according to the irreducible representations of the group of the molecule. The set of internal symmetry coordinates, $\boldsymbol{\sigma}_r$, which define the representation for the Wilson reduced $\boldsymbol{F}^W$ matrix do not contain translations or rotation and are not mass weighted. The $\boldsymbol{\sigma}_r$ coordinates are simply those linear combinations of the internal coordinates α_i which transform irreducibly according to the molecular group. The internal symmetry coordinates can be expressed uniquely in terms of the external coordinates (although the converse is not true) by the usual procedure[4] so that a rectangular matrix, $\boldsymbol{T}$ $(3n-6\times 3n)$, may be constructed which transforms the $\boldsymbol{\sigma}_r$ into the cartesian representation. Let us define the matrix $\boldsymbol{\sigma}$ to be a $(3n-6+r\times 3n-6)$ matrix whose columns are the non-redundant $\boldsymbol{\sigma}_r$ and let $\boldsymbol{f}$ be the matrix of (valence) force constants $(3n-6+r\times 3n-6+r)$ in the internal coordinate system, then the Wilson reduced force constant matrix, $\boldsymbol{F}^W$, $(3n-6\times 3n-6)$ in the internal symmetry coordinate system is given by

$$\boldsymbol{F}^W=\tilde{\boldsymbol{\sigma}}\boldsymbol{f}\boldsymbol{\sigma} \tag{3}$$

where $\tilde{\boldsymbol{\sigma}}$ $(3n-6\times 3n-6+r)$ is the transpose of the matrix $\boldsymbol{\sigma}$.

The cartesian coordinate matrix of force constants $\boldsymbol{F}^c$ $(3n\times 3n)$ is then given by

$$\tilde{\boldsymbol{F}}^c=\tilde{\boldsymbol{T}}\boldsymbol{F}^W\boldsymbol{T} \tag{4}$$

We may now transform the mass transformed interaction matrix[1] or dynamical matrix $\boldsymbol{D}=\boldsymbol{M}^{-1/2}\boldsymbol{F}^c\boldsymbol{M}^{-1/2}$ to the external symmetry coordinate system defined by the symmetry vectors $\boldsymbol{S}_t$ with result that

$$\boldsymbol{D}^s=\boldsymbol{S}^+\boldsymbol{D}\boldsymbol{S}=\boldsymbol{S}^+\boldsymbol{M}^{-1/2}\tilde{\boldsymbol{T}}\boldsymbol{F}^W\boldsymbol{T}\boldsymbol{M}^{-1/2}\boldsymbol{S} \tag{5}$$

where $\boldsymbol{S}^+$ is the Hermetian conjugate of $\boldsymbol{S}$, and $\boldsymbol{D}^s$ is the dynamical matrix in the cartesian or external symmetry coordinate system. $\boldsymbol{S}$, the unitary transformation from cartesian to cartesian symmetry coordinates and $\boldsymbol{M}$ the diagonal mass matrix, are discussed in Refs. 1 and 2.

A few properties of $\boldsymbol{D}^s$ should be noted; first, $\boldsymbol{D}^s$ is block diagonal in the different irreducible representations of the molecule. Furthermore, since the vibrational symmetry coordinates of $\boldsymbol{S}$ are orthogonalized to the rotation and translation eigenvectors there are no matrix elements joining the vectors to the remaining symmetry coordinates. Thus the rows and columns corresponding to rotations and translations have zero matrix elements. The matrix $\boldsymbol{D}^s$ is Hermitian and its eigenvalues are the frequencies squared. If we arrange the rotations and translations to correspond to the last 6 columns of $\boldsymbol{S}$ then a square matrix $\boldsymbol{B}$ can be defined[5]

$$\boldsymbol{B}=\{\boldsymbol{T}\boldsymbol{M}^{-1/2}\boldsymbol{S}\}_{\text{truncated}} \tag{6}$$

by removing the last 6 columns of $\boldsymbol{T}\boldsymbol{M}^{-1/2}\boldsymbol{S}$. Whereas the matrix $\boldsymbol{T}\boldsymbol{M}^{-1/2}\boldsymbol{S}$ is singular, the $\boldsymbol{B}$ matrix is non-singular, block diagonal, and its inverse can be constructed so that the Wilson $\boldsymbol{F}^W$ matrix elements can be given in terms of the symmetrized dynamical matrix.

4) See for example, Wilson, Decius and Cross, "Molecular Vibrations," McGraw-Hill, New York (1955). The connection between internal and cartesian coordinates has been discusssed previously by D. E. Mann (*J. Chem. Phys.*, **22**, 764 (1954)) and also by T. Shimanouchi and M. Tsuboi (*J. Chem. Phys.*, **35**, 1597 (1961)).

5) E. B. Wilson, J. C. Decius and P. C. Cross, *J. Mol. Spectroscopy*, ibid., **12**, 61, 74 (1964).

$$\boldsymbol{F}^W=\tilde{\boldsymbol{B}}^{-1}\boldsymbol{D}^s\boldsymbol{B}^{-1} \tag{7}$$

From Eq. 7 it follows that $\boldsymbol{B}\tilde{\boldsymbol{B}}$ is the Wilson $\boldsymbol{G}$ matrix for the molecule. The Wilson force constants can now of course be related directly to the cartesian force constants since $\boldsymbol{D}^s=\boldsymbol{S}^+\boldsymbol{D}\boldsymbol{S}=\boldsymbol{S}^+\boldsymbol{M}^{-1/2}\boldsymbol{F}^c\boldsymbol{M}^{-1/2}\boldsymbol{S}$. The relation between the internal force constants and the external cartesian force constants is given by

$$\boldsymbol{f}=\bar{\boldsymbol{\sigma}}\tilde{\boldsymbol{B}}^{-1}\boldsymbol{S}^+\boldsymbol{M}^{-1/2}\boldsymbol{F}^c\boldsymbol{M}^{-1/2}\boldsymbol{S}\boldsymbol{B}^{-1}\bar{\boldsymbol{\sigma}}^+ \tag{8}$$

where $\bar{\boldsymbol{\sigma}}$ is the $(3n-6+r\times 3n-6+r)$ matrix of all the $\boldsymbol{\sigma}_r$ including the redundant symmetry coordinates and r rows and columns of zero have been added to $\boldsymbol{F}^W$ to match the dimensionality of $\bar{\boldsymbol{\sigma}}$. (It is important to note that this corresponds to an arbitrary *definition* of f since as pointed out by Crawford and Overend[6] there is a true indeterminacy in the matrix elements associated with the redundant or null coordinates. This difinition is the same as that used in almost all force constant calculations and in particular for previous calculations for BX_3 force constants and allows us to make direct comparison with these other results. Other difinitions are, however, possible.) The matrix elements of $\boldsymbol{F}^W$ can be given directly in terms of the vibrational frequencies by making use of the spectral theorem. The matrix $\boldsymbol{D}^s$ is block diagonal and may be diagonalized by a unitary matrix $\boldsymbol{A}$ (the matrix of mixing parameters) which has non-zero matrix element only between rows and columns which correspond to the same row of the same irreducible representation, and thus $\boldsymbol{A}$ is also block diagonal. We have that

$$\boldsymbol{A}^+\boldsymbol{D}^s\boldsymbol{A}=\boldsymbol{\Lambda}$$

where

$$\boldsymbol{\Lambda}=\begin{bmatrix}\lambda_1 & & & & \\ & \lambda_2 & & & \\ & & \lambda_3 & & \\ & & & \ddots & \\ & & & & \lambda_{3N}\end{bmatrix} \tag{9}$$

is the diagonal matrix of eigenvalues. It should be noted that a knowledge of the mixing parameter matrix, $\boldsymbol{A}$, is equivalent to a knowledge of the $\boldsymbol{L}$ matrix discussed by Wilson, Decius, and Cross.[5] From Eq. 9 we can write

$$\boldsymbol{D}^s=\boldsymbol{A}\boldsymbol{\Lambda}\boldsymbol{A}^+ \tag{10}$$

so that

$$\boldsymbol{F}^W=\tilde{\boldsymbol{B}}^{-1}\boldsymbol{A}\boldsymbol{\Lambda}\boldsymbol{A}^+\boldsymbol{B}^{-1} \tag{11}$$

Since both $\boldsymbol{B}$ and $\boldsymbol{A}$ are block diagonal we can write an equation for the force constants corresponding to a particular symmetry type Γ_ν (the ν row of the Γth irreducible representation) involving only the mixing parameters for that block:

$$\{\boldsymbol{F}^W\}^{\Gamma_\nu}=\{\tilde{\boldsymbol{B}}^{-1}\}^{\Gamma_\nu}\{\boldsymbol{A}\}^{\Gamma_\nu}\{\boldsymbol{\Lambda}\}^{\Gamma_\nu}\{\boldsymbol{A}^+\}^{\Gamma_\nu}\{\boldsymbol{B}^{-1}\}^{\Gamma_\nu} \tag{12}$$

where $\{\ \}^{\Gamma_\nu}$ means the block whose rows and columns correspond to the νth row of the Γth irreducible representation. The dimensionality of the matrix Eq. 12 is equal to the number of vibrational symmetry coordinates which transform according to Γ_ν.

In VAI and VAII formulae for obtaining the mixing parameters using the Green's function approach were given. The mixing parameters, of course, allow the construction of the matrix A and thus the calculation of $\boldsymbol{F}^W$ from Eq. 11 or 12.

B. Application to the XY_3 Planar Molecule. —In this section we apply the preceding formalism to the XY_3 molecule and obtain the relations between the external and internal force constants. In anticipation of a following paper which deals with the XY_2Z planar molecule we have generalized the diagrams and force constants to the case of the XY_2Z molecule. The internal and external coordinate systems for the XY_3 and XY_2Z molecule are shown in Fig. 1.

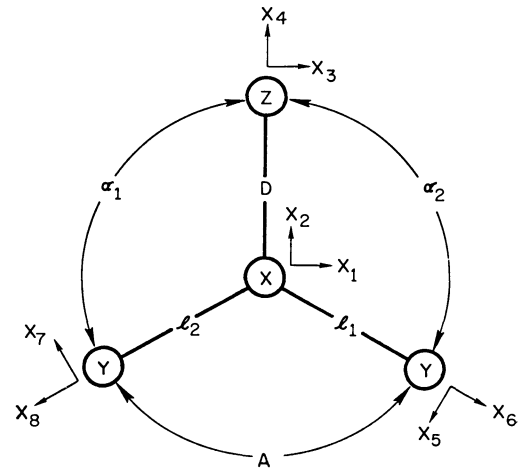

Fig. 1. Showing the internal and cartesian coordinate systems for the XY_2Z planer molecule.

In this section we shall be concerned with XY_3 molecules for which the bond lengths D, l_1 and l_2 are all of length l and the angles A, α_1 and α_2 are 120°, although no such restrictions need apply to the XY_2Z molecule. The external mass weighted symmetry coordinates for the XY_3 planar molecule given in VAII may be orthonormalized to give the unitary $\boldsymbol{S}$ matrix (13).

where $r^2=m_y/m_x$, $d_1{}^2=3r^2+1$, and $d_2{}^2=3r^2+2$. The first column of S corresponds to the A_1 symmetric stretch; the second column is a mass weighted E′ bending symmetry coordinate, and the third column is an E′ stretching symmetry coordinate which has been orthogonalized to column two. These three coordinates transform according to

6) B. Crawford and J. Overend, ibid., **12**, 307 (1964).

$$\boldsymbol{S}=\begin{pmatrix}
0 & 0 & 0 & \frac{\sqrt{3}r}{d_2} & \frac{-\sqrt{3}r}{d_1 d_2} & 0 & \frac{1}{d_1} & 0 \\
0 & \frac{\sqrt{3}r}{d_2} & \frac{-\sqrt{3}r}{d_1 d_2} & 0 & 0 & 0 & 0 & \frac{1}{d_1} \\
0 & 0 & 0 & \frac{-2}{\sqrt{3}d_2} & \frac{-\sqrt{3}r^2}{d_1 d_2} & \frac{1}{\sqrt{3}} & \frac{r}{d_1} & 0 \\
\frac{1}{\sqrt{3}} & 0 & \frac{d_2}{\sqrt{3}d_1} & 0 & 0 & 0 & 0 & \frac{r}{d_1} \\
0 & \frac{1}{d_2} & \frac{3r^2}{2d_1 d_2} & \frac{1}{\sqrt{3}d_2} & \frac{\sqrt{3}r^2}{2d_1 d_2} & \frac{1}{\sqrt{3}} & \frac{-r}{2d_1} & \frac{-\sqrt{3}r}{2d_1} \\
\frac{1}{\sqrt{3}} & 0 & \frac{-d_2}{2\sqrt{3}d_1} & 0 & \frac{d_2}{2d_1} & 0 & \frac{\sqrt{3}r}{2d_1} & \frac{-r}{2d_1} \\
0 & \frac{-1}{d_2} & \frac{-3r^2}{2d_1 d_2} & \frac{1}{\sqrt{3}d_2} & \frac{\sqrt{3}r^2}{2d_1 d_2} & \frac{1}{\sqrt{3}} & \frac{-r}{2d_1} & \frac{\sqrt{3}r}{2d_1} \\
\frac{1}{\sqrt{3}} & 0 & \frac{-d_2}{2\sqrt{3}d_1} & 0 & \frac{-d_2}{2d_1} & 0 & \frac{-\sqrt{3}r}{2d_1} & \frac{-r}{2d_1}
\end{pmatrix} \tag{13}$$

the A_1 irreducible representation for the group of the XY_2Z molecule. The fourth and fifth columns are E' bending and stretching coordinates which correspond to B_1 type coordinates for the XY_2Z molecule. The remaining columns are the in-plane rotation and translation normal modes. The internal coordinates are taken to be ΔD, Δl_1, Δl_2, $l\Delta A$, $l\Delta\alpha_1$, and $l\Delta\alpha_2$. The internal symmetry coordinates for the XY_3 molecule define the $\bar{\boldsymbol{\sigma}}$ matrix given below:

$$\bar{\boldsymbol{\sigma}}=\begin{pmatrix}
\frac{1}{\sqrt{3}} & \frac{2}{\sqrt{6}} & 0 & 0 & 0 & 0 \\
\frac{1}{\sqrt{3}} & \frac{-1}{\sqrt{6}} & 0 & \frac{1}{\sqrt{2}} & 0 & 0 \\
\frac{1}{\sqrt{3}} & \frac{-1}{\sqrt{6}} & 0 & \frac{-1}{\sqrt{2}} & 0 & 0 \\
0 & 0 & \frac{2}{\sqrt{6}} & 0 & 0 & \frac{1}{\sqrt{3}} \\
0 & 0 & \frac{-1}{\sqrt{6}} & 0 & \frac{-1}{\sqrt{2}} & \frac{1}{\sqrt{3}} \\
0 & 0 & \frac{-1}{\sqrt{6}} & 0 & \frac{1}{\sqrt{2}} & \frac{1}{\sqrt{3}}
\end{pmatrix} \tag{14}$$

The first of $\bar{\boldsymbol{\sigma}}$ is the A_1 symmetric stretch, the second is the E' stretching coordinate and the third is the E' bending. These three coordinates transform like A_1 modes for the XY_2Z symmetry. The fourth and fifth columns are E' stretching and bending coordinates which transform like B_1 modes for the XY_2Z molecule. The remaining column is the redundant symmetry coordinate and corresponds to a null vector in the cartesian coordinate system. The rectangular σ matrix is obtained from $\bar{\boldsymbol{\sigma}}$ by omitting the last column. The $\tilde{\boldsymbol{B}}$ and $\tilde{\boldsymbol{B}}^{-1}$ matrices for the XY_3 molecule are

$$\tilde{\boldsymbol{B}}=(m_y)^{-1/2}\begin{pmatrix}
1 & 0 & 0 & 0 & 0 \\
0 & \frac{-3r^2}{\sqrt{2}d_2} & \frac{-3d_2}{\sqrt{6}} & 0 & 0 \\
0 & \frac{\sqrt{2}d_1}{d_2} & 0 & 0 & 0 \\
0 & 0 & 0 & \frac{-3r^2}{\sqrt{2}d_2} & \frac{-3d_2}{\sqrt{6}} \\
0 & 0 & 0 & \frac{\sqrt{2}d_1}{d_2} & 0
\end{pmatrix} \tag{15}$$

and

$$\tilde{\boldsymbol{B}}^{-1}=(m_y)^{1/2}\begin{pmatrix}
1 & 0 & 0 & 0 & 0 \\
0 & 0 & \frac{d_2}{\sqrt{2}d_1} & 0 & 0 \\
0 & \frac{-\sqrt{6}}{3d_2} & \frac{-3r^2}{\sqrt{6}d_1 d_2} & 0 & 0 \\
0 & 0 & 0 & 0 & \frac{d_2}{\sqrt{2}d_1} \\
0 & 0 & 0 & \frac{-\sqrt{6}}{3d_2} & \frac{-3r^2}{\sqrt{6}d_1 d_2}
\end{pmatrix} \tag{16}$$

The internal force constant matrix $\boldsymbol{f}$ is

$$\boldsymbol{f}=\begin{pmatrix}
f_D & f_{Dd} & f_{Dd} & f_{DA} & f_{D\alpha} & f_{D\alpha} \\
f_{Dd} & f_d & f_{dd} & f_{dA} & f_{d\alpha} & f'_{d\alpha} \\
f_{Dd} & f_{dd} & f_d & f_{dA} & f'_{d\alpha} & f_{d\alpha} \\
f_{DA} & f_{dA} & f_{dA} & f_A & f_{A\alpha} & f_{A\alpha} \\
f_{D\alpha} & f'_{d\alpha} & f'_{d\alpha} & f_{A\alpha} & f_\alpha & f_{\alpha\alpha} \\
f_{D\alpha} & f_{d\alpha} & f_{d\alpha} & f_{A\alpha} & f_{\alpha\alpha} & f_\alpha
\end{pmatrix} \tag{17}$$

in the case of the XY_3 planar molecule $f_D=f_d\equiv f_r$, $f_A=f_\alpha\equiv f_\alpha$, $f_{dA}=f_{d\alpha}\equiv f_{r\alpha}$, $f_{DA}=f'_{d\alpha}\equiv f'_{r\alpha}$, $f_{dd}=f_{Dd}\equiv f_{rr}$, and $f_{A\alpha}=f_{\alpha\alpha}\equiv f_{\alpha\alpha}$.

where, following Lindeman and Wilson,[7] we have distinguished the adjacent angle-bond force constant, $f_{d\alpha}$, from the opposite angle-bond interaction, $f'_{d\alpha}$.

The redundancy conditions reduce the number of independent internal force constants to 9 in the case of the XY_2Z molecule with the relations

$$\left.\begin{aligned} f_{D\alpha} &= -\frac{1}{2}f_{DA} \\ f'_{d\alpha} &= -(f_{dA}+f_{d\alpha}) \\ f_{A\alpha} &= -\frac{1}{2}f_{A} \\ f_{\alpha\alpha} &= \frac{1}{2}f_{A}-f_{\alpha} \end{aligned}\right\} \quad (18)$$

For XY_3 molecules, $f_D=f_d$, $f_{Dd}=f_{dd}$, $f_A=f_\alpha$, $f_{DA}=f'_{d\alpha}$, and $f_{dA}=f_{d\alpha}$, which leaves four independent force constants. The Wilson reduced $\boldsymbol{F}^W$ matrix in the internal symmetry coordinates for the XY_2Z molcecule is

$$\boldsymbol{F}^W=\tilde{\boldsymbol{\sigma}}\boldsymbol{f}\boldsymbol{\sigma}=\left\{\begin{pmatrix} F_{11} & F_{12} & F_{13} \\ F_{12} & F_{22} & F_{23} \\ F_{13} & F_{23} & F_{33} \end{pmatrix}\begin{pmatrix} 0 & 0 \\ 0 & 0 \\ 0 & 0 \end{pmatrix}\right\} \quad (19)$$
$$\left\{\begin{pmatrix} 0 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}\begin{pmatrix} F_{44} & F_{45} \\ F_{54} & F_{55} \end{pmatrix}\right\}$$

The F_{ij} have been given in terms of the f_{ij} by Lindeman and Wilson; however, because of a number of typographical errors in their paper the corrected relations are listed here.[7]

$$\left.\begin{aligned} F_{11} &= \frac{1}{3}(f_D+2f_d+4f_{Dd}+2f_{dd}) \\ F_{12} &= \frac{1}{3\sqrt{2}}(2f_D-2f_d+2f_{Dd}-2f_{dd}) \\ F_{13} &= \frac{1}{3\sqrt{2}}(2f_{DA}-2f'_{d\alpha}+4f_{dA} \\ &\quad -2f_{d\alpha}-2f_{d\alpha}) \\ &= \frac{1}{\sqrt{2}}(f_{DA}+2f_{dA}) \\ F_{22} &= \frac{1}{6}(4f_D+2f_d-8f_{Dd}+2f_{dd}) \\ F_{23} &= \frac{1}{6}(4f_{DA}+2f'_{d\alpha}-4f_{dA}-4f_{D\alpha} \\ &\quad +2f_{d\alpha}) = f_{DA}-f_{dA} \\ F_{33} &= \frac{1}{6}(4f_A+2f_\alpha-8f_{A\alpha}+2f_{\alpha\alpha}) \\ &= \frac{3}{2}f_A \\ F_{44} &= f_d-f_{dd} \\ F_{45} &= f'_{d\alpha}-f_{d\alpha} = -(2f_{d\alpha}+f_{dA}) \\ F_{55} &= f_\alpha-f_{\alpha\alpha} = -\frac{1}{2}f_A+2f_\alpha \end{aligned}\right\} \quad (20)$$

In the case of the XY_3 molecule, $F_{12}=F_{13}=0$, $F_{22}=F_{44}$, $F_{33}=F_{55}$, and $F_{23}=F_{45}$. Using Eq. 7 one obtains the relations between the external symmetrized (mass weighted) force constants D_{ij}^s and the Wilson $\boldsymbol{F}^W$ force constants for the XY_3 molecule:

$$\left.\begin{aligned} F_{11} &= m_y D_{11}^s \\ F_{22} &= F_{44} = \frac{m_y d_2^2}{2d_1^2}D_{33}^s \\ F_{33} &= F_{55} = m_y\frac{2}{3d_2^2}D_{22}^s+\frac{2m_y r^2}{d_1 d_2^2}D_{23}^s \\ &\quad +\frac{3}{2}m_y\frac{r^4}{d_1^2 d_2^2}D_{33}^s \\ F_{23} &= -m_y\frac{1}{3d_1^2}\left\{d_1 D_{23}^s+\frac{3}{2}r^2 D_{33}^s\right\} \end{aligned}\right\} \quad (21)$$

Equation 7 may be inverted to give

$$\left.\begin{aligned} D_{11}^s &= F_{11}/m_y \\ D_{12}^s &= D_{13}^s = 0 \\ D_{22}^s &= \frac{9}{2m_y}\left(\frac{r^4}{d_2^2}F_{22}+\frac{2r^2}{\sqrt{3}}F_{23}\right. \\ &\quad \left.+\frac{d_2^2}{3}F_{33}\right) \\ D_{23}^s &= \frac{-3d_1}{m_y}\left(\frac{r^2}{d_2^2}F_{22}+\frac{1}{\sqrt{3}}F_{23}\right) \\ D_{33}^s &= \frac{2}{m_y}\frac{d_1^2}{d_2^2}F_{22} \\ D_{44}^s &= D_{22}^s \\ D_{45}^s &= D_{23}^s \\ D_{55}^s &= D_{33}^s \end{aligned}\right\} \quad (22)$$

The mixing parameter matrix for the XY_3 molecule is (see VAII)

$$\boldsymbol{A}=\begin{pmatrix} 1 & & & & & \\ & \frac{1}{A_0}\begin{pmatrix} a & 1 \\ 1 & -a \end{pmatrix} & & & & \\ & & \frac{1}{A_0}\begin{pmatrix} a & 1 \\ 1 & -a \end{pmatrix} & & & \\ & & & 1 & & \\ & & & & 1 & \\ & & & & & 1 \end{pmatrix} \quad (23)$$

where $A_0=(a^2+1)^{1/2}$.

Using Eq. 11 one obtains the Wilson force constants directly in terms of the frequencies of vibration and the mixing parameter a:

\end{aligned}\right\}\quad(24)$$

where in Eq. 24 we have used the fact that $\lambda_2=\lambda_4$ and $\lambda_3=\lambda_5$. $\boldsymbol{F}^W$ can also be given directly in terms of $\boldsymbol{F}^c$ with the result that for the XY_3 molecule

$$\left.\begin{aligned}
F_{11}&=F_{44}{}^c+2F_{46}{}^c\\
F_{33}&=\frac{1}{2}F_{33}{}^c\\
F_{23}&=F_{36}{}^c\\
F_{22}&=F_{44}{}^c-F_{46}{}^c
\end{aligned}\right\}\quad(25)$$

II. Force Constants For BCl_3 and BBr_3

In this section we apply the equations given by 24 and calculate the Wilson force constants. In order to accomplish this we must first determine the mixing parameter a. The quadratic equation which determines a is (see VAII)

$$\begin{aligned}
a^2\left\{\frac{\lambda_2+\lambda_3}{(1+\varepsilon)d_1{}^2}(d_1{}^2+\varepsilon)+\frac{3r^2\varepsilon}{(1+\varepsilon)d_1{}^2 d_2{}^2}(d_1{}^2\lambda_3+\lambda_2)\right.\\
\left.-(\lambda_2{}^{(i)}+\lambda_3{}^{(i)})^2\right\}+a\left(\frac{6r^2\varepsilon}{(1+\varepsilon)d_1 d_2}(\lambda_2-\lambda_3)\right)\\
+\left\{\frac{\lambda_2+\lambda_3}{(1+\varepsilon)d_1{}^2}(d_1{}^2+\varepsilon)+\frac{3r^2\varepsilon}{(1+\varepsilon)d_1{}^2 d_2{}^2}\right.\\
\left.\times(d_1{}^2\lambda_2+\lambda_3)-(\lambda_2{}^{(i)}+\lambda_3{}^{(i)})\right\}=0\qquad(26)
\end{aligned}$$

where $\varepsilon=(m^{(i)}-m)/m$, λ_1 is the symmetric stretching frequency, λ_2 is the degenerate asymmetric stretching frequency, and λ_3 is the degenerate bending frequency. $\lambda_2{}^{(i)}$ and $\lambda_3{}^{(i)}$ are the corresponding frequencies for the isotopic molecule. If m is in atomic mass units, and $\lambda_i=5.8894\times 10^{-2}\ \nu_i{}^2$ (ν_i is the observed frequency in cm^{-1}) then the F's are in units of dynes/cm. The λ's should be the zero order frequencies, and if these are available, then the equations constitute an exact determination of the molecular force constants.

The valence force constants are given by

$$\left.\begin{aligned}
f_r&=\frac{1}{3}(F_{11}+2F_{44}),\quad f'_{r\alpha}-f_{r\alpha}=F_{23}\\
f_{rr}&=\frac{1}{3}(F_{11}-F_{44}),\quad f_\alpha-f_{\alpha\alpha}=F_{55}
\end{aligned}\right\}\quad(27)$$

A number of sets of force constants available in the literature have recently been tabulated by Duncan[8] and consequently no summary of these calculations will be given in this paper. Various sets of observed frequencies are also available.[7,9,10] The frequencies used to compute the mixing parameters and force constants are listed in Table I. These sets were selected on the basis of reproducing results of other experiments on "perturbed systems" derived from the BX_3 molecules.[11] Selection of the mixing parameters from the two solutions of Eq. 26 was also made on this basis. Results for two sets of frequencies for the same molecule, BBr_3, are included to illustrate the effect of small changes in frequencies on the values of the force constants.

The results are shown in Table II. Calculations were made for $^{10}BY_3$ as the unperturbed molecule. Starting with the ^{11}B-species leads to slightly different values, due to anharmonicities. The force constants are quoted to five places only for comparison with those calculated in Ref. 3 for identical frequencies, which are also listed in Table I. The differences between our values and those of Ladd, Orville-Thomas, and Cox[3] are rather large. Small changes in F_{22} and F_{33} require a large change in F_{23}. This illustrates the inherent numeralogical difficulty of dealing with the non-linear equations. Inspection of the results for two different sets of input frequencies for BBr_3 emphasizes this point even more strongly. Thus, while it is possible, using the Green's function, to obtain a high degree of internal consistency, the force constants should in reality be considered known to, at most, two significant figures. The reason for the large variation in force constants with a small change in frequencies becomes apparent on inspection of Eq. 26: the mixing parameter is critically dependent on a small number, which is the difference between two large numbers.

11) See VAII for results on BCl_3-$HBCl_2$. Also, we have carried out calculations on a series of mixed boron halides, and on $HBBr_2$ and HBF_2 which have subsequently been prepared and observed (L. Lynds). The results of these experiments and calculations will be reported at a later date.

Conclusions

Using the Green's function approach to analyze the dynamics of molecular systems, we have obtained explicit expressions for the force constants of XY_3 planar molecules. Application of these formulae is quite simple and extremely convenient. It is important to point out that the variation in the force constants with the frequencies can be studied quite simply from Eqs. 24 and 26. For example, if a range of values is specified for the XY_3 and $XY_3{}^{(i)}$ vibrational frequencies then the corresponding range in the mixing parameter can be determined from Eq. 26. This range in the mixing parameter then determines the range of values for the force constants by use of Eq. 24.

Internal Coordinate Green's Function Analysis of Molecular Vibrations with Application to XY_2Z Planar Molecules

By Thomas WOLFRAM and Roger E. DEWAMES

North American Aviation Science Center, Thousand Oaks, California, U. S. A.

(Received January 26, 1965)

The Green's function formalism for the analysis of molecular vibrations has been formulated for the internal or valence coordinate system. A general procedure for calculating isotopic frequencies and changes in force constants associated with the characterization of a perturbed molecule in terms of the unperturbed molecule is developed. It is shown that the internal molecular Green's function can be constructed from the vibrational frequencies of the unperturbed molecule. Application is made to the XY_2Z planar molecule. Exact formulae for the $XY_2Y^{(i)}$ molecule are obtained. The shifts in the frequencies of an XY_2Z planar molecule due to mass and bond length changes are obtained. It is shown that the A_1 modes are unaffected by a change in the X–Z bond length while the B_1 modes move to higher frequencies as the bond distance decreases. An explicit expression for the change in the valence bond bending force constant, f_α, is obtained as an example of how force constant changes can be studied by means of the Green's function procedure. Qualitative results for $HBCl_2$ and $HBBr_2$ are obtained which indicate that f_α decreases in going from $BCl_3 \rightarrow HBCl_2$.

The purpose of this paper is to develop a well defined and exact procedure for relating the vibrational properties of similar molecules. The use of the Green's function procedure to obtain frequencies of isotopic molecules and approximate frequencies for $HBCl_2$ has been described in previous papers;[1-3] (hereafter referred to as VAI–III).

In these previous papers the Green's function procedure was developed for use in the cartesian coordinate system. The cartesian coordinate representation is reasonably convenient for treating the isotope problem but completely unsuited for introducing geometry changes. The Wilson FG representation appears to be the most convenient representation for formulating the general problem of relating the dynamics of similar molecules. For example, since the $\boldsymbol{G}$ matrix contains the geometry and masses of the molecule, changes in these parameters are conveniently handled by introducing a change in the $\boldsymbol{G}$ matrix, $\Delta\boldsymbol{G}$. It is also desirable to be able to separate the effects of force constant changes from these other effects. The essential idea of the approach may be illustrated as follows. Consider the problem of determining the force field of $HBCl_2$. One has at one's disposal the observed fundamental frequencies of $HBCl_2$ as well as those of BCl_3 and its isotopes. Using the Green's function formulae for isotopic substitution $XY_3 \rightarrow X^{(i)}Y_3$ one can determine the Green's function for BCl_3 as was demonstrated in a previous paper.[2] The first step in the analysis of $HBCl_2$ is to treat this molecule as if it possessed the same force field as BCl_3 and differed from BCl_3 only in that the hydrogen mass has replaced the chlorine mass and that the B–H bond length may be different from the B–Cl bond. The frequencies of this fictitious molecule, the mass-geometry shifted frequenceis, may be easily calculated using the Green's function procedure. These fictitious frequencies may be compared with the actual observed frequencies and the differences attributed entirely to changes in the Wilson $\boldsymbol{F}$ matrix. The point here is that two different molecules with identical $\boldsymbol{F}$ matrices will have different vibrational frequencies because of mass and geometry differences. The fictitious frequencies are corrected for these effects and comparison of these frequencies with the observed frequencies gives immediately a qualitative measure of the changes in the force constants. The last step in the analysis is to obtain by use of the Green's function method the change in force constants directly from the observed frequencies. This step-by-step analysis allows one to make maximum use of the similarity between the two systems. It should be pointed out here that the idea of using knowledge about one molecule to calculate the properties of another is not new. Previous techniques[4] which have been suggested, however, are perturbation schemes and depend upon the smallness of the off diagonal matrix elements. The Green's function procedure, on the other hand, is formally exact and imposes no such restrictions. A similar procedure has also been developed by the Uppsala Quantum Chemistry Group[5] for the study of molecular wave functions. In this paper we develop the Green's function approach for the internal or valence coordinate system. One advantage of this system is, of course, that one avoids the necessity of constructing the rotation and translation eigenvectors. Furthermore, correlation of molecules with different geometries appears to be most conveniently treated in the internal coordinate system because the geometry is contained explicitly in the Wilson $\boldsymbol{G}$ matrix.

In section I, the Green's function formalism is developed in the internal coordinate system for both the GF and FG representation. The analysis is oriented towards either calculating the frequencies of isotopic molecules or the force constants changes which characterize a new species.

By making extensive use of the spectral theorem for the dynamical matrix, and the transformation between internal and cartesian coordinates, it is shown in section II that the Green's function for the internal coordinates can be constructed directly from the "unperturbed" vibrational frequencies without a knowledge of the molecular force constants.

In section III the procedure is applied to the XY_2Z planar molecule. The frequencies of this molecule differ from those of the XY_3 molecule because of changes in mass, geometry and force constants. Explicit formulas for the mass and geometry corrected frequencies of an XY_2Z molecule whose X–Z bond length differs from the X–Y bond length of the XY_3 molecule are obtained. It is shown that this bond length change affects only the B_1 type vibrational modes and that the resulting frequency shifts can be quite large when the mass of the Z atom is much less than that of the Y atom. An explicit expression for studying the change in the valence bond-bending force constants, f_α, which includes the effects of changes in mass and X–Y bond length is derived. Using an X–Z bond length of 1.20 Å for $HBCl_2$ one arrives at the qualitative result that the bond bending force constant, f_α, is decreased on the order of 20% on going from BCl_3 to $HBCl_2$.

I. Internal Coordinate Green's Functions

In this section the Green's function formalism is developed in the internal or valence coordinate system from which the vibrational frequencies of a "perturbed" molecule can be obtained exactly in terms of the vibrational frequencies of the "unperturbed" molecule. The "perturbed" and "unperturbed" molecules are any two molecules whose internal coordinates can be set in a one to one correspondence. The utility of the approach is greatly enhanced when the two molecules whose vibrational properties are to be correlated are, in addition, physically similar. For example, if $^{10}B^{35}Cl_3$ is considered to be the "unperturbed" molecule, then the isotopes $^{11}B^{35}Cl_3$ and $^{10}B^{35}Cl_2{}^{37}Cl$ or the new species $H^{10}B^{35}Cl_2$ and $D^{10}B^{35}Cl_2$ may be selected as "perturbed" molecules.

The unperturbed molecule's vibrational frequencies are (in the internal symmetry coordinate system) determined, according to the Wilson procedure, by the secular matrix equation

$$(\boldsymbol{G}_0\boldsymbol{F}_0-\lambda)\boldsymbol{R}=0 \tag{1}$$

or

$$(\boldsymbol{F}_0\boldsymbol{G}_0-\lambda)\boldsymbol{G}_0{}^{-1}\boldsymbol{R}=0 \tag{2}$$

where $\boldsymbol{G}_0$ and $\boldsymbol{F}_0$ are the reduced Wilson $\boldsymbol{G}$ and $\boldsymbol{F}$ matrices for the unperturbed molecule. (The redundant coordinates are omitted) λ is the square of the angular frequency, $\boldsymbol{\omega}$ and $\boldsymbol{R}$ symbolize the internal symmetry coordinate vectors. Equation 2, of course, can be obtained from Eq. 1 by a similarity transformation with the matrix $\boldsymbol{G}_0$. The secular equation for the perturbed molecule is

$$\{(\boldsymbol{G}_0+\Delta\boldsymbol{G})(\boldsymbol{F}_0+\Delta\boldsymbol{F})-\lambda\}\boldsymbol{R}=0 \tag{3}$$

or

$$\{(\boldsymbol{F}_0+\Delta\boldsymbol{F})(\boldsymbol{G}_0+\Delta\boldsymbol{G})-\lambda\}\boldsymbol{G}_0{}^{-1}\boldsymbol{R}=0 \tag{4}$$

where $\boldsymbol{G}_p=\boldsymbol{G}_0+\Delta\boldsymbol{G}$ is the $\boldsymbol{G}$ matrix for the perturbed molecule. The $\Delta\boldsymbol{G}$ matrix accounts for changes in mass and geometry in going from the unperturbed to the perturbed system and $\Delta\boldsymbol{F}$ accounts for the force constant differences.

1. Isotope Case, $\Delta\boldsymbol{F}=0$.—When the perturbed molecule is an isotope of the initial molecule so that $\Delta\boldsymbol{F}=0$ we have for Eqs. 3 and 4

$$(\boldsymbol{G}_0\boldsymbol{F}_0-\lambda+\Delta\boldsymbol{G}\boldsymbol{F}_0)\boldsymbol{R}=0 \tag{5}$$

or

$$(\boldsymbol{F}_0\boldsymbol{G}_0-\lambda+\boldsymbol{F}_0\Delta\boldsymbol{G})\boldsymbol{G}_p{}^{-1}\boldsymbol{R}=0 \tag{6}$$

The eigenvalues are obtained by requiring the determinant to vanish. By factoring out $(\lambda-\boldsymbol{G}_0\boldsymbol{F}_0)$ from Eq. 5 we obtain the secular equations

$$|\boldsymbol{I}-\boldsymbol{J}_0(\lambda)\Delta\boldsymbol{G}\boldsymbol{F}_0|=0 \tag{7}$$

and

$$|\boldsymbol{J}_0{}^{-1}(\lambda)|=0 \tag{8}$$

where

$$\boldsymbol{J}_0(\lambda)=(\lambda-\boldsymbol{G}_0\boldsymbol{F}_0)^{-1}$$

is the Green's function for the unperturbed molecule and $\boldsymbol{I}$ is a unit matrix. Equation 8 gives the frequencies for the unperturbed molecule and Eq. 7 determines the isotopically shifted frequencies. Similarly we obtain from Eq. 6 the secular determinants

$$|\boldsymbol{I}-\boldsymbol{L}_0(\lambda)\boldsymbol{F}_0\Delta\boldsymbol{G}|=0 \tag{9}$$

$$|\boldsymbol{L}_0(\lambda)^{-1}|=0 \tag{10}$$

where

$$\boldsymbol{L}_0(\lambda)=(\lambda-\boldsymbol{F}_0\boldsymbol{G}_0)^{-1}=\boldsymbol{G}_0{}^{-1}\boldsymbol{J}_0(\lambda)\boldsymbol{G}_0 \tag{11}$$

Equation 9 is preferred to Eq. 7 when the $\Delta\boldsymbol{G}$ matrix is dimensionally smaller than $\boldsymbol{F}_0$ since Eq. 9 is truncated to the size of $\Delta\boldsymbol{G}$. Both Eqs. 7 and 9 can also be applied to the case in which geometry changes are considered. The utility of these equations obviously depends upon the elimination of the matrix $\boldsymbol{F}_0$. We shall show in the next section that the $\boldsymbol{F}_0$ matrix can, by making use of the spectral theorem, be replaced by a matrix involving the unperturbed vibrational frequencies.

All of the matrices involved are block diagonal according to the irreducible representation of the unperturbed molecule except for $\Delta\boldsymbol{G}$ which is block diagonalized according to the perturbed symmetry. Consequently, Eqs. 7 and 9 hold for each perturbed symmetry type, Γ,

$$|\boldsymbol{I}-\boldsymbol{J}_0{}^{\Gamma}(\lambda)\Delta\boldsymbol{G}^{\Gamma}\boldsymbol{F}_0{}^{\Gamma}|=0 \tag{7a}$$

or

$$|\boldsymbol{I}-\boldsymbol{L}_0{}^{\Gamma}(\lambda)\boldsymbol{F}_0{}^{\Gamma}\Delta\boldsymbol{G}^{\Gamma}|=0 \tag{9a}$$

where the superscript Γ refers to the Γ-type block of the matrices. $\boldsymbol{F}_0{}^{\Gamma}$, for example, contains those symmetry blocks of $\boldsymbol{F}_0$ which are coupled by $\Delta\boldsymbol{G}^{\Gamma}$ and gives rise to the Γ block of the perturbed symmetry. In subsequent equations it is to be assumed that an equivalent equation holds for each perturbed symmetry type.

2. General Case.—In the most general case both $\Delta\boldsymbol{F}$ and $\Delta\boldsymbol{G}$ are non-vanishing. One then obtains the determinantal equations

$$|\boldsymbol{I}-\boldsymbol{J}_p(\lambda)\boldsymbol{G}_p\Delta\boldsymbol{F}|=0 \tag{12}$$

$$|\boldsymbol{J}_p{}^{-1}(\lambda)|=0 \tag{13}$$

where

$$\boldsymbol{J}_p(\lambda)=(\lambda-\boldsymbol{G}_p\boldsymbol{F}_0)^{-1} \tag{14}$$

The matrix $\boldsymbol{J}_p(\lambda)$ is evidently the Green's function for a fictitious molecule having the geometry and mass of the perturbed molecule and the force constants of the unperturbed molecule. The eigenvalues of Eq. 12 are the vibrational frequencies of the perturbed molecule which are affected by $\Delta\boldsymbol{F}$ as well as $\Delta\boldsymbol{G}$. In the circumstance that a frequency is unaffected by $\Delta\boldsymbol{F}$ but shifted by $\Delta\boldsymbol{G}$ then this eigenvalue will be determined by Eq. 13.

(In section II we show that $\boldsymbol{J}_p(\lambda)$ can be obtained from $\boldsymbol{J}_0(\lambda)$. We can also obtain from Eq. 2

$$\boldsymbol{K}_p(\lambda)^{-1}[\boldsymbol{I}-\boldsymbol{K}_p(\lambda)(\boldsymbol{F}_0+\Delta\boldsymbol{F})\Delta\boldsymbol{G}]=0 \quad (15)$$

where

$$\boldsymbol{K}_p(\lambda)=[\lambda-(\boldsymbol{F}_0+\Delta\boldsymbol{F})\boldsymbol{G}_0]^{-1} \quad (16)$$

which leads to the determinants

$$|\boldsymbol{I}-\boldsymbol{K}_p(\lambda)(\boldsymbol{F}_0+\Delta\boldsymbol{F})\Delta\boldsymbol{G}|=0 \quad (17)$$

and

$$|\boldsymbol{K}_p(\lambda)^{-1}|=0 \quad (18)$$

Equation 18 gives the eigenvalues of a fictitious molecule with the perturbed molecule force constants and the geometry and mass of the unperturbed molecule, and Eq. 17 gives the perturbed molecular frequencies. This form of the secular equation is convenient when $\Delta\boldsymbol{G}$ truncates the matrix to a small dimension, or in the case that one makes a power series expansion of $\boldsymbol{K}_p(\lambda)$ for small $\Delta\boldsymbol{F}$.

A calculation of the force constant changes, $\Delta\boldsymbol{F}$, associated with the characterization of the new species XY_2Z may be made by using either Eq. 12 or 17. The matrix elements of $\Delta\boldsymbol{F}$ appear as parameters in the equations and if the perturbed frequencies are known then $\Delta\boldsymbol{F}$ may be determined. The frequencies of any isotope of the perturbed XY_2Z molecule can be utilized to give additiona equations for the $\Delta\boldsymbol{F}$ matrix elements. In Eq. 17 one simply substitutes $\Delta\boldsymbol{G}+\Delta\boldsymbol{G}_p(\text{isotope})$ for $\Delta\boldsymbol{G}$ where

$$\Delta\boldsymbol{G}_p(\text{isotope})=\boldsymbol{G}_p(\text{isotope})-\boldsymbol{G}_p \quad (19)$$

In Eq. 12 one must use the new Green's function

$$\begin{aligned}\boldsymbol{J}_p(\lambda)(\text{isotope})&=(\lambda-\boldsymbol{G}_p(\text{isotope})\boldsymbol{F}_0)^{-1}\\&=(\boldsymbol{I}-\boldsymbol{J}_p(\lambda)\Delta\boldsymbol{G}_p(\text{isotope})\boldsymbol{F}_0)^{-1}\boldsymbol{J}_p(\lambda)\end{aligned} \quad (20)$$

II. Construction of Green's Functions

In this section we show how the Green's functions $\boldsymbol{J}_0(\lambda)$, $\boldsymbol{J}_p(\lambda)$, $\boldsymbol{L}_0(\lambda)$, and $\boldsymbol{K}_p(\lambda)$ can be constructed starting from the spectral representation. It was shown in VAIII[3] that the vibrational part of the dynamical matrix in the cartesian symmetry representation, $\boldsymbol{D}^s$, was related to the Wilson reduced force constant matrix $\boldsymbol{F}$ by the congruent transformation

$$\tilde{\boldsymbol{B}}\boldsymbol{F}\boldsymbol{B}=\boldsymbol{D}^s \quad (21)$$

and that

$$\boldsymbol{B}\tilde{\boldsymbol{B}}=\boldsymbol{G} \quad (22)$$

where

$$\boldsymbol{B}=\boldsymbol{T}\boldsymbol{M}^{-1/2}\boldsymbol{S} \quad (23)$$

and $\tilde{\boldsymbol{B}}$ is the transpose of $\boldsymbol{B}$. $\boldsymbol{T}$ is the transformation from the internal symmetry coordinates to the cartesian coordinates, $\boldsymbol{M}$ is the diagonal mass matrix and $\boldsymbol{S}$ is the transformation from the cartesian coordinates to the orthonormal mass weighted cartesian vibrational symmetry coordinates.

The matrix $\boldsymbol{D}^s$ has the square of the angular vibrational frequencies, λ_i, for its eigenvalues and is diagonalized by the unitary matrix $\boldsymbol{A}$

$$\boldsymbol{A}^+\boldsymbol{D}^s\boldsymbol{A}=\boldsymbol{\Lambda} \quad (24)$$

$$\Lambda_{ij}=0 \quad i\neq j \quad (25)$$

$$\Lambda_{ii}=\lambda_i \quad (26)$$

where $\boldsymbol{A}^+$ is the Hermetian conjugate of $\boldsymbol{A}$. The matrix $\boldsymbol{A}$ is the matrix of mixing parameters discussed in previous papers,[1-3] where it was shown that $\boldsymbol{A}$ can be determined directly from isotope data on the XY_3 molecule. Making use of the above equations one finds that

$$\boldsymbol{F}_0=\tilde{\boldsymbol{H}}^{-1}\boldsymbol{\Lambda}\boldsymbol{H}^{-1} \quad (27)$$

$$\boldsymbol{G}_0\boldsymbol{F}_0=\boldsymbol{H}\boldsymbol{\Lambda}\boldsymbol{H}^{-1} \quad (28)$$

and

$$\boldsymbol{F}_0\boldsymbol{G}_0=\tilde{\boldsymbol{H}}^{-1}\boldsymbol{\Lambda}\tilde{\boldsymbol{H}} \quad (29)$$

where

$$\boldsymbol{H}=\boldsymbol{B}\boldsymbol{A} \quad (30)$$

Thus,

$$\boldsymbol{J}_0(\lambda)=\boldsymbol{H}(\lambda-\boldsymbol{\Lambda})^{-1}\boldsymbol{H}^{-1} \quad (31)$$

and

$$\boldsymbol{L}_0(\lambda)=\tilde{\boldsymbol{H}}^{-1}(\lambda-\boldsymbol{\Lambda})^{-1}\tilde{\boldsymbol{H}}=\tilde{\boldsymbol{J}}_0(\lambda) \quad (32)$$

Thus we see that $\boldsymbol{J}_0$ and $\boldsymbol{L}_0$ can be constructed from the unperturbed vibrational frequencies and the mixing parameters. The mixing parameters can be obtained from isotope data as discussed in VAI[1] and II[2] or from Coriolis and centrifugal distortion constants.[6] From Fq. 31 it is clear that $\boldsymbol{J}_0(\lambda)$ is just the internal coordinate representation of the vibrational part of the cartesian symmetry coordinate Green's function $\boldsymbol{D}^s$ discussed in VAIII.[3]

It should be pointed out again that all of the above equations hold for each of the symmetry types, Γ.

The matrix $\boldsymbol{J}_p(\lambda)$ can be constructed directly with the result that

$$\boldsymbol{J}_p(\lambda)=\boldsymbol{H}(\lambda-(\boldsymbol{I}+\Delta\boldsymbol{G}_t)\boldsymbol{\Lambda})^{-1}\boldsymbol{H}^{-1} \quad (33)$$

where $\Delta\boldsymbol{G}_t$ is the transformed $\Delta\boldsymbol{G}$ matrix

$$\Delta\boldsymbol{G}_t=\boldsymbol{H}^{-1}\Delta\boldsymbol{G}\tilde{\boldsymbol{H}}^{-1} \quad (34)$$

We may also construct $\boldsymbol{J}_p(\lambda)$ from $\boldsymbol{J}_0(\lambda)$ since

$$\boldsymbol{J}_p(\lambda)=[\boldsymbol{I}-\boldsymbol{J}_0(\lambda)\Delta\boldsymbol{G}\tilde{\boldsymbol{H}}^{-1}\boldsymbol{\Lambda}\boldsymbol{H}^{-1}]^{-1}\boldsymbol{J}_0(\lambda) \quad (35)$$

Similarly for $\boldsymbol{K}_p(\lambda)$ we obtain,

$$\boldsymbol{K}_p(\lambda)=\tilde{\boldsymbol{H}}^{-1}(\lambda-\boldsymbol{\Lambda}-\Delta\boldsymbol{F}_t)^{-1}\tilde{\boldsymbol{H}} \quad (36)$$

where $\Delta\boldsymbol{F}_t$ is the transformed $\Delta\boldsymbol{F}$ matrix

$$\Delta\boldsymbol{F}_t=\tilde{\boldsymbol{H}}\Delta\boldsymbol{F}\boldsymbol{H} \quad (37)$$

6) J. S. Margolis and C. D. Bass, *J. Chem. Phys.*, **40**, 1590 (1964).

$\boldsymbol{K}_p$ may also be written in terms of $\boldsymbol{L}_0$,

$$\boldsymbol{K}_p(\lambda)=[\boldsymbol{I}-\boldsymbol{L}_0(\lambda)\Delta\boldsymbol{F}\boldsymbol{G}_0]^{-1}\boldsymbol{L}_0(\lambda) \tag{38}$$

It is important to realize that in all cases the $\boldsymbol{H}$ matrix refers to the unperturbed molecule and one never needs the $\boldsymbol{H}$ matrix for the perturbed molecule.

III. Application to XY_2Z Planar Molecules

In this section, as an example, we apply the Green's function formalism developed in the preceding sections to the problem of the in-plane vibrational frequencies of the XY_2Z planar molecule. In determining the force constant changes, $\Delta\boldsymbol{F}$, associated with the characterization of the XY_3Z molecule in terms of the corresponding XY_3 molecule it is important to first calculate the frequency shifts due to changes in mass and geometry. These mass-geometry corrected frequencies can then be compared with the observed XY_2Z frequencies and the differences attributed to pure force constant changes. We consider in this section the problem of obtaining the mass-geometry corrected frequencies of XY_2Z planar molecules whose X–Z bond length differs from the X–Y bond length of the unperturbed XY_3 molecule. This situation arises in connection with the analysis of the dihaloboranes in terms of the parent boron trihalide. For example, $HBCl_2$ has the same 120° bond angles as BCl_3 but the H–B bond length is believed to be smaller than the B–Cl bond length.[7] The same circumstance obtains in the case of $HBBr_2$.

The internal coordinates and $\boldsymbol{G}$ matrix for an XY_2Z planar molecule with 120° bond angles has been discussed by Lindeman and Wilson.[8] The internal coordinates used in VAIII[3] are the same as those discussed by Lindeman and Wilson except that the angular coordinates are multiplied by the X–Y bond distance. Following this convention the $\Delta\boldsymbol{G}$ matrix elements associated with the characterization of the XY_2Z planar molecule are given by

$$\Delta G_{11}=\frac{1}{3}\Delta\mu$$

$$\Delta G_{12}=\frac{\sqrt{2}}{3}\Delta\mu$$

$$\Delta G_{22}=\frac{2}{3}\Delta\mu$$

$$\Delta G_{45}=\sqrt{3}\,\Delta l\mu_x$$

$$\Delta G_{55}=2\Delta\mu+2\Delta l[\mu_z(\Delta l+2)+\mu_x(\Delta l+3)]$$

$$\Delta\mu=\mu_z-\mu_y$$

$$\Delta l=(l-l')/l'$$

where μ_α is the reciprocal of the αth atom's mass, l is the X–Y bond length and l' is the Z–X bond length. All other $\Delta\boldsymbol{G}$ matrix elements vanish. It is evident that the A_1 modes are independent of the geometry change since the A_1 part of $\Delta\boldsymbol{G}$ (the upper 3×3) involves only mass changes. The ΔG_{45} matrix elements involve only pure geometry effects while ΔG_{55} contains both mass and geometry effects.

1. A_1 Modes.—In order to calculate the A_1 vibrational frequencies we solve the secular determinant given by Eq. 9

$$|\boldsymbol{I}-\boldsymbol{Z}|=0 \tag{40}$$

where

$$\boldsymbol{Z}=[\boldsymbol{L}_0(\lambda)\boldsymbol{F}_0\Delta\boldsymbol{G}]_{A_1} \tag{41}$$

The subscript refers to the A_1 block; the upper 3×3 matrix. It is convenient to transform Eq. 40 to a representation in which ΔG is diagonal

$$|\boldsymbol{I}-\boldsymbol{U}^+\boldsymbol{Z}\boldsymbol{U}|=0 \tag{40a}$$

where

$$\boldsymbol{U}=\frac{1}{\sqrt{3}}\begin{pmatrix}1 & \sqrt{2} & 0\\ \sqrt{2} & -1 & 0\\ 0 & 0 & \sqrt{3}\end{pmatrix} \tag{42}$$

In this representation $\Delta\boldsymbol{G}$ assumes the simple form

$$\boldsymbol{U}^+\Delta\boldsymbol{G}\boldsymbol{U}=\begin{pmatrix}\Delta\mu & 0 & 0\\ 0 & 0 & 0\\ 0 & 0 & 0\end{pmatrix} \tag{43}$$

so that Eq. 40a reduces to a 1×1 transcendental determinant

$$1-\{\boldsymbol{U}^+\boldsymbol{L}_0(\lambda)\boldsymbol{F}_0\boldsymbol{U}\}_{11}\Delta\mu=0 \tag{44}$$

where $\{\ \}_{11}$ is the $1-1$ matrix element. Thus we need only a single matrix element to determine the A_1 isotope frequencies. Using Eqs. 27 and 32 we find that

$$\begin{aligned}\{\boldsymbol{U}^+\boldsymbol{L}_0(\lambda)\boldsymbol{F}_0\boldsymbol{U}\}_{11}&=\{\boldsymbol{U}^+\tilde{\boldsymbol{H}}^{-1}[\Lambda(\lambda-\Lambda)^{-1}]\boldsymbol{H}^{-1}\boldsymbol{U}\}_{11}\\&=\{\boldsymbol{U}^+{}_1,\tilde{\boldsymbol{H}}^{-1}[\Lambda(\lambda-\Lambda)^{-1}]\boldsymbol{H}^{-1}\boldsymbol{U}_1\}\end{aligned} \tag{45}$$

One need only calculate the inner product given by Eq. 45 where $\boldsymbol{U}_1$ is the first column of $\boldsymbol{U}$ and $\boldsymbol{U}^+{}_1$ is the first row of $\boldsymbol{U}^+$. The matrices $\boldsymbol{A}$ and $\boldsymbol{B}$ are given in VAIII[3] and their product, $\boldsymbol{H}$, is

$$\boldsymbol{H}=\boldsymbol{B}\boldsymbol{A}=\begin{pmatrix}(BA)_{A_1} & 0\\ 0 & (BA)_{B_1}\end{pmatrix} \tag{46}$$

where

$$(BA)_{B_1}=\frac{\mu_y{}^{1/2}}{\sqrt{2}\,A_0d_2}\begin{pmatrix}(2d_1-3r^2a) & -(3r^2+2ad_1)\\ -\sqrt{3}\,d_2{}^2a & -\sqrt{3}\,d_2{}^2\end{pmatrix} \tag{47}$$

and

$$(BA)_{A_1}=\begin{pmatrix}\mu_y{}^{+1/2} & 0\\ 0 & (BA)_{B_1}\end{pmatrix} \tag{48}$$

7) L. Lynds and C. D. Bass, ibid., **40**, 1590 (1964).
8) P. Lindeman and M. K. Wilson, ibid., **24**, 242 (1956).

where

$$\left.\begin{aligned} d_1^2&=1+3r^2\\ d_2^2&=2+3r^2\\ r^2&=m_y/m_x\\ A_0^2&=1+a^2 \end{aligned}\right\} \qquad (49)$$

a=mixing parameter

Equation 45 leads to the following equations for mass shifted A_1 frequencies of the XY_2Z molecule,

$$\lambda_1^p\lambda_2^p\lambda_3^p=\lambda_1\lambda_2\lambda_3\left\{1+\frac{\Delta\mu}{3\mu}\left(1+\frac{d_2^2}{d_1^2}\right)\right\}, \qquad (50)$$

$$\lambda_1^p\lambda_2^p+\lambda_1^p\lambda_3^p+\lambda_2^p\lambda_3^p=\lambda_1\lambda_2+\lambda_1\lambda_3+\lambda_2\lambda_3 +\frac{\Delta\mu}{3\mu_y}\left\{\lambda_1(\lambda_2+\lambda_3)+\frac{d_2^2\lambda_1}{d_1^2A_0^2}(\lambda_2+a^2\lambda_3) +\frac{d_2^2}{d_1^2}\lambda_2\lambda_3\right\} \qquad (51)$$

$$\lambda_1^p+\lambda_2^p+\lambda_3^p=\lambda_1+\lambda_2+\lambda_3 +\frac{\Delta\mu}{3\mu_y}\left\{\lambda_1+\frac{d_2^2}{d_1^2A_0^2}(\lambda_2+a^2\lambda_3)\right\} \qquad (52)$$

where the λ^p are the square of the XY_2Z A_1 angular frequencies. λ_1 refers to the A_1 totally symmetric mode of the XY_3 molecule and λ_2 and λ_3 refer to the E′ modes of the XY_3 molecule. Equations 50—52 were derived in VAII[2] using the cartesian coordinate Green's function and are exact for the isotopic case $Z \rightarrow Y^{(i)}$.

2. B_1 Modes.—The mass and geometry corrected B_1 modes may be easily calculated from Eq. 7 which takes the form

$$|\boldsymbol{I}-\boldsymbol{Z}|=0 \qquad (53)$$

$$\boldsymbol{Z}=[\boldsymbol{J}_0(\lambda)\Delta\boldsymbol{G}\boldsymbol{F}_0]_{B1} \qquad (54)$$

It is convenient to proceed from the relation (for a 2×2 matrix)

$$|\boldsymbol{I}-\boldsymbol{Z}|=1+|\boldsymbol{Z}|-\mathrm{Tr}\boldsymbol{Z} \qquad (55)$$

since the determinant of Z can be written down by inspection,

$$|\boldsymbol{Z}|=\frac{|\boldsymbol{J}_0(\lambda)||\boldsymbol{G}_0\boldsymbol{F}_0||\Delta\boldsymbol{G}|}{|\boldsymbol{G}_0|} =\left[\frac{1}{(\lambda-\lambda_4)(\lambda-\lambda_5)}\right]\frac{(\lambda_4\lambda_5)(-3\Delta l\mu_x^2)}{3\mu_y(\mu_y+3\mu_x)} \qquad (56)$$

The trace of Z is given by

$$\mathrm{Tr}\boldsymbol{Z}=\mathrm{Tr}(\boldsymbol{J}_0(\lambda)\Delta\boldsymbol{G}\boldsymbol{F}_0)=\mathrm{Tr}(\boldsymbol{F}_0\boldsymbol{J}_0(\lambda)\Delta\boldsymbol{G}) =\frac{\lambda_4}{\lambda-\lambda_4}(\Delta\boldsymbol{G}_t)_{44}+\frac{\lambda_5}{\lambda-\lambda_5}(\Delta\boldsymbol{G}_t)_{55} \qquad (57)$$

where $\Delta\boldsymbol{G}_t$ is given by Eq. 34.

Equation 55 gives rise to the following set of equations for the mass-geometry corrected B_1 frequencies of the XY_2Z molecule,

$$\lambda_4^p\lambda_5^p=\lambda_4\lambda_5\left\{1-\frac{3\Delta l\mu_x}{\mu_y d_1^2}\left(\frac{\Delta l\mu_x}{3\mu_y}+r^2\right) +\frac{(\beta+2\Delta\mu)}{6\mu_y d_1^2}d_2^2\right\} \qquad (58)$$

$$\lambda_4^p+\lambda_5^p=(\lambda_4+\lambda_5) +\frac{\lambda_4}{\mu_y A_0^2}\left[\frac{-\sqrt{2}\,\alpha d_2}{d_1}+(\beta+2\Delta\mu) \times\left(\frac{\sqrt{6}\,a}{3d_2}+\frac{3r^2}{\sqrt{6}\,d_1d_2}\right)\right]\left[\frac{\sqrt{6}\,a}{3d_2}+\frac{3r^2}{\sqrt{6}\,d_1d_2}\right] +\frac{\lambda_5}{\mu_y A_0^2}\left[-\frac{\sqrt{2}\,\alpha d_2}{d_1}+(\beta+2\Delta\mu) \times\left(\frac{-\sqrt{6}}{3d_2}+\frac{3r^2a}{\sqrt{6}\,d_1d_2}\right)\right]\left[\frac{-\sqrt{6}}{3d_2}+\frac{3r^2a}{\sqrt{6}\,d_1d_2}\right] \qquad (59)$$

where

$$\alpha=\sqrt{3}\,\Delta l\mu_x \qquad (60)$$

and

$$\beta=2\Delta l[\mu_z(\Delta l+2)+\mu_x(\Delta l+3)] \qquad (61)$$

In the above equations λ_4^p and λ_5^p are the mass-geometry corrected B_1 eigenvalues of the XY_2Z molecule while λ_4 and λ_5 ($\lambda_4=\lambda_2$, $\lambda_5=\lambda_3$) are the E′ eigenvalues of the XY_3 molecule.

When $\Delta l=0$ Eqs. 58 and 59 reduce to the exact isotopic equations given in VAII[2] for $XY_2Y^{(i)}$. Positive (negative) Δl has an effect similar to decreasing (increasing) the molecular mass so that the geometry shift is towards higher (lower) frequencies. Furthermore, if μ_z is much larger than either μ_x or μ_y then the term with β will dominate the geometry dependent terms. In the case of the dihaloboranes this effect is comparable to the pure isotope or mass shift and explicit results will be published in a subsequent paper.

3. Example of Force Constant, Mass and Geometry Change.—As an example of how the force constant changes can be studied by means of the Green's function procedure let us consider the XY_2Z planar molecule treated in the preceding section in which the valence force constant f_α differs from that of the XY_3 unperturbed molecule. Knowing the XY_3 and XY_2Z vibrational frequencies we wish to calculate *directly* the change in f_α. We use Eq. 12 for this calculation. The bond bending constant f_α affects only the B_1 modes and ΔF is given by

$$\left.\begin{aligned} (\Delta F)_{44}&=0\\ (\Delta F)_{45}&=0\\ (\Delta F)_{55}&=2\Delta f_\alpha \end{aligned}\right\} \qquad (62)$$

and Eq. 12 can be rewritten in the simple form

$$\Delta f_\alpha=\frac{1}{2\{\boldsymbol{J}_p(\lambda)\boldsymbol{G}\}_{55}} \qquad (63)$$

The quantity $\{\boldsymbol{J}_p(\lambda)\boldsymbol{G}_p\}_{55}$ is the 5-5 matrix element of the matrix product of the B_1 block. A little manipulation shows that

$$\{\boldsymbol{J}_p(\lambda)\boldsymbol{G}_p\}_{55}=|\boldsymbol{J}_p(\lambda)|\{\lambda(\boldsymbol{G}_p)_{55}-|\boldsymbol{G}_p|F_{44}\} \qquad (64)$$

where F_{44} is the 4—4 element of the force constant matrix for the XY_3 unperturbed molecule and may be expressed directly in terms of the vibrational frequencies by application of Eq. 27 which (see VAIII) gives

$$F_{44}=\frac{m_y {d_2}^2(\lambda_2+a^2\lambda_3)}{2{A_0}^2{d_1}^2} \tag{65}$$

Next we make use of the fact that

$$|\boldsymbol{J}_p(\lambda)|=\frac{1}{(\lambda-\lambda^*_4)(\lambda-\lambda^*_5)}=\frac{1}{\mu(\lambda-\lambda^*)} \tag{66}$$

where $\lambda^*_{4,5}$ are the mass-geometry corrected frequencies calculated in section I.2. Thus we obtain the final result that

$$\Delta f_\alpha=\frac{\pi(\lambda-\lambda^*)}{2\{\lambda(\boldsymbol{G}_p)_{55}-|\boldsymbol{G}_p|F_{44}\}} \tag{67}$$

In this example Δf_α is overdetermined. Evaluating Eq. 67 by substitution of an XY_2Z B_1 frequency $\lambda_4{}^p$ or $\lambda_5{}^p$ for λ yields two values of Δf_α. If the fundamental (anharmonically corrected) frequencies were available and if only changes in f_α were involved the two values of Δf_α would coincide.

4. $HBCl_2$ Force Field.—The infrared spectrum of $HBCl_2$ was discussed in VAII. In this work an assignment of the vibrational bands was made on the basis of an "isotope" calculation in which $HBCl_2$ was treated as if the hydrogen was an isotope of chlorine. The observed in-plane frequencies for $H^{11}BCl_2$ were $\nu_1=740(729)$, $\nu_2=2617(2607)$, $\nu_4=1089(1000)$ and $\nu_5=892(851)$ cm^{-1}. (The isotopically calculated frequencies are in parenthesis.) ν_3 was calculated to be at 287 cm^{-1} and was outside the range of the instrument. The A_1 frequencies (ν_1, ν_2, and ν_3) are so close to the calculated values that corrections for force constant changes would be meaningless. Anharmonic corrections can be greater than these differences.

The apparent agreement of the calculated B_1 frequencies with the observed values is somewhat fortuitous. In the above calculation no correction was made for the change in bond length. When Eqs. 58 and 59 are used to obtain the mass-geometry corrected frequencies one gets the results $\nu_4=1363$ and $\nu_5=912$ for a B–H bond length of 1.20Å. The A_1 modes are not affected by the bond length change. If we assume that the force constants involved in the A_1 modes are essentially unchanged as suggested by the fact that the calculated frequencies are so close, then we must have changes in the force field which affect only the B_1 modes. There are two such constants, f_α and $f_{d\alpha}$ (see VAIII). Application of Eq. 67 (the frequencies and mixing parameter are given in VAII) using $\lambda_4{}^p(\lambda_4{}^p=\nu_4{}^2/4\pi^2)$ gives a value of $\Delta f_\alpha=-0.038$ mdynes/Å or 25% decrease in f_α in going from BCl_3 $\rightarrow HBCl_2$. With this single force constant change the calculated frequencies are $\nu_5=1089$, $\nu_5=912$. ν_5 is about 20 wave numbers higher than the value estimated from the band center in VAII indicating that some other small force constant changes may be involved. A similar calculation for $DBCl_2$ indicates about a 15% decrease in f_α and predicts frequencies $\nu_4=1005$ and $\nu_5=793$. ν_4 agrees exactly with the observed $DBCl_2$ frequency but ν_5 was not observed. The change in f_α is therefore qualitatively the same for both $HBCl_2$ and $DBCl_2$. This calculation is of course not intended to constitute an accurate determination of the force field. In fact, it is not possible to obtain accurate force constants without having the anharmonically corrected frequencies. For example, in VAIII one finds that two sets of BBr_3 data which differ by less than 5 wave numbers gives values of f_α which differ by 10%. Nevertheless, the preceding analysis gives a fairly quantitative picture of the $HBCl_2$ force field; it is nearly identical to the BCl_3 force field with a 15 to 25% decrease in the bending force constant f_α. A calculation for the molecules $HBBr_2$ and $DBBr_2$ in terms of BBr_3 yields almost identical results. A more detailed account of these results along with the infrared spectra will be published at a later date.

A more accurate determination of the force constants does not seem to be meaningful until the anharmonic corrections are known. It should also be noted that the change in f_α becomes smaller as one increases the B–H bond length and in fact goes to zero at about 1.56Å.

Discussion and Conclusions

In the preceding sections we have developed the Green's function procedure for molecular analysis in the internal coordinate system.

By making use of the spectral representation of the cartesian dynamical matrix and the transformation between internal and cartesian symmetry coordinates we have shown how to construct the internal molecular Green's function directly from observed vibrational frequencies of the unperturbed molecule. It was shown that the changes in force constants associated with the characterization of a perturbed molecule can be calculated without reference to the unperturbed force constants. This procedure circumvents to a large degree the difficulties encountered in a direct procedure in which the unperturbed molecular force constants vary wildly with small changes in the unperturbed molecular frequencies. It was shown that all of the internal Green's functions can be constructed from a knowledge of the transformation matrix $\boldsymbol{B}$ and the mixing parameters.

In section III we obtained explicit formulae for the mass and geometry frequency shifts in going from an XY_3 to an XY_2Z planar molecule with a different bond length. It was shown that the A_1 modes are unaffected by the change in bond length and that the B_1 modes were shifted to higher

(lower) frequencies whenever $\Delta l > 0$ ($\Delta l < 0$).

As an example of force constant changes, an explicit formula was obtained for the change in f_α directly in terms of the perturbed and unperturbed frequencies.

The Green's function formalism in the internal coordinate system appears to be a particularly simple and appealing procedure for correlating the vibrational properties of families of related molecular species.

A qualitative analysis of the $HBCl_2$ and $DBCl_2$ was given which shows that these molecules have a force field almost identical with the BCl_3 force field except that the bending force constant f_α is decreased by about 20%.

The authors wish to express their appreciation to G. W. Lehman and L. Lynds for valuable suggestions concerning the topics in this paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39. 214—219 (1966)

The Reactions of *N*-Phenyl Ethanolamine with Imido Phosphites, Amido Phosphites and Amino Phosphines

By Oyo MITSUNOBU,* Takashi OHASHI, Motokazu KIKUCHI and Teruaki MUKAIYAMA*

Technical Research Department, Bridgestone Tire Co., Ltd., Kodaira, Tokyo

(Received March 2, 1965)

Various symmetrical and unsymmetrical triesters of phosphorous acid have been obtained by the reactions of phosphazo compounds with alcohols or phenols. When a phosphazo compound, amido phosphites or amino phosphine is treated with 2 mol. of *N*-substituted ethanolamine, the corresponding bis(β-aminoethyl) phosphites or phosphonite is obtained. On the other hand, when the same reaction is carried out with 1 mol. of the ethanolamine, cyclic phosphorous compounds are obtained in fairly good yields. Further, it has been found that the treatment of bis(β-anilinoethyl)phenyl phosphonite with phenyl isocyanate gives 2-phenylimino-3-phenyl-1, 3-oxazolidine.

The reaction of ethyl *N*-phenylimino phosphite (ethoxyphosphazobenzene) with benzaldehyde and ethanol has recently been reported to afford diethyl phosphite and benzilideneaniline.[1] In the present study, addition reactions of phosphazo compounds with active hydrogen compounds, such as amines, alcohols, phenols and aminoalcohols, were attempted. When *N*-phenylamino *N'*-phenylimino phosphine (I) was treated with an equimolar amount of aniline in boiling toluene, trisanilino phosphine (II), an addition compound, could not be obtained; rather, 53.8% of the starting material (I) was recovered, along with an unidentified product (Eq. 1):

$$\underset{\text{I}}{C_6H_5\text{-}N{=}P\text{-}NHC_6H_5} + C_6H_5NH_2 \xrightarrow{\times} \underset{\text{II}}{P(NHC_6H_5)_3} \quad (1)$$

Ethyl dianilino phosphite (III), the expected addition compound, could not be obtained when I was treated with an equimolar amount of ethanol in boiling toluene, but triethyl phosphite and aniline were produced in 23.3 and 33.3% yields, and 21% of I was also recovered (Eq. 2):

$$\text{I} + \text{EtOH} \begin{cases} \xrightarrow{\times} \underset{\text{III}}{(C_6H_5NH)_2P\text{-}OEt} \\ \longrightarrow (EtO)_3P + 2C_6H_5NH_2 \end{cases} \quad (2)$$

On the other hand, the yield of triethyl phosphite was increased to 46% when 3 mol. of ethanol were used in the above reaction. In a similar manner, various trialkyl or triaryl phosphites were prepared by the reactions of 1 mol. of I with 3 mol. of alcohols or phenols (see Table I).

Similarly, unsymmetrical ethyl dialkyl or ethyl diphenyl phosphite was produced by the reaction of 1 mol. of ethyl *N*-phenylimino phosphite (IV) with 2 mol. of alcohols or phenol (Eq. 3). The results are summarized in Table II.

$$\underset{\text{IV}}{C_6H_5\text{-}N{=}P\text{-}OEt} + 2ROH \longrightarrow (RO)_2P\text{-}OEt + C_6H_5NH_2 \quad (3)$$

R=alkyl or phenyl

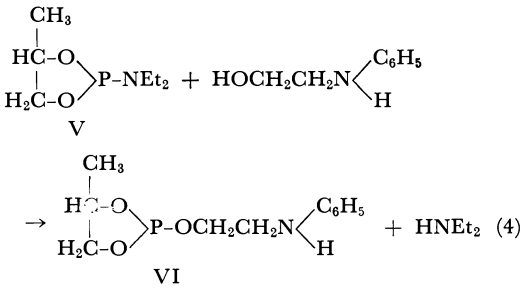
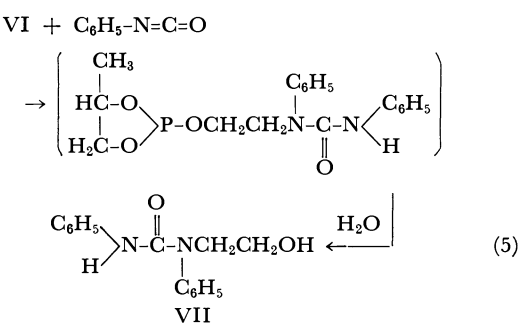
It has recently been reported by Burgade[2] and Petrov et al.[3] that alcohols or phenols react with amido phosphites and amino phosphines to give the corresponding phosphites or phosphonites, with the elimination of the original amino groups.

In view of the finding that imido phosphites, amido phosphites or amino phosphines react with alcohols much more readily than amines, such phosphorous compounds may be expected to react with amino alcohols to form ω-aminoalkyl phosphites or phosphonites primarily. For instance, when 2-diethylamino-4-methyl-1, 3, 2-dioxaphospholane (V) is treated with an equimolar amount of *N*-phenyl ethanolamine in boiling toluene for 3 hr., β-anilinoethyl propylene phosphite (VI) is obtained in a 86% yield (Eq. 4):

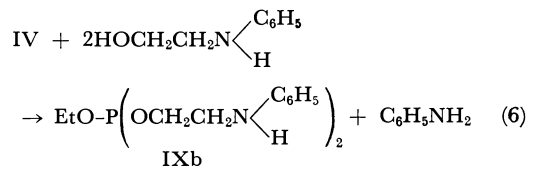


The structure of VI was confirmed by means of elemental analysis and a study of its infrared spectrum. The VI reacts with phenyl isocyanate to give a viscous oily product, the infrared spectrum of which shows the absorption at 1660 cm^{-1} due to the urea linkage. The liquid is readily hydrolyzed to give *N*-(β-hydroxyethyl)-*N*, *N'*-diphenyl urea (VII) in a good yield (Eq. 5):

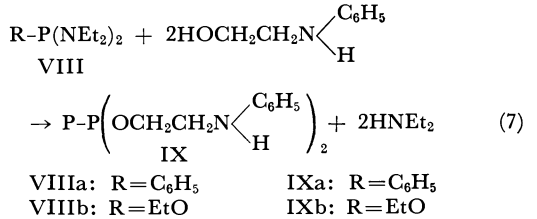


This fact shows that the nitrogen of the trivalent phosphorus-nitrogen bond is selectively replaced with the oxygen of the ethanolamine.

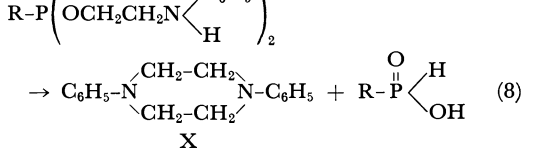
Further, when IV was treated with 2 mol. of *N*-phenyl ethanolamine while being refluxed in toluene for 5 hr., ethyl bis(β-anilinoethyl) phosphite (IXb) (b. p. 114—116°C/0.009 mmHg) was obtained in a 27% yield (Eq. 6):



Similarly, when phenyl bis(diethylamino) phosphine (VIIIa) or ethyl bis(diethylamido) phosphite (VIIIb) was treated with 2 mol. of *N*-phenyl ethanolamine at 130°C for 4 hr., bis(β-anilinoethyl)phenyl phosphonite (IXa) or ethyl bis(β-anilinoethyl) phosphite (IXb) was obtained in a 69% or a 20% yield respectively (Eq. 7):

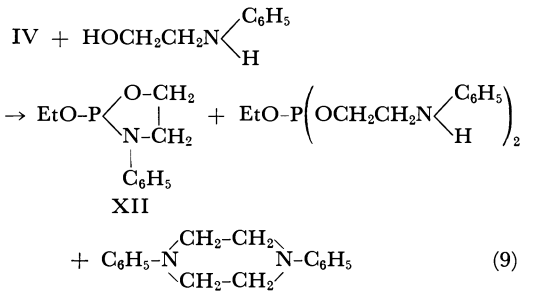


The resulting ethyl bis(β-anilinoethyl) phosphite or bis(β-anilinoethyl)phenyl phosphonite is rather unstable and is partly decomposed into *N*, *N'*-diphenyl piperazine (X) during distillation (Eq. 8):



The solvents, yields, and physical properties of the bis(β-aminoethyl) phosphites and phosphonite as well as the results of elementary analyses of these substances, are listed in Table III.

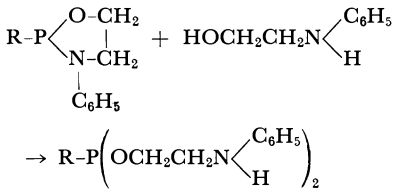
On the other hand, when VIIIa or VIIIb was reacted with an equimolar amount of amino alcohol, 2, 3-diphenyl-1, 3, 2-oxazaphospholidine (XI) or 2-ethoxy-3-phenyl-1, 3, 2-oxazaphospholidine (XII) was obtained in a fairly good yield. In the case of the reaction of 1 mol. of ethyl *N*-phenylimino phosphite with 1 mol. of *N*-phenyl ethanolamine, 2-ethoxy-3-phenyl-1, 3, 2-oxazaphospholidine and ethyl bis(β-anilinoethyl) phosphite were obtained in 55 and 21% yields respectively, along with a small amount of *N*,*N'*-diphenyl piperazine (Eq. 9): The results are summarized in Table IV.



2) R. Burgada, a) *Ann. Chim.* (*France*), 347 (1963); b) *Bull. soc. chim. France*, **1963**, 2335.

3) K. A. Petrov, E. E. Nifantev, T. N. Lysenko and V. P. Evdakov, *Zh. Obshch. Khim.*, **31**, 2377 (1961).

The resulting cyclic phosphorous compounds may be expected to yield bis(β-aminoethyl) phosphite or phosphonite by the ring-opening addition of the other amino alcohol, as is shown in the following equation (10):



(10)

When 2, 3 - diphenyl-1, 3, 2-oxazaphospholidine was treated with an equimolar amount of *N*-phenyl ethanolamine in xylene, bis(β-anilinoethyl)phenyl phosphonite was obtained in a 31% yield; 15% of the cyclic phosphorous compound was also recovered.

Next, in order to prepare the corresponding urea derivatives of bis(β-aminoethyl) phosphorous compounds, the reaction of bis(β-anilinoethyl)phenyl phosphonite with 2 mol. of phenyl isocyanate was attempted. Contrary to our expectation, the urea could not be isolated, although 2-phenylimino-3-phenyl-1, 3-oxazolidine was obtained in a 58.5% yield. The unexpected oxazolidine formation may result in the subsequent decomposition of the initially-formed ureas. Futher study of this new synthesis of oxazolidine derivatives is now in progress.

Experimental

Materials.—Aminoalcohols and phenyl isocyanate were obtained commercially and purified by distillation. *N*-Phenylamino *N'*-phenylimino phosphine[4] (m. p. 246—248°C), ethyl phosphorodichloridite[5] (b. p. 48—50°C/80 mmHg), ethyl *N*-phenylimino phosphite[1] (b. p. 153—155°C/0.09 mmHg), phenyl phosphonous dichloride[6] (b. p. 59—61°C/2 mmHg) and 2-chloro-4-methyl-1, 3, 2-dioxaphospholane[7] (b. p. 75—76°C/50 mmHg) were prepared according to the methods in the literature.

The Preparation of Phenyl Bis(diethylamino) Phosphine.—A solution of phenyl phosphonous dichloride (179 g., 1.0 mol.) in 800 ml. of dry benzene was stirred, drop by drop over a period of 1.5 hr., into a solution of diethylamine (146 g., 2.0 mol.) and triethylamine (202 g., 2.0 mol.) in 300 ml. of dry benzene which had been cooled in an ice-water bath. The mixture was then stirred for another hour and subsequently heated to reflux. Triethylamine hydrochloride was removed by filtration. After the solvent had been removed under reduced pressure from the filtrate, the residue was distilled to give 217 g. (86.3%) of phenyl bis(diethylamino) phosphine (b. p. 123—125°C/0.2 mmHg).

Found: N, 11.08. Calcd. for $C_{14}H_{25}N_2P$: N, 11.10%.

By the same procedure, ethyl bis(diethylamido) phosphite was prepared in a 71.3% yield; b. p. 81—83°C/9 mmHg.

Found: N, 12.62. Calcd. for $C_{10}H_{25}N_2PO$: N, 12.73%.

The Preparation of 2-Diethylamino-4-methyl-1, 3, 2-dioxaphospholane.—A solution of diethylamine (75 g., 1.03 mol.) in 100 ml. of ligroin was vigorously stirred, drop by drop, into a solution of 2-chloro-4-methyl-1, 3, 2-dioxaphospholane (70 g., 0.5 mol.) in 300 ml. of ligroin which had been cooled in an ice-water bath. The mixture was then stirred for an additional 2 hr. at room temperature. Diethylamine hydrochloride was removed by filtration. After the solvent had been removed from the filtrate under reduced pressure, the residue was distilled to give 2-diethylamino-4-methyl-1, 3, 2-dioxaphospholane, (52 g., 59.1%; b. p. 67—68°C/6.5 mmHg).

Found: N, 7.85. Calcd. for $C_7H_{16}NPO_2$: N, 7.91%.

The Reaction of *N*-Phenylamino *N'*-Phenylimino Phosphine (I) (1 mol.) with Aniline (1 mol.).—A solution of aniline (1.86 g., 0.02 mol.) in 10 ml. of dry toluene was added to a solution of I (4.28 g., 0.02 mol.) in 10 ml. of dry toluene at room temperature. The mixture was then refluxed for 5 hr. After the solution had been cooled, the starting material was recovered as precipitates (2.30 g., 53.8%). The filtrate was concentrated under reduced pressure to give unidentified solids (2.09 g.; m. p. 139—169°C) which could not be purified further.

The Reaction of *N*-Phenylamino *N'*-Phenylimino Phosphine (I) (1 mol.) with Ethanol (1 mol.).—A solution of ethanol (0.46 g., 0.01 mol.) in 5 ml. of dry toluene was added to a solution of I (2.14 g., 0.01 mol.) in 15 ml. of dry toluene at room temperature. The reaction mixture was then refluxed for 5 hr., after which time the reaction mixture was concentrated and the separated I (0.45 g., 21%; m. p. 234—241°C) was removed by filtration. The filtrate was fractionated in vacuo to give curde triethyl phosphite (0.39 g., 23.3%; b. p. 54—58°C/16 mmHg) and aniline (0.21 g., 33.3%; b. p. 34—39°C/3 mmHg). The infrared spectrum of triethyl phosphite was identical with that of an authentic sample.

The Reaction of *N*-Phenylamino *N'*-Phenylimino Phosphine (I) (1 mol.) with Ethanol (3 mol.).—In the same manner 3 mol. of ethanol (1.38 g., 0.03 mol.) was allowed to react with I (2.14 g., 0.01 mol.) thus producing triethyl phosphite (0.76 g., 45.8%; b. p. 52—63°C/26 mmHg) and aniline (1.76 g., 94.7%; b. p. 74—86°C/27 mmHg).

By a similar procedure, several trialkyl and triaryl phosphites were obtained, as Table I shows.

The Reaction of Ethyl *N*-Phenylimino Phosphite (IV) (1 mol.) with Ethanol (2 mol.).—A solution of ethanol (0.92 g., 0.02 mol.) in 10 ml. of dry benzene was added to a solution of IV(1.67 g., 0.01 mol.) in 10 ml. of dry beznene at room temperature. The reaction mixture was refluxed for 3 hr. After the solvent had been removed, triethyl phosphite (1.21 g., 72.6%; b. p. 75—78°C/40 mmHg) and aniline (0.91 g.,

4) H. W. Grimmel, A. Guenther and J. F. Morgan, *J. Am. Chem. Soc.*, **68**, 539 (1946).

7) H. J. Lucas, F. W. Mitchell, Jr., and C. N. Scully, *J. Am. Chem. Soc.*, **72**, 5491 (1950).

98.5%; b. p. 94—97°C/40 mmHg) were obtained by fractionation.

Similarly, some unsymmetrical phosphites were obtained, as is shown in Table II. In each case, a small amount of a mixture of various phosphites was formed by transesterification.

The Reaction of 2-Diethylamino-4-methyl-1, 3, 2-dioxaphospholane (V) (1 mol.) with *N*-Phenyl Ethanolamine (1 mol.).—A solution of V (10.62 g., 0.06 mol.) and *N*-phenyl ethanolamine (8.22 g., 0.06 mol.) in 20 ml. of dry toluene was refluxed for 3 hr. After the solvent and the evolved diethylamine had been removed under reduced pressure, the residure was distilled in vacuo, giving β-anilinoethyl propylene phosphite (12.5 g., 86.3%; b. p. 107—109°C/0.1 mmHg). Redistillation gave the pure phosphite (b. p. 107—109°C/0.1 mmHg).

Found: N, 5.89. Calcd. for $C_{11}H_{16}NPO_3$: N, 5.81%.

The Reaction of β-Anilinoethyl Propylene Phosphite (VI) (1 mol.) with Phenyl Isocyanate (1 mol.).—A solution of phenyl isocyanate (1.19 g., 0.01 mol.) in 10 ml. of dry toluene was added, drop by drop, to a solution (2.41 g., 0.01 mol.) of VI in 10 ml. of dry toluene. After an initial exothermic reaction had ceased, the reaction mixture was refluxed for 3 hr. After the solvent had then been removed under reduced pressure, an oily substance was obtained. The oily substance was solidified, with a slight heat liberation, by treatment with 5 ml. of water. The solid was filtered to give 2.46 g. (68.4%) of *N*-(β-hydroxyethyl)-*N*, *N'*-diphenyl urea (m. p. 80—83°C; recrystallized from ethyl acetate, m. p. 82—83°C).

Found: C, 69.92; H, 6.42; N, 11.23. Calcd. for $C_{15}H_{16}N_2O_2$: C, 70.29; H, 6.29; N, 10.94%.

The Reaction of Ethyl *N*-Phenylimino Phosphite (IV) (1 mol.) with *N*-Phenyl Ethanolamine (2 mol.).—A solution of IV (1.67 g., 0.01 mol.) and *N*-phenyl ethanolamine (2.74 g., 0.02 mol.) in 20 ml. of dry toluene was refluxed for 5 hr. After the solvent had been removed under reduced pressure, the residue was distilled, in vacuo giving aniline (0.19 g., 22%; b. p. 34—35°C/2 mmHg) and ethyl bis(β-anilinoethyl) phosphite (0.94 g., 27%; b.p. 114—116°C/0.009 mmHg); a tarry residue also remained. From this residue, *N*, *N'*-diphenyl piperazine (0.12 g.; m. p. 163—165°C) was extracted with boiling toluene; the residual substance gave an unidentified gray colored solid (m. p. 235°C).

The Reaction of Phenyl Bis(diethylamino) Phosphine (VIIIa) (1 mol.) with *N*-Phenyl Ethanolamine (2 mol.)—A mixture of VIIIa (5.04 g., 0.02 mol.) and *N*-phenyl ethanolamine (5.48 g., 0.04 mol.) was heated at 125—135°C (oil bath temperature) for 4 hr. After the diethylamine had been removed under reduced pressure, the residue was distilled in vacuo to give bis(β-anilinoethyl)phenyl phosphonite (5.27 g., 69.4%; b. p. 105—107°C/0.001 mmHg). Its infrared spectra showed absorption bands at 3350 (m), 1430 (m), 1175 (m), 1050(s), and 925(s) cm^{-1}.

Found: N, 7.45. Cacld. for $C_{22}H_{25}N_2PO_2$: N, 7.37%.

In a similar way, ethyl bis(β-anilinoethyl) phosphite, ethyl bis(β-ethylaminoethyl) phosphite and ethyl bis-(β-methylaminoethyl) phophite were prepared by the reactions of the corresponding ethanolamines with ethyl bis(diethylamido) phosphite (Table III).

The Reaction of Ethyl Bis(diethylamido) Phosphite (VIIIb) (1 mol.) with *N*-Phenyl Ethanolamine (1 mol.).—A mixture of VIIIb (22 g., 0.1 mol.) and *N*-phenyl ethanolamine (13.7 g., 0.1 mol.) was heated at 120—130°C (oil bath temperature) for 3 hr. The diethylamine was then collected in a trap cooled in an ice-water bath. The reaction mixture was distilled under reduced pressure to give 2-ethoxy-3-phenyl-1, 3, 2-oxazaphospholidine (17.79 g., 84.3%; b. p. 88—91°C/0.02 mmHg). Its infrared spectra displayed absorption bands at 1304(s), 1150(w), 1030(s), and 920(s) cm^{-1}.

Found: N, 6.79; mol. wt. (Ebulliometric) 218. Calcd. for $C_{10}H_{14}NPO_2$: N, 6.64%; mol. wt. 211.

In a similar way, 2, 3-diphenyl-1, 3, 2-oxazaphospholidine and 2-phenyl-3-methyl-1, 3, 2-oxazaphospholidine were prepared from phenyl bis(diethylamino) phosphine and the corresponding ethanolamines, as is shown in Table IV.

The Reaction of Ethyl *N*-Phenylimino Phosphite (IV) (1 mol.) with *N*-Phenyl Ethanolamine (1 mol.).—A solution of IV (16.7 g., 0.1 mol.) and *N*-phenyl ethanolamine (13.7 g., 0.1 mol.) in 200 ml. of dry toluene was refluxed for 5 hr. After the solvent had been removed, the residue was fractionated into four major fractions. Fraction 1: aniline (5.77 g., 62.2%; b. p. 58—64°C/6 mmHg). Fraction 2: 2-ethoxy-3-phenyl-1, 3, 2-oxazaphospholidine (11.48 g., 54.6%; b. p. 91—92°C/0.02 mmHg). (This fraction shows an infrared spectrum identical with that of the 2-ethoxy-3-phenyl-1, 3, 2-oxazaphospholidine obtained in the above experiment). Fraction 3: ethyl bis(β-anilinoethyl) phosphite (3.59 g., 20.6%; b. p. 117—119°C/0.03 mmHg). (Its infrared spectra shows absorption bands at 3350(m), 1270(s), 1150(m), 1020(s), 900(s) cm^{-1}. Fraction 4: 6.58 g., b. p. 131—151°C/0.006 mmHg. This fraction was partly solidified. The fraction was extracted with boiling toluene. After the extract had been cooled, *N*, *N'*-diphenyl piperazine (0.89 g., m. p. 163—165°C) was obtained. Recrystallization from toluene raised the melting point to 166—167°C, and the melting point was undepressed on admixture with an authentic sample.

Found: C, 79.63; H, 8.09; N, 11.96. Calcd. for $C_{16}H_{18}N_2$: C, 80.67; H, 7.57; N, 11.77%.

The Reaction of 2, 3-Diphenyl-1, 3, 2-Oxazaphospholidine (XII) (1 mol.) with *N*-Phenyl Ethanolamine (1 mol.)—A solution of XII (2.84 g., 0.01 mol.) and *N*-phenyl ethanolamine (1.53 g., 0.01 mol.) in 7 ml. of dry xylene was refluxed for 4 hr. After the solvent had been removed, the residue was fractionated into two fractions. Fraction 1: 0.65 g. (42.2%); b. p. 82—84°C/0.005 mmHg. (The infrared spectrum of the product was identical with that of *N*-phenyl ethanolamine). Fraction 2: 3.07 g., b. p. 104—110°C/0.008 mmHg. After this substance had stood in a refrigerator, 0.43 g. (15%) of XII (m. p. 75—77°C) was recovered. After the XII had been removed by filtration, the residue was distilled to give 1.39 g. (31%) of bis(β-anilinoethyl)phenyl phosphonite (b. p. 124—126°C/0.03 mmHg).

The Reaction of Bis(β-anilinoethyl) Phenyl Phosphonite (IXa) with Phenyl Isocyanate.—A solution of phenyl isocyanate (2.38 g., 0.02 mol.) in 10 ml. of dry toluene was stirred, drop by drop, into a solution of IXa (3.80 g., 0.01 mol.) in 10 ml. of dry

toluene at room temperature. After an initial exothermic reaction had ceased, the reaction mixture was refluxed for 3 hr. The solvent was removed under reduced pressure, and an oily substance was obtained. After the oily substance had been stored for several days at room temperature, a small amount of a white crystalline compound was precipitated. When 5 ml. of 99.5% ethanol was added to the mixture, a white crystalline compound (1.44 g., 58.5%; m. p. 115—116°C) was again obtained. This crystalline compound was purified by recrystallization from ethanol (m. p. 117—118°C). The compound was identical in its infrared spectrum with that of an authentic 2-phenylimino-3-phenyl-1, 3-oxazolidine[8] and with the results of the elemental analysis.

Found: C, 75.60; H, 6.11; N, 11.83. Calcd. for $C_{15}H_{14}N_2O$: C, 75.63; H, 5.83; N, 11.76%.

The authors wish to thank the Bridgestone Tire Co., Ltd., especially, its General Director, Mr. Kunio Yasutake, for permission to publish this work; they wish also to acknowledge the helpful advice given by Mr. Yoshitake Kubota and the late Mr. Koshiro Fujiwara.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 219—222 (1966)

The Fluorination of Ethylene and Ethane*

By Shunji NAGASE,† Kiyoshi TANAKA,†† Hajime BABA† and Takashi ABE†

† *Government Industrial Research Institute, Nagoya, Kita-ku, Nagoya*

†† *Research Laboratories, Central Glass Co., Ltd., Ohte-machi, Chiyoda-ku, Tokyo*

(Received March 15, 1965)

Ethylene and ethane were electrochemically fluorinated in an electrolytic fluorination cell equipped with a bubbler. Several fluorinated ethanes were obtained from these samples in reasonable total-yields with reasonable current efficiencies. The influence of operating conditions on the reaction was investigated. A probable mechanism was described for the formation of the characteristic procucts obtained in the fluorination reaction.

There have been a number of papers dealing with the fluorination of substituted ethylenes by various methods. However, no successful report has yet described the fluorination of ethylene itself by an electrochemical process.[1] The present work was carried out in order to examine the possibility of the electrochemical fluorination of ethylene which may undergo polymerization, fragmentation, or simple fluorination. It has been found that ethylene can be fluorinated without difficulty by using an electrolytic fluorination cell equipped with a bubbling arrangement[2]; fluorinated ethanes are thus produced in a reasonable yield and at a reasonable current efficiency. The electrochemical fluorination of ethane, which has already been reported briefly by Sartori,[3] was also carried out in order to compare the results with those of ethylene.

A representative mechanism will be described to account for the formation of the characteristic products obtained in the present electrochemical fluorination.

Experimental

Materials. — The ethylene, obtained from the Ohio Chemical & Surgical Equipment Co., was more than 99.5% pure. The ethane (99.7% pure) was obtained from the Takachiho Chemical Industrial Co. The hydrogen fluoride (more than 99% pure) was supplied by the Daikin Industries Co. The diluent employed was Airco helium gas.

Apparatus and Procedure.—The apparatus used for this fluorination was essentially the same as that used for the fluorination of methane.[2] The characteristic part of the fluorination cell was the bubbler. Many minute bubbles of the sample gas were produced in hydrogen fluoride by the use of this bubbler.

The experimental procedure was as follows. Hydrogen fluoride (1 l.) was placed in the cell, and before the introduction of the sample, electrolysis was carried out in a nitrogen atmosphere in order to remove a trace of an impurity; the electrolysis was carried out at an anodic current density of 2.7 amp./dm^2 and at 5—6°C until the cell voltage rose to 6.0 V. Then sodium fluoride was added, and the metered sample was introduced from the bottom of the cell, through the bubbler, into hydrogen fluoride maintained at 6—7°C,

* "Electrochemical Fluorination of Gases" Part II.

1) After this work had been completed, the authors read a review article (M. Schemisser and P. Sartori, *Chemie-Ing.-Techn.*, **36**, 9 (1964)) stating that the electrochemical fluorination of ethylene was not accomplished due to the polymerization of ethylene.

2) S. Nagase, K. Tanaka and H. Baba, This Bulletin, **38**, 834 (1965).

3) P. Sartori, *Angew. Chem.*, **75**, 417 (1963).

using a calibrated flow meter connected to a sample cylinder. In a few experiments, helium was admitted simultaneously with the sample into the bubbler. The sample was fluorinated at the anodic current density of 2.2 amp./dm^2. When the cell voltage became almost steady at 6—6.5 V. (after about 1 hr.), traps were immersed in ice and liquid nitrogen respectively, and electrolysis was carried out for the designated amp.-hr. period. Since the bubbler was found to be very effective in the fluorination of methane, all the present reactions were carried out using the bubbler.

The fluorinated gas evolved from the cell was passed through a condenser kept at −15°C and over sodium fluoride pellets in order to remove the hydrogen fluoride; then it was bubbled through a sodim sulfite solution containing a small amount of potassium iodide in order to eliminate a trace amount of explosive oxygen difluoride. The gas was subsequently passed through a trap in ice, and finally condensed in two traps placed in series in liquid nitrogen. Fluorination took place smoothly in all the experiments.

The product thus obtained was rectified in a low-temperature rectification unit and weighed in a glass ampule. The molecular weight of each fraction was measured by means of gas density balance. The mixture was then further separated by gas chromatography, using an activated charcoal column (2 m.) maintained at 120°C, using helium as the carrier.

The Fluorination of Ethylene.—The reaction conditions of six representative runs, and a typical example of the results of low-temperature rectification and chromatographic separation are given in Tables I and II respectively. As in the case of the fluorination of methane, the quantitative analysis by means of a gas chromatograph of the separated component was made on the assumption that the ratio of the peak areas of chromatogram is a direct measure of the percentage weight of the components.[4] However, in the case of fraction 1, which consisted of tetrafluoromethane, ethylene, and hexafluoroethane, the latter two components were not separated from each other chromatographically under the conditions applied; therefore this fraction was analyzed quantitatively by the use of the baseline method for the infrared spectrum.

Fraction 2 corresponded to hexafluoroethane but was contaminated by a negligible amount of trifluoromethane. Rather unexpectedly, ethane was also contained in this fraction, obtained from runs 2 and 5, in the amounts of 3 and 5 mol.% of the total fractions. (The amount of ethane was determined by means of the baseline method for the infrared spectrum).

Fraction 3 consisted of 1, 1, 1-trifluoroethane and pentafluoroethane. The azeotropic mixture of these two compounds is known to boil at −45°C.[5] Fraction 4 consisted of a mixture of isomers of 1, 1, 1, 2-tetrafluoroethane and 1, 1, 2, 2-tetrafluoroethane with the observed molecular weight of 102 to 103. The boiling point of the azeotropic mixture of these two compounds is known to be −29°C.[5]

Fraction 5 consisted mainly of a mixture of 1, 1-difluoroethane and 1, 1, 2, 2-tetrafluoroethane, plus a

4	−29——22	3.2	CF_3CH_2F, CHF_2CHF_2
5	Hold up	2.8	CF_3CH_2F, CHF_2CHF_2

a) This example was taken from run 2.

small amount of a compound, X, which could not be identified chemically or spectroscopically.

A small amount (0.2—0.4 g.) of a tarry polymeric material whose infrared spectrum showed the presence of a C-F bond and a C-H bond was found in the residue in the electrolytic cell after the distillation of hydrogen fluoride from the cell.

The Fluorination of Ethane.—The fluorination of ethane was carried out under the reaction conditions shown in Table III. Table IV shows a typical example of the results of low-temperature rectification and chromatographic separation. The products were analyzed quantitatively by a method similar to that used for ethylene. Fraction 1 consisted of an azeotropic mixture of hexafluoroethane and ethane, along with an insignificant amount of tetrafluoromethane. The elements of this azeotropic mixture, reported to boil at −92°C,[6] could not be separated from each other by gas chromatography under the conditions used. In a few runs, a negligible amount of trifluoromethane was detected in this fraction.

Fraction 2 corresponded to ehtane, but it was often contaminated with hexafluoroethane. Fractions 3 and 4 were essentially the same as those of fractions 3 and 4 in Table II. The components of fraction 5 were the same as those of fraction 4. In the other runs, however, an unidentified compound whose infrared spectrum was identical with that of the compound X obtained from ethylene was present.

It was interesting that monofluoroethane* was obtained in a considerable amount under the mild reaction conditions of run 4.

Results and Discussion

The results obtained from the fluorination of ethylene and ethane are summarized in Tables V and VI respectively; these results show that the milder and controllable fluorination reaction can be carried out by the use of an electrolytic cell equipped with a bubbler.

Table V. Collected results in the fluorination of ethylene

Run No.	Total yield mol.%	Total current eff., %[a]	Product comp., mol.%							
			CF_3CF_3	CF_3CHF_2	CF_3CH_2F	CHF_2CHF_2	CF_3CH_3	CHF_2CH_3	CF_4	X[b]
1	78.0	60.8	46.2	17.1	9.3	14.4	6.2	4.3	2.5	0
2	50.3	56.1	23.6	9.6	18.0	7.9	32.3	8.6	trace	1.2
3	73.5	42.9	36.5	14.6	13.7	20.7	7.3	5.9	1.3	2.2
4	79.9	59.3	36.8	12.6	10.5	19.7	6.7	11.4	2.3	0
5	44.5	59.6	18.2	16.8	22.1	16.0	19.2	4.8	2.9	2.0
6	73.2	57.7	28.2	16.6	16.1	20.3	12.0	6.0	0.8	0

a) The calculation of current efficiency was based on the amount of current assumed to be necessary for forming fluorine with a discharging fluoride ion which would react with the sample according to the following equations. Total current efficiency shown is the sum total of the current efficiency for each component.

$C_2H_4 + 10F = CF_3CF_3 + 4HF$ (1)
$C_2H_4 + 8F = CF_3CHF_2 + 3HF$ (2)
$C_2H_4 + 6F = CF_3CH_2F + 2HF$ (3)
$C_2H_4 + 6F = CHF_2CHF_2 + 2HF$ (4)
$C_2H_4 + 5F + H = CF_3CH_3 + 2HF$ (5)
$C_2H_4 + 3F + H = CH_3CHF_2 + HF$ (6)
$C_2H_4 + 12F = 2CF_4 + 4HF$ (7)

b) The amounts of X were given in unit of grams in this table and in Table VI.

Table VI. Collected results in the fluorination of ethane

Run No.	Total yield mol.%	Total current eff., %[a]	Product comp., mol.%						
			CF_3CF_3	CF_3CHF_2	CF_3CH_2F	CHF_2CHF_2	CF_3CH_3	CH_2FCH_3	X
1	48.5	65.0	56.2	14.2	12.1	10.3	7.2	0	0.9
2	40.7	62.2	51.2	14.8	13.4	10.4	10.2	0	0
3	40.4	49.6	49.5	20.6	10.3	13.9	5.7	0	1.6

a) The calculation of the current efficiency shown was made on the similar assumption to that in the case of ethylene, for instance, $C_2H_6 + 12F = C_2F_6 + 6HF$

6) J. D. Calfee, N. Fukuhara and L. A. Bigelow, ibid., **61**, 3552 (1939).

* The reference infrared spectrum obtained from the American Petroleum Institute, serial number 1302, was identical with this product.

With regard to the partial fluorination of these samples, the results obtained were not as striking as for methane.[1] The sample feed rate had a large effect, especially on the partial fluorination of ethylene. A higher feed rate made the reaction milder and gave less hexafluoroethane in the products. The amount of sodium fluoride and the electrolysis temperature also affected the results in the present experiments. Above all, the dilution of the feed with helium appeared to make the reaction milder and to give a large amount of less-fluorinated ethane from ethylene and a considerable amount of monofluoroethane from ethane.

Except for a kinetic study of fluorine addition to ethylene,[7] no information has been available on the fluorination of ethylene with elementary fluorine, but the kind and the ratio of the reaction products reported here appeared to be very close to what might be expected from the very mild fluorination of ethylene with elementary fluorine. Furthermore, the characteristics associated with the results obtained from the fluorination of ethane were comparable in many respects to those obtained from the vapor-phase fluorination of ethane with elementary fluorine,[6,8,9] which is known to proceed via a free-radical mechanism.

The fluorinating agent and the reaction mechanism in electrochemical fluorination are much in dispute.[10] However, the basic reaction which takes place during the present fluorination appears very likely to be a free-radical reaction on the anode surface. The effective dispersion of the reaction heat, the good agitation, the sparing solubility of the sample and fluorinated products, and the reaction in the very inert solvent, hydrogen fluoride, to fluorinating agent may account for the mildness of this fluorination reaction.

The important products from ethylene were 1, 1-difluoroethane and 1, 1, 1-trifluoroethane, which was isolated in a considerable amount. The formation of these may perhaps be represented simply as follows:

$$CH_2{=}CH_2 \xrightarrow{[F]} \underset{(I)}{CH_2F\text{-}CH_2F} \xrightarrow{-HF} \underset{(II)}{CHF{=}CH_2}$$

$$\xrightarrow{HF} \underset{(III)}{CHF_2\text{-}CH_3} \xrightarrow{[F]} \underset{(IV)}{CF_3CH_3}$$

The initial product I, which is well known to be unstable, may undergo dehydrofluorination to give II under these reaction conditions. The addition of hydrogen fluoride to II, which is known to proceed readily in accordance with Markownikoff's rule,[11] could yield III, which could be further fluorinated to give IV. The increasing stability of compounds with fluorine atoms attached to the same carbon atom[12] may suggest a possible pathway, although the reaction could and probably did follow different routes simultaneously.

In the case of ethane, which did not afford 1, 1-difluoroethane in a detectable amount, such isomerization could have occurred to a certain extent, but the lower concentration of the initial product I compared with that from ethylene can account for the observed fact. Ethylene may always give I in the initial step of the reaction.

A quite unexpected and interesting by-product from ethylene was ethane. It is believed that this was formed by the cathodic reduction of ethylene. Only one report has described the cathodic reduction, and that not in a typical electrochemical fluorination.[13]

The formation of a detectable amount of any other compound with a double bond or more carbon atoms than the parent compounds could not be confirmed through the experiments.

Summary

The electrochemical fluorination of ethylene and ethane has been carried out using a cell equipped with a bubbling arrangement. It appeared that the fluorination reaction could be controlled, especially for ethylene, in order to obtain either perfluoroethane or partially-fluorinated ethanes preferentially, in a reasonable yield and with reasonable current efficiency.

From ethylene, without any significant polymerisation or fragmentation, hexafluoroethane, pentafluoroethane, 1, 1, 1, 2-tetrafluoroethane, 1, 1, 2, 2-tetrafluoroethane, 1, 1, 1-trifluoroethane, 1, 1-difluoroethane, tetrafluoromethane, and a reduced product, ethane, and an unidentified minor product were formed. Ethane afforded similar fluorinated ethanes, together with monofluoroethane and a trace of tetrafluoromethane, but not 1,1-difluoroethane.

The influence of the operating conditions on these fluorination reactions and the mechanism involved have been discussed.

The authors wish to express their deep thanks to the Daikin Industries Co. for supplying some of the materials, and to Dr. Kan Inukai of this Institute for his interest in this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 223—227 (1966)

A Spectrophotometric Study of the Complex Formation between Iron(III) and Sulfosalicylic Acid

By Kin'ya OGAWA and Nobuko TOBE

Hitachi Research Laboratory, Hitachi, Ltd., Hitachi, Ibaraki

(Received April 8, 1965)

A spectrophotometric study of the complex formation between iron(III) and sulfosalicylic acid was carried out over the pH range up to 8; further, an attempt was made to test the applicability of sulfosalicylic acid as a reagent for the spectrophotometric determination of iron(III) in the presence of iron(II). The absorption maxima are found at 510 mμ independently of the pH between 1 to 2.5, while they shift in the direction of shorter wavelength as the pH rises. It was concluded that three complex species, Fe(Su), $Fe(Su)_2^{3-}$, and $Fe(Su)_3^{6-}$, are formed successively in acid solutions; their stability constants were determined to be:

$$\frac{[Fe(Su)]}{[Fe^{3+}][Su^{3-}]}=1.13\times10^{14} \qquad \frac{[Fe(Su)_2^{3-}]}{[Fe^{3+}][Su^{3-}]^2}=2.14\times10^{24} \qquad \frac{[Fe(Su)_3^{6-}]}{[Fe^{3+}][Su^{3-}]^3}=1.25\times10^{33}$$

where Su^{3-} denotes the sulfosalicylate anion, $C_6H_3(O^-)(COO^-)(SO_3^-)$. If the pH of the solution is adjusted from 3 to 4.5 and if the absorbancy measurements are made at 480 to 490 mμ, sulfosalicylic acid can be used as a reagent for determining iron(III) in the presence of iron(II). The optimum concentration of iron(III) is 2 to 10 p. p. m.; iron(II) does not interfere, even at a concentration of 100 p. p. m.

Sulfosalicylic acid, because it gives characteristic colors with iron(III), has been known as a reagent[1] for the colorimetric determination of iron(III). However, though several investigators have studied this complex-forming reaction, there have been some discrepancies between their results. For instance, Foley and Anderson[2,3] studied this reaction spectrophotometrically; they concluded that a 1 to 1 complex was formed in the pH range up to 8. On the other hand, Banks and Patterson[4] reported in their polarographic investigation that the molar ratio of sulfosalicylic acid to iron(III) in a complex formed in a solution of pH 9 was 3 to 1. Afterwards, Ågren[5] and Vareille[6] demonstrated the formation of more than one complex in their potentiometric and photometric studies.

The present study was undertaken in order to make possible a choice between the above alternative explanations and to test the applicability of sulfosalicylic acid as a reagent for determining spectrophotometrically iron(III) in the presence of iron(II).

Experimental

Reagents.—A standard solution of iron(III) was prepared by dissolving ammonium iron(III) sulfate, $Fe_2(SO_4)_3(NH_4)_2SO_4\cdot24H_2O$, in sulfuric acid. A standard solution of iron(II) was prepared by dissolving ammonium iron(II) sulfate, $FeSO_4(NH_4)_2SO_4\cdot6H_2O$, in sulfuric acid. The final concentration of acid in these solutions was adjusted to about 0.05 N. A solution of sulfosalicylic acid was prepared by dissolving a commercial product, $C_6H_3(OH)(COOH)(SO_3H)\cdot2H_2O$, in distilled water. For the adjustment of the pH, 1 N hydrochloric acid (pH<2), a 0.5 M monochloroacetic acid - sodium hydroxide solution (pH 2—3), a 1 M acetic acid - sodium acetate solution (pH 3—6.5), and a 1 M ammonium chloride - ammonium hydroxide solution (pH>7.5) were used. All the chemicals used were of the reagent grade.

Apparatus.—The absorption curves were recorded by using a Hitachi EPS-2-type Automatic Pen Recording Spectrophotometer, while a Hitachi EPU-2A-type Spectrophotometer was used for the absorbancy measurements. These spectrophotometers were equipped with absorption cells 10 mm. thick. The pH values were measured with a Horiba M-3-type pH meter equipped with a glass electrode.

Procedures.—An aliquot of a standard solution of iron(III) was taken, and the pH was adjusted to the required value by adding a buffer solution. After an aliquot of a solution of sulfosalicylic acid had been added, the solution was diluted to 100 ml. with distilled water. An absorbancy measurement was made on a part of the resulting solution within 3 hr. after the solution had been prepared, and, if necessary, an absorption curve

covering the range from 400 to 600 mμ was recorded and the pH was measured for the other part.

Preliminary experiments showed that solutions containing both 1.83×10^{-4} M of iron(III) and 7.3×10^{-3} M of sulfosalicylic acid gave the same absorption curves after 3 hr. of standing at room temperature for each pH value: 3.4, 4.5 and 5.2.

Results and Discussion

The Effects of the pH Values on the Absorption Curves.—Figure 1 shows the absorption curves for the solutions which contain 1.83×10^{-4} M of iron(III) and 8×10^{-3} M of sulfosalicylic acid at different pH values. The absorption maxima are found at 510 mμ independently of the pH between 1 to 2.5, while they shift to shorter wavelength as the pH rises. These color variations, from violet through deep red or rose in acid solutions to yellow in alkaline, suggest that more than one complex may be formed in aqueous solutions.

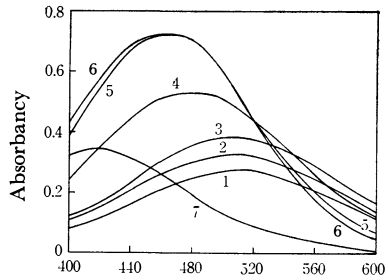

Fig. 1. Absorption curves. Solutions were 1.83×10^{-4} M in iron(III) and 8×10^{-3} M in sulfosalicylic acid.
Curve 1, at pH 1.38 in 0.05 M hydrochloric acid: 2, at pH 2.00; 3, at pH 2.49 in 0.05 M of total monochloroacetate: 4, at pH 3.08; 5, at pH 4.40; 6, at pH 5.34 in 0.05 M of total acetate: 7, at pH 7.88 in 0.05 M of total ammonium

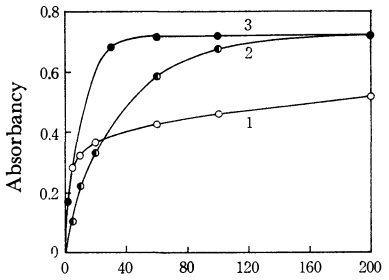

Fig. 2. Relation between absorbancy and C_{Su}/C_{Fe}, keeping C_{Fe} at 1.83×10^{-4} and varying C_{Su} up to 3.66×10^{-2} M in 0.05 M of total acetate.
Curve 1, at pH 3.39 for 480 mμ; 2 at pH 4.46 for 470 mμ; 3, pH 5.20 for 470 mμ

The Effects of the Molar Ratio of Sulfosalicylic Acid to Iron(III).—The relations between the absorbancies and the molar ratios of sulfosalicylic acid to iron(III) in solutions were obtained at different pH values; the results are shown in Fig. 2. In a solution of pH 5.20, a constant absorbancy is obtained with increasing molar ratios of over sixty parts of sufosalicylic acid to one of iron(III), while solutions in the lower pH region do not level off to a constant absorbancy in spite of the presence of more than a hundred moles of sulfosalicylic acid to one mole of iron(III). Judging from this, higher complexes seem to be produced successively with an increasing concentration of sulfosalicylic acid.

The Composition of the Complex.—The compositions of the complexes were determined by applying the continuous variation method.[7] Figure 3 shows the results obtained at different pH values by plotting Y, the difference between the observed absorbancy and that calculated assuming no complex formation, against the ratio of the total concentration of sulfosalicylic acid, C_{Su}, to the sum of the total concentration of iron(III) and that of sulfosalicylic acid, $C_{Fe}+C_{Su}$. The maximum value of Y in curve 1 occurs at a ratio of 0.5, indicating that a 1 to 1 complex is formed here. In curve 2 the maximum value of Y is found at a ratio of 0.6, and in curve 3, at a ratio of 0.75; this suggests that complex species in which the molar ratios of sulfosalicylic acid to iron(III) are 2 to 1 and/or 3 to 1 are formed in addition to the 1 to 1 complex at higher pH values.

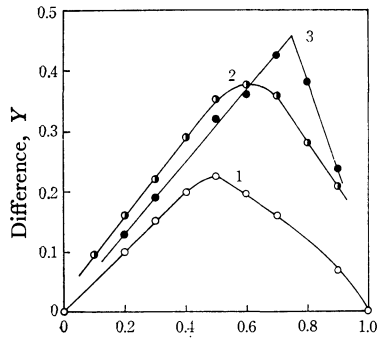

Fig. 3. Relation between Y and $C_{Su}/(C_{Fe}+C_{Su})$ in the application of the continuous variation method. Solutions were 4.57×10^{-4} M in $C_{Fe}+C_{Su}$, and 0.05 M in total monochloroacetate (curve 1) or 0.05 M in total acetate (curves 2 and 3).

7) A. E. Martell and M. Calvin, "Chemistry of the Metal Chelate Compounds," Prentice-Hall, New York (1952), p. 28.

The Stability Constant of the Complex.— From the aforementioned results, the complex-forming reaction between iron(III) and sulfosalicylic acid in an acid solution may be assumed to be represented in general as three successive steps:

$$Fe^{3+} + Su^{3-} \rightleftarrows Fe(Su) \quad (1)$$

$$Fe(Su) + Su^{3-} \rightleftarrows Fe(Su)_2^{3-} \quad (2)$$

$$Fe(Su)_2^{3-} + Su^{3-} \rightleftarrows Fe(Su)_3^{6-} \quad (3)$$

The corresponding equilibrium constants are, then:

$$K_1 = \frac{[Fe(Su)]}{[Fe^{3+}][Su^{3-}]} \quad (4)$$

$$K_2 = \frac{[Fe(Su)_2^{3-}]}{[Fe(Su)][Su^{3-}]} \quad (5)$$

$$K_3 = \frac{[Fe(Su)_3^{6-}]}{[Fe(Su)_2^{3-}][Su^{3-}]} \quad (6)$$

where Su^{3-} denotes the sulfosalicylate anion, $C_6H_3(O^-)(COO^-)(SO_3^-)$. The absorptions of both iron(III) and sulfosalicylic acid in the solution are so weak that they are negligible compared with the absorption of complexes over the range from 450 to 600 mμ. Therefore, the observed absorbancy, As, is expressed in general as:

$$As = \varepsilon_1[Fe(Su)] + \varepsilon_2[Fe(Su)_2^{3-}] + \varepsilon_3[Fe(Su)_3^{6-}] \quad (7)$$

where ε_1, ε_2 and ε_3 are the molar absorbancy indices of $Fe(Su)$, $Fe(Su)_2^{3-}$ and $Fe(Su)_3^{6-}$ respectively.

If a condition is now selected where only a 1 to 1 complex is formed, $[Fe(Su)_2^{3-}]$ and $[Fe(Su)_3^{6-}]$ become zero and K_1 is expressed as:

$$K_1 = \frac{[Fe(Su)]\Phi}{\{C_{Fe} - [Fe(Su)]\}\{C_{Su} - [Fe(Su)]\}} \quad (8)$$

$$= \frac{\varepsilon_1 As\Phi}{(\varepsilon_1 C_{Fe} - As)(\varepsilon_1 C_{Su} - As)} \quad (9)$$

where:

$$\Phi = 1 + \frac{[H^+]}{k_3} + \frac{[H^+]^2}{k_2 k_3} \quad (10)$$

where k_2 and k_3 are the second and the third acid dissociation constants of sulfosalicylic acid; these values, which were described in the literature,[8] will be used in subsequent calculations. The data at pH 2.20 were applied to Eq. 9, and K_1 and ε_1 were determined by the successive approximation method. As a first approximation, ε_1 for 480 mμ was assumed to be equal to 1.78×10^3 M^{-1} cm^{-1}, and the first approximations to K_1 were calculated from Eq. 9. Using the mean of these K_1 values, the second approximations to ε_1 were calculated from the absorbancy. Again using the mean of these values of ε_1, new values of K_1 were obtained from Eq. 9. This procedure was repeated four times. The results of these calculations are summarized in Table I.

Next, K_2 and K_3 can be determined when sulfosalicylic acid is present in a large excess over iron(III). Under these conditions, the concentration of the sulfosalicylic acid combining with iron(III) is negligible in comparison with its total concentration, so C_{Su} is nearly equal to $[Su^{3-}]\Phi$.

If a condition can be found where the reaction for the complex formation is represented as the two successive steps of reactions 1 and 2, $[Fe(Su)_3^{6-}]$ becomes zero, and from Eqs. 4, 5 and 7 the following relationship is derived;

$$\frac{C_{Fe}}{As} = \frac{1}{\varepsilon_1} + \frac{F_2}{\varepsilon_2\beta_2} \quad (11)$$

where:

$$F_2 = \frac{\Phi^2}{C_{Su}^2}\left\{1 + \frac{K_1}{\Phi}C_{Su} - \frac{\varepsilon_1 K_1 C_{Fe} C_{Su}}{As\Phi}\right\} \quad (12)$$

and where β is the overall stability constant of the complex, which is expressed in general as $\beta_n = \Pi K_n$. The plot of C_{Fe}/As against F_2 in Eq. 11 was applied to the data at pH 3.39, which gave a straight line, as is shown in Fig. 4. From the slope

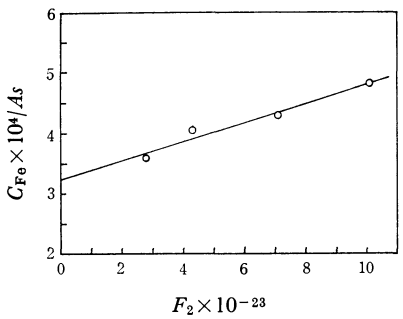

Fig. 4. Plot of C_{Fe}/As vs. F_2 at pH 3.39 for 480 mμ, keeping C_{Fe} at 1.83×10^{-4} M and varying C_{Su} from 3.6×10^{-3} to 3.66×10^{-2} M in 0.05 M of total acetate.

and the intercept at $F_2=0$, ε_2 and β_2 were then calculated: the results are included in Table II.

If, finally, a condition is selected where three complex species are formed, from Eqs. 4, 5, 6 and 7 the following equation is derived:

$$\frac{C_{Fe}}{As} = \frac{1}{\varepsilon_3} + \frac{F_3}{\varepsilon_3\beta_3} \quad (13)$$

where:

$$F_3 = \frac{\Phi}{C_{Su}^3}\left\{1 + \frac{K_1}{\Phi}C_{Su} + \frac{\beta_2}{\Phi^2}C^2{}_{Su}\right\} - \frac{C_{Fe}C_{Su}\left(\varepsilon_1\frac{K_1}{\Phi} + \varepsilon_2\frac{\beta_2 C_{Su}}{\Phi^2}\right)}{As} \quad (14)$$

The application of Eq. 13 to the data at pH 5.20

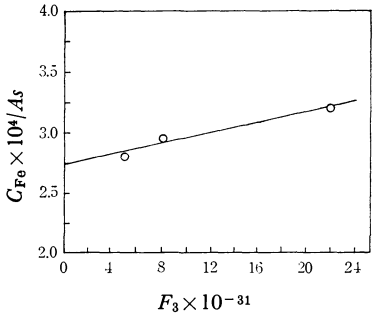

Fig. 5. Plots of C_{Fe}/As vs. for 480 mμ at pH 5.20 keeping C_{Fe} at 1.83×10^{-4} M and varying C_{Su} from 5.5×10^{-3} to 2.95×10^{-2} M in 0.05 M of total acetate.

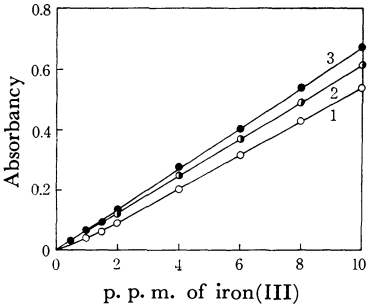

Fig. 6. Calibration curves. Solutions were 0.016 M in sulfosalicylic acid and 0.5 M in total acetate. Curve 1, at pH 3.40 for 480 mμ; 2, at pH 4.50 for 470 mμ; 3, at pH 5.20 for 470 mμ

gave a straight line plot, as is shown in Fig. 5. The results of the calculation of ε_3 and β_3 from the slope and the intercept at $F_3=0$ are included in Table II.

The logarithmic values of the stability constants calculated above are given in Table III, where they are also compared with those determined by Ågren[3] and by Vareille[6]. There are differences in ionic strength, temperature and buffer components between the findings of these investigations. Nevertheless, it may be concluded that the results obtained in these investigations are in

reasonable agreement.

The Spectrophotometric Determination of Iron(III) in the Presence of Iron(II).—*Calibration Curves.*—The calibration curves prepared for different pH values with a series of solutions containing up to 10 p.p.m. of iron(III) are shown in Fig. 6. A linear or nearly linear relation has been found between the absorbancy and the concentration of iron(III).

The Effect of Iron(II).—As is shown in Table IV, the determination of iron(III) at pH 3.40 and 4.50 is not interfered with or is given a negative error of only a few percentage points because of the presence of iron(II). At pH 5.20, the sensitivity is greater, but even small quantities of iron(II) produce a large positive error.

Table IV. Spectrophotometric determination of iron(III) with sulfosalicylic acid in the presence of iron(II)*

pH	Fe(II) present p. p. m.	Absorbancy	Fe(III) found p. p. m.	Error %
3.40	10	0.409(480 mμ)	7.8	−3
	50	0.408(480 mμ)	7.7	−4
	100	0.408(480 mμ)	7.7	−4
4.50	10	0.499(470 mμ)	8.1	+1
	50	0.490(470 mμ)	8.0	0
	100	0.490(470 mμ)	8.0	0
5.20	10	0.552(470 mμ)	8.2	+3
	50	0.577(470 mμ)	8.6	+8
	100	0.784(470 mμ)	11.7	+46

* The amount of Fe(III) taken in each case was 8 p. p. m. Solutions were 0.016 M in sulfosalicylic acid and 0.5 M in total acetate.

Summary

A spectrophotometric study of the complex formation between iron(III) and sulfosalicylic acid has been carried out over the pH range up to 8. Three complex species, Fe(Su), $Fe(Su)_2^{3-}$, and $Fe(Su)_3^{6-}$, have been concluded to be formed in acid solutions, and their stability constants have been determined to be:

$$\frac{[Fe(Su)]}{[Fe^{3+}][Su^{3-}]} = 1.13 \times 10^{13}$$

$$\frac{[Fe(Su)_2^{3-}]}{[Fe^{3+}][Su^{3-}]^2} = 2.12 \times 10^{24}$$

$$\frac{[Fe(Su)_3^{6-}]}{[Fe^{3+}][Su^{3-}]^3} = 1.25 \times 10^{33}$$

Also, it has been ascertained that sulfosalicylic acid can be used as a reagent for determining iron(III) in the presence of iron(II) if the spectrophotometric measurements are made in the pH range from 3 to 4.5.

The authors wish to express their deep gratitude to Professor Sôichirô Musha of the University of Osaka Prefecture for his interest, as well as to Assistant Professor Makoto Munemori for his helpful discussions, and to Dr. Takeshi Nakatogawa and Dr. Natsuki Kawashima of the Hitachi Research Laboratory, Hitachi, Ltd., for their guidance and encouragement throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 227—232 (1966)

A Spectrophotometric Study of the Complex Formation between Iron(III) and Salicylic Acid

By Kin'ya OGAWA and Nobuko TOBE

Hitachi Research Laboratory, Hitachi, Ltd., Hitachi, Ibaraki

(Received April 8, 1965)

A spectrophotometric study of the complex formation between iron(III) and salicylic acid was carried out over the pH range up to 6; further, an attempt was made to test the applicability of salicylic acid as a reagent for the spectrophotometric determination of iron(III) in the presence of iron(II). The absorption maxima of the mixture of iron(III) and salicylic acid are found at 530 mμ independently of the pH between 0.7 to 2.5, while they shift to shorter wavelength when the pH rises above 3. The isosbestic point occurs at 550 mμ between pH values from 3 to 6. It was concluded that three complex species, $Fe(Sa)^{+}$, $Fe(Sa)_2^{-}$, and $Fe(Sa)_3^{3-}$, are formed successively in acid solutions; their stability constants were determined to be:

$$\frac{[Fe(Sa)^{+}]}{[Fe^{3+}][Sa^{2-}]}=2.25\times10^{15} \qquad \frac{[Fe(Sa)_2^{-}]}{[Fe^{3+}][Sa^{2-}]^2}=1.57\times10^{27} \qquad \frac{[Fe(Sa)_3^{3-}]}{[Fe^{3+}][Sa^{2-}]^3}=1.86\times10^{36}$$

where Sa^{2-} denotes the salicylate anion, $C_6H_4(O^-)(COO^-)$. If the pH of the solution is adjusted from 2 to 3 and if absorbancy measurements are made at 515 to 500 mμ, salicylic acid can be used as a reagent for determining iron(III) in the presence of iron(II). The optimum concentration of iron(III) is 2 to 12 p. p. m.; iron(II) does not interfere, even at a concentration of 100 p. p. m.

Salicylic acid has been known as a reagent[1] for determining iron(III), since it gives characteristic colors with iron(III). The initial investigation of the nature of the complex formation between iron(III) and salicylic acid was undertaken by Babko,[2,3] who demonstrated the formation of more than one complex in an aqueous solution. Afterward, Ågren[4] determined the equilibrium constants for the complex-forming reaction.

The present authors were interested in the color variations, from violet through red to yellow with a rise on the pH values, which had been noted in earlier analytical studies.[5,6] For the present paper, therefore, the color-forming reaction between iron(III) and salicylic acid was studied spectrophotometrically, and, further, an attempt was made to test the applicability of salicylic acid as a reagent for the spectrophotometric determination of iron(III) in the presence of iron(II).

Experimental

Reagents.—The iron(III), iron(II) and buffer solutions were prepared in manners described previously.[7] A solution of salicylic acid was prepared by dissolving a commercial product, $C_6H_4(OH)(COOH)$, in ethanol.

Apparatus.—The two spectrophotometers and the pH meter used in the present work were the same as those described previously.[7]

Procedure.—The volume of the iron(III) solution was calculated and the pH was adjusted to the required value by adding a buffer solution. After the calculated volume of the salicylic acid solution had been added, the whole was diluted to the proper volume and allowed to stand for two hours. The absorbancy was observed in a part of the resulting solution, and/or, if necessary, the absorption curve over the range from 400 to 600 mμ was recorded, while the pH was measured for the other part. Preliminary experiments showed that the solutions reached an equilibrium within two hours and showed no measurable variation thereafter for periods of less than twenty-four hours.

Results and Discussion

The Effects of pH on the Absorption Curve.—Figure 1 shows the absorption curves for the mixture of iron(III) and salicylic acid at different pH values. The absorption maxima are found at 530 mμ, independently of the pH values when those values are between 0.7 to 2.5, while they shift to a shorter wavelength when the pH rises above 3. The isosbestic point occurs at 550 mμ at pH values between 3 and 6. This behavior suggests that only one complex is formed in a strongly acid solution between pH 0.7 and 2.5, but that the formation of more than one complex may be involved in a weakly acid solution between pH 3 and 6.

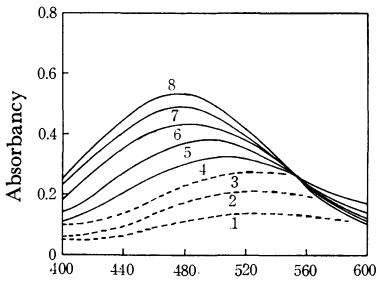

Fig. 1. Absorption curves. Solutions were 1.83×10^{-4} M in iron(III) and 7.3×10^{-3} M (for dotted line) or 1.45×10^{-2} M (for full line) in salicylic acid.

to iron(III) in their mixture were obtained at different pH values. The results are shown in Fig. 2. There is neither a sharp break nor a leveling-off to a constant absorbancy at any pH value for ratios up to as high as ten moles of salicylic acid to one mole of iron(III); this shows that the colored complexes are appreciably dissociated and that, hence, a large excess of salicylic acid over iron(III) is required to bring the reaction to completion.

The Composition of the Complex.—The compositions of the complexes were determined by applying the continuous variation method.[8] Figure 3 shows the results obtained at different pH values by plotting Y, the difference between the observed absorbancy and that which would be obtained if no reaction had taken place, against the ratio of the total concentration of salicylic acid, C_{Sa}, to the sum of the total concentration of iron(III) and that of salicylic acid, $C_{Fe}+C_{Sa}$. The maximum value of Y in curve 1 occurs at a ratio of 0.5, indicating that salicylic acid combines with iron(III) in a molar ratio of 1 to 1. In each of the curves from 2 to 5 the maximum of Y is found in the neighborhood of a ratio of 0.7, while in curve 6 it is found at a ratio of about 0.75. This indicates that complex species in which salicylic acid combines with iron(III) in molar ratios of two to one and/or three to one are formed in addition to the 1 to 1 complex, and that the molar ratio of salicylic acid to iron(III) in the complex increases with the rising pH values. This behavior is interpreted as taking place because iron(III) competes with hydrogen ions in taking away salicylate anions.

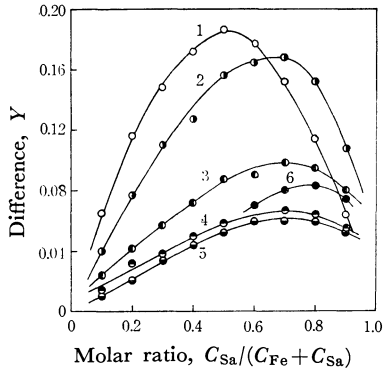

Fig. 3. Relations between Y and $C_{Sa}/(C_{Fe}+C_{Sa})$ in the application of continuous variation method. Solutions were 4.57×10^{-4} M (curves 1 to 5) or 9.13×10^{-1} M (curves 6) in $C_{Fe}+C_{Sa}$ and 0.05 M in total monochloroacetate (curve 1) or 0.05 M in total acetate (curves 2 to 6).
Curve 1, at pH 2.70 for 520 mμ; 2, at pH 3.33 for 505 mμ; 3, at pH 3.80 for 500 mμ; 4, at pH 4.02 for 485 mμ; 5, at pH 4.80 for 480 mμ; 6, at pH 5.94 for 475 mμ

The Stability Constant of the Complex.—The method described by McConell and Davidson[9] was used for determining the stability constants of the complexes. Since there are three complex species in the acid solution, the reaction for the complex formation may be written in general in terms of the following successive steps:

$$Fe^{3+}+Sa^{2-} \rightleftarrows Fe(Sa)^{+} \quad (1)$$

$$Fe(Sa)^{+}+Sa^{2-} \rightleftarrows Fe(Sa)_2^{-} \quad (2)$$

$$Fe(Sa)_2^{-}+Sa^{2-} \rightleftarrows Fe(Sa)_3^{3-} \quad (3)$$

where Sa^{2-} denotes the salicylate anion, $C_6H_4(O^-)(COO^-)$. The corresponding equilibrium constants are, then;

$$K_1=\frac{[Fe(Sa)^{+}]}{[Fe^{3+}][Sa^{2-}]} \quad (4)$$

$$K_2=\frac{[Fe(Sa)_2^{-}]}{[Fe(Sa)^{+}][Sa^{2-}]} \quad (5)$$

$$K_3=\frac{[Fe(Sa)_3^{3-}]}{[Fe(Sa)_2^{-}][Sa^{2-}]} \quad (6)$$

When salicylic acid is present in a large excess over iron(III), the concentration of the salicylic acid combining with iron(III) is negligible compared with its total concentration. Therefore, Eqs. 4, 5, and 6 are converted into the following:

$$K_1=\frac{[Fe(Sa)^{+}]\Phi}{\{C_{Fe}-([Fe(Sa)^{+}]+[Fe(Sa)_2^{-}]+[Fe(Sa)_3^{3-}])\}C_{Sa}} \quad (7)$$

$$K_2=\frac{[Fe(Sa)_2^{-}]\Phi}{[Fe(Sa)^{+}]C_{Sa}} \quad (8)$$

$$K_3=\frac{[Fe(Sa)_3^{3-}]\Phi}{[Fe(Sa)_2^{-}]C_{Sa}} \quad (9)$$

where C_{Fe} and C_{Sa} represent the total concentrations of iron(III) and of salicylic acid respectively, and

$$\Phi = 1+\frac{[H^+]}{k_2}+\frac{[H^+]^2}{k_1k_2} \quad (10)$$

where k_1 and k_2 are the first and the second acid dissociation constants of salicylic acid. The absorptions of both iron(III) and salicylic acid in the solution are so weak that they are negligible compared with the absorption of the complexes over the range from 450 to 600 mμ. Therefore, the observed absorbancy, As, may be expressed as:

$$A_S=\varepsilon_1[Fe(Sa)^{+}]+\varepsilon_2[Fe(Sa)_2^{-}]+\varepsilon_3[Fe(Sa)_3^{3-}] \quad (11)$$

where ε_1, ε_2, and ε_3 represent the molar absorbancy

9) H. McConell and N. Davidson, *J. Am. Chem. Soc.*, **72**, 3164 (1950).

indexes of $Fe(Sa)^+$, $Fe(Sa)_2^-$, and $Fe(Sa)_3^{3-}$ respectively.

From Eqs. 7, 8, 9, and 11 the following equation is derived:

$$\frac{C_{Fe}}{As}=\frac{1}{\varepsilon_3}+\frac{F_3}{\varepsilon_3\beta_3} \tag{12}$$

where:

$$F_3=\frac{\Phi^3}{C_{Sa}{}^3}\left\{1+\frac{K_1}{\Phi}C_{Sa}+\frac{\beta_2}{\Phi^2}C_{Sa}{}^2-\frac{C_{Fe}C_{Sa}\left(\varepsilon_1\frac{K_1}{\Phi}+\varepsilon_2\frac{\beta_3 C_{Sa}}{\Phi^2}\right)}{As}\right\} \tag{13}$$

and where β is the overall stability constant of the complex, which is expressed in general as $\beta_n=\Pi K_n$. In Eqs. 12 and 13, C_{Fe} and C_{Sa} have known values; As is an observed quantity, and ε_1, ε_2, K_1 and β_2 can be obtained from subsequent equations. If a suitable condition is chosen, the plotting of C_{Fe}/As against F_3 gives a straight line, the slope of which is $1/\varepsilon_3\beta_3$. The molar absorbancy index, ε_3, can be estimated from the intercept at $F_3=0$, which is obtained by extrapolation. In all subsequent equations, as in this, C_{Fe}/As is plotted against F terms, and the desired constants are obtained from the slopes and the intercepts of the straight lines.

If a condition is now selected where the reaction for the complex formation is represented as the two successive steps of reactions 1 and 2, $[Fe(Sa)_3^{3-}]$ becomes zero, and, from Eqs. 7, 8 and 11, it follows that:

$$\frac{C_{Fe}}{As}=\frac{1}{\varepsilon_2}+\frac{F_2}{\varepsilon_2\beta_2} \tag{14}$$

where:

$$F_2=\frac{\Phi^2}{C_{Sa}{}^2}\left\{1+\frac{K_1}{\Phi}C_{Sa}-\frac{\varepsilon_1 K_1 C_{Fe}C_{Sa}}{As\Phi}\right\} \tag{15}$$

Equations 14 and 15 permit the determination of both ε_2 and β_2, which are necessary for Eq. 13.

If a condition can be found where only a 1 to 1 complex is formed, both $[Fe(Sa)_2^-]$ and $[Fe(Sa)_3^{3-}]$ become zero, and, from Eqs. 7 and 11, there comes the following equation:

$$\frac{C_{Fe}}{As}=\frac{1}{\varepsilon_1}+\frac{F_1}{\varepsilon_1 K_1} \tag{16}$$

where $F_1=\Phi/C_{Sa}$, which permits the determination of both ε_1 and K_1, necessary for Eq. 14.

First, in order to determine the K_1 value, plots of Eq. 16 were applied to the data at pH 2.04 and 2.81; the results are shown in Fig. 4. Next, plots of Eq. 14 were applied to the data at pH 3.51 in order to determine β_2; the results are given in Fig. 5. Finally, β_3 was determined from the results of the application of Eq. 12 to the data at pH 5.96, as is shown in Fig. 6.

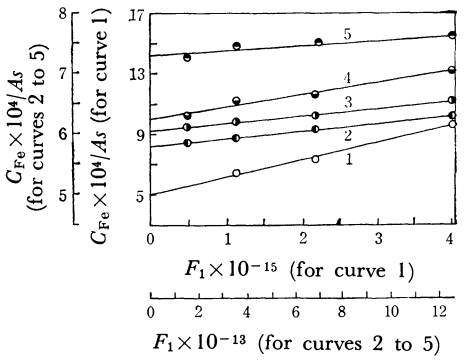

Fig. 4. Plots of C_{Fe}/As vs. F_1, keeping C_{Fe} at 1.83×10^{-4} M and varying C_{Sa} from 2.0×10^{-3} to 1.45×10^{-2} M in 0.05 M of total monochloroacetate.
Curve 1, at pH 2.04 for 530 mμ; 2, at pH 2.81 for 530 mμ; 3, at pH 2.81 for 550 mμ; 4, at pH 2.81 for 480 mμ; 5, at pH 2.81 for 460 mμ.

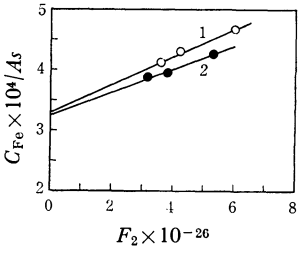

Fig. 5. Plots of C_{Fe}/As vs. F_2 at pH 3.51, keeping C_{Fe} at 1.83×10^{-4} M and varying C_{Sa} from 7.3×10^{-3} to 3.62×10^{-2} M in 0.05 M of total acetate.
Curve 1, for 460 mμ; 2, for 480 mμ.

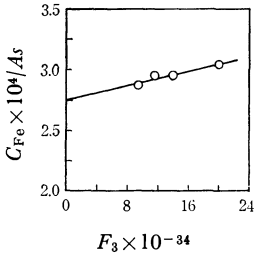

Fig. 6. Plots of C_{Fe}/As vs. F_3 at pH 5.96 for 480 mμ, keeping C_{Fe} at 1.83×10^{-4} M and varying C_{Sa} from 3.6×10^{-3} to 2.90×10^{-2} M in 0.05 M of total acetate.

In Table I are tabulated the results of the calculation of the desired constants from Figs. 4, 5 and 6. The values of the first and the second acid dissociation constants of salicylic acid used in these calculations were those described in the literature.[10] The logarithmic values of the stability constants calculated above are given in Table II, where they are also compared with those determined by

* The amount of iron(III) taken in each case was 8.16 p. p. m. Solutions were 0.036 M in salicylic acid and 0.5 M in total monochloroacetate or total acetate.

and 3.70 has a positive error of a few percentage points because of the presence of iron(II). At pH 4.50, the sensitivity is greater, but even small quantities of iron(II) produce a large positive error.

Summary

A spectrophotometric study of the complex formation between iron(III) and salicylic acid has been carried out over the pH range up to 6. Three complex species, $Fe(Sa)^+$, $Fe(Sa)_2^-$, and $Fe(Sa)_3^{3-}$, have been concluded to be formed in acid solutions, and their stability constants have been determined to be:

$$\frac{[Fe(Sa)^+]}{[Fe^{3+}][Sa^{2-}]}=2.24\times10^{15}$$

$$\frac{[Fe(Sa)_2^-]}{[Fe^{3+}][Sa^{2-}]^2}=1.57\times10^{27}$$

$$\frac{[Fe(Sa)_3^{3-}]}{[Fe^{3+}][Sa^{2-}]^3}=1.86\times10^{36}$$

Also, it has been ascertained that salicylic acid can be used as a reagent for determining iron(III) in the presence of iron(II) if the spectrophotometric measurements are made in the pH range from 2 to 3.

The authors wish to express their deep gratitude to Professor Sôichirô Musha of the University of Osaka Prefecture for his interest, as well as to Assistant Professor Makoto Munemori for his helpful discussions. Thanks are due also to Dr. Takeshi Nakatogawa and Dr. Natsuki Kawashima of the Hitachi Research Laboratory, Hitachi, Ltd., for their guidance and encouragement throughout this work.

Intermediates in the Photoreduction of Eosine as Revealed by a Flash-Photolysis Study

By Takeshi OHNO, Shunji KATO and Masao KOIZUMI

Department of Chemistry, Facultry of Science, Tohoku University, Katahira-cho, Sendai

(Received April 15, 1965)

Besides the triplet state, semi-reduced eosine (Rd) and semi-oxidized eosine (Ox) were observed as transient intermediates in an aqueous solution; the former has a peak at 408 mμ, and the latter, one at 456 mμ. These two species are produced by the reaction $D^T + D \rightarrow Rd + Ox$ or $D^T + D^T \rightarrow Rd + Ox$. The sum of the rate constants for the reactions $D^T + D \rightarrow Ox + Rd$ and $D^T + D \rightarrow 2D$ is about 8.0×10^8 M^{-1} sec^{-1}, approximately equal to the sum of the rate constants for $D^T + D^T \rightarrow 2D$ and $D^T + D^T \rightarrow Ox + Rd$. Triplet eosine, by reacting with ATU or EDTA, produces two kinds of half-reduced eosine, Rd' and Rd'', which have absorption spectra similar to those of Rd but with different life-times. These are perhaps loose compounds of half-reduced dye and a half-oxidized reductant. The rate constants for $D^T + ATU \rightarrow Rd'$ and $D^T + EDTA \rightarrow Rd''$ are 3.4×10^5 M^{-1} sec^{-1} and 5×10^5 M^{-1} sec^{-1} respectively. Rd disappears bimolecularly by means of the $Rd + Ox \rightarrow 2D$ reaction with the rate constant of 8.8×10^7 M^{-1} sec^{-1}. Ox, by reacting with EDTA or ATU, regenerates the original dye with the rate constants of 1×10^6 and 8×10^5 M^{-1} sec^{-1} respectively. The results enable us to conclude that the D-D mechanism occurs under suitable conditions.

It has been proposed by two of the present authors[1] (Koizumi and Ohno) that, in the continuous-light photoreduction of eosine by allylthiourea (ATU), the reaction proceeds by one of two alternative paths, depending on the experimental conditions. Thus, in the case of higher ATU concentrations, the primary step is the reaction between the triplet dye (D^T) and a reducing agent (the D-R mechanism), while at lower concentrations of ATU the primary step is the electron transfer between D^T and D (the D-D mechanism). The rate constants of some elementary processes have also been evaluated.

The first evidence for the electron transfer between two D^T molecules or between D^T and D was presented by Lindqvist in his extensive study of the transient intermediates of fluorescein by means of a flash technique[2]; further evidence was presented by Kato et al. in the case of methylene blue.[3]

Meanwhile, Grossweiner and Zwicker reported,[4] in their paper dealing with a flash-photolytic investigation of the eosine-phenol system, that there is no evidence for the production of semi-reduced and semi-oxidized eosine in an evacuated aqueous eosine solution. These quite different aspects of the behavior of fluorescein and eosine seemed to us rather odd, although Grossweiner himself attributed them to their different electronic configurations.

In view of our findings in steady-illumination experiments and the above disagreement between the two groups of investigators, we made flash-photolytic studies of aqueous solutions of eosine in connection with our steady-light studies.

The purpose of the present paper is to report that half-reduced and half-oxidized eosine does come into existence in the flash-illuminated aqueous eosine solution.

In addition, we have investigated the behavior of these intermediates as well as that of the triplet dye.

Experimental

Apparatus.—The flash apparatus reported on in a previous paper[3] was used to record the transient spectra.

Another apparatus, with a shorter duration of the photolysis flash, was used to trace the change in the transient absorption. It was assembled from a grating monochrometer (Narumi RM-23), a synchroscope (Iwasaki SS-5151) and a 150W. xenon short arc lamp (Ushio UXL-150). Two quartz flash lamps filled with xenon were set parallel and were connected, in series, with an air gap for triggering and a carbon rod (15 cm. long and 4.5 mm. in diameter) for electric damping. The lamps were powered by a 1 μF condenser and operated at 10 kV. The half-height duration of the flash was 4.5 μsec.

The relative light doses of flashes with and without the carbon rod were compared by the use of a ferrioxalate actinometer; it was found that the rod reduced the light dose to 55 per cent of the value without it. Thus, the flash energies recorded in this paper are 55 per cent of the input electrical energies.

The green plastic plates, always used as filters were transparent from 420 to 600 mμ and had a maximum transmittance of 60 per cent at 520 mμ. To change the light intensity, darkened photographic plates with a known transmittance were employed as neutral filters, instead of changing the electrical conditions. Accordingly, the profile of the incident flash light was always of the same shape.

Materials.—Eosine (Merck) was recrystallized three times from an ethanol solution. ATU, β-sulfonylanthraquinone, disodium hydrogen phosphate, potassium dihydrogen phosphate and $NaClO_3$, all of a G. R. grade, were recrystallized three times from aqueous solutions. Benzoquinone was recrystallized two times from ethanol and then washed with water. The other substances, all of a G. R. grade, were used without further purification.

All the sample solutions were prepared in a 0.1 M phosphate buffer solution, pH=7.2. The samples were degassed by cycles of freezing, pumping and thawing.

Results

General Features of the Reaction and the Assignment of the Transient Absorption Spectra.—It was established that the permanent bleaching of dye by a single flash (19J) is less than 1%. The transient spectra at 65, 360 and 1410 μ sec. after the excitation flash are shown in Fig. 1. Four maxima are apparent, at 580, 456, 408 and 325 mμ, of which the first one and the last one

Dotted line; flash (55J), a, 610 mμ; b, 450 mμ; c, 405 mμ

completely disappear at 360 μsec., of the two remaining peaks, 408 mμ has the longer life. This is clear from Fig. 2, in which the decay at 405 and at 450 mμ in a later stage is shown. The recovery of the main absorption band of the original dye (480 mμ) is also included in this figure.

The rise and fall of each absorption maximum in an early stage are shown in Fig. 3. There is no doubt from these three figures that 325 mμ and 508 mμ, which appear to be produced only during illumination and which decay at the same rate, belong to a primary intermediate. These two bands may most plausibly be assigned to the triplet state of the dye. The peaks at 405 and 450 mμ, which grow with the decline of 325 and 580 mμ, can be attributed to the second-step intermediates.

When ATU, EDTA, $NaClO_3$, $NaHAsO_4$ or oxygen was added, a more or less permanent bleaching of the dye resulted from a single flash. The extent of bleaching is particularly large in the cases of EDTA and ATU.

In the cases of β-sulfonylanthraquinone and *p*-benzoquinone, there is scarcely any permanent bleaching observed. The triplet absorption spectra were not observable when an ample quantity of any of the above-mentioned substances, except $NaClO_3$ and $NaHAsO_4$, were added.

The transient spectra from the system containing ATU or EDTA have only a 408 mμ peak, as is shown in Fig. 4, whereas the only observable peak in the case of the system to which β-sulfonylanthraquinone or oxygen has been added is the one at 456 mμ. $NaClO_3$ and $NaHAsO_4$ scarcely affect the transient spectra at all.

The spectra for the system containing *p*-benzoquinone are complicated, as can be seen in Fig. 5. Besides the 450—460 mμ band, four peaks are apparent, at 430, 410, 380 and 355 mμ; these may most plausibly be attributed to the half-reduced forms of benzoquinone, in ionic and neutral forms.

To sum up the effect of the added substances, there is scarcely any doubt that the peaks at 408 and 456 mμ can be assigned to semiquinone (Rd) and half-oxidized eosine (Ox) respectively, because

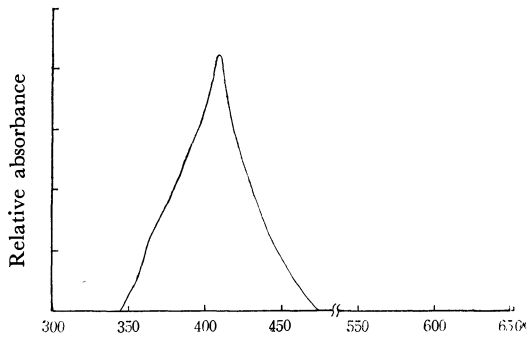

Fig. 4. Absorption spectra of transient species in the presence of 3×10^{-2} M allylthiourea at 65 μsec. after flashing. Eosine: 13 μM

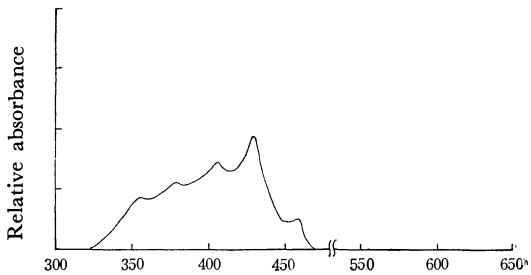

Fig. 5. Absorption spectra of transcient species in the presence of 10^{-3} M *p*-benzoquinone at 360 μ sec. after flashing. Eosine: 13 μM

the addition of oxidants removes the 405 mμ peak, while reductants eliminate the 456 mμ absorption. This conclusion will be further substantiated below.

Some Observations Concerning the Behavior of Transient Intermediates.—The relation between the absorbances at 450 and 408 mμ, due, respectively, to the existence of Ox and Rd at 80 μsec. after flashing, is shown in Fig. 6; the concentrations of these intermediates were varied by changing the intensity of the light flash. It is certain from this figure that the two intermediates are always produced in the same ratio, irrespective of the experimental conditions. In order to determine this ratio, one must know the molar extinction coefficients of Rd and Ox. These were derived in the following way.

As is evident from Fig. 2, only Rd survives at a later stage. If one assumes that both Rd and Ox return completely to the ground-state dye under any circumstances, the molar extinction coefficient

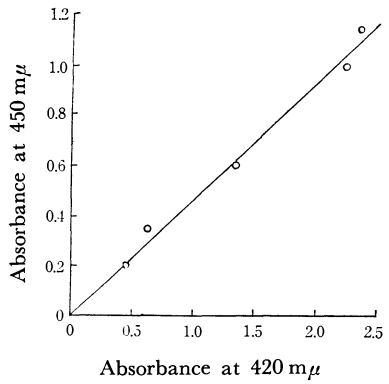

Fig. 6. Relation between the formation of Ox and Rd at 80 μsec. after flashing. Eosine concentration is 13 μM.

of Rd can easily be calculated, since its concentration in the later stage can be equated to that of the ground-state dye recovered after the corresponding time point. This, although not conclusive, appears to be justified if one recalls that the fluorescein semiquinone produced from the interaction of leuco- and oxidized-forms returns completely to the ground-state dye, probably by losing molecular hydrogen.[5] The molar extinction coefficient of Rd at 408 mμ thus obtained is 2.5×10^4. The molar extinction coefficient of Ox can, then, be obtained from the absorbance at 458 mμ in the stage where there is no triplet absorption remaining, by using the concentration data of the ground-state eosine and of Rd, both of whose coefficients are known. The coefficient of Ox thus obtained at 458 mμ is 1.2×10^4.

By the use of the above ε-values, the ratio of Rd to Ox was found to be about unity. This implies that Rd and Ox are produced by the reaction:

$$D^T + D \rightarrow Rd + Ox \qquad (1)$$

or

$$D^T + D^T \rightarrow Rd + Ox \qquad (2)$$

Although the procedure used above is somewhat ambiguous, the coefficients so obtained are used tentatively in the present paper. Grossweiner's value[4] for ε_{408} is $3.8\times10^4\pm0.4$, which is not very different from ours.

The relation between the yield of Rd and the dye concentration was examined using a flash light of such an intensity that most of the dye was converted to the triplet state, while the production of the triplet state was considered to be roughly proportional to the dye concentration.

In Fig. 7 the absorbances at 408 mμ measured 80 μ sec. after flashing are plotted against the dye concentration. The shape of the curve favors the view that the predominant reaction is $D^T+D^T \rightarrow Rd+Ox$, but it does not obviate the possible participation of the process $D^T+D \rightarrow Rd+Ox$.

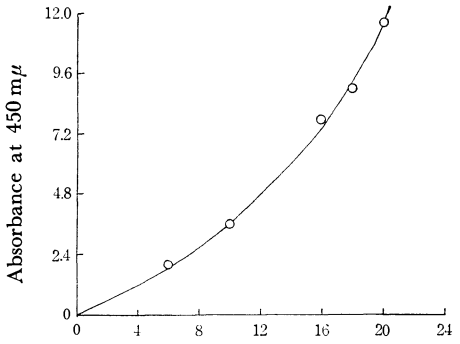

Fig. 7. Formation of Ox at various eosine concentrations at 80 μsec. after flashing. (55J, 77.5J)

To investigate further which reaction, 1 or 2, is the more efficient, the dependence of the yield of Rd on the triplet dye concentration was examined. Since the decay of the triplet state is exponential with the rate constant, independent of the light intensity (see below), the quantities of the triplet state produced by single flashes of various intensities are proportional to the absorbance density at 610 mμ at a fixed time point after flashing. Figure 8 gives the plot of the absorbance at 610 mμ, A_{610}, against the relative light intensity.

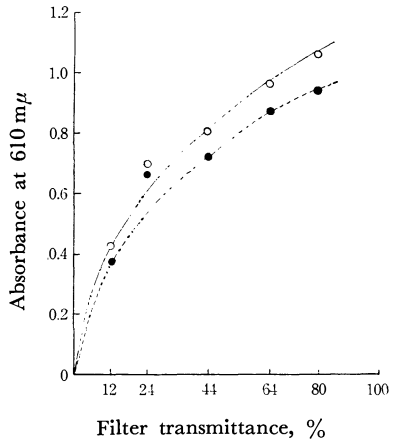

Fig. 8. Formation of triplet state by various light energies observed at various time interval.
—○— 30 μsec. after flashing
—●— 40 μsec. after flashing

Then, at various light intensities, the maximum values of A_{408} after flashing were compared with the values of A_{610}. As is shown in Fig. 9, A_{408} is approximately proportional to A^2_{610}. Although exact analysis is difficult, the results strongly suggest

5) Y. Momose, K. Uchida and M. Koizumi, This Bulletin, 38, 1601 (1965).

the predominance of the reaction 2 under the present experimental conditions.

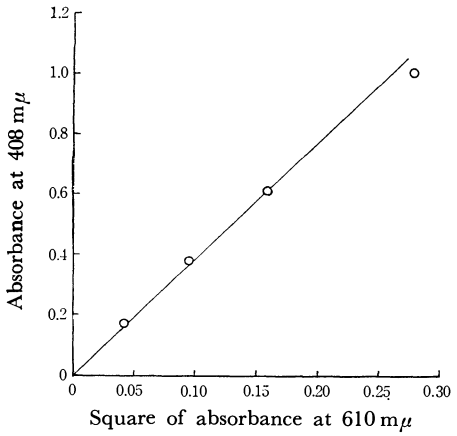

Fig. 9. Relation between the formation of Rd and triplet state.

When ATU or EDTA is added, the yield of Ox decreases with the increase in the reductant concentration. The yield of Rd, on the other hand, is not affected to any large extent. However, the decay of Rd, which will be treated quantitatively later, shows a sharp breaking point, after which the rate becomes very slow; yet the shape of the absorption spectrum remains the same. The phenomenon is similar in both reductants. It is reasonable to explain this break by assuming two somewhat different species, species which have the same absorption spectra but which differ in life time. The one with the shorter life time and that with a longer life time will conventionally be denoted as Rd and Rd' respectively in the case of ATU, and as Rd and Rd'' respectively in the case of EDTA. Both Rd' and Rd'' increase with the concentration of reductants. Tables I and II give some of the results; one example is shown in Fig. 10.

TABLE I

[ATU] $\times 10^2$	Rd+Rd' (Op. dens.)	Rd (Op. dens.)	Rd' (Op. dens.)	Ox
0	0.670	0.670	0	0.360
2	0.609	0.385	0.244	0.12
4	0.560	0.243	0.316	0
5	0.652	0.286	0.366	0

TABLE II

[EDTA] $\times 10^2$	Rd+Rd''	Rd	Rd''	Ox
0	0.670	0.67	0	0.360
1	0.49	0.26	0.24	0.24
2	0.95	0.56	0.39	0
3	0.97			0
5	1.14	0.76	0.38	0

At first sight there appear to be two ways in which the nature of Rd' and Rd'' can be explained. One is to consider, as has been mentioned above, that they are slightly different species from Rd and are produced by a direct reaction between D^T and the reductants; the other interpretation is to consider that they are the same species as Rd but that, since the reductants eliminate Ox, the remaining Rd, with no Ox to react, behaves in quite a different way. The data in the above table show that quite a large quantity of Rd still exists after the Ox has been exhausted; hence, the first interpretation is more plausible. The problem will be discussed later, after the studies of the decay of the transient intermediates have been described.

The quantity of Rd' is proportional to the quantity of the permanent bleaching of the dye; if one assumes that the extinction coefficients of Rd' and Rd'' are same as that of Rd, then the quantity of Rd' is exactly the same as the permanent bleaching. Thus Rd' is completely converted to leuco eosine. Rd'' is also proportional to the quantity of permanent bleaching, but the ratio of the former to the latter is 1 : 2.3 in this case. (Fig. 11)

When 10^{-3} M of *p*-benzoquinone is added, the absorption spectra of the triplet dye do not appear

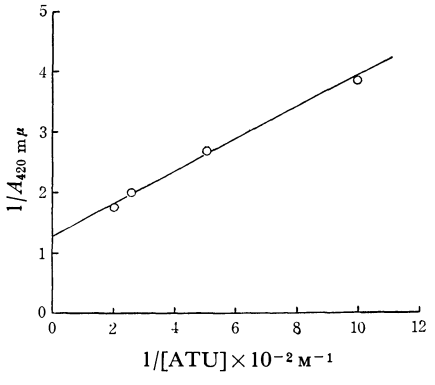

Fig. 10. Formation of Rd' for various allylthiourea concentration.

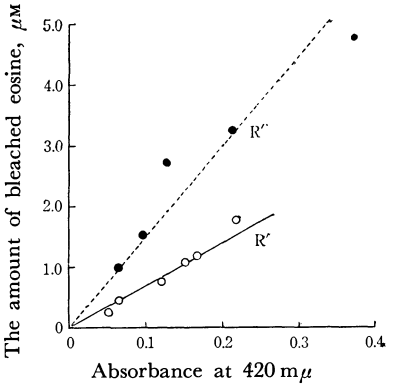

Fig. 11. Relation between the formation of Rd' or Rd'' and permanent bleaching of eosine.

at all, and the quantity of Ox reaches its maximum value immediately after the flashing. The quantity of Ox is exactly proportional to the absorbance at 430 mμ which is due to benzosemiquinone. This is shown in Fig. 12. Hence, one may say that the reaction between benzoquinone and D^T yields Ox and the half-reduced form of *p*-benzoquinone very efficiently.

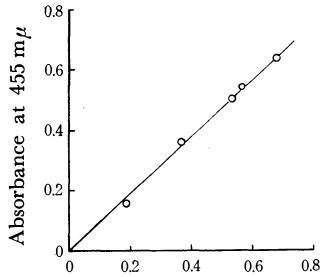

Fig. 12. Relation between the formation of Ox and that of benzosemiquinone ion.

The Decay of the Intermediates.—The decay of the triplet state was measured at 580 mμ.

As Fig. 13 shows, the decay rate is scarcely influenced at all by a variation in the intensity of the exciting light. This suggests that the decay is not affected by the concentration of D^T. The decay is well expressed as a first-order process, seemingly suggesting the absence of any bimolecular processes. However, this is not the case, because the first order decay constant increases with the concentration of dye, as is shown in Fig. 14. Hence, the rate formula for the decay should be written as follows:

$$\frac{-d[D^T]}{dt}=\{k_{sp}+k[D]_0\}[D^T] \qquad (3)$$

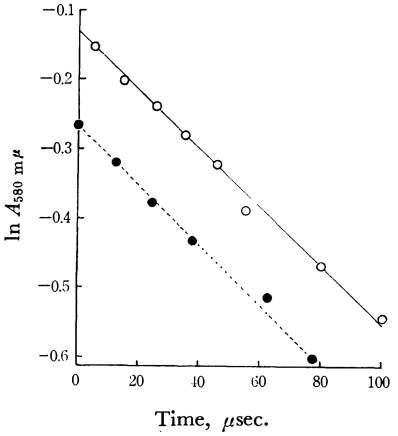

Fig. 13. Decay of triplet state for various light energies. Eosine concentration is 25 μM.
—○— Input-energy 55J
—●— Input-energy 2.5J

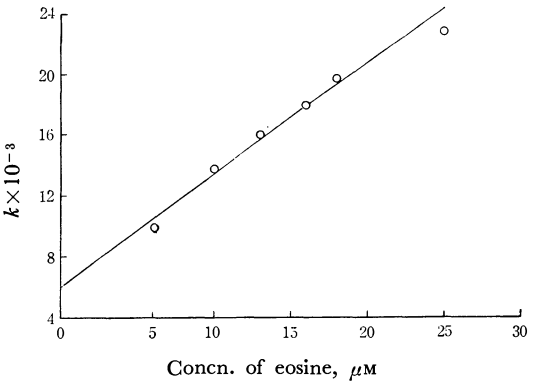

Fig. 14. Decay constant of triplet state for various eosine concentrations.

where k_{sp} is a unimolecular rate constant and $[D]_0$ is the concentration of the dye. From the intercept, $k_{sp}\approx6\times10^3\ sec^{-1}$, and from the slope, $k=8.0\times10^8\ M^{-1}\ sec^{-1}$.

The above results imply that, along with the reaction between two triplet molecules, deactivation by the ground-state dye takes place at about the same efficiency, for at an initial stage, where no appreciable quantities of Rd and Ox exist, the sum of $[D^T]$ and [D] is equal to $[D]_0$.

In a later stage of the decay curves in Fig. 14, quite a large quantity of Rd and Ox may be expected to exist, so there is a great possibility that these species are equally efficient quenchers of D^T. From the above results, one may approximately put $k_{T-T}=k_{T-S}=8.0\times10^8\ M^{-1}\ sec^{-1}$, where k_{T-T} and k_{T-S} are the second-order rate constants for, respectively reaction $D^T+D^T\rightarrow$ and the $D^T+D\rightarrow$reaction.

The decay of Rd was measured at 405 mμ. As Fig. 15 shows, the decay is a second-order process with regard to Rd, but deviation becomes apparent at a later stage. A second-order rate constant is 8.8—$10^7\ M^{-1}\ sec^{-1}$.

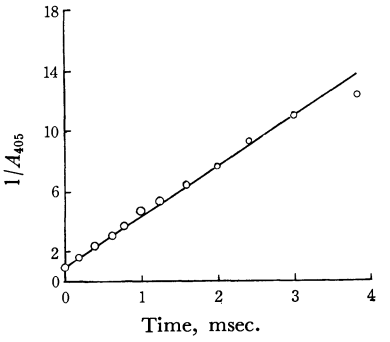

Fig. 15. Decay of Rd at 20 μM eosine.

The decay of Ox was measured at 450 mμ. The decay is complicated and cannot be expressed by a simple rate formula. It seems that first-order

and second-order processes are superimposed. At higher concentrations of Ox, the participation of the second-order process seems to increase.

If one puts

$$-\frac{dC}{dt}=k_1C+k_2C^2$$

then one can estimate the values of k_1 and k_2 by analysing the experimental data. They are $k_2=8.7\times10^8$ M^{-1} sec^{-1} and $k_1=9\times10^2$ sec^{-1}. The value of k_2, although not so reliable, agrees with the value of the decay constant for Rd, supporting the occurrence of the process Rx+Od→2D.

The nature of the superimposing first-order process is unknown.

As for the decay of the triplet state of the dye, it is accelerated more or less by the addition of oxygen, β-sulfonylanthraquinone, *p*-benzoquinone, ATU and EDTA. The air-saturated solution (10^{-4} M) and the solution containing 10^{-3} M *p*-benzoquinone do not give any appreciable triplet absorption spectra.

Figure 16 shows the relation between the first-order decay constant and the concentrations of EDTA and ATU.

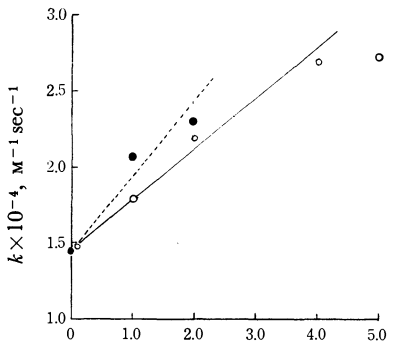

Fig. 16. Decay constant of triplet state for various reductant concentrations. Eosine: 10 μM
—○— Allylthiourea
--●-- EDTA

From the plots, one obtains, as the second-order rate constant for D^T+ATU→ and D^T+EDTA→ respectively, 3.4×10^5 M^{-1} sec^{-1} and 5×10^5 M^{-1} sec^{-1}.

The addition of ATU or EDTA promotes the decay of Ox. The decay curve is expressed by a simple first-order rate formula, as is shown in Fig. 17. From the plots, the rate constants for Ox+EDTA→D+EDTA$^+$ and Ox+ATU→D+ATU$^+$ are found to be respectively, 8×10^5 M^{-1} sec^{-1} and 1.0×10^6 M^{-1} sec^{-1}.

In the air-saturated solution, the absorption spectra near 450 mμ appear slightly only with quite a large input of energy. The addition of

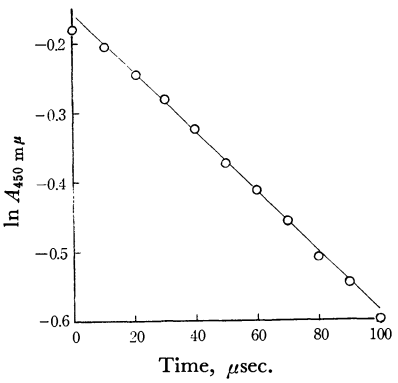

Fig. 17

$NaClO_3$ or $NaHAsO_4$ slightly lengthens the life of Ox. In the system containing *p*-benzoquinone, the life of Ox is only about 20 μsec., and the decay cannot be analyzed.

In the system containing $NaClO_3$ or $NaHAsO_4$, the decay of Rd at an earlier stage is a second-order process, while in a later stage it is a first-order process. The latter process may be attributed to the reaction between Rd and oxidants. Its rate constant is below 10^4 M^{-1} sec^{-1}.

In the case of ATU and EDTA, the decay consists of two parts, as has already been described. The decay for Rd'' (in the case of EDTA) is a first-order process, as Fig. 18 shows.

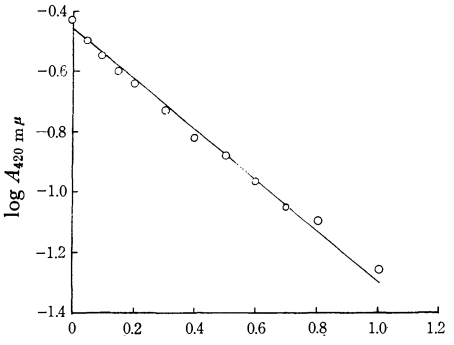

Fig. 18

The first-order rate constants is 1.0 sec^{-1}, independent of the concentration of EDTA. For ATU we did not succeed in getting a reliable value because of the bad reproducibility of the experiment.

Summary and Discussion

The elementary reactions established in the present paper may be summarized as follows:

D^T

$D^T \rightarrow D$ $\quad k \approx 6\times10^3\ sec^{-1}$

$D^T + D \rightarrow Ox + Rd$ (1a)
$D^T + D \rightarrow 2D$ (1b)
} For the sum of the two $k = 8.0\times10^8\ l.mol^{-1}\ sec^{-1}$

$D^T + D^T \rightarrow Ox + Rd$ (2a)
$D^T + D^T \rightarrow 2D$ (2b)
} For the sum of the two $k = 8.0\times10^8\ l.mol^{-1}\ sec^{-1}$

$D^T + ATU \rightarrow Rd'$ (3) $\quad k = 3.4\times10^5\ l.mol^{-1}\ sec^{-1}$

$D^T + EDTA \rightarrow Rd''$ (3') $\quad k = 5\times10^5\ l.mol^{-1}\ sec^{-1}$

The rate constants for 3 and 3', which had been obtained from the steady-light experiments,[1] are, respectively, $k = 3.1\times10^5$ and 4.1×10^5; these values are in excellent agreement with the above values.

The rate of reaction 2a is probably larger than that of 2b, but no comparison can be made between la and 1b.

Rd. Rd produced by la or 2a disappears by a second-order process, at least in the initial stage;

$$k = 8.8\times10^7\ l.mol^{-1}\ sec^{-1} \quad (4)$$

$Rd' \rightarrow$ leuco eosine
$Rd'' \rightarrow$ leuco eosine
} (not certain)

O x The reaction of Ox is rather complicated; it seems to be a superimposition of a first-order and a second-order reaction. The rate constants are, respectively:

$$k_5 = 9\times10^{-2}\ sec^{-1} \quad (5)$$

$$k_6 = 8.7\times10^8\ M^{-1}\ sec^{-1} \quad (6)$$

These data are not very reliable.

$$Ox + EDTA \rightarrow D + (EDTA)^+$$
$$k = 1\times10^6\ M^{-1}\ sec^{-1} \quad (7)$$

$$Ox + ATU \rightarrow D + (ATU)^+$$
$$k = 8\times10^5\ M^{-1}\ sec^{-1} \quad (7)$$

From the above rate constants, one can say definitely that the D–D mechanism (in the present case, the reaction between two D^T molecules) occurs under certain experimental conditions. Thus, from the rate constants for reactions 1, 2 and 3, the rate for the reaction between two dye molecules (the D–D-mechanism) is of the same order as that for the reaction between eosine and a reductant (ATU or EDTA) when the concentration of [D] is $\sim10^{-5}$ M and that of the reductant is $\sim10^{-2}$ M. If the reductant concentration is lower, the reaction due to the D-D mechanism will predominate.

The Ox thus produced will then react with the reductant or disappear according to 5 or 6. From the rate constant for 6, $8\times10^5\ M^{-1}\ sec^{-1}$, and for 7, $1\times10^6\ M^{-1}\ sec^{-1}$, the reaction 7 will predominate if $[Ox]=[Rd]\leqq10^{-8}$ M and if EDTA $\approx10^{-2}$ M. Hence, in such situations Rd will survive and will turn into leuco dye. This is just what may be expected via a D–D mechanism. Thus, the discussion so far, we believe, thoroughly confirms a D–D mechanism.

Most of the other results obtained in the present paper can be understood in terms of this scheme. Thus, the finding that $[Rd]\propto[D^T]^2$ can be interpreted on the assumption that the rate of the reaction is proportional to $D^T\times D^T$. No comment is needed for the fact that the yield ratio of Rd and Ox is 1 : 1.

However, the extent to which the back reaction, $Rd + Ox \rightarrow 2D$, occurs, is not yet clear enough, since some of Rd and some of Ox react independently of each other. The answers to such questions must await further study.

As to the nature of Rd' and Rd'', they are probably loose compounds of a half-reduced dye and a half-oxidized reductant. This conclusion depends on the following reasons: Firstly, from the rate constant of la on the one hand and that of 3 and 3' on the other, one can say that D–D and D–R mechanisms occur as competing processes under the experimental conditions in which Rd' and Rd'' are produced (see Tables I and II). Secondly, the fact that Rd'' obeys the first-order decay with the same rate constant, irrespective of the concentration of EDTA, can be interpeted by the above model, but perhaps not so well by other models.

It is very interesting that such a compound has a life as long as l sec., and that its absorption spectra are quite similar to those of free semiquinone. There is no assurance, however, that its molar absorbance is the same as that of the latter. Hence, the statement given regarding the ratio of Rd' or Rd'' to leuco dye is not decisive.

Studies of Scandium in Various Solutions. I. An Ion-Exchange Study of Scandium(III) Chloride and Nitrate Complexes

By Tatsuya SEKINE and Yuko HASEGAWA

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received April 30, 1965)

The complex formation of scandium(III) with chloride and nitrate ions has been investigated at 25°C. Scandium-46 was employed in conjunction with a cation-exchange resin (Dowex 50W X-12, 100—200 mesh) in the H^+-form and the ionic strength was maintained at 4.0 M with perchloric acid. The stability constants have been obtained graphically by a curve-fitting method and the following results were obtained.

	$\beta_n=[ScL_n^{3-n}]/[Sc^{3+}][L^-]^n$		
	$\log \beta_1$	$\log \beta_2$	$\log \beta_3$
Chloride	−0.12	−0.84	−1.40
Nitrate	0.28	−0.28	—

The chemical properties of trivalent scandium are known to be somewhat similar to those of trivalent lanthanides and yttrium. Scandium(III) is often included among the rare earth elements. However, its smaller ionic size and its higher electronegativity sometimes make this ion different from the other rare earth ions. Actually, the scandium ion in solutions is believed to be a better acceptor of various complex-forming ligands than the other rare earth ions.

This series will report on our studies of the chemical behavior of scandium in various solutions. Paper I will report on a study of scandium(III) complexes with chloride or nitrate ions.

The complex formation of scandium(III) in concentrated hydrochloric acid and nitric acid may easily be supposed from the ion-exchange adsorption or the solvent extraction of this ion from these acid media.[1-3] However, because of the low stability of these complexes, no quantitative data on the stabilities have been presented until quite recently.

The stability constants of scandium(III) chloride complexes were first studied by Paul[4] by potentiometry in perchlorate solutions at 0.5 M. The stability constants were also determined by Reed, Sutton and Morris[5] from an ion-exchange study in perchloric acid media at 0.691 M. However, no report on the stability constants of scandium(III) nitrate complexes seems to have been presented.

In the present work, the cation-exchange equilibria of scandium(III) at a tracer concentration were determined radiometrically at 25°C between an ion-exchange resin and 4.0 M H(Cl, ClO_4) or 4.0 M H(NO_3, ClO_4). These ionic media were chosen in order to make it possible to compare the results with those on trivalent lanthanide and americium complexes obtained in other work.[6]

The stability constants were determined graphically by a curve-fitting method[7] from the decrease in the ion-exchange adsorption with the increase in the ligand concentration in the aqueous phase.

Statistical Treatment

The distribution ratio of scandium(III) in equilibrium between a cation-exchange resin phase and an aqueous phase is defined as:

$$D=\frac{[Sc(III)]_R}{[Sc(III)]}=\frac{\text{Sc(III) per g. resin}}{\text{Sc(III) per ml. solution}} \quad (1)$$

where the subscript "R" denotes a species in the resin phase.

This can be calculated by radioactivity measurements as:

$$D=(T-vA)/(G\times A) \quad (2)$$

where T is the total radioactivity in the whole

system; A is the radioactivity per ml. of the aqueous phase in equilibrium with the resin; v is the volume of the aqueous phase (ml.), and G is the weight of the resin (g.).

When no complex-forming ligand exists in the system, the distribution constant, K_{d_0}, can be written as:

$$K_{d_0}=[Sc^{3+}]_R/[Sc^{3+}] \quad (3)$$

where the subscript "0" denotes the absence of the ligand.

When the metal ion forms complexes with a mono-negative ligand, L^-, the net distribution ratio of the metal ion between the resin and the aqueous phase can be written as:

$$D=\frac{[Sc^{3+}]_R+[ScL^{2+}]_R+[ScL_2^{+}]_R}{[Sc^{3+}]+[ScL^{2+}]+[ScL_2^{+}]+[ScL_3]+\cdots} \quad (4)$$

The ion-exchange equilibrium constant for the "nth" complex may be defined as:

$$K_{d_n}=[ScL_n^{3-n}]_R/[ScL_n^{3-n}] \quad (5)$$

The formation and the over-all stability constant, β_n, of the "nth" complex can be described as:

$$Sc^{3+}+nL^- \rightleftarrows ScL_n^{3-n} \quad (6)$$

$$\beta_n=[Sc_n^{3-n}]/[Sc^{3+}][L^-]^n \quad (7)$$

By introducing Eqs. 3, 5 and 7 into Eq. 4, the following equation is obtained:

$$\frac{D}{K_{d_0}}=\frac{1+(K_{d_1}/K_{d_0})\beta_1[L^-]+(K_{d_2}/K_{d_0})\beta_2[L^-]^2}{1+\beta_1[L^-]+\beta_2[L^-]^2+\beta_3[L^-]^3+\cdots} \quad (8)$$

The constants in Eq. 8 can be determined by a curve-fitting method.[7]

In order to obtain a simpler function, a variable, a, and two parameters, R and B, are introduced into Eq. 8. Here a, R and B are $\beta_2^{1/2}$ $[L^-]$, $\beta_1\beta_2^{-1/2}$ and K_{d_1}/K_{d_0} respectively. Then:

$$\frac{D}{K_{d_0}}=\frac{1+BRa+(K_{d_2}/K_{d_0})a^2}{1+Ra+a^2+\beta_3\beta_2^{-3/2}a^3+\cdots} \quad (9)$$

It may be possible to discuss the problem more generally, but here the following assumptions are made as the first approximation:

(i) K_{d_2} is negligible compared to K_{d_1}.

(ii) Only the first and the second complexes exist in the solution.

On the basis of these assumptions, Eq. 9 can be written as:

$$y=(1+BRa)/(1+Ra+a^2) \quad (10)$$

By introducing various sets of values into R and B in Eq. 10, families of standard curves represented by the following equations are obtained:

$$\left.\begin{aligned} Y=\log y&=-\log(1+Ra+a^2)+\log(1+BRa)\\ X&=\log a\end{aligned}\right\} \quad (11)$$

One of these curves will be found to fit the plot of the experimental data, $\log(D/K_{d_0})$ vs. $\log[L^-]$.

The equilibrium constants can be determined from the parameters of this particular standard curve as follows:

From the definition,

$$\log a=\frac{1}{2}\log\beta_2+\log[L^-]$$

The value of $1/2\log\beta_2$ can be determined graphically from the difference between the value on the abscissa of the standard curve ($X=\log a$) and the value on the abscissa of the experimental data ($X=\log[L^-]$).

For example, one may compare the abscissa of the experimental data (plotted as $\log D/K_{d_0}$ vs. $\log[L^-]$) with that of the best-fitted curve (plotted as $\log y$ vs. $\log a$ (Eq. 11)). Then one can read the $\log[L^-]_0$ value on the abscissa of the experimental plot which coincides with the point, $\log a=0$, on the abscissa of the standard curve; this $\log[L^-]_0$ value should give the $\log a$—$\log[L^-]$ value.

From this $\log[L^-]_0$, $\log\beta_2$ can be determined as:

$$\log\beta_2=-2\log[L^-]_0$$

The $\log\beta_1$ value can then be determined as:

$$\log\beta_1=\log R+\frac{1}{2}\log\beta_2$$

and K_{d_1} can be determined as:

$$K_{d_1}=BK_{d_0}$$

If the assumptions i and ii cannot be adopted, the terms K_{d_2}/K_{d_0} and/or $\beta_3\beta_2^{-3/2}a^3$, etc., should be introduced into Eq. 11. Then the followings are obtained:

$$\log y=-\log(1+Ra+a^2+\beta_3\beta_2^{-3/2}a^3)+\log(1+BRa) \quad (12)$$

$$\log y=-\log(1+Ra+a^2)+\log\{1+BRa+(K_{d_2}/K_{d_0})a^2\} \quad (12')$$

$$\log y=-\log(1+Ra+a^2+\beta_3\beta_2^{-3/2}a^3)+\log\{1+BRa+(K_{d_2}/K_{d_0})a^2\} \quad (12'')$$

.....

and the curve-fitting can be continued as above.

More details of this method may be found in other articles (for instance, Ref. 7).

Experimental

Reagents.—The perchloric acid, the hydrochloric acid and the nitric acid used were of a reagent grade. The concentration of the acids was determined by titrations using potassium acid carbonate as the standard substance.

Radioactive Tracer.—Scandium-46 was used as the tracer. It was obtained from the Radiochemical Center, Amersham, England, as a hydrochloric acid solution. This tracer was purified by a solvent extraction method and diluted with 4.00 M hydrochloric

acid, nitric acid or perchloric acid. These solutions were then used as the stock solutions.

Cation-exchange Regin.—A Dowex 50 W X-12, 100—200 mesh, was used. The resin was conditioned alternately with 4 M hydrochloric acid and 4 M sodium chloride solution several times. The resin was finally made into a H^+-form and dried in an air-bath at 60°C overnight. Then it was equilibrated in the open air for several days and stored in a closed bottle. The exchange capacities of this resin were 3.62 meq./g. for Na^+ and 3.60 meq./g. for H^+.

Procedures.—All of the procedures were carried out in a thermostatted room at 25±0.5°C. About 100 mg. of resin was placed in glass-stoppered tubes (volume, 20 ml.) and weighed. The tracer solution and various amounts of hydrochloric acid or nitric acid were placed in the tubes, and then perchloric acid was added to make the aqueous phase 5.0 ml. and the ionic strength 4.0 M. The tubes with the contents were agitated by a mechanical rotator for about four hours in order to ensure an equilibrium. It was found in the preliminary experiments that the ion-exchange equilibrium was reached within two hours by the rotation. After the rotation was finished, the substances were centrifuged at 2000 r.p.m. for about three minutes. A two-milliliter aliquot of the solution was then pipetted out and transferred into a small test tube, and the γ-radioactivity of the aqueous phase was measured with a well-type (NaI) scintillation counter.

Results

The distribution ratios of scandium(III) between the resin and the aqueous perchlorate solutions with various amounts of chloride ions or nitrate ions are given in Table I. The plots of log (D/K_{d_0}) against log $[Cl^-]$ and log $[NO_3^-]$ are shown in Fig. 1.

The stability constants of the complexes were determined by the curve-fitting as follows. The plots in Fig. 1 were first compared with the families of the standard curves defined by Eq. 11. The plot of the data in the nitrate system was found to be well fitted by a standard curve which was obtained with the parameters $R=2.5$ and $B=0$. The stability constants were therefore determined from these values and $\log[L^-]_0=-0.14$. However, it was not possible to find a standard curve for the chloride system among the curves defined by Eq. 11, which fits the plot over all the ligand concentration region. The standard curve obtained by introducing $R=2$ and $B=0$ into Eq. 11 fits the plot in the lower concentration region when $\log[L^-]_0$ was 0.42, but it deviated from the plot upward as the ligand concentration increased. This seemed to indicate the formation of the third complex, $ScCl_3$. After many trials, a curve given by Eq. 12 was found to fits best when $R=2$, $B=0$ and $\beta_3\beta_2^{-3/2}=0.6$ were introduced into the equation. The log $[L^-]_0$ value was found to be 0.42 even after the introduction of the third term. The equilibrium constants were calculated from these values.

1.60	5.74×10	0.12	2.54×10^2
1.52	5.92×10	0.08	2.55×10^2
1.44	6.15×10	0.04	2.65×10^2
1.28	6.66×10		

From these results, the constants were determined to be as shown in Table II.

Conclusion

From the results, the following conclusions may be drawn:

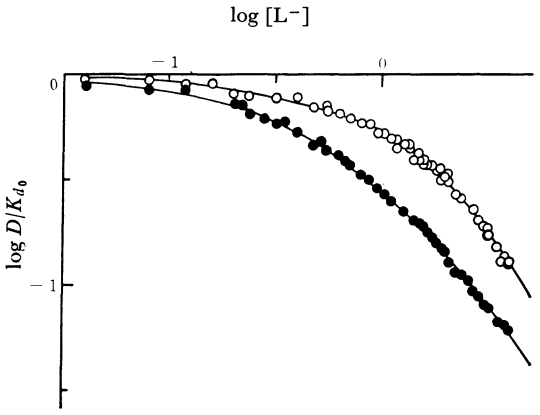

Fig. 1. The plot $\log D/K_{d_0}$ vs. $\log [L^-]$ of scandium(III) in nitrate and chloride media.
Ion-exchange resin: Dowex 50 W X-12 100—200 mesh
Aqueous phase: 4.0 M H(Cl, ClO_4) -○-
4.0 M H(NO_3, ClO_4) -●-
The curves drawn for the plots are
$\log D/299 = -\log (1+1.9[NO_3^-]+0.53[NO_3^-]^2)$
$\log D/299 = -\log (1+0.76[Cl^-]+0.14[Cl^-]^2 +0.04[Cl^-]^3)$

(1) The adsorption of scandium(III) from 4 M H(Cl, ClO_4) or 4 M H(NO_3, ClO_4) to Dowex 50W X-12 decrease with the increase in the ligand concentration. When the ligand concentration is the same, the decrease is always larger in the nitrate system.

(2) The change in the distribution ratio is explained by Eq. 4, together with the equilibrium constants in Table II.

(3) The constants in Table II seem to indicate that:

(a) The ScL^{2+} and ScL_2^+ species are formed both in the nitrate and in the chloride system.

(b) The ScL_3 species is negligible in the nitrate system, but it is formed in the chloride system.

(c) The adsorption of the ScL^{2+} or ScL_2^+ complexes to the ion-exchange resin is negligible.

Table II. Equilibrium constants for the ion-exchange adsorption and the stability constants for the chloride and the nitrate complexes of scandium(III) in 4.0 M H(Cl, ClO_4) and 4.0 M H(NO_3, ClO_4) at 25°C
Ion-exchange resin: Dowex 50 W X-12
$K_{d_0}=[Sc^{3+}]_R/[Sc^{3+}]$, $K_{d_1}=[ScL^{2+}]_R/[ScL^{2+}]$
$\beta_n=[ScL_n^{3-n}]/[Sc^{3+}][L^-]^n$

	Chloride	Nitrate
K_{d_0}	299	
K_{d_1}	0	0
$\log \beta_1$	−0.12	0.28
$\log \beta_2$	−0.84	−0.28
$\log \beta_3$	−1.40	—

In the present study, the above conclusions were reached by assuming the constancy of the activity coefficients of the chemical species. More precise argument will be possible when many more thermodynamical data are available.

The stability constants reported by Paul[4] and by Reed et al.[5] are summarized in Table III. The present results may not, however, be compared directly with those results because those experiments were carried out in aqueous solutions of a lower ionic concentration.

Table IV summarizes the stability constants of chloride complexes of lanthanum(III), europium(III), lutetium(III) and americium(III) in 4 M Na(Cl, ClO_4).[6]

From Tables II and IV, it may be concluded that the stability constants for the complexes MCl^{2+} and MCl_2^+ of these five metal ions are in the same order, but that only scandium(III) forms a MCl_3 complex under these experimental conditions.

Some part of the work was carried out at the Laboratory of Nuclear Chemistry, Institute o Physical and Chemical Research, Tokyo. The authors are so grateful to Professor Nobufusa Saito, the head of the laboratory.

Studies of Scandium in Various Solutions. II. The Extraction of Scandium(III) with Tributyl Phosphate from Perchlorate-Chloride and Perchlorate-Nitrate Media

By Tatsuya SEKINE, Takeshi HAMADA and Mitsuo SAKAIRI

Department of Chemistry, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received June 12, 1965)

The distribution of scandium(III) between organic tributyl phosphate solutions and aqueous perchlorate, nitrate, chloride solutions or mixed solutions of perchlorate-nitrate, perchlorate-chloride has been determined.

The distribution of scandium between 50% tributyl phosphate - chloroform and 4 M H(Cl, ClO_4) or 4 M H(NO_3, ClO_4) in some chloride or nitrate concentration region was higher than any of that distribution between the organic phase and 4 M perchloric acid, 4 M hydrochloric acid or 4 M nitric acid. It seems that the enhancement of the distribution ratios can be attributed to the extraction of mixed ligand complexes, but no simple relationship has been established between the distribution ratios and the proportion of the complex species in the aqueous phase as calculated from the previous data.

The extraction of scandium(III) in hydrochloric or nitric acid solutions with tributyl phosphate (TBP) was studied by Peppard, Mason and Maier.[1] They reported that the extraction of the metal ion increases very sharply with the increase in the acid concentration.

The complex formation of scandium(III) with chloride ions or nitrate ions in 4 M perchloric acid media was studied by Sekine and Hasegawa[2] by an ion-exchange method, and the stability constants for the complex species, $ScCl^{2+}$, $ScCl_2^+$, $ScCl_3$, $ScNO_3^{2+}$ and $Sc(NO_3)_2^+$, were determined.

For the present work, the authors determined the distribution of scandium(III) between organic solutions containing TBP and aqueous solutions of 4 M H(Cl, ClO_4) or 4 M H(NO_3, ClO_4) in order to study the variation in the metal distribution with the formation of scandium complexes in the aqueous phase.

Experimental

Tracers and Reagents.—^{46}Sc, ^{140}La, $^{152+154}Eu$, ^{177}Lu and ^{241}Am were used as the radioactive tracers. All the reagents used were of analytical grade. The preparation and the purification of the tracers and the reagents were carried out in ways which have been described previously.[2-5]

Procedures.—All the procedures were carried out in a thermostatted room at 25±0.5°C. The concentration of the sodium perchlorate solutions was determined by weighing the residue left after a certain amount of the solution had been evaporated in an air-bath at 120°C. The concentration of the acids was determined by titrations using potassium hydrogen carbonate as the standard. The organic phases were pre-equilibrated with the corresponding aqueous phase just before the experiments. In the experiments with sodium perchlorate, the aqueous phase was buffered with a small amount of acetate at pH 4 to 5. The organic and aqueous phases were agitated in glass tubes with a stopper by a mechanical shaker and then centrifuged. Two-milliliter aliquots were pipetted from both phases, and the γ-radioactivity was determined. The distribution ratios of the metal ions were calculated as:

$$D=\frac{\gamma\text{-count-rate per ml. of org. phase}}{\gamma\text{-count-rate per ml. of aq. phase}}$$

Results and Discussion

The results are given in Figs. 1 to 4. The organic phase was 10% TBP (by volume) in hexane for the experiments in Fig. 1, and 50% TBP (by volume) in chloroform for the other experiments.

The results in the figures may be summarized as follows:

i) Scandium(III) is extracted from perchlorate media into the organic phase better than trivalent lanthanides or americium. The results for the other four ions showed nearly the same tendency as had been reported previously.[6,7] (Fig. 1)

ii) The distribution of scandium(III) from 4 M (H, Na)ClO_4 is independent of the change in

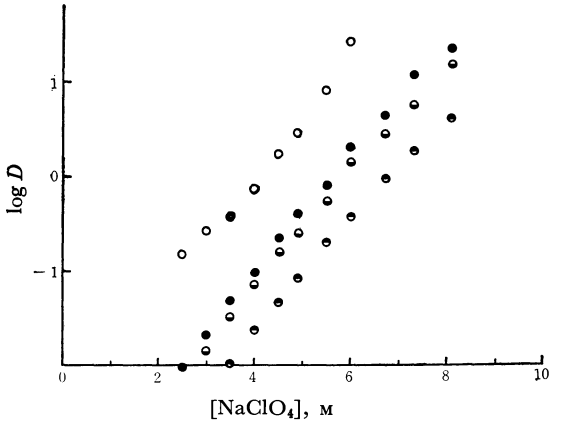

Fig. 1. Variation of the distribution ratios of Sc(III) (○), La(III) (●), Lu(III) (◒) and Am(III) (◓) between 10% TBP in hexane and sodium perchlorate solutions at various concentrations (pH 4—5). The results of Eu(III) are nearly the same as La(III).

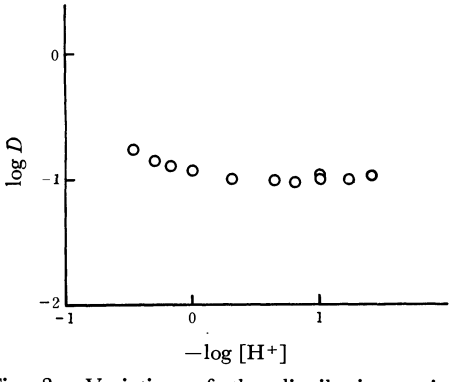

Fig. 2. Variation of the distribution ratio of Sc(III) between 50% TBP in chloroform and 4 M (H, Na)ClO_4 with the hydrogen ion concentration.

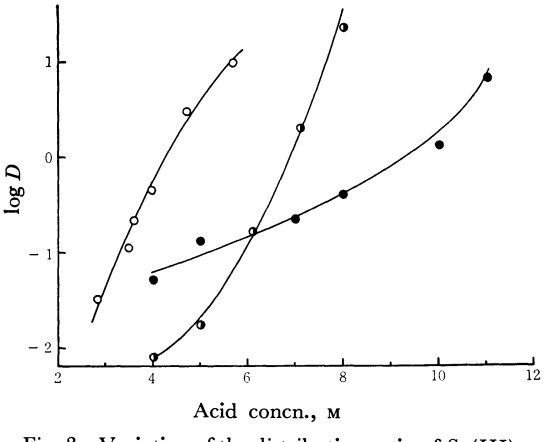

Fig. 3. Variation of the distribution ratio of Sc(III) between 50% TBP in chloroform and perchloric acid (○), hydrochloric acid (◑) or nitric acid (●) with the acid concentration.

the hydrogen ion concentration. However, it is slightly increased when the hydrogen ion concentration is above 1 M. (Fig. 2)

iii) The distribution of scandium from the perchloric acid solutions into the organic phase is much higher than that from hydrochloric or nitric acid solutions. Below 6 M, the distribution of scandium(III) from nitric acid is higher than that from hydrochloric acid, but the distribution ratios show an inverse order above 6 M. (Fig. 3)

iv) The distribution of scandium(III) from 4 M perchloric acid is enhanced by a replacement of the acid with 4 M hydrochloric or nitric acid. The enhancement is made larger by replacements with nitric acid than by those with hydrochloric acid. When the nitric acid content in the aqueous phase is about 0.6 M, the distribution ratio is four times that from pure perchloric acid, but the distribution ratio becomes lower than that from pure perchloric acid when more than half of the

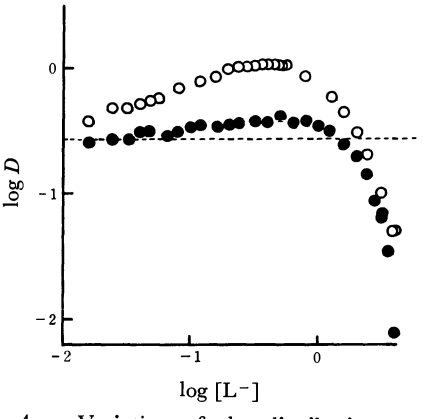

Fig. 4-a. Variation of the distribution ratio of Sc(III) between 50% TBP in chloroform and 4 M H(Cl, ClO_4) (●) or 4 M H(NO_3, ClO_4) (○) as functions of the chloride or nitrate concentration.

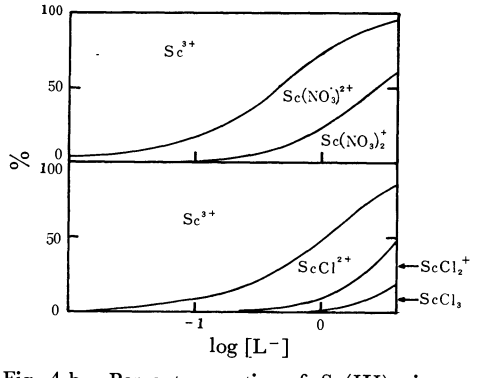

Fig. 4-b. Percentage ratios of Sc(III) nitrate or chloride complex species in 4 M perchloric acid as a function of the ligand concentration calculated from the stability constants given in Ref. 2.

acid is replaced with nitric or hydrochloric acid. (Fig. 4-a)

When L denotes nitrate or chloride ions, the scandium species in the organic phase distributed from the mixed acid media may generally be described as;

$$Sc(ClO_4)_aL_bH_{a+b-3}(TBP)_c$$

From the results in Fig. 4-a, one may conclude that the distribution of the mixed complex species is higher than that of the species containing only one kind of anion.

However, it seems difficult to establish any simple relationship between the variation in the distribution ratios and the compositions of the complex species in the corresponding aqueous phase, which are given in Fig. 4-b.

Part of the work was carried out at the Laboratory of Nuclear Chemistry, Institute of Physical and Chemical Research, Tokyo. The authors are very grateful to Professor Nobufusa Saito, the head of the laboratory. The authors are also grateful to Miss Yuko Hasegawa and Mr. Ichiro Kobayashi of the present laboratory for their experimental aid and valuable discussions.

The Spectra and the Conductances of Alizarine Saphirol SE in Water-Ethanol Mixtures

By Masaru MITSUISHI and Gensaku AIDA

Faculty of Fiber Science and Technology, Shinshu University, Ueda, Nagano

(Received April 30, 1965)

In order to explore the behavior of Alizarine Saphirol SE in water-ethanol mixtures, the absorption spectrum and the conductance of the dye solution were obtained. A characteristic spectrum of the dye aggregate in water is found to change gradually into a monomer spectrum with an increase in the proportion of an added ethanol. Moreover, the dye is found to show marked McBain effect in water, while showing a conductance curve typical of a weak electrolyte in 58.7% (v/v) ethanol.

A characteristic spectrum for an aggregate has been found in some solutions of such aromatic compounds as dyes.[1-4] In the spectrum of the solution of such compounds, with an increase in the proportion of an added organic solvent, the monomer peak is found to be intensified at the expense of the dimer and the higher multimers. This reduction of the aggregation has generally been ascribed to the reduced polarity of the medium.

Further, the so-called McBain effect has been found in equivalent conductances of such compounds in aqueous solutions, in which ionic micells are formed.[5-7] The McBain effect is, however, supposed to diminish as a result of the reduction of the aggregation of such compound in water-ethanol mixtures.

Some of these compounds, which behave as strong electrolytes in water, are supposed to behave as weak electrolytes in water - organic solvent mixtures with low dielectric constants as a result of the increase in the Coulombic attraction between ions of opposite charges.

Very little comparative investigation of the spectrum and the above-described conductance has been made. Alizarine Saphirol SE (sodium salt of 1, 5-dihydroxy-4, 8-diamino anthraquinone-2-sulfonic acid) may be considered, judging from its structure, to aggregate strongly in an aqueous solution. Therefore, it seemed valuable to explore the behavior of the dye in water-ethanol mixtures.

Experimental

Materials.—Alizarine Saphirol SE (C. I. Acid Blue 43, sodium salt of 1, 5-dihydroxy-4, 8-diaminoanthraquinone-2-sulfonic acid) was supplied by the Mitsui Chemical Industries Co., Ltd., and was purified as follows. The benzene-soluble impurities in the dye were removed by extraction with purified benzene. After the salting-out with sodium chloride from an aqueous solution had been repeated, sodium ions and chloride ions were removed completely through cation exchange

resin (Amberlite IR-120) and also anion exchange resin (Amberlite IRA-410). Finally, the solution was neutralized with sodium hydroxide, concentrated under reduced pressure, and dried at 105°C.

Ethanol and urea of a guaranteed reagent grade were used.

Spectrophotometric Measurements.—The spectrophotometric measurements were carried out in a Shimadzu Spectrophotometer, QV50, using a 10 mm. cell.

Conductance Measurements.—The circuit of the conductance bridge is shown in Fig. 1, in which R is a General Radio variable resistance (10 kΩ—0.1 Ω)

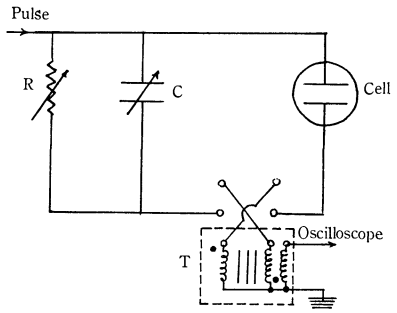

Fig. 1. Circuit of bridge.

with an error of 0.05%, C is an air-variable condenser, and T is a pulse-transformer. An oscilloscope was used as an indicator of the bridge balance. Conductances were measured at 25±0.1°C in a Komatsu-Yamato Coolnics CTR-1 thermostat. The specific conductances of the solvents were always less than 1.0×10^{-6} mhos. Two conductance cells with different cell constants, 0.05336 and 0.26706, were used.

Results and Discussion

The absorption spectra of Alizarine Saphirol in water are shown in Fig. 2, in which the spectrum is characterized by a prominent peak at about 590 mμ, or an α band, and a small shoulder at about 620 mμ, or a β band. With an increase in the concentration of the dye, Beer's law does not hold; the extinction coefficients at about 590 mμ and 620 mμ diminish, and also the shoulder falls progressively. This may be ascribed to the formation of aggregates of the dye in water.

The absorption spectra of Alizarine Saphirol in water-ethanol mixtures are shown in Fig. 3, in which both the α and β band are intensified and shift slightly towards longer wavelengths, with an increase in the proportion of an added ethanol, and in which the β band is more intensified than the α band in 30%, 40% (v/v) and richer ethanol solvents. This effect of ethanol on the spectrum of the dye is supposed to be the reduction of the aggregation due to the reduced polarity of the medium. A similar effect of ethanol was found by Rabinowitch and Epstein on Methylene Blue.[1]

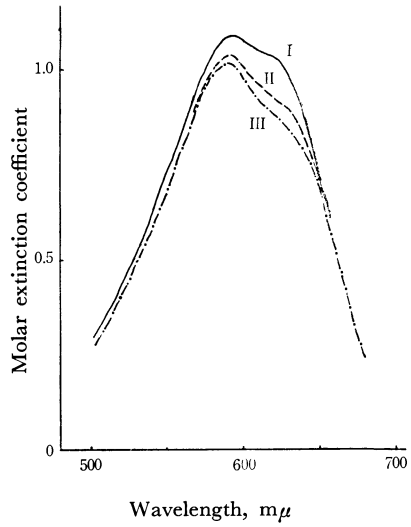

Fig. 2. Spectrum of Alizarine Saphirol SE in water at room temperature.
Concentration of the dye:
Curve I, 1.274×10^{-5} M; II, 6.370×10^{-5} M; III, 12.74×10^{-5} M

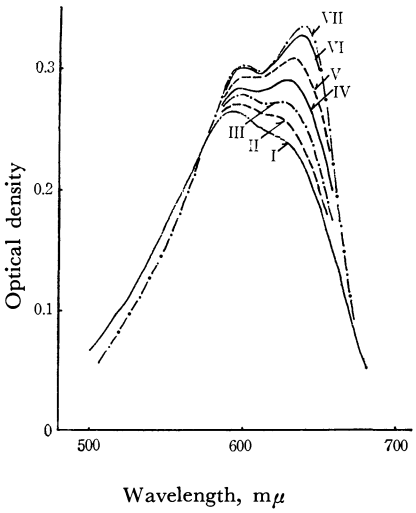

Fig. 3. Spectrum of Alizarine Saphirol SE in water-ethanol mixtures at room temperature.
Optical densities determined in 10 mm. cells.
Concentration of ethanol by volume: curve I, 0%; II, 10%; III, 20%; IV, 30%; V, 40%; VI, 60%; VII, 90%(v/v)

In order to compare the effect of ethanol with that of urea on the spectrum of the dye, the spectrum of Alizarine Saphirol in the presence of urea is shown in Fig. 4, in which, with an increase in the proportion of an added urea, both the α and the β band shift towards longer wavelengths. The optical density of the β band is larger than that of the α band in 7.2 M urea aqueous solution. The effect of the addition of urea is very similar

qualitatively to that of ethanol, as is shown in Fig. 3. Thus urea is considered to reduce the aggregation of the dye in water.

The effects of the temperature on the spectra of Alizarine Saphirol in water-ethanol mixtures are shown in Fig. 5. In Fig. 5, both the α and β bands of the dye in water and 30% (v/v) ethanol are intensified with raising the temperature, although β band appears to be intensified more than the α band. The rise in the temperature seems to reduce the aggregation due to the change in structural properties of water. No marked temperature effect on the spectrum of Alizarine Saphirol is, however, found in either 60 or 90% (v/v) ethanol. From these findings in the spectra, it may be considered that the shift of the spectra with an increase in the concentration of Alizarine Saphirol in an aqueous solution in Fig. 2 is due to the increase in number of aggregates, while the shift of the spectra with an increase in the proportion of an added ethanol (in Fig. 3) or urea (in Fig. 4) is due to the inhibition of the aggregation. These findings in the spectra, however, give no suggestion whether ethanol and urea prevent aggregation by interacting with water molecules related with the aggregation mechanism, or by interacting with Alizarine Saphirol directly.

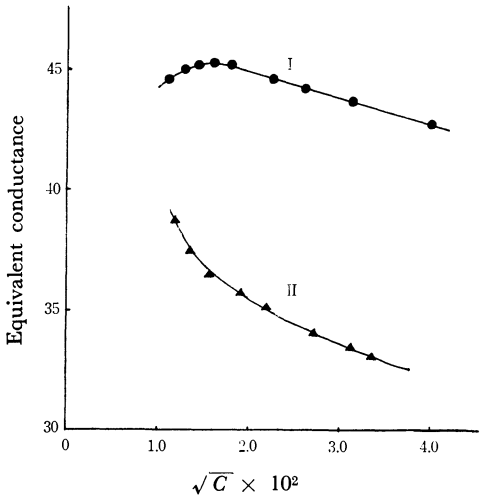

Fig. 7. Equivalent conductance of Alizarine Saphirol SE in water-ethanol mixtures at 25± 0.1°C.
Concentration of ethanol by weight: curve I, 34.9%, II, 58.7%.

The equivalent conductances (Λ) of Alizarine Saphirol in water are plotted against the square root of the molar concentration, $\sqrt{C}$, in Fig. 6. The Λ-$\sqrt{C}$ curve reaches a maximum, and the so-called McBain effect is found in the curve which suggests the presence of ionic micells. The curves I and II in Fig. 7 show the equivalent conductances in 34.9 and 58.7% (v/v) ethanol respectively. Also the McBain effect is found in 34.9% ethanol (curve I), the conductances decrease gradually with an increase in the concentration of the dye in 58.7% ethanol (curve II). This conductance behavior of curve II is similar to that of a weak electrolyte. Thus, in 58.7% ethanol, Alizarine Saphirol is supposed not to form aggregates, but to exist as a monomer. These conductance findings are in agreement with the considerations made from the spectrophotometric evidence.

Since Alizarine Saphirol is the sodium salt of a sulfonic acid, it will behave as a strong electrolyte in an aqueous solution. However, it is natural for Alizarine Saphirol to behave as a weak electrolyte in water-ethanol mixtures of a low dielectric constant due to the increase in Coulombic attraction between ions of opposite charges.

Summary

The absorption spectra and the conductances of Alizarine Saphirol SE (sodium salt of 1, 5-dihydroxy-4, 8-diaminoanthraquinone-2-sulfonic acid) in water-ethanol mixtures have been obtained, and the dispersed states of the dye have been examined qualitatively.

1) A characteristic spectrum of the dye aggregate in water has been obtained; a prominent peak at about 590 mμ and a small shoulder at about 620 mμ were found in the spectrum, and Beer's law did not hold. Alizarine Saphirol showed a marked McBain effect in an equivalent conductance in water.

2) The small shoulder of the spectrum at about 620 mμ changed to a prominent peak with an increase in the proportion of ethanol added, and the absorptions at both about 590 and about 620 mμ shifted towards longer wavelengths. The dye did not show any McBain effect, and the typical conductance curve of a weak electrolyte was obtained in 58.7% (v/v) ethanol.

The authors wish to thank Professor Masatoki Yokoi for his helpful discussions.

The Chlorine Quadrupole Resonances of Ethane Derivatives

By Seiichi KONDO

Laboratory of Physical Chemistry, Osaka University of Liberal Arts and Education, Tennoji-ku, Osaka

(Received May 1, 1965)

The temperature broadening of the chlorine quadrupole resonance line-width was studied in three ethane derivatives (1, 1, 1-trichloroethane, hexachloroethane and 1, 1, 1, 2-tetrachloro-2, 2-dimethylethane) below the plastic crystalline phases. Most of the resonance frequencies observed at the temperature of liquid nitrogen were equal to those reported in the literature. The energies of activation (2.2, 2.6 and 4 kcal./mol. respectively for the three compounds mentioned above) were obtained from the line-width versus temperature curves in the low temperature phases. It was suggested, considering the smallness of the energies of activation, that the vibrational rotation of the molecule as a whole rather than the internal axial rotation may exist in those phases.

Gutowsky and McCall[1] and Tatsuzaki and Yokogawa[2] reported a temperature shift of the chlorine quadrupole resonance frequencies in chlorine-substituted hydrocarbons. Many of these compounds possess plastic crystal phases just below the melting points, and the molecules are in rotational or disordered states in such phases. These authors showed, from an analysis of the temperature shift of the resonance frequencies, that the resonance signals of these compounds fades out at certain temperatures below the plastic crystal phases; they interpreted this phenomenon as resulting from the increase in the degree of molecular rotation. The purpose of the present investigation is to study this phenomenon in further detail with respect to the temperature effect of the line-width and of the

signal-to-noise ratio of chlorine quadrupole resonance signals for 1, 1, 1-trichloroethane, hexachloroethane and 1, 1, 1, 2-tetrachloro-2, 2-dimethylethane at atmospheric pressure.

Experiments

Materials.—Hexachloroethane and 1, 1, 1-trichloroethane of a commericial reagent grade were vacuum-sublimed into glass ampoules for the resonance measurement. The observed melting and transition points are summerized in Table I; they are in satisfactory agreement with those reported in the literature. 1, 1, 1, 2-Tetrachloro-2, 2-dimethylethane was synthesized from chloretone and phosphorus pentachloride by the method reported by McElvin and Stevens.[3] The raw material thus obtained was recrystallized several times from an ethanol solution and sublimed under vacuum into glass ampoules for the measurement. The same material was used for the dielectric measurement. The observed melting and transition points are listed in Table I. The chlorine content of the material purified in this way was analyzed to be 71.74%, almost equal to the calculated values of 72.4%. The electric capacity versus the temperature curve changed quite sharply at the transition point, as is shown in Fig. 1, indicating that the material was quite pure. The plastic crystal phase of this material was observed to be isotropic by optical measurements, and the X-ray diffraction lines of a powder sample of this phase were interpreted satisfactorily as having a body-centered cubic structure.

Chlorine Quadrupole Resonance Measurements.—A self-quenching super-regenerative detector described by Dean[4] was used for the detection of the resonance signals. When the signal was strong, the resonance frequency was measured by an oscilloscope with a heterodyne-frequency meter calibrated by JJY, with an accuracy of ±1 k c. p. s. In order to determine the resonance characteristics, the resonance signal was frequency-modulated with the modulation frequency of 80 c. p. s. amplified with a narrow-band amplifier of the feed-back type, with a band-width of 2 c. p. s. and 80 db. amplification, and then recorded through a phase-sensitive detector. In this case, the accuracy of the frequency measurement was about ±2 k c. p. s.

Measurements at Low Temperatures.—The samples were kept in a petroleum ether bath cooled with liquid nitrogen from outside of the container bath. Below the solidifying temperature of petroleum ether, approximately 120°K, powder of the sodium chloride was mixed with petroleum ether in order to increase the thermal conductivity of solid ether; the temperature was kept very nearly constant, within ±0.1°C/min., during the measurements. Since these substances have marked phase transitions, they have to be cooled very slowly through the transition point in order to make the resonance characteristics reproducible under thermal equilibrium conditions. In the present case, about three hours were required to cool the sample from room temperature to stable and reproducible resonance conditons at the temperature of liquid nitrogen.

Dielectric Measurements.—The dielectric measurements of 1, 1, 1, 2-tetrachloro-2, 2-dimethylethane were carried out using a low-frequency bridge described elsewhere.[5] Since this material decomposes quite easily near the melting point, the measurement was undertaken only below room tempareture with a powder sample kept in a vacuum-sealed glass cell and with a platinum electrode installed inside the cell. By this apparatus, the absolute value of the dielectric constant could not be obtained, but a relative change in the electric capacity of the sample cell with the variation in temperature was measured, as shown in Fig. 1.

Experimental Results and Discussion

1, 1, 1-Trichloroethane.—Three resonance lines a, b and c were observed at the temperature of liquid nitrogen, as Table I shows, in an intensity ratio of roughly 2 : 3 : 1. The a and b lines were identified with those already reported by Gutowsky and McCall.[1] The curves of the temperature versus frequency, the half-value width and the signal-to-noise ratio for the b line are illustrated in Figs. 2, 3 and 4 respectively. The a and c lines have characteristics similar to those of the b line. The contribution of the intramolecular or overall rotational motions of the molecule to the line-width, $\Delta\nu$, of the signal becomes important as the temperature approaches the rotational phase transition point, as is shown by the broken line in Fig. 3 (from 110°K to 170°K). As has been discussed by Das and Hahn,[6] the activation energy, E, for

the molecular rotation can be obtained from the slope of the curve shown in Fig. 3. For example, Buyl-Bodin[7] described this curve by the following expression;

7) M. Buyl-Bodin, *Ann. Phys.*, (12) **10**, 533 (1955).

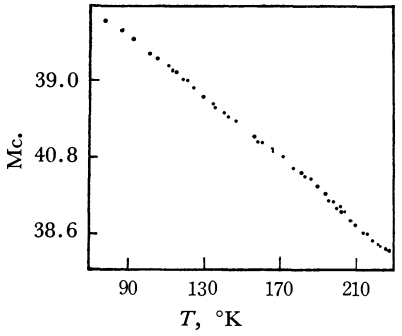

Fig. 8. Frequency versus temperature curve of the a line of $CCl_3CCl(CH_3)_2$.

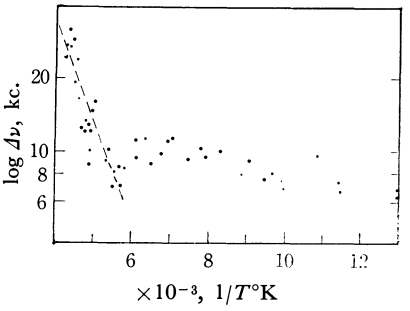

Fig. 9. Half-value width versus temperature curve of the a line of $CCl_3CCl(CH_3)_2$.

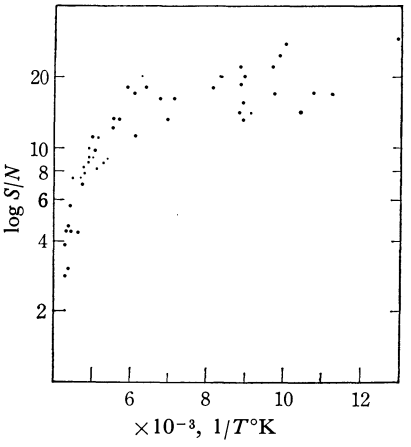

Fig. 10. Signal-to-noise ratio versus temperature curve of the a line of $CCl_3CCl(CH_3)_2$.

$$\frac{1}{\Delta\nu}\frac{d\Delta\nu}{dT}=\frac{E}{RT^2}$$

where T is the absolute temperature and R is the gas constant. From this equation, the value of E is calculated to be 2.2 kcal./mol. in the temperature range from 110°K to 170°K. Since the methyl groups of this molecule start rotating at about −180°C, according to the study of nuclear magnetic resonance by Powles and Gutowsky,[8] it seems that the internal rotation of the constituent groups and

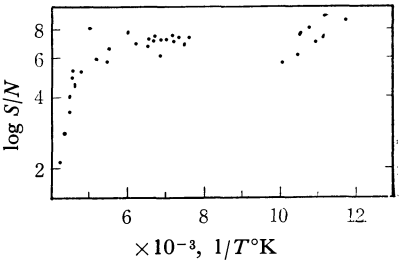

Fig. 13. Signal-to-noise ratio versus temperature curve of the c line of $CCl_3CCl(CH_3)_2$.

the rotatation of the molecule as a whole occur simultaneously near the fade-out temperature.

Hexachloroethane.—The four resonance lines, a, b, c and d, observed at 77°K, can clearly be identified with those reported by Gutowsky and McCall[1] and by Tatsuzaki and Yokogawa[2]. The curves of the frequency, the line-width and the signal-to-noise ratio versus the temperature for the a line are shown in Figs. 5, 6 and 7 respectively. The corresponding curves of the other lines are similar to those of the a line. The activation energy for rotation, obtained in the same way as in the case of 1, 1, 1-trichloroethane from Fig. 6, (in the temperature range from 160°K to 250°K), is about 2.6 kcal./mol. This value seems to correspond

8) J. P. Powles and H. S. Gutowsky, *J. Chem. Phys.*, **21**, 1695 (1953).
9) R. Livingston, *J. Phys. Chem.*, **57**, 496 (1957).

to the activation energy of the rotation of the molecule as a whole, since the value is much smaller than the activation energy of the internal rotation of this molecule (about 10 kcal./mol.) obtained by Morino and Iwasaki.[10]

1, 1, 1, 2-Tetrachloro-2, 2-dimethylethane.— Three resonance lines a, b and c were observed as shown in Table I. The a and b lines have frequencies higher than that of the c line. As has been discussed by Hooper and Bray,[11] the a and b lines can be assigned to the three chlorine atoms bonded (more covalently) to the same carbon atom at the position 1 while the c line can be assigned to the single carbon atom bonded (less covalently) to carbon 2.

The curves of the frequency, the line-width and the signal-to-noise ratio versus the temperature for the a and c lines are shown in Figs. 8 through 13. These three lines fade out at about 230°K; this is just below the phase transition temperature (234°K) obtained by the dielectric measurements illustrated in Fig. 1. The activation energies obtained from the line-width versus the temperature curves of the lines a and c shown in Figs. 9 and 12 are about 4 kcal./mol. Figures 9, 10, 12 and 13 indicate that the activation energy and the temperature dependence of the line-width and the signal-to-noise ratio are quite similar in the lines a and c; this may imply that the motions of the chlorine atoms at the positions 1 and 2 are nearly alike as far as the present measurements are concerned. This result may provide further indirect support for the assumption that the molecule as a whole rotates in this temperature range.

The author wishes to express his thanks to Professor Shizuo Fujiwara for his help in the course of the present study, and also to Miss Michiko Motoi, and Messrs. Sumitoshi Kumimoto, Masaji Ura, Tatsuyoshi Matsu-ura for their experimental assistance.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 253—256 (1966)

Pyrazolotropolones and Their Derivatives[1)]

By Shô Itô, Kahei Takase, Norio Kawabe and Hiroshi Sugiyama

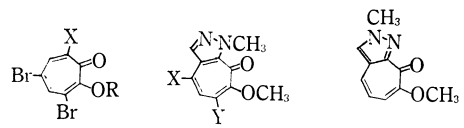
Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received May 4, 1965)

Two new methods have been developed to synthesize pyrazolotropone derivatives. 2-Methoxy-3, 5, 7-tribromotropone reacts with diazomethane to yield 4, 6-dibromo-7-methoxy-1-methyl-8(1*H*)-cyclohepta[c]pyrazolone, whereas the alkaline treatment of 4-acetyltropolone tosylhydrazone provides 3′-methylpyrazolo[3, 4-c]tropolone and 3′-methylpyrazolo[4, 3-d]tropolone. The structure of these products has been elucidated.

The reaction of diazomethane with troponoids, apart from the normal methylation of the tropolone hydroxyl, has been studied by Nozoe et al.,[2)] who found that the reagent attacked 2-halotropones and 4-methoxytropone to form pyrazolotropone derivatives, although the exact location of the pyrazole ring on the tropone nucleus was not established. We now wish to report on the structure of the products from a similar reaction of halomethoxytropones, as well as a new method to synthesize pyrazolotropolones.

3, 5, 7-Tribromotropolone[3)] (I), when treated in methanol with an excess of ethereal diazomethane at room temperature, first formed 2-methoxy-3, 5, 7-tribromotropone (II); this soon dissolved to an orange-red solution. The evaporation of the solvent, which served to liberate the hydrogen bromide, followed by alumina chromatography, yielded pale yellow, silky needles of III (m. p. 158°C) in a 30% yield. The same compound was also prepared in a 54% yield by the action of diazomethane on II.



I R=H, X=Br
II R=CH_3, X=Br
XII R=X=H

III X=Y=Br
IV X=Cl, Y=Br or X=Br, Y=Cl
Va X=Y=H

Table I. NMR data*1

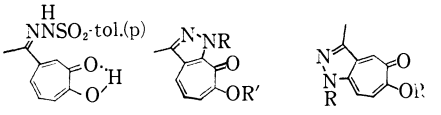
Compd No.	C-CH_3	O-CH_3	N-CH_3	CH_3CO	Aromatic protons on 7-membered ring	Aromatic protons on 5-membered ring
III		3.97*2	4.47		7.63	8.08
IV		3.96	4.47		7.40	8.11
V		3.88	4.46		6.4—6.9(m)*3	7.84
					7.0—7.3(q)*3	
IX	2.49			2.36	7.16(d, J=13)	
				3.61	7.40	
					8.88(d, J=13)	
XI	2.51	3.94	4.47		6.5—6.9(m)*3	
					7.0—7.3(q)*3	
XIII		3.93	4.15		7.80	8.46

*1 Spectra are refered to for deuteriochloroform solution. Chemical shift (δ) is expressed in p. p. m. from internal tetramethylsilane, coupling constants (J) being in c. p. s.
*2 Singlet unless shape of signal is stated by d for doublet, q for quartet and m for multiplet.
*3 ABX type of pattern, representing two and one proton respectively.

The ultraviolet spectrum indicates the presence of a tropone nucleus in III, while its NMR spectrum (cf. Table I) shows the presence of O-CH_3 (3.97 p. p. m.),[4] N-CH_3 (4.47 p. p. m.), and two isolated nuclear protons at 7.63 p. p. m. and 8.08 p. p. m. These spectroscopic observations, together with the analytical data and the fact that hydrogen bromide was liberated during the reaction, indicate that III is a dibromomethoxy-*N*-methylpyrazolotropone.

The permanganate oxidation of III gave, after thermal decarboxylation, 1-methylpyrazole-4-carboxylic acid, the structure of which was confirmed by the NMR spectrum of its methyl ester. This reaction establishes the presence of a pyrazole ring in III. The functional groups in the compound III are very inactive, and the only reaction registered was the acid-catalyzed exchange of one of the bromine atoms for a chlorine, thus yielding the corresponding bromochloro compound, IV (NMR Table I), although the position of the chlorine atom was not established. The catalytic reduction of III resulted in the absorption of two moles of hydrogen, and yielded V as yellow granules; the analysis and the ultraviolet spectrum of these granules suggest that the product is the corresponding methoxy-*N*-methylpyrazolotropone. Its NMR spectrum (cf. Table I) showed a singlet at 7.84 p. p. m. due to a proton on the pyrazole ring, and a complex multiplet, representing 3 protons, probably of the ABX type, between 6.4 and 7.3 p. p. m., besides signals due to a O-CH_3 (3.88 p.p.m.) and a N-CH_3 (4.46 p.p.m.). Compound V must, therefore, have one of the alternative structures, Va and Vb, deduced from the above evidence and from a consideration of the mode of action of diazomethane on α, β-unsaturated ketones. However, the appearance of the *N*-methyl signal at such a low field in the NMR spectrum of V and no substantial deviation between those signals in IV and V can more easily be explained on the basis of the structure Va; the low field shift is apparently due to the paramagnetic anisotropy of the carbonyl group at the peri-position.[5]

During the investigation of the various reactions of 4-acetyltropolone, we have also found an effective, simple method for the synthesis of pyrazolotropolone. The *p*-tosylhydrazone VI of 4-acetyltropolone[6] was treated with potassium hydroxide in ethanol. The product was a mixture of VII (pale yellow needles; 40% yield) and VIII (orange prisms; 22% yield), both of which showed a positive ferric chloride coloration and exhibited ultraviolet spectra



VI VII R=R'=H VIII R=H
X R=H, R'=$COCH_3$ IX R=$COCH_3$
XI R=R'=CH_3

suggestive of the presence of a tropolone ring. That both VII and VIII contain a pyrazole ring fused with the tropolone nucleus was established by their permanganate oxidation, which yielded 5-methylpyrazole-3, 4-dicarboxylic acid. Although the acetylation of VIII gave the colorless *O*, *N*-diacetate (IX), the same reagent under similar conditions converted VII to only a pale yellow *O*-acetate (X), which gave a negative ferric chloride test. The methylation of VII, under the conditions described above for tribromotropolone, gave the corresponding *O*, *N*-dimethyl compound (XI), the NMR spectrum of which (Table I) could almost be imposed on that of V, except for the appearance of a

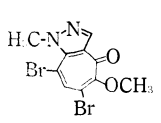
4) The assignment followed many precedences in bromotropolone methyl ethers; the methyl signal invariably appears in the region from 3.90 to 4.00 p. p. m. (J. Tsunetsugu and S. Itô, unpublished observation).

5) Similar situations can be found in the Varian NMR spectra catalog, Vol. I and II, Varian Associate, Palo Alto.

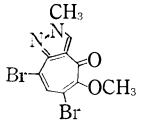
6) T. Nozoe, K. Takase and M. Ogata, *Chem. & Ind.*, **1957**, 1070.

singlet due to a C–CH_3 at 2.51 p.p.m. and the disappearance of the singlet at 7.84 p.p.m. due to the pyrazole proton. Once again, the appearance of the N–CH_3 signal at such a low field suggests the position of the methyl group. On the other hand, the NMR spectrum of IX showed an AB-type quartet and a singlet (Table I) in the aromatic region, thus disclosing the structures.

The reaction of diazomethane on tribromotropolone was extended to other bromotropolones, but it gave no definite product besides their methyl ether with the exception of 3, 5-dibromotropolone (XII). In the reaction, XII gave, together with 3, 5-dibromo-2-methoxytropone and 3, 5-dibromo-7-methoxytropone, colorless needles (XIII) with a m. p. of 235—236°C(decomp.), and with a molecular formula of $C_{10}H_8O_2N_2Br_2$. XIII exhibits an



XIIIa



XIIIb

ultraviolet spectra completely different from that of III, although it still retain a tropone nucleus. NMR spectrum (Table I) of XIII discloses the presence of O–CH_3, N–CH_3 and two isolated aromatic protons. The N–CH_3 signal appears at a much higher field than those in III, IV, V and XI, showing that they are free from the paramagnetic anisotropy of a carbonyl group, and that, therefore, they are remote from the carbonyl groups. On the other hand, the pyrazole proton at 8.46 p. p. m. is in an extremely low field compared with its counterparts in III, IV and V; this indicates that the pyrazole protons suffer from the anisotropy of the carbonyl group. With this information, the two alternative structures, XIIIa and XIIIb, were derived. However, study was discontinued because of the limited amount of material available.

Experimental[7]

4, 6-Dibromo-7-methoxy-1-methyl-8(1*H*)-cycloheptapyrazolone (III).[8]— *a) From 3, 5, 7-Tribromotropolone (I).*—An excess of diazomethane (an ethereal solution) was added to the warm suspension of I (10 g.) in methanol (150 ml.). After all the solid had disappeared, leaving an orange red solution, the reaction mixture was left in the dark for two days at room temperature with further addition of diazomethane. The colorless needles (m. p. 155—156°C) which crystallized out were collected (2.77 g.) by filtration; the filtrate was evaporated to leave a dark tarry material (the liberation of hydrogen bromide was detected), which was then chromatographed on alumina, eluted with ether to give a further 0.70 g. of the material. Total yield; 2.97 g. (30.6%). Recrystallization from methanol-chloroform gave colorless silky needles (m. p. 158°C).

Found: C, 34.58; H, 2.47; N, 7.62. Calcd. for $C_{10}H_8O_2N_2Br_2$: C, 34.51; H, 2.32; N, 8.05%.

UV λ_{max}^{MeOH} mμ (log ε): 245 (sh. 4.27), 264(4.34), 324(3.74), 335(sh. 3.70), 370(3.78).

IR: 1608, 1572, 1420, 1220, 986, 895, 861 cm^{-1}.

b) From 2-Methoxy-3, 5, 7-tribromotropone (II).—An ethereal diazomethane was added to a solution of 2.181 g. of II in 150 ml. of methanol; the solution thus obtained was left in the dark at room temperature for 2 days. After crystals had formed (943 mg., m. p. 148—151°C), the solution was treated exactly in the manner described above. The total yield of the crystals was 1.087 g. (53.5%). The compound was identified as III by a mixed melting point determination and by a comparison of the ultraviolet, infrared and NMR spectra.

7-Methoxy-1-methyl-8(1*H*)-cycloheptapyrazolone (V).—III (1.247 g.) was hydrogenated in a mixture of acetic acid (6 ml.) and ethyl acetate (60 ml.) in the presence of sodium acetate (990 mg.) and 5% palladium on charcoal (93 mg.). After a 2-molar uptake of hydrogen and the removal of the catalyst, the solvent was removed by distillation, leaving a brown residue; this residue was sublimed in vacuo to give yellow prisms (361 mg., 53%). Recrystallization from ethyl acetate yielded pale yellow prisms (m. p. 135—136°C).

Found: C, 63.06; H, 4.79; N, 14.48. Calcd. for $C_{10}H_{10}O_2N_2$: C, 63.15; H, 5.30; N, 14.73%.

UV λ_{max}^{MeOH} mμ (log ε): 230(4.56), 255(4.41), 306 (4.06), 321(4.10), 380(3.91).

IR: 1600, 1553, 1429, 1215, 1052, 896, 854, 794, 780 cm^{-1}.

4(or 6)-Bromo-6(or 4)-chloro-7-methoxy-8-(1*H*)-cycloheptapyrazolone (IV).—III (93 mg.) was heated under reflux for 3 hrs. with 6 N hydrochloric acid (9 ml.) in methanol (20 ml.), and then left overnight at room temperature. The colorless crystals which were thus formed were taken up (64 mg., 79%). Recrystallization from methanol yielded colorless plates (m. p. 143.5—144.5°C).

Found: C, 39.59; H, 2.82; N, 8.55. Calcd. for $C_{10}H_8O_2N_2BrCl$: C, 39.57; H, 2.66; N, 9.23%.

1-Methylpyrazole-4-carboxylic Acid.—An aqueous solution (100 ml.) of potassium permanganate (4.5 g.) was added, at 65—75°C, to III (679 mg.) dissolved in acetone (150 ml.). After the temperature had been kept constant for 6 hr., the reaction mixture was left overnight. The removal of the MnO_2 which had been precipitated and the evaporation of the solvent from a yellow filtrate left a colorless solid. The extraction of the residue by dry acetone and the concentration of the solvent gave colorless crystals (m. p. 175—177°C; 126 mg.; 38% yield). The sublimation of the crystal at 160°C yielded 65 mg. of colorless crystals (m. p. 169°C).

Found: C, 47.88; H, 4.72; N, 21.31, mol. wt. 124 (titration). Calcd. for $C_5H_6O_2N_2$: C, 47.62; H,

7) All melting points are uncorrected. The infrared spectra are referred to Nujol mull unless otherwise stated.

8) This nomenclature is based on the name, 1, 8-dihydrocycloheptapyrazole, of the hypothetic compound XV (numbering shown).

p-Toluenesulfonylhydrazone (VI) of 4-Acetyltropolone.—A mixture of 4-acetyltropolone (5.00 g.), *p*-toluenesulfonylhydrazine (6.00 g.) and ethanol (30 ml.) was heated. The mixture changed into a solution at once, and soon the *p*-toluenesulfonylhydrazone (VI) was crystallized out as pale yellow prisms (m. p. 220°C (decomp.)) (10.52 g.).

Found: C, 57.57; H, 4.52; N, 8.22. Calcd. for $C_{16}H_{16}O_4SN_2$: C, 57.83; H, 4.85; N, 8.43%.

UV λ_{max}^{MeOH} mμ (log ε); 228 (4.36), 292(4.19), 384 (3.68).

3'-Methylpyrazolo[3, 4-c]tropolone (VII) and 3'-Methylpyrazolo[4, 3-d]tropolone (VIII).—To a solution of potassium hydroxide (3.0 g.) in ethanol (60 ml.), VI (5.10 g.) was added; the mixture was then refluxed for 7 hr. After the addition of water (40 ml.) and acidification with 6 N hydrochloric acid, the solution was allowed to stand overnight. The crystals thereby formed were colledted by filtration and recrystallized from dimethylformamide to give 3'-methylpyrazolo-[3, 4-c]tropolone (VII) as pale yellow needles (m. p. 211—212°C) (1.09 g.).

Found: C, 58.15; H, 4.38; N, 15.11. Calcd. for $C_9H_8O_2N_2 \cdot 1/2H_2O$: C, 58.73; H, 4.90; N, 15.13%.

UV λ_{max}^{MeOH} mμ (log ε): 226(4.28), 255(4.38), 305(3.80), 318(3.87), 379(sh. 3.88), 390(3.93).

Acetate X: m. p. 216—218°C, pale yellow needles (from ethanol).

Found: C, 60.51; H, 4.30; N, 12.83. Calcd. for $C_{11}H_{10}O_3N_2$: C, 60.54; H, 4.62; N, 12.84%.

UV λ_{max}^{MeOH} mμ (log ε): 233(4.30), 294(3.82), 307(3.79), 365(3.79), 380 (sh. 3.73).

The removal of ethanol from the mother liquor gave an oily material, which was solidified by allowing it to stand. This was warmed with methanol, and the sparingly-soluble part (m. p. 215—222°C) (1.00 g.) was recrystallized from dimethylformamide to give 3'-methylpyrazolo[4, 3-d]tropolone (VIII) as orange prisms (m. p. 225—226°C) (0.60 g.).

Found: C, 60.83; H, 4.34; N, 15.72. Calcd. for $C_9H_8O_2N_2$: C, 61.36; H, 4.58; N, 15.90%.

UV λ_{max}^{MeOH} mμ (log ε): 228(4.27), 280(sh. 4.27), 287(4.31), 296(sh. 4.28), 398(3.61), 435(3.55).

Acetate IX: m. p. 169—170°C; colorless micro-needles (from acetic acid).

Found: C, 60.16; H, 4.26; N, 10.51. Calcd. for $C_{13}H_{12}O_2N_2$: C, 59.99; H, 4.65; N, 10.77%.

UV λ_{max}^{MeOH} mμ (log ε): 282(4.46), 315(sh. 4.02).

From the methanol-soluble part, *p*-tolyl *p*-toluenethiolsulfonate (0.60 g.), was obtained as colorless needles (m. p. 75—76°C (reported 76°C[9])) after recrystallization from methanol.

1, 3-Dimethyl-7-methoxy-8-(1*H*)-cycloheptapyrazolone (XI).—VII (603 mg.) was methylated with diazomethane under the conditions described for the compound III. After the reaction mixture had been left overnight, the solvent was distilled off, and the residue was chromatographed on alumina. Elution with benzene gave yellow crystals (587 mg., 84.5%). Recrystallization from benzene - petroleum ether (b. p. 60—80°C) gave yellow prisms (m. p. 81.5—82°C).

Found: C, 64.96; H, 5.55; N. 13.50. Calcd. for $C_{11}H_{12}O_2N_2$: C, 64.69; H, 5.90; N, 13.70%.

UV λ_{max}^{MeOH} mμ (log ε): 230(4.37), 250(4.37), 302(3.98), 316(4.03), 370(3.94).

IR: 1623, 1603, 1553, 1425, 1214, 1028, 793, 768 cm^{-1}.

The Permanganate Oxidation of Pyrazolotropolones VII and VIII.—Into a solution of VII (0.53 g.) in a 0.4 N potassium hydroxide solution (25 ml.), finely-powdered potassium permanganate was stirred in small portions at room temperature; 2.65 g. of permanganate was thus smoothly consumed. After the mixture had been allowed to stand overnight, the excess permanganate was decomposed on the addition of methanol and the manganese dioxide was filtered off. The filtrate was slightly acidified with 6 N hydrochloric acid and concentrated under reduced pressure until crystals had begun to separate out. Acetone was then added, and the inorganic salts thereby separated were filtered off. After the mother liquor had been treated repeatedly in the same way, the acetone solution was evaporated to dryness; the subsequent addition of a small amount of water gave oxalic acid. From the water-soluble part, 5-methylpyrazole-3, 4-dicarboxylic acid (0.11 g.) was obtained as colorless microcrystals; this acid was identified with an authentic specimen[10] by a comparison of the infrared spectra.

Found: C, 38.60; H, 4.30; N, 14.77. Calcd. for $C_6H_6N_2 \cdot H_2O$: C, 38.30; H, 4.29; N, 14.89%.

The same oxidation of VIII (0.30 g.) with potassium permanganate also gave 5-methylpyrazole-3, 4-dicarboxylic acid (0.05 g.).

The Reaction of Diazomethane with 3, 5-dibromotropolone (XII).—The reaction was carried out with 100 mg. of XII in exactly the same way as was described in the above section. The product obtained by the evaporation of the solvent from the reaction mixture in vacuo was chromatographed on alumina. Elution with benzene gave colorless cytstals (30 mg.), which were recrystallized from chloroform to give colorless silky needles (XIII) (m. p. 235—236°C(decomp.)).

Found: C, 34.61; H, 2.30; N, 7.54. Calcd. for $C_{10}H_8O_2N_2Br_2$: C, 34.51; H, 2.32; N. 8.02%.

UV λ_{max}^{MeOH} mμ (log ε): 240(sh. 4.70), 253(4.77), 260 (sh. 4.69), 347(4.24).

IR: 3125, 1616, 1587, 1221, 1012, 903, 865, 785, 765 cm^{-1}.

The authors wish to express their gratitude to Professor Tetsuo Nozoe, Tohoku University, for his interest, and to Professor W. A. Ayer, University of Alberta, Canada, for some of the NMR spectra included in this paper.

Studies of the Chemiluminescence of Several Xanthene Dyes. I. Kinetic Studies of Uranine and Eosine Chemiluminescence

By Isao KAMIYA

Department of General Education, Nagoya University, Chikusa-ku, Nagoya

and Ryojirô IWAKI

Aichi Gakugei University, Chemical Laboratories, Okazaki, Aichi

(Received May 12, 1965)

A kinetic study of the chemiluminescence in alkaline solutions of several xanthene dyes with hydrogen peroxide was carried out in the hope of gaining some insight into the mechanism of the luminescent reaction. When the concentrations of sodium hydroxide and hydrogen peroxide were kept constant, the decay curve of the luminescence was represented by $I_t = A \exp(-at)$, where I_t is the light intensity at time t ; a is equal to the rate constant of the decomposition of the dye (first order with respect to the dye concentration) and A is a parameter proportional to the initial dye concentration. The lifetime of the luminescent reaction was prolonged by the addition of such organic solvents as alcohol and dioxane; the a value decreased, while the A value remained unchanged. Both the a value and the A value increased with the elevation of the reaction temperature.

In 1924, Keaney[1] observed a glow when ozonized oxygen was passed through a solution of aesculin in water, methyl alcohol, ethyl alcohol or propyl alcohol. A short time later, Biswas and Dhar[2] investigated a similar glow, using fifty different fluorescent and non-fluorescent dyes; they concluded that the luminescent intensity was roughly proportional to the fluorescence efficiency of the dyes. Moreover, they found that the same glow was obtained when the dyes were oxidized by hydrogen peroxide, using ferrous sulfate as a catalyst. Strehlar and Shoup[3] have discovered the chemiluminescence of riboflavin and showed that the spectral energy distribution of the luminescence is very similar to that of the fluorescence emission of riboflavin.

Thus, it is very probable that the light emitted in the chemiluminescence of a fluorescent dye is the fluorescence emission of the dye, although little is known as to how the dye can be excited to emit fluorescence in the chemiluminescent reaction. It was with this in mind that the present authors[4] began to study the chemiluminescence of several xanthene dyes.

It has been established that, when the dyes are oxidized by hydrogen peroxide, hydroxyl ion, iodide ion, hypochlorite ion or lead acetate acts as a catalyst for the light production, as does ferrous sulfate. Moreover, when a hydrogen peroxide solution is added to alkaline solutions of the dyes, the emission is very much enhanced and is quite reproducible.

For the present paper, kinetic studies of uranine and eosine chemiluminescence were carried out in order to establish the mechanism for light production.

Experimental

The Preparation of the Luminescent System.—Two milliliters of a sodium hydroxide solution was added to 6 ml. of a uranine or eosine solution; the mixed solution was then kept at a definite temperature. After 1 ml. of a hydrogen peroxide solution has been added to the mixed solution, a portion of the reacting solution (4—5 ml.) was transferred quickly into a cell (2.8 cm. high, 2.0 cm. wide and 1.0 cm. thick); then the cell was placed in a thermostat, with water circulating at a constant temperature.

Uranine and eosine were recrystallized from a 60—70% ethanol solution. One gram of each dye was dissolved into 100 ml. of water or a water - organic solvent mixture in order to prepare the original solution; when necessary, this was further diluted to 1/2, 1/4, 1/8, and so on. The sodium hydroxide, the hydrogen peroxide solution (30 %) and organic solvents of an analytical grade were used without further purification.

Measurements of the Light Intensity versus the Time.—The light-measuring apparatus is shown diagramatically in Fig. 1. It was composed of a small thermostat and a photomultiplier-tube box, both of which were covered with a large dark box. The reaction cell in the thermostat was clamped on so as to face a glass window, through which the emitted light was

detected with a photomutiplier-tube (Matzuda MS9SY). The tube was coupled with a linear amplifier, and the output current was lead to a self-recording micro-ammeter, so that the curve of the light intensity versus the time could be recorded automatically.

Measurements of the Decomposition Rate of the Dyes.—The dyes were decomposed during the luminescent reaction; no emission was observed when the dye was not decomposed. In order to determine the decomposition rate of the dye, 1 ml. of the reacting solution was withdrawn at a definete interval in order to mix it with 250 ml. of water (the reaction was stopped upon dilution); the concentration of unoxidized dye was determined spectro-photometrically with a Shimadzu QR-50-type electro-spectrophotometer, at the wavelength of 492 mμ for uranine and of 517 mμ for eosine.

Experimental Results

In general, the curve of the emission intensity versus the time (the *I-t* curve) rises to reach a maximum at the initial stage and then decays slowly. The *I-t* curve was reproducible except in the initial stage. (The initial curve was not quite reproducible because hydrogen peroxide decomposed after a short induction period.)

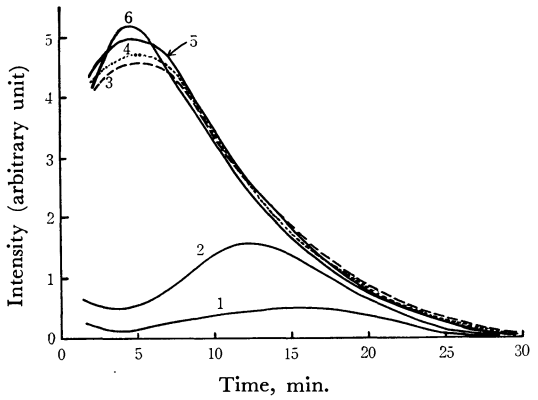

Fig. 2. Effect of hydrogen peroxide concentration on *I-t* curve for uranine chemiluminescence.
(Original solution, 2.5 N NaHOaq., 30°C)
(1) 5%, (2) 10%, (3) 15%, (4) 20%, (5) 25%, (6) 30%

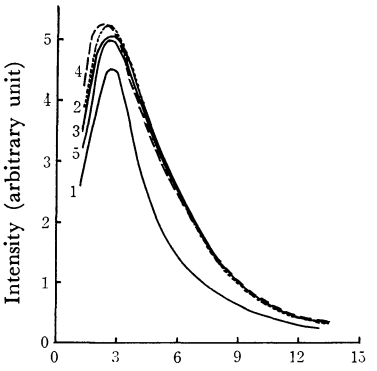

Fig. 3. Effect of hydrogen peroxide concentration on *I-t* curve for eosine chemiluminescence.
(Original solution, 0.5 N NaOHaq., 41°C)
(1) 10%, (2) 15%, (3) 20%, (4) 25%, (5) 30%

The Effect of the Hydrogen Peroxide Concentration on the *I-t* Curve—The results are shown in Figs. 2 and 3. It is there demonstrated that the decay curve is little affected by the change in the concentration of the added hydrogen peroxide solution when its concentration is comparatively high (20—30%). When the concentration is low, however, the *I-t* curve becomes lower and is greatly affected by a change in the concentration of the added hydrogen peroxide solution. The optimum concentration of the added hydrogen peroxide solution for the kinetic studies is found to be 20—30%.

The Effect of the Sodium Hyroxide Concentration on the *I-t* Curve.—The correlation between the *I-t* curve and the added sodium

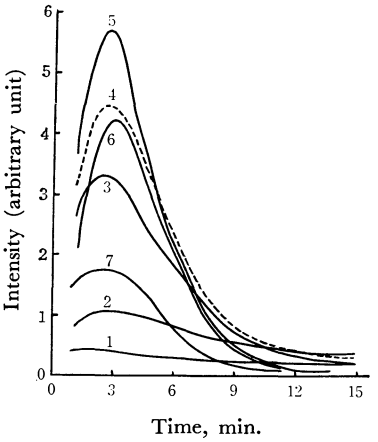

Fig. 4. Effect of sodium hydroxide concentration on *I-t* curve for uranine chemiluminescence.

hydroxide concentration is not so simple, because the aspects of the *I-t* curve differ according to the concentration of hydrogen peroxide as well as according to the dye concentration. The effect is probably due to the fact that the alkali concentration controls both the rate of the decomposition of hydrogen peroxide and the luminescent reactivity of the dye. Typical examples are shown in Fig. 4 for uranine and in Fig. 5 for eosine. These figures show that the optimum concentration of the added sodium hydroxide solution should be 2—3 N for uranine and 0.5 N for eosine.

The Effect of the Dye Concentration on the *I-t* Curve.—*I-t* curves measured at 16°C in uranine chemiluminescent systems of different

dye concentrations are shown in Fig. 6, where the concentrations of the added sodium hydroxide and hydrogen peroxide solutions are 3.0 N and 20% respectively (optimum concentration). From numerical analysis, every curve can be represented by the following general equation (1):

$$I_t = A\exp(-at)/\{1+B\exp(-bt)\} \qquad (1)$$

where I_t is the emission intensity at time t; a is the decay costant, and A, B and b are parameters which differ according to the experimental conditions. The curves shown in Fig. 6 can be represented by the following equation:

Uranine concn. (ratio to the original soln.)	Equation
1	$I_t=400\exp(-0.10t)/\{1+16\exp(-0.28t)\}$
1/2	$I_t=200\exp(-0.09t)/\{1+5\exp(-0.25t)\}$
1/4	$I_t=100\exp(-0.10t)/\{1+\exp(-0.28t)\}$
1/8	$I_t=48\exp(-0.10t)$
1/16	$I_t=22\exp(-0.10t)$

Table I shows both the calculated values and the observed values. The calculated values are in fairly good agreement with the observed values except for a slight deviation at the initial stage. From the results, the following important conclusions are obtained:

i) Since the second term of the denominator in Eq. 1, $B\exp(-bt)$, can be disregarded except in the initial stage, the decay part of the I-t curve is represented by:

$$I_t = A\exp(-at) \qquad (2)$$

ii) The decay constant, a, is not affected by the dye concentration.

iii) The value of A is proportional to the initial dye concentration. This fact indicates that the luminescent decay is of the first order with respect to the dye concentration.

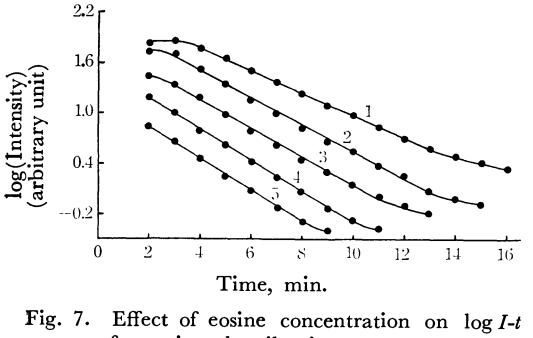

Fig. 7. Effect of eosine concentration on log I-t curve for eosine chemiluminescence.
(0.5 N NaOHaq., 30% H_2O_2aq., 41°C)
(1) Original solution, (2) 1/2 conc. to original solution, (3) 1/4 conc. to original solution, (4) 1/8 conc. to original solution, (5) 1/16 conc. to original solution

The intensities of emission measured at 41°C in eosine chemiluminescent systems of different dye concentrations are shown in Fig. 7, where the logarithm of I_t is plotted against the time. These plots are almost on straight lines except in the initial and final stages. Therefore, the decay curves may also be represented as follows:

Eosine concn. (ratio to the original soln.)	Equation
1	$I_t=180\exp(-0.28t)$
1/2	$I_t=150\exp(-0.41t)$
1/4	$I_t=78\exp(-0.41t)$
1/8	$I_t=39\exp(-0.41t)$
1/16	$I_t=20\exp(-0.41t)$

It is shown that, when the concentration of eosine is comparatively high, the values of A and a are smaller than the expected values. Moreover, the curves deviate from Eq. 2 at the final stages in both uranine and eosine chemiluminescence.

This deviation will be discussed in a succeeding paper.

The Effect of an Added Organic Solvent on the *I-t* Curve.—In general, the emission intensity was enhanced when such organic solvents as alcohol, dioxane and glycerol were added to the system. The *I-t* curves obtained from uranine chemiluminescence in water-methanol systems of different methanol concentrations at 20°C, with the uranine concentration kept constant, are shown in Fig. 8. The curves obtained from the systems with different uranine concentrations and with a constant methanol concentration are shown in Figs. 9 and 10. These curves were also represented as:

TABLE III. EFFECT OF TEMPERATURE ON THE VALUES OF *A* AND *a* UNDER SEVERAL EXPERIMENTAL CONDITIONS

1. Uranine chemiluminescence in aqueous solution
(1/4 concn. to original solution, 20% H_2O_2aq.)

NaOHaq., N	Temp., °C	*A*	*a*
3.0	21	155	0.13
3.0	31	800	0.35
3.0	41	3100	0.47
3.0	50	7700	1.02
3.0	59	17400	1.63
2.0	21	105	0.072
2.0	31	580	0.20
2.0	41	2640	0.40
2.0	50	6660	0.70
2.0	59	14000	1.05

2. Eosine chemiluminescence in aqueous solution
(1/4 concn. to original solution, 0.5 N NaOHaq., 30% H_2O_2aq.)

Temp., °C	*A*	*a*
21	11	0.11
32	35	0.27
41	80	0.41
51	180	0.77
59	390	1.38

3. Uranine chemiluminescence in water-methanol system (25%).
(Original solution, 2.5 N NaOHaq., 20% H_2O_2aq.)

Temp., °C	*A*	*a*
22	147	0.031
30	412	0.060
39	1540	0.10
51	4980	0.28
57	13800	0.47

4. Eosine chemiluminescence in water-isopropanol system (40%)
(1/2 concn. to original solution, 0.5 N NaOHaq., 30% H_2O_2aq.)

Temp., °C	*A*	*a*
23	83.5	0.017
30	126	0.022
37	221	0.038
45	394	0.063
52	1338	0.14

1/4	30	$I_t = 72\exp(-0.14t)$
1/4	50	$I_t = 78\exp(-0.08t)$
1/8	10	$I_t = 40\exp(-0.31t)$
1/8	30	$I_t = 38\exp(-0.15t)$
1/8	50	$I_t = 38\exp(-0.08t)$

From these results, it can be seen that the decay constant, a, which is independent of the dye concentration, decreases with an increase in the concentration of added methanol, while A, which is proportional to the initial dye concentration, is little affected by the addition of methanol. It may, therefore, be concluded that the stimulation of luminescence by the addition of methanol is due to the prolongation of the luminescent lifetime. In other water - organic solvent systems, the same correlation is obtained between the values of A and a and the concentration of the added organic solvent. These results are shown in Table II.

The Effect of the Temperature on the *I-t* Curve.—*I-t* curves were also investigated at several different temperatures. Every curve can be represented by Eq. 2. The values of A and a obtained either in an aqueous system or in a water - organic solvent system are listed in Table III. It may be seen that in all of the systems both A and a increase with the increase in the temperature.

The Decomposition Rate of Dye in the Luminescent Reaction.—Typical decomposition curves obtained from uranine and eosine chemiluminescence are shown in Figs. 12 snd 13 respectively, where the logarithm of the dye concentration (in arbitrary units) is poltted against the reaction time. An almost straight line is obtained in each

case. These results indicate that the decomposition is first order with respect to the dye concentration. The decomposition rate constants under several different expermental conditions are tabulated in Table IV. The values of a (the decay constant) obtained under the same experimental conditions are also given in the last column. It is interesting to note that the decomposition rate constant is almost equal to the corresponding a value in every system.

Studies of several different aspects of chemiluminescence will be presented in a succeeding paper; the combined results, including those of the present experiment, will be discussed thereafter.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 264—269 (1966)

Studies of the Chemiluminescence of Several Xanthene Dyes. II. The Chemiluminescence Emission Spectra of Uranine and Eosine

By Isao KAMIYA

Department of General Education, Nagoya University, Chikusa-ku, Nagoya

and Ryojirô IWAKI

Aichi Gakugei University, Chemical Laboratories, Okazaki, Aichi

(Received May 12, 1965)

The emission spectra of uranine and esoine chemiluminescence with hydrogen peroxide were measured photoelectrically and were compared with the fluorescence spectra of the dyes. The apparent spectra did not give the true energy distribution of the emitted light, because self-absorption took place. When the dyes were oxidized with ozonized air, the apparent emission spectra were very similar to those obtained when the dyes were oxidized with hydrogen peroxide. This would indicate that the emitting species are the same in the two reaction systems. The emission from the dye-ozone reaction was intense, and the spectrum could be compared with the fluorescence spectrum by employing a system with a low dye concentration. The coincidence of the two spectra was clearly demonstrated. The chemiluminescence spectrum of uranine at a high dye concentration in the presence of hydrogen peroxide was compared to the "chemi-fluorescence" spectrum of the luminol-dye system. The two systems gave almost the same spectrum. It may be concluded that the emissions from uranine and eosine chemiluminescence are the fluorescence emissions of the dyes and that the emitting species are the excited singlet states of uranine and eosine.

Since organic compounds which emit chemiluminescent light often fluoresce, the chemiluminescence emission spectra can conveniently be compared with the fluorescence emission spectra. The chemiluminescence spectrum is not always the same as the fluorescence spectrum; in luminol chemiluminescence, it has been found[1] that the emitting species is the excited aminophthalic acid ion produced by the reaction. Light emittted by lophin chemiluminescence has also been found[2] not to correspond to the fluorescence of the compound.

On the other hand, the chemiluminescence emission spectra of lucigenin[3] and riboflavin[4] were found to be very similar to their fluorescence emission spectra. The chemiluminescence emission observed when hydrogen peroxide was added to an alkaline solution of uranine or eosine seemed to correspond to the fluorescence of the dye. However, no comparison of the two spectra has yet been made except for a rough observation with the naked eye.[5]

There is a severe restriction in the measurement of the emission spectra; the apparent chemiluminescence spectra of the dyes do not give the true energy distribution, because the dye solutions absorb the emitted light. In a dilute dye solution where the self-absorption is not apreciable, the intensity

of the chemiluminescence is too weak for reliable measurements. Therefore, other, supplementary methods for estimating the emission spectra should be employed together with direct measurements.

Experimental

Measurements of Emission Spectra in Uranine and Eosine Chemiluminescence with Hydrogen Peroxide.—The luminescent system was prepared in the method described previously.[6] The emission spectra were measured photo-electrically with the apparatus shown diagramatically in Fig. 1. A was a hard-glass reaction tube about 20 mm. in diameter; it was placed in a cylindrical copper thermostat, B. Water circulated between the cylinder, B, and a large thermostat through pipes, D, so the reaction tube could be kept at a constant temperature. C was a dark box. Light emitted from the reaction tube was conducted through a convex lens, E, into a electro-spectrophotometer, F. By dialing a wavelength adjuster with a motor, a spectral curve was recorded on G. It took about 2 min. to scan the whole curve. As a result of the decay of the emission intensity during the recording, the recorded spectral curve was corrected by the decay curve which had been measured under the same experimental conditions. In the present work, where the chemiluminescence emission spectra are compared with the fluorescence spectra, no correction was made for the characteristic sensitivity of the photomultiplier, because the fluorescence was measured with the same photomultiplier.

The Measurement of Emission Spectra in Uranine and Eosine Chemiluminescence with Ozone.—When ozonized air was passed through ethanol solutions of uranine and eosine, light was also produced and the apparent emission spectra were similar to those observed when the dyes were oxidized with hydrogen peroxide. The intensity of the emission in this system was more pronounced, although the reproducibility was somewhat poor; hence, the emission spectra could be measured in a solution of such a low dye concentration that self-absorption was not appreciable.

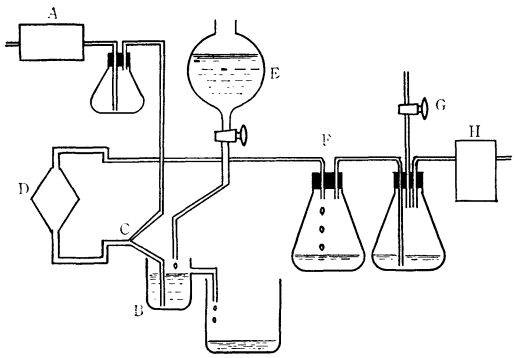

Fig. 2. Diagram of measuring apparatus for the emission spectra of dye chemiluminescence with ozone.

A: Ozonizer B: Beaker
C: Nozzle D: Reaction vessel
E: Sample-solution flask
F: Waste-solution flask
G: Cock H: Pump

The measurement of the emission spectra in the system was carried out with the apparatus shown diagramatically in Fig. 2. Four hundred milliliters of an ethanol solution of uranine or eosine in a flask, E, was dropped into a beaker, B. By pumping out the entire vessel via H, the ozonized air produced in an ozonizer, A, was introduced from a nozzle, C, and reacted with the dye solution. The reacting solution was carried to F through a vessel, D. D is a lozenge-shaped vessel (3.7 cm. wide, 5.4 cm. high) consisting of two parallel glass plates 2 mm. apart, the back of one glass plate being coated with silver. The spectra were measured by inserting D into the A of Fig. 1. As the intensity of emission was practically constant for about 10 min., no correction was needed for the variation with the reaction time. All the measurements were carried out at room temperature because the temperature dependence of the intensity was not appreciable.

Experimental Results

The apparent emission spectra observed in uranine and eosine chemiluminescence with hydrogen peroxide are shown in Figs. 3 and 4. The conentrations of uranine and eosine were 1 g. per 100 ml. and 0.5 g. per 100 ml. respectively. The measurements were carried out in a 60% methanol solution at 60°C. Figures 5 and 6 show the same spectral curves in other solvents, such as ethanol, *n*-propanol, isopropanol and glycerol. It is sohwn that every (apparent) spectrum has the same maximum, at 560 mμ for uranine and at 580 mμ for eosine. These apparent spectra, however, do not give the true energy distribution of the emitted light, because the dye solutions absorb the light. (The absorption spectra of uranine and eosine have maxima at 492 mμ and 517 mμ respectively.) Therefore, no direct comparison of the spectra with fluorescence spectra could be made.

The apparent chemiluminescence spectra observed when ozonized air was passed through ethanol solutions of different uranine concentrations are shown in Fig. 7. The spectra for eosine solutions are shown in Fig. 8. The apparent spectra in a concentrated dye solution are similar to those obtained with hydrogen peroxide. This would indicate that the emitting species is the same in the two reactions. It is very interesting to see that the peak shifts towared a shorter wavelength with a decrease in the dye concentration. In dilute dye solutions, the spectra have maxima at 530 mμ for uranine and at 560 mμ for eosine.

1: 1.44×10^{-2} mol./l. 2: 7.22×10^{-3} mol./l.
3: 3.61×10^{-3} mol./l. 4: 1.81×10^{-3} mol./l.
5: 9.03×10^{-4} mol./l. 6: 4.52×10^{-4} mol./l.

As will be shown later, these maxima correspond to the peaks of the fluorescence of the dyes.

Chemi-fluorescence Emission Spectra in Luminol-Uranine and Luminol-Eosine Systems.—When a dilute hydrogen peroxide solution was added to an aqueous alkaline solution of luminol and a fluorescent dye such as uranine or eosine, a green fluorescence of the dye appeared at the expense of the blue luminescence of luminol. (In such a reaction system, the added dye is almost unoxidized as a result of the low concentration of hydrogen peroxide.) This phenomenon was discovered by Plotnikov[7] and called "Chemi-fluorescence" or "Induced Chemiluminescence." Tamamushi[8] investigated it further and found that both blue light and green light were observed when less than 0.02% of fluoresceine was added to 0.0025% of a luminol solution, and that the blue

3: 0.1 g./l. 4: 0.625 g./l.

light changed completely to green light when the dye was more than 0.02%. The light was gradually enfeebled by the further addition of the dye.

With the aid of this phenomenon, the variation in the shape of apparent emission spectra with the dye concentration could be investigated. To initiate the luminol reaction, 3 ml. of 10% of a hydrogen peroxide solution was added to mixtures of 6 ml. of an alkaline luminol solution (0.25 g. of luminol and 2 g. of sodium hydroxide were dissolved in 100 ml. of water) and 21-ml. portions of uranine solutions of various concentrations. The chemi-fluorescence spectra were measured with the apparatus shown in Fig. 1. The reaction was carried out at 31°C; the results are illustrated in Fig. 9. It is shown that the spectrum in a dilute dye solution has two maxima, at 420 mμ and 530 mμ, due to luminol chemiluminescence and uranine chemi-fluorescence respectively. The second peak shifts to longer wavelengths with an increase in the dye concentration, which is very similar to the red shift observed in the apparent chemiluminescence emission spectrum of the uranine-ozone system. This similarity would indicate that the chemiluminescence is the fluorescence of the dye.

Fluorescence Spectra of Uranine and Eosine.—In order to compare the chemiluminescence emission spectra with the fluorescence spectra, the apparent fluorescence spectra were investigated in methanol solutions of uranine and eosine of various concentrations. The spectra were measured with a fluoro-meter attached to the electro-spectro-photometer of Fig. 1 (Fig. 10). The results are shown in Figs. 11 and 12. It is there shown that the peaks of the apparent fluorescence spectra also shift towards longer wavelengths with an increase in the dye concentration.

—○— Uranine system (curve 1 in Fig. 3)
—●— Uranine-luminol system (curve 4 in Fig. 9)

Figs. 7 and 8 are compared with the fluorescence spectra of Figs. 11 and 12 in Figs. 13 for uranine and in Fig. 14 for eosine. A correspondence between the two spectral curves is clearly demonstrated, although a slight deviation is found in the eosine system. The same comparison was made between the spectrum of uranine chemiluminescence in the presence of hydrogen peroxide and that of chemi-fluorescence in the luminol-uranine system. This is shown in Fig. 15. The coincidence is apparent.

On the basis of this experimental evidence, it may be concluded that the emissions from the uranine and eosine chemiluminescence are fluorescence emissions of the dyes and that the emitting species are the excited singlet states of uranine and eosine.

Further evidence in support of the present conclusion will be given in a succeeding paper.

Studies of the Chemiluminescence of Several Xanthene Dyes. III. The Effect of Added Foreign Dyes on Light Production

By Isao KAMIYA

Department of General Education, Nagoya University, Chikusa-ku, Nagoya

and Ryojirô IWAKI

Aichi Gakugei University, Chemical Laboratories, Okazaki, Aichi

(Received May 12, 1965)

The intensity of uranine chemiluminescence decreased when trypaflavine was added to the system. The enfeebling action seemed to be due to external quenching. On the contrary, the intensity of eosine chemiluminescence was enhanced by the presense of uranine. The values of Δ and σ are defined by the following equations:

$$\Delta=\int_0^T (I_{UE}-I_U-I_E)dt \qquad \sigma=\Delta\Big/\int_0^T I_E dt$$

where I_{UE}, I_U and I_E are the intensities measured in uranine-eosine, uranine and eosine systems respectively, and where T is the duration of eosine chemiluminescence. Δ increased with the increase in either the concentration of uranine or that of eosine, while σ increased only when the ratio of the uranine concentration to the eosine concentration increased. Δ increased with the increase in the temperature, while σ was little affected by the temperature. Δ increased upon the addition of organic solvents, while σ was little affected by the addition of the organic solvents. The enhancing action is due neither to the production of a stable compound which emits strongly nor to the increase in the rate of the decomposition of the dye. One possible mechanism of the enhancing action is that energy is transferred from an energy-rich intermediate produced by the reaction to an unoxidized uranine or eosine.

The intensity of chemiluminescence is affected more or less by the addition of foreign substances. Biswas and Dhar[1] have studied the subject extensively with a number of foreign substances and have found that all of them were inhibitors of the luminescent reaction. Bersis,[2] however, has succeeded in showing that the intensity of the chemiluminescence of polyphenol is remarkably enhanced by the presence of rhodamine B. In the present paper, the chemiluminescence of uranine and eosine will be investigated in the presence o foreign dyes, in the hope that a full examination of the effect of foreign substances will give some insight into the mechanism of the luminescent reaction. The results may be summarized as follows:

1) The intensity of uranine chemiluminescence decreases in the presence of trypaflavine (an enfeebling action). This has also been found to be true in uranine-erythrosine and in eosine-erythrosine systems.

2) The intensity of eosine chemiluminescence

1) N. N. Biswas and N. R. Dhar, *Z. anorg. u. allgem. Chem.*, **173**, 125 (1928).

2) D. S. Bersis, *Z. phys. Chem.* (*Neue Folge*), **26**, 359 (1960).

increases in the presence of uranine, and (an enhancing action).

Experimental

The luminescent systems were prepared, and both the luminescence intensities and the rates of the decomposition of the dyes were measured in the ways described in a preceding paper.[3]

Results and Discussion

I) Enfeebling Action.

Figure 1 shows the effect of added trypaflavine on the intensity of uranine chemiluminescence; curves I, II, III and IV represent, respectively, the results obtained from the uranine-trypaflavine sample solutions of I, II, III and IV listed in Table I. Each luminescent reaction was started by the addition of 1 ml. of a 20% hydrogen peroxide solution to a mixture of 7 ml. of the sample solution and 2 ml. of a 2.5 N sodium hydroxide solution at 40°C. We can see an "enfeebling action" of the added trypaflavine. The higher the concentration of added trypaflavine, the stronger becomes the enfeebling action. By numerical analysis, the curves can be represented as:

$$I_t = A\exp(-at)/\{B + Q\exp(-qt) + C\exp(-ct)\} \quad (1)$$

where I_t is the intensity of the emission at time t and A, a, B, Q, q, C and c are all parameters which differ according to the experimental conditions. Curves I, II, III and IV of Fig. 1 can be represented as the following equations:

Curve

$$\text{I:}\quad I_t = 500\exp(-0.46t)/\{1 + 6.0\exp(-0.80t)\} \quad (1a)$$

$$\text{II:}\quad I_t = 460\exp(-0.46t)/\{1.14 + 5.5\exp(-0.80t) + 6.3\exp(-0.53t)\} \quad (1b)$$

$$\text{III:}\quad I_t = 430\exp(-0.46t)/\{1.29 + 5.2\exp(-0.80t) + 16.2\exp(-0.51t)\} \quad (1c)$$

$$\text{IV:}\quad I_t = 357\exp(-0.46t)/\{1.53 + 4.5\exp(-0.80t) + 26.4\exp(-0.47t)\} \quad (1d)$$

Both the calculated values and the observed values are tabulated in Table II. The calculated values are in fairly good agreement with the observed values except for a slight deviation at the initial stage.

In the reaction system of uranine-trypaflavine, no emission was observed as resulting from the decomposition of trypaflavine. It is difficult to determine the decomposition rate of trypaflavine in the uranine-trypaflavine system by measuring the absorbancy of the dye at 452 mμ, because uranine absorbed light appreciably at that wavelength. However, as the rate of the decomposition of trypaflavine was found to be almost independent of the amount of uranine, its rate in the system could be estimated from a separate experiment in an isolated trypaflavine system. The rate of the decomposition of trypaflavine was measured in a system composed of 7 ml. of a trypaflavine solution, 2 ml. of a 2.5 N sodium hydroxide solution, and 1 ml. of a 20% hydrogen peroxide solution. The results are shown in Fig. 2, where the concentrations of trypaflavine in II', III' and IV' are equal to those in II, III and IV of Fig. 1 respectively. These decomposition curves can be represented as:

$$[D]_t = \alpha + \beta(-k_t t) \quad (2)$$

where $[D]_t$ is the concentration of trypaflavine at time t, both α and β are parameters which differ according to the experimental conditions, and k_t is the rate constant. The curves of Fig. 2 can be expressed as:

$$\text{Curve II'}\quad [D]_t = 0.036 + 1.74\exp(-0.53t) \quad (2a)$$

$$\text{Curve III'}\quad [D]_t = 0.076 + 4.27\exp(-0.53t) \quad (2b)$$

The results indicate that the decomposition of trypaflavine is first order with respect to its concentration.

We shall first discuss the physical meaning of the parameters, a, A, etc.

Parameter a.—It was shown in a previous paper[3] that all the curves of the intensity versus the time measured in uranine chemiluminescence could be represented by a single equation in the form of Eq. 1a, in which a was found to correspond to the rate of the decomposition of uranine. Perhaps this may also be the case with Eqs. 1b—1d. We may also assume that parameter a is the rate of the decomposition of uranine, which is not affected by the addition of trypaflavine.

Parameter A.—From the same argument, A should be a value proportional to the initial concentration of uranine. Since an equal amount of uranine was added to each solution, the values A should be equal to one another. However, the values of A in the equations of 1b—1d are not constant. This deviation can be accounted for by the following consideration.

When a large amount of trypaflavine was added to a uranine solution, a small amount of a white precipitate was produced. Assuming that the amount of the precipitate is proportional to the product of the initial concentrations of uranine $[U]_0$ and trypaflavine $[T]_0$, the final concentration of uranine is given as $[U]=[U]_0(1-p[T]_0)$, where p is a proportionality constant. In the present case, [U] is given by the following equations, since the ratio of $[T]_0$ is 0 : 1 : 2 : 3.

Sample	Equation
I	$[U]=[U]_0$
II	$[U]=[U]_0(1-p')$
III	$[U]=[U]_0(1-2p')$
IV	$[U]=[U]_0(1-3p')$

where p' is a new constant. If $[U]_0$ and p' are put equal to 500 and 0.08 respectively in arbitrary units, the [U] values in the four specimens are

calculated to be 500, 460, 420 and 380 respectively. These values agree with the corresponding A value in Eqs. 1b—1d. Therefore, it may be concluded that A is a value proportional to the initial concentration of uranine.

Parameters c and C.—The third term of the denominator in Eq. 1, $C\exp(-ct)$, is found only in Eqs. 1b, 1c and 1d, not in Eq. 1a. This would indicate that the term corresponds to the effect of the addition of trypaflavine. If we assume the values of c in Eqs. 1b, 1c and 1d (0.53, 0.51 and 0.47 min^{-1}) to be approximately equal to one another, c is very likely to be the rate constant of the decomposition of trypaflavine (0.53 min^{-1} under the same experimental conditions). Moreover, the values of C in Eqs. 1b, 1c and 1d are almost proportional to the values of β in Eqs. 2a, 2b and 2c. Hence, it may be concluded that C is a value proportional to the initial concentration of trypaflavine. The actual concentration of trypaflavine may decrease upon the addition of uranine, but it is still proportional to the initial concentration (Table I).

Parameter B.—The mutual ratio of (B-1) values (0.14 : 0.29 : 0.53) is approximately equal to the ratio of α values in Eqs. 2a, 2b and 2c. The value of (B-1), therefore, is proportional to the initial concentration of trypaflavine.

From the same argument, parameters q and Q seem to correspond, respectively, to the decomposition rate constant and the initial concentration of a substance inhibiting light production.

On the basis of this discussion, Eq. 1 can be rewritten as:

$$I_t = A'[\mathrm{U}]_0 \exp(-k_\mathrm{U}t)/[1 + Q\exp(-qt) + [\mathrm{T}]_0 \times \{1 + B' \exp(-k_\mathrm{T}t)\}] \quad (3)$$

where A' and B' new constants, $[\mathrm{U}]_0$ and $[\mathrm{T}]_0$ are the initial concentrations of uranine and of trypaflavine respectively, and K_U and K_T are the rate constants of the decomposition of uranine and trypaflavine respectively.

At the initial stage of the reaction, Eq. 3 becomes:

$$I_t = A'[\mathrm{U}]_0/\{1 + Q + (1 + B)[\mathrm{T}]_0\} \quad (4)$$

This equation is similar to the Stern-Volmer equation for the quenching of fluorescence, if Q and $[\mathrm{T}]_0$ are the concentrations of the quenching substances. According to Wilhelmann, Lumry and Eyring,[4] the fraction of excited molecules which emit light in the chemiluminescence is given by:

$$\phi = k_1/(k_1 + k_2 + \sum_i k_i q_i)$$

where k_1, k_2 and k_i are the rates of the emission process, the internal quenching and the external quenching respectively, and q_i is the concentration of the ith quencher. The equation is very similar to Eq. 4.

From the above considerations, it may be concluded that the enfeebling action of trypaflavine is probably the external quenching.

II) Enhancing Action.

Figure 3 shows the curves of the intensity versus the time measured in a reaction system composed of 1 ml. of a 20% hydrogen peroxide solution, 2 ml. of a 3 N sodium hydroxide solution and 6 ml. of a uranine, eosine or uranine-eosine mixed solution, where the notation I_UE (3-1-2), for example, refers to a system composed of 3 ml. of a uranine

solution (0.5 g./100 ml.), 1 ml. of an eosine solution (0.5 g./100 ml.) and 2 ml. of water. Similarly, I_U (3-0-3) and I_E(0-3-3), for example, refer respectively to the systems of (3 ml. of a uranine solution)+(3 ml. of water) and (3 ml. of an eosine solution)+(3 ml. of water). In every case, the I_{UE}-curve is lower than the corresponding (I_U+I_E) curve (shown by a dotted line); that is, an enfeebling action was found under these experimental conditions. Figure 4 involves similar intensity-time curves, which have been measured with the systems except that the 3 N sodium hydroxide solution is replaced by a 1.5 N solution. In this case, the I_{UE}-curve is slightly higher than the (I_U+I_E)-curve; that is, the enhancing action is exhibited under the conditions employed. This enhancing

action becomes stronger when 2 ml. of a 0.5 N sodium hydroxide solution is used instead. Hence, it may be concluded that the enhancing action arises only in a system of low alkali concentration.

It is worth noting that every I_{UE}-curve in Fig. 5 approaches the I_U-curve when the I_E-curve falls to zero. This allows the "increment of the total light emission" to be defined as:

$$\Delta = \int_0^T (I_{UE} - I_U - I_E)dt \qquad (5)$$

where I_{UE}, I_U and I_E are the intensities of the emission measured in uranine-eosine, uranine and eosine systems respectively, and T is the duration of eosine chemiluminescence. Furthermore, the results indicate that the enhancing action can be seen only when eosine chemiluminescence takes place; in other words, the processes of eosine chemiluminescence seem to be necessary for the enhancing action. In a system of such a low alkali concentration, uranine decomposes so slowly that the intensity of its chemiluminescence is practically zero, so the ratio of Δ to the total light emission of eosine chemiluminescence can be taken as the value of the "relative increment," σ:

$$\sigma = \Delta \Big/ \int_0^T I_E dt \qquad (6)$$

The values of Δ and σ were investigated under various experimental conditions. In order to obtain the pertinent values for I_{UE}, I_U and I_E, the I-t cruves were integrated graphically.

The Dependence of Δ and σ on the Concentration of the Dye.—The values of Δ and σ measured in systems with different uranine concentrations but with a constant eosine concentration are shown in Table III. The Δ and σ values in the systems with different eosine concentrations but with a constant uranine concentration are also shown in Table III. These results indicate that Δ increases with an increase in the initial concentration of either uranine ($[U]_0$) or eosine ($[E]_0$), while σ increases only when the ratio of $[U]_0/[E]_0$ increases. As will be discussed in a succeeding paper, Δ and σ are given by:

$$\Delta = M[U]_0 \log \{1 + N([E]_0/[U]_0)\}$$

$$\sigma = M'([U]_0/[E]_0) \log \{1 + N([E]_0/[U]_0)\}$$

where M, M' and N are the parameters.

The Temperature Dependence of Δ and σ.—Table IV illustrates the values of Δ and σ as measured in systems of (3-3-0), (3-0-3) and (0-3-3) at several different temperatures. It is there shown that Δ increases with an increase in the temperature, while σ is almost completely insensitive to the temperature.

The Dependence of Δ and σ on the Concentration of Added Organic Solvent.—It has been found that the total amount of emission is enhanced when organic solvents, such as alcohol, acetone, dioxane and glycerol, are added to the luminescent system. Therefore, Δ and σ have been determined in several water-organic solvent systems (Table V). We see that Δ increases as the concentration of the organic solvent increases, while σ remains constant. The results will be discussed in a succeeding paper.

The Absorption Spectrum of the Uranine-Eosine System.—The enhancing action arises from an interaction between uranine and eosine. To decide what kind of the interraction this is, the absorption spectrum of the uranine-eosine system was measured. The results are shown in Fig. 6, where T_U and T_E are the absorption curves of the solutions of uranine (0.5 g./100 ml.) and eosine (0.5 g./100 ml.), and T_{UE} is that of a uranine-eosine mixed solution (0.5 g. uranine and 0.5 g. eosine per 100 ml.). It can be seen that the I_{UE}-curve is very close to the $\sqrt{T_U \times T_E}$-curve (shown by a dotted line). This fact indicates that no stable substance is produced when the two dyes are mixed.

The Rates of the Decomposition of Uranine and Eosine in the Uranine-Eosine System.—

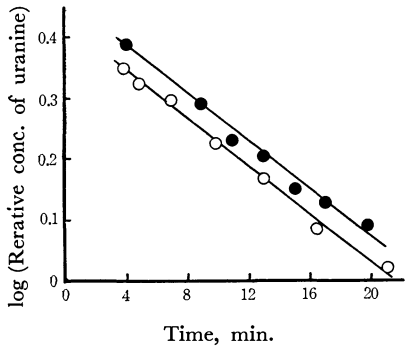

Fig. 7. Rates of uranine decomposition in uranine eosine system and in isolated uranine system. (0.5 N NaOHaq., 20% H_2O_2aq., 41°C)
-●- Isolated uranine system
-○- Uranine-eosine system

The rate of the decomposition of uranine in the system of uranine-eosine can easily be determined by spectrophotometry at 490 mμ, bceause practically no eosine absorbed that light. The measurements were carried out in a system composed of 12 ml. of a (6-6-0) sample solution, 4 ml. of a 0.5 N sodium hydroxide solution and 2 ml. of a 20% hydrogen peroxide solution. The results are shown in Fig. 7. It shows that the decomposition of uranine in the uranine-eosine system is first order with respect to the uranine concentration. The rate constant is 0.048 min^{-1}, which is almost identical with the decay constant of uranine chemiluminescence in an isolated uranine system under the same experimental conditions. Hence, it may be concluded that the rate of uranine decomposition is not affected by the addition of eosine.

As has been shown before, the I_{UE}-curve approaches the I_U-curve when the I_E-curve falls to zero. This fact would mean that the duration of eosine chemiluminescence in mixed system is the same as that in an isolated system, because the enhancing action is found only when the chemiluminescent reaction of eosine takes place. Hence, it seems that the rate decomposition of eosine is little affected by the addition of uranine.

It follows from the above considerations that the enhancing action is due neither to the production of a stable substance which emits strongly nor to the increase in the rate of the decomposition of uranine or eosine.

One possible mechanism for the enhancing action would be that eosine is oxidized to an energy-rich intermediate at the first stage of the reaction; then the energy is transferred from the intermediate to an oxidized dye, thereby exciting both eosine and uranine to emit fluorescence. The same mechanism for the light production was proposed by Kautsky,[5] who studied the luminescent reaction of siloxen ($Si_6O_3H_6$) in the presence of rhodamine. He found that the spectral distribution of the luminescence was similar to that of the fluorescence of rhodamine, although the dye was not oxidized; he concluded that energy was transferred from siloxene to the dye by some sort of collision. Similar results have been reported by Schales,[6] Tamamushi[7] and Vassil'ev[8].

Spruit van der Burg[9] has reported that the emission of lucigenin chemiluminescence is blue in a hot, dilute solution and that it may arise from the energy-rich product, methyl acridone, while the emission is green in a cold, concentrated solution. This fact is suggestive of the same energy-transfer mechanism as that of the emission in the uranine-eosine system.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 277—281 (1966)

Studies of the Chemiluminescence of Several Xanthene Dyes. IV. Theoretical Considerations

By Isao KAMIYA

Department of General Education, Nagoya University Chikusa-ku, Nagoya

and Ryojirô IWAKI

Aichi Gakugei University, Chemical Laboratories, Okazaki, Aichi

(Received May 12, 1965)

On the basis of the results shown in the previous papers, the following reaction scheme was proposed for the chemiluminescent reaction. Hydrogen peroxide decomposes spontaneously to the radical (R·). A portion of the radical then reacts with the dye molecule (E) to produce an energy-rich intermediate (M_E*): $E+R\cdot \rightarrow M_E^*$ The energy-transfer takes place from M_E* to an unoxidized dye, so the dye is excited electronically: $M_E^*+E \rightarrow E^*+\cdots$ However, most of the M_E* is decomposed by non-radiative processes. E* is deactivated by fluorescence emission processes ($E^* \rightarrow E+h\nu$) or quenching processes ($E^*+E \rightarrow E+E$). According to this reaction scheme, most of the experimental results can be explained reasonably. It is expected that further experimental evidence, such as the detection of an intermediate, will verify the theory.

The present authors have investigated the chemiluminescence of several xanthene dyes and obtained the following results:[1]

1) The intensity of the emission versus the time at the decay stage was represented by:

$$I_t = A \exp(-a t) \quad (1)$$

where I_t is the intensity of the emission at time t, a (the decay constant) is equal to the rate constant of the decomposition of the dye, and A is a parameter which is proportional to the initial concentration of the dye. This indicates that the decay of the luminescence is first order with respect to the concentration of the dye. The curve was much affected by the concentration of the added sodium hydroxide solution, while it was not affected by the concentration of added hydrogen peroxide when its concentration was high.

2) The energy distribution of the chemiluminescence emission was very similar to that of the fluorescence emission. This indicates that the emitting species are probably excited singlet states of the dye molecule.

3) The luminescent light was enfeebled by the addition of some kind of foreign dye. The enfeebling action seemed to be due to external quenching; it was found in all of the uranine-trypaflavine, uranine-erythrosine and eosine-erythrosine systems.

On the contrary, the intensity of the emission was enhanced when uranine was added to the eosine chemiluminescent system. However, the enhancing action was found only when the concentration of alkali was too low to cause the decomposition of uranine. The enhancing action was due neither to the production of a stable compound which emitted light strongly nor to the increase in the rate of decomposition of the dyes. A possible mechanism may be proposed, in which eosine is oxidized to an energy-rich intermediate and the energy is transferred from the intermediate to unoxidized eosine and uranine, thereby exciting both dyes to emit fluorescence.

Concideration

Reaction Scheme.—On the basis of the results summarized above, the following mechanism seems plausible for the luminescent reaction.

In an alkaline solution, hydrogen peroxide decomposes spontaneously to radicals, R·, such as OH· and O_2H·. Some of the radicals react with the dye to produce an energy-rich intermediate. In a uranine-eosine system with a low alkali concentration, the radical reacts only with eosine, E, to produce an energy-rich intermediate, M^*_E:

$$E + R\cdot \rightarrow M^*_E \quad [I] \text{ reaction rate: } k_1$$

Recently, Hayashi and Maeda[2] have shown that the intermediate in lophin chemiluminescence is a radical. Steele[3] has reported, in his studies of the photo-induced chemiluminescence of riboflavin in water containing hydrogen peroxide, that the emission is mediated by an excited metastable triplet state of riboflavin. White and

1) I. Kamiya and R. Iwaki, This Bulletin, **39**, 257, 264, 269 (1966).

2) T. Hayashi and K. Maeda, ibid., **35**, 2057 (1962).

3) R. H. Steele, *Biochem.*, **2**, 529 (1963).

Bursey[4] proposed that an excited triplet state of the aminophthalic acid ion was an intermediate in luminol chemiluminescence. However, no information as to M^*_E has yet been obtained.

An energy-transfer takes place from M^*_E to unoxidized eosine and uranine, so the dyes are excited electronically.

$$M^*_E + E \rightarrow E^* + \cdots \qquad [II]: k_2$$
$$M^*_E + U \rightarrow U^* + \cdots \qquad [III]: k_3$$

Since the efficiency of the emission of the luminescent reaction is low, most of M^*_E would be decomposed or deactivated by non-radiative processes. E* and U* are deactivated either by fluorescence emission processes or by quenching processes:

$$M^*_E \rightarrow \cdots \qquad [IV]: k_4$$

E* and U* are deactivated either by fluorescence emission processes or by quenching processes:

$$E^* \rightarrow E + h\nu \qquad [V]: k_5$$
$$U^* \rightarrow U + h\nu \qquad [VI]: k_6$$
$$E^* + E \rightarrow E + E \qquad [VII]: k_7$$
$$E^* + U \rightarrow E + U \qquad [VIII]: k_8$$
$$U^* + E \rightarrow U + E \qquad [IX]: k_9$$
$$U^* + U \rightarrow U + U \qquad [X]: k_{10}$$

Although further quenching may take place at the initial stage, as has been shown in a previous paper, our discussion will be limited to the decay stage, where the intensity versus time is represented by Eq. 1.

The Curve of the Intensity versus the Time ((I-t Curve) in a Uranine-Eosine System with Low Alkali Concentration.—According to the mechanism proposed above, the intensity of chemiluminescence in a uranine-eosine system, I_{UE}, is given by:

$$I_{UE} = \phi_E[E^*] + \phi_U[U^*] = k_2[M^*_E][E]\phi_E + k_3[M^*_E][U]\phi_U \qquad (2)$$

where ϕ_E and ϕ_U are the fluorescence efficiencies of eosine and uranine respectively and are given by:

$$\phi_E = k_5/\{k_5+k_7[E]+k_8[U]\}$$
$$\text{and} \quad \phi_U = k_6/\{k_6+k_9[E]+k_{10}[U]\}$$

In luminescent reaction systems, the apparent fluorescence is so weak that

$$\left.\begin{aligned} k_5 &\ll k_7[E] + k_8[U] \\ \text{and} \\ k_6 &\ll k_9[E] + k_{10}[U] \end{aligned}\right\} \qquad (3)$$

are obeyed approximately.

From Eq. 3 and the assumption that $k_7=k_9$ and $k_8=k_{10}$, I_{UE} is reduced to:

$$I_{UE} = [\{k_2k_5[E]+k_3k_6[U]\}/\{k_7[E]+k_8[U]\}][M^*_E] \qquad (4)$$

$d[M^*_E]/dt$ is then given by:

$$d[M^*_E]/dt = k_1[R\cdot][E]-k_2[M^*_E][E]-k_3[M^*_E][U]-k_4[M^*_E] \qquad (5)$$
$$= k_1[R\cdot][E]-k_4[M^*_E]$$

because $k_4 \gg k_2 + k_3$.

It has been found that the decay curve is not affected by the concentration of hydrogen peroxide when its concentration is high and that the intensity of emission is increased by the addition of a dye solution at the final stage of the reaction. These facts indicate that the concentration of R· does not vary during the luminescent reaction, provided the concentration of the added hydrogen peroxide is high (in excess). Furthermore, the experimental results show that the concentrations of eosine and uranine are given by:

$$[E]=[E]_0\exp(-K_Et), \quad [U]=[U]_0$$

where $[E]_0$ and $[U]_0$ are the initial concentrations of eosine and uranine respectively, and where K_E is the rate constant of the decomposition of eosine. (The decomposition of uranine can be disregarded.) Therefore, Eq. 5 can be rewritten approximately as:

$$d[M^*_E]/dt = k_1[R\cdot][E]_0\exp(-K_Et) - k_4[M^*_E] \qquad (6)$$

Since [R·] is independent of the time, Eq. 6 can easily be resolved to:

$$[M^*_E] = \{k_1[R\cdot][E]_0/(k_4-K_E)\} \times \{\exp(-K_Et)-\exp(-k_4t)\}$$

It seems likely that $k_4 \gg K_E$, so:

$$[M^*_E] = \{k_1[R\cdot][E]_0/k_4\}\exp(-K_Et) \qquad (7)^{**}$$

From Eqs. 4 and 7, I_{UE} is finally given by:

$$I_{UE} = k_1[R\cdot](k_2k_5[E]^2+k_3k_6[E][U]_0)/k_4(k_7[E]+k_8[U]_0) \qquad (8)$$

The I-t Curve for Eosine and Uranine Systems.—By taking into account reactions I, II, IV and VII, the intensity of the emission of eosine chemiluminescence, I_E, at time t can similarly be derived as:

$$I_E = k_1k_2k_5[R\cdot][E]/k_4k_7 = (k_1k_2k_5[R\cdot][E]_0/k_4k_7)\exp(-K_Et) \qquad (9)$$

Similarly, the intensity of the emission of uranine chemiluminescence, I_U, in a solution with a high alkali concentration is given by:

$$I_U = k_1'k_2'k_5'[R\cdot][U]/k_4'k_7' = (k_1'k_2'k_5'[R\cdot][U]_0/k_4'k_7')\exp(-K_Ut) \qquad (10)$$

4) E. H. White and M. M. Bursey, *J. Am. Chem. Soc.*, **86**, 941 (1964).

** Equation 7 can also be obtained by the "Steady-State Method," $d[M^*_E]dt=0$.

The experimental results in a previous paper have shown that I_E and I_U can be represented by Eq. 1. This seems to give support to the present equations of 9 and 10. However, when the concentration of hydrogen peroxide is low, Eqs. 9 and 10 are no more obeyed, because [R·] is no longer constant during the reaction. Moreover, k_5 is not ignorable compared to k_7[E] in the final stage, because the concentration of the dye becomes low.

The Value of Δ in a Uranine-Eosine System with a Low Alkali Concentration.—The value of Δ (the increment of the total emission) observed in a uranine-eosine chemiluminescent system with a low alkali concentration was defined as:

$$\Delta=\int_0^T (I_{UE}-I_U-I_E)\mathrm{d}t \tag{11}$$

where T is the duration of the chemiluminescence of eosine. Using Eqs. 8 and 9, and recalling that $I_U=0$, Eq. 11 becomes:

$$\Delta=(k_1[\mathrm{R}\cdot]/k_4)\int_0^T \{(k_2k_5[\mathrm{E}]^2+k_3k_6[\mathrm{E}][\mathrm{U}]_0)/(k_7[E]+k_8[\mathrm{U}]_0)-(k_2k_5/k_7)[\mathrm{E}]\}\mathrm{d}t$$

or

$$\Delta=(k_1[\mathrm{R}\cdot][\mathrm{U}]_0/k_4)(k_3k_6-k_2k_5k_8/k_7)\times\int_0^T \{[\mathrm{E}]/(k_7[\mathrm{E}]+k_8[\mathrm{U}]_0)\}\mathrm{d}t \tag{12}$$

On substituting the relation $[\mathrm{E}]=[\mathrm{E}]_0\exp(-K_Et)$ and $[\mathrm{E}]_0\exp(-K_ET)=0$, Eq. 12 is integrated to:

$$\left.\begin{aligned}\Delta&=(k_1[\mathrm{R}\cdot]/k_4K_Ek_7)(k_3k_6-k_2k_5k_8/k_7)[\mathrm{U}]_0\times\ln(1+k_7[\mathrm{E}]_0/k_8[\mathrm{U}]_0)\\ \text{or}\\ \Delta&=2.30P[\mathrm{U}]_0\log(1+Q[\mathrm{E}]_0/[\mathrm{U}]_0)\end{aligned}\right\} \tag{13}$$

where

$$P=(k_1[\mathrm{R}\cdot]/k_4K_Ek_7)(k_3k_6-k_2k_5k_8/k_7)$$
$$Q=k_7/k_8$$

$u'=37u/16$, $e'=37e/16$;
* Δcalcd.$=6.5m\log(1+6.5n/m)$

In a system composed of 3 ml. of an eosine solution (1 g./100 ml.), 3 ml. of a uranine solution (1 g./100 ml.), 2 ml. of a 0.3 N sodium hydroxide solution and 1 ml. of a 20% hydrogen peroxide solution, $[\mathrm{U}]_0$ and $[\mathrm{E}]_0$ are put, for illustrative convenience, as $32u$ and $32e$ respectively, so u and e are equal to 1.4×10^{-4} and 7.5×10^{-5} mol./l. respectively. The concentration of uranine or eosine is successively reduced by half ($16u$, $8u$, etc.) and the values of Δ are calculated with Eq. 13, where $2.3\times(Pu)$ is taken to be 1.6 and (Qe/u), 6.5:

$\Delta=1.6\,m\log(1+6.5n/m)$ (m and n are integers). They are shown in Table I, together with the observed values. Table II tabulates the Δ-values observed when the concentration of the added sodium hydroxide solution is slightly higher (0.5 N), so that I_U can no longer be ignored. It also includes values calculated by the following equation:

$$\Delta=6.5m\log(1+6.5n/m) \tag{14}$$

In both cases, the calculated values are in fairly good agreement with the observed values. It is worth noting that, whether I_U is smaller or not, the values of Δ can be expressed by the same equation. This means that the uranine chemiluminescence is not enhanced by the presence of eosine.

The Values of σ.—The relative increment, σ, was defined as:

$$\sigma = \Delta\Big/\int_0^T I_E\mathrm{d}t \tag{15}$$

From Eqs. 9 and 15, we obtain:

$$\int_0^T I_E\mathrm{d}t = k_1[\mathrm{R}\cdot]k_2k_5[\mathrm{E}]_0/k_4K_Ek_7 \tag{16}$$

since $[\mathrm{E}]_0\exp(-K_ET)=0$.

On substituting Eqs. 13 and 16 into Eq. 15, we obtain:

$$\sigma=\{(k_3k_6/k_2k_5)-k_8/k_7\}([\mathrm{U}]_0/[\mathrm{E}]_0)\times\ln(1+k_7[\mathrm{E}]_0/k_8[\mathrm{U}]_0) \tag{17}$$

Equation 17 indicates that σ is constant when the ratio of $[\mathrm{U}]_0$ to $[\mathrm{E}]_0$ remains constant (at a constant temperature). The experimental values

of σ obtained at several different concentrations of uranine and eosine but at a constant ratio of $[U]_0/[E]_0$ are shown in Table III. As is to be expected, the values of σ are almost constant except in the systems with low dye concentrations. The value of σ probably decreases in a system with a low dye concentration because the energy-transfer from M^*_E to U can no longer take place.

TABLE III. OBSERVED VALUES OF σ IN URANINE-EOSINE SYSTEMS WITH THE CONSTANT RATIO OF $[U]_0$ TO $[E]_0$
(0.5N NaOHaq., 20% H_2O_2aq., 40°C)

$[U]_0$	$32u$	$16u$	$10.7u$	$8u$	$5.3u$	$4u$	$2.7u$
$[E]_0$	$32e$	$16e$	$10.7e$	$8e$	$5.3e$	$4e$	$2.7e$
σ	1.24	1.22	1.20	1.23	0.59	0.43	0.22

The Effect of the Temperature on the Luminescent Reaction.—It is reasonable to assume that there are two processes with a heat of activation in the reaction; one is the process of reaction I, reaction between R· and the dye, the other is that of II (III); an energy-transfer from an energy-rich intermediate to an unoxidized dye. Thus, the rate constants of k_1 and k_2 (and k_3) are much more affected by the temperature than any other rate constants in the reaction scheme. On this arguments, we can derive the conclusion that the values of A and a in Eq. 1 and the value of Δ increase with an increase in the temperature, while σ is not affected by the temperature from the consideration that A is second order; a and Δ are first order, and σ is zero-th order with respect to the rate constants of k_1 and k_2 (k_3) since K_E seems to be k_1.

The activation energy of reaction I can be estimated from the plot of log a (log K_E) against the reciprocal of the absolute temperature. Figure 1 is the plot obtained from the system composed of 6 ml. of a uranine solution, 2 ml. of a sodium hydroxide solution, and 1 ml. of 20% hydrogen peroxide. Figure 2 is a similar plot in eosine chemiluminescence (6 ml. of an eosine solution, 2 ml. of a 0.5 N sodium hydroxide solution, and 1 ml. of 30% hydrogen peroxide). The activation energies of uranine and eosine chemiluminescent reactions are found to be 13 and 11 kcal./mol. respectively. We can see that the activation energy for the reaction in an aqueous system is equal to that in a water-organic solvent system, although the light intensity in the former is lower than that in the later. Moreover, the energy is practically the same, irrespective of the concentration of the added sodium hydroxide solution.

The Effect of the Added Organic Solvent on the Intensity of Emission.—In Table IV, the products of Δ and K_E in methanol-water and ethanol-water systems of different alcohol concentrations are shown. It may be seen that the product is almost constant in each system.

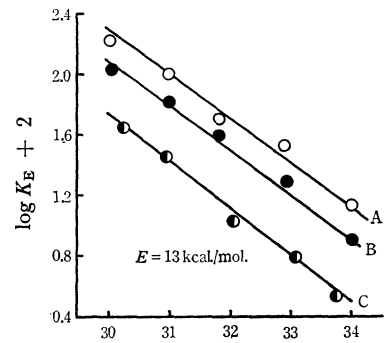

Fig. 1. Log K_E - 1/T plots in uranine chemiluminescence.
A: 3N NaOHaq., 20% H_2O_2, 1/4 conc. to original solution ($[U]_0=8u$): aq. solution
B: 2N NaOHaq., 20% H_2O_2, original solution ($[U]_0=32u$): aq. solution
C: 2.5N NaOHaq., 20% H_2O_2, original solution ($[U]_0=32u$): 25% water-methanol solution

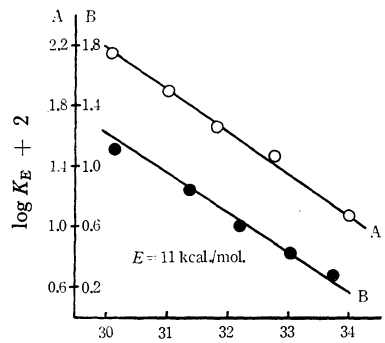

Fig. 2. Log K_E - 1/T plots in eosine chemiluminescence.
A: 0.5N NaOHaq., 30% H_2O_2, 1/4 conc. to original solution ($[E]_0=8e$): aq. solution
B: 0.5N NaOHaq., 30% H_2O_2, 1/2 conc. to original solution ($[E]_0=16e$): 30% water-isopropanol solution

TABLE IV. RELATIONSHIP BETWEEN Δ-VALUE AND K_E (EOSINE)

(1) Ethanol-water systems (at 25°C)

Ethanol concentration (% in volume)	10	20	30	40	60
K_E (min^{-1})	0.32	0.11	0.083	0.062	0.046
Δ (relative unit)	8.9	26.9	34.2	46.8	51.7
$K_E\Delta$ (×10)	28.5	29.6	28.4	29.1	23.8

(2) Methanol-water systems (at 45°C)

Methanol concentration (% in volume)	10	20	40	60
K_E (min^{-1})	0.30	0.20	0.16	0.09
Δ (relative unit)	16.0	24.6	28.0	40.4
$K_E\Delta$	4.8	4.9	4.5	3.6

From Eqs. 13 and 17, $K_E \times \Delta/\sigma$ is given by the following equation:

$$K_E \times \Delta/\sigma = k_1 k_2 k_5 [R\cdot][E]_0/k_4 k_7 = A[E]_0 \quad (18)$$

σ, as has been shown in a previous paper, does not change in the systems; hence, A ($E_E \times \Delta/\sigma$) should remain constant. This invariability of A is consistent with the experimental finding that the value of A remains constant upon the addition of organic solvent.

Conclusion

By the reaction scheme proposed in the present paper, most of the experimental results reported in preceding papers can be explained reasonably. This would indicate that the present theory is plausible. It is expected that further experimental evidence, such as the detection of an intermediate or end product, will verify the theory.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 281—285 (1966)

The Reaction of Aminotropones with Diketene. II. The Structure of the By-product in the Reaction of 5-Aminotropolone with Diketene

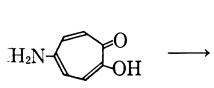
By Shuichi SETO, Hiroko SASAKI and Kyozo OGURA

The Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-cho, Sendai

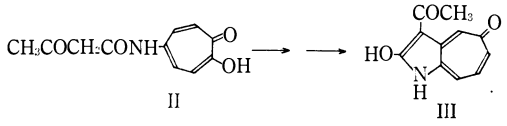
(Received May 19, 1965)

The reaction of 5-aminotropolone with diketene gave a minor product and 5-aceto acetamidotropolone, which had previously been described (K. Ogura et al., This Bulletin, **38**, 306 (1965)). This unknown compound was obtained as a main product when 5-acetoacetamidotropolone was treated with diketene in the presence of triethylamine. From its oxidative degradation and its NMR spectrum, this compound was proved to be 3-acetyl-4-hydroxy-6-methyl-1-(tropolon-5'-yl)pyridone-2. Furthermore, for the sake of the structural determination, 3-acetyl-4-hydroxy-6-methylpyridone-2 and its deacetylated product were prepared.

In the previous paper of this series, it was reported that the reaction products of aminotropones with diketene were useful for the synthesis of 3-acetyl derivatives of 1-azaazulan-2-one and their related compounds. For example, the reaction of 5-aminotropolone (I) with diketene gave 5-acetoacetamidotropolone (II), which could then be converted into 3-acetyl-2-hydroxycyclohepta-[b]pyrrol(1*H*)-5-one (III).[1]



I



II III

The present authors have since examined the reaction of I with diketene in more detail, and found that another product, IV, was a by-product in this reaction. This paper will concern the structure of the compound IV.

The mixture of the reaction products obtained by the treatment of I with a large excess of diketene was separated by recrystallization into II and IV, the yields of which were 65 and 10% respectively. The compound IV was considered to be a *N*, *N*-disubstituted derivative of I from the fact that its ultraviolet absorption spectrum is of the *N*-acyl-aminotropolone type and from its infrared absorption spectrum. It shows a broad band at 3200 cm^{-1} due to the hydroxyl group and two bands at 1660 and 1625 cm^{-1} for the carbonyl groups in the chloroform solution. The NMR spectrum of IV in deuterochloroform exhibits signals for a methyl group attached to the double bond (2.04), an acetyl group (2.61), aromatic protons of the tropolone ring (near 7.2), and two signals for hydroxyl groups at 9.00 and 16.10 p.p.m. (with tetramethylsilane as a standard). The signal at the lower field (16.10) can be attributed to the enolic hydroxyl group, which is strongly chelated with the carbonyl group, while the higher one (9.00 p.p.m.) corresponds to the hydroxyl group of tropolone.

The treatment of IV with diazomethane gave a monomethyl ether (V). In the NMR spectrum of V, a new signal, at 3.97 p.p.m., for the methoxyl

1) K. Ogura, H. Sasaki and S. Seto, This Bulletin, **38**, 306 (1965).

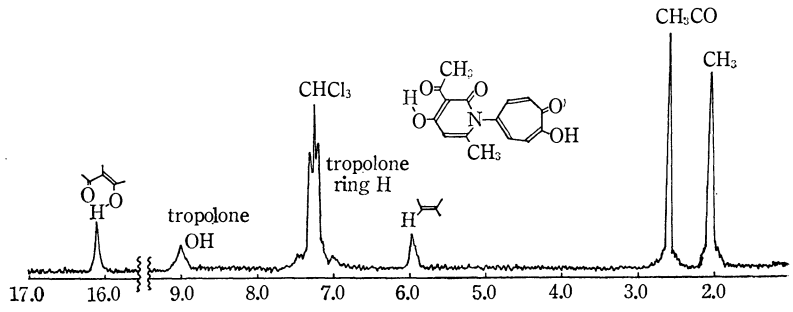


Fig. 1. NMR spectrum of IV in $CDCl_3$.

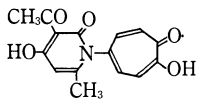
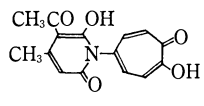
group appears instead of the hydroxyl group of tropolone in IV, while the signal for the enolic hydroxyl group is still observed at 15.90 p. p. m., indicating that V is the 2-methoxytropone derivative.

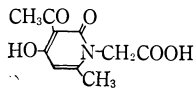
These facts and the elemental analysis of IV corresponding to $C_{15}H_{13}O_5N$ suggest that IV has a pyridone moiety formed by the addition of II to another molar equivalent of diketene, followed by dehydration. Two kinds of pyridone derivatives, the 4-hydroxy type (IVa) and the 6-hydroxy type (IVb), can be expected, according to the manner of addition. Garatt and Shemin reported that the reaction of glycine with diketene in the alkaline solution gave no *N*-acetoacetylglycine, but it did give 3-acetyl-1-carboxymethyl-4-hydroxy-6-methyl-pyridone-2 (VI).[2] Kato also obtained the corresponding pyridone derivative from 4-amino-pyridine.[3]



IVa



IVb



VI

Our spectral data for compound IV mentioned above correspond well with those for VI obtained by Garatt; IV seems to be 3-acetyl-4-hydroxy-6-methyl-1-(tropolon-5'-yl)pyridone-2 (IVa) by analogy. These data alone, however, can not exclude another structure (IVb), so the following experiments were carried out in order to determine the structure precisely.

The oxidation of IV with potassium permanganate gave colorless needles (VII). The fact that VII has an absorption maximum at 326 mμ indicates that VII is no longer a tropolone derivative, but a pyridone derivative which is probably a key compound for the structural determination of IV. The same compound VII could be obtained by the reaction of acetoacetamide with diketene in the presence of triethylamine. The infrared spectrum exhibits complicated bands in the region

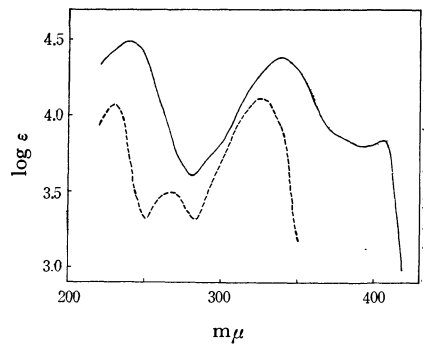


Fig. 2. Ultraviolet spectra of IV (——) and VII (----) in methanol.

3200—2500 cm^{-1} and ν_{CO} bands at 1670 and 1625 cm^{-1}. The NMR spectrum of VII in deuterodimethylsulfoxide indicates the existence of an enolic hydroxyl group (15.65) which chelates strongly with the acetyl group (2.50 p.p.m.).

The ultraviolet spectrum and the chemical behavior of both 4-hydroxy- and 6-hydroxypyridone-2 are known through the literature,[4,5] but no data on their acyl derivatives have yet been reported. It is also known that the treatment of dehydroacetic acid (VIII) with ammonia gives 4-lutidone (IX) and that 4-hydroxy-6-methyl-pyrone-2 (X) obtained from VIII, on treatment with ammonia, is converted into the corresponding pyridone derivative XI.[6,7] The present authors examined these reactions and obtained compound XI, whose structure was confirmed by

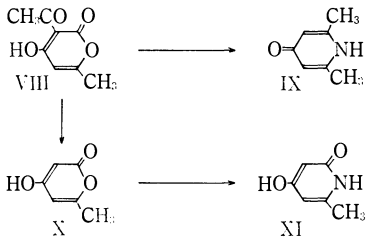
7) M. A. Butt and J. A. Elvidge, *J. Chem. Soc.*, **1963**, 4483.



a study of its ultraviolet, infrared and NMR spectra. Thus, the removal of the acetyl group from the compound VII was desirable for the elucidation of the structure.

The deacetylation of VII was successful in affording colorless crystals, crystals which a comparison of the ultraviolet and infrared absorption spectra showed to be quite identical with IX. The compound XI shows an absorption maximum at 283 mμ in methanol and at 265 mμ in the acidic solution.

The NMR spectrum of XI in deuterodimethylsulfoxide exhibits a doublet (J, 2.5 c.p.s.) at 5.34 p.p.m. for the proton in the 3-position and a multiplet at 5.58 p.p.m. for the proton in the 5-position.

This identification undoubtedly indicates that the by-product IV is 3-acetyl-4-hydroxy-6-methyl-1-(tropolon-5'-yl)pyridone-2 (IVa). Furthermore,

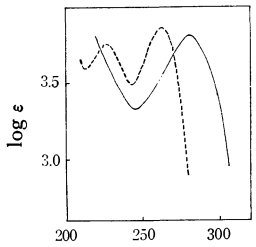


Fig. 3. Ultraviolet absorption spectra of XI in methanol (——), and in 0.1 N HCl - methanol (----).

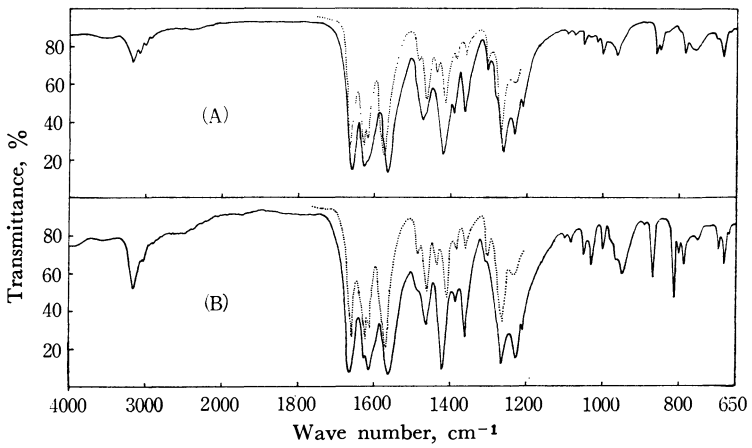

Fig. 4. Infrared absorption spectra of IV (crystals A and B) in KBr disk (——) and in chloroform solution (----).

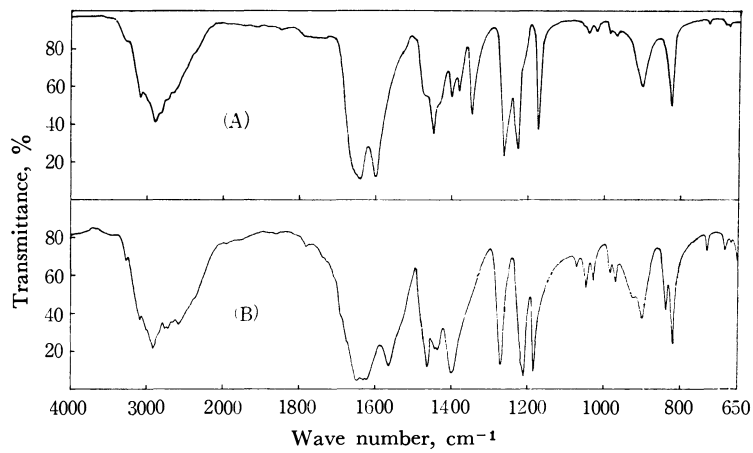

Fig. 5. Infrared absorption spectra of XI (crystals A and B) in KBr disk.

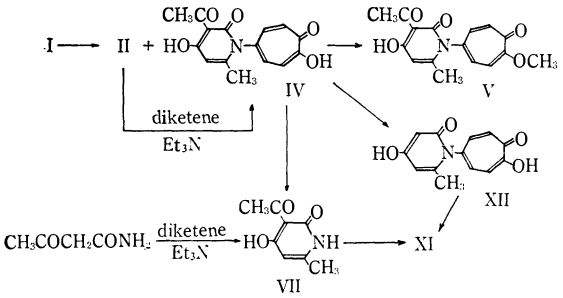
it was found that the treatment of IV with sulfuric acid gave the deacetylated compound XII, from which XI was also obtained, though in such a low yield that identification was possible only by a means of comparison of the ultraviolet absorption spectrum in both methanolic and acidic solutions.

The treatment of II with an equivalent amount of diketene in benzene resulted only in the recovery of II. However, IV could be obtained in a good yield when a small amount of triethylamine was added to the above reaction mixture. The reaction of I with diketene in the presence of triethylamine gave IV directly and exclusively. These facts suggest that, in the reaction of I and diketene in the absence of triethylamine, 5-aminotropolone (I) itself acts as a catalyzer to give a small amount of IV.



The compound IV has two crystalline forms (A and B), which are convertible into one other. These two forms exhibit slightly different infrared absorption spectra in the solid state, as is shown in Fig. 4, but their spectra in the solution, as well as their ultraviolet and NMR spectra, are quite identical. Analogous phenomena are observed also in the case of the compound XI. The infrared spectra of the two forms (A and B) of XI are shown in Fig. 5.

Experimental*

3-Acetyl-4-hydroxy-6-methyl-1-(tropolon-5'-yl)-pyridone-2 (IV).—a) A solution of I (4 g.) in diketene (20 ml.) was heated at 80°C for 1 hr. The yellow crystalline mixture that separated out on cooling was then collected. The recrystallization of this mixture from methanol-chloroform gave a major product, II (4.2 g.), which had been already reported in our previous paper,[1] and pale yellow crystals (IV). Yield, 850 mg. The repeated recrystallization of IV from methanol-chloroform gave two forms of crystals, A (globules) and B (prisms). Both A and B decomposed at 250 °C, and no depression of the mixed melting point was observed. The crystals A, when recrystallized from their methanol-chloroform solution by adding tiny crystals of B as seed, were converted into crystals B. The crystals B, however, were easily changed again to A by the acidification of the alkaline solution of B.

b) A suspension of I (500 mg.) in dry benzene (10 ml.), with a catalytic amount of triethylamine added, was stirred at 80°C, while a solution of diketene (680 mg.) in dry benzene (5 ml.) was being dropped into the suspension over a 30 min. The mixture was then kept at the same temperature while being stirred for 1 hr. During this reaction the crystals of I gradually dissolved, and orange crystals newly appeared. The crystals were collected and recrystallized from methanol-chloroform to give IV. Yield, 300 mg.

c) A suspension of II (550 mg.) in dry benzene (10 ml.), with one drop of triethylamine added, was heated at 80°C and stirred, while a solution of diketene (450 mg.) in dry benzene (5 ml.) was being added, drop by drop, to the suspension over a 1 hr. Then the mixture was stirred at 80°C for 2 hr. The crystals that separated out on cooling were collected and recrystallized from methanol-chloroform to give IV. Yield, 500 mg. λ_{max}^{MeOH} mμ (log ε): 240(4.49), 340(4.39), 405(3.85).

Found: C, 62.55; H, 4.78; N, 4.11. Calcd. for $C_{15}H_{13}O_5N$: C, 62.71; H, 4.65; N, 4.56%.

3-Acetyl-4-hydroxy-6-methylpyridone-2 (VII).—a) To a mixture of IV (100 mg.) and a potassium hydroxide solution (potassium hydroxide, 70 mg.; water, 1 ml.), a potassium permanganate solution (potassium permanganate, 580 mg.; water, 15 ml.) was added slowly. After the addition of potassium permanganate solution had been completed, the manganese dioxide was removed by filtration. This filtrate was acidified with hydrochloric acid, adjusted to pH 3. After the water had been completely removed under reduced pressure, the residue was extracted with acetone. The evaporation of the acetone afforded colorless crystals, which were then collected and recrystallized from acetone to give colorless needles, m. p. 256°C (decomp.).

b) A suspension of acetoacetamide (1 g.) in dry benzene (20 ml.), with a catalytic amount of triethylamine added, was heated at 80°C while being stirred. After a solution of diketene (1.3 g.) in dry benzene (10 ml.) had been slowly added, the mixture was stirred at 80—85°C for an additional 1.5 hr. The precipitate that separated out on cooling was collected and recrystallized from acetone-methanol to give colorless needles (m. p. 256°C (decomp.)). Yield, 500 mg. λ_{max}^{MeOH} mμ (log ε): 260(4.07), 263(3.49), 326(4.11).

Found: C, 57.68; H, 5.30; N, 8.38. Calcd. for $C_8H_9O_3N$: C, 57.48; H, 5.43; N, 8.38%.

The Methylation of IV.—After ethereal diazomethane had been added to a suspension of IV (100 mg.) in methanol (10 ml.) until portions of the solution were no longer colored with ferric chloride, the mixture was allowed to stand at room temperature for 2 hr. The pale yellow crystals that separated out were collected and recrystallized from methanol to give V (225°C (decomp.)). Yield, 45 mg. λ_{max}^{MeOH} mμ (log ε): 230(4.52), 330(4.30).

Found: C, 63.51; H, 4.31; N, 4.91. Calcd. for $C_{16}H_{15}O_8N$: C, 63.78; H, 5.02; N, 4.65%.

The Deacetylation of IV.—A mixture of IV (500

* All melting points are uncorrected. The microanalyses were carried out by Misses Yoko Endo and Noriko Matsukawa of this Institute, to whom the authors are indebted. The measurements of the ultraviolet and infrared absorption spectra were made with a Cary recording spectrophotometer model 14 and with a Hitachi EPI-S2 spectrophotometer respectively. The NMR spectra were measured in a deuterochloroform or deuterodimethylsulfoxide solution, using tetramethylsilane as an internal standard, on a Varian A-60 spectrometer.

mg.) and sulfuric acid (2 ml.) was heated at 200°C for 30 min.; then the mixture was poured into ice water. The colorless precipitate thereby obtained was recrystallized from methanol to give colorless crystals, m. p. 284—285°C (decomp.). Yield, 270 mg. λ_{max}^{MeOH} $m\mu$ (log ε): 206(4.55), 240(4.49), 290(3.81), 340(4.09).

Found: C, 63.75; H, 4.49; N, 4.93. Calcd. for $C_{13}H_{11}O_4N$: C, 63.67; H, 4.52; N, 5.71%.

4-Hydroxy-6-methylpyridone-2 (XI).—a) After a mixture of VIII (2.0 g.) and 93% sulfuric acid (6 g.) had been allowed to stand at room temperature for 1 hr., the mixture was heated at 130°C for 7 min. When cracked ice was added into the reaction mixture, a pale yellow precipitate was immediately deposited. The recrystallization of this precipitate gave pale yellow crystals of X (1.9 g.), m. p. 183—184°C. A solution of X (350 mg.) in a 28% ammonium hydroxide solution (4 ml.) was heated on a water bath. The removal of an excess of ammonium hydroxide gave colorless crystals, which were then recrystallized from water to afford colorless needles, m. p. 320°C (decomp.). Yield, 50 mg.

b) A mixture of VII (200 mg.) and concentrated sulfuric acid (0.4 ml.) was heated at 180°C for 7 min. After it had been cooled, the mixture was poured into ice water and neutralized with a barium hydroxide solution. The barium sulfate that separated out was removed by filtration. When the filtrate was concentrated under reduced pressure, colorless needles of XI were obtained.

c) To a solution of XII (120 mg.) in a potassium hydroxide solution (potassium hydroxide, 90 mg.; water, 2 ml.), a potassium permanganate solution (potassium permanganate, 790 mg.; water, 20 ml.) was added slowly. After this addition had been completed, the manganese dioxide that precipitated out was removed by filtration and the filtrate was acidified with hydrochloric acid, adjusted to pH 3. After the water from the filtrate had been completely removed under reduced pressure, the residue was extracted with acetone. The evaporation of the acetone gave colorless crystals in a very poor yield. λ_{max}^{MeOH} $m\mu$ (log ε): 280(3.82). $\lambda_{max}^{MeOH-HCl}$ $m\mu$ (log ε): 225(3.75), 263(3.86).

Found: C, 57.40; H, 5.42; N, 11.34. Calcd. for $C_6H_7O_2N$: C, 57.59; H. 5.64; N, 11.20%.

The authors wish to express their thanks to the Sankyo Co., Ltd., which defrayed a part of the expenses of the present research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 285—287 (1966)

Mineral Acids as Photoinitiators of Vinyl Polymerization in Aqueous Media

By Mihir K. SAHA*

Indian Association for the Cultivation of Science, Jadavpur, Calcutta-32, India

(Received May 26, 1965)

A few mineral acids, namely hydrochloric, hydrobromic and sulfuric acid, have been used as photoinitiators for the polymerization of methyl methacrylate in aqueous media in the presence of ultraviolet light. The endgroups incorporated in the resulting polymers have been determined by the application of the sensitive "Dye Techniques" lately developed in our laboratory. On the basis of the endgroup results, attempts have then been made to explain the mechanism of such polymerization, and also the nature of the initiating species involved.

Mineral acids have been used as the initiators of vinyl polymerization to a very limited extent; a few of the instances quoted in the literature[1,2] are supposed to proceed through an ionic mechanism. The present communication will describe the use of some mineral acids, viz., hydrochloric, hydrobromic and sulfuric acids, as photoinitiators for the aqueous polymerization of methyl methacrylate. The endgroups incorporated in the resulting polymers have been determined by the application of the "Dye Techniques"[3] lately developed in our laboratory in order to get an idea of the nature of the initiating species involved in such processes.

Experimental

Purified methyl methacrylate (MMA) was used as the monomer. The acids employed as initiators were of an analytical grade and were free of traces of iron.

Polymerization experiments were carried out in clean pyrex conical flasks in a nitrogen atmosphere in the presence of ultraviolet light, without any filter, and at a temperature of 30°C, the concentration of the monomer being kept at 0.094 mol./l. in all the experiments. The induction period for the polymerization varied from about half an hour to about 3 hr., depending on the nature and concentration of the acids empolyed as initiators. Polymers were obtained as a coarse precipitate after the polymerization was over. The polymers were then washed free of acid, dried in an air oven at 45°C, and purified by repeated reprecipitations from a benzene solution by a mixture of alcohol and petroleum ether.

The purified polymers were then subjected to the "Dye Tests" in order to determine the endgroups incorporated in them. The halogen endgroups were determined by the application of the "Dye partition test" using a Disulfine blue reagent after the quaternisation of the polymers with pyridine.[4] The sulfate endgroup was estimated by the "Dye partition test" employing a methylene blue reagent.[5]

Results and Discussion

The usual features of these polymerization, e. g., the initiation of polymerization only in the presence of light, a fairly long induction period, the polymerization over a considerable period of time (about 2—5 hr.), and the complete inhibition of the polymerization in the presence of oxygen, are suggestive of a typical radical polymerization process.

Initiation by Halo Acids.—Both hydrochloric and hydrobromic acid could initiate the polymerization of MMA in the presence of ultraviolet light, while hydroiodic acid failed to do so under identical conditions, probably because of the strong inhibitive action of the iodine liberated. The polymers obtained with both hydrochloric and hydrobromic acid were found to bear halogen endgroups to a varying extent (about 0.3 to 0.8 per chain) (Table I). This definitely indicates that some of the polymer chains are initiated by halogen atoms generated in the systems by the photolysis of the halo acids or, more precisely, by that of the halide ions in question; thereby they appear as polymer endgroups. The generation of halogen atoms probably takes place by the following mechanism:

$$HX \rightleftarrows H^+ + X^-$$

$$X^- + HOH \xrightarrow{h\nu} X\cdot + H\cdot + OH^- \quad [X=Cl \text{ or } Br]$$

It appears, therefore, that both the radicals, X· (Cl· in the case of hydrogen chloride and Br· in the case of hydrogen bromide) and the hydrogen atom (H·), may bring about the initiation of polymerization. (It has been indicated by Dainton[6] that the hydrogen atom (H) produced by irradiation with X-ray or γ-ray can initiate the polymerization of acrylonitrile in aqueous media.)

a) Number average molecular weight ($\overline{M}_n$) of the polymers was obtained viscometrically by the application of the following equation[9]:

$$\overline{M}_n = 2.81 \times 10^5 \times [\eta]^{1.32}$$

(for P. MMA in benzene)

The hydroxyl endgroups in these polymers could not be determined by the application of "dye techniques" due to the extensive hydrolysis of the ester units to a carboxyl group, a process which rendered the polymer increasingly insoluble in benzene and chloroform. The determination of the halogen endgroup in the polymer by the above spectrophotometric method is based on the process of quaternisation, which is extremely slow and sluggish at the end of the reaction,[7] especially when the quantity of halogen is extremely low, as in the case of the polymer endgroup. This leads to some uncertainty as to the quantitative values obtained herein; hence, there is hardly any order in the endgroup values obtained. However, allowing for these uncertainties, it can be easily demonstrated that the polymers obtained by using

hydrogen chloride and hydrogen bromide as photoinitiators incorporate halogen endgroups at least in part.

Initiation by Sulfuric Acid.—The polymers obtained with sulfuric acid as a photoinitiator have been found to incorporate sulfate endgroups to an average extent of about only 0.1 to 0.2 per chain (Table I); this is indicative of initiation by sulfate ion radicals, at least in part. The generation of sulfate ion radicals may take place in the following way:

$$H_2SO_4 \rightleftarrows 2H^+ + SO_4^{2-}$$

$$SO_4^{2-} + HOH \xrightarrow{h\nu} S\overline{O}_4\cdot + H\cdot + OH^-$$

Both $S\overline{O}_4\cdot$ and $H\cdot$ may initiate the polymer chain and may, thereby, appear as polymer endgroups. The ability of $S\overline{O}_4\cdot$ to initiate the vinyl polymerization has been widely studied.[5,8] It is also probable that, due to the acidity of the medium, sulfate ion radicals react readily with water to generate hydroxyl radicals, e. g.;

$$S\overline{O}_4\cdot + \begin{matrix} H \\ \diagdown \\ \overset{+}{O}—H \\ \diagup \\ H \end{matrix} \rightarrow H_2SO_4 + OH\cdot$$

This reaction probably occurs more readily at higher concentrations of acids.[5] However, the hydroxyl endgroups in these polymers could not be examined because of a difficulty similar to that indicated in the case of halo acids.

Fractures in Thin-sectioned Corundum Crystals

By Goro YAMAGUCHI, Yasushi KUBO and Hiroshi OGAWA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received May 26, 1965)

The fracture properties of corundum crystals have been examined on various artificial corundums, such as electrically-fused corundum, Verneuil-flame-fused corundum and hydrothermally-synthetised corundum. The specimens were ground to a tihckness of less than 5/100 mm. The microcracks generated in the grinding process were observed by means of a polarizing microscope. The orientation of the c-axis (C) and the crack normal to the section normal (T) was measured using a universal stage. The direction of the crack has a close relation to the crystal orientation of the thin section. Frequent irregular cracks intercrossing one another occur in crystals ground with T$\wedge$C angles from 0° to 50°. Cleavage cracks along the $\{10\bar{1}1\}$ plane take place prominently in the range of T$\wedge$C angles from 50° to 80°. Rare irregular cracks streaming in one direction take place in the range of T$\wedge$C angles from 80° to 90°. The heat treatment in air of titania-containing corundum decreases the number of cracks in the crystal. The results have been interpreted on the basis of the cohesion strength theory of M. D. Shappel (*Am. Mineralogist,* **21**, 75 (1936)). In order to explain the limited range of the ocurrence of cleavage cracks, a model has been proposed in which the shearing along the cleavage plane takes place prior to the crack nucleation in the corundum crystal.

The fracture properties of corundum are of practical importance as well as of theoretical interest. Its abrasive properties are inferred to depend on the relation between the hardness and the toughness of the corundum.

According to the literature, fabricators of jewel bearings know by experience a certain technique for avoiding breakage loss. The fracture mechanisms in such materials as metals and ductile minerals have been discussed on the basis of the dislocation theory, but discussion of such brittle minerals of a high hardness and strength as corundum has not progressed.

Information has, however, been provided on the fracture properties of artificial corundums observed in thin sections. In a microscopic observation of electric-furnace-fused alumina abrasives, attention was called to the fact that many microcracks, regular or irregular, were generated in corundum crystals lying in various crystallographic

orientations in thin sections. These carcks were found to develop when the crystal was ground to a thickness of below about 5/100 mm. Careful observation of these cracks by quantitative determination revealed a certain law of fracture in thin-sectioned corundum. Various artificial specimens from electrically-fused corundum, Verneuil-flame-fused corundum and hydrothermally-synthesized corundum were observed.

The results will, in this paper, be compared with a model based on the cohesion strength theory of the crystal plane. A mechanism will be proposed which gives an adequate explanation of the discrepancy in the minimum cohesion strength model and which agrees splendidly with the observations.

Experimental

Specimens.—*Regular and White Alumina.*—Most of the specimens employed were commercial 16-mesh grains of electric-furnace-fused alumina abrasives produced by the Carborundum Company, abrasives which contain from 95 to 97% alumina and the impurities shown in Table I. Corundum is the predominating crystalline phase, and impurities are present for the most part as impure minerals, except that only titania is present in corundum in a solid solution, as is shown in the fifth and sixth rows in Table I.

TABLE I. THE IMPURITY COMPOSITION OF THE SPECIMENS

Specimen	SiO_2	Fe_2O_3	TiO_2	
C32	0.51	0.12	2.46	
R41	0.49	0.15	2.49	
C37	0.26	0.04	tr.	
Japanese commercial abrasive	0.86	0.21	2.34	#24 as-received
	0.10	0.10	1.50	#220 treated with Na_2CO_3-K_2CO_3-H_3BO_3 flux

These grains are made up of from one to twenty corundum crystals, euhedral or anhedral, 2 mm. to 1/10 mm. in size. Small amounts of impure minerals are contained in corundum or form the matrix. Titania-containing corundums in the specimens designated as C32 and R41 range in color from brown to pink. The C37 specimen is the one made from Bayer-process white alumina, with few impurities, though it contains some beta alumina.

Heat-treated Titania-containing Abrasive Grains.—Corundum containing titania in a solid solution is known to change color from pink or brown to bluish, and then to opaline, upon the segregation of titania along a certain crystal plane by heat treatment in air. In titania-containing abrasive aluminas, this change in color is accompanied by a marked improvement in the toughness of the grains.

Fracture properties in thin section were observed to change in this process when Japanese commercial 24-mesh grains were used as received and heat-treated in air at 1250°C for 1 hr.; the latter turns bluish with 3.1% weight increase upon oxidation. The impurity compositions of these grains are shown in the fifth and sixth rows in Table I.

Verneuil and Hydrothermally-synthesized Corundum.—The effect of the crystal-growth technique on fracture properties in thin sections was examined using Verneuil corundum and hydrothermally-synthesized corundum which had been grown on the seed of Verneuil corundum.

The Observation of Microcracks in Thin Sections.—Specimens were ground with a 600-mesh SiC abrasive on a motor-driven disk to a thickness of about 5/100 mm., and then refined with boron carbide finer than 600-mesh by manual grinding to about 2/100 mm. Microcracks were generated in this grinding process, as Fig. 1 shows, when the specimens were thinner than 5/100 mm.

The orientation of the c-axis and of the crack normal relative to the section normal was determined by the microscopic method using a universal stage and subsidiarily by the X-ray Laue back-reflection method.

Results

Characteristics of Fractures Related to the Crystallographic Orientation of the Ground Surface.—Figures 1(a), 1(b), 2(a) and 2(b) show thin sections of grains composed of a number of corundum crystals with various crystallographic orientations relative to the section normal. One can see fractures of various kinds exhibited in each of the crystals, depending on their orientations.

The disposition of the c-axis (C) measured on each of crystals with respect to the section normal (T) and the aspect of fracturing are expressed on stereographic projections of Fig. 1(c) and Fig. 2(c).

One can see a definite tendency, in the range of the $T \wedge C$ angle from 0° to 60°, for fracturing to be prominent; from 60° to 80°, it is prominent or medium, while from 80° to 90° there is little fracturing. Smooth crystals with no fractures, such as 2, 3 and 15 in Fig. 1 and 8, 15 and 16 in Fig. 2, have, almost without exception, the c-axis lying in the section plane.

Irregular Cracks.—Two sorts of fractures can be discriminated in Fig. 1(a) and Fig. 2(a); one consists of linear cracks occurring parallel to one another, while the other consists of curved irregular cracks occurring in random directions. The latter is the cleavage crack taking place parallel to a particular crystal plane. In Fig. 1(a) the irregular crack is prominent, while in Fig. 2(a) the cleavage crack is prominent.

Irregular cracks show a definite dependency on the inclination of the c-axis with respect to the section normal. Characteristic irregular cracks intercrossing in three directions, as is shown in Fig. 3, take place in the crystal with the c-axis perpendicular to the section plane ($T \wedge C = 0$). Inclining from this disposition up to the $T \wedge C$ angle of about 60° gives rise to irregular cracks with a tendency to intercross with one another, as Fig.

Fig. 1 (a) Fig. 1 (b) Fig. 1 (c)

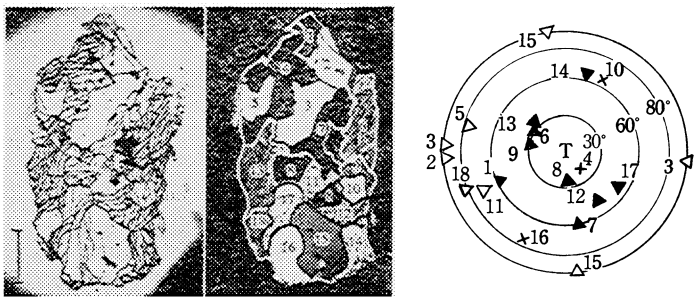

Fig. 1. Aspect of fractures in corundum crystals with various orientations in thin section. Disposition of the c-axis is expressed in (c) by stereographic projection on the section plane where all projections are of the upper intersection, with solid triangles for prominently fractured crystals, open triangles for fractured ones and crosses for medium ones, respectively. Figures affixed to crystals in (b) correspond to ones in (c). ((a) Parallel nicols, (b) Crossed nicols, Specimen R41)

Fig. 3 (a) Fig. 3 (b) Fig. 3 (c)

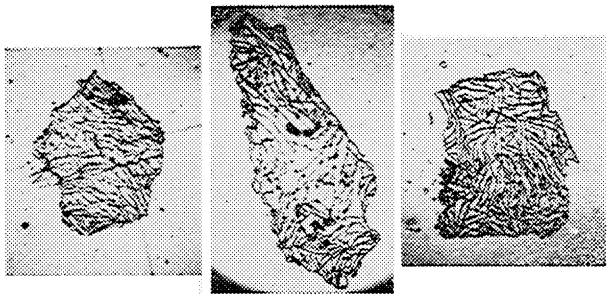

Fig. 3. Fractures in crystals ground perpendicular to the c-axis. (a) Specimen C32, (b) Specimen R41 and (c) Specimen C37

4 shows. The irregular cracks occurring in the region of the T∧C angle between 80° to 90° have a tendency to stream in one direction, as is shown in Fig. 5. In the T∧C range from 50° to 80°, cleavage cracks are the predominating fractures, as will be mentioned in the following section, while at the T∧C angle of 90° no fractures occur.

The dependency on the azimuthal orientation can not be treated separately because of experimental difficulties.

The Cleavage Crack.—The orientation of the c-axis (C) and the cleavage crack normals (P_1, P_2 and P_3, in the order of predominance) with respect to the section normal (T) were determined for crystals in which cleavage cracks take place in different directions in two or three sets. The results for various cases are shown by

the stereographic projection on the section plane in Fig. 6(b)—9(b), where the orientation corresponds to that of Fig. 6(a)—9(a). These were converted into the stereographic projection on the basal (0001) plane in Fig. 6(c)—9(c) to show the symmetry and the polar angle with respect to the c-axis. The plots by the cross and the open circle represent, as usual, the projection of the upper intersection and the lower intersection respectively. The value of the polar angle measured on a number of crystals is in the 57.5°±5° range, corresponding to that of the rhombohedral $\{10\bar{1}1\}$ plane. The symmetry of the cleavage crack patterns, however, can be interpreted as trigonal or hexagonal for Fig. 6(c), but only as hexagonal for Fig. 7(c)—9(c). This incompatibility may be considered to be due to the formation of basal twinning in electric-furnace-fused corundum.

The conditions for the generation of the cleavage crack were examined, on all of the crystals exhibiting the cleavage crack in a section containing about

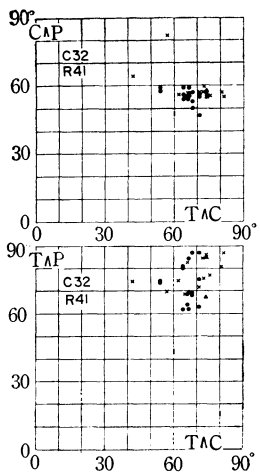

Fig. 10. Condition for generation of the cleavage crack expressed by the angles T∧C, T∧P and C∧P. solid circles represent cleavage cracks with hexagonal arrangement due to basal twinning, solid triangles ones with trigonal and crosses ones with single, respectively. (Specimen C32, R41)

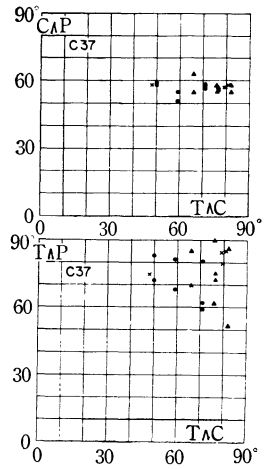

Fig. 11. Condition for generation of the cleavage crack. Expression is the same as in Fig. 10. (Specimen C37)

eighty grains, for the C32, R41(titania-containing) and C37(white alumina) specimens by measuring the T∧C, T∧P and C∧P angles. The results are plotted in Figs. 10 and 11, with solid circles for the hexagonal cleavage, solid triangles for the apparent trigonal cleavage, and crosses for the single cleavage.

It is clear that almost all of the cleavage cracks occur when the crystal is ground with a T∧C angle between 50° and 80° and with a T∧P angle between 60° and 90°.

The Effect of the Heat Treatment on the Fracture Properties of Titania-containing Corundum.—Fig. 12(a) shows the thin sections of corundum crystals as received, containing titania in a solid solution and colored a pale brown. Figure 12(b) shows that of crystals treated in air at 1250°C for 1 hr.; they turned bluish.

A remarkable change in fracture properties is observed when specimens are heat-treated. In the heat-treated specimen, the cleavage crack comes not to take place, but large cracks dividing the crystal into relatively small numbers of blocks appear characteristically.

Fig. 12 (a)

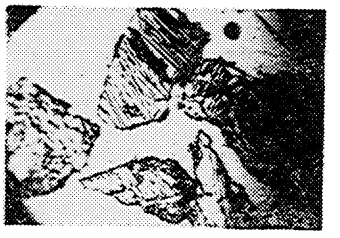

Fig. 12 (b)

Fig. 12. Change of fracture property of titania-containing corundums by heat treatment, (a) as-received and (b) heat treated in air at 1250°C for 1hr to bluish.

Fractures in Verneuil Corundum and Hydrothermal Corundum.—Figure 13 shows a microphotograph with crossed nicols of a thin section of Verneuil corundum on the left of the dividing line, and one of hydrothermal corundum on the right, which has been grown on the seed of the Verneuil corundum with the same crystallographic orientation. Basal fractures are striking in the hydrothermal corundum: they occur in the contact region along the stripes with a high birefringence, but they are interrupted at some distance from the boundary. This region of high birefringence has been shown by an electron probe microanalyzer to be twice as rich in iron content introduced from an autoclave as other regions of the hydrothermal corundum. Outside the contact region of the hydrothermal corundum and in the Verneuil corundum, the cleavage cracks along $r\{10\bar{1}1\}$ take place as usual. The crystal has an orientation with a T∧C angle of 81° and a T∧P angle of 77°.

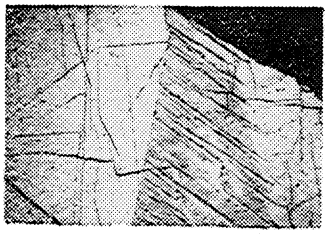

Fig. 13. Fractures in Verneuil corundum and in hydrothermal corundum. Hydrothermal corundum on the right was grown on the seed of Verneuil corundum on the left with the same crystallographic orientation. Stripes in hydrothermal corundum are regions with high birefringence. The crystal was ground with the angle T∧C of 81° and T∧P of 77°. The trace of $r\{10\bar{1}1\}$ and $c\{0001\}$ is shown in the figure. (Crossed nicols)

Discussion

Regarding fracture properties, corundim is known[1] to show no cleavages but two possible partings, one parallel to the basal {0001} plane, and the other parallel to the rhombohedral $\{10\bar{1}1\}$ plane, which is often characterized by the appearance of twin laminations along the same plane. This description is based on a study by Judd[2] which demonstrated that the supposed cleavages in corundum are due to alteration along definite planes of the crystal. When alteration does not exist, the natural corundum is quite destitute of any trace of cleavage, but is usually breaking with an irregular or conchoidal fracture as in quartz; however, a tendency to break up along certain planes, such as $c\{0001\}$, $r\{10\bar{1}1\}$ and $m\{10\bar{1}0\}$, is the result of the incipient alteration, which gives rise to corroded cavities along these planes.

This is obviously incorrect in the case of artificial corundum, such as the electrically-fused, the flame-fused or the hydrothermally-synthesized corundum, which exhibits well-defined cleavages along $r\{10\bar{1}1\}$ in thin sections, as has been shown above.

The fracture properties of materials are usually determined on a relatively large rod, as in loading tests. In such tests corundum exhibits rather conchoidal fractures which bear no clear relation to its crystal structure or to the inherent structural weakness. In thin sections, however, where the bulk strength is extremely reduced, fractures characterized by the structure become predominant. This means that the type of fracture depends on the way it is produced. Therefore, such discussion of corundum as concerns cleavage, parting and conchoidal fracture is meaningless unless the testing method is clearly described.

The cohesion strength of the crystal plane in thin sections has been estimated on corundum and compared with the results obtained above. Using Shappel's cleavability,[3] $V_{|hkl|}$ is defined as:

$$V_{|hkl|} = \frac{A_{|hkl|}}{\sum_i n_i f_i \cos\theta_i}$$

where f_i is the bond strength between a pair of the ions with the cleavage face interpose between them; θ_i, the angle between the bond and the normal of the crystal plane; n_i, the number of such bonds for the ith ion, and $A_{|hkl|}$, the area element

of the crystal plane. The estimated cohesion strength, $F_{|hkl|}$, of the crystal plane in thin sections is derived as:

$$F_{|hkl|} = \frac{\text{cosec}(\text{T}\wedge\text{P})}{V_{|hkl|}}$$

where T∧P is the angle between the section normal and the normal of the crystal plane and where cosec(T∧P) represents the cross area of the crystal plane in thin sections. The value of the cleavability, $V_{|hkl|}$, of corundum was calculated by Shappel to be as given in the seventh column of Table II, where the bond strength, f_i, is estimated from the coordination theory of ionic structures.

The value of the cohesion strength, $F_{|hkl|}$, at different T∧C angles along main zones has been calculated for each of the crystal planes, as is given in Fig. 14. The crystallographic data on main crystal planes of corundum are shown in Table II and Fig. 15.

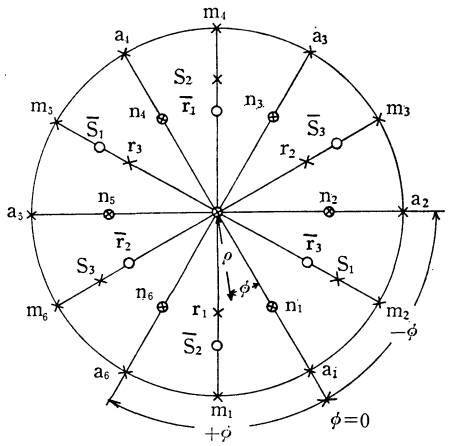

Fig. 15. Stereographic projection showing main crystal planes of corundum and designation in this paper.

In the range of T∧C angles larger than about 20°, the cohesion strength of $r\{10\bar{1}1\}$ becomes conspicuously lower than in other ranges. The basal (0001) plane can not be a cleavage plane; this conclusion, based on the cohesion strength calculation, is in conformity with the fact that the basal fracture in hydrothermally-synthesized corundum, in the contact region with the seed, may be referred to as the parting which is produced by the zonal segregation of the impurity iron along the same plane.

For the crack in the thin section with the T∧C angle of 0°, a possible interpretation is that the main direction of the irregular cracks are parallel to the $m\{10\bar{1}0\}$; the crack faces are nearly perpendicular to the section plane, and the small differences in cohesion strength among the crystal planes in this orientation cause an irregular deviation in the crack direction.

In order to estimate the strength of corundum at various crystallographic orientations of the ground surface, we will define the strength factor, [F], as:

TABLE II. CRYSTALLOGRAPHIC DATA ON MAIN CRYSTAL PLANES OF CORUNDUM

Form	Index: Morphological rhombohedral	Index: Hexagonal (adopted in this paper)	Index: Structural hexagonal	σ in Fig. 15	Φ in Fig. 15	Shappel's cleavability
c	111	0001	0001	0°00′	—	9.5
m	$2\bar{1}\bar{1}$	$10\bar{1}0$	$01\bar{1}0$	90°00′	30°00′	10.2
a	$10\bar{1}$	$11\bar{2}0$	$11\bar{2}0$	90°00′	0°00′	9.2
r	100	$10\bar{1}1$	$01\bar{1}2$	57°35′	30°00′	12.4
s	$11\bar{1}$	$02\bar{2}1$	$10\bar{1}1$	72°23′	−30°00′	8.6
n	$31\bar{1}$	$22\bar{4}3$	$11\bar{2}3$	61°11½′	0°00′	

$$\frac{1}{[F]} = \frac{1}{n}\sum_{i=1}^{n}\left(\frac{1}{F_i}\right)$$

where F_i corresponds to $F_{|hkl|}$ and where $[F]$ is shown approximately as follows:

$$\frac{1}{[F]} = \frac{1}{13}\left(\frac{1}{F_{a_1}}+\frac{1}{F_{a_2}}+\frac{1}{F_{a_3}}+\frac{1}{F_{s_1}}+\frac{1}{F_{s_2}}+\frac{1}{F_{s_3}}+\frac{1}{F_{m_1}}+\frac{1}{F_{m_2}}+\frac{1}{F_{m_3}}+\frac{1}{F_c}+\frac{1}{F_{r_1}}+\frac{1}{F_{r_2}}+\frac{1}{F_{r_3}}\right)$$

We may expect qualitatively that the increase of $[F]$ will correspond to the decrease in fracturing. The calculated values in each azimuthal direction (ϕ) are shown by dotted lines in Fig. 14. From this we can see that $[F]$ increase as the T∧C angle increases from 0° to 90°, regardless of the azimuthal direction; this finding coincides with the observation that fracturing decreases as the T∧C angle increases from 0° to 90°.

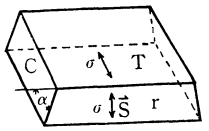

Fig. 16. Schematic representation of each planes, T the surface plane, c the basal plane and r the cleavage plane. Cleavage cracks take place only in the range of the angle T∧C from 50° to 80°. α represents the angle T∧C.

The limited range of the occurrence of cleavage cracks might have the significance explained below, in view of the crystal structure of corundum. Figure 17 illustrates the packing of ions parallel to the $\{10\bar{1}1\}$ plane. On the cleavage surface, there exist the directions shown by the arrows designated $\vec{S}$, with the angle of 18° from the trace of the basal (0001) plane and with the T∧C angle of 75°, which corresponds to the direction leading to a saddle point, and the other direction shown by the arrows $\vec{R}$ with the angle of 29° from the trace of the basal (0001) plane and with the T∧C angle

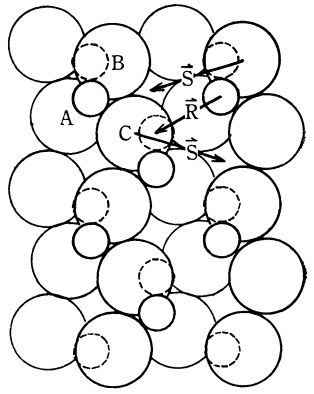

Fig. 17 (a)

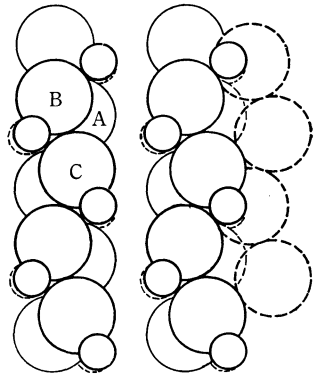

Fig. 17 (b)

Fig. 17. Packing of ions normal to $\{10\bar{1}1\}$. Two layers of ions on both sides of cleavage surface are shown in (a), and arrangement after the shear $\vec{R}$ is shown in (b).

of 66°, which corresponds to the direction in which the Al ions on the upper layer may be transported to just above the Al ions on the lower layer. Most of the plots fall in the T∧C regions between 66° and 75°. If a shear is applied between these two layers, a great resistance may be anticipated in directions other than the adjacent region of the $\vec{S}$ direction. When the shear shown by the $\vec{R}$ vector is applied, it gives rise to the arrangement of ions on both sides of the cleavage surface shown

in Fig. 17, where no bonding exists between the two crystal faces, and where only repulsions work between anions and between cations. Therefore, the experimental results have been interpreted as suggesting a fracture mechanism in which a shear along the cleavage face is required prior to the cleavage-crack nucleation.

The change in fracture properties upon heat treatment on titania-containing corundum may be interpreted on the assumption of this mechanism that the exsolution of the titania[4] nuclei in the corundum makes the shear quite difficult by nailing up the crystal plane.

Conclusion

1) When corundum crystals are ground in thin sections below the thickness of about 5/100 mm., fractures characterized by the inherent structure occur in the grinding process. The previous descriptions of the fracture properties of corundum are not sufficient in that they neglect the dependence of the type of fracture on the testing method.

2) These microcracks have a close relation to the section direction with respect to the crystal orientation. Irregular cracks with a tendency to intercross with one another occur frequently in crystals ground with T∧C angles from 0° to 50°. Cleavage cracks along the $r\{10\bar{1}1\}$ plane take place prominently in the range of the T∧C angles from 50° to 80°. Irregular cracks with a tendency to stream in one direction occur rarely in the range from 80° to 90°.

3) The results have been interpreted in terms of the cohesion strength of the crystal plane calculated on the basis of the ionic-bonding-strength theory. In order to explain the limited range of the occurrence of cleavage cracks, a model based on the shearing along the cleavage face prior to the crack nucleation has been proposed.

4) Heat treatment in air on titania-containing corundum has a conspicuous effect on the fracture properties.

5) Verneuil corundum and hydrothermal corundum exhibit no conspicuous differences in fracture properties, and the basal parting in the contact region of hydrothermal corundum on a seed is due to the zonal segregation of the iron impurity.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 295—299 (1966)

Twinning in Electric Furnace-fused Corundum

By Goro YAMAGUCHI, Yasushi KUBO and Hiroshi OGAWA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received July 20, 1965)

In an investigation into the fracture properties of thin-sectioned corundum crystals, it was noticed that microcracks in electrically-fused corundum obey a hexagonal symmetry in spite of the rhombohedral symmetry of the corundum structure. This fact suggests that the corundum crystals consist of several twins, which have the same optical direction and which cannot be distinguished microscopically. The X-ray Laue back-reflection and etching techniques were applied to commercial 16-mesh grains of electric furnace-fused alumina abrasives. Corundum crystals grown over the crystal size of hundreds of μ to 1 mm. in electric-furnace fusions were found to be generally composed of several penetration twins with a twinning plane (0001). The twins are considered to be growth twins arising in the cooling process. The impurity composition and heat treatment have no marked effect on twinning. The twin junction is highly stable both mechanically and chemically. Cleavage cracks generated in individual crystals are stopped at the twin boundary.

Recently many studies have been made of the imperfection structures of corundum as background for such applications as alumina ceramics, jewel instruments, lasers and masers.

In one investigation into the effect of imperfection sturctures on the abrasive properties of corundum, it was noticed that corundum crystals from electric-furnace-fused ingot consist of several twins ranging in size from hundreds of μ to 1 mm.; these twins have the same optic direction and can not be distinguished microscopically. This fact was initially noticed in examining microcracks generated in thin-sectioned corundum crystals,[1]

1) G. Yamaguchi, Y. Kubo and H. Ogawa, This Bulletin, **39**, 287 (1966).

which obey a hexagonal symmetry in spite of the rhombohedral symmetry of the corundum structure.[2] X-Ray Laue back-reflection and etching techniques were applied, thus revealing the characteristic features of this fine basal twinning with the penetration twin boundary. The cause of twinning and the effect on the abrasive properties will be discussed.

Experimental

Specimens.—Most of the specimens examined were commercial 16-mesh grains of electric-furnace-fused alumina abrasives obtained from Carborundum Company, with the impurity contents given in Table I. These specimens were obtained from large ingots of electric-furnace-fusions and were composed predominantly of corundum with crystal sizes of from 2 mm. to 1/10 mm. and of impure minerals forming a matrix or included in corundum crystals. Of these impurities, only titania was present in a conceivable amount in corundum in a solid solution. The texture varies depending on the raw materials and on the processing. A detailed description of the texture of these products may be found in the article by Baumann.[3]

TABLE I. IMPURITY COMPOSITION OF THE SPECIMENS

Specimen	SiO_2	Fe_2O_3	TiO_2	
C32	0.51	0.12	2.46	
R41	0.49	0.15	2.49	
C37	0.26	0.04	tr.	
Japanese commercial abrasives	0.86	0.21	2.43	# 24 as received
	0.10	0.10	1.50	# 220 treated by Na_2CO_3-K_2CO_3-H_3BO_3 flux

The specimens, designated G52, C32, R41 and C37, are so-called high or low-titania fused aluminas widely used for abrasives. C36 is an electric-furnace made white alumina made from Bayer-process raw material; it contains beta alumina as impurity. R71 is a special alumina containing a considerable amount of ZrO_2; in it corundum crystals grow as dendrite or fine euhedral crystalites in a matrix of impurities. Commercial Verneuil corundum and hydrothermally-synthesized corundum were also studied for the sake of comparison.

The effect of heat treatment on twinning was examined using as received Japanese commercial 24-mesh abrasive alumina containing titania in a solid solution; it has been heat-treated in air at 1250°C for 1 hr.

The Observation of Cleavage Cracks in Thin Sections.—When corundum crystals were ground in thin sections, numerous microcracks, regular or irregular, appeared in various places. These microcracks were not observed until the section was ground to a thickness of less than 5/100 mm.; they were closely related to the crystallographic orientation of the ground section.

When the ground section made an angle of from 50° to 80° with the basal (0001) plane and one of from 60° to 90° with the rhombohedral $\{10\bar{1}1\}$ plane, cleavage cracks parallel to the $\{10\bar{1}1\}$ plane took place predominantly.

The orientation of the c-axis and the cleavage crack normals with respect to the section normal was determined on thin-sectioned corundum crystals approximately 2/100 mm. thick using a universal stage and expressed in terms of stereographic projection. The symmetry exhibited by the cleavage cracks was then examined.

X-Ray Laue Back-reflection Photographs.—By the Laue back-reflection method, the orientation of the crystal in thin sections was examined and compared with the data determined by the measurement of cleavage cracks. Crystals with the c-axis nearly perpendicular to the section plane were selected in thin sections. Laue back-reflection photographs of them were then taken, and the symmetry of the reflection patterns was examined. The Laue pattern obtained from the single corundum crystal should be of a trigonal symmetry, so the hexagonal crystal gives evidence of basal twinning.

Etching on the Basal (0001) Surface.—In order to examine the twin junction and the size of twin individuals, the basal (0001) surface was etched. Etching techniques developed by Scheuplein and Gipps[4] using phosphoric acid and by Stephens and Alford[5] using potassium bisulfate were applied.

Results

The Arrangement of Cleavage Cracks in Thin Sections.—The orientations of the section normal (T), the c-axis (C) and the cleavage crack normals (P_1, P_2 and P_3) as determined on a thin-sectioned corundum crystal of Fig. 1(a), which exhibits three sets of cleavage cracks, are shown in Figs. 1(b) and 1(c) by stereographic projection to show the symmetry of the cleavage cracks.

These cleavage cracks correspond to the rhombohedral $(10\bar{1}1)$ plane, with an angle of 57°35′ with relation to the basal plane. The arrangement of cracks, however, can only be interpreted as of a hexagonal symmetry. By careful observation of Fig. 1(a) it can be seen that the sets of cleavage cracks never intercross with each other and that they separates a crystal into regions, in each of which one of the sets predominates. Almost all of the crystals exhibiting more than two sets of cleavage cracks were found to possess hexagonal crack patterns.

A Laue Back-reflection Photograph.—One of the Laue back-reflection photographs taken along the c-axis of nearly basal sections of electric-furnace-fused corundum is given in Fig. 2(a); the corundum is seen to be made up, by basal twinning, of the superposition of the usal trigonal pattern of a single corundum crystal and its 180° rotated or mirror-reflected pattern.

The Twin Structure Revealed by Etching on the Basal (0001) Plane.—Etch pits on the (0001) surface showed the region of twin individuals by means of the reversal of the triangular etch pits. Twin junctions were not affected at all or were only obscurely etched, as is shown in Fig. 3 and Fig. 4; this differs from Alford's observation of the basal twin of flux crystals, where the trace of the composition plane $(10\bar{1}0)$ on the basal plane was marked by a row of rectangular or diamond-shaped etch pits.[5]

The twin boundaries drawn from the distribution of etch pits are shown in Fig. 5. The size of the individual crystal is determined to vary from hundreds of μ to 1 mm. in diameter, and the twin boundary is not planar but interpenetrating.

The Effect of Impurities, Texture, and Heat Treatment on Twinning.—The presence of twinning was examined on each of the specimens, which differ in impurity composition and in texture. The results are shown in Fig. 6, where measured grains are marked at positions on the abscissa expressing the crystal size in mm.; the single crystal is marked by a one-sided arrow head, and twin composed of more than two individuals, by a two-sided arrow head.

↕ Twin composed of more than two individuals
↑ Single crystal

Except for the R71 sample, which has a singular composition and texture, no striking difference was observed between the specimens with regard to twin formation. In any specimen corundum crystals grown over the crystal size of hundreds of μ are composed of interpenetrating basal twins. Heat treatment in air at 1300°C on titania-containing crystals caused no change in the twin structure.

Discussion

The twinning of corundum has been described in the literature as follows; commonly with a twinning plane $(10\bar{1}1)$ and less commonly with (0001), the latter being usually lamellar and producing a lamellar structure and striae on $c(0001)$ and $r(01\bar{1}1)$, and even less commonly, penetration twins or, rarely, arrowhead twins with tabular crystals parallel to $(11\bar{2}0)$.[2]

Recently, Stephans and Alford[6] reported that a basal twinning with a $(10\bar{1}0)$ composition plane and a (0001) twin axis, which was observed by Mekczer as a rare form on natural corundum, is generally present on flux crystals grown from PbO-PbF_2 flux systems at temperatures up to 1250°C. Pressure twinning produced on $(10\bar{1}1)$ and on (0001) under pressures of from 13000 to 18000 atmospheres was studied in detail by Veit[7] and interpreted on the basis of dislocation mechanisms by Kronberg.[8] This study has shown another form of twinning in electric-furnace fused corundum crystals.

Skeletal crystals (so designated by Baumann), which grow on the surface of shrinkage pipes in cooled ingots, were also found to be basal twins coupled on a longitudinal twin boundary, on each side of which rhombohedral corundum crystals pile up along the c-axis, thus forming a skeletal needle, on which no comment was made by Baumann.

The cause and process of twin formation can only be inferred qualitatively. The observed twins are considered to be growth twins arising from the strain peculiar to the cooling of large ingots of electric-furnace fusions. The cohesion of a twin junction is as strong as the internal cohesion of a single crystal; the etch pits usually observed in other cases on the traces of a twin boundary are not revealed, and the cleavage cracks generated in the region of single crystals are stopped at the twin boundary, not propagating beyond it, as is shown in Fig. 1(a).

The fracture properties of electrically-fused corundum are supposed to be affected by twinning. Whether twinning increases the toughness of corundum or not remains to be established, however.

Conclusion

1) Corundum crystals grown over the crystal size of from hundreds of μ to 1 mm. in electric-furnace fusions have been found generally to be composed of several penetration twins with a twinning plane (0001).

6) W. J. Alford, *J. Am. Ceram. Soc.*, **47**, 81 (1964).
7) K. Veit, *Jb. Min. Beil.*, **45**, 121 (1921).
8) M. L. Kronberg, *Acta. Met.*, **5**, 507 (1957).

2) These twins have been considered to be growth twins arising in the cooling process. The impure content and heat treatment have no marked effect on the twinning.

3) The twin junction is highly stable, both mechanically and chemically. Cleavage cracks generated in individual single crystal are stopped at the twin boundary. By chemical etching on the basal plane, the trace of the twin boundary is not affected at all or, in some cases, is only obscurely etched.

4) The fracture properties of corundum may be supposed to be affected by twinning, but the relation between the toughness of abrasives and the twinning remains to be established.

Kinetic Studies of Solvolysis. XI.* The Steric Course of the Phenolyses of Optically Active α-Phenylethyl Chloride in Mixtures of Various Phenols and Organic Solvents—A Mechanism for the S_N1 Reaction with a Net Retention of Configuration

By Kunio Okamoto, Hiroto Yamada, Issei Nitta and Haruo Shingu

Department of Fuel Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received May 27, 1965)

The S_N1 phenolyses of optically active α-phenylethyl chloride in binary mixtures of organic solvents and certain substituted phenols (i. e., phenol, *p*-cresol, *p*-chloro- and *p*-nitro-phenol) proceed in the presence of aniline and of triethylamine to give the corresponding α-phenylethyl substituted-phenyl ethers with a predominantly-retained configuration. In binary mixtures of benzene and various phenols, the extents of retention for the ethers are slightly reduced at the higher base concentrations. However, in binary solvents of acetonitrile and certain phenols, the optical purities of the ethers with retained configurations decrease continuously with the base concentrations, while at the higher concentrations (~0.4 M) the steric courses change to the inverted course. The *C*-alkylated (α-phenylethylated) derivatives of these phenols, isolated along with the phenyl ethers, have inverted configurations, irrespective of the configurations of the corresponding phenyl ethers. These results are all consistent with a mechanism in which a molecule of the phenol reacts with the S_N1 ion-pair intermediate of the phenolysis to give a phenyl ether with a retained configuration, probably by S_Ni-like four-center substitution, whereas the reaction of a phenoxide anion with the S_N1 intermediate proceeds predominantly by the Walden inversion mechanism yielding a phenyl ether and α-phenylethylated phenols with inverted configurations.

It has been demonstrated in the literature that the S_N1 solvolyses of optically active α-phenylethyl chloride ordinarily proceed with a net inversion of the configuration in methanol,[1] ethanol,[1] aqueous acetone[1] and acetic acid[2]. The results[3] in our laboratories have also revealed that a net inversion is standard for the α-phenylethyl system in S_N1 solvolyses in such solvents as cyclohexanol, formic acid, trifluoroacetic acid and pivalic acid.

In contrast to these facts, however, we found[4] that the S_N1 phenolysis of optically-active α-phenylethyl chloride in a phenol-benzene mixture gave α-phenylethyl phenyl ether with a net retention of the configuration in the presence of a base such as aniline. In this earlier investigation, it was not clear whether the retention of the configuration was a result typical of all phenolyses in the substituted phenols, nor was it clear which nucleophile (a phenoxide anion or a phenol molecule) was responsible for this unordinary steric course.

In this paper we wish to report on the results of studies undertaken in order to answer the above questions. It will be shown that the S_N1 phenolyses of optically active α-phenylethyl chloride in various

substituted phenols, i. e., *p*-cresol, *p*-chlorophenol, and *p*-nitrophenol, yielded the corresponding α-phenylethyl substituted-phenyl ether with a predominantly retained configuration, and that this retention of configuration is caused by the attack, probably of the four-center type, of the undissociated molecules of the phenols on the S_Ni ion-pair intermediate, whereas the ambident phenoxide anions react with the S_Ni intermediate by the Walden-inversion mechanism to yield the corresponding ethers and α-phenylethylphenols with an inverted configuration.

Part I. The Steric Course of Phenyl Ether Formation in the S_Ni Phenolyses of Optically Active α-Phenylethyl Chloride

The Effect of the Nature of the Organic Solvent on the Steric Course of the Formation of α-Phenylethyl Phenyl Ether from Optically Active α-Phenylethyl Chloride. — Optically active α-phenylethyl chloride was subjected to phenolysis in phenol-organic solvent mixtures (about 1 : 1 by weight). The reactions were carried out in the presence of aniline as a base at 40.0°C for ten half-lives. The half-life for each reaction was estimated from the results of the kinetic runs carried out at 40.0°C under conditions similar to those used in the product studies. α-Phenylethyl phenyl ether was isolated by chromatography on silica gel or basic alumina.

Table I compares the effect of the organic solvent variation on the stereochemical outcome of phenolysis. In all runs, α-phenylethyl phenyl ether had a retained configuration, accompanied by 50 to 80% racemization.

It has been postulated that the retained steric course in the decomposition of secondary aliphatic chlorosulfites is due to the back-side participation of the solvents, such as ethers or alkyl halides, in a positive center of the ion-pair intermediate of this reaction.[5] An examination of the data in Table I, however, reveals that there can be hardly any specific relationship between the nucleophilic coordination power of these organic solvents and the extent of the net retention of the configuration. Therefore, the organic solvent molecule seems to play no primary rôle in the retention of the configuration; rather, the presence of the compound "phenol," i. e., a phenol molecule, a phenoxide anion, or an ion-pair of the phenoxide ion, seems to control the net steric course.

Furthermore, in those runs carried out in similar phenol concentrations there is a clear trend toward a larger racemization of the product ether with higher phenolysis rates (Table I). This trend may be explained if one assumes that the higher rates are responsible for the looser ion-pair intermediates, which in turn result in a larger racemization of the ether so formed.

The Effect of the Composition of Phenol-Organic Solvent Mixtures on the Steric Course of the Formation of α-Phenylethyl Phenyl Ether from Optically Active α-Phenylethyl Chloride.—In order to obtain further evidence for the essential rôle of phenol in the retention of the configuration, phenolyses of α-phenylethyl chloride were carried out in phenol-benzene and the phenol-acetonitrile mixtures with various phenol concentrations. As is shown by the degree of the retention of the configuration of α-phenylethyl phenyl ether (Table II), the higher concentration of phenol is not a necessary condition for the retention of the steric course. In fact, in a phenol-acetonitrile mixture with such a small concentration as 0.55 M of phenol in the

presence of 0.165 M triethylamine, the extent of retention for α-phenylethyl phenyl ether still amounts to 24.1%, in spite of the fact that the reaction was carried out at a rather higher temperature because of the low rate in the solvent ranges with such low phenol concentrations. This is another support for the conclusion in the preceding section, i. e., the primary rôle of the compound "phenol" in the steric course with a net retention of the configuration.

The Effect of the Base Concentration on the Steric Course of the Formation of α-Phenylethyl Phenyl Ether from α-Phenylethyl Chloride in *p*-Substituted Phenol-Organic Solvent Mixtures.—In order to differentiate the rôles of a phenol molecule and a phenoxide anion (or ion-pair) on the steric course of the phenyl ether formation, the effect of the base concentration on the extent of the retention of the configuration of α-phenylethyl *p*-substituted-phenyl ether was examined in mixtures of various *p*-substituted phenols and benzene (or acetonitrile). The results are illustrated in Fig. 1 and in Table IV (see Experimental Section).

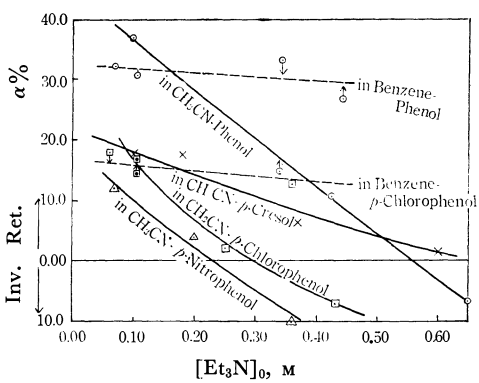

Fig. 1. Effect of base concentration on the steric course for the formation of α-phenylethyl *p*-substituted-phenyl ethers optically active α-phenylethyl chloride in *p*-substituted phenol-organic solvent mixtures (1 : 1 by weight).

In a benzene-phenol mixture (1 : 1 by weight) the extent of retention of α-phenylethyl phenyl ether shows a slight trend towards lower optical purities at higher triethylamine concentrations; this trend becomes more pronounced in an acetonitrile - phenol mixture (1 : 1 by weight). Finally, the run carried out in the presence of 0.65 M triethylamine afforded α-phenylethyl phenyl ether with an "inverted" configuration.

Similarly, in a *p*-chlorophenol - acetonitrile mixture (1 : 1 by weight), the net steric course of *p*-chlorophenolysis changes from a 37% retention to a 6.5% inversion as the concentration of triethylamine is increased from 0.1 to 0.6 M ,whereas in a benzene - *p*-chlorophenol mixture (1 : 1 by weight) the extent of retention of α-phenylethyl *p*-chlorophenyl ether does not show such a large decrease in optical purities as in the mixtures of acetonitrile - *p*-chlorophenol.

Similar trends are also observed in *p*-cresolysis and in *p*-nitrophenolysis in mixtures of these phenols and acetonitrile (1 : 1 by weight).

These results suggest that the reactions of the phenoxide anions of various phenols (or the triethylammonium salt of these phenols) with the S_Ni intermediate proceed predominantly with an inversion of the configuration. Accordingly, it may be concluded that the reaction of these undissociated phenol molecules with the intermediate is responsible for the retention of the configuration.

The most probable course for the retention of the configuration caused by the reaction of a phenol molecule and the S_Ni ion-pair intermediate would be a four-center reaction, such as the one depicted below:

Table III. Steric course of *C*-alkylation in phenolysis of α-phenylethyl chloride in *p*-substituted phenol-organic solvent mixtures (1 : 1 by weight) at 40.0°C

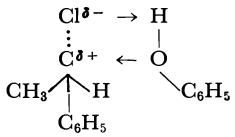
a) Rotations of starting α-phenylethyl chloride, taken neat, calcd. for $l=1$ dm.
b) Specific rotations of *p*-substituted-*o*-α-phenylethylphenol, taken in benzene.
c) See foot note d), Table I; rotations (neat, $l=1$ dm.) for optically pure materials are taken to be 27.85° for *o*-α-phenylethylphenol (see text), 10.26° for *p*-α-phenylethylphenol (see text), 17.1° for *o*-α-phenylethyl-*p*-cresol,[7] and 44.7° for *o*-α-phenylethyl-*p*-chlorophenol (calculated from the results[13] of the S_N2 reaction between optically active α-phenylethyl chloride and potassium *p*-chlorophenoxide in acetone, assuming the same optical purities for the *O*-alkylated and the *C*-alkylated product.
d) See the 7th column, Table III, except the runs 97 and 70.
e) For the mixture of ortho-isomer (90%) and para-isomer (10%).
f) Calculated for the mixture, assuming the same optical purities for the ortho and the para isomer.
g) For the mixture of ortho-isomer (79%) and para-isomer (21%).



Considering that in relatively non-polar benzene-phenol mixtures the base concentration has not so much effect on the optical purities of the ethers as in polar acetonitrile-phenol mixtures, we may suggest that the more effective reaction species in the inversion of configuration would not be triethylammonium phenoxide (an ion-pair) but, rather, a phenoxide anion (a dissociated anion).

The Determination of the Configurations and Maximum Rotations of α-Phenylethyl *p*-Chlorophenyl Ether and α-Phenylethyl *p*-Nitrophenyl Ether.—In order to establish the configuration and the maximum rotation of α-phenylethyl *p*-chlorophenyl ether, a dioxan solution of α-phenylethyl chloride, ($[\alpha]_D^{16}$ −35.4° (benzene)) and sodium *p*-chlorophenoxide was refluxed for 6.5 hr.; this gave α-phenylethyl *p*-chlorophenyl ether ($[\alpha]_D^{15}$ −5.80° (benzene)) and unchanged α-phenylethyl chloride ($[\alpha]_D^{15}$ −35.7° benzene)). From these results of the S_N2 reaction, the maximum rotation, $[\alpha]_D$ in benzene, for R-α-phenylethyl *p*-chlorophenyl ether was estimated to be −22.40° (see Experimental Section).

In order to determine the configuration and the maximum rotation of α-phenylethyl *p*-nitrophenyl ether, a dimethyl sulfoxide solution of *p*-nitrobromobenzene and potassium α-phenylethoxide, which afforded α-phenylethyl alcohol (α_D^{24} +15.6° ($l=1$ dm., neat)) after hydrolysis, was maintained at 40.0°C for 17 hr. After the usual treatment, the reaction mixture afforded α-phenylethyl *p*-nitrophenyl ether ($[\alpha]_D^{26}$ +15.3° (benzene)) and unchanged potassium α-phenylethoxide, recovered as α-phenylethyl alcohol with α_D^{26} +13.4° ($l=1$ dm., neat). Assuming that the optical activity of potassium α-phenylethoxide decreases linearly during the reaction, we took the arithmetic mean of the rotations before and after the reaction as the rotation of the α-phenylethoxide in the course of the reaction. The estimated maximum rotation of R-α-phenylethyl *p*-nitrophenyl ether amounted to +46.6° (see Experimental Section).

Part II. The Steric Course of α-Phenylethylphenol Formation in the S_N1 Phenolyses of Optically Active α-Phenylethyl Chloride

The Steric Course of Various α-Phenylethylphenol Formations in *p*-Substituted Phenol - Organic Solvent Mixtures (1 : 1 by Weight).—The phenoxide anion, as an ambident

a) Rotations of starting α-phenylethyl chloride, taken neat, calculated for $l=1$ dm.
b) Rotations of *p*-subsituted-phenyl α-phenylethyl ether, taken neat (calcd. for $l=1$ dm.) or in benzene.
c) See foot note d) Table I; the specific rotations (in benzene) of optically pure materials are taken to be −22.40° for R-α-phenylethyl *p*-chlorophenyl ether (see text), 46.6° for R-α-phenylethyl *p*-nitrophenyl ether (see text), 20.4° for S-α-phenylethyl *p*-cresyl ether. Reported value for the *p*-cresyl ether, 18°,[11] was recalculated on the basis of the new value for the maximum rotation of the chloride (see Table I, foot note d)).

ion,[6] reacts bimolecularly in acetone with α-phenylethyl chloride to afford not only α-phenylethyl phenyl ether but also *o*- or *p*-phenylethylphenol (*C*-alkylation products).[7] Accordingly, the S_N1 intermediate formed from α-phenylethyl chloride should also react with the phenoxide anion to give *C*-alkylation products as well as *O*-alkylation products (α-phenylethyl phenyl ethers). In this case, it may be anticipated that *C*- and *O*-alkylation will both have the same steric outcome, because both reactions proceed by the anion transfer mechanism. Regarding the steric course of such *O*-alkylation of the phenoxide anion, we concluded in the preceding part that the reaction proceeds with an inversion of the configuration with respect to α-phenylethyl chloride. Therefore, we can expect to obtain inverted α-phenylethylphenols also in the *C*-alkylation of the phenoxide anion by the S_N1 reaction.

The possibility of the concomitant *C*-alkylation of the phenol molecule by the S_N1 intermediate can be eliminated because its rate is slower[4] than the rate for the phenoxide anion.

Thus, we isolated the *C*-alkylated phenols in several runs carried out in the presence of a base. The yields and net steric courses of the *C*-alkylation are summarized in Table III. For purposes of comparison, the net steric courses of the *O*-alkylations are also illustrated in that table.

As expected, in all runs carried out for ten half-lives, the *C*-alkylated phenols, i. e. α-phenylethylphenol (the ortho and the para isomer), *o*-α-phenylethyl-*p*-cresol and *o*-α-phenylethyl-*p*-chlorophenol, had rotations which demonstrated that the *C*-alkylation process involved a predominant inversion of the configuration.

The Determination of the Configuration and the Maximum Rotation for *p*-α-Phenylethylphenol.—In order to determine the configuration and the maximum specific rotation for *p*-α-phenylethylphenol, the permanganate oxidation[7] of optically active *p*-α-phenylethylphenol ($[\alpha]_D^{21.5}$ +1.845° (benzene)) was conducted in acetone.

6) N. Kornblum, R. A. Smiley, R. K. Blackwood and D. C. Iffland, ibid., 77, 6269 (1955).
7) H. Hart and H. S. Eleuterio, ibid., 76, 516 (1954).

From the specific rotation of the α-phenylpropionic acid so obtained ($[\alpha]_D^{23.1}$ +14.57°), the maximum rotation of *p*-s-α-phenylethylphenol was estimated to be +10.26° (benzene). Using this value for the optically-pure para isomer and the value, −24.8°, estimated for the mixture of optically pure *o*- and *p*-s-α-phenylethylphenol (92 : 8),[7] the specific rotation for the pure ortho isomer was evaluated as −27.85° (s-configuration).

Experimental[8]

Materials.—The preparations of racemic and optically active α-phenylethyl chloride followed previous practice.[9] All the reagents employed were of a reagent-grade quality, and all were purified by fractional distillation except *p*-nitrophenol (commercial material, m. p. 111—114°C); acetone, b. p. 55.0—56.0°C; acetonitrile, b. p. 82.0—83.0°C; anisole, b. p. 152.0°C; benzene, b. p. 79.5—80.0°C; *p*-chlorophenol, b. p. 110—116°C/32 mmHg, m. p. 42.5—43.5°C; *p*-cresol, 99.5—102.0°C/24 mmHg; phenol, b. p. 180—181°C; aniline, b. p. 182—183°C; triethylamine, b. p. 89.3°C.

Kinetic Measurements.—The previous procedure[10] was followed. For the runs measured at 25.0±0.05°C, 1-cc. aliquots were removed at intervals from 20 cc. of the reaction mixture placed in a glass-stoppered flask. For the runs at 40.0±0.05°C, the usual sealed-ampoule (1 cc.) technique was employed. The diminution of base concentrations was followed by titration with standard perchloric acid in acetic acid, using crystal violet as an indicator. The phenol concentrations at the reaction temperature were calculated from the weight compositions and the densities of the phenol-organic solvent mixtures. All the rate data were treated graphically by a plot of log $a/(a-x)$ against the time. In each case the reaction was followed to at least 80% conversion and a smooth linear relationship was obtained. Infinity titers were determined after at least ten half-lives and gave reproducible results. These results are summarized in Tables I, II and IV.

The Isolation of the Reaction Products (General Procedure).—In a 100-cc. ampoule or a 100-cc. glass-stoppered round-bottomed flask, there were placed ca. 100 cc. of a mixture of a phenol, an organic solvent and the calculated amount of base (triethylamine or aniline). The concentration of the base was determined by titration of a 1-cc. aliquot (see Kinetic Measurement section). Finally, 1-cc. (0.00757 mol.) of optically active α-phenylethyl chloride was added. The sealed tube or the flask was then placed in a constant-temperature bath for at least ten half-lives. To the reaction mixture, 100 cc. of benzene was added; then the benzene solution was washed with three 70 cc.-portions of 10% aqueous sodium chloride, three 100 cc.-portions of 10% aqueous sodium hydroxide, and several 70 cc.-portions of 10% aqueous sodium chloride. After being dried with magnesium sulfate, the benzene solution was distilled and the residual oil was chromatographed over 25 g. of basic alumina. The *n*-hexane fractions afforded α-phenylethyl phenyl ether, whereas various α-phenylethyl substituted-phenyl ethers were obtained from the *n*-hexane - benzene (1 : 1 by volume) eluent. In the run in which aniline was used as the base, an excess of aniline was recovered from the benzene fractions. Various α-phenylethylphenols were obtained from the ethanol fractions. The phenyl ethers so obtained were used for the measurement of the rotation after structural verification by means of a comparison of the infrared spectrum with that of an authentic sample. Some of the ethers were sent for microanalysis. The *C*-alkylation products were distilled under reduced pressure, and the rotations of the distillates were taken in a benzene solution. These phenols were identified by infrared spectra and by microanalyses. The ortho and para compositions of α-phenylethylphenol were estimated by using the infrared spectrum of the mixture. Some of the mixtures were separated by chromatography on silica gel. The results are summarized in Tables I—IV. The details of the experimental procedure for representative runs are cited below.

The Phenolysis of Optically Active α-Phenylethyl Chloride in a Phenol-Acetonitrile (1 : 1 by Weight) Mixture (Run 53).—In a 100-cc. ampoule, 100 cc. of a mixture of phenol-acetonitrile (1 : 1 by weight), 5.00 cc. of triethylamine (0.340 mol./l.), and 1.00 cc. (0.00757 mol.) of α-phenylethyl chloride (b. p. 45—46°C/1mmHg, $\alpha_D^{15.5}$ +14.75±0.01°, 0.5 dm., neat) were placed. The ampoule was then sealed and maintained at 40.0°C for 46 hr. After the treatment mentioned above, 1.26 g. of an oily material was chromatographed over 25.0 g. of basic alumina. *n*-Hexane - benzene (1 : 1 by volume) eluent left 0.900 g. (60.1% yield, based on the starting chloride) of α-phenylethyl phenyl ether. M. p. 34.0—35.3°C (Lit. m. p. 38—39°C[11]) (Found: C, 85.09; H, 7.32. Calcd. for $C_{14}H_{14}O$: C, 84.81; H, 7.12%); λ_{max}^{neat} 8.07 μ; $\alpha_D^{15.5}$ −0.82±0.01°, 0.5 dm., neat. The ethanol (99%) fractions afforded 0.291 g. of a pale yellow oil, which was then distilled under reduced pressure to give 0.85 g. (5.67% yield) of a mixture of *o*- and *p*-α-phenylethylphenol; b. p. 110—115°C (bath, 0.3 mmHg) (Found: C, 83.17; H, 7.30. Calcd. for $C_{14}H_{14}O$: C, 84.81; H, 7.12%); $[\alpha]_D^{25.5}$ −5.38±0.33°, benzene, *c* 39.4. The ratio between the *o*- and the *p*-α-phenylethylphenol in the mixture was estimated to be 90 : 10 by infrared analysis. The characteristic bands used for the analysis were 6.62 and 6.72 μ.

The *p*-Cresolysis of Optically Active α-Phenylethyl Chloride in a Mixture of *p*-Cresol and Acetonitrile (1 : 1 by Weight) (Run 59).—Into a 100-cc. ampoule, 100 cc. of a mixture of *p*-cresol and acetonitrile (1 : 1 by weight), 2.60 cc. of triethylamine (0.182 M), and 1.00 cc. (0.00757 mol.) of α-phenylethyl chloride (b. p. 45—46°C/1 mmHg, $\alpha_D^{25.5}$ −25.11±0.015°, 0.5 dm., neat) were placed; the ampoule was sealed. After the mixture had been maintained for 65.7 hr. 40.8°C and subsequent usual treatment, 1.312 g. of an oily material was chromatographed over 25.0 g. of basic alumina. The *n*-hexane - benzene (1 : 1 by volume) eluent left 0.905 g. (56.4% of the starting chloride) of α-phenylethyl *p*-cresyl ether; m. p. 54.0—56.0°C.

8) All melting points are uncorrected. The microanalyses were performed by the Microanalytical Center, Kyoto University, Kyoto. The infrared spectra were obtained from a Shimadzu model IR-27 spectrometer. Optical rotations were measured with a Zeiss-Winkel "Kreispolarimeter 0.01°."

54.0—56.0°C (Lit. m. p. 49—50°C[11]); (Found; C, 85.02; H, 7.84. Calcd. for $C_{15}H_{16}O$: C, 84.87; H, 7.60%); $\lambda_{max}^{CCl_4}$ 8.07 μ; $[\alpha]_D^{22.0}$ +1.45±0.11° (benzene, *c* 46.16). A pale yellow oily material (0.905 g.), obtained from ethanol fractions, was distilled in vacuo giving 0.295 g. (18.4% yield) of *o*-α-phenylethyl-*p*-cresol; b. p. 125°C (bath, 0.2 mmHg.) (Lit. b. p. 175—177°C/13 mmHg[12]); (Found: C, 84.09; H, 7.90. Calcd. for $C_{15}H_{16}O$: C, 84.87 H, 7.60%); $[\alpha]_D^{21.2}$ −4.43±0.39° (benzene, *c* 31.34); λ_{max}^{neat} 2.82 and 2.96 μ.

The *p*-Chlorophenolysis of Optically-Active α-Phenylethyl Chloride in a Mixture of *p*-Chlorophenol and Acetonitrile (1 : 1) by Weight (Run 57). —A reaction mixture was prepared from 100 cc. of a mixture of *p*-chlorophenol and acetonitrile (1 : 1 by weight), 3.75 cc. of triethylamine (0.249 M; determined by titration), and 1.00 cc. (0.00757 mol.) of α-phenylethyl chloride (b. p. 45—46°C/1 mmHg, α_D^{18} −26.01±0.015°, 0.5 dm., neat.). A part (10 cc.) of the mixture was pipetted out for the rate measurement. The remaining part was sealed into a 100-cc. ampoule and kept at 40.0°C for 90.8 hr. After the usual treatment, 1.086 g. of white crystals was chromatographed over 25.0 g. of basic alumina. The *n*-hexane - benzene (1 : 1 by volume) fractions gave 0.879 g. (56.5% of the starting chloride) of α-phenylethyl *p*-chlorophenyl ether; m. p. 65—67.6°C (Lit. m. p. 66.4—67.0°C[13]); (Found: C, 72.01; H, 5.52. Calcd. for $C_{14}H_{13}OCl$: C. 72.26; H, 5.63%); $\lambda_{max}^{CCl_4}$ 8.07 μ; $[\alpha]_D^{22}$ +0.195±0.15° (benzene, *c* 41.08). An oily material (0.112 g.), obtained from ethanol fractions, was distilled in vacuo to give 0.0805 g. (a 5.7% yield) of *o*-(α-phenylethyl)-*p*-chlorophenol, b. p. 120°C (bath temp., 0.1 mmHg) (Lit. b. p. 155°C/2 mmHg[13]); (Found: C, 72.30; H, 6.38. Calcd. for $C_{14}H_{13}OCl$: C, 72.26; H, 5.63%); $[\alpha]_D^{25.8}$ −6.28±0.46° (benzene, *c* 10.98); λ_{max}^{neat} 2.85 and 2.96 μ.

The *p*-Nitrophenolysis of Optically Active α-Phenylethyl Chloride in a Mixture of *p*-Nitrophenol and Acetonitrile (1 : 1 by Weight) (Run 46).—A mixture of 49.97 g. of *p*-nitrophenol, 49.89 g. of acetonitrile, and 3.75 g. of triethylamine (0.358 M, as determined by titration) was prepared. To 100 cc. of the mixture there was added 2.00 cc. (0.0150 mol.) of α-phenylethyl chloride (b. p. 43—47°C/2 mmHg; $\alpha_D^{17.0}$ +21.07°, 0.5 dm., neat). From the reaction mixture so prepared, 8 cc. of an aliquot was removed for the rate measurement; the remaining mixture was sealed into an 100-cc. ampoule and kept at 40.0°C for 54 hr. To the reaction mixture were added 150 cc. of benzene and 150 cc. of 10% aqueous sodium hydroxide. The crystals of sodium *p*-nitrophenoxide, which precipitated in an aqueous layer, were filtered off; then the benzene solution was treated in the usual manner described above. Benzene was distilled off from the dried benzene solution, and the residue was distilled in vacuo to give 1.35 g. (37% yield, based on the chloride) of α-phenylethyl *p*-nitrophenyl ether; b. p. 122—124°C/0.1 mmHg; $[\alpha]_D^{17.2}$ −1.55±0.04° (benzene, *c* 6.29); (Found: C, 69.92; H, 5.47. Calcd. for $C_{14}H_{13}O_3N$: C, 69.12; H, 5.39%). For the authentic sample, see below.

Optically Active α-Phenylethyl *p*-Nitrophenyl Ether from Optically Active Potassium α-Phenylethoxide and *p*-Bromonitrobenzene.—Potassium α-phenylethoxide was prepared in 50 cc. of *t*-butanol (b. p. 81.8°C) from 5.10 g. (0.042 mol.) of α-phenylethyl alcohol (b. p. 68.5°C/5 mmHg, $\alpha_D^{22.3}$ +9.995°, 0.5 dm., neat) and potassium *t*-butoxide, which had been prepared by the addition of 1.41 g. (0.036 g.-atom) of potassium to *t*-butanol. After the distillation of the *t*-butanol, the excess α-phenylethyl alcohol was evaporated in vacuo, leaving 5.95 g. (0.036 mol.) of crude potassium α-phenylethoxide.

The optical purity of the potassium α-phenylethoxide was determined by the measurement of that of the recovered α-phenylethyl alcohol after the hydrolysis. A part (1.53 g.) of the potassium α-phenylethoxide was hydrolysed by the addition of 10 cc. of water; the alcohol was extracted with ether, and the oily material obtained after the evaporation of the ether was chromatographed over 25 g. of basic alumina. Ether fractions afforded 0.226 g. of acetophenone (identity established by a study of the infrared spectrum), and the ethanol fractions gave 0.574 g. of a yellow oil, which was distilled in vacuo to yield 0.4373 g. of α-phenylethyl alcohol, b. p. 75°C/6 mmHg, $\alpha_D^{24.4}$ +7.78±0.02° (0.5 dm., neat), identified by a study of the infrared spectrum.

To the solution of the optically active potassium α-phenylethoxide (1.60 g.) in dimethyl sulfoxide (50 cc., b. p. 81.0°C/2 mmHg.), 1.80 g. (0.00892 mol.) of *p*-bromonitrobenzene (m. p. 117—120°C) was added. After 17 hr. at 40.0°C under a nitrogen atmosphere, 40 cc. of ether was added to the black reaction mixture; the mixture was then washed with 50 cc. of 10% aqueous sodium chloride. The ether solution was dried with magnesium sulfate and evaporated under reduced pressure to give a black viscous mass, which was then extracted with *n*-hexane. The aqueous layer was extracted with *n*-hexane, and the combined *n*-hexane extracts were dried with magnesium sulfate and evaporated in vacuo to yield 1.4023 g. of an oil containing yellow crystals. The mixture was chromatographed over 25 g. of basic alumina. The first half of the *n*-hexane - benzene fractions gave 0.5108 g. of *p*-bromonitrobenzene (m. p. 111—119°C), while the second half afforded 0.1475 g. of α-phenylethyl *p*-nitrophenyl ether, m. p. 65.5—67.0°C; $[\alpha]_D^{25.9}$ +15.28 ±0.43° (benzene, *c* 14.22); $\lambda_{max}^{CCl_4}$ 7.97 μ.

Found: C, 68.70; H, 5.41. Calcd. for $C_{14}H_{13}O_3N$: C, 69.12; H, 5.39%.

The ether fractions afforded 0.013 g. of an oil, while the ether-ethanol (1 : 1 by volume) fractions gave 0.2527 g. of an oil. The combined oily materials were distilled under reduced pressure to give 0.1369 g. of α-phenylethyl alcohol, b. p. 58.0°C/2 mmHg, $\alpha_D^{25.6}$ +6.70±0.104° (0.5 dm., neat). From these results, the maximum specific rotation of α-phenylethyl *p*-nitrophenyl ether has been estimated to be as follows: 15.28×44.2/(7.78×6.70)=46.6° (benzene) (see text).

Optically Active α-Phenylethyl *p*-Chlorophenyl Ether from Sodium *p*-Chlorophenoxide and Optically Active α-Phenylethyl Chloride. — To ethanolic sodium ethoxide, prepared from 0.33 g. (0.0147 g.-atom) of metallic sodium and 25 cc. of 99% ethanol, there was added 1.92 g. (0.0149 mol.) of *p*-chlorophenol; the solution was then evaporated in

vacuo to give white crystalls of sodium *p*-chlorophenoxide. A solution of sodium *p*-chlorophenoxide was prepared by refluxing a mixture of the chlorophenoxide crystals so prepared and 88 cc. of dioxan (b. p. 101.0—102.0°C). α-Phenylethyl chloride (1.00 cc., 0.00760 mol., b. p. 45—46°C/1 mmHg), $\alpha_D^{16.6}$ −16.20° (0.5 dm., neat), $[\alpha]_D^{16.0}$ −35.43° (benzene, *c* 6.833) was then added to the solution, and the mixture was refluxed for 6.3 hr. The reaction mixture was concentrated, and, after the addition of 80 cc. of benzene, the solution was washed with 120 cc. of 10% aqueous sodium chloride, two 50-cc. portions of aqueous sodium hydroxide, and seven 50-cc. portions of 10% aqueous sodium chloride. The benzene layer was dried with magnesium sulfate and evaporated under reduced pressure to give an oily material, which was distilled in vacuo to afford 0.40 g., of α-phenylethyl chloride (b. p. 35—37°C/0.5—0.8 mmHg, $[\alpha]_D^{15.2}$ −35.7°, benzene, *c* 13.78) and 0.30 g. of an oil (b. p. 105—120°C/0.7—1.0 mmHg.). The redistillation of the oil afforded 0.20 g. of *p*-chlorophenyl α-phenylethyl ether, b. p. 130—140°C (bath temp., 0.5 mmHg); $[\alpha]_D^{15.2}$ −5.80±0.06°, benzene, *c* 17.23; m. p. 64.0—65.5°C (99% ethanol) (lit. m. p. 66.4—67.0°C[13]); (Found: C, 72.01; H, 5.52. Calcd. for $C_{14}H_{13}OCl$: C, 72.25; H, 5.63%); $\lambda_{max}^{CCl_4}$ 48.07 μ. The maximum specific rotation of α-phenylethyl *p*-chlorophenyl ether was estimated to be as follows: (5.80×125)/(16.20×2)=22.40° (benzene) (see text).

The Phenolysis of Optically Active α-Phenylethyl Chloride in a Phenol Benzene Mixture (1 : 1 by Weight) (Run 97).—A triethylamine solution (0.408 M) in a phenol-benzene mixture was prepared from 11.4 cc. of triethylamine and 190 cc. of a mixture of benzene and phenol (1 : 1 by weight). After the solution had been kept in a 200-cc. round-bottomed flask at 40.0°C for 0.5 hr., 5.06 g. of α-phenylethyl chloride ($\alpha_D^{17.8}$ +27.33°, 0.5 dm., neat) was added to the solution. After a 3 hr. reaction and the subsequent addition of 200 cc. of benzene, the benzene solution was washed with two 50-cc. portions of 10% aqueous sodium hydroxide, and ten 100-cc. portions of 10% aqueous sodium hydroxide, and ten 100-cc. portions of 10% aqueous sodium chloride, and then dried with magnesium sulfate. After the concentration of the solution, 7.4 g. of a yellow-brown oil was chromatrographed over 70 g. of silica-gel (Nakarai, No. F 1, 100—200 mesh). The column was eluted with *n*-hexane - benzene (1 : 1 by volume) and then with benzene, 45-cc. portions being taken. Fractions 1—6, using *n*-hexane - benzene, gave 4.204 g. of α-phenylethyl ether, m. p. 30.0—31.5°C, $\alpha_D^{16.6}$ −2.325° (0.5 dm., neat); λ_{max}^{neat} 8.07 μ, while fractions 8—15, using benzene, gave 0.980 g. of *o*-(α-phenylethyl)-phenol, b. p. 130—131°C/2 mmHg (Lit. b. p. 127—127.5°C/0.9 mmHg[14]); n_D^{30} 1.5850 (Lit.[14] n_D^{20} 1.5923); $\alpha_D^{16.6}$ −2.325° (0.5 dm. neat); λ_{max}^{neat} 2.34 μ; (Found: C, 84.26; H, 7.14. Calcd. for $C_{14}H_{14}O$: C, 84.81; H, 7.12%) and fractions 19—52, using benzene, afforded 0.914 g. of *p*-(α-phenylethyl)-phenol, m. p. 49.0-51.0°C (Lit. m. p. 56.0—56.3°C[14]); $[\alpha]_D^{21.5}$ +1.845±0.07° (benzene, C 30.37); $\lambda_{max}^{CCl_4}$ 2.73 and 2.99μ; (Found: C, 84.84; H, 6.88. Calcd. for $C_{14}H_{14}O$: C, 84.81; H, 7.12%). An intermediate fraction, 7, using benzene, 10.6 mg. of a mixture of α-phenylethyl phenyl ether and *o*-(α-phenylethyl)-phenol, and the other intermediate fractions, 16—18, afforded 39.6 mg. of a mixture of *o*- and *p*-(α-phenylethyl)-phenol. On the basis of the infrared spectra, the intermediate fractions were estimated to be 1 : 1 mixtures of the relevant two components. The total analysis was 4.209 g. (62.5% of the chloride) of α-phenylethyl phenyl ether; 1.054 g. (14.8% yield) of *o*-(α-phenylethyl)-phenol, and 0.934 g. (13.3% yield) of *p*-(α-phenylethyl)-phenol.

The Oxidation of Optically Active *p*-(α-Phenylethyl) - Phenol to α-Phenylpropionic Acid. — Optically active *p*-(α-phenylethyl)-phenol was oxidized according to the procedure of Hart and Eleuterio.[7] To a solution of 0.6722 g. (0.00339 mol.) of *p*-(α-phenylethyl)-phenol, obtained in the run 97 ($[\alpha]_D^{21.5}$ +1.845°, benzene, *c* 30.37), in 200 cc. of acetone, there was added 4.1 g. of potassium permanganate in 200 cc. of water at 13—15.5°C for 25 min. The mixture was then stirred for 1.8 hr. and acidified with 6 N sulfuric acid, and the precipitated manganese dioxide was destroyed with sodium bisulfite. The mixture was extracted with 10% sodium bicarbonate (four 50-cc. portions), and the extracts were acidified with 90-cc. of 6 N hydrochloric acid and extracted with four 50-cc. portions of benzene. The benzene solution was dried with magnesium sulfate, after the solvent had been removed, it was distilled in vacuo to give 96.8 mg. (19.0% yield) of α-phenyl-propionic acid, b. p. 120°C (bath temp., 0.2 mmHg) (Lit. b. p. 145—148°C/15 mmHg[7]); n_D^{20} 1.5239; neut. equiv. 151.4 (Calcd. 150); $[\alpha]_D^{23.1}$ +14.57° (ethanol, *c* 14.46). Since this reaction does not involve the asymmetric carbon atom, the configurations of α-phenylpropionic acid and *p*-(α-phenylethyl)-phenol should be identical. Thus, the specific rotation of optically pure *p*-(s-α-phenylethyl)-phenol may be estimated to be +10.26° (in benzene) (Lit. $[\alpha]_D$ +7.78°, benzene[15]) on the basis of the value for optically pure s-α-phenylpropionic acid, +81.1° (in ethanol).[7]

Kinetic Studies of Solvolysis. XII.* The Question of a Single Mechanism for the "Borderline" S_N Reactions — The Solvolysis of Optically Active α-Phenylethyl Chloride in Aqueous Ethanol

By Kunio OKAMOTO, Nobuko UCHIDA, Seiki SAITÔ and Haruo SHINGU

Department of Fuel Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received July 14, 1965)

Competitive solvolysis has been conducted in binary solvents of water and ethanol on optically active α-phenylethyl chloride at 40.0°C. The extents of inversion (α%) for solvolysis products, i. e., α-phenylethyl alcohol and α-phenylethyl ethyl ether, have been calculated from the optical rotations of these products isolated after ten half-lives, and the values of α% have been plotted vs. the volume percentage of water. In the region of 90% aqueous ethanol, the two α% lines for the alcohol and the ether intersect with each other. This intersection of the two lines conflicts with any single mechanism for the borderline S_N reactions, whereas the dual mechanism can explain this phenomenon without any difficulty. In the region of a 100% water-solvent (a typical medium for the S_N1 solvolysis), the two lines do not converge to the same α% value. On the basis of these findings, a general mechanism of racemization for the S_N1 solvolysis has also been discussed.

The single and the dual mechanisms for the "borderline" S_N reactions have been a long-standing question, and there have been several arguments in support of both sides.[1-6]

On the basis of reaction kinetics, which describes the homogeneous reaction in a solution or in the gas phase as a combination of elementary reactions (Urreaktionen[7]) with "integral" molecularity, the view[4,6] that a borderline reaction must be expressible as a sum of concurrent elementary reactions, i. e., the unimolecular (S_N1) and the bimolecular (S_N2) process, seems to be only the self-evident representation of the borderline cases; there have been in the literature several examples of borderline cases which cauld be explained on the basis of the dual mechanism.[8]

On the other hand, if one ignored the significance of the reaction-kinetical mechanism mentioned above, the view[1-3] that a single mechanism of an intermediate character operates in borderline S_N reactions might be superficially tempting inasmuch as there have been presented no definitive experimental results which are inexplicable by this single mechanism.

Thus, the question as to which picture is more reasonable has been currently described as "difficult"[9] or "to some extent a question of definition."[10]

However, Weiner and Sneen[5] recently presented data which they interpreted to mean that two distinct paths, i. e., the S_N1 and the S_N2 processes, were followed in a borderline case. Namely, when the hydrolysis of optically active 2-octyl brosylate was conducted in the presence of large amounts of sodium azide, the resulting inverted 2-octanol, formed in competition with 2-octyl azide, proved to be 100% optically pure. If one recognized that sodium azide (a strong nucleophile) would react preferentially with the S_N1 intermediate to form alkyl azide, thus preventing its conversion to alcohol, and that a nucleophilic S_N2 displacement by water would furnish inverted alcohol, the data mentioned above would consequently mean the presence of two distinct paths for the hydrolysis of 2-octyl brosylate.

In this paper we will report on a new phenomenon observed in the competitive hydrolysis and ethanolysis of optically active α-phenylethyl chloride, a phenomenon which also seems to favor the dual mechanism.

The Extent of Inversion for the Products of the Competitive Solvolyses of Optically Active α-Phenylethyl Chloride in Aqueous Ethanol. —Solvolysis was conducted in mixtures of water with ethanol at 40.0°C on optically active α-phenylethyl chloride. After ten half-lives, as calculated from the rate constants interpolated from the data[11] at other temperatures, α-phenylethyl alcohol and α-phenylethyl ethyl ether with an inverted configuration, accompanied by racemization, were isolated by elution chromatography over basic alumina. The styrene were found to amount at most to 3% of the chloride in the solvent range from 50 to a 95% aqueous ethanol (see Table II). The extent of inversion for the alcohol and that for the ether were calculated from the optical rotations of these reaction products. The results are shown in Fig. 1 in the form of a plot of α% (the degree of inversion) vs. the volume percentage of water in aqueous ethanol solvents.

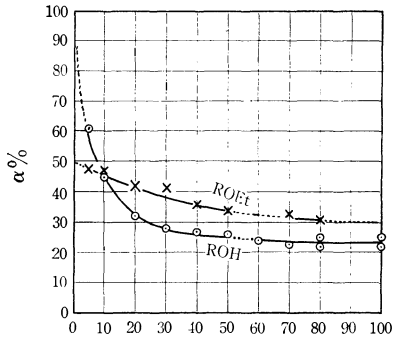

Fig. 1. Extent of inversion (α%) of solvolysis products of α-phenylethyl chloride in aqueous ethanol at 40.0°C.

For the solvent ranges of 60 to 100% water, the solvolyses were conducted under heterogeneous conditions; the reaction was continued until at least 98% of the chloride has been converted to hydrogen chloride. Despite the difference in stirring conditions, the extents of inversion for duplicate runs carried out in 100% water and in 80% water were similar to each other (see Fig. 1). Therefore, these results in heterogeneous regions seem actually to be caused by homogeneous reactions with rather low concentrations of the chloride.

As is illustrated by the α% line in Fig. 1, the degree of inversion for the α-phenylethyl alcohol so formed decreases from 61 to 25% as the water content of these binary solvents is increased from 5 to 50%; then at higher water contents it remains relatively constant at a level of from 22 to 25%.

The extent of inversion for α-phenylethyl ethyl ether also diminishes from 47 to 34% upon an increase in water content from 5 to 50%, while at higher water contents it remains at a level of about 30%.

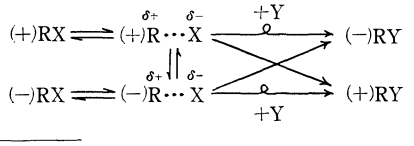
The possible racemization of α-phenylethyl alcohol in the presence of hydrogen chloride under the reaction conditions has been ruled out, since it was found that in 90 and 70% aqueous ethanol and in water optically active α-phenylethyl alcohol was not appreciably racemized (less than 3%) in the presence of 0.1 to 0.5 N hydrogen chloride at 40.0°C for the reaction time for which each solvolysis was conducted (Table III).

An Interpretation of the Results in Solvent Ranges Close to 100% Water.—In 100% water or in the solvent ranges close to it, the solvolysis of α-phenylethyl chloride proceeds by a typical S_N1 mechanism; this may be understood as follows.

The solvolysis rate of this compound is known to be 10^5[12] as high in water as in 100% ethanol; this rate ratio is enormously high compared with the ratio (10-10^2[13]) to be expected in "S_N2" solvolyses in water and in 100% ethanol. Therefore, the possibility of inversion due to the S_N2 hydrolysis may be ruled out in these solvent ranges and the observed extent of inversion may be derived exactly from the stereochemical characteristics of the "S_N1" solvolysis.

If one assumes for the S_N1 solvolyses that an optically active S_N1 intermediate reacts with all molecules of the nucleophile on its back-side as a result of the presence of the anionic-leaving group on the front-side, and that the racemization of the product is caused only by the intramolecular inversion of the intermediate to its antipode,[14] the extents of the inversions of the products of two kinds, formed by the competitive back-side attack of nucleophiles of two kinds, should be the same as one another. Actually, however, this is not the case. The α% line for α-phenylethyl ethyl ether runs at a higher level than that for α-phenylethyl alcohol, as is illustrated in Fig. 1.

This gap in the α% lines can be explained by the following general mechanism for the racemization, a mechanism which contains a third path to the product, i. e., the front-side attack of a nucleophile on the intermediate, in addition to the above mentinoed two paths to the products (an intramolecular inversion of the intermediate and a back-side attack of a nucleophile on the intermediate). This may be schematically illustrated as follows.



11) A. H. Fainberg and S. Winstein, *J. Am. Chem. Soc.*, **79**, 1597 (1957).

12) At 50°C, Ref. 11.

13) e. g., for the S_N2 solvolyses of methyl bromide k_{H_2O}: k_{EtOH} ratio is estimated to be 26.8 at 50°C.[1]

14) See a) K. Okamoto, K. Takeuchi and H. Shingu, This Bulletin, **35**, 525 (1962); b) H. Weiner and R. A. Sneen, *J. Am. Chem. Soc.*, **87**, 292 (1965).

According to this general mechanism for racemization, the extent of the inversion of the product is controlled not only by the intramolecular inversion of the optically active intermediates, but also by the competition of the front- and back-side attack of a nucleophile. As a result of this competition, the extents of inversion (or retention) should vary significantly with the nature of the nucleophile. In our experiments, as may be expected from this mechanism, the extents of inversion for α-phenylethyl alcohol and α-phenylethyl ethyl ether are not the same; this is reflected by the different natures of the two attacking nucleophiles, water and ethanol.

An Interpretation of the Results in Solvent Ranges Close to 100% Ethanol.—In 95% aqueous ethanol, both α-phenylethyl alcohol and α-phenylethyl ethyl ether show rather high optical purities, 61 and 47% respectively. In addition, as is illustrated in Fig. 1, the α% line of α-phenylethyl alcohol for the solvent ranges close to 100% ethanol can be extrapolated to 100% from the values for 95 and 90% aqueous ethanol solvents, whereas the α% line for α-phenylethyl ethyl ether points to a value of about 50% for a 100% ethanol solvent.

According to the dual mechanism, this would indicate that in the solvent ranges from 95 to 100% ethanol most of the water molecules react with α-phenylethyl chloride by means of S_N2 mechanism, whereas in the same solvent ranges ethanol molecules react by means of both S_N1 and S_N2 mechanisms and a significant part (at least 50%) of the ethanol molecules still react by means of the S_N1 mechanism.

The facts observed in these solvent ranges might also be explicable by the single mechanism. According to the single mechanisms,[1-3] which postulate only one transition state for a single borderline case, one could assume transition states of two kinds corresponding to the competitive hydrolysis and ethanolysis in 95% aqueous ethanol. Thus, if one uses the representation for the transition state of the single mechanism proposed by Winstein et al.,[1] the greater extent of inversion for α-phenylethyl alcohol as compared with that for α-phenylethyl ethyl ether would be explained by the greater contribution of the sturcture II[1] (see below) for the transition state containing more nucleophilic water molecules as compared with that for the transition state composed of less-nucleophilic ethanol molecules.

$$\underset{\text{I}}{Z:\ R\text{–}X} \longleftrightarrow \underset{\text{II}}{Z\text{–}R:\ X} \longleftrightarrow \underset{\text{III}}{Z:\ R:\ X}$$

(RX, α-phenylethyl chloride; Z, water or ethanol)

Furthermore, if one uses the terms[15] derived from the conception of a "concerted" displacement reaction, i. e., a single mechanism proposed by Swain,[3,15] this fact would be explicable as due to the greater "bond-making" extent at the transition state of hydrolysis as compared to that of the ethanolysis, since the extents of "bond-breaking" in ethanolysis and hydrolysis would be identical in this binary solvent.

However, as will be illustrated in the following section, the intersection of two α% lines for α-phenylethyl alcohol and for α-phenylethyl ethyl ether seems difficult to explain by any single mechanism.

The Inadequacies of the Single Mechanism in Interpreting the Intersection of Two α% Lines.—According to the single mechanism, the greater extent of inversion for α-phenylethyl alcohol than that for α-phenylethyl ethyl ether may be anticipated not only for a 95% aqueous ethanol solvent but also for the solvent ranges with a much greater water content in this binary solvent, because the contribution of the structure II or the extent of "bond-making" for the transition state composed of the water molecule with the greater nucleophilic reactivity should become greater as the content of water is increased in aqueous ethanol solvents, whereas the extent of "bond-breaking" or the contribution of the structure III in the transition state would be of the same magnitude for both hydrolysis and ethanolysis in this binary solvolytic medium.

As is illustrated in Fig. 1, however, the two α% lines intersect with each other in the region of 90% aqueous ethanol, and in the solvent ranges with a higher water content the α% line for α-phenylethyl alcohol runs at a lower level than that for α-phenylethyl ethyl ether. This is in conflict with the above-mentioned anticipation of the single mechanism, which expected the α% line for the alcohol to run at a higher level than that for the ether over the entire range of this binary solvent.

On the other hand, the intersection of two α% lines does not conflict with the dual mechanism; it may be interpreted as an incidental result of the superposition of two α% lines corresponding to the concurrency of two independent reaction, i. e., hydrolysis and ethanolysis, each of which is composed of S_N1- and S_N2-type reactions.

Experimental[16]

Materials.—The preparation of optically active and racemic α-phenylethyl chloride followed previous practice.[17] The solvolysis infinity values indicated a purity of from 98 to 99% for the chloride. Ethanol

15) C. G. Swain and W. P. Langsforf, *J. Am. Chem. Soc.*, **73**, 2813 (1951).

16) Optical rotations were measured with a Zeiss-Winkel "Kreis-Polarimeter 0.01°." The infrared spectra were obtained on a Shimadzu model IR-27. The ultraviolet spectra were obtained with an Shimadzu model UV-50M. The gas-liquid chromatograms were obtained with an Ohkura model 2100 equipped with a flame ionization detector.

a) Taken at 25—28°C.

was purified by the process of Lund and Bjerrum.[18] Aqueous ethanol solvents (x vol.%) were prepared by mixing x volumes of ethanol and $100-x$ volumes of water, each with temperatures of from 20 to 25°C before mixing. Racemic α-phenylethyl ethyl ether for an authentic sample was prepared by refluxing α-phenylethyl chloride (6.7 g.) in 99% ethanol (175 cc.) for 10 hr. After the usual treatment, 5.19 g. (71.2% yield) of racemic α-phenylethyl ethyl ether, b. p. 54.0°C/5 mmHg; $n_D^{30.0}$ 1.4821, was obtained. Racemic α-phenylethyl alcohol, the commercial material, was distilled in vacuo b. p. 85—86°C/7 mmHg.

Results.—The details of the results for solvolyses in aqueous ethanols are tabulated in Table I. The results of composition analyses of the solvolysis products are illustrated in Table II. α-Phenylethyl alcohol and α-phenylethyl ethyl ether were estimated by the gas-liquid chromatography of the reaction mixtures. The column was made from 4.0 mm. i. d. × 4 m. annealed copper tubing. The packing was prepared from Diasolid (60—80 mesh) using PEG 6000 as a liquid; the packing was 5% liquid phase by weight. The retention times for α-phenylethyl alcohol and α-phenylethyl ethyl ether were, respectively, 7.5—8.5 and 17.5—18.0 min.; these times were determined at 160°C using nitrogen as the carrier gas (flow rate 50—60 cc./min.). Because of the failure to separate the styrene peak and the α-phenylethyl alcohol peak under the operation conditions of this chromatography, the concentration of styrene in the reaction mixtures was estimated by ultraviolet spectroscopy, using 244 mμ as a characteristic band for styrene. The cell length was 1 cm.; one volume of the reaction mixture was diluted with 99 volumes of distilled water. Absorbances caused by the benzenoid absorption of α-phenylethyl alcohol and α-phenylethyl ether were subtracted from the observed styrene absorbance of the sample. The precentage of α-phenylethyl alcohol as estimated by gas-liquid chromatography was corrected by the subtraction of the styrene percentage.

The results of racemization experiments for α-phenylethyl alcohol in the presence of hydrogen chloride are illustrated in Table III. The details of procedures for the isolation of the solvolysis products and for the racemization experiments of α-phenylethyl alcohol are illustrated in the descriptions of some representative runs which follow.

The Solvolysis of Optically Active α-Phenylethyl Chloride in 80 vol.% Aqueous Ethanol at 40.0°C.—To 100 cc. of 80 vol.% aqueous ethanol in a 200-cc. round-bottomed flask maintained at 40.0°C, 2.16 g. (0.0154 mol.) of α-phenylethyl chloride, $\alpha_D^{24.9}$ −13.240° (0.5 dm., neat); b. p. 56.0°C/3 mmHg. was added. After it has been maintained for 30.2 hr. at 40.0±0.05°C, the reaction mixture was neutralized with 0.65 g. of sodium hydroxide pellets and then fractionally distilled to give 80 cc. of ethanol, b. p. 77—80°C. To the residue 7.0 g. of sodium chloride was added, and the organic layer was extracted with three 15-cc. portions of ether. The concentration of the combined ether solutions, dried with magnesium sulfate, afforded an oily material which was distilled in vacuo to give 1.01 g. of the mixture of α-phenylethyl alcohol and α-phenylethyl ethyl ether, b. p. 55—60°C/5—4 mmHg. The mixture was then chromatographed over 25 g. of basic alumina. The fractions (No. 1—5, for each 25 cc.) eluted with n-hexane consisted of α-phenylethyl ethyl ether, (0.29 g., b. p. 37°C/2 mmHg; $\alpha_D^{24.2}$ +4.20° (0.5 dm., neat) n_D^{30} 1.4840). α-Phenylethyl alcohol (0.309 g.; b. p. 64°C/3 mmHg; $\alpha_D^{25.2}$ +1.475° (0.5 dm., neat) n_D^{30} 1.5231) was eluted with 99% ethanol fractions (Nos. 8 and 9, for each 15 cc.). The alcohol and the ether showed infrared spectra identical with those of the authentic samples.

The Heterogeneous Solvolysis of Optically Active α-Phenylethyl Chloride in Water.—To 110 cc. of water, maintained at 40.0°C, in a 100-cc. four-necked flask equipped with a reflux condenser, a stirrer and a thermometer, there was added 2.00 g. (0.0142 mol.) of α-phenylethyl chloride, $\alpha_D^{24.1}$ +6.155° (0.5 dm., neat); b. p. 54.0°C/5 mmHg, in one portion. After a 0.7 hr. stirring, the reaction mixture was extracted with five 20-cc. portions of ether. The concentration of the combined ether solutions, dried with magnesium sulfate, afforded 1.76 g. of an oily material which was then distilled in vacuo to give 1.47 g. of α-phenylethyl alcohol, $\alpha_D^{24.4}$ −0.488° (0.5 dm., neat); n_D^{30} 1.5239; b. p. 66°C/5 mmHg; identical infrared spectrum with an authentic sample.

An Examination of the Racemization of Optically Active α-Phenylethyl Alcohol in 90% Aqueous Ethanol in the Presence of 0.15 N Hydrogen Chloride.—To 54 cc. of 0.15 N hydrogen chloride in 90% aqueous ethanol, prepared by mixing 7.00 cc. of concentrated hydrogen chloride and 63 cc. of 100% ethanol in a 100-cc. round-bottomed flask, 1.00 g. (0.00821 mol.) of α-phenylethyl alcohol ($\alpha_D^{22.9}$ +5.965° (0.5 dm., neat)) was added. After it had stood for 120 hr. at 40.0°C, the mixture was neutralized with 0.30 g. of sodium hydroxide pellets (silightly basic to litmus) and then fractionally distilled to give 36 cc. of ethanol. To the residue 10 g. of sodium chloride was added; it was then extracted with five 15-cc. portions of ether. The combined ether extracts were concentrated and distilled in vacuo to give 0.80 g. of α-phenylethyl alcohol, b. p. 84°C/6 mmHg, $\alpha_D^{24.9}$ +5.965° (0.5 dm., neat.)

The authors wish to thank Mr. Yoshihisa Matsui for his assistance in the analyses of styrene.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 312—315 (1966)

The Volatile Constituents of Some Plants of the Compositae Family

By Naoko TSUBAKI, Kiichi NISHIMURA and Yoshio HIROSE

The Institute of Food Chemistry, Kita-ku, Osaka

(Received May 27, 1965)

Full analyses of the essential oils obtained from Yomena (*Aster indicus* L.), Yomogi (*Artemisia princepts* Pamp.) and Hog weed (*Ambrosia elatior* L.) were carried out. Each essential oil was separated by fractional distillation under reduced pressure, and the fractions thus obtained were identified.

The so-called Yomena and Yomogi (the *Aster indicus* L. and *Artemisia princepts* Pamp. respectively) are the most common plants of the Compositae family which grow wild all over in Japan. Hog weed (*Ambrosia elatior* L.), which was derived from North America at the beginning of the Meiji era, has been naturalized and is widely distributed in this country now.

Some studies have been reported on the essential oils obtained from these plants. Uchida[1], for instance, analyzed the oil derived from all ground parts of the Yomena obtained in the northeastern district of China and found dipentene, bornyl formate, bornyl acetate, a monoterpene alcohol with a myrtenol-like odor, a sesquiterpene hydrocarbon, and a monocyclic tertiary sesquiterpene alcohol. Nakao and Shibue[2] isolated cineol and α-thujone from the volatile oil derived from Japanese Yomogi grass, and Sörensen[3] identified a polyacetylene compound called dehydromatricaria ester in the same plant of foreign origin.

This paper will present full analyses of the essential oils obtained from these three plants of the Compositae family, Yomena, Yomogi, and hog weed.

Method

The analyses of these oils were carried out as follows. Each essential oil was subjected to fractional distillation under reduced pressure with a Podbielniaks 13 mm. Heli-Grid column, and the fractions thus obtained were analyzed by gas chromatography (GLC) and infrared spectroscopy (IR). Further fractionations by means of column chromatography on silicic acid were applied to the fractions which seemed to be complicated. Moreover, for the final estimation these methods were supplemented with ultraviolet spectroscopy, nuclear magnetic resonance spectroscopy and mass spectrometry (MS).

Gas Chromatography.—Gas chromatography was carried out using a Shimadzu GC-2C-type gas chromatograph with polyethylene glycol (30%) on celite and a Hitachi F-6 gas chromatograph with a capillary column (HB-2000). In both of these cases, nitrogen was adopted as the carrier gas.

Liquid Chromatography. — Mallinchrodt's silicic acid was used as the adsorbent, and a hexane solution of ether (3%, 5%, 10%, 30%), as the elute solvent.

Mass Spectrometry.—The mass spectrometry was measured by means of a Hitachi mass spectrometer, RMU 6-type, under the following conditions: ionization voltage, 80 V.; ion source temperature, 250°C, ion accelerative voltage, 2 kV.; inlet vapor temperature, 150°C.

Experimental and Results

Yomena Oil.—Eighty-seven kilograms of the leaves and above-ground parts of the grass gathered at the beginning of October was steam-distilled; 34 cc. of the essential oil was thus obtained. This oil was subjected to fractional distillation and divided into seven fractions. The distillation residue was then steam-distilled to recover the higher boiling components.

The results are summarized in Table I.

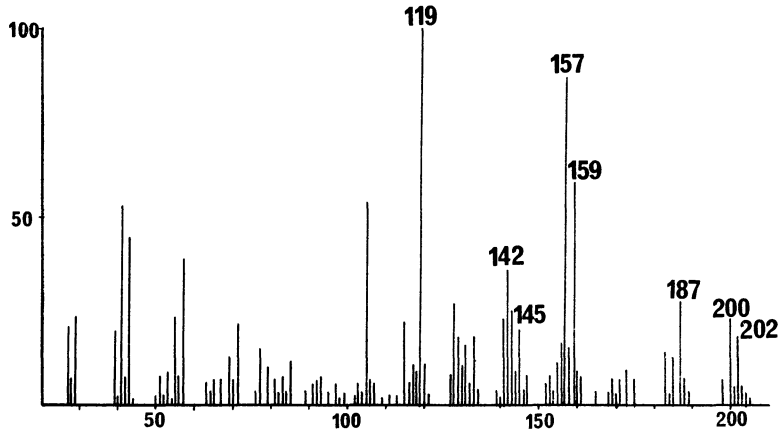

Fig. 1. The mass spectrum of calamenene fraction.

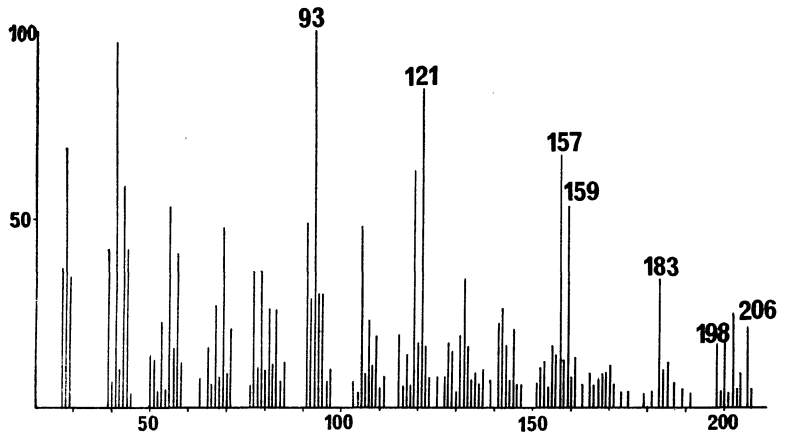

Fig. 2. The mass spectrum of calamenene and calacorene fraction.

Fraction 1 contained *p*-cymene, limonene, bornyl acetate, citronellyl acetate, phenylethyl acetate, borneol and terpineol. A hydrocarbon which was very similar to myrcene in its IR spectrum but not in its GLC was isolated from this fraction. Its spectroscopic character (IR: 6.1, 6.2, 9.02, 10.1, 11.2, 13.2 μ. UV: $\lambda_{max}^{Ethanol}$ 234.9 mμ) indicates the presence of conjugated dienes, at least one of which has an end methylenic feature. This is further supported by the fact that the hydrocarbon suffers oxidation and polymerization rather soon after being exposed to the atmosphere. These characteristics suggest that the hydrocarbon is likely to be ocimene.

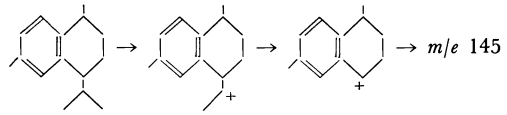
Fractions 2 to 4 were found to contain β-elemene as the main constituent, together with small amounts of bornyl acetate, benzyl alcohol, camphor, borneol and phenylethyl alcohol.

Fractions 5 to 7 and the volatile part recovered from the distillation residue were composed solely of sesquiterpene hydrocarbons. From these fractions, β-elemene, caryophyllene, humulene, α-curcumene, calamenene, δ-cadinene and γ-cadinene were identified by means of IR and GLC measurements. In addition to these compounds, a hydrocarbon corresponding to β-selinene in GLC was isolated. Its MS spectrum was also very similar to that of β-selinene. However, the IR and MS spectra of β-selinene has no remarkable characteristics to distinguish them from others, and further attempts to identify it definitely were discontinued because of the limited amount of material available.

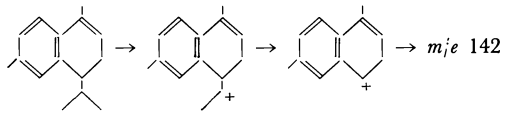
The volatiles recovered from the distillation residue contained humulene, caryophyllene, γ- and δ-cadinene, calamenene and a sesquiterpene hydrocarbon whose IR spectrum was very similar to β-cadinene. The calamenene separated by the chromatography of this fraction was shown to include calacorene by IR, GLC and MS spectrum studies. The MS spectrum of calamenene fraction is shown in Fig. 1.

The peaks at *m/e* 187, 159, 145 and 202 are derived by the fragmentation of calamenene (MW. 202), while the peaks at *m/e* 200, 185, 157 and 142 are derived by the fragmentation of calacorene (MW.

200). These fragments can be illustrated as follows:



Calamenene



Calacorene

The compounds identified from Yomena oil are listed in Table II.

Table II. Compounds identified from Yomena oil

Compound	Content, %
p-Cymene	0.4
Ocimene ?	0.9

α-Curcumene	1.3
Calamenene	4.2
Calacorene	2.8

Yomogi Oil.—Yomogi oil (160 cc.) obtained by the steam distillation of 58 kg. of the grass dried in the shade was submitted to fractional distillation under diminished pressure and then divided into 16 fractions. A mixture of borneol and camphor (15 g.) was removed from the pot material by filtration in the course of distillation, because the crystallization of those compounds at the take-off arm of the distillation column obstructs further operation; the distillation was then carried on again. The distillation residue was steam-distilled to recover the volatiles (Fraction 17).

The results are summarized in Table III.

Fractions 1 to 3 consisted of α-pinene, camphene, myrcene, *p*-cymene and cineol, which was the principal constituent of these fractions.

Table III. Fraction of the Yomogi oil

γ-Terpinene, cineol, artemisia ketone, matsutakeol and α-thujone were separated from Fraction 4 by column chromatography. Artemisia ketone was identified by comparing its IR, MS spectra and GLC results with those of an authentic sample*1 obtained from the volatile oil of *Artemisia annua* L.

Fractions 5 to 7 contained bornyl acetate, camphor, piperitone and borneol. A sesquiterpene hydrocarbon which was separated by the chromatography of Fraction 7 displayed major absorption peaks in the IR spectrum at 11.1 and 14.3 μ and gave predominant peaks in its MS spectrum at *m/e* 189, 175, 161 and 119 (base peak) indicating that it might be a patchoulene-type compound.

Fraction 8 contained ylangene, caryophyllene, β-elemene, creosol, borneol and an aromatic acid. Fractions 9 and 10 consisted mainly of caryophyllene. As Fractions 8 to 10 were shown to contain some carbonyl compounds by a study of their IR spectra, a mixture of these fractions was treated by a Girard T reagent in the usual manner; the small amounts of carbonyl compounds were separated which were shown by GLC to contain at least three compounds. One of them was identified as α-ionone by means of IR, MS spectra and GLC.

Fractions 11 to 16 contained β-elemene, caryophyllene, humulene, curcumene, γ-cadinene, δ-cadinene and a sesquiterpene keotne, which gave a 2, 4-dinitrophenyl hydrazone (m. p. 167—173°C). The chromatographic fraction containing calamenene and calacorene separated from Fraction 17 was shown by its MS spectrum to include two additional hydrocarbons.

*1 The authors wish to thank Professor Tsunematsu Takemoto for providing us with an authentic sample of artemisia ketone.

The two series of peaks at *m/e* 202 and 159 and at *m/e* 200 and 157 are derived by the fragmentation of calamenene and calacorene respectively. The peaks at *m/e* 206, 121 and 93 show the existence and the fragmentation of a perhydro-sesquiterpene hydrocarbon whose molecular weight is 206. The peaks at *m/e* 198 and 183 are derived from a dehydrogenated sesquiterpene hydrocarbon, which is likely to be a naphthalene compound, such as cadalene or eudalene, with a molecular weight of 198.

The results of the analysis of Yomogi oil are shown in Table IV.

Table IV. The constituents of Yomogi oil

Compound	Content, %
α-Pinene	0.6

Hog Weed Oil.—Upon the steam distillation of the hog weed grass (60 kg.) collected in the middle of October, 19 cc. of volatile oil was obtained. The oil was subjected to fractional distillation and was divided into four fractions (Table V). Each fraction was treated in the way described above.

Table V. Fraction of hog weed grass oil

Fraction No.	Volume ml.	Calcd. b. p. °C/760 mmHg
1	2.9	155—190
2	2	190—252
3	2	252—273
4	0.7	273—300

Fraction 1 consisted solely of monoterpene hydrocarbons; the gas chromatogram of this fraction showed that these hydrocarbons were α-pinene, camphene, β-pinene, myrcene and limonene.

Fractions 2 to 4 consisted of rather complicated sesquiterpene hydrocarbons and contained at least nine compounds. The chromatographic analyses of those fractions showed the presence of ylangene, δ-cadinene, γ-cadinene and curcumene. As to the other compounds, however, no further characterization could be attained owing to the small quantities of them available and difficulties in separating them from each other.

The composition of hog weed oil is shown in Table VI.

Table VI. Composition of the volatile fraction of hog weed grass

Compound	Content, %
α-Pinene	4.7
Camphene	0.1
β-Pinene	0.5
Myrcene	0.5
Limonene	9.8
Ylangene	0.5
δ-Cadinene	2.5
γ-Cadinene	2.0
α-Curcumene	5.0
Unidentified five hydrocarbons	24.3

Summary

Volatile oils obtained from three kinds of plants of the Compositae family have been analyzed.

Yomena oil contained *p*-cymene, ocimene, limonene, borneol, camphor, bornyl acetate, citronellyl acetate, terpinyl acetate, phenylethyl acetate, terpineol, phenylethyl alcohol, benzyl alcohol, β-elemene, caryophyllene, humulene, γ-cadinene, δ-cadinene, β-cadinene, α-curcumene, calamenene, calacorene, and an aromatic hydrocarbon.

Yomogi oil contained α-pinene, camphene, myrcene, *p*-cymene, γ-terpinene, cineol, artemisia ketone, matsutakeol, α-thujone, bornyl acetate, camphor, piperitone, borneol, α-ionone, creosol, ylangene, caryophyllene, β-elemene, humulene, γ-cadinene, δ-cadinene, β-cadinene, α-curcumene, calamenene, calacorene, β-selinene, three kinds of sesquiterpene hydrocarbon, and a sesquiterpene ketone.

Hog weed oil contained α-pinene, camphene, β-pinene, myrcene, limonene, ylangene, δ-cadinene, γ-cadinene, α-curcumene and five unidentified hydrocarbons.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 316—320 (1966)

The Reactions of *cis, trans, trans*-1, 5, 9-Cyclododecatriene. IV.[1] Selective Reactions with *cis*-Addition Reagents

By Masaji OHNO, Masaru OKAMOTO and Seiichi TORIMITSU

Basic Research Laboratories, Toyo Rayon Company Ltd., Tebiro, Kamakura

(Received June 1, 1965)

The addition reactions of *cis, trans, trans*-1, 5, 9-cyclododecatriene with *cis*-addition reagents, such as osmium tetroxide, potassium permanganate, diimide, and nitrosyl chloride, have been investigated. It has been shown that the first attack of each reagent preferentially takes place at one of the *trans* double bonds. The reactions with osmium tetroxide and potassium permanganate at room temperature afforded *cis*-5, *trans*-9-cyclododecadiene-*trans*-1, 2-diol in 89 and 59% yields respectively. The glycol was then further oxidized with osmium tetroxide into *cis*-9-cyclododecene-1, 2, 5, 6-tetrol in a 60% yield. The reduction of the cyclotriene with diimide, generated in situ by the oxidation of hydrazine, afforded *cis*-cyclododecene in 60—82% yields. The addition of nitrosyl chloride in the presence of hydrochloric acid afforded 2-chlorocyclododecadienone oxime in a quantitative yield; this was then reduced into cyclododecanone oxime, obtained in a quantitative yield, by catalytic reduction with palladium-charcoal.

The discovery of an elegant synthesis of *cis, trans, trans*-1, 5, 9-cyclododecatriene (I) by means of the cyclotrimerization of butadiene with Ziegler catalysts[2,3] has prompted investigations into the reactions of this cyclotriene; the results of these investigations are summarized in Table I. On the basis of our own findings and these previous results, we would like to point out that the competitive reactivities between the *cis* and *trans* double bonds are closely connected with the mode of the addition of reagents.

The oxidation of *cis, trans, trans*-1, 5, 9-cyclododecatriene with osmium tetroxide or potassium permanganate showed a high selectivity and afforded *cis*-5, *trans*-9-cyclododecadiene-*trans*-1, 2-diol; the results are shown in the following scheme:

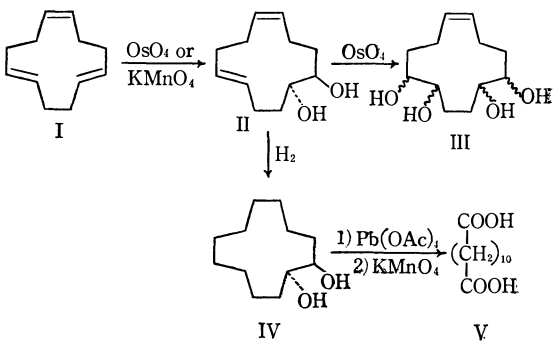

TABLE I. REACTIONS WITH VARIOUS REAGENTS

Reagent	Mole	Product	Addition mechanism	Double bond preferentially attacked	Yield, %	Ref.
Br_2	1	1-Bromocyclododecatriene Tetrabromocyclododecene	*trans*	no selectivity	61 20—30	7
Br_2	2	Tetrabromocyclododecene	*trans*	*cis* and *trans*	20—40	5, 7
Cl_2	1	Dichlorocyclododecadiene	*trans*	no selectivity	70	7
$PhCO_3H$	1	Monoepoxide	*cis*	*trans*	80—90	4, 5a
$PhCO_3H$	2	Diepoxide	*cis*	*trans* and *cis*	80	4, 5a
H_2O_2-HCO_2H	1	Monoepoxide	*cis*	*trans*	76	5b
Et_2BH	3	$(C_{12}H_{21})(BEt_2)_3$	*cis*	*	80	6
$HCl/FeCl_3$	Excess	Mono- and dichlorides	*trans*	no selectivity	20—40	8
$AcOH/BF_3$	Excess	Monoacetate	*trans*	no selectivity	50	8

* It was observed that the *trans* double bond reacted faster than the *cis* one.

cis, trans, trans-1, 5, 9-Cyclododecatriene in aqueous acetone was treated with a one-mole equivalent of potassium permanganate with stirring while being kept at 20°C. A colorless crystalline material, m. p. 168—169°C, was batined in a 59% yield and was proved to be *cis*-5, *trans*-9-cyclododecadiene-*trans*-1, 2-diol (II) by an elemental analysis of it and a study of its infrared spectrum. The infrared spectrum showed that the absorption intensity characteristic of the *trans* double bond at 980 cm^{-1} decreased, while that of the *cis* double bond at 707 cm^{-1} remained unchanged, showing that only one of the *trans* double bonds was subjected to the oxidation. The glycol was quantitatively converted into known cyclododecane-*trans*-1, 2-diol[9] (IV), m. p. 102—103°C, by catalytic hydrogenation; in turn this was converted into known dodecanedioic acid[10] (V) oxidation with lead tetraacetate and then with potassium permanganate. The same *cis*-5, *trans*-9-cyclododecadiene-*trans*-1, 2-diol was also obtained in a 89% yield from a reaction with a one-mole equivalent of osmium tetroxide at room temperature.

The further oxidation of *cis*-5, *trans*-9-cyclododecadiene-1, 2-diol with osmium tetroxide gave *cis*-9-cyclododecane-1, 2, 5, 6-tetrol (III), m. p. 212—214°C, in a 60% yield. The infrared spectrum showed only an absorption characteristic of the *cis* double bond at 707 cm^{-1}; the catalytic hydrogenation of the unsaturated tetrol yielded cyclododecane-1, 2, 5, 6-tetrol, showing no infrared absorption at 707 cm^{-1}.

Clearly, the first attack by such reagents takes place at one of the *trans* double bonds, and there is difference enough in reactivity between the *cis* and *trans* double bonds to control the product.

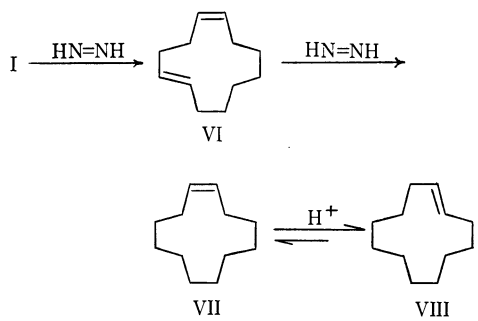
The above oxidation provides a simple method of preparing cyclododecane-*trans*-1, 2-diol, which has previously been obtained by a reaction of *trans*-cyclododecene with osmium tetroxide.[9]

Next, the reduction of *cis, trans, trans*-1, 5, 9-cyclododecatriene with diimide has been investigated in order to clarify which double bond of I is more easily reduced with diimide. As for other olefins, Hünig[11] showed that fumaric acid is more rapidly reduced than maleic acid with diimide, although Aylward[12] showed that elaidic acid is more slowly reduced than oleic acid.

cis, trans, trans-1, 5, 9-Cyclododecatriene dissolved in ethanol was treated with a large excess of hydrazine hydrate in the presence of a catalytic amount of cupric sulfate with a vigorous bubbling-in of air and with vigorous stirring for 24—48 hr. The reaction was found to be highly exothermic. Aliquots of the reaction mixture were subjected to spectroscopic and vapor-phase chromatographic analyses at intervals.

Their infrared spectra showed that only the absorption intensity at 980 cm^{-1} for the *trans* double bond decreased; that at 707 cm^{-1} for the *cis* double bond remained unchanged during the reaction.

Vapor-phase chromatography showed the presence of three components. On the basis of their retention times, two of them were confirmed to be the starting material and *cis*-cyclododecene (VII); another fraction was attributed to *cis, trans*-1, 5-cyclododecadiene (VI). No detectable amount of *trans*-cyclododecene was identified. The reaction was continued until the absorption band at 980 cm^{-1} essentially disappeared, affording a colorless liquid, b. p. 64—65°C/1.0 mmHg, in 60—82% yields from the reaction product. Vapor-phase chromatography using PEG 6000 showed that the liquid was 90—95% *cis*-cyclododecene (VII) and 5—10% cyclododecane. Pure *cis*-cyclododecene was esaily obtained by preparative gas chromatography; its infrared spectrum is completely identical with that of an authentic sample.[9] The above reactions are shown in the following scheme:



On the other hand, when the cyclododecene was subjected to equlibration by Cope's method,[13] it afforded a mixture of *trans*-cyclododecene (VIII) and *cis*-cyclododecene (VII) in a ratio of about 2 to 1.

Therefore, the attack by diimide takes palce more easily at the *trans* double bonds, and the reduction presents a simple and valuable method of synthesizing *cis*-cyclododecene, which has previously been prepared by a tedious method.[9]

Finally, the reaction of the cyclododecatriene with nitrosyl chloride was studied. The addition of one mole equivalent of nitrosyl chloride in the presence of hydrochloric acid to *cis, trans, trans*-1, 5, 9-cyclododecatriene (I), in either methylene chloride at −10°C or trichloroethylene at 10°C, was found to be exothermic and to provide 2-chlorocyclododecadienone oxime in nearly quantitative yields. It melted at 110—115°C, even after several recrystallizations from ligroin, and it was easily

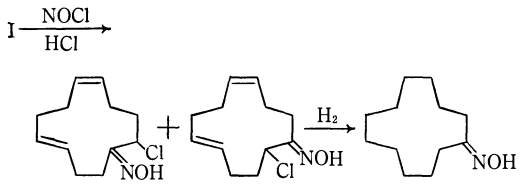
Table II. Reactions with *cis*-addition reagents

Reagent	Mole	Product	Double bond preferentially attacked	Yield, %
OsO_4	1	*cis*-5, *trans*-9-Cyclododecadiene-*trans*-1, 2-diol (II)	*trans*	89
OsO_4	2	*cis*-9-Cyclododecene-1, 2, 5, 6-tetrol (III)	*trans*	60
$KMnO_4$	1	*cis*-5, *trans*-9-Cyclododecadiene-*trans*-1, 2-diol (II)	*trans*	59
HN=NH	Excess	*cis*-Cyclododecene (VII)	*trans*	60—82
NOCl/HCl	1	2-Chlorocyclododecadienone oxime (IXa and IXb)	*trans*	95

hydrogenated to a known cyclododecanone oxime (X) by catalytic reduction. Its infrared spectra showed only that the absorption intensity at 980 cm^{-1} characteristic of the *trans* double bond decreased and that the one at 707 cm^{-1} characteristic of the *cis* double bond remained unchanged. Therefore, the product is probably a mixture of 2-chloro-*cis*-5, *trans*-9-cyclododecadienone oxime (IXa) and 2-chloro-*trans*-5, *cis*-9-cyclododecadienone oxime (IXb).



XIa XIb X

All the results obtained above are summarized in Table II.

Discussion

The results obtained by the present investigation have shown clearly that the first attack by *cis*-addition reagents, such as osmium tetroxide,[14] potassium permanganate, diimide,[15] and nitrosyl chloride,[16-18] takes place at one of the *trans* double bonds of *cis*, *trans*, *trans*-1, 5, 9-cyclododecatriene, and that, as far as *cis* addition reagents are concerned, there is difference enough in reactivity between the *cis* and *trans* double bonds to control the product.

Obviously, the selectivity of the reactions of *cis*, *trans*, *trans*-1, 5, 9-cyclododecatriene depends on the addition mechanism of the reagents, as is shown in Tables I and II.

A survey of *cis*, *trans*, *trans*-1, 5, 9-cyclododecatriene using the Dreiding model shows that there is no considerable difference in steric approach control toward the *cis* and *trans* double bonds, and that the cyclic system is so flexible that no rigid conformation can be considered.

cis, *trans*, *trans*-1, 5, 9-Cyclododecatriene is very stable to usual Lewis acids and bases[3]; this suggests that there is no marked difference in the thermodynamic stability of the *cis* and *trans* double bonds.

The reactions of mixture of *cis*- and *trans*-cyclododecene with osmium tetroxide[19] and nitrosyl chloride[3] also show a high selectivity, high enough to control the product; thus, only *trans*-cyclododecene can be converted into addition products. Therefore, it may be reasonable to assume that the reactivity of the *cis* and *trans* double bonds of *cis*, *trans*, *trans*-1, 5, 9-cyclododecatriene is very similar to that of a mixture of *cis*- and *trans*-cyclododecene.

On the other hand, Cope[20] has shown that there is a slight predominance of the *trans* isomer at equilibrium for cyclododecene (ΔF=0.49 kcal./mol.).

More strained acyclic olefins or *cis* olefins react much faster than *trans* olefins with *cis*-addition reagents, as has been demonstrated by Brown[21] in the case of the hydroboration of olefins.

However, the present investigation has disclosed that the more stable *trans* double bond of the 12-membered ring reacts preferentially with *cis*-addition reagents; no satisfactory explanation of this can be obtained from a discussion of the thermodynamic stability of the normal state of the starting material.

Such competitive reactivities might be explained in terms of the conformational stability at four-, five- and six-center transition states or intermediates in the *cis*-addition reactions. The transition states or intermediates for the *trans* double bonds seem to be more stable than those for the *cis* double bond because of the difference in eclipsing effect.[22]

Experimental

All melting points are uncorrected.

The Reaction of *cis*, *trans*, *trans*-1, 5, 9-Cyclododecatriene (I) with Potassium Permanganate.—

The cyclotriene[23] (I, 10 g.), dissolved in 200 ml. of acetone, and 40 ml. of water were placed in a 500-ml. three-necked flask equipped with a stirrer, a thermometer, and a reflux condenser. Potassium permanganate (7 g.) was added into the solution in small portions, and then the mixture was cooled at 20°C for one hour. After the reaction mixture had been stirred for 2 more hr. at room temperature, a solid fraction was removed by filtration and washed with 50 ml. of acetone. After the acetone had been removed under reduced pressure from the filtrate, a colorless solid material (7.6 g., 59%) was separated from the residue by filtration. It melted at 168—169°C after recrystallization from benzene; its infrared spectrum showed absorptions at 980 cm^{-1} for the *trans* double bond and at 707 cm^{-1} for the *cis* double bond. Therefore, the *cis*-5, *trans*-9-cyclododecadiene-*trans*-1, 2-diol (II) structure was assigned.

Found: C, 73.51; H, 10.47. Calcd. for $C_{12}H_{20}C_2$: C, 73.43; H, 10.27%.

The Reaction of *cis, trans, trans*-1, 5, 9-Cyclododecatriene (I) with Osmium Tetroxide.—The cyclotriene (I, 1.27 g.), dissolved in 50 ml. of ether, and pyridine (0.8 g.) were placed in a 100-ml. three-necked flask equipped with a stirrer, a thermometer, and a separatory funnel. An ethereal solution of osmium tetroxide (2.0 g.) was then added into the solution, the reaction temperature was kept at 0°C for over 2 hr. After the reaction mixture had been allowed to stand for 12 hr. at room temperature, it was treated with sodium bisulfite and extracted with chloroform, according to Baran's method.[24] The chloroform solution was dried over sodium sulfate; the removal of the solvent afforded 1.37 g. (89%) of a colorless material. This material melted at 168—169°C after recrystallization from benzene and was proved by a mixed melting point determination and by a study of its infrared spectrum to be identical with the product of permanganate oxidation.

The Hydrogenation of *cis*-5, *trans*-9-Cyclododecadiene-1, 2-diol (II).—The diol (II, 7 g.) dissolved in a mixed solvent of ethanol (50 ml.) and cyclohexane (50 ml.) was hydrogenated with 1 g. of 5% palladium charcoal under atomospheric pressure at room temperature.

It took 12 hr. to absorb 2 mol. equivalents of hydrogen. When, after the reaction, the solvents were removed under reduced pressure, a colorless solid (7 g.) was obtained. It melted at 103—104°C after recrystallization from ether, and its infrared spectrum was identical with that of cyclododecane-*trans*-1, 2-diol.[9]

Found: C, 71.73; H, 11.91. Calcd. for $C_{12}H_{24}O_2$: C, 71.95; H, 12.08%.

The Oxidative Cleavage of Cyclododecane-*trans*-1, 2-diol (IV).—Lead tetraacetate (6.4 g.) was added to a benzene solution of the saturated diol (IV, 3 g.). The reaction mixture was then heated for 40 min. over a steam bath. After the precipitate had been removed by filtration, the benzene solution was washed with water and dried over sodium sulfate. The removal of the solvent left 3.0 g. of a colorless solid. Its infrared spectrum showed the absorptions at 1725 cm^{-1} and 2800 cm^{-1} characteristic of an aldehyde; it was therefore considered to be dodecanedial. It was dissolved in 10% aqueous acetone (100 ml.) and further oxidized with potassium permanganate (6 g.). After the usual treatment, 2.5 g. of a colorless solid was obtained. This solid melted at 125—126°C after recrystallization from aqueous methanol and was proved to be dodecanedioic acid (V) by a study of its infrared spectrum.

Found: C, 62.79; H, 9.63. Calcd. for $C_{12}H_{24}O_4$: C, 62.58; H, 9.63%.

The Reaction of *cis*-5, *trans*-9-Cyclododecadiene-*trans*-1, 2-diol (II) with Osmium Tetroxide.—According to a procedure similar to that described above, the treatment of the unsaturated diol (II, 2.3 g.) with osmium tetroxide (3 g.) afforded 1.7 g. of a colorless solid. It was recrystallized from ether and melted at 212—214°C. Its infrared spectrum showed no absorption 980 cm^{-1} for the *trans* double bond, only an absorption at 707 cm^{-1} for the *cis* double bond; it was therefore considered to be *cis*-9-cyclododecene-1, 2, 5, 6-tetrol (III).

Found: C, 62.45; H, 9.63. Calcd. for $C_{12}H_{22}O_4$: C, 62.58; H, 9.63%.

When the unsaturated tetrol (III) was hydrogenated with palladium-charcoal, a saturated tetrol, m. p. 169—170°C, was obtained in a quantitative yield. Its infrared spectrum showed no absorption at 707 cm^{-1}.

Found: C, 61.83; H, 10.49. Calcd. for $C_{12}H_{24}O_4$: C, 62.04; H, 10.41%.

The Reduction of *cis, trans, trans*-1, 5, 9-Cyclododecatriene (I) with Diimide.—The cyclotriene (I, 60 g.), hydrazine hydrate (300 g.) and cupric sulfate (3 g.) were placed in a one-liter three-necked round-bottom flask equipped with a stirrer, a condenser, and an inlet air tube. Ethanol (200 ml.) was added to the above mixture until the reaction mixture became homogeneous. Air was bubbled into the solution with vigorous stirring. The reaction generated a considerable amount of heat, and the reaction temperature easily rose as high as 50—60°C. It was kept below 50°C by cooling it with ice-water. The reaction mixture gradually turned brown, and the blue color of the cupric ion was deposited on the wall of the reaction vessel in 30—40 hr. It took about 45 hr. for the generation of heat to become negligible. Then the reaction mixture was filtered to remove the catalyst and extracted with ether. The ethereal solution was washed with 2 N hydrochloric acid to remove the excess hydrazine; then it was washed with water and dried over sodium sulfate. The ether was removed under reduced pressure, the residue was distilled in a vacuum. A fraction (42 g.), b. p. 64—65°C/1.0 mmHg, was the main component of the reaction product, which was proved by gas chromatography (PEG 6000) to consist of 91% *cis*-cyclododecene (VII) and 9% cyclododecane. Pure *cis*-cyclododecene was obtained by a preparative gas chromatography, and the compound showed an infrared spectrum identical with that of an authentic sample.[9]

Found: C, 86.48; H, 13.32. Calcd. for $C_{12}H_{22}$: C, 86.66; H, 13.34%.

On the other hand, aliquots of the reaction mixture were subjected to infrared and vapor phase chromatographic analyses at intervals during the reaction. Their infrared spectra showed that only the absorption intensity at 980 cm^{-1} for the *trans* double bond diminished,

23) Supplied by Hüls Co., Ltd., and the sample contained 98% of *cis, trans, trans*-1, 5, 9-cyclodedecatriene and 1.8% of *trans, trans, trans*-1, 5, 9-cyclododecatriene.

24) J. S. Baran, *J. Org. Chem.*, **25**, 257 (1960).

while that at 707 cm^{-1} for the *cis* double bond remained unchanged during the reaction. Vapor phase chromatography showed the presence of three components. Two of them were confirmed by their retention times to be the starting material and *cis*-cyclododecene (VII), while the other fraction was attributed to *cis, trans*-1, 5-cyclododecadiene (VI). No detectable amount of *trans*-cyclododecene was identified.

At the end of the reaction, a small amount of cyclododecane was observed by vapor phase chromatography, and the ratio of *cis*-cyclododecene to cyclododecane was seen to depend upon the reaction time. Prolonged treatment with diimide caused an increase in the amount of cyclododecane, showing that *cis*-cyclododecene was slowly hydrogenated.

In order to confirm the structure further, the cyclododecene obtained by means of diimide was converted into cyclododecane-*cis*-1, 2-diol in the following way. The cyclododecene (1.32 g.) was dissolved in ether (40 ml.) and treated with pyridine (2 ml.) and osmium tetroxide (2 g.) for 3 days. After the adduct had been decomposed with Baran's reagent,[23] a crude glycol (1.42 g.) was obtained. It melted at 157—158°C after recrystallization from a mixed solvent of benzene and ligroin and was proved by a study of its infrared spectrum to be identical with an authentic sample prepared by Prelog.[9]

Found: C, 72.04; H, 12.05. Calcd. for $C_{12}H_{24}O_2$: C, 71.95; H, 12.08%.

The Reaction of *cis, trans, trans*-1, 5, 9-Cyclododecatriene (I) with Nitrosyl Chloride in the Presence of Hydrochloric Acid.—The cyclododecatriene (I, 200 g.) dissolved in 1 l. of trichloroethylene was placed in two-liter three-necked flask equipped with a stirrer, a condenser, and an inlet tube for nitrosyl chloride. Nitrosyl chloride (81 g.) and hydrogen chloride gas were bubbled into the solution over 3 hr. while the reaction temperature was kept below 12°C. After the addition of nitrosyl chloride, hydrogen chloride was further passed into the solution for 1 hr. After the reaction, the solvent was removed under reduced pressure and a pale yellow crude product (287 g.) was obtained. When this was recrystallized from ligroin, it showed a m. p. of 110—115°C; when it was further recrystallized from aqueous ethanol, it showed a m. p. of 127—129°C.

Found: C, 63.15; H, 7.85; N, 5.85; Cl, 15.99. Calcd. for $C_{12}H_{18}NOCl$: C, 63.3; H, 7.92; N, 6.16; Cl, 15.6%.

Its infrared spectrum showed an absorption at 980 cm^{-1} characteristic of the *trans* double bond and one at 707 cm^{-1} characteristic of the *cis* double bond, showing that one of the *trans* double bond was preferentially attacked by nitrosyl chloride. Besides the above absorptions, a N–OH absorption was observed at 3210 cm^{-1}. No skeletal change or transannular reaction was observed, since its hydrogenation with palladium charcoal afforded cyclododecanone oxime in a quantitative yield. Therefore, the product must be 2-chlorocyclododecadienone oxime (IXa and IXb).

Similar reactions using methylene chloride, chloroform, and carbon tetrachloride showed that there was no essential change in the product; 2-chlorocyclododecadienone oxime was thus afforded in yields of 60—90%.

Summary

Addition reactions of *cis, trans, trans*-1, 5, 9-cyclododecatriene (I) with *cis* addition reagents, such as osmium tetroxide, potassium permanganate, diimide, and nitrosyl chloride, have been investigated. It has been shown that the first attack of each reagent preferentially takes place at one of the *trans* double bonds. From a synthetic point of view, simple methods for preparing cyclododecane-*trans*-1, 2-diol (IV), *cis*-cyclododecene (VII), and cyclododecanone oxime (X) have been presented. An account of such selective reactions has been given in terms of conformational stabilities of the transition states or intermediates in the *cis* manner addition reactions.

The authors wish to express their thanks to Messrs. Keizo Ono, Sei Ogura and Isamu Usui for their help with these experiments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 321—326 (1966)

Studies of the Chemical Reactions of Uranium Iodide with Oxygen and Iodine at High Temperatures

By Muneo HANDA

Division of Fuel Research and Development, Japan Atomic Energy Research Institute, Tokai-mura, Naka-gun, Ibaraki

(Received June 4, 1965)

Uranium tetraiodide is oxidized to triuranium octoxide through three intermediates, which are deposited on silica powder heated to temperatures of about 400, 300 and 200°C respectively. The intermediates are produced by the action of oxygen contained in small amounts in a helium stream (1/100—1/10000 atm.) on uranium tetraiodide. The intermediates are considered to be compounds consisting of uranium, iodine and oxygen. Chemical analysis, the measurement of the melting point and X-ray analysis show that the compound deposited at the temperature of 400°C is uranium triiodide, while the compounds deposited at 300 and 200°C are both uranium tetraiodides. Three hypotheses have been formulated to interpret the above phenomenon, in which the reaction of uranium iodides with iodine has been studied.

In the author's previous studies of the chemical behavior of fission products captured in graphite powder, it was found that fission iodine diffusing out of the uranium dioxide and graphite is not an elementary iodine but a chemical form of uranium tetraiodide.[1-2] Uranium tetraiodide attracts moisture and is oxidized in air to triuranium octoxide and iodine; therefore, it should be handled in a dry, inert atmosphere. The graphite and beryllia used as moderators for a high-temperature gas-cooled reactor have many gaseous impurities, such as hydrogen, oxygen, and water vapor, adsorbed on the surface.[3] These gaseous impurities are released gradually as the reactor operates. In order to ascertain the chemical behavior of fission iodine in a reactor fuel, the reactions between uranium tetraiodide and these gaseous impurities must be studied carefully.

As has already been reported in a previous paper,[4] the reactions between uranium tetraiodide and oxygen were studied by using a thermochromatograph. It was found that uranium tetraiodide was oxidized to triuranium octoxide through three intermediates, which deposited on silica powder heated to temperatures of about 400, 300 and 200°C.

These intermediates were produced by the action of oxygen contained in small amounts in a helium stream (1/100—1/10000 atm.) on uranium tetraiodide. The intermediates were considered to be compounds consisting of uranium, iodine and oxygen, although the existence of these compounds in their solid state has not been reported in the literature.

The present work was undertaken in order to estimate the chemical form of these intermediates. Chemical analysis, melting-point measurements and X-ray analysis were carried out for these intermediates. The results of these experiments showed that these intermediates were not compounds consisting of uranium, iodine and oxygen; the compound deposited at the temperature of 400°C was uranium triiodide, while the compounds deposited at 300°C and at 200°C both consisted of uranium tetraiodide. These results indicate that uranium triiodide and tetraiodide moved to positions in the thermochromato-tube at which the temperatures were much lower than the melting points. Three hypotheses were made in order to interpret the above phenomenon; by means of these hypotheses, the reaction of uranium iodides with iodine was studied.

As a result, the following mechanism was found to account for the above phenomenon. First, the oxygen reacts with uranium tetraiodide and produces an elementary iodine. Then this iodine reacts with adjacent uranium tetraiodide, producing a compound of uranium tetraiodide to which iodine has been added. This addition compound has a low melting point, and so moves to a lower temperature in the thermochromato-tube and is decomposed to uranium triiodide, tetraiodide and iodine.

Experimental and Results

Sample Preparation. — *Uranium Tetraiodide Packed in Silica Breakable.*—Uranium tetraiodide

I: Vessel for trapping carrier gas

was prepared by the direct combination of uranium and iodine, as has been described in the literature.[5] From 0.2 to 10 g. of the uranium tetraiodide was packed in a silica breakable with a ball joint, which was in turn placed in a glove box filled with purified helium gas. Then a cock was attached to the breakable with a ball-joint holder, and the entire assembly was taken out of the glove box. The helium gas in the breakable was evacuated, and the part of the breakable containing the sample was sealed off by an oxy-hydrogen flame.[4]

Apparatus.—The apparatus used is shown schematically in Fig. 1. The apparatus had an automatic Toepler pump, making possible experiments with oxygen of various concentrations as the carrier gas. Buffer tanks were installed at the entrance and exit of the automatic Toepler pump, in order to stabilize the flow rate of the carrier gas; the volumes of these buffer tanks were 0.5 and 25.0 l. respectively. These large-volume buffer tanks can be used to keep the concentration of oxygen constant when some of it is consumed in the oxidation of the sample material.

The experimental apparatus also had a bypass gas purification system which made possible experiments with purified helium carrier gas. The thermochromato-tube, made of transparent silica, was 1.2 cm. in inner diameter and 100 cm. long. An empty silica tube was used as the thermochromato-tube, and so the sample packed in the silica breakable was held by silica wool packed in the tube. The tube was heated by the thermochromato-furnace so as to produce a linear temperature gradient of 600°C to room-temperature along its axis.

Procedure.—The entire apparatus was evacuated with a rotary pump, and then arbitrary volumes of helium and oxygen were introduced into the apparatus to a one-tenth atmosphere. The gases were completely mixed together by circulating them for 5 hr. through the apparatus with the automatic Toepler pump.

However, when the experiment was carried out in an inert atmosphere, only helium was introduced; the gas was purified by circulation for 5 hr. through the gas purification system with the automatic Toepler pump. After the apparatus had been filled with the carrier gas, the breakable containing the sample was broken, with an iron bar sealed in the silica tube, from outside the thermochromato-tube. Then the thermochromato-furnace was started in order to heat the tube. After the temperature of the furnace had reached 600°C, the circulation of the carrier gas was continued for a further 5 to 10 hr. The thermochromato-tube was then cooled, and the top and bottom of the tube were sealed by an oxy-hydrogen flame. The sealed tube was transferred to a glove box

5) N. W. Gregory, UCRL, RL-4, 6, 272 (1944).

filled with purified helium, and the compounds deposited on the wall of the silica tube, which had been heated at 400, 300 and 200°C, were taken out of the tube by cutting it with a baby grinder. These compounds were weighed and packed in silica breakables for chemical analysis and for measurement of the melting point; they were also packed in capillary tubes for X-ray analysis.

The Determination of the Uranium and Iodine in the Compounds Deposited on Silica Tubes Heated at 400, 300 and 200°C.—The breakable containing a sample was broken above a beaker of water and rapidly immersed. The three samples were completely dissolved in water. A reddish-purple solution was obtained from the compound deposited at 400°C, while a green solution was obtained from the compounds deposited at 300 and 200°C. The reddish-purple solution immediately turned green. Each solution was placed in a 100-ml. measuring flask and was diluted with water to 100 ml. A few milliliters of the solution were then put in a separating funnel and nitric acid was added. The iodine was extracted by carbon tetrachloride. The iodine in the carbon tetrachloride, which turned reddish-purple, was directly determined by colorimetry at the wavelength of 575 mμ. Sulfuric acid was added to the residue solution, from which the iodine had been extracted, and the solution was heated almost to dryness. After the nitric acid had been expelled by repeating the above procedure three times, the pH of the solution was adjusted with ammonium hydroxide (not containing the carbonate radical) and the uranium was extracted by an oxine-chloroform solution. The uranium content of the chloroform was determined by colorimetry at 380 mμ. The analytical results are shown in Table III.

The Determination of Oxygen in the Compounds Deposited at 400 and 300°C.—The method of determining oxygen by subtracting the weights of uranium and iodine from the total weight of the sample is inferior to the method of determining oxygen directly. Therefore, the oxygen was determined directly. The compounds of uranium, iodine and oxygen were oxidized to triuranium octoxide and iodine when heated in the air at 600°C. From the determinations of the uranium and iodine in these compounds, it was shown that the iodine/uranium ratio was 3.0 for the compound deposited at 400°C and 4.0 for the compounds deposited at 300 and 200°C. If oxygen is present in these compounds, the amount consumed in their oxidation should decrease in proportion to that which they already contain. This is because these compounds, like the oxidation products, must consist of stoichiometric compositions of uranium, iodine or oxygen. The calculated volumes of oxygen consumed in the oxidation of 1 g. of various compounds are shown in Table I.

Table I. Oxygen volumes consumed to oxidize 1 g. of compound ($U_xI_yO_z$) to uranium oxide and iodine

Compound	Oxygen volumes consumed for reaction ml. at S.T.P.	Chemical equation
U	130.0	$3U+4O_2=U_3O_8$
UI_2	69.9	$3UI_2+4O_2=U_3O_8+3I_2$
UI_3	48.3	$6UI_3+8O_2=2U_3O_8+9I_2$
UI_4	40.2	$3UI_4+4O_2=U_3O_8+6I_2$
UOI_3	29.9	$6UOI_3+5O_2=2U_3O_8+9I_2$
UOI_4	24.5	$6UOI_4+5O_2=2U_3O_8+12I_2$
UO_2I_3	11.4	$6UO_2I_3+2O_2=2U_3O_8+9I_2$
UO_2I_4	9.7	$3UO_2I_4+O_2=U_3O_8+6I_2$

The oxygen consumed for the reactions was measured by means of a B. E. T. apparatus.[6] The B. E. T. apparatus can measure amounts of oxygen as small as 0.02 ml. at S. T. P. The results obtained are shown in Table II.

Table II. Determination of oxygen in the compounds deposited at the temperatures of 400 and 300°C

Compound	Sample weight g.	Oxygen consumed ml. at S.T.P.	Oxygen consumed to oxidize 1 g. of sample ml. at S.T.P.	Ref.
Compound deposited at 400°C	0.356	16.6	46.5	
	0.692	31.5	45.5	UI_3(1 g.)
	1.117	56.1	47.9	48.3 ml.
	0.319	14.7	46.2	
Compound deposited at 300°C	0.643	25.3	39.4	UI_4(1 g.)
	0.377	15.5	41.1	40.2 ml.

The Measurement of the Melting Point.—The melting point was measured in an inert gas atmosphere, using a fused salt bath (lithium chloride - potassium chloride eutectic mixture). The apparatus for measuring the melting point is shown in Fig. 2. The melting point of the compound deposited at 400°C was found to be 788±10°C, while that for the compound at 300°C, was 506±10°C.

Discussion

Before the experiment, it was thought that the compounds depositing at 400, 300 and 200°C would all consist of uranium, iodine and oxygen. However, the results of their chemical analyses, which are given in Table III, show that the deposit at 400°C was uranium triiodide, while the deposits at 300 and 200°C were uranium tetraiodide.

6) S. Brunauer, P. H. Emmett and E. Teller, *J. Am. Chem. Soc.*, **60**, 309 (1938).

TABLE III. CHEMICAL FROM OF THE COMPOUNDS DEPOSITED AT 400, 300 AND 200°C

Compound	Sample No.	Iodine g. atom	Uranium g. atom	Oxygen g. atom	Ratio of I/U	Result
Compound deposited at 400°C	1	2.86×10^{-3}	9.86×10^{-4}	0	2.90	UI_3
	2	2.69×10^{-3}	9.19×10^{-4}	0	2.93	
	3	4.33×10^{-3}	1.44×10^{-3}	0	2.90	
	4	1.73×10^{-3}	5.76×10^{-4}	0	2.95	
Compound deposited at 300°C	1	3.48×10^{-3}	8.64×10^{-4}	0	4.03	UI_4
	2	2.00×10^{-3}	5.19×10^{-4}	0	3.85	
Compound deposited at 200°C	1	8.66×10^{-5}	2.09×10^{-5}	—*	4.14	UI_4
	2	8.27×10^{-5}	2.17×10^{-5}	—*	3.81	
	3	9.29×10^{-5}	2.30×10^{-5}	—*	4.04	

* The oxygen was not analyzed since only a small amount of sample could be obtained.

Further, the melting points of the compounds deposited at 400 and 300°C were 788 and 506°C, nearly equal to those of uranium triiodide (780°C) and uranium tetraiodide (508°C), as reported by other workers.[7-8] The X-ray patterns (powder method) obtained for the compounds deposited at 400 and 300°C also agreed with those for the uranium triiodide and tetraiodide prepared in the laboratory. When the compound deposited at 400°C was dissolved in water, the reddish-purple color characteristic of the uranium ion (III) appeared. The compounds deposited at 300 and 200°C, on the other hand, exhibited a green color characteristic of the uranium ion (IV).

On the basis of these data, it may be reasonable to conclude that the compound deposited at 400°C is uranium triiodide and that the compound deposited at 300 and 200°C is uranium tetraiodide.

Using a thermochromatograph, the deposition temperature was determined for many metal iodides in an inert gas atmosphere using an experimental time of 2 hr. It was found that many metal iodides deposited at temperatures near their melting points.[9]

When purified helium was used as the carrier gas, uranium tetraiodide deposited on the wall of a silica tube heated at 550°C. When the carrier gas contained a small amount of oxygen (1/10000 to 1/10 atm.), uranium triiodide and uranium tetraiodide deposited at 400, 300 and 200°C.

The above observations indicate that there must be a metastable compound present with a low melting point. The discussions below will deal with mechanisms for the movement of uranium tetraiodide and triiodide toward temperatures lower than the melting points.

Three possible mechanisms may be considered in accounting for the above phenomenon:

1) A metastable compound, consisting of uranium, iodine and oxygen, is produced by the action of oxygen on uranium tetraiodide. The compound moves toward lower temperatures, being carried by the helium gas, and decomposes to uranium triiodide, uranium tetraiodide, iodine and oxygen. The chemical equation postulated is as follows:

$$aUI_4+bO_2 \rightarrow cU_xI_yO_z \begin{cases} \nearrow dUI_4+eI_2+fO_2 \\ \searrow gUI_3+hI_2+iI_2 \end{cases} \quad (1)$$

2) A metastable compound, produced similarly, disproportionates to uranium triiodide, uranium tetraiodide, uranium oxide and iodine:

$$aUI_4+bO_2 \rightarrow cU_xI_yO_z \begin{cases} \nearrow dUI_4+eU_3O_8+fI_2 \\ \searrow gUI_3+hU_3O_8+iI_2 \end{cases} \quad (2)$$

7) J. J. Katz and E. Rabinowitch, "The Chemistry of Uranium: The Element, Its Binary and Related Compounds," Dover Publications, New York (1951).
8) M. M. Popov and M. D. Senin, *Zh. Neorgan. Khim.*, **2**, 1479 (1957).
9) S. Yajima, K. Shiba and M. Handa, unpublished work.

3) In the first step of a third mechanism, oxygen reacts with uranium tetraiodide, producing elementary iodine and uranium oxide. Then this iodine reacts with uranium tetraiodide, present nearby, and the addition compound which is produced moves toward lower temperatures, decomposing to uranium triiodide, uranium tetraiodide and iodine:

$$3UI_4+4O_2 \rightarrow U_3O_8+6I_2 \quad (3)$$

$$aUI_4+bI_2 \rightarrow cUI_{4+x} \begin{cases} \nearrow dUI_4+eI_2 \\ \searrow fUI_3+gI_2 \end{cases} \quad (4)$$

The first mechanism appears unreasonable in explaining the phenomenon because of the reported heats of formation for uranium iodides and uranium oxides:[7]

$$U(\text{solid})+3/2I_2(\text{gas})=UI_3(\text{solid}) \quad (5)$$

$\Delta H_{298°K}=-136.9\pm0.6$ kcal. per mol.

$$U(\text{solid})+2I_2(\text{gas})=UI_4(\text{solid}) \quad (6)$$

$\Delta H_{298°K}=-156.6\pm0.6$ kcal. per mol.

$$U(\text{solid})+O_2(\text{gas})=UO_2(\text{solid}) \quad (7)$$

$\Delta H_{298°K}=-256.6$ kcal. per g. of U

$$U(\text{solid})+4/3O_2(\text{gas})=1/3U_3O_8(\text{solid}) \quad (8)$$

$\Delta H_{298°K}=-281.7$ kcal. per g. of U

The heats of formation for uranium oxides are much greater than those for uranium iodides. In other words, the binding energy of uranium with oxygen is much greater than that with iodine. Therefore, the postulated metastable compound, $U_xI_yO_z$, which decomposes to uranium iodides, iodine and oxygen, cannot be considered seriously.

In view of the heats of formation mentioned above, it seems that the disproportionation reaction of the metastable compound is probable, as has been suggested in the second mechanism. The binding energy of uranium with oxygen is much greater than that with iodine. Uranium oxide is isolated first, from the metastable compound; the chemical bond between uranium and iodine is left as it is, and the excess iodine is released as elementary iodine. Since the uranium oxide is isolated as a compound with a high melting point, it cannot move in the thermochromato-tube once it separates from the metastable compound. Consequently, uranium oxide must deposit near the uranium iodide if the intermediate is present and moves toward lower temperatures. However, uranium oxide could not be found at any positions of the thermochromato-tube except where the sample had been packed. Therefore, it is not reasonable to assume this mechanism for the phenomenon mentioned above.

Two kinds of experiments were carried out in attempting to confirm the third mechanism. In one experiment, an amount of elementary iodine equal to that produced when a sample is completely oxidized was sealed in a silica breakable in a similar manner. The silica breakable containing this elementary iodine was placed on a sample in the thermochromato-tube, the temperature there being about 60°C. The helium carrier gas was purified and the thermochromato-furnace was heated to produce a linear temperature gradient from 600°C to room-temperature. Both of the silica breakables were broken, and then the sample heating furnace was started. The temperature was maintained for 2 hr. after it reached 600°C. The iodine sublimate passed through the sample, flowing down the tube. Iodine from the tube was trapped in a liquid nitrogen-cooled trap. Then the reactions of iodine with uranium tetraiodide and triiodide were examined. The results obtained for the reactions were the same as those obtained for the oxygen-helium mixed carrier gas; that is, uranium triiodide deposited at 400°C and uranium tetraiodide at 300 and 200°C. The amount of uranium tetraiodide deposited at 200°C was very small. From these facts, it may be considered that the uranium tetraiodide deposited at 200°C is formed by the action of iodine on the uranium iodides already deposited at 400 and 300°C, through the mechanism by which uranium iodides move and deposit at 400 and 300°C.

In the second experiment, stoichiometric amounts of iodine, required to produce uranium hexaiodide (UI_6) and uranium decaiodide (UI_{10}), were mixed with uranium tetraiodide in a helium gas atmosphere; these mixtures were sealed in silica vessels after the helium gas had been evacuated. Then the silica vessels were heated for 10 hr. at 600 to 700°C. After the vessels, had been cooled, the substances obtained were taken out, weighed, and placed in silica breakables. These materials were unstable compounds, releasing iodine vapor even when they were taken out in a helium gas atmosphere.

The experimental results obtained for both the samples with a purified helium carrier were the same as those obtained when iodine was placed on the uranium tetraiodide.

The results in the first experiment indicate that there exists a compound, UI_{4+x}, with a much lower melting point than that of uranium tetraiodide. In the second experiment, because the materials release iodine in the helium gas atmosphere, they exist only under a certain iodine vapor pressure. The results obtained for the uranium hexaiodide and uranium decaiodide show that these compounds decompose to uranium triiodide, uranium tetraiodide and iodine in an inert gas atmosphere.

From the foregoing experiments and discussions, it seems reasonable to conclude that the phenomenon in which uranium triiodide and uranium tetraiodide move toward temperatures

lower than their melting points and deposit there takes place via the formation of an iodine addition compound of uranium tetraiodide.

Foster and Tvrzicky have reported that, when uranium tetraiodide is left in air, uranyl iodide (UO_2I_2) and uranous oxyiodide (UOI_2) are produced.[6] However, the results of the present studies on the oxidation of uranium tetraiodide have shown that such compounds are too unstable to be produced by the direct oxidation of uranium tetraiodide.

The author wishes to thank Professor Seishi Yajima and Mr. Koreyuki Shiba for valuable discussions and suggestions, and Professor Takanobu Shiokawa for his continuing interest in and encouragement of this work. He is also indebted to Dr. Thomas Olsen for his kindness in making corrections of the grammatical errors in English.

Oxidation of Alcohols with *t*-Butyl Chromate. IV. The Course of the Formation of the Ester*

By Takayuki SUGA and Tamon MATSUURA

Department of Chemistry, Faculty of Science, Hiroshima University

(Received June 7, 1965)

The results obtained in the preceding papers (Parts I—III) of this series showed that, on oxidation with *t*-butyl chromate, the primary alcohol without a π-electron system on the carbon α to the hydroxymethyl group yields the corresponding ester in a comparable yield, together with the aldehyde and the acid, and also that the cyclic α-glycol with two secondary hydroxyl groups affords the corresponding cyclic ester, along with the glycol fission product. Chemical examination and infrared spectroscopic study have now proved that the course of the formation of these esters does not follow the direct esterification of the alcohol with the acid formed from it by oxidation, but rather involves the formation of a hemiacetal intermediate between the original alcohol and the aldehyde produced from the alcohol, and the subsequent oxidation of the hemiacetal. The oxidation of alcohols with *t*-butyl chromate has also been discussed generally on the basis of the results of our previous papers and of the present work.

Our previous papers[1-3] showed that, on oxidation with *t*-butyl chromate, saturated primary alcohols, such as aliphatic and β-phenylethyl alcohols and cyclohexylcarbinol, yielded mixtures of the corresponding aldehyde, acid and ester in comparable yields, while unsaturated primary alcohols, such as *trans*-cinnamyl and benzyl alcohols, geraniol and myrtenol, did not produce the ester, but yielded only the corresponding aldehyde and acid.

The ester might be formed in one of the following two courses: the direct esterification of the alcohol with the acid formed from it by oxidation,[4,5] or the hemiacetal formation between the original alcohol and the aldehyde produced from it by oxidation, and the subsequent oxidation to the ester.[6,7] We have now tried to clarify the course of the formation of the ester, together with the reason for the oxidation mode being different depending on the type of alcohol. In addition, generalizations as to the *t*-butyl chromate oxidation of alcohols have been given.

In the *t*-butyl chromate oxidation of *n*-butyl alcohol, *n*-butyric acid produced was removed by extracting the benzene solution with alkali before the solvent was removed (Exp. 1). The amount of *n*-butyl *n*-butyrate thus obtained was identical with that of the ester (Exp. 5 in Ref. 1) obtained without this treatment. A similar result (Exp. 2) was also observed in the oxidation of cyclohexane-*trans*-1, 2-diol, which yielded *trans*-1, 2-adipoxycyclohexane (II) as an ester (Exp. 5 in Ref. 3). Besides, *n*-butyl alcohol was not esterified (Exp. 3) by *n*-butyric acid during the agitation

of a mixture of the alcohol and the acid in benzene under conditions similar to those in the oxidation. Moreover, if the ester were formed by direct esterification, *n*-hexyl acetate would be produced together with *n*-hexyl *n*-caproate when *n*-hexyl alcohol is oxidized in the presence of acetic acid. However, this oxidation (Exp. 4) did not give any *n*-hexyl acetate; it afforded only *n*-hexyl *n*-caparoate.

If another aldehyde (R''-CHO) is added to a mixture of an alcohol (R'-CH_2OH) and an aldehyde (R'-CHO) produced from it, two kinds of hemiacetals (R'-CH(OH)·O·CH_2-R' and R'-CH(OH)·O·CH_2-R'') should be formed and then oxidized to two esters (R'-CO·O·CH_2-R' and R'-CO·O·CH_2-R'' respectively). The oxidation of an equimolar mixture of *n*-hexyl alcohol and *n*-butyraldehyde (Exp. 5) showed the formation of *n*-hexyl *n*-butyrate and *n*-hexyl *n*-caproate; this was in agreement with the expectation. These results suggest that the course to the ester involves the hemiacetal oxidation.

The infrared spectra of mixtures of an aldehyde and an alcohol were examined in order to establish the formation of a hemiacetal as an intermediate. Two absorption cells, one filled with an aldehyde and the other with an alcohol, were placed in series so that the recorded spectrum was the sum of the spectra of two samples. On the other hand, an equimolar mixture of an aldehyde and an alcohol was placed in one cell and the spectrum was again recorded. A comparison was then made between the "separate" and "mixed" spectra. The spectra of the pair, *n*-butyraldehyde and *n*-hexyl alcohol (Fig. 1), showed considerable

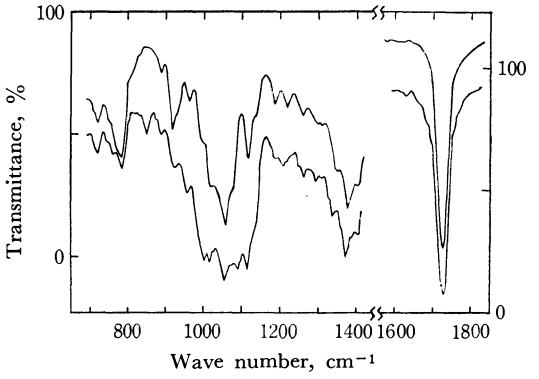

Fig. 1. The "separate" (upper line) and "mixed" (lower line) infrared spectra of *n*-butyraldehyde and *n*-hexyl alcohol in a carbon disulfide solution.

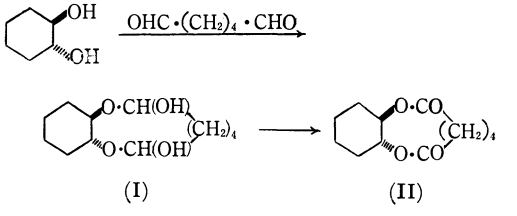
differences between the "separate" and "mixed" spectra. In the "mixed" spectrum the strong new bands were found at about 850, 1000—1015, 1090, 1115, and 1140 cm^{-1} and were assignable to an ether-linkage of a hemiacetal.[8,9] The same phenomena as above were also observed in the spectra of the other pairs, *n*-butyraldehyde and *n*-butyl alcohol, and β-phenylacetaldehyde and β-phenylethyl alcohol. The formation of the ester has been observed in the oxidation of these alcohols and is in harmony with the appearance of new bands which can be ascribed to the formation of an intermediate hemiacetal in the spectra of mixtures of the alcohols and the corresponding aldehydes. In contrast, a complete agreement was observed between the "separate" and "mixed" spectra of the two pairs, benzaldehyde and benzyl alcohol, and *trans*-cinnamaldehyde and *trans*-cinnamyl alcohol. This is coincident with the finding of our previous work[2] that the *t*-butyl chromate oxidation of these alcohols does not produce the ester; this can be ascribed to the failure of these pairs to form a hemiacetal.

The agreement observed between the "separate" and "mixed" spectra of the two pairs, benzaldehyde and *n*-hexyl alcohol, and *trans*-cinnamaldehyde and *n*-butyl alcohol, also indicated no formation of a hemiacetal between these pairs, while the formation of a hemiacetal was shown by the differences observed between the spectra of two other pairs, caproaldehyde and benzyl alcohol, and *n*-butyraldehyde and *trans*-cinnamyl alcohol. Accordingly, it was found that the hemiacetal formation does not depend on the structure of the alcohol, but on that of the aldehyde, namely, on the substitution system on the carbon α to the carbonyl group.

A previous paper[3] of this series showed that the *t*-butyl chromate oxidation of *trans*-cyclohexane-1, 2-diol produces *trans*-1, 2-adipoxycyclohexane (II), the formation of which has not yet been reported in the oxidation of this diol. Recently, Head[10] has observed the reaction of *trans*-cyclohexane-1, 2-diol with glyoxal at room temperature to give a crystalline bishemiacetal, *trans*-hexahydro-2, 3-dihydroxy-1, 4-benzodioxane. The formation of II can, therefore, be explained by the process by which the hemiacetal (I) shown in the following equation is first formed by the



(I) (II)

interaction of *trans*-cyclohexane-1, 2-diol and adipaldehyde probably produced by the glycol-fission of the 1, 2-diol, and is subsequently oxidized.

In conclusion, our previous findings[1-3] and the present work on the *t*-butyl chromate oxidation of alcohols permit us to generalize the oxidation

as follows. The oxidation of the primary alcohol without a π-electron system on the carbon α to the carbinol carbon, such as the alcohol which contains the group shown below:

$$R\text{-}CH_2\cdot CH_2OH \quad (R=H, \text{Alkyl, or Phenyl})$$

yields a mixture of the corresponding aldehyde, acid and ester in a comparable yield. On the other hand, the oxidation of the primary alcohol with a π-electron system on the carbon α to the hydroxymethyl group, such as the following system:

$$-CR{=}CR\cdot CH_2OH \quad (R=H \text{ or Alkyl})$$

$$C_6H_5\cdot CH_2OH$$

produces not the ester, but the corresponding aldehyde in a high yield and acid in a low yield. A secondary alicyclic alcohol and a cyclic α-glycol with a secondary and a tertiary hydroxyl groups are selectively oxidized to the corresponding ketone and α-hydroxyketone respectively, while the oxidation of a cyclic α-glycol with two secondary hydroxyl groups does not give the corresponding α-diketone, but the glycol fission product and the cyclic ester.

Moreover, there was evidence that the course of the formation of the ester did not involve direct esterification, but hemiacetal oxidation.

Experimental

Samples.—The alcohols were the same ones as were used in the previous papers[1-3] of this series; the aldehydes were obtained from a commercial source. All the samples were purified repeatedly by distillation or recrystallization just before use.

Oxidation or Reaction.—A benzene solution of *t*-butyl chromate was prepared in the manner used in a preceding paper.[1] The quantity of each component in this solution is shown in Table I, which also lists the quantity of the sample and its solvent. After the oxidation or the reaction was carried out at 1—2°C for 6 hr. (except in Exp. 2, which had a reaction time of 3 hr. at 35°C), the reaction mixture was treated with oxalic acid and water, as has been shown in Ref. 1. The separated benzene solution was subjected to the described examinations in each experiment. Each of the constituents of the reaction product was identified by a comparison of its infrared spectrum with that of the authentic sample and by a mixed melting point determination; the yield of the constituents is shown below.

The Oxidation of *n*-Butyl Alcohol (Exp. 1).—After the oxidation, the reaction mixture was treated with oxalic acid and water, and then the separated benzene solution was repeatedly extracted with a sufficient amount of a 5% sodium carbonate solution; this alkaline solution gave *n*-butyric acid (31.5% yield based on the alcohol; b. p. 99—100°C/79 mmHg, n_D^{25} 1.3957, d_4^{25} 0.9614) on acidification. The removal of the solvent from the neutral benzene solution afforded *n*-butyl *n*-butyrate (34.3%; b. p. 94—95°C/77 mmHg, n_D^{25} 1.4059, d_4^{25} 0.8663; $\nu_{ester}^{liq.}$ 1741, 1187 cm^{-1}).

The Oxidation of Cyclohexane-*trans*-1, 2-diol (Exp. 2).—The reaction mixture was treated in the manner described in Exp. 1. The neutral product obtained was subjected to examinations similar to those used in Exp. 5 in Ref. 3; *trans*-1,2-adipoxycyclohexane (m.p. and mixed m.p. 103—104°C; ν_{ester}^{KBr} 1733, 1270, 1154 cm^{-1}) was thus obtained in a 7% yield.

The Agitation of a Mixture of *n*-Butyl Alcohol and *n*-Butyric Acid in Benzene (Exp. 3).—After a mixture of *n*-butyl alcohol and *n*-butyric acid in benzene had been stirred under the conditions shown above, the solvent was removed from the solution under an atmospheric pressure without previous treatment by an alkaline solution. The remaining liquid was analyzed by gas chromatography (column: silicone DC-550 on Celite, 130°C, 50 ml. helium/min.) and infrared spectroscopy. Not even a trace of *n*-butyl *n*-butyrate was detected; the liquid consisted of only the original samples.

The Oxidation of *n*-Hexyl Alcohol in the Presence of Acetic Acid (Exp. 4).—After the oxidation had been carried out in benzene containing acetic acid corresponding to about a 5% concentration in the whole reaction mixture, the reaction mixture was treated as in Exp. 1. The sodium carbonate extracts afforded *n*-caproic acid (26.0%; b. p. 195—200°C, n_D^{25} 1.4129, d_4^{25} 0.9284) on acidification, while the removal of the solvent from the neutral benzene solution gave a neutral product; this was then fractionated by distillation and subjected to gas chromatographic analysis (column: silicone DC-550 on Celite, 140°C, 60 ml. helium/min.). The reaction product did not contain even a trace of *n*-hexyl acetate; it consisted of capraldehyde (12.3%; b. p. 128—135°C, n_D^{25} 1.4070, d_4^{25}

1	*n*-Butyl alcohol	20.0	60	27.0	54.0	100
2	Cyclohexane-*trans*-1,2-diol	30.0	26	77.4	143.4	774
3	*n*-Butyl alcohol *n*-Butyric acid	20.0 10.0	140	—	—	—
4[a]	*n*-Hexyl alcohol	40.0	87	39.1	66.6	159
5	*n*-Hexyl alcohol *n*-Butyraldehyde	51.1 36.1	111	50.0	100.0	195

a) To the benzene solution of *t*-butyl chromate, 20 g. of glacial acetic acid was added.

0.8238; $\nu_{CHO}^{liq.}$ 1724, 2723 cm^{-1}), *n*-hexyl *n*-caproate (46.5%; b. p. 110—113°C/8 mmHg; n_D^{25} 1.4226, d_4^{25} 0.8573; $\nu_{e\ ter}^{liq.}$ 1738, 1168 cm^{-1}) and unchanged alcohol (3.3%; b. p. 93—100°C/49 mmHg).

The Oxidation of a Mixture of *n*-Hexyl Alcohol and *n*-Butyraldehyde (Exp. 5).—As soon as a benzene solution of an equimolar mixture of *n*-hexyl alcohol and *n*-butyraldehyde had been prepared under ice-cooling, the oxidation was conducted under the conditions shown above; then the reaction mixture was worked up as has been described above. The distillation of the acidic product gave *n*-butyric acid (10.5%; b. p. 83.5—84°C/40 mmHg, n_D^{25} 1.3958, d_4^{25} 0.9535) and *n*-caproic acid (8.4%; b. p. 121°C/40 mmHg, n_D^{25} 1.4136, d_4^{25} 0.9236). On the other hand, a combination of fractional distillation, gas chromatography and infrared spectroscopy indicated that the neutral product consisted of caproaldehyde (6.5%; b. p. 125—132°C, n_D^{25} 1.4041, d_4^{25} 0.8290), *n*-hexyl *n*-butyrate (18.6%; b.p. 97—98°C/19 mmHg, n_D^{25} 1.4142, d_4^{25} 0.8612; $\nu_{ester}^{liq.}$ 1734, 1184 cm^{-1}; ester number 331), *n*-hexyl *n*-caproate (5.4%; b. p. 127°C/19 mmHg, n_D^{25} 1.4224, d_4^{25} 0.8601; $\nu_{ester}^{liq.}$ 1741, 1170 cm^{-1}; ester number 280), unchanged alcohol (9.2%), and unchanged aldehyde (14.7%). The hydrolysis of the esters gave the corresponding alcohol and acid respectively.

The Measurement of the "Separate" and "Mixed" Infrared Spectra of the Aldehydes and the Alcohols.—The spectrometer used was a Hilger H-800 double-beam spectrophotometer fitted with a sodium chloride prism. Each of the cells used for the "separate" spectra measurements was 0.1 mm. thick, and the aldehyde and the alcohol were each a carbon disulfide solution of 1 molar concentration. In the "mixed" spectra measurements, the cell was 0.2 mm. long, and a carbon disulfide solution of an equimolar mixture of an aldehyde and an alcohol was prepared in a 1-molar concentration of each sample.

Summary

1) The formation of the ester which is produced when the alcohol without a π-electron system on the carbon α to the carbinol carbon and the cyclic α-glycol with two secondary hydroxyl groups are oxidized with *t*-butyl chromate, has been found to follow the course of the formation of an intermediate hemiacetal between the original alcohol and the aldehyde produced from it by oxidation, and subsequent oxidation.

2) The oxidation of alcohols with *t*-butyl chromate has been generally described on the basis of results obtained in our previous papers (Parts I—III) and in the present work.

The authors are indebted to Messrs. Keiichi Kihara and Tadahisa Yanagihara for their help in this research. This work was partly supported by a grant-in-aid of the Ministry of Education.

and Yuzuru TAKAGI

The Institute of Physical and Chemical Research, Bunkyo-ku, Tokyo

(Received June 8, 1965)

The hydrogenation of aniline with the hydroxide-black catalysts of ruthenium and rhodium was investigated, using various alcohols as solvents. The formation of dicyclohexylamine increased in the following order with respect to the solvents: *t*-butyl alcohol≅isopropyl alcohol≪ethyl alcohol<methyl alcohol. It was shown that the addition of a small amount of alkali greatly hinders the formation of dicyclohexylamine. The effects of added ammonia and dicyclohexylamine were also investigated. The addition of ammonia retarded the rhodium-catalyzed hydrogenation much more seriously than the hydrogenation with ruthenium, but it was found that in the presence of alkali the hydrogenation with rhodium was not inhibited by the addition of ammonia.

In the preceding paper,[1] it was reported that the hydroxide-blacks of ruthenium and rhodium are catalysts excellent in activity and selectivity in the hydrogenation of aromatic compounds. The method of the preparation of the hydroxides is very simple; ruthenium hydroxide is much more

1) Part I: Y. Takagi, T. Naito and S. Nishimura, This Bulletin, **38**, 2119 (1965).

active than the ruthenium dioxide prepared by the method of Pichler and Buffleb,[2] and rhodium hydroxide is nearly as active as the rhodium oxide of the Adams type.[3] It was further suggested that the hydroxides, though they were precipitated with a strong alkali, contained much less alkali than the oxides mentioned above. This paper will deal with the hydrogenation of aniline and the effects of solvents and added alkalis on the reactions using the hydroxide-black catalysts of ruthenium and rhodium.

Usually the hydrogenation of aniline to cyclohexylamine is accompanied by the formation of dicyclohexylamine, and it has been known that the addition of metal oxides of a basic character, such as the oxides of calcium and magnesium, is effective in depressing the formation of the secondary amine in the hydrogenations with cobalt and nickel catalysts.[4-7] It has recently been accepted that ruthenium is the most effective of the platinum metals for the hydrogenation of aromatic amines to alicyclic amines.[8-14] Ruthenium dioxide has often been used for this hydrogenation.[8-10,12,13] More recently, rhodium and rhodium-platinum catalysts have been used successfully for the hydrogenation of aniline.[14-16] However, no detailed study of the effects of added alkalis and solvents seems to have been done in the hydrogenation of aniline, especially with ruthenium and rhodium catalysts. Only the effects of added ammonia and dicyclohexylamine have recently been studied with reference to ruthenium and rhodium catalysts supported on carbon.[14]

Experimental

Catalysts.—The hydroxides of ruthenium and rhodium were prepared in a method described previously.[1] Ruthenium dioxide was prepared by the method of Pichler and Buffleb.[2] Rhodium oxide was prepared by a modification of Adams' method described in a previous paper.[3]

Hydrogenation.—A 200 ml. autoclave of an electromagnetically-stirring type was charged with 0.1 g. of the catalyst, 0.1 mol. of aniline, and 50 ml. of the solvent at an initial hydrogen pressure of 80 kg./cm^2. The temperature was raised to 80°C under stirring and maintained constant during the hydrogenation. After the completion of the hydrogenation, the hydrogen pressure dropped to 45 kg./cm^2 at 80°C. For the addition of ammonia, ammonia gas was led into the solvent through a soda-lime tube; the amount of ammonia dissolved was determined by the titration method. Probably some loss of the ammonia occurred during loading and purging operations. Sodium hydroxide and lithium hydroxide were added as a 10% aqueous solution. The products were analyzed directly by means of gas chromatography using a column containing PEG-6000.

Results and Discussion

The Effects of Solvents.—An acidic medium is often used with platinum catalysts to avoid poisoning by nitrogen bases, but it has been shown that the use of acetic acid increases the formation of dicyclohexylamine in hydrogenation with a (7 : 3) rhodium-platinum catalyst, although the rate is the greatest in the acid.[16] In this study, the effects of various alcohols on the selectivity of the hydrogenation of aniline were investigated, using ruthenium hydroxide as the catalyst. From the results shown in Table I, it may be seen that the formation of dicyclohexylamine increases in the following order with respect to the solvents: *t*-butyl alcohol$\cong$isopropyl alcohol$\ll$ethyl alcohol $<$methyl alcohol. The formation of dicyclohexylamine was observed to be very little in *t*-butyl and isopropyl alcohols, whereas it was much larger in ethyl and methyl alcohols. This order of selectivity indicates that the more basic the alcohol used as the solvent, the more unfavorable it is for the formation of dicyclohexylamine;[17] this is in line with the previous observation that acetic acid increases the formation of dicyclohexylamine.

When the hydrogenation was carried out using alcohols as the solvents, the hydrogenation with ruthenium hydroxide proceeded rather rapidly to completion, whereas the hydrogenation with rhodium hydroxide was almost completely inhibited after about 80 to 90% of aniline had been hydrogenated. These results suggest that the rhodium catalyst is much more easily poisoned by nitrogen bases than is the ruthenium catalyst.

The Effects of Added Alkalis.—The addition of ammonia has been shown to suppress the formation of secondary amines in the hydrogenation of nitriles[18] and aniline[4]. However, the presence

a) Aniline (0.1 mol.) was hydrogenated with 0.1 g. of unsupported catalysts or 1 g. of supported catalysts in 50 ml. of the solvent at 80°C and 80 kg./cm^2 of initial hydrogen pressure.
b) Yields are given in weight per cent of the products.
c) The use of carefully purified ethanol was necessary for rapid hydrogenation, otherwise the rate decreased markedly with the coloration of the solvent.
d) Hydrogenation was strongly inhibited in the course of the reaction and not completed.

of ammonia strongly retards the hydrogenation of aniline,[4] especially with rhodium and ruthenium catalysts.[14] Probably the most effective and simplest way to suppress the formation of secondary amines is to add a small amount of strong alkali to the reaction mixture.[19,20] Thus, it was found that the addition of only 4 mg. of sodium hydroxide or 20 mg. of lithium hydroxide per 100 mg. of the hydroxide catalyst extremely depresses the formation of dicyclohexylamine with ruthenium hydroxide and almost completely inhibits it with rhodium hydroxide (see Table II). It is noteworthy that, in the presence of the added alkali, the rhodium-catalyzed hydrogenation proceeded rapidly to completion, although the hydrogenation in the absence of alkali was strongly poisoned in the course of the hydrogenation. The addition of an excess amount of alkali (7 mg. of sodium hydroxide) prevented the hydrogenation with rhodium hydroxide from being completed, but not that with ruthenium hydroxide. Neither the ruthenium dioxide prepared by Pichler's method nor the rhodium oxide of the Adams type gave any dicyclohexylamine, even in the absence of added alkali.

19) M. Fluchaire and F. Chambret, *Bull. Soc. Chim. France*, **11**, 22 (1944).
20) M. Taniyama, N. Sawa, T. Nagaoka and T. Takeda, Japanese Pat. 21353 (1963) [*Chem. Abstr.*, **60**, 2756 (1964)].

It is obvious that these oxide catalysts in themselves contain alkaline substances which were contaminated during preparation.[21] Commercial 5% ruthenium- and rhodium-on-carbon catalysts* gave considerable yields of dicyclohexylamine, even in *t*-butyl alcohol, and the addition of a small amount of alkali was of little effect in supressing the formation of the secondary amine (see Table II). Presumably the added alkali was adsorbed on carbon rather than on the catalyst metal.

From the fact that, without the addition of alkali, the hydrogenation with rhodium hydroxide was strongly inhibited before it could be completed, it was supposed that the ammonia and/or dicyclohexylamine produced during the hydrogenation may have poisoned the catalyst. Therefore, the effects of the addition of ammonia and of dicyclohexylamine were studied in isopropyl alcohol using rhodium hydroxide as the catalyst. As may be seen in Fig. 1, the addition of 0.06 mol. of dry ammonia inhibited the hydrogenation almost completely, whereas the addition of 0.05 mol. of dicyclohexylamine retarded the hydrogenation only to a little extent.[22] Thus it is obvious that it was ammonia rather than dicyclohexylamine which inhibited the hydrogenation seriously. The hydrogenation with ruthenium hydroxide was also retarded by the addition of ammonia, though to a much lesser extent. The decrease in the rate observed at the later stages of the hydrogenations in ethyl alcohol and in methyl alcohol, when compared with those in isopropyl and *t*-butyl alcohols, may be attributed to the action of the ammonia formed along with dicyclohexylamine in the course of the hydrogenation (see Fig. 2 and Table I). However, it has been found that, in the presence of a slight amount of added alkali, the hydrogenation with rhodium hydroxide proceeded rapidly to completion, even when 0.077 mol. of ammonia was added (Fig. 1)[23] It is probable that the added alkali eliminated the poisoning action of ammonia by preventing or weakening its adsorption on the catalyst. In connection with these findings, it is of interest to note that, in the synthesis of ammonia, the role of potassium oxide in the doubly-promoted iron catalysts may be explained by assuming that the alkali metal oxide eliminates the poisoning by adsorbed NH-NH_2- and NH_3-species, thus promoting the synthesis of ammonia.[24,25]

E EtOH

The mechanism of the formation of dicyclohexylamine is probably the same as that proposed for the production of secondary amines in the hydrogenation of nitriles.[26] Dicyclohexylamine is probably formed by the following reaction sequence via enamine and imine intermediates.[14] However, it is not obvious which step of the reaction leading

to the formation of dicyclohexylamine is retarded by alkali. It is probable that the elimination of ammonia by reaction 3 or by reaction 4 is depressed by the presence of alkali, but the present results also suggest another possibility, that the alkali prevents a longer stay of cyclohexylamine on the catalyst surface and thus depresses the addition of it to the Ib imine by reaction 2. In some cases, a small amount of cyclohexanol was obtained (see Tables I and II), the formation of which probably results from the hydrolysis of imine intermediates (Ib and IV). The formation of dicyclohexylamine from two moles of cyclohexylamine was not observed at all under the conditions used in this study, though the condensation is known to occur at higher temperatures.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 333—343 (1966)

An Analysis of the Proton Magnetic Resonance Spectra of Acrylic Acid in Solution: A Comparative Discussion of the Methods of the Analysis of ABC Spin Systems

By Takeo YAMAMOTO and Shizuo FUJIWARA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received June 14, 1965)

In an attempt to examine various existing methods for the analysis of high-resolution NMR spectra, the statistical theory has been applied to the least-squares iteration method presented by Arata, Shimizu and Fujiwara. The standard errors of chemical shifts and spin-spin coupling constants, and the singularity in the normal equation, have been discussed. Two sets of parameters which are placed close together have a possibility of producing a singularity in the normal equation. A way of eliminating the singularity has been presented. The method thus presented has then been applied to an analysis of the vinyl proton spectra of acrylic acid in carbon tetrachloride and in aqueous solutions of various pH values. It has been found that the spin-spin coupling constants do not change beyond the range of experimental errors under the conditions of the present study. The change in chemical shifts has been discussed in terms of the possible conformations of the molecules.

The theory of the analysis of high-resolution NMR spectra seems to be fairly complete. When a set of chemical shifts and coupling constants (molecular constants) is given, ordinary methods[1] of perturbation or exact diagonalization, as well as the direct method of Banwell and Primas,[2] can be used to calculate the spectrum. When a series of measurements is given in an attempt to estimate the most probable molecular constants, the experimental spectrum must first be assigned to the transitions among the energy levels. This is usually done by the trial-and-error method, supplemented by intensity and frequency sum rules.[3,4] Because of the non-uniqueness of the assignments and because of the inevitable experimental errors, however, the procedure is often difficult, and ^{13}C–H satellite line data[5] and double-quantum line data[6] have been used to confirm

the assignment.

For an ABC spin system, however, Castellano and Waugh[3] have shown that all the possible assignments (energy diagrams) can be obtained from a precise knowledge of all the 15 absorption line positions (the CW method for assignment). When an assignment is obtained, there are two ways to use the observed data for the calculation of the molecular constants. One is to use the data directly for a least-squares adjustment of the molecular constants; the other is to use the absorption line-position data to obtain a set of energy levels, and subsequently to deduce the molecular constants from the energy levels. The former method (the ASF method) was developed by Arata, Shimizu and Fujiwara[7]. Swalen and Reilly[4] (the SR method) obtained the molecular constants by adjusting the calculated energy levels to the "observed" constants by least-squares iterations. Castellano and Waugh[3] (the CW method for calculating molecular constants) used the "observed" energy levels to find, by explicit algebraic calculations, all the sets of molecular constants that regenerate the energy-level diagram.

The ASF method has the advantage over other methods that a suitable choice of the Jacobian matrix enables us to use not only the line positions and intensities, but also the other physical quantities, as input data.[8] The more fundamental advantage of the method is that it provides direct and unambiguous relations between the variance in the observed values and that in the calculated results. These points, which were not fully examined in the previous paper,[7] will be discussed later.[9] The above-mentioned relations are expressed rather indirectly in the SR method, and no such relation has been given for CW method. There are, however, some limitations in the practice of the ASF method, most of which limitations are shared by all least-squares iteration calculations. It will be shown that one of the most serious limitations, i. e., the problem of finding suitable starting constants for all the possible solutions, can be solved by a reduction in the order of the normal equation and by a complementary use of the CW method. Another limitation, the singularity of the normal equation and its eventual omission, will also be discussed.

The analysis was applied to acrylic acid in carbon tetrachloride and in aqueous alkaline media. The chemical shifts and coupling constants obtained will be discussed in connection with possible states of acrylic acid in the above media. The changes in chemical shifts are internal and do not suffer from the large and ambiguous variations caused by macroscopic susceptibility and by other interactions affecting the entire solute molecule.

Method of Analysis

The Calculation of the Spectra.—A spin Hamiltonian for a ABC-type nuclear spin system can be written as follows:

$$\mathscr{H} = -\nu_A I_{AZ} - \nu_B I_{BZ} - \nu_C I_{CZ} + J_{AB}\vec{I_A}\cdot\vec{I_B} + J_{BC}\vec{I_B}\cdot\vec{I_C} + J_{CA}\vec{I_C}\cdot\vec{I_A} \quad (1)$$

Here notations are used in the usual way. In the present work, the vinyl protons cis, geminal and trans to the carboxylic group in an acrylic acid molecule were assigned to A, B and C respectively. When the ν_A, ν_B, ν_C, J_{AB}, J_{BC}, and J_{CA} molecular constants (hereafter called collectively $\{q_i\}$ or $\{q\}$) are known, one can calculate the positions of the absorption lines $\{\omega_j\}$ and the corresponding relative intensities $\{I_j\}$. On the basis of the zeroth order eigenfunctions $\{\varphi_m{}^0\}$ $(m=1,\ldots,8)$ for a three spin $(I=1/2)$ system, the Hamiltonian (1) is represented in a matrix form:

$$(\mathscr{H}_{mn}) = \begin{pmatrix} A & & & & & & & \\ & B & R & Q & & & & \\ & R & C & P & & 0 & & \\ & Q & P & D & & & & \\ & & & & E & R & Q & \\ & 0 & & & R & F & P & \\ & & & & Q & P & G & \\ & & & & & & & H \end{pmatrix} \quad (2)$$

Matrix 2 can be diagonalized by some orthogonal matrices, T, without violating the ordering among the partial matrices in 2:

$$\tilde{T}(\mathscr{H}_{mn})T = \begin{pmatrix} E_1 & & & & & & & \\ & E_2 & & & & & & \\ & & E_3 & & 0 & & & \\ & & & E_4 & & & & \\ & & & & E_5 & & & \\ & & 0 & & & E_6 & & \\ & & & & & & E_7 & \\ & & & & & & & E_8 \end{pmatrix} \quad (3)$$

Since the matrix consists of two 1×1 and two 3×3 matrices, there are $(1!)^2\cdot(3!)^2=36$ T transformations of 2 into Form 4. The eigenfunctions, $\{\varphi_m\}$ $(m=1,\ldots,8)$, are calculated as:

$$T\begin{pmatrix} \varphi_1{}^0 \\ \vdots \\ \varphi_8{}^0 \end{pmatrix} = \begin{pmatrix} \varphi_1 \\ \vdots \\ \varphi_8 \end{pmatrix}$$

The positions of the absorption lines $\{\omega_j\}$ and the relative intensities $\{I_j\}$ are obtained as:

$$\omega_j = \omega_{m\leftarrow n} = E_m - E_n$$

$$I_j = I_{m\leftarrow n} = a|\langle\varphi_m|I_x|\varphi_n\rangle|^2$$

The normalization coefficient, a, is taken to be $\sum_j I_j = 100$ in the present work.

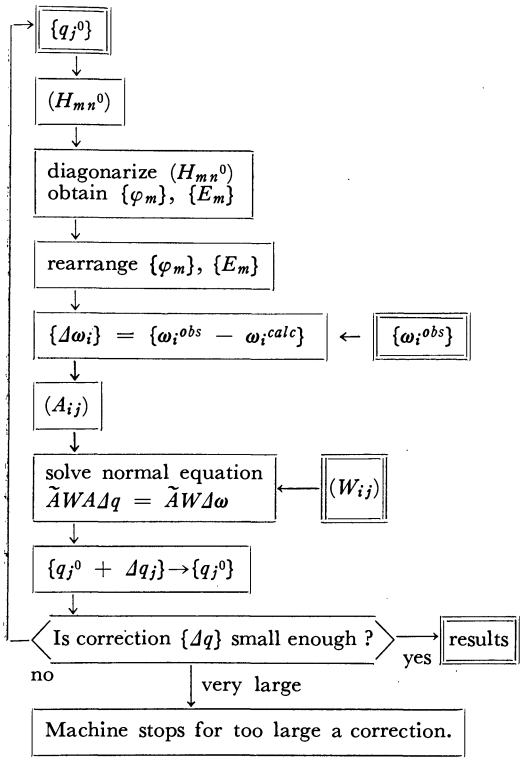

Fig. 1. Flow chart for the ASF method.

Double frames stand for the input and the output data.

The ASF Method.—The flow-chart for the ASF method is reproduced in Fig. 1, where W is the weight matrix for the observed quantities and A is the Jacobian matrix, which contains the differential of the observed quantities with respect to the parameters to be determined. The figure refers to a special case where the weighted squares of the residuals of line positions at a certain resonance frequency are minimized. The method is, however, applicable to any physical quantities expressed as functions of q_i, such as the intensities and the resonant positions at several radiofrequencies.

The estimated variance of the most probable q_i value (the solution of the analysis), $\sigma^2[q_i]$, may be expressed by the variance of an observation of unit weight, σ^2, and by the ii-component of the inverse matrix of the coefficient matrix $\tilde{A}WA$, of the normal equation, $(\tilde{A}WA)^{-1}{}_{ii}$:

$$\sigma^2[q_i] = (\tilde{A}WA)^{-1}{}_{ii} \cdot \sigma^2 \tag{4}$$

The correlation factor between two most probable values of the parameters, q_i and q_j, is given by:

$$\rho[q_i, q_j] = (\tilde{A}WA)^{-1}{}_{ij} \cdot \frac{\sigma^2}{\sigma[q_i] \cdot \sigma[q_j]} = \frac{(\tilde{A}WA)^{-1}{}_{ij}}{\{(\tilde{A}WA)^{-1}{}_{ii} \cdot (\tilde{A}WA)^{-1}{}_{jj}\}^{1/2}} \tag{5}$$

The σ^2 quantity in Eq. 4 can be evaluated in two ways.[12] One way consists of estimating it from the differences (residual vector) between the "observed" and the "calculated" values:

$$\sigma_1{}^2 = \frac{\Delta\tilde{\omega}W\Delta\omega}{N - M} \tag{6}$$

where N is the number of observed quantities (here, the number of absorption lines) and M is the dimension of the normal equation. It must be noted that the "observed" value is obtained by averaging several measurements. The "calculated" value is obtained from the converged parameters $\{q_i\}$.

The other way consists of estimating σ^2 from the variance of the values in individual observations around their mean values, that is, the "observed values" for the analysis:

$$\sigma_2{}^2 = \frac{\sum_{j=1}^{n} (x_j - x)^2}{n(n-1)} \tag{7}$$

where x is the average line position of unit weight; x_j is the jth observed value for that position, and n is the number of runs in the observation. The $\sigma_2{}^2$'s thus obtained are different for all the lines; their average can be used to estimate σ^2. In each analysis, σ_1 and σ_2 must be normally of the same order of magnitude. When $\sigma_1 \gg \sigma_2$ or $\sigma_1 \ll \sigma_2$, the σ in Eq. 4 must be estimated from the larger value, σ_1 or σ_2.

When the analysis is confined to the line positions obtained at a single frequency, the Jacobian matrix (A_{ij}) can be calculated[7]:

$$\begin{aligned}\tilde{A}_{ij} = A_{ji} &= \left(\frac{\partial E_m}{\partial q_i}\right)_{q^0} - \left(\frac{\partial E_n}{\partial q_i}\right)_{q^0} \\ &\simeq 1/\Delta q_i \{\langle\varphi_m|\mathscr{H}(q_i{}^0 + \Delta q_i)|\varphi_m\rangle \\ &\quad - \langle\varphi_m|\mathscr{H}(q_i{}^0)|\varphi_m\rangle - \langle\varphi_n|\mathscr{H}(q_i{}^0 \\ &\quad + \Delta q_i)|\varphi_n{}^0\rangle + \langle\varphi_n{}^0|\mathscr{H}(q_i{}^0)|\varphi_n\rangle\}\end{aligned} \tag{8}$$

where $q_i{}^0$ is the assumed value of the parameter, q_i, and, where Δq_i is the coreection for it.

A Discussion of the ASF Method

The Order in Energy Levels.—In the present work, the Hamiltonian matrix 2 was diagonalized into Form 3 by the Jacobi method. In this method, the choice of the transformation, T, from the 36 possible transformations cannot be controlled, and sometimes a sudden jump in the ordering of the calculated spectrum is observed. The iteration is impossible, in such a case.

12) Y. Murata and Y. Morino, This Bulletin, **38**, 104 (1965).

In order to avoid this inconvenience, the transformation, T, which gives a definite inequality in energy levels (i. e., $E_2 \geq E_3 \geq E_4$ and $E_5 \geq E_6 \geq E_7$) was chosen for the subsequent analysis.

This, however, introduces another difficulty, one which will be discussed in the next section.

The Validity of Approximation for the Jacobian Matrix.—Two conditions are required for the first-order approximation (8) for the Jacobian matrix: (1) the non-degeneracy of energy levels (E_2, E_3, E_4) and (E_5, E_6, E_7) and (2) the closeness of the starting constants, $\{q^0\}$, to the final value, $\{q\}$.

Condition 1 is not always warranted; i. e., there can be "cross-over" among the energy levels, in each 3×3 partial matrix in Eq. 3, as the parameters, $\{q\}$, are varied. In the case of cross-over, second-order or higher-order perturbation methods might be applied. However, another difficulty would occur in that case. Figure 2-1 and 2-2 illustrate this kind of situation. In Fig. 2-1, the values of a parameter q_i are plotted against the remaining parameters, $\{q'\}$. A point on the plane represents a point in the multidimensional space, $\{q\}$, that is, a set of values of the parameters. When a set of observed line positions, $\{\omega_j^{obs}\}$, and the weight matrix, W, are given, the weighted sum of residuals for the data, $\Delta\tilde{\omega}W\Delta\omega$, can be calculated for each $\{q\}$ point. The contour lines in the figure build hypersurfaces, on which the values of $\Delta\tilde{\omega}W\Delta\omega$ are invariant. Figure 2-2 shows a sectional diagram of Fig. 2-1 cut along the straight line X–Y. Point O gives a minimum in $\Delta\tilde{\omega}W\Delta\omega$. On the PQR curve (hypersurface), a cross-over occurs in the energy levels. When the $\{q\}$ parameters are varied on XY from O to Q, the displacement in the calculated line positions makes $\Delta\tilde{\omega}W\Delta\omega$ increase. The differential function is discontinuous at Q. Then, $\Delta\tilde{\omega}W\Delta\omega$ decreases as $\{q\}$ values are varied from Q to Y. This phenomenon has nothing to do with the fact that the estimation of the Jacobian matrix was not carried on above the first-order of approximation. At any rate, the least-square calculation cannot converge into the true minimum, O, when the starting set of constants, $\{q^0\}$, is on the right-hand side of the PQR curve in Fig. 2-1. This means that, when the true solution is near the "cross-over region," a spectrum is hard to analyze unless the starting constants are known with a sufficiently good approximation, as is stated in Condition 2.

When the set of starting constants, $\{q^0\}$, is not beyond the cross-over, the violence of Condition 2 may lead to three faults: a halt of the iteration, a falling into a trap on a hillside, and a jumping over the cross-over line. When Condition 2 is violated, the value of the correction, $\{\Delta q\}$, obtained from $\{q^0\}$ may be such that the Jacobian matrix for the

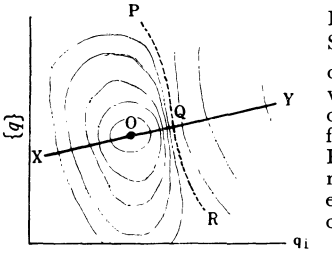

Fig. 2-1. Schematic behavior of $\Delta\tilde{\omega}W\Delta\omega$, the weighted square sum of residuals, as function of $\{q\}$. PQR represents a ridge way where energy levels cross over each other.

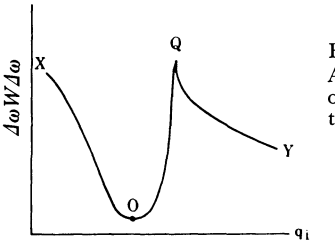

Fig. 2-2. A sectional diagram of Fig. 2-1 cut along the line X–Y.

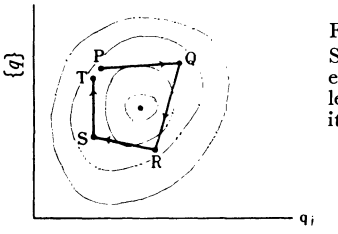

Fig. 2-3. Schematic representation of a halted least-squares iteration.

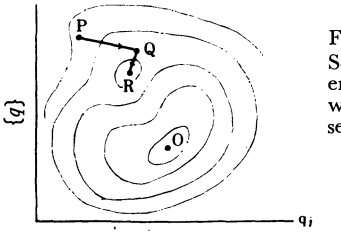

Fig. 2-4. Schematic representation of a case where the iteration settles in a trap.

next cycle of iteration (A_{ij}^1) is significantly different from the original one (A_{ij}^0). Then (A_{ij}^2) may also differ significantly from (A_{ij}^1), in which case an oscillation or circulation of the iteration sets in. This is shown in Fig. 2-3, where the coordinates and the contour lines have the same meaning as in Fig. 2-1. The iteration procedure gives the P, Q, R, S and T points in turn. If there is a trap on the way, the iteration may converge into the trap. This is shown in Fig. 2-4. Starting from P, a false set of constants R is obtained. Near the "cross-over" line, the large correction, $\{\Delta q\}$, may cause the next set of constant, $\{q\}$, to jump over the line. This is the third case.

The Singularity of the Normal Equation.—In the present work, 10 to 14 data of line positions were used to obtain 6 parameters in the least-squares analysis. The symmetry of the molecule

is sufficiently low for there to be no identity among the molecular constants. It might be supposed that there would be little possibility for the normal equation to be singular. It was, however, found that the normal equation could sometimes be almost singular.

Table I shows a set of observed line positions and five weight matrices. Table II lists the results obtained for the five weight matrices by the standard ASF least-squares method. These tables show that small changes in input data sometimes result in considerable variations in the converged constants. In Cases I and II, the same line positions and only one change of weight, from 1 to 0, resulted in a difference of 0.3 c.p.s., or of 15%, in the J_{AC} value. When the starting constants or the line positions were varied by small amounts, the least-squares iterations sometimes showed a slow convergence, and in some cases oscillation resulted.

In the above cases, the inverse matrix of the coefficient matrix of the left-hand side of the normal equation $(\tilde{A}WA)^{-1}$ had abnormally large elements. Table III shows the matrix $(\tilde{A}WA)^{-1}$ for the converged value of Case II in Table II. Accordingly, the estimated normal deviations for the resultant values of parameters, $\sigma[q_i]$, were large. This may be seen, for example, in the values in Table III, Column 1, obtained for the 1 data in Table I. In this case, the accuracy for the observed values and that for the result, $\{q\}$, are not, as has often been assumed, of the same order of magnitude.

TABLE I. ABSORPTION LINE POSITION DATA FOR PURE ACRYLIC ACID

The same set of line position data ω_j was used with five sets of weight matrices W_{jj}. Line positions ω_j were obtained by averaging 30 charts, measured at 60 Mc., at room temperature, from an arbitrary zero-point, by c.p.s. Intensities I_j and standard deviations σ_2 were used in the subsequent analysis.

The correlation matrix for the six parameters, $(R_{ij})=(\rho[q_i, q_j])$, was calculated, as is shown in Table IV, from the inverse matrix in Table III. It has large off-diagonal elements near unity, indicating strong correlations among the parameters.

The above-mentioned features indicate that the normal equation is nearly singular in these cases. The iteration calculations were, therefore, carried out with one parameter fixed. First, the J_{AB}

TABLE III. INVERSE MATRIX FOR THE COEFFICIENTS OF THE NORMAL EQUATION, $(\tilde{A}WA)^{-1}$, FOR A "NEARLY SINGULAR" CASE

Values of molecular constants for this cycle of the iteration are; $\nu_A=21.217728$ c.p.s., $\nu_B=0$ c.p.s., $\nu_C=-12.310128$ c.p.s., $J_{AB}=16.851388$ c.p.s., $J_{BC}=10.350362$ c.p.s., $J_{CA}=2.058250$ c.p.s., representing the converged set of molecular constants for weight matrix No. II, Table I. The matrix is symmetric.

j \ i	ν_A	ν_B	ν_C	J_{BC}	J_{CA}	J_{AB}
ν_A	4.22					
ν_B	1.16	0.84				
ν_C	−5.39	−1.80	7.77			
J_{BC}	−3.52	−1.28	4.84	3.59		
J_{CA}	15.23	4.78	−20.91	−13.36	59.50	
J_{AB}	−11.65	−3.50	15.80	10.16	−44.27	33.78

TABLE IV. A CORRELATION MATRIX (R_{ij}) AMONG THE SIX PARAMETERS FOR A "NEARLY SINGULAR" CASE

Molecular constants used are the same as in Table III. The matrix is symmetric.

j \ i	ν_A	ν_B	ν_C	J_{BC}	J_{CA}	J_{AB}
ν_A	1					
ν_B	0.61	1				
ν_C	0.94	0.71	1			
J_{BC}	0.90	0.74	0.92	1		
J_{CA}	0.96	0.68	0.97	0.91	1	
J_{AB}	0.98	0.66	0.98	0.92	0.99	1

parameter was fixed. Then, the remaining five parameters, $\{q'\}$, were no more correlated. As may be seen from Table V and Table VI, the inverse matrix has no diagonal element much larger than unity, and the off-diagonal elements in the correlation matrix are much smaller than unity.

The result obtained when J_{AB} is fixed at J_0, $\{q'; J_0\}$, is a point on the $J_{AB}=J_0$ hypersurface, where the square sum of weighted residuals, $\Delta\tilde{\omega}W\Delta\omega$, reaches a minimum. When J_0 is varied by small increments and $\{q'; J_0\}$ is obtained for each J_0 value, the sum, $\Delta\tilde{\omega}W\Delta\omega$, is a function of J_0 and can be minimized at $J_0=J_0{}^{min}$. Then, the point $\{q'; J_0{}^{min}\}$ gives a minimum point of the sum in the $\{q\}$ space. Although this procedure gives the same result as that obtained by directly solving the original 6×6 normal equation, it enables us to start from more crude trial constants, $\{q^0\}$. Sometimes, as in the analysis of the pH-5.03 aqueous solution of acrylic acid in Table X, the 6×6 method failed to converge from all the starting constants tried; the 5×5 method was the only means to obtain a solution.

TABLE V. A 5×5 INVERSE MATRIX $(\tilde{A}WA)^{-1}{}_{ij}$ OBTAINED BY FIXING J_{AB}

Molecular constants are the same as in Table III.

j \ i	ν_A	ν_B	ν_C	J_{BC}	J_{CA}
ν_A	0.20				
ν_B	−0.04	0.48			
ν_C	0.05	−0.17	0.38		
J_{BC}	−0.02	−0.25	0.10	0.55	
J_{CA}	−0.05	0.22	−0.22	−0.08	1.54

TABLE VI. A CORRELATION MATRIX (R_{ij}) AMONG THE REMAINING FIVE PARAMETERS WHEN A PARAMETER J_{AB} IS FIXED

Molecular constants used are the same as in Table III.

j \ i	ν_A	ν_B	ν_C	J_{BC}	J_{CA}
ν_A	1				
ν_B	0.13	1			
ν_C	0.21	0.39	1		
J_{BC}	0.05	0.49	0.22	1	
J_{CA}	0.08	0.26	0.28	0.09	1

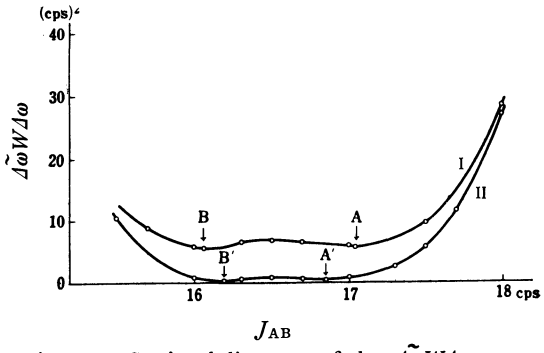

Fig. 3-1. Sectional diagrams of the $\Delta\tilde{\omega}W\Delta\omega$ surface, as obtained by fixing J_{AB}. Curves I and II correspond to data I and II of Table II. Singularity is produced when the saddle point between A and B is low.

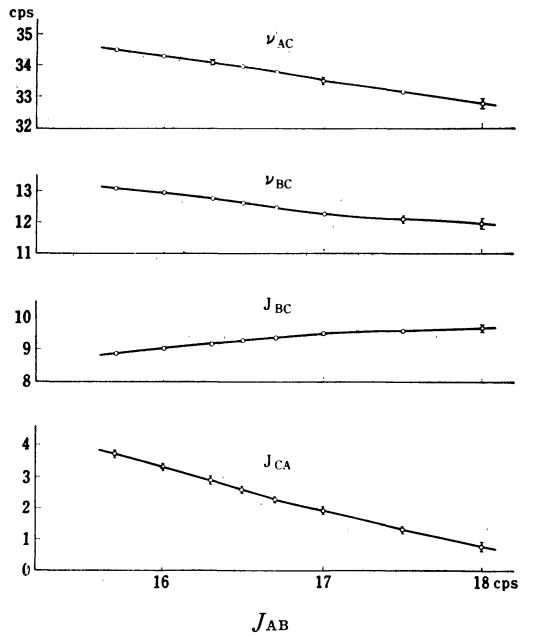

Fig. 3-2. The remaining constants $\{q'\}$ obtained by fixing J_{AB}.

Furthermore, the 5×5 method may be used to study the detailed shape of $\Delta\tilde{\omega}W\Delta\omega$ as a function of $\{q\}$. The values of $\Delta\tilde{\omega}W\Delta\omega$ and the corresponding $\{q'; J_0\}$ are plotted against J_0 in Figs. 3-1 and 3-2. The two curves in Fig. 3-1 are sectional sideviews similar to the curve in Fig. 2-2. The straight line, X–Y, in Fig. 2-2 is now replaced by a curve tracing the bottom of the valley. The abscissa is J_{AB}. Curves I and II correspond to data I and II in Table I respectively.

	15	0.00	0.00	0.00	0.00	0.00	0.00

In Fig. 3-2, the remaining constants, $\{q'\}$, for the data I are plotted. The short perpendicular bars are the standard deviations estimated from Formulas 4 and 6.

A remarkable feature of the curves in Fig. 3-1 is that each of them has two minima with a low saddle point. The two minima in the curve gave the same line positions and very similar absorption intensities. $\{q'\ ;\ J_0\}$ points between and near the minima also gave very similar spectra. Table VII shows the calculated spectra for several points, $\{q'\ ;\ J_0\}$, on Curve I, Fig. 3-1. It may be seen that a large (and correlated) variation in the constants causes little variation in the line positions. For example, the variation in J_{AC} from 3.65 c.p.s. to 0.12 c.p.s. causes line 11 to displace only 0.30 c.p.s, and this is the most prominent of all the line position displacements. The calculated intensities for the two minima for the data are presented in Table VIII. The intensities are not very different.

The above-mentioned results show that, when there are two closely-placed minima in the $\Delta\tilde{\omega}W\Delta\omega$ vs. $\{q\}$ curve, there may be an incomplete singularity in the original least-squares method and a large inaccuracy in the results obtained. Therefore, it is not appropriate to ask whether or not two results of analysis, $\{q^1\}$ and $\{q^2\}$, represent the same solution without considering their normal deviations. A set of data may give $\{q^1\}$, while another set, a little different from the former, or even the same data when processed on another computor, may give $\{q^2\}$, which seems to be substantially different from $\{q^1\}$.

The same situation may be encountered[13] in dealing with the CW method for calculating molecular constants. In the above-mentioned cases of two minima, the solutions from the CW method were also strongly affected by minute changes in the adjusted (observed) line positions and rounding

errors in the calculations.

In conclusion, two closely-placed minima cause a poor convergence in the calculation and large estimated normal deviations in the result. The convergence may be improved by the reduction of the parameter, but the only way to eliminate uncertainty in the result is to introduce independent information, such as a change in the medium, data at another radiofrequency, or the parameters of related compounds.

The Starting Constants.—In an analysis of an unknown ABC spin system with the ASF method, the first one or two sets of solutions are usually easy to obtain. A few trial-and-error assumptions of starting constants based on a first-order analysis, chemical or structural considerations or explicit analysis can give the desired result. When the iteration does not converge, it may be improved by reducing a parameter.[14]

However, it is sometimes difficult to obtain all the possible solutions by the trial-and-error method.[15] The CW method for calculating molecular constants is suitable for this purpose. The calculated spectrum of the first solution can be used for the "adjusted absorption frequencies data." When the biquadratic equation described in Ref. 3 yields complex solutions with small imaginary components, the real part may be used to obtain an approximate set of molecular constants. The refinement by the ASF method then removes the uncertainty about the line-adjustment[13] and the reliability of the result.

14) In order to reduce the parameters, the choice of the new set of parameters is important. In principle, it may be selected by solving a secular equation for the $\{q\}\sim\Delta\omega W\Delta\omega$ solid. A set of linear combinations of the original parameters is obtained. The most efficient way to eliminate the singularity is to fix one of the linear combinations and to take the others for the new set of parameters. In the present work, in order to simplify matters, the new set chosen was similar to the original one except for the fixed parameter. The parameter, J_{AB}, was fixed because the correlation matrix had comparatively large elements in the corresponding column. The choice proved to be effective, as has been discussed in the text. We also tried to fix all the parameters in turn and to make the calculation self-consistent; that is, one parameter was fixed in a cycle and the solution was used for the input data of the next cycle, where another parameter was fixed. This method failed to improve the convergence, however.

15) Swalen and Reilly[4] say that there is no problem of uniqueness about their iteration method. However, energy levels are not uniquely determined from a set of observed line positions. Even when the levels are determined from double quantum lines or by other techniques, other sets of solutions are still possible. Their "transformation vector," which diagonalizes the approximate Hamiltonian, is not a constant vector when the correction, $\{\Delta q\}$, is large. It follows that if they start from different sets of approximate constants, different solutions will be obtained. The situation is the same between the SR method and the ASF method as far as the uniqueness is concerned.

Experimental

The acrylic acid and carbon tetrachloride were purified by distillation from commercial products. The pH measurements were made to a precision of ±0.1 pH units with glass electrodes calibrated with standard buffer solutions. The concentrations were determined by weight.

The NMR measurements were made with a standard 60 Mc. apparatus without NMR control, at room temperature. The sideband frequencies were calibrated by a frequency counter to a precision of ±0.1 c.p.s. The absorption line positions were measured from a line in the spectrum which served as a zero point. One sample was measured for 5—40 sweeps. These charts were then averaged to obtain one set of observed data.

A digital computor, PC-2, was used for the statistical processing of the charts, the CW method for calculating molecular constants, and the ASF least-squares calculations. The ASF method with or without the J_{AB} parameter fixed, and the CW method were used for analyses.

In the ASF method, the weight matrices were taken to be diagonal.[16] Except for the data listed in Table I, the diagonal elements were taken to be 1 or 0, depending on whether or not the corresponding line was observed. The lines which were not observed clearly because of weakness or line overlapping were given weights of 0.5 or 0.

16) In the above case, the line-position data from a chart sheet are not mutually-independent measurements, and the weight matrix may have some off-diagonal elements.[12] This point was, however, not studied in the present work. When the diagonal elements were varied, there were no significant changes in the results provided the normal deviation was taken into account.

Results and Discussion

Acrylic Acid in Carbon Tetrachloride.— Four sets of molecular constants, $\{q\}$, were obtained as the results of the analysis of pure acrylic acid. They are shown in Table IX. In view of the intensity data, Sets III and IV are obviously not suitable, whereas Sets I and II almost equally fit to the observed spectrum. Though the intensities of Lines No. 9 and No. 14 seem to be favorable to Set I, the choice is not clear. The estimated standard deviations are large in both cases.

In order to determine which of the two sets is the more suitable, the spectrum of a carbon tetrachloride solution of acrylic acid, 11% by weight, was analyzed. Two sets of molecular constants were obtained near Sets I and II of the pure substance, as is shown in Table IX. One of them, Set I, has very similar coupling constants to those of Set I in the pure substance. Though the observed spectra of the two systems are rather similar, the other sets of molecular constants, the II sets, were considerably different. The saddle-point between the two minima was found to increase in height, and the calculated absorption intensity for the two sets I and II was also appreciably different, in the 11% solution. In this case, therefore, there was little ambiguity in choosing Set I as the better set.

The spectra in 63% and 2% solutions were also analyzed. Again there was a series of sets of constants with small variations in coupling constants and with good agreement in intensities. From those facts we have concluded that the sets corresponding to the Set I in pure substance are the correct sets of the molecular constants of the systems. These results are shown in Fig. 4, together with other results.

Acrylic Acid in Aqueous Alkaline Media.— The variation in $\{q\}$ was studied for a 10%-in-wt. aqueous solution of acrylic acid at various pH values. The pH was adjusted by the addition of sodium hydroxide. In these systems, the fact that we again obtained the Set II of molecular constants caused some difficulty. The variation in these two sets of solutions with the pH of the system is shown in Table X. This table shows that, in Set I, J_{AB} and J_{AC} are not changed by more than ± 0.2 c.p.s. by the cange in pH, while in Set II they vary over a wide range. The pH dependence of the shifts is smooth in Set I, while in Set II it is irregular. These facts suggest that Set I is the more suitable solution. Moreover, a comparison of the intensities shows that in the two extreme cases, i. e., in the aqueous solution and in the pH-13 solution, Set I gives the correct intensity while Set II does not. Hence, Set I may be said to represent the true molecular constants over the entire pH range.

In the intermediate range of pH, where the two sets approach and cross each other, the estimated normal deviations of $\{q\}$ became broad and convergence was difficult to obtain, as has been discussed in the previous section. At pH 5.03, the least-squares analysis was made by the 5×5 method because convergence was not reached by the 6×6 method. The corresponding reliability range, shown in Table XIII, is very large. When, however, the calculation is made by assuming the J_{AB} constant to be in the same reliability range as it is at the other pH's, i. e., at 17.4 ± 0.2 c.p.s, the corresponding range of the other parameters becomes much narrower, as is shown by the perpendicular bars in Fig. 4.

Figure 4 also shows that the coupling constants do not vary appreciably with the pH. The following assumptions were made to explain the pH dependence of the chemical shifts:

(a) The only solute species in a 10% aqueous solution and in a pH $\sim$13 alkaline solution are an acid monomer molecule, HA, and a monoanion, A^-, respectively.

(b) In a solution with an intermediate pH

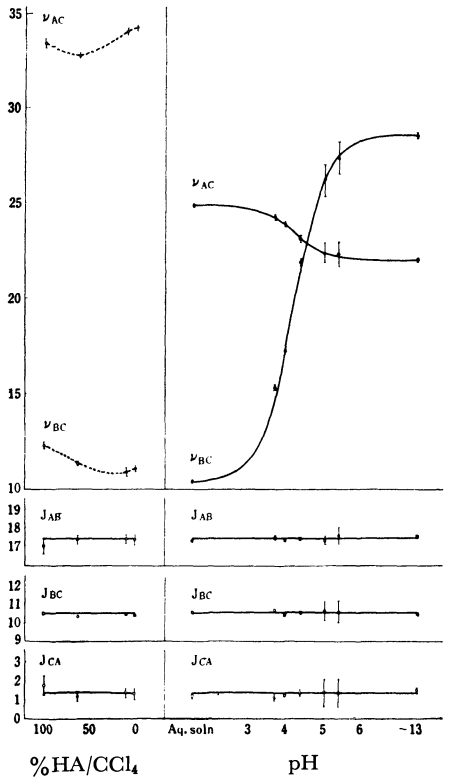

Fig. 4. Variation of the molecular constants. The left half of the figure shows the molecular constants of acrylic acid in CCl_4, and the right one those in 10% aqueous solutions of various pH. Perpendicular bars are the estimated normal deviations (see text). Solid curves for ν_{AC} and ν_{BC} represent theoretical lines for a pK_a of 4.20.

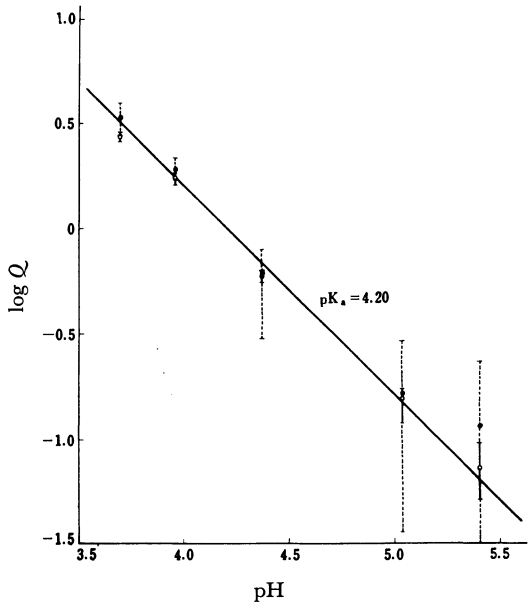

Fig. 5. The relation between log Q and pH. White circles refer to log Q's obtained by ν_{AC} and black circles to those by ν_{BC}. Solid or broken bars attached to each circle represents the variation in each value.

value, HA and A^- exist in a chemical equilibrium:

$$[H^+]\cdot[A^-] = [HA]\cdot 10^{-pK_a} \quad (9)$$

and the exchange between them is sufficiently fast. The activity expressed in Eq. 9 by a square bracket can be approximated by the analytical concentration.

Therefore,

$$pK_a - pH = \log Q$$

where

$$Q = \frac{q_A - q_{HA}}{q - q_{HA}} - 1$$

Figure 5 shows the log Q vs. pH plot for $q=\nu_{AC}$ and for $q=\nu_{BC}$. The perpendicular bars are estimated widths, corresponding to the standard deviations of q, q_{A^-} and q_{HA}. The points agree with the solid straight line with a gradient of -1. From the intercept of the straight line with the line for log $Q=1$, $pK_a=4.20\pm0.10$ was deduced. This value agrees fairly well with the value of 4.25 reported in the literature, which was determined potentiometrically.

The results given above suggest that the molecular constants for a 10% aqueous solution and a pH ~13 aqueous solution of acrylic acid represent those of a monomer acid molecule and a monoanion respectively. The chemical shifts can be explained in terms of bond-anisotropy. It was assumed that an acid monomer molecule has a *s-cis* structure; that the C=O bond susceptibility tensor is axially symmetric with an anisotropy of $\Delta\chi$ and with the axis perpendicular to the molecular plane, and that the induced dipole is at the center of the bond. The monoanion COO^- group was assumed to have a similar group anisotropy, $\Delta\chi'$, and the induced dipole was assumed to be at the center of gravity of two C–O bonds. The reported values of anisotropy in C=O[17,18] and CO_3^{2-} [19] groups leads to $\Delta\chi$ and $\Delta\chi'$ values of -5——10×10^{-6} e.m.u. If we take $\Delta\chi=\Delta\chi'=-8\times10^{-6}$ e.m.u., $\nu_{AC}=22.6$ c.p.s. and $\nu_{BC}=13.9$ c.p.s. in an acid monomer, and $\nu_{AC}=12.1$ c.p.s. and $\nu_{BC}=22.3$ c.p.s. in a monoanion. These values are in fairly good agreeement, in order of magnitude and in sense of variation, with the observed values. The difference of about 10 c.p.s. in ν_{AC} value between the 10% aqueous solution and carbon tetrachloride solutions seems to reflect the change from the acid monomer structure interacting with the solvent water molecules to the acid dimer or polymer structure interacting with the other solute molecules. A simple explanation in terms of bond-anisotropy was not sufficient for a more quantitative discussion. Solutions in carbon tetrachloride showed only a small change in chemical shifts with the concentration, suggesting that dilution with the nonpolar solvent carbon tetrachloride down to 2 wt.% or 5 mol.% affects the solute-solute interactions little.

According to the concept of electronegativity, a –COOH group must be considerably different from a $-COO^-$ group, and the relationship between coupling constants and electronegativity in vinyl compounds predicts corresponding changes in coupling constants. Such changes were not observed, however. The coupling constants and, particularly, their sums are quite invariable in spite of the great change in molecular states and in chemical shifts.

The authors wish to thank Drs. Yuzuru Fujiwara, Masaharu Toyama and Yoji Arata for valuable discussions. We are also much indebted to Dr. Osamu Yamamoto of the Government Chemical Research Institute, Tokyo, and Dr. Ichiro Yamaguchi of Japan Atomic Energy Research Institute for their aid in NMR measurements.

The Effect of the pH Value on the Crystallization of Strontium Sulfate in the Presence of Triphosphate

By Masaji MIURA, Hiromitu NAONO and Mitunori HARA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received June 16, 1965)

The crystallization of strontium sulfate has been conductometrically investigated in the presence of triphosphate under various pH values of the solution. The amount of triphosphate adsorbed on the crystal surface of strontium sulfate has been estimated as a function of the pH of the solution. The action of triphosphate in stabilizing the supersaturated solution of strontium sulfate and the amount of triphosphate adsorbed on the crystal surface depend remarkably on the pH of the solution; further, the two are closely correlated with each other. It has been concluded from these facts that the adsorption of triphosphate plays an important role in the stabilization of the supersaturated solution of strontium sulfate.

Several investigators have studied the characteristic phenomena caused by the action of condensed phosphates on the crystallization of sparingly-soluble inorganic salts from their supersaturated solution.[1-5] As has been reported previously,[2-4] the crystallization of strontium sulfate is extremely retarded and its supersaturated solution is stabilized by the coexistence of a minute amount of triphosphate. Recently, it has been clarified that the main function of triphosphate is the suppression of nuclei formation from the supersaturated solution of strontium sulfate.[6] On the other hand, such a stabilizing action is closely correlated to the adsorption of triphosphate on the crystal surface of strontium sulfate.[2-4]

The works mentioned above have treated the stabilizing action and the adsorptive behavior of triphosphate in a neutral solution.[2-4] It has been found, however, that when the pH of the solution is varied, remarkable differences arise in the stabilizing action, and also in the adsorptive behavior, of triphosphate. Accordingly, it seems of great interest to investigate these problems at various pH values.

Experimental

Materials.—Strontium chloride and potassium sulfate were purified by recrystallizing the special-grade reagents three times from their aqueous solutions. Pure sodium triphosphate labeled with ^{32}P was prepared by a procedure which has been described previously.[5] Strontium sulfate crystals used as an adsorbent were prepared by a procedure similar to that described in a previous paper,[3] except that the experiment was carried out in a nitrogen atmosphere in order to avoid the formation of strontium carbonate.

Crystallization.—The crystallization of strontium sulfate was traced by measuring the conductivity decrease in the supersaturated solution, which was prepared by mixing equal volumes of 0.02 M solutions of strontium chloride and potassium sulfate, the latter containing various amounts of triphosphate.

Adsorption.—The experiment of adsorption was carried out by a radiotracer method with the aid of triphosphate labeled with ^{32}P.[2]

The pH of the solution was adjusted by adding hydrochloric acid or sodium hydroxide. Crystallization and adsorption experiments were carried out at 25°C in a nitrogen atmosphere in order to restrain the pH change during the procedures.

Results and Discussion

As has been reported in the previous papers,[3,4] such a minute amount of triphosphate as 5×10^{-6} M practically inhibits the crystallization from a 0.01 M strontium sulfate solution when the solution is neutral. With its concentration kept at 5×10^{-6} M, the action of triphosphate on the crystallization of strontium sulfate was examined conductometrically at various pH values. As may be seen in Fig. 1, the stabilizing action of triphosphate becomes weak as the pH of the solution is lowered. In Fig. 3, the decrease in specific conductivity after 100 min, is plotted as a function of the pH of the solution. It must be emphasized that the stabilizing action changes abruptly within a certain pH range and practically disappears below pH 5. Figure 2 shows the pH dependence of the stabilizing

action of triphosphate, its concentration being 3×10^{-5} M. An abrupt change in the stabilizing action is also observed, but it occurs in a somewhat lower pH region than in the above case, as may be seen in Fig. 3.

Next, the crystallization of strontium sulfate was studied at various pH values in the absence of triphosphate. Figure 4 shows that the crystallizations are somewhat different at different pH values. The lower the pH of the solution, the more rapidly the crystallization begins, but the effect of pH on the crystallization is small compared with that in the presence of triphosphate mentioned above. Consequently, it is clear that the remarkable change in the stabilizing action with the pH value in the presence of triphosphate is mainly due to the change in the action of triphosphate with the pH.

It has been considered so far that the stabilization of the supersaturated solution of strontium sulfate by triphosphate is to be attributed to the adsorption of triphosphate. It may, therefore, be expected that a remarkable difference will also appear in the adsorptive behavior of triphosphate on the surfaces of strontium sulfate crystals.

A pH=3.32, B pH=6.50, C pH=9.95

It has been reported previously that triphosphate adsorbed from a neutral solution forms a monomolecular layer on the surfaces of strontium sulfate crystals.[3] It is, therefore, apparent from the

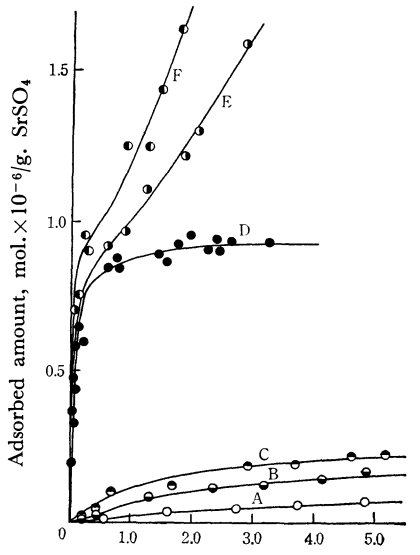

Fig. 5. Adsorption isotherms of triphosphate at various pH.
A pH=2.5, B pH=3.2, C pH=3.5,

isotherms in the acid region that the adsorbed triphosphate covers merely a small fraction of the adsorbent surface. On the other hand, on the alkaline side the amount adsorbed far exceeds that corresponding to the monomolecular layer.

Now, let us discuss the pH dependence of the stabilizing action of triphosphate in connection with that of the amount adsorbed at the concentration of triphosphate, 3×10^{-5} M. It is obvious from Figs. 2 and 6 that both the stabilizing action and the adsorbed amount change remarkably in the vicinity of pH 4; that is, the stabilizing action increases rapidly with the abrupt change in the adsorbed amount. This fact indicates that the adsorption plays an important role in the stabilizing action, as has been considered previously. In the present work, no large difference in the stabilizing action was observed on the alkaline side, though the amount adsorbed was far larger than that in the neutral region.

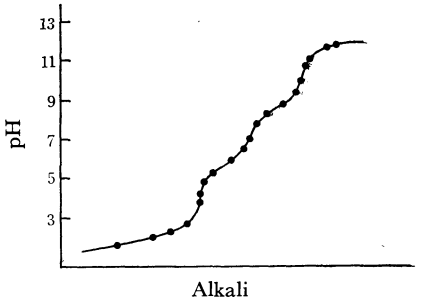

Fig. 7. Titration curve of triphosphoric acid with tetramethyl ammonium hydroxide. After J. I. Watter et al.[7]

When triphosphoric acid is titrated with alkali, three inflection points can be obtained, corresponding to three different ionic species, namely, $H_2P_3O_{10}^{3-}$, $HP_3O_{10}^{4-}$ and $P_3O_{10}^{5-}$, as may be seen in Fig. 7.[7] A comparison between the titration (Fig. 7) and the adsorption (Fig. 6) curves shows that the ionic species, $HP_3O_{10}^{4-}$ and $P_3O_{10}^{5-}$, have a much greater ability to be adsorbed on the crystal surface than does $H_2P_3O_{10}^{3-}$. On the other hand, the stability of the complex between strontium and triphosphate ions increases with an increase in the pH of the solution.[8] Therefore, triphosphate ions of a higher valency may be adsorbed on the strontium sulfate crystal, forming a surface complex with strontium ions and thus playing an important role in stabilizing the supersaturated solution of sutrontium sulfate.

Summary

The pH of the solution exerts a profound influence on the action of triphosphate in stabilizing the supersaturated solution of strontium sulfate, and also on the amount of triphosphate adsorbed on its crystal surface. Both of these functions of triphosphate show a remarkable change in the vicinity of pH 4 when the concentration of triphosphate is 3×10^{-5} M. Above pH 4, the stabilizing action and the amount of triphosphate adsorbed

increase remarkably. On the other hand, it has been reported that the stability of the strontium complex with triphosphate increases with the increase in the pH. These facts have led us to the conclustion that the stabilizing action in the higher pH range is mainly due to the strong interaction between triphosphate ions of a higher valency and the surfaces of strontium sulfate crystals.

The Effects of Polyamines on the Melting of Polyriboinosinic Acid Plus Polyribocytidylic Acid Complex in Solution

By Kimiko MATSUO and Masamichi TSUBOI

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo Tokyo

(Received June 21, 1965)

The thermal transition profile (melting profile) of the double-helical complex of polyriboinosinic acid plus polyribocytidylic acid, poly(I+C), into random coils in solution has been examined by the observation of the ultraviolet absorbance at 248 mμ of the solution. The effects of Na^+, Mg^{2+}, NH_4^+, $CH_3NH_3^+$, $NH_3^+(CH_2)_nNH_3^+$ (where $n=2$, 3, 4, 5, 6, and 8), spermidine, spermine, actinomycin D, and poly-L-lysine upon the melting profile have been observed. Among the diamines examined, that with $n=3$ has been found to have the maximum effect. Poly-L-lysine has been found to form a complex with poly(I+C) in the solution with a stoichiometric mole ratio of $NH_2 : P = 0.5 : 1$.

The interactions of polyamines with nucleic acids seem to play important roles in some stages of many biological processes. Spermine NH_3^+-$(CH_2)_3NH_2^+(CH_2)_4NH_2^+(CH_2)_3NH_3^+$, for example, which is widely distributed in biological materials,[1] is known to affect the deoxyribonucleic acid (DNA) multiplication in some bacterial systems. In the chromosomes of higher organisms, DNA is found as a complex with histon, which is a lysine- and arginine-rich basic protein. In view of such biological importance, we have attempted to obtain fundamental knowledge about the interactions of polyamines with nucleic acids.

Polyriboinosinic acid (poly I) and polyribocytidylic acid (poly C) are synthetic polymers which have the same ribosephosphate backbone as natural ribonucleic acid (RNA).[2] A 1 : 1 mixture of poly I and poly C is known to form a double-stranded helical complex, poly(I+C), in solution.[3] Its structure[4] is considered to be similar to that of natural double-stranded DNA.[5] Some general discussions of the "melting" of such a double-helical nucleic acid were given in a previous paper.[6] Along this line we have been observing the effects of polyamines on the "melting" profile of poly-(I+C) in solution. Quite recently, however, a similar work with poly(I+C), which was done independently of our work, has been reported by Mehrotra and Mahler,[7] as have been a few similar examinations made previously with DNA.[8-10] Some of our results, which differ from those reported in other papers, will be presented in this paper and Discussed.

Experimental

The polyriboinosinic acid (poly I) and polyribocytidylic acid (poly C) used in this work were prepared by the use of the polynucleotide phosphorylase obtained from *Azotobacter vinelandii*. Both polynucleotides showed a sedimentation coefficient of 4s—8s in ultracentrifugal examination. The polynucleotide concentration in each standard solution was determined by measuring the phosphorus content.[11,12] Ethylenediamine dihydrochloride $NH_3^+(CH_2)_2NH_3^+ \cdot 2Cl^-$, 1, 4-diaminobutane

dihydrochloride $NH_3^+(CH_2)_4NH_3^+\cdot 2Cl^-$, 1, 5-diaminopentane dihydrochloride $NH_3^+(CH_2)_5NH_3^+\cdot 2Cl^-$, 1, 6-diaminohexane dihydrochloride $NH_3^+(CH_2)_6NH_3^+\cdot 2Cl^-$ and 1, 8-diaminooctane dihydrochloride $NH_3^+(CH_2)_8NH_3^+\cdot 2Cl^-$ were obtained from the Tokyo Kasei Co. 1, 3-Diaminopropane dihydrochloride was obtained by introducing hydrogen chloride into 1, 3-diaminopropane (purchased from the Tokyo Kasei Co.) dissolved in ethanol. Spermidine trihydrochloride $NH_3^+(CH_2)_3NH_2^+(CH_2)_4NH_3^+\cdot 3Cl^-$ was obtained from the Nutritional Biochemicals Corporation, and spermine tetrahydrochloride $NH_3^+(CH_2)_3NH_2^+(CH_2)_4NH_2^+(CH_2)_3NH_3^+\cdot 4Cl^-$ from the Sigma Chemical Co. Poly-L-lysine hydrobromide with average molecular weight of 60000 was purchased from Pilot Chemicals, Inc. The poly-L-lysine concentration in our standard solution was determined by hydrolyzing it with 6 N hydrochloric acid and by then measuring the lysine content by the use of 2, 4-dinitrofluorobenzene.[13]

The ultraviolet absorption measurements were made by the use of an Ito Spectrophotometer, model QU-3. The temperature of the sample chamber was controlled by circulating ethylene glycol from a Haake Thermostat, model F. The sample chamber was thermally insulated from the other parts of the spectrophotometer by using two insulating plates and by having cooling water flow between the two plates. The temperature of the sample solution was measured with a cupper-Constantan thermocouple.

Results and Discussion

The Melting of Poly(I+C) Observed by Tracing the Absorbance at 248 mμ.—First, a few preliminary examinations were made of the ultraviolet absorption spectra of our samples of polyribonucleotides and their mixtures. It was found that our poly I and poly C in a citrate buffer (pH 7.0) give exactly the same spectra as those reported by Davies and Rich[3] in the 220—300 mμ region. The spectrum of a 1 : 1 mixture of these polymers indicates that a strong interaction takes place in 0.01 M sodium chloride plus 0.01 M sodium citrate buffer (pH 7.0), while no interaction takes place in a 0.001 M sodium-citrate buffer (pH 7.0) without sodium chloride. In the 0.05 M sodium chloride plus 0.01 M sodium-citrate buffer (pH 7.0), the absorbance was measured at 233 mμ for several mixtures containing varying proportions of poly I and poly C, while the total nucleotide concentration was kept constant. The resulting mixing curve is similar to what Davies and Rich[3] observed at 235 mμ in a cacodylate buffer (pH 6.7). It is composed of two straight lines which intersect sharply at a 1 : 1 mole ratio, demonstrating the formation of a 1 : 1 complex, poly(I+C). This complex is considered to have a double-helical conformation.[3,4] When solution of this complex is heated, there is a general increase in absorbance in the 230—270 mμ region. This increase is considered to correspond to the "melting" of the double-helical poly(I+C) into single-stranded random coils, poly I and poly C. The increase in absorbance is greatest at 248 mμ. Therefore, the melting process of poly(I+C) was followed by observing the absorbance at 248 mμ throughout the rest of the present work. The melting temperature, T_m, is defined as the midpoint of the increase in absorbance just mentioned.

The Effect of Na^+.—The melting process of poly(I+C) is influenced by the Na^+ concentration in the solvent in two ways. When the Na^+ concentration is lowered, the melting temperature, T_m, of poly(I+C) is lowered, and at the same time the melting process loses its reversibility. As may be seen in Fig. 1, the T_m of poly(I+C) is 65°C in the medium with 0.1 M Na^+ while it is 49.5°C with 0.01 M Na^+. In the former solution the reformation of the complex takes place rapidly (within 9 min.), while in the latter it takes a very long time (about 24 hr.). This lower reaction rate may be attributed to a high activation energy. Without shielding by a cation atmosphere, two negatively-charged polymers (poly I and poly C) cannot easily approach to each other. In Fig. 2, T_m is plotted against the logarithm of the Na^+ concentration [s]. As was expected in a previous paper,[6] the curve gives an S shape. On the basis of what was described in Section 3 in a previous paper,[6] $K'=1/[s]$ at the inflection point. Here, K' is the equilibrium constant at T_m of each of the reactions:

$$\text{Poly(I + C)} + Na^+ = \text{poly(I + C)}Na^+$$

$$\text{poly(I + C)}Na^+ + Na^+ = \text{poly(I + C)}{Na^+}_2$$

.....

and

$$\text{poly(I+C)}{Na^+}_{N-1} + Na^+ = \text{poly(I+C)}{Na^+}_N$$

From an inspection of Fig. 2, $K'=15$—$20\ M^{-1}$. An inspection of Fig. 2 also shows that the T_m change in the variation of $[s]$ is smaller than that for poly(A+U) and that for DNA. Very probably this means that the α value is smaller for poly(I+C) than for poly(A+U) or for DNA.[6] Here α is the increase in the enthalpy of the melting of poly(I+C) caused by the adsorption of one cation.[6]

The Effects of a Few Other Cations.—As may be seen in Fig. 3, the effect of the ammonium ion on the T_m of poly(I+C) is almost the same as that of Na^+. The effect of the methylammonium ion is somewhat smaller, while the effect of Mg^{2+} is markedly greater than the effect of the ammonium ion.

The Effects of Diamines.—When a NH_3^+-$(CH_2)_n NH_3^+$-type diamine is added to the poly(I+C) solution, an appreciable elevation of T_m is again observed (Fig. 4). The amount of elevation ΔT_m, is found to depend upon the value of

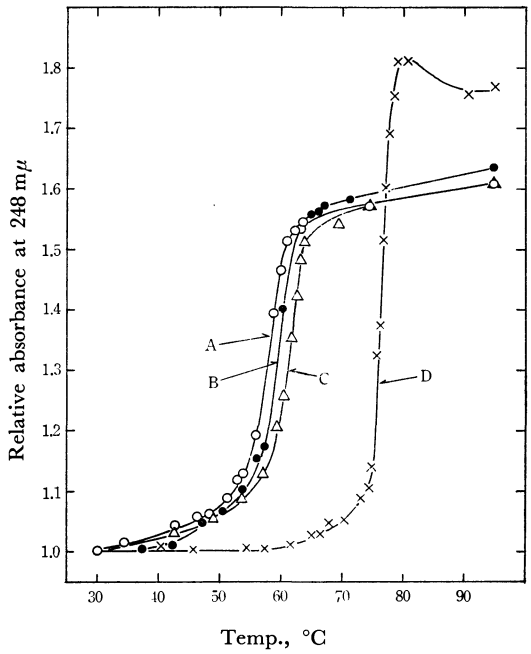

Fig. 3. The variation of the absorbance of poly(I+C) solutions at 248 mμ with temperature.

D Solution A plus 0.01 M $MgCl_2$

n, the number of the methylene groups placed between the two amino groups of the diamine. When the concentration of the diamines is kept constant (0.01 M), the greatest ΔT_m value of poly(I+C) is found at $n=3$. $NH_3^+(CH_2)_3NH_3^+$ has an effect on the T_m of poly(I+C) greater not only than $NH_3^+(CH_2)_2NH_3^+$ but also than Mg^{2+}. This fact suggests that the $n=3$ cation functions not only as a shielder of the PO_2^- charges of the poly I and poly C chains, but also as a clamp which tends to keep the two polynucleotide chains together and gives an additional stability to the intertwined double-helical structure. If so, the $NH_3^+\cdots NH_3^+$ distance in this cation should reflect the distance from an oxygen atom of a PO_2^- group belonging to a poly I chain to that belonging to the poly C chain which is intertwined with the poly I chain.

The Effects of Spermidine and Spermine.—The effect of spermidine, $NH_3^+(CH_2)_3NH_2^+$-$(CH_2)_4NH_3^+$ (see Fig. 5, B), is much greater than that of the 1, 3-diaminopropane described above (Fig. 4, C). Thus, the addition of the former in only half the amount (0.005 M) of the latter causes a greater change in the T_m value (from 57°C to 84°C, i. e., $\Delta T_m=27$°C). The effect of spermine, $NH_3^+(CH_2)_3NH_2^+(CH_2)_4NH_2^+(CH_2)_3NH_3^+$, is even more dramatic (Fig. 5, C). Only 0.0005 M

of it causes an elevation of T_m from 57°C to 91°C. This suggests that the equilibrium constant, K', of the binding reaction of spermine to poly(I+C) is to the order of 10^4 or more. Mandel[9] examined the interaction of spermine with DNA, and found that the extent of the increase in T_m is proportional to the adenine-thymine content of the DNA sample. On the basis of what he found, one might suggest that there is no effect of spermine upon a double-helical polynucleotide structure without an adenine-thymine pair. What we have observed here, however, shows that this is not necessarily the case. There is certainly a marked effect of spermine upon poly(I+C), a double-helical polynucleotide without an adenine-thymine or an adenine-uracil pair. As may be seen in Fig. 5, D, the dialysis of the poly(I+C) plus spermine solution against the buffer for 40 hr. results in a great lowering of T_m, from 91°C to 66°C. Its T_m, however, is still appreciably higher than that of poly(I+C) alone in the same buffer. This fact indicates that the poly(I+C)-spermine binding is a very strong one; however, there seems to be no chemical reaction between them.

The Effect of Actinomycin D.—In a previous work,[14] 31.8 μg./ml. of actinomycin D was found

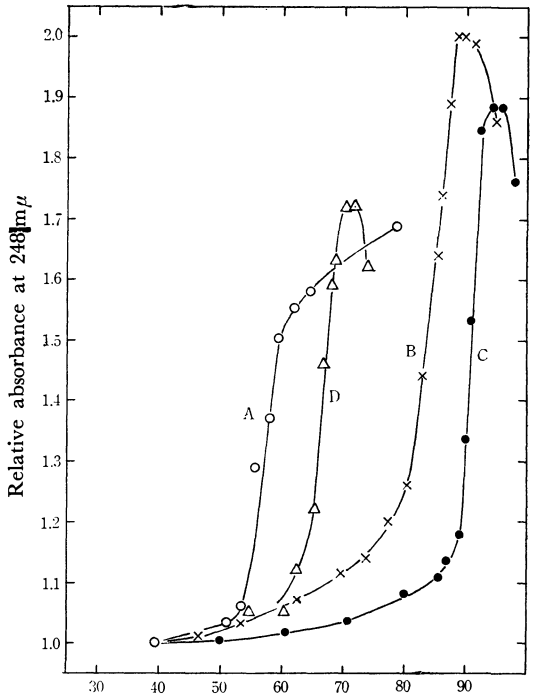

Fig. 5. The variation of the absorbance of poly-(I+C) plus polyamines at 248 mμ with temperature.

A Poly I 2.5×10^{-5} M plus poly C 2.5×10^{-5} M in 0.05 M NaCl plus 0.001 M Na-citrate buffer, pH 7.0

D A solution obtained by a dialysis of the solution C against 0.05 M NaCl plus 0.001 M Na-citrate buffer, pH 7.0, for 40 hr.

to cause an elevation of the T_m of DNA from 72°C to 87°C in a 0.01 M tris buffer. The same amount of actinomycin D, however, has now been found to have almost no effect on the melting profile of poly(I+C) in 0.05 M sodium chloride plus a 0.01 M sodium citrate buffer.

The Effect of Poly-L-lysine.—When poly-L-lysine is added to $0.8_3\times10^{-5}$ M to a solution of 2.5×10^{-5} M poly(I+C) ($NH_2:P=0.16_6:1$), two-step melting is observed instead of one-step melting (Fig. 6, A). Roughly two-thirds of the total increase in absorbance at 248 mμ takes place at 57°C, and the rest at 89°C. When the concentration of poly-L-lysine is increased to $1.6_6\times10^{-5}$ M (now $NH_2:P=0.33:1$), only 1/3 of the total increase in absorbance takes place at the first-step melting; the rest takes place at the second step. However, the melting temperatures remain at 57°C and 89°C (Fig. 6, B). The melting temperature of the first step (57°C) is the same as

14) M. Tsuboi, S. Higuchi, Y. Kyogoku, K. Matsuo and A. Wada, *Chem. Pharm. Bull.*, **12**, 501 (1964).

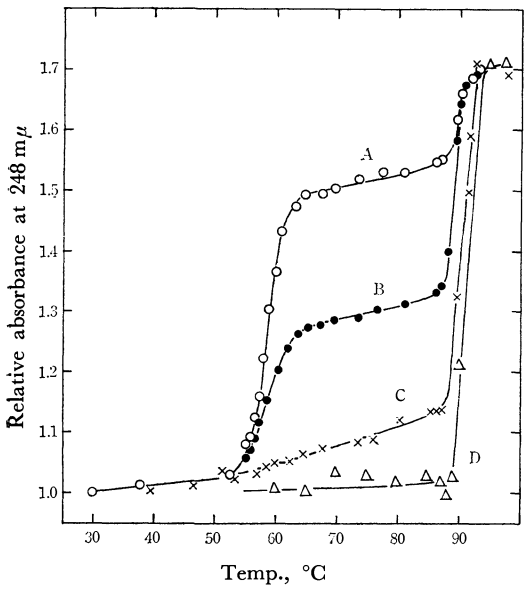

Fig. 6. The variation of the absorbance of poly-(I+C) plus poly-L-lysine solutions with temperature. Solvent: 0.05 M NaCl in 0.001 M Na-citrate buffer, pH 7.0.

A Poly I 2.5×10^{-5} M plus poly C 2.5×10^{-5} M plus poly-L-lysine $0.8_3\times10^{-5}$ M (NH_2 : P= 0.16_6 : 1).

B Poly I 2.5×10^{-5} M plus poly C 2.5×10^{-5} M plus poly-L-lysine $1.6_6\times10^{-5}$ M (NH_2 : P= 0.33 : 1).

C Poly I 2.5×10^{-5} M plus poly C 2.5×10^{-5} M plus poly-L-lysine 2.5×10^{-5} M (NH_2 : P= 0.5 : 1).

D Poly I 2.5×10^{-5} M plus poly C 2.5×10^{-5} M plus poly-L-lysine $3.7_5\times10^{-5}$ M (NH_2 : P= 0.75 : 1).

the T_m value of poly(I+C) alone in the solvent in question (0.05 M sodium chloride plus 0.001 M sodium citrate buffer, pH 7.0). When the concentration of poly-L-lysine is increased to 2.5×10^{-5} M (now NH_2 : P=0.5 : 1), the first-step melting at 57°C almost disappears, and only the melting at 89°C takes place (Fig. 6, C).

These experimental results indicate that there is a complex of poly-L-lysine and poly(I+C) with a definite mole ratio and with a T_m of 89°C in the solution. It has recently been shown[15] that, in poly-L-lysine plus DNA system, all the poly-L-lysine molecules added are bound by the DNA molecules and no poly-L-lysine molecules remain free, if the amount added is less than the amount sufficient to saturate the DNA molecules with poly-L-lysine. This is probably the case also for the poly-L-lysine plus poly(I+C) system. If so, the composition of the poly-L-lysine+poly-(I+C) complex in question can easily be determined. The NH_2: P ratio in the complex should be 0.5 : 1, since the melting of poly(I+C) free from poly-L-lysine (at 57°C) disappears at this mole ratio. This knowledge of the composition of the complex enables us to conjecture to some extent about its structure. It may be concluded, for example, that a molecular model similar to that of deoxyribonucleoprotamine, as proposed by Wilkins et al.[16,17] is not acceptable for the poly-L-lysine+poly(I+C) complex. In this model, an almost fully-extended polypeptide chain winds helically around the doubly-stranded polynucleotide chains. The pitch of the polypeptide helix is the same as that of polynucleotide helices. This model requires one amino acid residue per nucleotide residue, i. e., NH_2 : P=1 : 1, while in the poly-L-lysine+poly(I+C) complex in question, NH_2: P=0.5 : 1. In a fully-extended polypeptide chain, one amino acid residue corresponds to a translation of 3.4 Å along the chain axis. In the A-form of poly(I+C), the translation along the helix axis per nucleotide pair is 3.0 Å.[4] Therefore, such a chain axis of poly-L-lysine should be inclined about

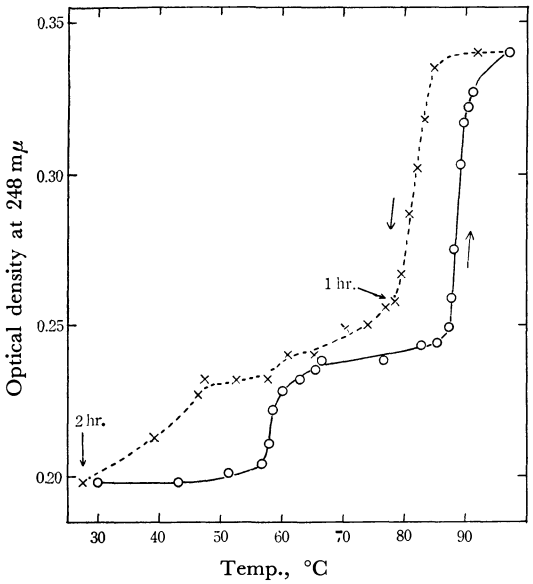

Fig. 7. The variation of the absorbance of a poly(I+C) plus poly-L-lysine solution on heating (full line) and on cooling (broken line). Poly I 2.5×10^{-5} M plus poly C 2.5×10^{-5} M plus poly-L-lysine $1.6_6\times10^{-5}$ M (NH_2 : P=0.33: 1) in 0.05 M NaCl plus 0.001 M Na-citrate buffer, pH 7.0. Each of the figures given on the cooling curve indicates the time taken by cooling the solution from 97°C to the temperature in question.

15) M. Tsuboi, K. Matsuo and P. O. P. Ts'o, *J. Mol. Biol.*, in press.

16) M. Feughelman, R. Langidger, W. E. Seeds, A. R. Stokes, H. R. Wilson, C. W. Hooper, M. H. F. Wilkins, R. K. Barclay and L. D. Hamilton, *Nature*, **175**, 834 (1955).

17) M. H. F. Wilkins, *Cold Spring Har. Quant. Biol.*, **21**, 75 (1956).

arc cos (3.0/3.4)=28° to the helix axis of the poly-(I+C) in the complex in question. Thus a possible model of the complex may be suggested in which the fully-extended poly-L-lysine chain winds around the double helices of poly(I+C) core along a helix with a long pitch.

The poly-L-lysine concentration was further increased from that corresponding to $NH_2 : P=0.5 : 1$. As may be seen in Figs. 6, C and D, the poly-L-lysine plus poly(I+C) solution with $NH_2 : P=0.75 : 1$ gives a heating curve similar to that of the solution with $NH_2 : P=0.5 : 1$. There is, however, a slight difference between them. In the latter there is a gradual increase in absorbance from 50°C to 88°C before a steep increase in absorbance takes place, whereas in the former no such gradual increase is observed; the curve is practically horizontal up to 89°. This fact may be taken as indicating that the excess poly-L-lysine molecules in the solution with $NH_2 : P=0.75 : 1$ serve to keep the complex rigid throughout the emperature range from 50°C to 89°C, and that without such excess poly-L-lysine molecules the poly-L-lysine+poly(I+C) complex is somewhat flexible.

Figure 7 shows the results of an examination of the reversibility of the two-step meltings now in question. As may be seen here, an almost complete reformation of the poly-L-lysine+poly(I+C) complex takes place in the solvent in question when the solution is kept at about 80°C for an hour after the melting.

The authors wish to express their deep thanks to Professor Fujio Egami, Professor Tyunosin Ukita, Professor Den-ich Mizuno, and their collaborators, and to the members of the Research Laboratories of the Meiji Seika Kaisha, Ltd., for their kind help in our preparation of poly I and poly C. This work was supported by a grant from the United States Public Health Service (No. GM 10024-02) and a grant from the Ministry of Education of Japan.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 352—356 (1966)

The Determination of Micro Amounts of Polythionates. III.* A Photometric Method for the Determination of Tetrathionate by Means of Its Cyanolysis[1]

By Tomozo KOH and Iwaji IWASAKI

Laboratory of Analytical Chemistry and Geochemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received June 22, 1965)

A photometric method capable of determining tetrathionate by exactly the same procedure as that used for pentathionate and hexathionate has been established. The optimum pH ranges for the reactions of tetrathionate, pentathionate and hexathionate with cyanide are 8.3—12.1, 8.0—8.8, and 7.8—8.9 respectively for the recommended procedure. From a consideration of the above experimental facts, it has been concluded that tetrathionate can be determined accurately by exactly the same procedure as that used for pentathionate and hexathionate when the pH value is within the range from 8.3 to 8.8. To the standard tetrathionate solution first the buffer solution and then a solution of sodium cyanide are added in order that the pH value of the mixture solution after the addition of the cyanide solution may be within the 8.3—8.8 range. The mixed solution is kept in the thermostat at 40°C for 30 min.; the tetrathionate is thereby converted into thiocyanate quantitatively. After the addition of a ferric nitrate - perchloric acid solution, the absorbancy of the solution of ferric-thiocyanate complex formed is measured at the wavelength of 460 mμ.

Nietzel and DeSesa[2] have presented a spectrophotometric method for the determination of low concentrations of tetrathionate, a method which is based on the formation of thiocyanate from tetrathionate by reaction with cyanide in an alkaline medium, and on the subsequent formation of a ferric-thiocyanate complex with ferric iron. At the same time, they have pointed out that their method can also be used for pentathionate and

* Part II: This Bulletin, **38**, 2135 (1965).

1) Presented at the Scientific Meeting on Chemistry, Tokyo, November, 1964.

2) O. A. Nietzel and M. A. DeSesa, *Anal. Chem.*, **27**, 1839 (1955).

hexathionate, because the higher polythionates react more easily with cyanide to form thiocyanate.

On the other hand, Urban[3] has modified the Nietzel-DeSesa method and applied it to the evaluation of n, the mean number of sulfur atoms in the formula, $S_nO_6^{2-}$, for polythionates above trithionate, on the assumption that pentathionate and hexathionate would react with cyanide to be quantitatively converted into thiocyanate under the same conditions as those used for the estimation of tetrathionate.

However, the higher polythionates, as has been reported in the first paper of this series,[4] undergo a partial alkaline decomposition under the conditions of the Nietzel-DeSesa and the Urban methods,[2,3] because of the higher pH value arising from the addition of a sodium cyanide solution. Therefore, their methods are not suitable for the higher polythionates.

The present authors[5] have previoulsy reported a method for the determination of a small amount of hexathionate, a method based on the reaction of hexathionate with cyanide, with the subsequent formation of thiocyanate from hexathionate, and on the photometric determination of the thiocyanate with ferric iron. In the above investigation, it has been found that the hexathionate can be determined sufficiently rapidly, precisely, and accurately by the very same procedure as is used for pentathionate.[4]

The present authors have now investigated, in greater detail, a method for the determination of tetrathionate using the reaction:

$$S_4O_6^{2-}+3CN^-+H_2O = S_2O_3^{2-}+SO_4^{2-}+2HCN+SCN^-$$

followed by the photometric determination of the thiocyanate thus formed with ferric iron; they have thus established an excellent method for determining a small amount of tetrathionate by the very same procedure as is used for pentathionate[4] and hexathionate[5]; they have found the conditions under which tetrathionate is also quantitatively converted into thiocyanate under the same conditions as are used for pentathionate and hexathionate, by varying the cyanide amount, the pH, the reaction time, and the temperature.

The present investigation was undertaken to see if the method for the determination of pentathionate[4] and hexathionate[5] could be used for tetrathionate also; the authors have their ultimate object analyzing the polythionates when they are mixed with one another.

Experimental

Apparatus and Materials.—Unless otherwise stated, the apparatus and materials used in this study were the same as those described in the first paper of this series.[4]

Potassium Tetrathionate.—This salt was prepared according to the directions of Stamm and Goehring.[6] The raw tetrathionate obtained was recrystallized with redistilled water at a temperature below 60°C and dried at room temperature for 4 days. The water content physically adsorbed in the tetrathionate was estimated to be 0.6% by the Karl Fischer method.

The purity of this salt was estimated by determining the total potassium and sulfur as follows. The potassium tetrathionate was decomposed into potassium sulfate by heating it at about 800°C; $K_2S_4O_6 \rightarrow K_2SO_4$. The potassium was determined by weighing[7] the potassium sulfate thus formed.

As for the sulfur, the tetrathionate was oxidized[4,5,7] by bromine in an alkaline medium upon heating; the sulfate ions formed were determined by the usual gravimetric method.

233.2	231.8	710.5	42.10	

* Water content was estimated to be 0.6%.

Tables I and II show that this potassium tetrathionate is pure enough for the purposes of this investigation.

The Standard Tetrathionate Solution.—The standard solution, a 1.0×10^{-3} M stock solution of tetrathionate, was prepared by dissolving 152.1 mg. of the potassium tetrathionate (water content: 0.6%) in redistilled water, and then diluting it to 500 ml. This stock solution proved to be stable; even after six months, no measurable change was found by the present method when it was kept at 5±2°C in a refrigerator. The working standard solutions were prepared by diluting the stock solution properly.

Buffer Solution.—Phosphate buffer (0.2 M) and sodium hydroxide (0.01 to 1 N) solutions were employed to adjust the pH to the values required.

Procedure.—A sample solution of 10.0 ml. is placed in a 25 ml. volumetric flask. To this solution there are added, first 4.0 ml. of the phosphate buffer solution of pH 7.4, and then 2.6 ml. of 0.05 M sodium cyanide; the pH of the solution is thereby brought to 8.6.

The volumetric flask is kept in the thermostat at 40±1°C for 30 min.; the tetrathionate is thereby converted into thiocyanate quantitatively. Then 3.0 ml. of a .1.5 M ferric nitrate - perchloric acid solution is

7) F. Martin and L. Metz, ibid., **127**, 83 (1923).

added. After the flask has been filled with redistilled water to the mark, the contents are mixed well. The absorbancy of the solution of the ferric-thiocyanate complex thus formed is measured at the wavelength of 460 mμ, using distilled water as a reference.

Results and Discussion

Calibration Curves.—The calibration curves shown in Fig. 1 were obtained by the procedure described above, using standard tetrathionate and thiocyanate solutions.

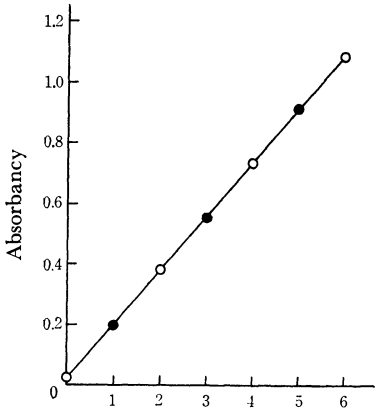

Fig. 1. Calibration curves.
○ Tetrathionate ● Thiocyanate

The absorbancy and the concentration were in a good linear relationaship, as can be seen in Fig. 1. When one ion of tetrathionate undergoes cyanolysis, one ion of thiocyanate is formed. Therefore, if the tetrathionate is pure enough and if it is, moreover, converted into thiocyanate stoichiometrically and quantitatively, the calibration curve of tetrathionate should be in full accord wtih that of thiocyanate when plotted by the mole concentration for tetrathionate and thiocyanate. In fact, Fig. 1 shows that the calibration curve for tetrathionate is in exact accordance with that for thiocyanate, demonstrating that the reaction of tetrathionate with cyanide goes well to completion and that it is stoichiometric.

The Effect of the Amount of Sodium Cyanide.—As will be disclosed below, it was confirmed that the optimum pH value for the reaction of tetrathionate with cyanide ranges from 8.3 to 12.1 under the conditions of the procedure mentioned above. 0.5 ml. of a 0.025 M sodium cyanide solution and from 0.5 to 4.0 ml. of a 0.05 M sodium cyanide solution were employed, in all cases the final solution being buffered to the optimum pH value. The resulting effect of the amount of sodium cyanide upon the cyanolysis is shown in Fig. 2.

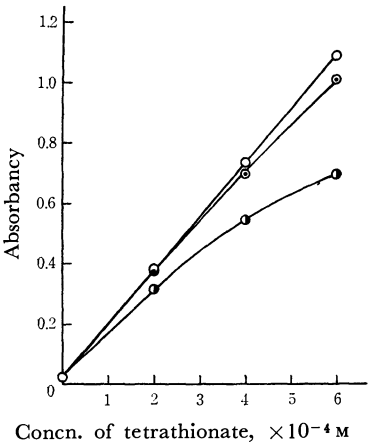

Fig. 2. The effect of the amount of sodium cyanide.
The pH was adjusted to 8.4—12.1 in all cases.
Cyanolysis time: 30 min. at 40°C
◑ 0.025 M NaCN 0.5 ml. (I)
⊙ 0.05 M NaCN 0.5 ml. (II)
○ 0.05 M NaCN 1.0, 2.0, 2.6, and 4.0 ml. (III)

The calibration curves with 0.5 ml. portions of 0.025 and 0.05 M sodium cyanide solutions do not form straight lines (see I and II), indicating that tetrathionate is not completely converted into thiocyanate because of insufficient amounts of cyanide. It can be concluded from Fig. 2 that 1.0 ml. of a 0.05 M sodium cyanide solution is sufficient for the complete conversion of tetrathionate into thiocyanate, and that the amount of sodium cyanide does not have any effect on this method as long as it is sufficient and the pH is adjusted to an optimum value.

The Effect of the pH.—The reaction should be carried out below a pH value of 12.1, because tetrathionate undergoes alkaline decomposition in addition to cyanolysis at higher pH levels.

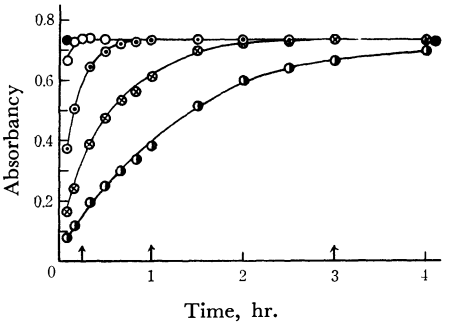

Fig. 3. Effect of pH on the rate of cyanolysis at 25°C.
● 4.0×10^{-4} M SCN^-
○ pH 10.3 and 11.8 (I)
⊙ pH 8.7 (II)
⊗ pH 8.0 (III)
◑ pH 7.5 (IV)
} 4.0×10^{-4} M $S_4O_6^{2-}$

Figure 3 shows the dependence of the rate of cyanolysis on the pH of the solution at 25°C.

The maximum absorbancy, which corresponds to the complete and stoichiometric reaction of tetrathionate with cyanide, is attained in 15 min. at pH 10.3 and 11.8, and thereafter remains constant (see I), while the reactions at pH 8.7 and 8.0 go to completion in 1 hr. and 3 hr. respectively (see II and III). However, the reaction at pH 7.5 does not reach completion even within 4 hr. (see IV).

As can also be seen from Fig. 3, the higher the pH of the solution, the more rapid the rate of cyanolysis; therefore, it is desirable that the procedure is carried out at a higher pH level as long as it is below 12.1. However, pentathionate and hexathionate, as has been reported in previous papers,[4,5] undergo a partial alkaline decomposition at pH levels higher than pH 9.0. Consequently, we made our study at pH values below 8.7. In order to accelerate the rate of cyanolysis, the reaction temperature was raised from 25°C to 40°C. Figure 4 shows how the pH of the solution affects the rate of cyanolysis at 40°C.

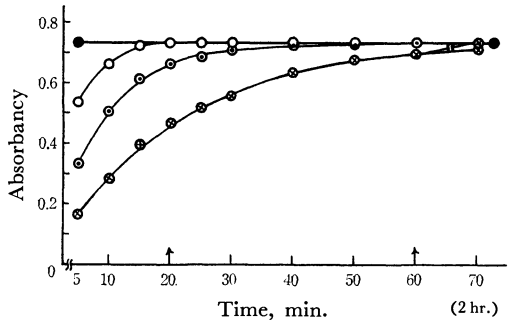

Fig. 4. Effect of pH on the rate of cyanolysis at 40°C.

● 4.0×10^{-4} M SCN^-
○ pH 8.7 (I)
⊙ pH 8.0 (II) } 4.0×10^{-4} M $S_4O_6^{2-}$
⊗ pH 7.5 (III)

The reactions at pH 8.7 and 8.0 go well to completion, and are stoichiometric, in 20 min. and 1 hr. respectively (see I and II in Fig. 4). On the other hand, the reaction at pH 7.5 goes stoichiometrically to completion in 2 hr. (see III).

It was observed that tetrathionate also undergoes thermal decomposition as well as cyanolysis at 70°C, as do pentathionate and hexathionate.

The reaction of tetrathionate with cyanide at various pH values was carried out both at 25°C for 70 min. and at 40°C for 30 min. The results are shown in Fig. 5, where the complete and stoichiometric reaction occurs over the pH range from 8.5 to 12.1 at 25°C for 70 min. (see I) and over the pH range from 8.3 to 12.1 at 40°C for 30 min. (see II).

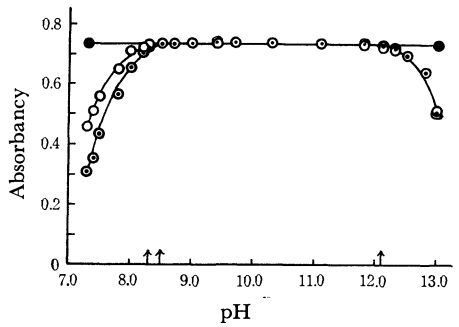

Fig. 5. Effect of pH.

● 4.0×10^{-4} M SCN^-
○ 30 min. at 40°C (II) } 4.0×10^{-4} M $S_4O_6^{2-}$
⊙ 70 min. at 25°C (I) }

The decrease in absorbancy above the pH value of 12.2 may be due to the alkaline decomposition of tetrathionate. The optimum pH range for the reaction of tetrathionate with cyanide can be extended from either 8.3 or 8.5 to a lower pH by making the cyanolysis time longer, because the rate of cyanolysis decreases with a lowering of the pH value.

Figure 6 shows how the pH affects the cyanolysis of tetrathionate, pentathionate, and hexathionate under the conditions of the procedure described above.

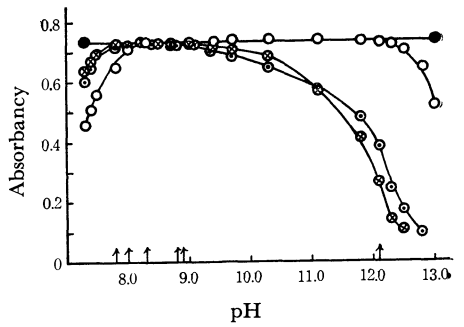

Fig. 6. Effect of pH.
Cyanolysis time: 30 min. at 40°C

● 4.0×10^{-4} M SCN^-
○ 4.0×10^{-4} M $S_4O_6^{2-}$
⊙ 2.0×10^{-4} M $S_5O_6^{2-}$
⊗ 1.33×10^{-4} M $S_6O_6^{2-}$

As can be seen in Fig. 6, the optimum pH ranges for tetrathionate, pentathionate, and hexathionate are between 8.3 and 12.1, 8.0 and 8.8, and 7.8 and 8.9 respectively. In view of the experimental results shown in Fig. 6, it may be concluded that tetrathionate can be determined accurately by the very same procedure as that used for pentathionate and hexathionate, where the pH value is 8.6.

Calibration Curves of Tetrathionate, Pentathionate, and Hexathionate.—Solutions

containing various amounts of thiocyanate, tetrathionate, pentathionate, and hexathionate were treated by the preceding procedure; the results are shown in Figs. 7 and 8. When one ion of tetrathionate, pentathionate, and hexathionate undergoes cyanolysis, one, two, and three ions of thiocyanate are, respectively, formed.

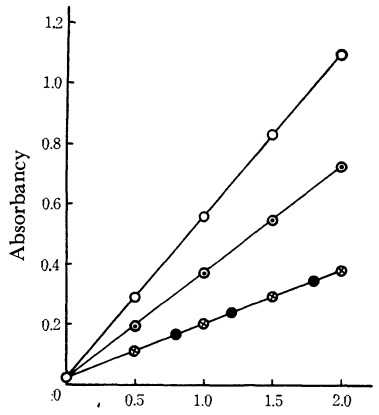

Fig. 7. Calibration curves
● Thiocyanate ⊗ Tetrathionate
⊙ Pentathionate ○ Hexathionate

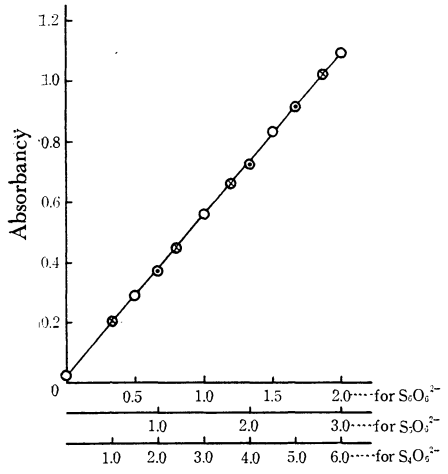

Fig. 8. Calibration curves.
⊗ Tetrathionate ⊙ Pentathionate
○ Hexathionate

In fact, Fig. 7 shows that the calibration curves of tetrathionate, pentathionate, and hexathionate are once, twice, and three times, respectively, as sensitive as that of thiocyanate. As can also be seen in Fig. 8, their calibration curves exactly coincide with one another when the scales of the concentration of tetrathionate and pentathionate are made one-third and two-thirds of the hexathionate concentration, indicating that all three of these polythionates can be easily determined by the same procedure.

A similar method, one suitable for the determination and for the evaluation of the composition of the polythionates mixed with each other, will be reported on in another paper.

Summary

The photometric method for the determination of a small amount of tetrathionate has been developed; it is based on the formation of thiocyanate equivalent to the tetrathionate, and on the determination of the thiocyanate with an excess of ferric iron. The conditions capable of determining a small quantity of tetrathionate by the very same procedure as that used for pentathionate and hexathionate have been established by varying the cyanide amount, the pH, the reaction time and the temperature.

The authors wish to thank Dr. Satori Utsumi of Nihon University, and Mr. Takejiro Ozawa and Dr. Minoru Yoshida of the Tokyo Institute of Technology for their many valuable discussions and suggestions during this study. Thanks are also given to Dr. Kaname Muroi, the Central Research Laboratory of Mitsubishi Chemical Industries, Ltd., for the estimation of the water content in the tetrathionate by the Karl Fischer method.

The Polarographic Behavior of Tris(1, 10-phenanthroline)cobalt Complexes and the Univalent Phenanthroline-Cobalt Complex.*1

By Kenichi MORINAGA, Kunio NAKANO, Shigeru SAITO*2 and Keizo NAKAMURA*3

Department of Chemistry, College of Science, St. Paul's University (Rikkyo Daigaku), Toshima-ku, Tokyo

(Received June 22, 1965)

The oxidation-reduction behavior of tris(1, 10-phenanthroline)cobalt complexes at a dropping mercury electrode has been studied by the d. c. and a. c. polarographic methods. The trivalent cobalt-phenanthroline complex ion is reduced in two steps in 1 M sodium sulfate in a quite similar way as the trivalent cobalt-dipyridyl complex ion. Both electrode processes, cobalt(III)→cobalt(II) and cobalt(II)→cobalt(I), are considered to be reversible. The univalent cobalt-phenphenanthroline complex has been obtained as a black powder by the reduction of the divalent cobalt complex with sodium borohydride; the atomic ratio of nitrogen to cobalt has been found to be close to six. The ethanolic solution is brown-black, in remarkable contrast with that of the corresponding dipyridyl complex, deep blue.

It is well known that the lower valency states of transition metals can be stabilized by coordinating ligands, such as carbonyl, cyanide, and dipyridyl which are likely to form bonds of a partly double-bond character between a central metal ion and the ligands.[1] A polarographic method has been proved to be very useful for detecting such abnormal valency states in many metal complex compounds.[2-9] From polarographic studies of cobalt-dipyridyl complexes, it has been shown that the tris(2, 2'-dipyridyl)cobalt(III) complex ion is reduced in two steps, from cobalt(III) to cobalt(II) and from cobalt(II) to cobalt(I). The isolation of the univalent cobalt complex has also been reported.[4,6] The cobalt complexes of phenanthroline, however, in spite of its strong resemblance to dipyridyl as a ligand, have never been studied in detail by the polarographic method. Therefore, the present authors have investigated the polarographic behavior of the tris(1, 10-phenanthroline)cobalt(III or II) ion in a 1 M sodium sulfate medium and found a great similarity between the d. c. polarogram of the tris(1, 10-phenanthroline)cobalt ion and that of the tris-(2, 2'-dipyridyl)cobalt ion, which has been reported on in a previous short communication.[10] They have also attempted to isolate the univalent cobalt complex and define its formula. The results will be presented in the present paper.

Experimental

Direct-current (d. c.) and alternating-current (a. c.) polarograms were recorded with a Yanagimoto model PS-52 photorecording polarograph and a Yanagimoto model PA-101 pen-recording polarograph respectively. A Yanagimoto controlled-potential electrolyzer was also used in an attempt to prepare and to identify the univalent cobalt complex in a solution. The absorption spectra were measured using a Hitachi EPU 2 spectrophotometer. The cell equipment used for the polarographic measurements was the same as has been reported on previously except that the saturated calomel electrode was replaced by the saturated mercurous sulfate electrode.[11] The dropping mercury electrode employed had an m value of 0.855_9 mg./sec. and a drop-time of 8.52 sec. when measured in distilled water at a 58.2 cm. height of the mercury reservoir with an open circuit. The cell temperature was maintained at 25 ± 0.1°C by means of a water thermostat. The oxygen dissolved in the electrolytic solution was removed by bubbling pure nitrogen gas through the solution. $[Co(phen)_3](ClO_4)_2$ and $[Co(phen)_3](ClO_4)_3 \cdot 2H_2O$ (phen=1, 10-phenanthroline) were prepared according to the procedures described in the literature.[12] A 1 M sodium sulfate solution was used as a supporting electrolyte, while no maximum suppressor was added. containing the divalent cobalt complex were carefully prepared in order to prevent it from oxidation. All the chemicals used were of guaranteed reagent grade.

Results and Discussion

On the D. C. and A. C. Polarograms.—$[Co(phen)_3]^{3+}$ ions are reduced in two steps in 1 M sodium sulfate, as has been shown in Fig. 1 of a previous paper.[10] The first wave appears around +0.10 V. vs. SCE, and the second one accompanying a small prewave appears around −1.0 V. vs. SCE. A small minimum was observed on the plateau of the first wave. $[Co(phen)_3]^{2+}$ ions show an oxidation wave and a reduction wave at the respective potentials corresponding to the first and the second waves of $[Co(phen)_3]^{3+}$ ions. Since the solubility of $[Co\ phen_3]\ (ClO_4)_2$ was very low, the reduction waves of the $[Co(phen)_3]^{3+}$ ion were studied under varied conditions. The dependence of the limiting current on the mercury column height is given in Table I. The characteristics of the d. c. polarograms at various concentrations of the depolarizer are given in Table II.

A typical example of the logarithmic plot for the first reduction wave with 0.6_3 mmol./l. $[Co(phen)_3]^{3+}$ is shown in Fig. 1. The reciprocal slope in the upper part decreases with the increase in the depolarizer concentration up to 1.5 mmol./l. Beyond that point, the d. c. polarogram is distorted to a greater extent with an increase in the concentration. The main second wave has a discontinuity at its beginning, and the decomposition potential shifts to a more positive potential with an incerase

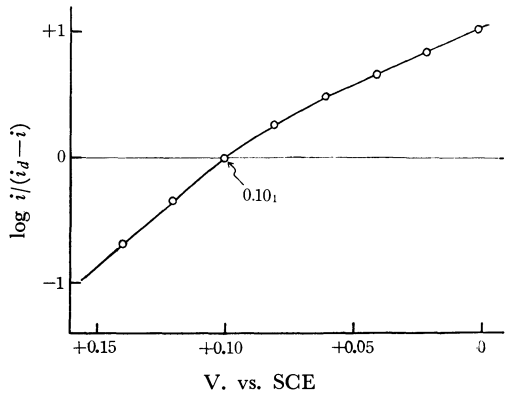

Fig. 1. Logarithmic plot for the reduction wave of 0.6_3 mM $[Co(phen)_3](ClO_4)_3$ in 1 M Na_2SO_4.

in the depolarizer concentration. The first and the second (including the prewave) waves are concentration-dependent and are evidently diffusion-controlled. The prewave has the characteristic of an adsorption wave in that its height is independent of the depolarizer concentration.[13] Since adsorption phenomena seem to play an important role over a wide potential range, the drop time was measured at different potentials. The results are shown in Fig. 2. The irregularity of the electrocapillary curve is exactly reflected in the d. c. and a. c. polarograms. The a. c. polarograms at various concentrations of the depolarizer are shown in Fig. 3, together with the a. c. polarograms obtained in the presence of gelatine.

13) R. Brdička, *Z. Elektrochem.*, **48**, 278 (1942).

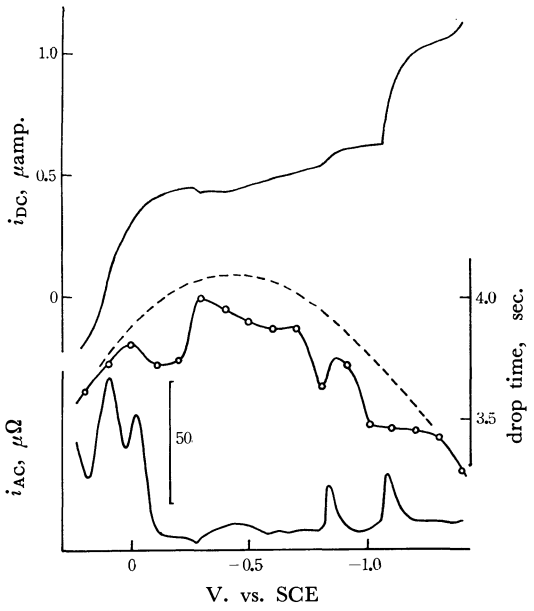

Fig. 2. Electrocapillary curve and d.c. and a.c. polarograms of 0.3 mM $[Co(phen)_3](ClO_4)_3$ in 1 M Na_2SO_4.

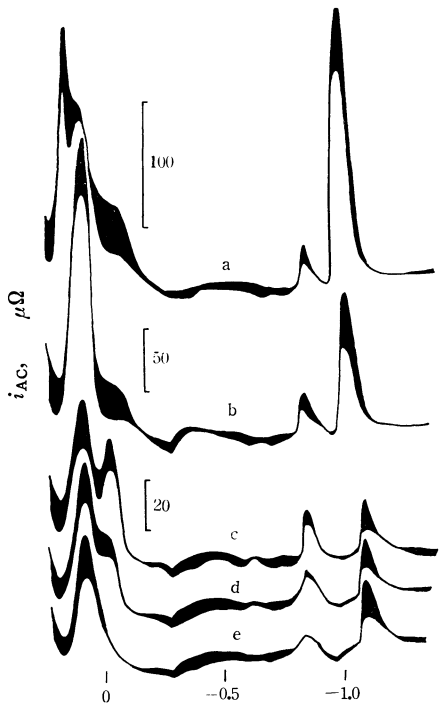

Fig. 3. A. c. polarograms of $[Co(phen)_3](ClO_4)_3$ in 1 M Na_2SO_4. The concentration of $[Co(phen)_3](ClO_4)_3$: a) 1.5 mM, b) 0.9 mM, c) 0.3 mM, d) 0.3 mM (+0.01% gelatine) and e) 0.3 mM (+0.03% gelatine).

It should be noted that the a. c. peak height corresponding to the first d. c. wave is not proportionate to the concentration of the depolarizer, and that the two a. c. peaks are observed at the potential for the first d. c. wave with 0.3 mmol./l. $[Co(phen)_3]^{3+}$.

On the Reduction Mechanism.—From the diffusion current constants for the first and the second waves, the first wave can be attributed to the reduction of cobalt from a trivalent to a divalent state and the second, to the reduction of divalent to univalent cobalt. A similar reduction process has been already proposed for several cobalt complexes.[4-7] In the case of the tris(dipyridyl) complex, Waind and Martin[6] concluded that the first reduction wave is reversible, while Vlček[4] pointed out that the second reduction wave is reversible.

The inflection of the logarithmic plot at the upper part for the first step and the appearance of a minimum on the d. c. polarogram may be explained qualitatively by assuming the following electrode reaction:

$$[Co(phen)_3]^{3+} + e^- \rightarrow [Co(phen)_3]^{2+}$$
$$\downarrow\uparrow$$
$$\text{Hg-phen complex} + e^- \leftarrow Hg + phen + [Co(phen)_2]^{2+}$$

The $[Co(phen)_3]^{2+}$ ion produced at the electrode surface, because of its lower stability, dissociates partly to the lower complex, liberating phenanthroline; the phenanthroline is very likely to be adsorbed onto the electrode surface, where it will interfere with the passage of the current and cause a minimum. At a certain potential dependent on the depolarizer concentration, the free phenanthroline adsorbed on the surface accelerates the dissolution of mercury through the formation of a mercury-phenanthroline complex; this oxidation process will compensate for a part of the reduction current, thus causing an inflection of the logarithmic plot and also a distinct deformation of the d. c. polarograms with an increase in the depolarizer concentration. These reduction and oxidation processes give the two peaks around +0.1 V. on an a. c. polarogram.

The peak at a negative potential is confirmed to correspond to the oxidation process since its peak height increases when a small amount of excess free phenanthroline is added. At higher concentrations of the depolarizer, the two opposite processes take place at almost the same potential, resulting in an apparent lowering of the a. c. peak height. If a more strongly adsorbable substance than phenanthroline covers the electrode surface, the dissolution of mercury will be hindered. This expectation can be fully realized by adding 0.03% gelatine to the electrolytic solution, as has been shown in Fig. 3. In spite of the addition of gelatine, however, the polarographic reversibility is very high, as is shown in Table III. The polarographic

TABLE III. VALUES OF $i_p/(ni_d\sqrt{\tau})$

* 0.05 with 0.8 mM$[Co(phen)_3]^{3+}$

reversibility is defined as $i_p/(ni_d\sqrt{\tau})$, where i_p, i_d and τ represent an a. c. peak height, a limiting diffusion current of the d. c. polarogram and a drop time respectively.[14] Also, from the approximate coincidence of the half-wave potential values for the oxidation of cobalt(II) (aver. +0.093 V.) and the reduction of cobalt(III) (aver. +0.095 V.), it can be concluded that the electrode process for the reduction of cobalt(III) to cobalt(II) is highly reversible in the phenanthroline system.

The prewave of the second wave can be attributed to the adsorption of the cobalt(I)-complex produced through the following electrode reaction:

$$[Co(phen)_{2-3}]^{2+} + e^- \rightarrow [Co(phen)_{2-3}]^+$$

The uncommon univalent cobalt complex ion can be produced in solution by the controlled-potential electrolysis method. The existence of the cobalt(I)-complex can be shown by the oxidation curve, as is shown in Fig. 4. From the polarographic reversibility and the constancy of the half-wave potential for the redox waves, the reduction of cobalt(II) to cobalt(I) is also considered

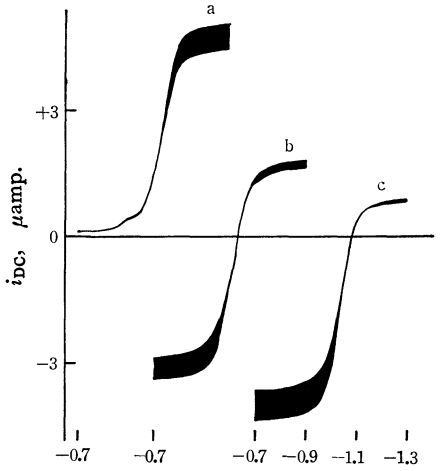

Fig. 4. D. c. polarograms obtained with a 1 : 3 mixture of cobalt(II) and phenanthroline in 0.5 M LiCl ethanolic solution: (a) 0, (b) 0.5 and (c) more than 3 hr. after controlled-potential electrolysis was started.

to be reversible in the present system.

From the above results, it can definitely be concluded that the polarographic behavior of the tris-(1,10-phenanthroline)cobalt complex is quite similar to that of the tris(dipyridyl) complex as regards both the mechanism and the reversibility of the electrode reaction.

On the Composition of the Univalent Cobalt Complex.—In the case of the dipyridyl complex, two formulas, $[Co(dipy)_3]ClO_4$ and $[Co(dipy)_2]ClO_4$, have been proposed for the univalent cobalt complex by different authors.[4,6] Therefore, the present authors attempted to isolate the univalent cobalt phenanthroline complex in a pure state and to determine its chemical composition. Since the controlled-potential electrolysis method proved unsuccessful in its isolation, a reduction method similar to that employed in the preparation of the dipyridyl complex was used; $[Co(phen)_3](ClO_4)_2$ suspended in an ice-cold methanol (20%)-water mixture was reduced by slowly adding a cold aqueous solution of sodium borohydride in an atmosphere of nitrogen. The black solid which had precipitated was filtered, washed with cold water, and dried in a vacuum desiccator. It is highly sensitive to oxidation and turns brown-black on exposure to the air. Chemical analysis gave the atomic ratio of Co : N : Cl = 1 : 5.75 : 0.90. (Found: Co, 8.2; N, 11.20; ClO_4, 12.4%). Preliminary measurements revealed that the magnetic moment is much less than the value to be expected for a complex of octahedral symmetry, with its central metal ion having a d^8-electron configuration. From these results and from the fact that the prolonged electrolysis did not completely diminish the reduction wave of divalent cobalt, it may be supposed that the univalent cobalt complex obtained by the above method is not in a pure state. The color of the solid and the solution also suggests the possibility that the product is either entirely or partly a polynuclear complex. This situation leads to the conclusion that the authors are unable to decide definitely whether the univalent cobalt complex is $[Co(phen)_3]^+$ or $[Co(phen)_2]^+$,

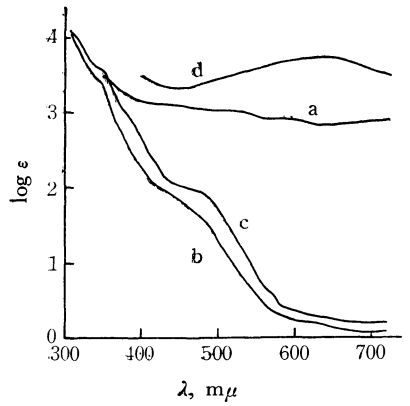

Fig. 5. Absorption spectra.
(a) $[Co(phen)_{2-8}]^{+}$, (b) $[Co(phen)_3]^{2+}$, (c) $[Co(phen)_3]^{3+}$, (d) $[Co(dipy)_3]^{+}$ plotted from the data obtained by Waind and Martin.[6]

although the atomic ratio of nitrogen to cobalt is close to six.*

The brown-black solution obtained by electrolyzing the 1 : 3 mixture of cobalt(II) and phenanthroline in a 0.5 M lithium chloride ethanolic solution (50% by volume) was used to measure the absorption spectrum. No definite absorption maxima are observed on the absorption curve, as is shown in Fig. 5. The color of the solution is in remarkable contrast with that of the dipyridyl complex, which has been shown to be a deep blue, its λ_{max} being 640 mμ.[6] Although the color of the solution and that of the solid are quite similar, there still remains some uncertainty with regard to the identity of the primary electrode reaction product and the solid obtained above. More detailed studies are needed.

* Independent of the present work, it has been reported that the phenanthroline cobalt(I) perchlorate is the hexacoordinated complex, $[Co(phen)_3]ClO_4$. N. Maki, M. Yamagami and H. Itatani, *J. Am. Chem. Soc.*, **86**, 514 (1964).

Summary

Tris(1, 10-phenanthroline)cobalt(III) complex ions are reduced in two steps in 1 M sodium sulfate. The first wave, which appears around +0.10 V. vs. SCE, corresponds to the reduction of cobalt from a trivalent state to a divalent, while the second, which appears around −1.0 V. vs. SCE, corresponds to the reduction of divalent to univalent cobalt. Tris(1, 10-phenanthroline)cobalt(II) ions show an oxidation wave and a reduction wave at the respective potentials corresponding to the first and the second waves of trivalent cobalt complex ions. A small minimum is observed on the plateau of the first wave, and a small prewave is accompanied by the second wave. Both electrode processes are considered to be reversible.

The univalent cobalt-phenanthroline complex has been prepared by the reduction of the divalent cobalt complex with sodium borohydride. It is a black powder, and the atomic ratio of nitrogen to cobalt is found to be nearly six, though not exactly six.

Asymmetric Hydrogenation with Modified Raney Nickel. VI

By Yoshiharu IZUMI, Susumu TATSUMI, Masami IMAIDA
Yoshio FUKUDA and Shiro AKABORI

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received June 26, 1965)

The asymmetric hydrogenation catalyst has been prepared by the modification of Raney nickel with solutions of (−)-2-methyltartaric acid (A), (+)-2-methyltartaric acid (B) and (+)-2, 3-dimethyltartaric acid, and its asymmetric hydrogenation activity has been measured by the hydrogenation of methyl acetoacetate to optically active methyl 3-hydroxybutyrate. The asymmetric activity of the catalyst is much influenced by the pH and the temperature of the modifying solution. Generally, (+)-2-methyltartaric acid (B) and (+)-2, 3-dimethyltartaric acid have a high asymmetric activity in reaction to Raney nickel. The highest asymmetric activity has been obtained by modification with (+)-2-methyltartaric acid (B) and with it the specific rotation of the hydrogenation product has been found to be $[\alpha]_D^{20}$ +11.72° (without a solvent) under the optimum conditions. This value means that the product is 78% composed

of the dextro- and 22% of the levorotatory form. On the other hand, the asymmetric activity of the catalyst modified with (−)-2-methyltartaric acid (A) is very low and quite different from that of the catalyst modified with (+)-2-methyltartaric acid (B). It has been supposed that this difference depends on the stereoisomerism of the threo-erythro form of the 2-methyltartaric acid molecule.

The previous papers of this series[1-5] reported the asymmetric hydrogenation of methyl acetoacetate to methyl 3-hydroxybutyrate using Raney nickel catalysts modified with optically active 2-amino and 2-hydroxy carboxylic acids. It was found that the asymmetric activity of the catalysts is much influenced by the pH and temperature of the modifying solution. An especially high asymmetic activity was obtained when the catalyst was modified at 100°C with a D-tartaric acid solution, the pH of which had been adjusted to 5.1—5.2.[2]

In the present work, optically active 2-methyltartaric and 2, 3-dimethyltartaric acid will be tested as modifying reagents in an attempt to study the role of substituents on asymmetric carbon atoms of tartaric acid in the modification of the Raney nickel catalyst.

Materials

Modifying Reagents.*—2-Methyltartaric acid has two racemic forms, the melting points of which are 146°C and 161°C. Both racemic substances were synthesized from ethyl acetoacetate and resolved with brucine by the fractional crystallization of the diastereomers in water. The optical rotation values of the four isomers were as follows;

(A) From the racemic form with the lower melting point (2-methyltartaric acid A):

(+)-isomer $[\alpha]_D^{20}$ +8.90° (*c* 3.7, water) (I)

(−)-isomer $[\alpha]_D^{20}$ −8.94° (*c* 3.7, water) (II)

(B) From the racemic form with the higher melting point (2-methyltartaric acid B);

(+)-isomer $[\alpha]_D^{20}$ +5.88° (*c* 3.2, water) (III)

(−)-isomer $[\alpha]_D^{20}$ −5.60° (*c* 3.2, water) (IV)

2, 3-Dimethyltartaric acid has two optically inactive modifications; the one is the racemic (m. p. 187°C), and the other is the meso form (m. p. 180°C). Both substances were prepared from diacetyl, while the optical resolution of the racemic form was performed with brucine. The optical rotation values of the two optical isomers of this hydroxy carboxylic acid were as follows:

(+)-isomer $[\alpha]_D^{20}$ +13.4° (*c* 4.0, water) (V)

(−)-isomer $[\alpha]_D^{20}$ −13.4° (*c* 4.0, water) (VI)

In the present asymmetric hydrogenation experiments, optically active (−)-2-methyltartaric acid (A) (II), derived from the racemate with the lower melting point; (+)-2-methyltartaric acid (B) (III), derived from the racemate with the higher melting point, and (+)-2, 3-dimethyltartaric acid (V) were used as the modifying reagents.

Results and Discussion

The Effect of the pH of the Modifying Solution.—Measurements were made of the asymmetric activities of catalysts modified at 0°C with aqueous solutions of substances II, III and V, the pH of which had been adjusted to specified values with a 1 N (*f*=0.893) sodium hydroxide solution according to the titration curve shown in Fig. 1. The results are shown in Fig. 2.

The catalysts modified at 0°C with these hydroxy carboxylic acids hydrogenated methyl acetoacetate predominantly to dextrorotatory methyl 3-hydroxybutyrate. Higher asymmetric activities were observed on modification with III and V, when the catalysts were less influenced by the pH of the modifying solutions. In the case of modification

with II, however, the asymmetric activity was very low and was not at all influenced by the pH of the modifying solution.

The effect of the pH value of the modifying solution at 100°C on the asymmetric activities of the modified catalysts is shown in Fig. 3.

As is shown in Fig. 3, upon modification with III the asymmetric activity was greater and was much influenced by the pH of the modifying solution. The greatest asymmetric activity was obtained at pH 5.0 when the specific rotation value of the hydrogenation product was $[\alpha]_D^{20}$ +11.72° (without a solvent). There was a considerable decrease in activity at both lower and higher pH values. Under acidic conditions below pH 4.5, the catalytic activity of the modified catalyst was too low to permit any hydrogenation experiments. On modification with V, although a high asymmetric activity was obtained, it was lower than with III; and the asymmetric activity curve showed a tendency similar to that shown on modification at 0°C. In the case of modification with II, however, the asymmetric activity was very low and the levorotatory product was obtained at pH values below the pH jump of the titration curve of this acid shown in Fig. 1.

The Effect of the Modifying Temperature. —The effect of the temperature of the modifying solution was studied at pH 5.0—5.2; the results are shown in Fig. 4.

As is shown in Fig. 4, the asymmetric activity of the catalyst modified with III was greater than

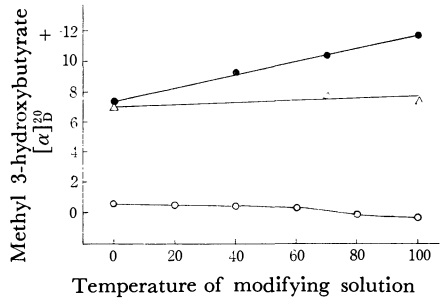

Fig. 4. Effect of temperature of modifying solution.
—○— (−)-2-Methyltartaric acid (A) (pH 5.0)
—●— (+)-2-Methyltartaric acid (B) (pH 5.0)
—△— (+)-2, 3-Dimethyltartaric acid (pH 5.1—5.2)

that of the catalyst modified with V, and it clearly increased with elevation of the modifying temperature. On modification with V, however, the activity was hardly influenced at all by the temperature. In the case of modification with II, the asymmetric activity was very low and the hydrogenation product was dextrorotatory below 70°C, although it showed the opposite optical rotation above this temperature.

As is shown in Figs. 2, 3 and 4, on modification with (+)-2-methyltartaric acid (B) (III), the catalyst had a higher asymmetric activity than tartaric acid[2] and gave the dextrorotatory product. Under optimum conditions the specific rotation value of the product was $[\alpha]_D^{20}$ +11.72°; this means that the product was 78% composed of the dextro- and 22% of the levorotatory form. On the other hand, (−)-2-methyltartaric acid (A) (II) has only a small asymmetric effect upon Raney nickel.

2-Methyltartaric acid has a structure in which a methyl group is introduced into one of the asymmetric carbons of tartaric acid in place of a hydrogen atom. Thus it is characterized by the existence of two types, the threo and erythro form, which are 2-methyltartaric acid (A) and (B). Although it is unknown at the present time which steric isomer is threo and which is erythro, it is conceivable that the difference in the asymmetric effects of (−)-2-methyltartaric acid (A) and (+)-2-methyltartaric acid (B) depends on their threo-erythro isomerism. On modification with (+)-2, 3-dimethyltartaric acid, however, the asymmetric activity shows a tendency similar to that shown on modification with tartaric acid, except for the difference in the asymmetric direction.

The relationship between the asymmetric activity of the catalyst and the stereoisomerism of the modifying reagent will be discussed after the steric configurations of (−)-2-methyltartaric acid (A), (+)-2-methyltartaric acid (B) and (+)-2, 3-dimethyltartaric acid have been confirmed.

Experimental

The preparation and modification of the Raney nickel catalyst, the hydrogenation of methyl acetoacetate, and the measurement of the asymmetric activity of the catalyst were performed as described in a previous paper.[3]

Summary

1) The asymmetric activities of Raney nickel catalysts modified with (−)-2-methyltartaric acid (A), (+)-2-methyltartaric acid (B) and (+)-2, 3-dimethyltartaric acid have been measured by the hydrogenation of methyl acetoacetate.

2) The highest asymmetric acitivity has been obtained by modification with (+)-2-methyltartaric acid; with it the specific rotation of the hydrogenation product was $[\alpha]_D^{20}$ +11.72° under optimum conditions.

3) The asymmetric activity of the catalyst modified with (−)-2-methyltartaric acid (A) was very low and quite different from that of the catalyst modified with (+)-2-methyltartaric acid (B). This difference depends on the stereoisomerism of the threo-erythro form. On modification with (+)-2, 3-dimethyltartaric acid, the asymmetric activity showed a tendency similar to that shown on modification with D-tartaric acid, except for the difference in the asymmetric direction.

The Synthesis of Sulfoxides by the Oxidation of Sulfide with the Bromine Complex of 1, 4-Diazabicyclo(2, 2, 2)octane[1,2]

By Shigeru OAE, Yutaka OHNISHI, Seizi KOZUKA and Waichiro TAGAKI

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka

(Received July 5, 1965)

1, 4-Diazabicyclo(2, 2, 2)octane readily forms an addition complex with two moles of bromine. This complex has been found to be an excellent oxidizing agent for the selective oxidation of various sulfides to the corresponding sulfoxides when the reaction is performed in an aqueous medium. The bromine-addition complexes of pyridine and quinoline have also been found to be useful for the same purpose. The reaction has been shown to be a superb way of incorporating ^{18}O into sulfoxides.

A number of methods for the oxidation of sulfides to sulfoxides are known.[3] Among these, the oxidation by halogenating agents, such as molecular halogens or hypohalites, is one of the least-studied procedures. Molecular halogens have been known to add to sulfides to form addition compounds which are then readily hydrolyzed to give sulfoxides; on the other hand, hypohalites have been shown to oxidize higher dialkyl sulfides to the corresponding sulfoxides,[3] while lower sulfides are likely to be oxidized by the reagents directly to their sulfones.[3] However, the use of such halogenating agents for the oxidation of sulfides has been limited to only a certain type of sulfides, since many sulfides are known to undergo different reactions to give undesirable side products.

Recently we have found that some sulfides are successfully oxidized to the corresponding sulfoxides in high yields when the sulfides are treated with *N*-bromosuccinimide (NBS) in aqueous media.[4] Meanwhile, *p*-substituted phenyl methyl sulfides have been found to form, with bromine, the corresponding bromine addition complexes which, upon hydrolyses, are found to afford the corresponding sulfoxides.[5] The same sulfides, however, gave only the C–S bond cleavage products when treated with NBS. These observations seem to

suggest that the mode of oxidation varies with the type of halogenating agent.

In the present investigation, we have examined the possibility of the oxidation of sulfides by the bromine complexes of a few stable tertiary amines; we have found that the bromine complex of 1, 4-diazabicyclo(2, 2, 2)octane can oxidize a variety of sulfides to sulfoxides without the formation of sulfones. Some of the sulfides which could not be oxidized to the corresponding sulfoxides either by NBS or molecular bromine were readily oxidized to the sulfoxides by this reagent.

Tertiary amines, such as pyridine and quinoline, are known to form bromine-addition complexes when treated with bromine in an inert solvent,[6-12] and these complexes can be used in situ as brominatting agents.[8,9] These complexes are usually very sensitive to light, heat and moisture, and hence have to be used immediately after they are prepared. Unlike the bromine complexes of other amines, however, that of 1, 4-diazabicyclo-(2, 2, 2)octane is very stable,[13] although its structure and the reason for its stability are not well understood yet.

The six different sulfides subjected to this oxidation were dialkyl, aryl-alkyl, benzyl-alkyl, benzyl-aryl, diaryl sulfides and thianthrene. The first three sulfides undergo C–S bond cleavage by NBS, but they were found to be readily oxidized selectively by the new method to the corresponding sulfoxides. All these sulfides were oxidized with the above three complexes in 70% aqueous acetic acid. The reactions were very rapid, like the similar oxidation by NBS. When the reaction proceeded nicely, the initial heterogeneous reaction mixture usually turned to a homogeneous solution within a few minutes, with or without heating. Therefore, one could use the rapid change of the state of solution for the diagnosis of the successful oxidation. The results are shown in Table I, where they may be compared with the results obtained by the oxidation with NBS.

In all cases, the bromine complex of 1, 4-diazabicyclo(2, 2, 2)octane gave the corresponding sulfoxides in satisfactory yields. Neither the cleavage of the aliphatic C–S bond, which was observed in the oxidation of aliphatic sulfides by NBS, nor the bromination of the aromatic ring, which takes place in the oxidation by molecular bromine, was observed. Here again the sulfoxides thus obtained were found to be completely free from the sulfones. When ^{18}O-enriched water was used in the reaction of diphenyl sulfide, a ^{18}O-labeled sulfoxide was obtained in which the sulfoxide oxygen was found to be incorporated with almost the same ^{18}O-enrichment as that of the original water, as is shown in Table II. This implies that the ^{18}O scrambling between acetic acid and water is not important in this rapid reaction. The present oxidation is therefore, a more convenient and a better method for labeling sulfoxide oxygen with ^{18}O than our previous methods, that by the oxygen-exchange reaction of sulfoxide in concentrated sulfuric acid[14,15] or

Table II. ^{18}O-labeling with the bromine complex of 1, 4-diazabicyclo(2, 2, 2)octane

that by the oxidation of sulfide with NBS in ^{18}O-enriched water.[4]

Experimental

Oxidation with Bromine Complexes of Pyridine and Quinoline.—The quinoline-bromine complex was prepared by slowly mixing equimolecular amounts of quinoline and bromine in carbon tetrachloride.[11] The pyridine-bromine complex was prepared similarly.

To a solution of benzyl phenyl sulfied (0.68 g., 0.0034 mol.) in 70% aqueous acetic acid, the freshly-prepared quinoline-bromine complex (0.99 g., 0.0034 mol.) was added; the whole mixture was then stirred at room temperature until it became homogeneous (within a few minutes). The resulting solution was poured into an excess of water, and the benzyl phenyl sulfoxides which separated were collected and recrystallized; yield, 0.65 g. (89%). If necessary, the quenched reaction mixture was made alkaline with potassium carbonate, and the sulfoxide was extracted with ether. The oxidation by the pyridine-bromine complex was carried out similarly. The results are shown in Table I.

The Bromine Complex of 1, 4-diazabicyclo-(2, 2, 2)octane.—The diamine was supplied by the Houdry Corp. and was recrystallized from *n*-hexane before use. Into the diamine solution of an inert solvent, such as carbon tetrachloride or benzene, equimolar amounts of bromine in the same solvent were slowly stirred at room temperature in the case of benzene and warmed up to 50°C in the case of carbon tetrachloride. The pale yellow precipitates which formed immediately were collected, washed with a fresh solvent, and dried (m. p. 150—160°C with decomposition). The same precipitates (m. p. 150—160°C with decomposition) were also obtained by adding two moles of bromine. The complexes can be used for the reaction in a similar manner.

Calcd. for $C_6H_{12}N_2Br_2$: Br, 74.07; found Br, 70.80 (obtained from the treatment of 1-to-1 mol. of bromine) and 73.30% (obtained from the treatment of 2 mol. of bromine).

Oxidation with the Bromine Complex of 1, 4-diazabicyclo(2, 2, 2)octane. — Half-molar amounts of the complex which had been prepared by treatment with 2 mol. of bromine were used, and a small excess was employed for the complex which had been prepared by treatment with 1 mol. of bromine. Diamine could be recovered from the reaction mixture as a hydrobromide salt. The procedure for the oxidation of various sulfides with the diamine-bromine complex was similarly applied to those of pyridine- or quinoline-dibromide.

The Identification of the Sulfoxides.—*Di-n-butyl Sulfoxide,* $(n\text{-}C_4H_9)_2SO$.—B. p. 105°C/3 mmHg; very hygroscopic.

p-Tolyl Methyl Sulfoxide, $p\text{-}CH_3C_6H_4SOCH_3$—B. p. 107°C/3 mmHg; m. p. 38.5°C (from benzene-hexane).

Thianthrene dioxide,  .—M. p. and mixed m. p. >200°C (sublimation).

Diphenyl sulfoxide, $C_6H_5SOC_6H_5$.—M. p. and mixed m. p. 69—71°C (with an authentic sample).

All these sulfoxides showed the infrared bands at 1040—1050 cm^{-1} characteristic of sulfoxides.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 366—369 (1966)

Ion-pair Formation of Some Substitution-inert Complexes and Sulfate Ions. Determination of Association Constants Using Polarographic Diffusion Current

By Nobuyuki TANAKA, Kazuko OGINO (née EBATA) and Gen SATÔ*

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received July 6, 1965)

The polarographic diffusion current of some tervalent substitution-inert complex cations decreases by the addition of sulfate. From the change in diffusion current the association constants of substitution-inert complex and sulfate ions are obtained at ionic strength 0.1 ($NaClO_4$) and 25°C. The values are 69 ± 8, 58 ± 8 and 4×10 for $[Co(NH_3)_6]^{3+}$–SO_4^{2-}, $[Cr(NH_3)_6]^{3+}$–SO_4^{2-} and $[Cr(H_2O)_6]^{3+}$–SO_4^{2-} respectively. The formation of $[Co(NH_3)_6]^{3+}$–HSO_4^- is negligibly small compared with that of $[Co(NH_3)_6]^{3+}$–SO_4^{2-}.

* Present address: Department of Chemistry, Sophia University, Chiyoda-ku, Tokyo.

It has been reported that the polarographic reduction waves of tervalent complex cations such as $[Co(NH_3)_6]^{3+}$ and $[Cr(NH_3)_6]^{3+}$ are affected by the presence of sulfate[1-5]; the half-wave potential shifts to more negative potentials and the diffusion current decreases upon the addition of sulfate. These were attributed mainly to the effect of ion-pair formation of the tervalent complex cations and sulfate ions. The shift in the half-wave potential was used for the determination of the association constants both in the case of a reversible electrode process[2,5] and in that of an irreversible electrode process[4]. However, the change of the structure of the electrical double layer caused by the addition of sulfate ions affects the rate of the electrochemical step, and hence the half-wave potential when the electrode process is irreversible. In such cases, it seems not appropriate to determine the association constant from the change of the half-wave potential.

In this paper, a method for the determination of the association constant using the polarographic diffusion current is presented and is applied to the ion-pairs $[Co(NH_3)_6]^{3+}$–SO_4^{2-}, $[Cr(NH_3)_6]^{3+}$–SO_4^{2-} and $[Cr(H_2O)_6]^{3+}$–SO_4^{2-}.

Experimental

Hexamminecobalt(III) perchlorate and hexamminechromium(III) perchlorate were obtained by the precipitation from aqueous solutions of the corresponding chlorides by the addition of perchloric acid, the chlorides of the ammine complexes being prepared with procedures given in literatures.[6,7] The solution of hexaquochromium(III) in perchloric acid was obtained by the reduction of sodium dichromate with hydrogen peroxide.[8]

Measurements were carried out at 25°C in solutions of ionic strength 0.1 ($NaClO_4$) containing 0.005% gelatin and an appropriate amount of perchloric acid. The diffusion current was recorded with a Yanagimoto PB-4 pen-recording polarograph.

Treatment of the Data

Consider the electrode reaction

$$M^{m+} + X^{x-} \rightleftarrows MX^{(m-x)+} \quad (1)$$

$$M^{m+} \text{ or } MX^{(m-x)+} + ne \rightarrow \text{Reduction product} \quad (2)$$

where M^{m+} corresponds to a complex cation, X^{x-} a counter ion and $MX^{(m-x)+}$ an ion-pair. The magnitude of the polarographic diffusion current for this system depends on the ion-pair formation: When reaction 1 is in equilibrium, the apparent diffusion coefficient, D, is given by[9,10]

$$D=\frac{D_M+KD_{MX}C_X}{1+KC_X} \quad (3)$$

where C_X is the concentration of X^{x-}, D_M and D_{MX}, the diffusion coefficients of M^{m+} and $MX^{(m-x)+}$ respectively and K the association constant of M^{m+} and X^{x-}:

$$K=C_{MX}/(C_MC_X) \quad (4)$$

where C_M and C_{MX} denote concentrations of M^{m+} and $MX^{(m-x)+}$ respectively. When values of D_M and D at various C_X are available, several methods,[11] i. e., elimination methods, linear plots methods and curve fitting methods, can be used for the calculation of the association constant. Among them, one of the linear plots methods is most appropriate in the present case. Eq. 3 is transformed to

$$\frac{C_X}{D_M-D}=\frac{1+KC_X}{K(D_M-D_{MX})} \quad (5)$$

where the left-hand side can be obtained experimentally. Equation 5 shows that when its left-hand side is plotted against C_X, a straight line is obtained and from the ratio of its slope and intercept, the association constant is obtained.

The advantage of this method is that it can be applied both to reversible and to irreversible electrode processes, irrespective of the relative electroactivity of M^{m+} and $MX^{(m-x)+}$.

Results

Since a part of sulfate ion combines with hydrogen ion to form hydrogensulfate ion in solutions of pH<3, the effect of hydrogensulfate ion on the equilibrium of the ion association was examined with hexamminecobalt(III) which shows a well-difined one-electron reduction wave both in neutral and in acid media. A series of measurements was carried out in solutions with 0.08 M hydrogen ion and in neutral solutions. The changes in current at −0.7 V. vs. SCE (saturated calomel electrode) with the increase of sodium sulfate concentration are shown in Figs. 1 and 2. In Fig. 1, where the abscissa is the total concentration of sulfate (the sum of sulfate ion and hydrogensulfate ion), the change of the current in acid media is less pronounced than that in neutral media. The sulfate ion concentration, which was calculated

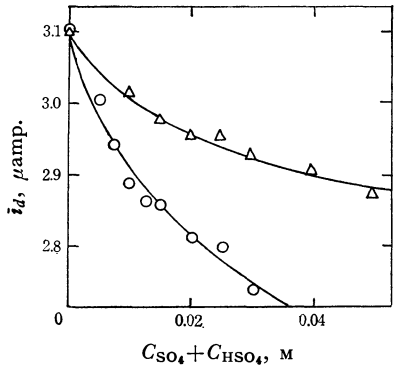

Fig. 1. Variation of the mean diffusion current ($\bar{i}_d$) of the reduction wave of $[Co(NH_3)_6]^{3+}$ with the change of the total sulfate concentration in neutral solutions (○) and in solutions containing 0.08 M hydrogen ion (△).

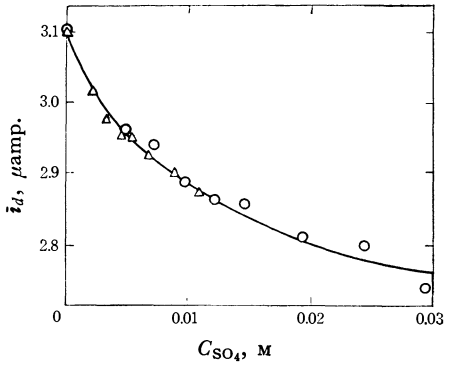

Fig. 2. Variation of the mean diffusion current ($\bar{i}_d$) of the reduction wave of $[Co(NH_3)_6]^{3+}$ with the change of the concentration of sulfate ion in neutral solutions (○) and in solutions containing 0.08 M hydrogen ion (△).

from the total sulfate and the hydrogen ion concentrations and the second dissociation constant of sulfuric acid,* is taken as the abscissa in Fig. 2, where the two sets of plots lie almost on a single curve. It may be concluded from these plots that the association of hydrogensulfate ion is negligible compared with that of sulfate ion.

The measurements for the determination of association constants were carried out in 0.003 N perchloric acid solutions because it was reported that the reduction wave of hexamminechromium(III) is not well-defined in neutral media, but well-defined in acid solutions,[3,12] and that hexaquochromium(III) ions polymerize and hydrolyze in pH ranges higher than 3 and lower than 0.[8] In plotting the left-hand side of Eq. 5, the sulfate

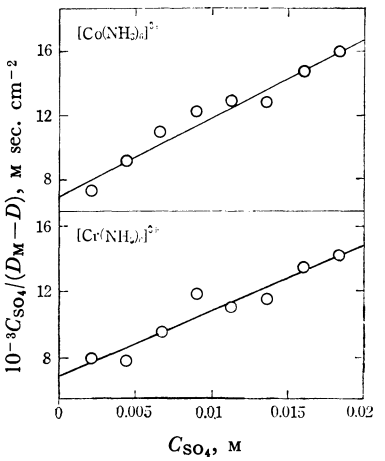

Fig. 3. Relation between the value of the left-hand side of Eq. 5 and sulfate concentration.

concentration, C_{SO_4}, was obtained by subtracting the concentrations of the ion-pair and the hydrogensulfate from the total sulfate concentration. The diffusion coefficient was calculated by the Ilkovič equation from the mean diffusion currents at −0.8 V. in the case of hexamminecobalt(III) and those at −1.1 V. in the cases of hexamminechromium(III) and hexaquochromium(III). The values of D_M were obtained from the diffusion current observed in the absence of sodium sulfate. The plots of of Eq. 5 are shown in Fig. 3. The slopes and the intercepts of the straight lines were calculated by the method of least square, and the association constants were obtained as given in Table I.

TABLE I. ASSOCIATION CONSTANTS OF ION-PAIRS
μ=0.1, 25°C

Ion-pair	K
$[Co(NH_3)_6]^{3+}$-SO_4^{2-}	69±8
$[Cr(NH_3)_6]^{3+}$-SO_4^{2-}	58±8
$[Cr(H_2O)_6]^{3+}$-SO_4^{2-}	4×10

Discussion

The association constant of hexamminecobalt(III) with sulfate ion has been reported by several researchers[13]; the logarithmic constant at infinite dilution ranges between 2.89 and 3.60. Corrected for the effect of activity coefficient,[14] the logarithmic association constant at infinite dilution obtained from our result becomes 3.21, which is in agreement with the values in the literature, and with that expected from Bjerrum's theory[15] of ion as-

* The pK_a of the second dissociation step of sulfuric acid at ionic strength 0.1 was taken as 1.6, which was obtained from the value at infinite dilution (L. G. Sillén and A. E. Martell, "Stability Constants of Metal-Ion Complexes," Chemical Society, London (1964), p. 232.) by correcting for the effect of activity coefficient.

sociation due to coulombic interaction between tervalent and bivalent ions of opposite charge at the distance of closest approach 5 Å.

The association constant of $[Cr(NH_3)]_6^{3+}-SO_4^{2-}$ has not been reported. Though detailed comparison of the constant with that of $[Co(NH_3)_6]^{3+}-SO_4^{2-}$ is limited because of the rather large error, it may be said that $[Cr(NH_3)_6]^{3+}-SO_4^{2-}$ is slightly less stable than $[Co(NH_3)_6]^{3+}-SO_4^{2-}$.

In the case of hexaquochromium(III), only a rough estimate of the association constant is obtained because of the rather small change in diffusion coefficient accompanying association. But it may be concluded that the value of K for $[Cr(H_2O)_6]^{3+}-SO_4^{2-}$ is about the same with or less than those for [hexammine complexes]$^{3+}-SO_4^{2-}$, contrary to the result by Tsuchiya and Umayahara[16] who reported that the association constant of $[Cr(H_2O)_6]^{3+}-SO_4^{2-}$ was about twenty times larger than that of $[Co(NH_3)_6]^{3+}-SO_4^{2-}$.

In deriving Eq. 5, only the association of one cation and one anion was taken into consideration. With the precision of the present experiment it is difficult to determine the extent of the ion association involving more than one sulfate ion. The formation of such species is negligibly small compared with the formation of the species such as $[Co(NH_3)_6]^{3+}-SO_4^{2-}$, as far as the association is assumed to depend mainly on the coulombic interaction between ions.

The authors wish to thank the Ministry of Education for the financial support granted for this research.

The Electron Spin Resonance and Electronic Spectra of 4-Substituted Pyridinyl Radicals

By Michiya ITOH* and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Azabu, Tokyo

(Received July 7, 1965)

The ESR and electronic absorption spectra have been measured with the 1-methyl-4-carbomethoxy-, 1-methyl-4-carbamido-, 1-methyl-4-acetyl- and 1-methyl-4-cyanopyridinyl radicals. From the analysis of their ESR spectra by the aid of a spectrum accumulator, we have been able to determine the nitrogen and hydrogen hyperfine splitting constants of these pyridinyl radicals, from which the spin distributions have then been evaluated. These radicals except for the 1-methyl-4-carbamidopyridinyl radical, have been found to show three absorption bands, at 300—350 mμ, at about 400 mμ and at about 600 mμ. From the results of the ESR and electronic absorption spectra, the electronic structures of these pyridinyl radicals have been concluded to be similar to those of the 4-substituted pyridine anion radicals. The preparation of 1, 2, 6- and 1, 3, 5-trimethyl-4-substituted pyridinyl radicals has been attempted. The latter radicals, except for the 1, 3, 5-trimethyl-4-cyanopyridinyl radical, were not detected by the ESR and electronic absorption spectra, because the steric hindrance of the methyl groups at the 3 and 5 positions prevents them from achieving the resonance stabilization due to the 4-substituent.

Schwarz et al.[1] have reported that the electrochemical reduction of the pyridinium ion in acetonitrile produces a dilute solution of the pyridinyl radical in the presence of tetra-*n*-butylammonium perchlorate as an electrolyte. Kosower et al.[2] have reported that a stable free radical can be prepared by bringing 1-ethyl-4-carbomethoxypyridinium iodide into contact with zinc dust in acetonitrile, and that the radical can be isolated in a pure form by distillation under a high vacuum. They proposed that this free radical is the 1-ethyl-4-carbomethoxypyridinyl radical.

The present authors[3] have studied the electronic structures of 3- and 4-nitropyridine anion radicals by combining the experimental results of the ESR and electronic spectra with the theoretical studies based on the molecular orbital method.

In the course of their investigations, the present authors have attempted to prepare various substituted pyridinyl radicals and to measure their ESR electronic spectra. The present investigation includes the 1-methyl-4-carbomethoxy-, 1-methyl-4-carbamido-, 1-methyl-4-acetyl-, and 1-methyl-4-cyanopyridinyl radicals. The spin distributions and electronic structures of the pyridinyl radicals will be discussed on the basis of the ESR hyperfine splitting constants and the electronic spectra, special attention being paid to a comparison of these results with those concerning the substituted pyridine anion radicals which were reported in previous papers.[3]

Experimental

Materials. — 1-Methyl-4-carbomethoxypyridinium iodide, m. p. 190—191°C,[4] 1-methyl-4-cyanopyridinium iodide, m. p. 197°C,[4] 1-methyl-4-acetylpyridinium iodide, m. p. 172—173°C,[5] and 1-methyl-4-carbamidopyridinium iodide, m. p. 255°C[6], were prepared from the respective 4-substituted pyridines and methyl iodide. Ion exchange resin IRA-410 was used to prepare the 1-methyl-4-carbomethoxypyridinium chloride, m. p. 265—270°C (decomp.). The melting points of these compounds were in good agreement with those reported in the literature.

1-Deuteromethyl-4-carbomethoxy pyridinium bromide was obtained by the treatment of the corresponding substituted pyridines with deuteromethyl bromide (Merck; molecular weight 97.96). 1-Deuteromethyl-4-carbomethoxypyridinium bromide, m. p. 165°C.

Found: C, 40.97, H, (D), 6.04; N, 5.97. Calcd. for $C_8H_7D_3NO_2Br$: C, 40.85; H (D), 5.53; N, 5.95%.

1, 3, 5-Trimethyl- and 1, 2, 6-trimethyl-4-carbomethoxypyridinium iodides, m. p. 218—219°C and m. p. 198°C (decomp.), 1, 3, 5-trimethyl- and 1, 2, 6-trimethyl-4-cyanopyridinium iodides, m. p. 217°C and m. p. 225°C (decomp.), and 1, 3, 5-trimethyl- and 1, 2, 6-trimethyl-4-carbamidopyridinium iodides, m. p. 258°C and m. p. 215°C (decomp.) were prepared from the 2, 6-dimethyl- and 3, 5-dimethyl-4-substituted pyridines which had been obtained from the corresponding dimethyl-4-cyanopyridines.[7,8] The 2, 6-dimethyl-4-cyanopyridine was prepared by the reaction of the 1-methoxy-2, 6-dimethylpyridinium iodide with potassium

cyanide.[8] The 3, 5-dimethyl-4-cyanopyridine was obtained from 1-amino-3, 5-dimethylpyridinium iodide and potassium cyanide.[9] The melting points of these pyridinium iodides are in good agreement with those reported in the literature.

Solvents.—Acetonitrile was purified by repeated distillation from phosphorus pentoxide. Dimethoxyethane (DME) and dioxane were treated with potassium metal and distilled from lithium aluminum hydride.

The Preparation of Pyridinyl Radicals and Measurements.—The substituted pyridinyl radicals were prepared at room temperature by bringing the corresponding pyridinium salts into contact with zinc mirror in acetonitrile. In DME or doixane, the pyridinyl radicals were prepared by bringing them into contact with sublimated potassium metal. All the solvents were purified and degassed before use. The zinc and potassium metals were purified by repeated sublimation in vacuo. The preparation of the pyridinyl radicals and the measurements of ESR and electronic spectra were performed in vacuo by the method described in previous papers.[8] The ESR and electronic spectra were measured with a Hitachi ESR spectrometer, model MPU-2B (X-band 100 kc. modulation) and with a Cary recording spectrophotometer, model 14 M, respectively.

Experimental Results

The 1-Methyl-4-carbomethoxypyridinyl Radical. — The acetonitrile solutions of 1-methyl-4-carbomethoxypyridinium chloride and 1-deuteromethyl-4-carbomethoxypyridinium bromide (10^{-3} -10^{-4} mol./l.) were colored a yellowish green by coming into contact with pure sublimated zinc metal in vacuo. The observed ESR spectra of these solutions are shown in Figs. 1a and 1b.

The DME or dioxane solution of the 1-methyl-4-carbomethoxypyridinium chloride became slightly yellow upon coming into contact with sublimated potassium mirror in vacuo. As is shown in Fig. 1c, the ESR spectrum of the dioxane solution showed an intense hyperfine structure. The ESR spectra of the DME or dioxane solution of the 1-deuteromethyl-4-carbomethoxypyridinyl radical were also measured. Furthermore, 1-methyl-4-carbomethoxypyridinyl radical was prepared by zinc metal in dioxane. The ESR spectrum of the radical prepared by zinc metal in dioxane was exactly the same as that of the radical prepared by potassium metal in the same solvent. Therefore, it may be said that the metal cation does not exert any observable effect upon the hyperfine structure of the ESR spectrum.

The electronic absorption spectrum of the acetonitrile solution of the 1-methyl-4-carbomethoxypyridinyl radical was measured parallel with the ESR spectrum. The results are shown in Fig. 2. The spectrum consists of three absorption bands, at 307, 396 and 650 mμ. The electronic spectra

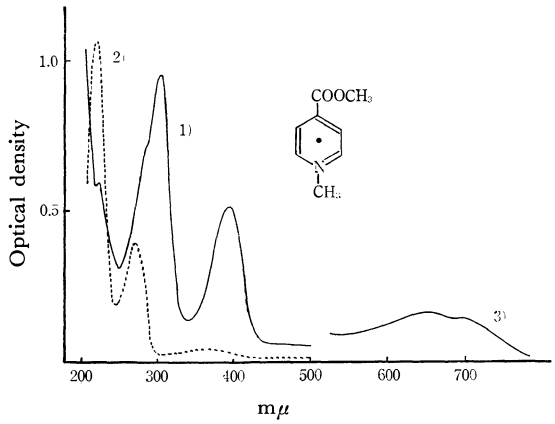

Fig. 2. The electronic absorption spectrum of the 1-methyl-4-carbomethoxypyridinyl radical. (The vertical axis is arbitrary scale.)

2) The radical solution exposed to air.
3) The solution about ten times as concentrated as solution 1).

of this pyridinyl radical in the other solvents are similar to those obtained with the acetonitrile solution. The three absorption bands of the radical solution disappeared when the solutions were exposed to air.

The 1-Methyl-4-acetylpyridinyl Radical.—The acetonitrile solution of the 1-methyl-4-acetylpyridinium iodide turned reddish yellow when it came into contact with sublimated zinc metal in vacuo.* The ESR and electronic absorption spectra of this solution were measured, with the results given in Figs. 3 and 4 respectively.

The 1-Methyl-4-carbamidopyridinyl Radical.—The 1-methyl-4-carbamidopyridinyl radical was prepared by bringing it into contact with zinc mirror in acetonitrile or DME.* The ESR and electronic spectra of this radical are shown in Figs. 5 and 6 respectively. This radical is rather unstable and, therefore, shows an ESR spectrum with a less resolved hyperfine structure.

The 1-Methyl-4-cyanopyridinyl Radical.—The DME solution of 1-methyl-4-cyanopyridinium iodide became an orange yellow when brought into contact with sublimated potassium metal. The observed ESR spectrum of this radical is shown in Fig. 7. The electronic spectrum was also measured with the DME solution of the radical. As is shown in Fig. 8, the spectrum consists of three absorption bands, at 342, 410 and ca. 600 mμ. These bands disappeared when the solution was exposed to air.

The acetonitrile solution of 1-methyl-4-cyanopyridinium iodide became an intense blue-black when brought into contact with zinc metal. The ESR and electronic spectra of the acetonitrile

solution were measured. The observed ESR and electronic spectra were exactly identical with those of the methylviologen cation radical recently reported by Kosower et al.[10] It may be inferred from the present experimental results that the 1-methyl-4-cyanopyridinyl radical easily dimerizes to form the methylviologen cation radical in polar solvents such as acetonitrile, although it is considerably stable in such less polar solvents as DME.

The Determination of the Hyperfine Splitting Constants and Simulated Spectra. — The hyperfine splitting constants associated with the nitrogen and hydrogen (deuterium) atoms of the above-mentioned pyridinyl radicals were determined from the ESR spectra. All the results are summarized in Table I. The theoretical spectra were simulated from the estimated splitting constants by the aid of a spectrum accumulator, JNM-RA-1, of the Japan Electron Optics Laboratory. The simulated spectra match well with the observed spectra, as is shown in Figs. 1, 3 and 7.

The Preparation of the Other Methyl Substituted Pyridinyl Radicals and Their

2) The solution about ten times as concentrated as solution 1).
3) The DME solution exposed to air.

Stability.—We also attempted to prepare 1, 2, 6-trimethyl-and, 1, 3, 5-trimethyl-4-substituted (substituents: $-COOCH_3$, $-CONH_2$, and $-CN$) pyridinyl radicals. The three 1, 2, 6-trimethyl-4-substituted pyridinyl radicals and the 1, 3, 5-trimethyl-4-cyanopyridinyl radical could be obtained from the respective pyridinium iodides. However, the 1, 3, 5-trimethyl-4-carbomethoxy and 1, 3, 5-trimethyl-4-carbamidopyridinyl radicals could not be obtained despite careful and repeated experiments. The stability of these substituted pyridinyl radicals in acetonitrile is summarized in Table II. It seems that the results given in Table II can be explained by considering the steric hindrance of the methyl groups at the 3 and 5 positions. This point will be discussed in a later part of the present paper.

Discussion

The Spin Distribution of Pyridinyl Radicals.—The hyperfine splitting constant associated with the nitrogen atom of the aromatic ring has been

e) The result of the 4-acetylpyridine anion radical obtained by Fraenkel et al.[15]

considered to depend not only on the spin density of the nitrogen atom, but also, via indirect polarization, on the spin densities of the adjacent atoms. Carrington et al.,[11] however, proposed the following equation for the relationship between the nitrogen splitting constant, A_N, and the spin density on the nitrogen atom concerned, ρ_N, by disregarding the indirect polarization;

$$A_N=Q_N\rho_N \quad (1)$$

They estimated Q_N to be 25.3 gauss for the anion radicals.

Bolton et al.[12] suggested that the hyperfine splitting constant associated with the protonated nitrogen atom in the nitrogen semiquinone cation radical could be represented similarly by Eq. 1. By combining the observed nitrogen splitting constants with the spin densities on the 4,4'-dipyridyl semiquinone cation and the pyrazine semiquinone cation radicals as calculated by the Hückel molecular orbital method, they determined the value of Q_N to be 32—36 gauss[12] for the cation radicals. Rieger and Fraenkel[13] studied the spin density distribution in a number of nitrile anion radicals. They reported that the nitrile-nitrogen splitting, A_N, should be approximately proportional to the spin density, ρ_N, on the nitrogen atom: $A_N=K\rho_N$. Furthermore, they showed that when the least-squares method is applied to the observed nitrile-nitrogen splitting constants, it gives $K=18.8\pm0.7$ gauss for the Hückel spin densities.

In the present paper, the electronic state of the nitrogen atom in the pyridinyl radicals was assumed to be the same as that of the protonated nitrogen atom in the nitrogen semiquinone cation radicals. In other words, the value of Q_N in Eq. 1 was taken to be 32 gauss for the pyridinyl radical. By combining the observed hyperfine splitting constants with the above-mentioned relations for nitrogen splittings and the well-known relation for the proton hyperfine splittings ($A_H=-22.5\rho_C$), we have evaluated the spin densities on the nitrogen and carbon atoms of the substituted pyridinyl radicals. The results are summarized in Table III. The hydrogen splitting constant of the *N*-methyl group is considered to be proportional to the spin density of the nitrogen atom concerned, as in the case of the hydrogen splitting of the methyl group attached to the aromatic carbon atom[14]:

$$A'_H=Q'_H\rho_N \quad (2)$$

According to the present results, the Q'_H value is 28.4 gauss on the basis of the nitrogen spin densities of the pyridinyl radicals and the methyl hydrogen splitting constants shown in Table I.

From the spin densities summarized in Table III, it may be inferred that an odd electron is not localized on the ring nitrogen atom which has a positive formal charge in the pyridinium cation, but is distributed over the pyridinyl radical. This shows that the neutral pyridinyl radicals are of the π-type, as is usual for aromatic anion radicals.

The present authors[3] have reported elsewhere their studies of the ESR and electronic structures of the 4-nitropyridine and its 1-oxide anion radicals. Fraenkel et al.[13,15] have reported on the spin distribution of the electrochemically-generated 4-cyano- and 4-acetylpyridine anion radicals. The spin densities of these anion radicals are also shown in Table III. The results summarized in Table III show that the spin densities on the ring nitrogen and carbon atoms are remarkably larger in the substituted pyridinyl radicals than in the substituted pyridine anions. Furthermore, by comparing the spin densities of the 1-methyl-4-cyano- and 1-methyl-4-acetylpyridinyl radicals with those of the

14) J. R. Bolton, A. Carrington and A. D. McLachlan, *Mol. Phys.*, **5**, 31 (1962).
15) P. H. Rieger and G. K. Fraenkel, *J. Chem. Phys.*, **37**, 2811 (1962).

pyridine anion radicals with the same substituent groups at the 4-position, we can conclude that the spin densities on the nitrile-nitrogen or carbonyl-carbon atoms of the neutral radicals are smaller than those of the anion radicals. This is because the pyridinium ring is more electronegative than the pyridine ring; therefore, the spin density of the pyridinyl ring of these neutral radicals is larger than that of the pyridine ring in the corresponding pyridine anion.

The Electronic Spectra of Pyridinyl Radicals.—As is clearly seen from Figs. 2, 4, 6 and 8, all these pyridinyl radicals in acetonitrile, except for the 1-methyl-4-carbamidopyridinyl radical, show three absorption bands in the visible and ultraviolet regions. The observed maximum wavelengths summarized in Table IV show that the shortest wavelength absorption bands of these neutral radicals shift to longer wavelengths with the increase in the electron-attracting ability of the 4-substituents. The order is as follows: $-CONH_2 < -COOCH_3 < -COCH_3 < -CN$.

Table IV. The electronic absorption band of substituted pyridinyl radicals

Pyridinyl radical	λ_{max} mμ		
4-$CONH_2$	300	403	—
4-$COOCH_3$	307	396	650*
4-$COCH_3$	326	432	ca. 600*
4-CN**	342	410	ca. 610*

* Very weak band.
** The result of the DME solution.

The present authors[3] have also demonstrated elsewhere that the electronic spectrum of the 4-nitropyridine anion showed three absorption bands, at 313, 440 and 640 mμ. The molecular orbital calculation allows us to regard the 440 mμ and 313 mμ bands as the intramolecular charge-transfer band and as the blue-shifted band of the band pertinent to the pyridine anion respectively. The electronic structures of the pyridinyl radicals with the electron-attracting groups, like the carbomethoxy, nitrile or acetyl groups, may be essentially similar to that of the 4-nitropyridine anion, although the valence state ionization potential of the nitrogen atom is considerably greater in the *N*-methyl pyridinyl radical than in the pyridine anion. On this assumption, the 300—350 mμ bands and the 390—440 mμ bands of the pyridinyl radicals may be thought to correspond to the 313 mμ band and the 440 mμ band of the 4-nitropyridine anion radical respectively.

The Effect of the Steric Hindrance of Methyl Groups upon the Stability of the Radicals.—The 1, 3, 5-trimethyl-4-carbomethoxy- and 1, 3, 5-trimethyl-4-carbamidopyridinyl radicals could not be obtained. It seems that this fact can be explained by considering the steric hindrance of the methyl groups at 3- and 5-positions. The $-COOCH_3$ and $-CONH_2$ groups at the 4-position can probably be prohibited by the steric hindrance from coplanarity with the pyridinium ring. This noncoplanarity decreases the resonance stabilization due to the $COOCH_3$ and $CONH_2$ groups.[16] This seems to be a reason why the 1, 3, 5-trimethyl-4-carbomethoxy- and 1, 3, 5-trimethyl-4-carbamidopyridinyl radicals could not be obtained. The above explanation is also supported by the fact that the 1, 3, 5-trimethyl-4-cyanopyridinyl radical can be prepared stably. In this case, the cyano group may reasonably be thought not to be susceptible to the steric hindrance of the methyl groups.

The Metal Cation Effect upon the Hyperfine Splitting Constants.—One electron transfer from zinc or alkali metal into the substituted pyridinium cation results in the formation of the neutral pyridinyl radicals and the metal cations. The alkali metal effect upon the nitrogen and hydrogen hyperfine splittings has been observed for the substituted nitrobenzene or substituted benzophenone anion radical reduced by alkali metal in THF or DME[17,18] This metal effect has been attributed to the electronic interaction between the anion radical and the metal cation.[19] As for the 1-methyl-4-carbomethoxypyridinyl radical, no metal effect upon the ESR hyperfine splitting was observed. This seems to show that the neutral pyridinyl radicals are different from the usual ion radicals in their interaction with the metal cations.

The authors wish to thank Mr. Masaaki Hirobe and Mr. Akio Ohsawa of the Faculty of Pharmaceutical Sciences, the University of Tokyo, for supplying some of the materials. The kind help given by Mr. Eiji Tsurumachi and Mr. Kohji Yanagi of the Japan Optics Lab. Co., Ltd., in obtaining the simulated ESR spectra is also gratefully acknowledged.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 376—379 (1966)

The Reaction of Thiols with Propylene Oxide in the Presence of Free Radical Sources[1]

By Matsuji TAKEBAYASHI, Tadao SHINGAKI and Takakimi MIHARA

Department of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received July 19, 1965)

The effect of free radical sources on the reaction of thiols with propylene oxide has been studied. In the presence of free radical sources, such as benzoyl peroxide, tetraphenylhydrazine and tetramethylthiuram disulfide, the reaction gives a single addition product, 1-aryl(or aralkyl)thio-2-propanol, in the same manner as when alkaline catalysts are employed. When *l*(+)-propylene oxide is used, an optically-active 1-thio-2-propanol is obtained. However, azobisisobutyronitrile manifests no catalytic influence on the reaction. Mercury-vapor light also has no effect on the interaction of thiols and propylene oxide, while the light leads to the decomposition of thiols. The mechanism of the reaction has been discussed in terms of a thiyl anion intermediate.

It has been reported that the reactions of thiols with cyclic ethers to give hydroxysulfides are promoted by alkaline catalysts.[2] Searles,[3] investigating the reaction of thiophenol with trimethylene oxide, obtained a good yield of 3-phenylthio-1-propanol with an alkaline catalyst, but a very poor yield of the product with an acid catalyst. The observation of Schuetz[4] has shown that the interaction of thiophenol and propylene oxide in the presence of an alkaline catalyst gives a single product, 1-phenylthio-2-propanol, in an excellent yield, while in the presence of an acid catalyst a mixture of the two possible isomers, 1-phenylthio-2-propanol and 2-phenylthio-1-propanol, is obtained in a poor yield. In these reactions, thiophenol reacts ionically on cyclic ethers, and the position of the ring opening of the cyclic ethers depends on the nature of the catalysts employed and also on the polarity or the steric effect of substituents on the carbon atom of the oxide ring.[5]

On the other hand, it has been recognized that benzoyl peroxide[6] and azobisisobutyronitrile[7] are effective catalysts in the homolytic addition of thiophenol to unsaturated compounds, and that tetraphenylhydrazine, triphenylmethyl peroxide and hexaphenylethane also accelerate the radical decomposition of aromatic azides in thiols.[8] In the light of such experimients, we investigated the reaction of thiols with propylene oxide in the presence of such free radical sources as benzoyl peroxide, tetraphenylhydrazine, tetramethylthiuram disulfide and azobisisobutyronitrile.

Results and Discussion

The reaction of thiols (0.3 mol.) with propylene oxide (0.2 mol.) has been carried out with a small amount (0.01 mol.) of free radical sources at 80°C in an atmosphere of nitrogen. The results are shown in Table I.

Two kinds of reaction products, I and II, may be expected.

$$CH_3CH-CH_2 + RSH \quad (\text{O bridge}) \rightarrow \begin{cases} CH_3CH(OH)-CH_2SR & (I) \\ CH_3CH(SR)-CH_2OH & (II) \end{cases} \qquad (1)$$

However, the reaction gave a single product (I) in the same manner as when alkaline catalysts were employed. No reaction took place in the absence of free radical sources.

Among the free radical sources employed, tetraphenylhydrazine and tatramethylthiuram disulfide act as the most effective catalysts on the reaction. Benzoyl peroxide promotes the reaction to some extent, though without any conspicuous evolution of carbon dioxide. On the other hand, azobisisobutyronitrile manifests practically no catalytic influence on the reaction.

	$(CH_3)_2CN=NC(CH_3)_2$ (CN, CN)	0	90	

a) Mole % based on the amount of propylene oxide.
b) Mole % based on the amount of free radical source added.
c) Syrupy oil (2.36 g.) containing sulfur atom.

In these experiments, the disulfides corresponding to the thiols used were obtained nearly quantitatively; diphenylamine and benzoic acid were also produced in good yields during the reactions with tetraphenylhydrazine and benzoyl peroxide respectively.

Another experiment investigated the reaction using L(+)-propylene oxide. The L(+)-propylene oxide shows practically no change in its optical activity ($[\alpha]_D^{15}$: +16.51° in ether) during the course of being heated with benzylmercaptan at 80°C for six hours in an atmosphere of nitrogen. Therefore, the reaction of L(+)-propylene oxide with benzylmercaptan has been carried out in the presence of tetramethylthiuram disulfide under the conditions described above. (−)-Benzylthio-2-propanol ($[\alpha]_D^{15}$: −17.73° in ether) was obtained in a good yield (78%). This suggests that no bonds at the asymmetric carbon atom of propylene oxide are made or broken during the reaction.

When quinone or hydroquinone was added as a free radical scavenger in the reaction mixture, the reaction was slightly suppressed. Therefore, a mixture of propylene oxide (0.30 mol.) and thiophenol (0.45 mol.) was exposed to a mercury-vapor light of 2537 and 3500 Å at 10°C for 24 hr. in an atmosphere of nitrogen. Diphenyl disulfide, hydrogen sulfide and hydrogen were thus obtained, without any reaction product corresponding to I or II; most of the propylene oxide was also recovered.

Thiophenol has strong absorption bands in the regions of 2350 Å (ε_{max} 8500) and 2690 Å (ε_{max} 720),[9] and the ArS–H and Ar–SH bond dissociation energies of thiophenol are close to 86 and 74 kcal./mol. respectively. The absorption of light of 2537 Å in one mole of a substance corresponds to that of an energy ($E=N_A h\nu$) of 112 kcal. per mol. Therefore, thiophenol may be dissociated in two ways by the absorption of the light:

$$C_6H_5SH \xrightarrow{h\nu} \cdot C_6H_5 + \cdot SH \qquad (2)[10]$$

$$C_6H_5SH \xrightarrow{h\nu} C_6H_5S\cdot + H\cdot \qquad (3)[11]$$

The free radicals, $\cdot C_6H_5$, $\cdot SH$ and H, produced by the reactions 2 and 3 react on thiophenol to give the thiyl radical, $C_6H_5S\cdot$:

$$C_6H_5SH + \cdot C_6H_5 \rightarrow C_6H_5S\cdot + C_6H_6 \qquad (4)$$

$$C_6H_5SH + \cdot SH \rightarrow C_6H_5S\cdot + H_2S \qquad (5)$$

$$C_6H_5SH + H\cdot \rightarrow C_6H_5S\cdot + H_2 \qquad (6)$$

If the thiyl radical attacks propylene oxide, the reaction products, I and/or II, should be produced. However, the thiyl radical dimerized to give disulfide without any reaction toward propylene oxide.

$$2\ C_6H_5S \rightarrow C_6H_5S\text{-}SC_6H_5 \quad (7)$$

The results presented above suggest that the reaction is not initiated by thiyl radicals derived from the reactions of thiols with free radical sources. The reaction may, then, reasonably explained as follows.

In the first place, the thermal decomposition of free radical sources occurs, giving rise to the corresponding free radicals:

$$\left.\begin{array}{l} (C_6H_5)_2N\text{-}N(C_6H_5)_2 \rightarrow 2\ (C_6H_5)_2N\cdot \\ C_6H_5CO\text{-}OCC_6H_5 \rightarrow 2\ C_6H_5CO\cdot \\ \quad\ \ O\quad\ \ O\qquad\qquad\quad\ \ O \\ (CH_3)_2NCS\text{-}SCN(CH_3)_2 \rightarrow \\ \quad\ \ S\quad\ \ S \\ \qquad\qquad 2\ CS_2 + 2(CH_3)_3N\cdot \end{array}\right\} \quad (8)$$

These free radicals have lone-pair electrons on their free radical atoms. Therefore, a proton-transfer reaction 9 to give thiyl anion must take place in addition to the abstraction of hydrogen (10). For instance:

$$(C_6H_5)_2N\cdot + RSH \rightarrow (C_6H_5)_2\overset{+}{N}H + RS^- \quad (9)$$

$$(C_6H_5)_2N\cdot + RSH \rightarrow (C_6H_5)_2NH + RS\cdot \quad (10)$$

The thiyl anion attacks the primary carbon atom of propylene oxide as a result of the inductive effect of the methyl group, and the reactions 11 and 12 will proceed in a chain mechanism:

$$CH_3\text{-}\underset{\diagdown O \diagup}{CH} - CH_2 + RS^- \rightarrow CH_3\text{-}\underset{O^-}{CH}\text{-}CH_2SR \quad (11)$$

$$CH_3\text{-}\underset{O^-}{CH}\text{-}CH_2SR + RSH \rightarrow CH_3\text{-}\underset{OH}{CH}\text{-}CH_2SR + RS^- \quad (12)$$

The reaction chain my be terminated by the reactions 13 and 14:

$$(C_6H_5)_2\overset{+}{N}H + RS^- \rightarrow (C_6H_5)_2NH + RS\cdot \quad (13)$$

$$2\ RS\cdot \rightarrow RS\text{-}SR \quad (14)$$

Experimental

Materials.—*Propylene Oxide (racemic).*—Commercial propylene oxide was refluxed for 2 hr. over pellet potassium hydroxide and fractionated, the fraction boiling at 34.5—35°C being used.[12]

L(+)-*Propylene Oxide.*—Levene's synthesis was employed.[12] α-Bromoacetone was converted to acetol by treating it with ethyl formate in methanolic potassium hydroxide; the acetol was then reduced to L-propylene glycol by the reductase of yeast. The propylene glycol was converted to L-propylenebromohydrin with dry hydrogen bromide, and the bromohydrin was then cyclized to L(+)-propylene oxide with concentrated aqueous potassium hydroxide. The crude material was purified by refluxing it over potassium hydroxide pellets; b. p. 34.5—35°C, $[\alpha]_D^{15}$: +16.51° (in ether).

Thiophenol.—Benzenesulfonyl chloride was reduced by zinc and sulfuric acid to thiophenol.[13] The crude distillate was fractionated; b. p. 61°C/15 mmHg.

Benzylmercaptan.—A mixture of benzyl alcohol and hydrobromic acid (48%) was refluxed for 12 hr.; the reaction product was then hydrolyzed by an alkaline solution.[14] The benzyl mercaptan produced was purified by fractionation; b. p. 65°C.

Tetraphenylhydrazine.—A solution of diphenylamine in acetone was oxidized by potassium permanganate.[15] The crude material was recrystallized in benzene; m. p. 144°C

Tetramethylthiuram Disulfide.—To a hot solution of commercial material in chloroform, ethanol was added; then the mixture was cooled. The precipitate was dissolved again in hot benzene and cooled after ether had been added.[16] The treatment was repeated twice; the disulfide melting at 146°C was used.

Benzoyl Peroxide was purified by treating it with chloroform and methanol;[17] m. p. 107—107.5°C.

Azobisisobutyronitrile was recrystallized in 95%-alcohol;[18] m. p. 102—103°C.

The Reaction of Thiols with Propylene Oxide in the Presence of Free Radical Sources.—Propylene oxide (0.2 mol., 11.6 g.), thiol (0.3 mol.) and a free radical source (0.01 mol.) were placed in a hard glass reaction tube, which had been cooled in an ice-salt bath, avoiding the entrance of moisture. After it had been flushed with dry nitrogen, the tube was sealed immediately. The sealed tube was then agitated and placed in a constant temperature bath (at 80—0.5°C) for an appropriate time. After the required reaction time, the tube was cooled in ice water and opened. After the unreacted propylene oxide had then been evaporated at room temperature under diminished pressure, the unreacted thiophenol and benzylmercaptan were distilled off at 61—62°C/15 mmHg and 64—65°C/3 mmHg, respectively, and the reaction products were separated by fractionation and column chromatography.

(A) In the reaction of thiophenol with propylene oxide, a fraction boiling at 103—110°C/1 mmHg was collected and redistilled. Nearly all of the fraction was distilled at 103—105°C/1 mmHg, and the liquid product was confirmed to be 1-phenylthio-2-propanol (Found: C, 64.16; H, 7.21; S, 18.90%).[19] The ultraviolet absorption curve (λ_{max} 254 mμ, ε_{max} 8.70×10^3) of this product accorded completely with that of the 1-phenylthio-2-propanol, which had been prepared according

19) The isomer, 2-phenylthio-1-propanol: b. p. 125—126°C/1 mmHg; UV absorption band, λ_{max} 256 mμ, ε_{max} 5.97×10^3.

to the directions of Schuetz,[20] and the 3, 5-dinitrophthalate of this product showed no melting-point depression when mixed with an authentic sample (m. p. 112°C). The residue, a crystalline mass, was treated as follows.

When tetraphenylhydrazine was used as a free radical source, the residue was dissolved in a small amount of alcohol, dried on a water bath after concentrated hydrochloric acid had been added, and treated with benzene. Diphenyl disulfide (2.09 g.) was obtained from the benzene solution, and diphenylamine hydrochloride (3.82 g.) from the residue.

When benzoyl peroxide was used, the residue was dissolved in ether and treated with a 10%-aqueous solution of sodium hydroxide. Diphenyl disulfide (2.18 g.) was obtained from the ether layer, and benzoic acid (2.27 g.) from the aqueous layer, after acidification.

When tetramethylthiuram disulfide was used, the residue was recrystallized from a small amount of alchohol. Diphenyl disufide (2.72 g.) was thus separated from the solution. The solution was then evaporated, and the residue was treated by column chromatography using 50 g. of active alumina. Diphenyl disulfide (1.20 g.) was isolated again by elution with petroleum ether (b. p. 30—40°C); a small amount of a syrupy substance was also obtained by elution with methanol.

When azobisisobutyronitrile was used, no principal product, phenylthiopropanol, was detected in spite of the evolution of nitrogen, while diphenyl disulfide was obtained in a good yield (3.91 g.).

(B) In the reaction of benzyl mercaptan with propylene oxide, the reaction products were treated in the way described above. The fraction boiling at 115—116°C/1 mmHg was identified as 1-benzylthio-2-propanol (Found: C, 65.82; H, 7.80; S, 17.52%).[21] The ultraviolet absorption curve of this product accorded completely with that of 1-benzylthio-2-propanol (λ_{max} 260.3 mμ, ε_{max} 3.40×10^3 and λ_{max} 267.0 mμ, ε_{max} 2.03×10^3).

Dibenzyl disulfide was also obtained nearly quantitatively except when benzoyl peroxide was used as a free radical source. In the latter case, the residue of fractionation was treated by column chromatography using active alumina. Dibenzyl disulfide (1.60 g.) was isolated by elution with petroleum ether, while syrupy products, boiling at 120—123°C/0.5 mmHg (1.0 g.) and 134—145°C/0.5 mmHg (1.36 g.), were obtained by elution with benzene and methanol respectively. The syrupy products gave positive results in tests to detect sulfur.

20) R. D. Schuetz, *J. Am. Chem. Soc.*, **73**, 1881 (1951).

21) The isomer, 2-benzylthio-1-propanol: b. p. 124—125°C/1 mmHg.

Summary

The reaction of thiols with propylene oxide leads to the formation of 1-aryl(or aralkyl)-thio-2-propanol in the presence of such free radical sources as tetraphenylhydrazine, tetramethylthiuram disulfide and benzoyl peroxide. In the presence of azobisisobutyronitrile, however, no principal product is obtained.

The reaction of benzylmercaptan with L(+)-propylene oxide in the presence of tetramethylthiuram disulfide gives (−)-benzylthio-2-propanol. When a mixture of thiol and propylene oxide is exposed to a mercury-vapor light, no principal procuct is detected.

It has been suggested that the reaction proceeds not by means of thiyl radicals but by means of thiyl anions in a chain mechanism.

The authors wish to express their hearty thanks to Professor Naoki Inamoto and to Dr. Katsumi Tokumaru for their kind discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 380—386 (1966)

Color Reactions of Dinitrobenzyl Pyridine and Related Compounds

By Hiroyuki HIRAOKA* and Russell E. HARDWICK

Department of Chemistry, University of California, Los Angeles 24, California, U. S. A.

(Received July 19, 1965)

Upon treatment with certain reagents, the photochromes, α- and γ-(2, 4-dinitrobenzyl)pyridine and 2, 4, 2', 4'-tetranitrodiphenylmethane form stable, blue-colored compounds which probably have chromophoric structures similar to those of the photochromic modifications of the original compounds (two examples of the permanently colored compounds are the N-methyl bases and the products from reactions with epoxy compounds). Kinetic and spectrophotometric studies of these colored compounds and of the anions of the original photochromes are reported. These results are compared with data on the photochromic tautomers.

It is well known,[1] that α-(2, 4-dinitrobenzyl)-pyridine (α-DNBP) develops a deep blue color upon irradiation with ultraviolet light (4000 to 3000 Å) either in the crystalline state or in solutions. In the crystals, the blue color fades quite slowly in the dark but in solutions disappears rapidly (within a few milliseconds to a few seconds at room temperatures depending upon the solvent and the acidity). The γ isomer of DNBP shows the same behavior in solution, but the crystals are not phototropic.** The blue colored substances may also be generated chemically, but transiently, upon neutralization of the anions of the photochromic compounds.

In the present investigation, we continue our study of the photochromic reaction and its products, primarily through comparison with the ordinary chemistry of DNBP. This report covers the following:

A. Formation and properties of stable, conjugated molecular modifications of DNBP.
B. Spectral properties of these conjugated species.
C. Kinetic studies, including
   1. Formation of the DNBP anion in base solutions.
   2. Kinetics of the reaction of DNBP with epoxides.
   3. Comparison of the fading rates of the conjugated form of α- and γ-DNBP as produced chemically and phototropically.

Experimental

The γ-DNBP was prepared by the method[1b] already described. Carbon disulfide, benzene, and isooctane were of spectro grade, Matheson, Coleman and Bell, and carbon tetrachloride of spectro grade, Merck. All other chemicals were Eastman CP and were used without further purification.

To prepare the epoxy addition compounds, DNBP was dissolved in an excess of epichlorohydrin; this solution was used directly for some measurements. To prepare the solid for extinction measurements, the solution was allowed to reach equilibrium, i. e., the optical density reached a constant value, then the solvent was evaporated away under high vacuum. The resulting platelets were ground with KBr and pressed into pellets for the infrared spectra. Other samples of the platelets were dissolved in various solvents for taking spectral and reaction data.

The spectra were taken with a Cary 14 spectrophotometer, and the rate measurements were made by a "stop-flow method" with a detection system having a DuMont 6292 photomultiplier, a simple monochromater and a Speedomax recorder type C. The scanning beam was passed through a Corning glass filter 3-69 and a heat filter before entering a reaction tube. The schematic diagram of the reaction tube is shown in Fig. 1.

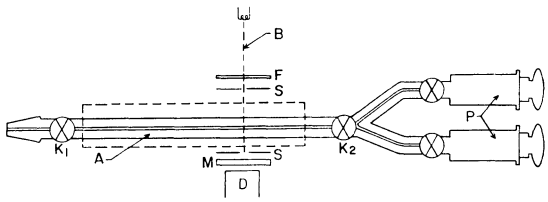

Fig. 1. Schematic diagram of stop-flow apparatus.

The reaction takes place in the 3 mm. capillary cell A, into which liquid is driven by the pressurized pistons P. Sequentially, the cell is evacuated through stopcock K_1, which is then closed; K_2 is opened and solutions flow from the separate cylinders, mixing at the tube junction. As the front of the rapidly moving

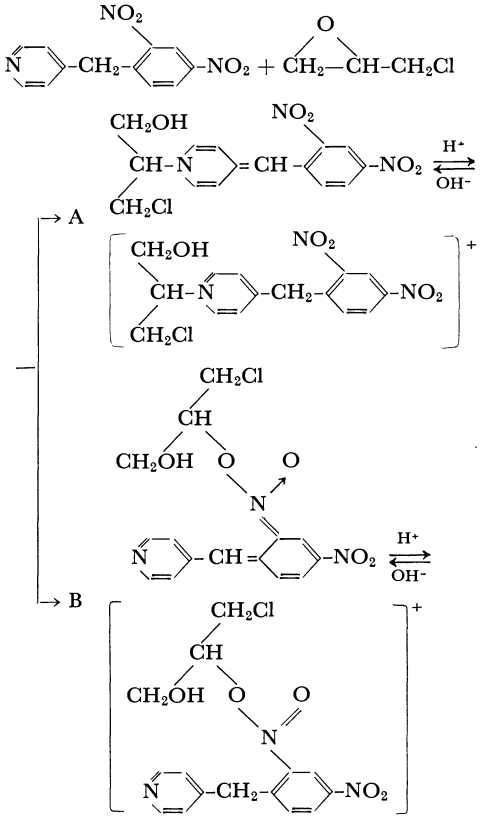
Results and Discussion

A. Stable Conjugated Compounds with Photochromic Absorption Spectra.—We have found that when dissolved in epoxy compounds such as epichlorohydrin, epoxy benzene, etc., such photochromic compounds as α-DNBP, γ-DNBP, and 2, 4, 2′ 4′-tetranitrodiphenylmethane acquire absorption spectra which are the same as those typical of their photochromic reactions. The blue colors formed by the photochromic substances and epoxy compounds are stable in the dark,

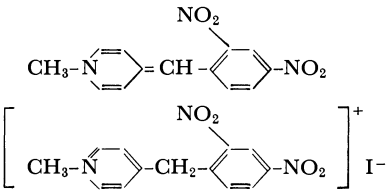
unlike those arising from photochromic reactions, although the former colors fade upon irradiation by near ultraviolet light. It is noticed that α-DNBP, and especially 2, 4, 2', 4'-tetranitrodiphenylmethane, do not form the blue substance in as great an amount as that characteristic of γ-DNBP.

The nature of this visible absorption is probably the allowed transition, discussed below, which is also very likely the source of the photochromic colors. The blue color disappears upon the addition of H^+ and appears again upon the addition of OH^-.* The color appears more rapidly upon the addition of the epoxy compounds to the anions of the photochromic substances than to the neutral photochrome. In a solution originally neutral, the amount of H^+ necessary to destroy the blue color is just equivalent to the number of the moles of the photochromic substances contained.

One possibility for the reaction between γ-DNBP +epichlorohydrin is the following:



The fact that 2, 4, 2', 4'-tetranitrodiphenylmethane also forms a blue substance in epoxy compounds, albeit with low intensity, indicates that B can not be neglected. However, the infrared spectrum of the blue substances, Fig. 2, clearly shows the $\equiv C-\overset{+}{N}\diagdown$ frequency at 1635 cm^{-1}, which is also found with similar intensity in



where ordinary DNBP does not have any absorption at this frequeccy. Although a C–O–N structure might possibly exhibit absorption at this energy, this more usually occurs at smaller frequencies, i. e., lower than 1600 cm^{-1}. We have prepared *N*-methyl γ-DNBP from γ-DNBP+CH_3I, followed by the addition of aqueous sodium hydroxide solutions; m. p. 161°C. The hydrogen bond frequency (3450 cm^{-1}) is displayed by crystals of the blue substance prepared from the solutions of γ-DNBP and epoxy compounds as well as in *N*-methyl γ-DNBP. The most characteristic feature in the infrared spectrum common to all the permanent blue modifications, (the epoxy complex and the *N*-alkylated compounds) is the near disappearance of the C–H stretching frequency peaks around 3000 cm^{-1}. The light induced and thermo-chromic blue mixtures show no detectable change at 3000 cm^{-1} presumably because only a very small proportion of the compound is changed.

B. Visible Absorption Spectra of the Conjugated Compounds.—In the process of taking extinction coefficients of the product of γ-DNBP and epichlorohydrin, we made Beer Law plots by successively diluting solutions which were prepared by dissolving crystals of the product in isopropyl alcohol. These gave curves which were linear within our experimental error of about 1%. From these measurements, the calculated decadic extinction coefficient was 2.40×10^4 l./mol.-cm. at the absorption peak at 5880 Å, taken on the basis of 100% conversion.*

As we have seen, the two rings of γ-DNBP may also be coupled through methylation of the ring nitrogen, giving a deep blue solution. As with the epoxide complex, this blue product shows a peak at 5800 Å; its decadic extinction coefficient is 2.4×10^4 l./mol.-cm. for the γ-isomer and 1.97×10^4 l./mol.-cm. for the α-isomer.

So far, we do not know the extinction coefficient

* The appearance of blue color is immediate when base is added to an acidified solution of DNBP-epoxy compound, even though the original reaction between DNBP and epoxy is usually very slow. For this reason, we feel that the DNBP-epoxy compound is not decomposed by acid and reconstituted by base, but that it merely assumes a colorless, cationic form in the presence of acid.

* We believe that the equilibrium between γ-DNBP and epichlorohydrin favors almost complete formation of the complex. The reasons for this conclusion are that the extinction coefficient of the complex (calculated on 100% conversion) is the same as that of the *N*-methyl base (see below), which has a similar absorbing structure. Moreover, when the complex is isolated by pumping off the solvent, no trace of the original γ-DNBP remains.

The fact that Beer's Law is followed to extreme dilution by both alcohol and epichlorohydrin solutions of the blue compound argues that the equilibrium constant of the reaction of γ-DNBP+ epichlorohydrin must be extremely high.

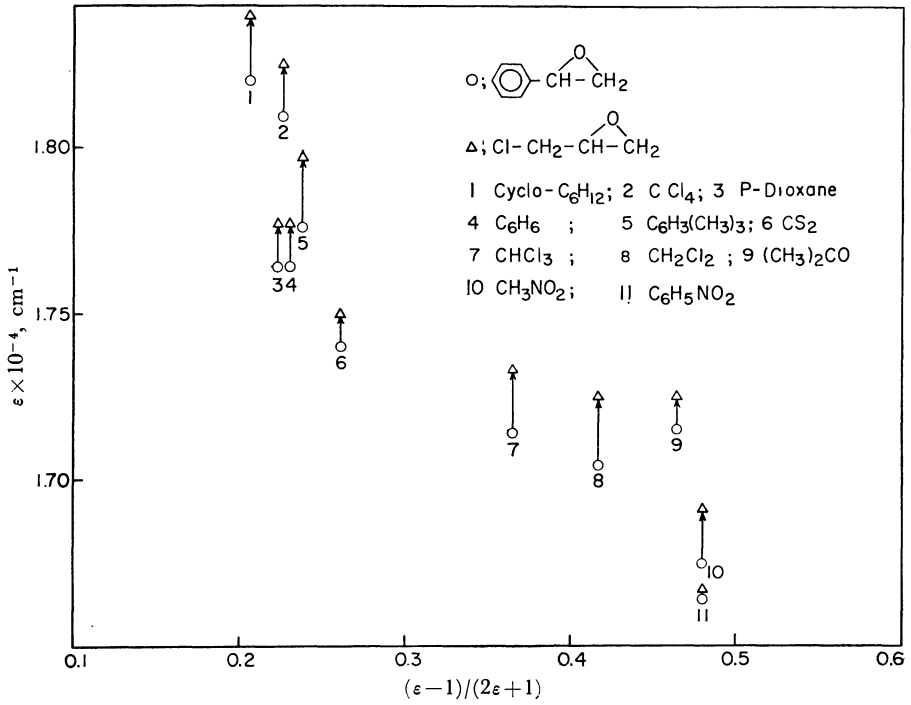


Fig. 4. Relation between frequency shift and dielectric constant.

of the blue photochromic product of γ-DNBP, but it is reasonable to believe that it might very well be approximately the same as that of the conjugated structure produced by either of the permanent chemical reactions discussed above. If we take this assumption, however, we find that the amount of photochromic conversion in solutions of γ-DNBP (or for that matter in either the crystalline form or the solutions of α-DNBP) can be only a few percent. As proposed in an earlier paper of this series, this effect may arise from a photoequilibrium which is established through the destruction of the blue tautomer by radiation in the ultraviolet region (all the photochromic products are stable to irradiation at 5800 Å). We are continuing to investigate this possibility.

The maximum color density developed by either α-DNBP or 2, 4, 2', 4'-tetranitrodiphenylmethane in epichlorohydrin never even remotely reaches that shown by the gamma isomer, the "apparent" decadic extinction coefficients being only 53 l. mol^{-1} cm^{-1} and 9.3 l. mol^{-1} cm^{-1} respectively at 36°C. Since we know of no obvious reason why the conjugated forms of these two substances should not have approximately the same absorption efficiency, we believe that the effect must be caused in the former compounds by incomplete dissociation of the bridge hydrogen or by the existence of an equilibrium which is not favorable to the product formed with epichlorohydrin.

We have found that the color formed by γ-DNBP and various epoxy compounds shifts from blue to pink as the original product is diluted with solvents of decreasing dielectric constant. Figure 3 shows several spectra of solutions made up by mixing 10 ml. of various solvents with 0.1 ml. of a solution consisting of 10^{-3} mol. of γ-DNBP in 1 ml. of epichlorohydrin;* it may be seen that the absorption curve moves to longer wavelengths with increasing dielectric constant of the medium. This red shift would be expected if the excited state of the absorbing molecule were to be of a more polar nature than the ground state, i. e., increasing interaction with the solvent would lower the energy of the excited state. One transition which would fulfill this requirement is that to the antibonding π^* state.

According to theory,[2] the relative frequency shift of the absorption, $\Delta\nu/\nu$, of a vibrating dipole in a spherical cavity of radius a, surrounded by a continuum of dielectric constant ε, is proportional to $(\varepsilon-1)/(2\varepsilon+1)\cdot(1/a^3)$. In Fig. 4, the

* Similar results are found for the product of the reaction between γ-DNBP and  , i. e., possibly

Since the added benzene ring is not conjugatively linked to the DNBP structure, it does not directly influence the $\pi^*\leftarrow\pi$ transition.

2) H. H. Jaffe and M. Orchin, "Theory and Application of Ultraviolet Spectroscopy," John Wiley & Sons, Inc., New York (1962), pp. 190, 222.

maximum absorption frequency of the γ-DNBP epoxy compound is shown as a function of $(\varepsilon-1)/(2\varepsilon+1)$ of the solvent. The approximate linear relationship suggests that the absorption may be the $\pi^*\leftarrow\pi$ transition of the conjugated system.

If the solutions are made using solvents with very weak intermolecular forces: e. g., isooctane ($\delta=6.9$), freon 113 ($\delta=7.3$) and cyclohexane ($\delta=8.2$), there appear two maximum absorption peaks, which are not found in the solvents with solubility parameter[3] higher than carbon tetrachloride ($\delta=8.6$). In these bifurcated spectra, the absorption peak of shorter wavelength, ~5400 Å or less may correspond to the absorption found in the other solvents; however, the long wavelength peak, 6000 to 7000 Å, is probably different in nature, because even in the highly polar solvents no absorption has been found in this region. The latter transition may arise from dimers or higher aggregates which could not be dispersed to monomer form owing to the weaker intermolecular forces of the solvents.

The absorption wavelength arising from the transiton of a π-electron to its first excited state is given by the free electron model[2] as:

$$\lambda=\frac{8ma^2C}{(2k+1)\boldsymbol{h}}$$

where a is the length of the potential well, k the number of orbitals occupied by the π-electrons in the conjugated systems, m the electron mass, C the light velocity, and $\boldsymbol{h}$ Planck's constant. In applying the free electron theory to our systems there are very serious problems of hetero atoms with different electronegativity; however as a zeroth order approximation, we neglect this difference. Taking an average C–C bond distance of 1.4 Å and those of C–N and of N–O as 1.2 Å we obtain the following results for the neutral conjugated systems and for the anion (in the latter, we use k_N+1 to account for the extra electron), Table I.

Table I. Calculated and experimental absorption wavelengths

Species	Absorption wavelength mμ: Neutral molecule Calcd.	Neutral molecule Obs.	Anion Calcd.	Anion Obs.
 *	585	575	585 500	640 480
 *	700	712	700 610	700 —
	690	650	690 527	650 527

* Shown as one of the possible photochromic modifications.

In the anion, calculations are made for transition of the extra electron ($n=6$ to $n=7$) and again for the optical electron as in the neutral molecule ($n=5$ to $n=6$); this action is supported by the double peak found in the anion spectrum. It may be seen that, at least in the neutral molecule, the free electron theory makes a fairly good prediction of the wavelength which is observed, thus lending support to the proposed structures and to the assignment of $\pi^*\leftarrow\pi$ for the transition. In the 585 mμ band for γ-DNBP it is noticed that, although the agreement between calculation and experiment is good for the neutral molecule, in the anion the discrepancy runs to ~65 mμ. This misbehavior of the ion may be due to large solvation effects arising out of the fact that the anion has a charge. The agreement of the calculated wavelengths and the observed ones is excellent when we consider the approximation used. Probably this is largely fortuitous, yet the evidence does support the conclusion that the absorption is due to the $\pi^*\leftarrow\pi$ transition.

When the anions of γ-DNBP are diluted with certain polar solvents such as nitromethane or *p*-dioxane, the characteristic green color disappears, and the typical blue-violet color of the neutral conjugated systems appears transiently. This may possibly be caused by transfer of the excess charge from the anion to the solvent. In acetone, however, a stable pink color gradually appears, Figure 5, possibly arising from complex formation.

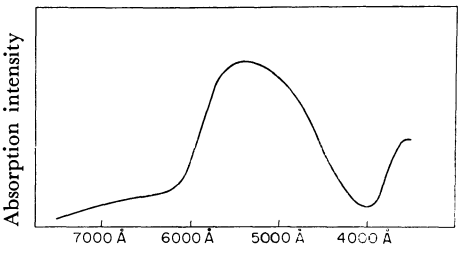

Fig. 5. Spectrum of pink solution of DNBP anion in acetone. (Concn. 2.08×10^{-7} mol./l.)

C. Kinetic Studies. — *1) Anion Formation Reaction.*—The rates of formation of the anions of DNBP have been measured with the "stop-flow method." Typically, α-DNBP solution of 1.07×10^{-4} mol. dissolved in 25 ml. of isopropanol was mixed in the reaction tube with an aqueous solution of 0.098 molar sodium carbonate. The relative proportions of DNBP solution to base solution varied from 1.0 to 2.0; however, the rate

3) J. H. Hildebrand and R. L. Scott, "Regular Solutions," Prentice-Hall Inc., New Jersey (1962).

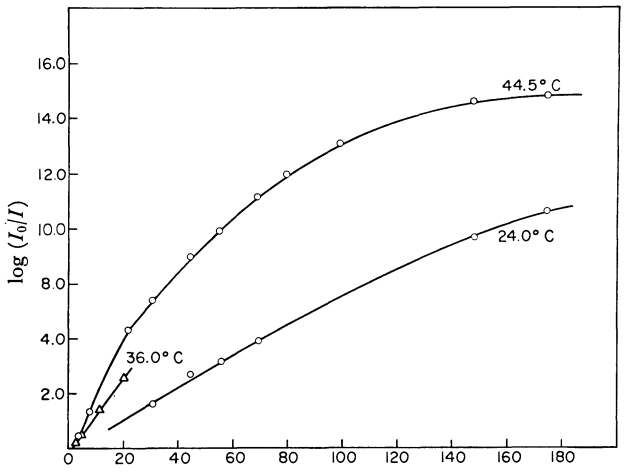

Fig. 6. Reaction rate of γ-DNBP+Cl·CH_2·CH·CH_2·O.

constants measured did not change in this range of concentration. The final pH of the one-to-one solution was 12.8. The rate of formation of the anion was found to follow first order kinetics under our conditions of a large excess of base. Sample rates of anion formation in solutions of α-DNBP mixed with sodium hydroxide are shown in Table II. With OH^- in excess, our observed rate constant is given by:

for α-DNBP

$$k_{\text{anion}}=1.29\times10^{6}\exp\left(-\frac{10.5\times10^{3}}{RT}\right)\text{sec}^{-1}$$

Table II. The rate of formation of anions from α-DNBP+aq. NaOH

Concn. of α-DNBP in isopropanol; 3.8×10^{-6} mol./ml.,
pH of aq. NaOH=12.0

Temp. °C	Vol. of α-DNBP / Vol. of aq. NaOH	$\tau_{1/2}$ sec.	k sec^{-1}
27.5	0.50/0.50	24.8	2.80×10^{-2}
27.0	0.45/0.50	23.6	2.94×10^{-2}
27.0	0.40/0.60	23.6	2.94×10^{-2}
27.0	—	23.6	2.94×10^{-2}
26.5	0.45/0.55	24.0	2.89×10^{-2}
36.0	0.40/0.65	16.5	4.20×10^{-2}
37.0	0.35/0.60	13.8	5.03×10^{-2}
37.0	0.65/0.55	14.1	4.92×10^{-2}
43.0	0.45/0.55	9.2	7.55×10^{-2}
43.0	0.45/0.50	8.2	8.46×10^{-2}
43.0	0.50/0.60	11.0	6.30×10^{-2}
43.0	0.45/0.60	10.0	6.94×10^{-2}
15.5	0.35/0.50	38.0	1.825×10^{-2}
14.5	0.30/0.50	42.2	1.644×10^{-2}
16.0	0.40/0.60	37.4	1.735×10^{-2}
16.0	0.40/0.50	32.0	2.165×10^{-2}

and for γ-DNBP

$$k_{\text{anion}}=2.82\times10^{7}\exp\left(-\frac{11.2\times10^{3}}{RT}\right)\text{sec}^{-1}$$

2) Reaction of DNBP+Epoxy Compounds.— α-DNBP and γ-DNBP were dissolved in pure Cl·CH_2·CH·CH_2O and the rates of formation of the blue conjugated compounds were measured by following the absorption intensity at the wavelength of the maximum absorption. It was found that the rate followed 1st order kinetics. The results are given by the following:

for α-DNBP

$$k=5.4\times10^{4}\exp\left(-\frac{13.6\times10^{3}}{RT}\right)\text{sec}^{-1}$$

for γ-DNBP

$$k=1.06\times10^{3}\exp\left(-\frac{12.6\times10^{3}}{RT}\right)\text{sec}^{-1}$$

It is seen that the reaction, α-DNBP+$ClCH_2$·CHCH$_2$O requires a slightly higher activation energy than that of γ-DNBP+$ClCH_2$·CHCH$_2$O, but the former has the higher frequency factor, probably due to the proximity of nitrogen atom in pyridine ring to $-CH_2-$ bridge. As mentioned earlier, the equilibrium is far more favorable to the formation of the conjugated system in γ-DNBP than in α-DNBP.

3) Study of the Conjugated Form of γ-DNBP as Produced Chemically and Phototropically. — Other work in this laboratory[4] has shown that when the brown-green anion of γ-DNBP is neutralized, the blue color, characteristic of the phototropic modification, appears fleetingly before the solution becomes colorless. We feel that it

is reasonable to assume that the species which gives the blue color upon neutralization may very well be the same as that which arises photochemically, thus we are attempting to compare the two in as many ways as possible. The previous report has discussed the low temperature decay rates and spectra of the two systems of γ-DNBP, the discussion below gives rates at higher temperatures and compares activation energies for the fading of the systems as produced chemically and phototropically.

This experiment was made by mixing solutions of γ-DNBP anion with HCl solutions, the concentrations being adjusted such that the pH of the final mixtures came very near to pH=7. In order to increase the solubility of γ-DNBP, isopropanol was added, the concentration of which was 25% of the final solution upon neutralization, With these conditions we have found the following results, Table III.

Table III. Fading-rate of the blue, conjugated form as chemically produced

Temp., °C	k, sec^{-1}
11.0	0.56±0.09
2.1	0.14±0.02

It has been reported previously[4] that the rate of the disappearance of the blue, colored form of γ-DNBP chemically produced was about 2×10^{-3} sec^{-1} at 173°K. By combination with this result, we may calculate the activation energy to be 5.0×10^{3} cal./mol. for the fading rate. This value may be compared to that of 4.5×10^{3} cal. reported earlier[5] for the fading of the phototropic blue γ-DNBP in tetrahydrofuran solutions. The comparison is only approximate because of the differences in solvent and the sensitivity of the stop-flow measurements to small errors in pH adjustment, but taken with other reported similarities, this agreement again supports the argument that the chemically and phototropically produced species are identical.

This research was supported by the Atomic Energy Commission under Contract No. AT(11-1)-34, Project 88. We also gratefully acknowledge many conversation, suggestions and other valuable contributions made by Professor Harry S. Mosher.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 386—390 (1966)

Electrical Conduction of Organic Semiconductors under High Pressure

By Ichimin SHIROTANI, Hiroo INOKUCHI and Shigeru MINOMURA

The Institute for Solid State Physics, The University of Tokyo, Azabu, Tokyo

(Received July 27, 1965)

The electrical conductivity and the temperature dependency of the organic semiconductors, five simple polycyclic aromatic compounds, two charge transfer complexes and a free radical, have been observed up to 1.6×10^5 kg./cm^2. The conductivity thus increases to 10^5-10^7 times that at atmospheric pressure, while the band gaps decrease to about one fifth of the ordinary values. These abrupt changes may be caused by the overlapping of π-electron clouds of adjacent aromatic molecules.

In 1955, we studied the effect of pressure on the resistance of an organic semiconductor, iso-violanthrone, by means of a simple instrument and found that the resistance at 8×10^3 kg./cm^2 was decreased to five-hundredths that at atmospheric pressure.[1] Recently, Drickamer and his collaborators have found that the electrical conductivity of polycyclic aromatics rises very rapidly until the pressure reaches the 10^5 kg./cm^2 region.[2] No quantitative treatment for these abrupt changes has, however, yet been reported.

It is reasonable to assume that the increase in the electrical conductivity is caused by the overlapping of π-electron clouds of adjacent aromatic molecules. In this report, we will present some findings on the electrical conductivity and on the temperature dependency of polycyclic aromatic compounds and will discuss the contraction of the band gaps of the organic semiconductors.

Experimental Procedures

Materials.—The materials applied were purified by several methods, as will be described in the following

1) H. Inokuchi, This Bulletin, **28**, 570 (1955).
2) G. A. Samara and H. G. Drickamer, *J. Chem. Phys.* **37**, 474 (1962).

paragraphs.

Polycyclic Aromatic Compounds.—1) Coronene ($C_{24}H_{12}$). This compounds was provided by the Badish Anilin Soda Fabrik A. G., of Germany. By repeated recrystallizations from 1, 2, 4-trichlorobenzene, plate-like crystallites of the hydrocarbon were obtained. When this material was then chromatographed under argon, it yielded pale yellow needles; these were twice sublimed at 200°C under a vacuum of 10^{-5} mmHg.[3]

2) Quaterrylene ($C_{40}H_{20}$). This stable aromatic hydrocarbon was purified by a method of vacuum sublimation, because it is virtually insoluble in all solvents at room temperature. Before applying the sublimation techique, an extraction of the impurities included in the matrix with trichlorobenzene was effective. After a vacuum sublimation was repeated at about 450°C, the compound was composed of dark green microcrystals. The details of the purification of this compound have already been reported.[4]

3) Pentacene ($C_{22}H_{14}$). This dark-blue five-ringed aromatic hydrocarbon was provided by the Rütgerswerk A. G., of Germany. In order to purify the material, pentacene was sublimed in vacuo at about 250°C. Because of its instability against ultraviolet light, the hydrocarbon had to be kept in a dark room.

4) Tetrathiotetracene ($C_{18}H_8S_4$). The compound was provided by Matsunaga.[5] This sulphur compound was purified by recrystallizations from trichlorobenzene and also by fractional sublimation. The electronic properties of the material will be reported elsewhere.[6]

5) α, α' - Diphenyl - β - picrylhydrazyl (DPPH). DPPH was prepared by the reaction of α, α'-diphenylhydrazine with picrylchloride in chloroform.[7] To prevent a complex formation with an applied solvent, a recrystallization of the free radical from a carbon disulphide solution was carried out.

6) Violanthrone (Violanthrone A; $C_{34}H_{16}O_2$). This dyestuff was synthesized from purified benzanthrone by a carefully-controlled alkali-fusion. An unstable by-product, denoted as violanthrone B, was removed by a vatting method.[8] The synthesized violanthrone was washed with chlorobenzene or with a sodium hydroxide solution and then recrystallized from concentrated sulphuric acid. Further, the material was repeatedly sublimed under a vacuum, it thus yielded dark-blue needle crystallites.

The Charge Transfer Complexes.—1) Violanthrene-iodine Complex ($C_{34}H_{18}$-$2I_2$). The complex was provided by Uchida. The complex formation between purified violanthrene and pure iodine was carried out by Clar's method.[9,10]

2) Perylene-iodine Complex ($C_{20}H_{12}$-$3I_2$). This complex was also prepared by Clar's method from perylene, which was purified through repeated chromatographical purification, and pure iodine.

Both of the complexes had to be kept in sealed glass vessels to avoid decomposition.

Resistance Cell.—The materials described above were compressed between two steel plates under a few kbars* pressure to make a thin sheet, the thickness of which was about 0.1 mm. These samples were then fitted into a high pressure resistance cell. The cell applied in the experiment was similar to those used by Balchan and Drickamer.[11] Figure 1 shows a schematic diagram of the cell.

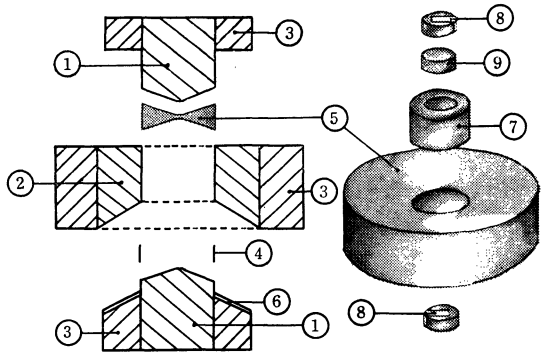

Fig. 1. Resistance cell.
1 Carboloy piston, 2 Carboloy insert, 3 steel jackets, 4 0.02 mm. mica ring, 5 pyrophyllete pellet, 6 Bakelite insulating ring, 7 pyrophyllete ring, 8 electrodes and 9 specimen

The Carboloy insert (2) was ground to a tight slip fit on the Carboloy pistons (1), and then pressed into the steel outer jacket (3). One end of each insert was ground in the truncated cone shape, with an 18° taper and 2.4 mm. diameter flat. One of the pistons was reduced in outside diameter by 0.02 mm. to permit an electrical insulation from the chamber wall with a thin strip of mica (4). A pellet of pyrophyllite (5), 0.33 mm. thick at the centre, was applied as the supporting medium for the taper. Bofore use, the pellet was dried in an electric oven for a few hours to remove a small amount of adsorbed water. The details of the arrangement of the electrodes in the resistance cell are illustrated in the same figure. The electrical resistances of the samples were measured by the potential drop method. To increase the electrical insulation of the cell, a boron nitride pellet (5) and ring (7) were used instead of pyrophyllite ones. As a result of this imporvement, the bulk resistance of the cell reached around 10^8 Ω.

Pressure Calibrations**—A sharp change in the electrical resistance of bisumth at 2.54×10^4 kg./cm^2 and 8.8×10^4 kg./cm^2 was used in the calibration of the pressure of the resistance cell, Further, the phase transition point of lead at 1.61×10^5 kg./cm^2 was used.

Experimental Results

As has been mentioned previously,[12] the abrupt change in the electrical resistance of the purified organic semiconductors was found at a lower pressure range, 10^4 kg./cm^2. At a higher pressure region, three different curves between the applied pressure and the resistivity were found. Figure 2-(a) shows the pressure-resistivity curve for the first group, which displayed a leveling-off behaviour. Quaterrylene and violanthrone belonged to this group.

Table I. The electrical resistivity of organic semiconductors under high pressure
($\rho=\rho_0 \exp(\Delta\varepsilon/2kT)$)

Compound	At atmospheric pressure		at 1.61×10^5 kg./cm^2	
	ρ_{15}(Ωcm.)	$\Delta\varepsilon$	ρ_{15}(Ωcm.)	$\Delta\varepsilon$
Quaterrylene	10^8	0.60	7×10^3	0.16
Violanthrone A	2.3×10^{10}	0.78	3.7×10^3	0.20
Coronene	1.7×10^{17}	1.7	$>10^6$	—
DPPH	10^{13}	1.7	1.1×10^4*	0.21*
Pentacene	10^{14}	1.5	2.3×10^3	0.14
Violanthrene-iodine	96**	0.15	2.3***	0.17
Peryleneiodine	10	0.06	0.6	—
Tetrathiotetracene	4×10^4**	0.4—0.5	1.6×10^2	0.34

* Under a pressure of 1.27×10^5 kg./cm^2
** Under a pressure of 10^3 kg./cm^2
*** At 1.20×10^5 kg./cm^2 compression

In the second group, the behaviour of the pressure-resistivity relation was almost identical with that of the first group. However, the resistivity was increased gradually under a constant pressure of around 10^5 kg./cm^2 (Fig. 2-(b)). Two charge transfer complexes, pentacene and DPPH, belonged to this group. In the second one, the resistivity of tetrathiotetracene decreased monotonously, even at a higher pressure range (Fig. 2-(c)). All of the materials examined in this experiment exhibited a sharp decrease in the band gap, as was observed from the temperature dependency of the resistivity, which is listed in Table I.

Discussion

In a previous work,[12] we assumed that the increment in electrical conductivity under the high pressure is contributed by electroncloud overlappings between molecules in the molecular lattice. The compressibility of a few of the organic molecular crystals has been observed as a function of the applied pressure.[2] Recently, Danno and Kajiwara have measured the Young modulus of a series of polycyclic aromatic compounds by means of a vibrating-reed method under atmospheric pressure; the value for triphenylene was 1.19×10^{10} dyne/cm^2; for 1, 2, 3, 4-dibenzanthracene, 2.81×10^{10} dyne/cm^2; for coronene, 1.10×10^{10} dyne/cm^2, and for the acridine-I_2 complex, 1.67×10^{11} dyne/cm^2.[13] From their results, we found that the average compressibility of these molecular crystals is one hundred times those of ordinary metals. The volume contraction of organic crystals by compression was expected to be anomalously large: the volumes at 1.6×10^5 kg./cm^2 for these molecular crystals were estimated to be 69% of those at atmospheric pressure.[2]

The decrease in the volume upon compression is caused by the contraction of the lattice distances of adjacent molecules. The contraction, however, is not isotropic, because almost all of the crystals examined in this experiment have monoclinic or triclinic crystal structures. It is not difficult to assume that the direction perpendicular to the molecular plane, the distances of which are listed in Table II, is more compressible than the other directions. Therefore, a great increase in the electron flow in that direction of the crystal may be expected under compression.

To simplify the theoretical treatment of the charge flow in the compressed crystal, we assumed that the contraction of the crystal was isotropic. When we applied these contractions to the treatment of the tight-binding approximation, and also assumed that the carrier-scattering can be described by the constant mean free time, $\tau(k)=\tau_0$, the mobility components were given by:

$$\mu_{ij}=e\tau_0\langle v_i v_j\rangle/kT$$

where v_i is the ith component of the carrier velocity, v, which is described by $v=(1/\hbar)\ \partial E(k)/\partial k$.[14] The $\langle v_i v_j\rangle$ quantity is a statistical average over the band. The average value of μ_{ij} in the three directions of the crystal was estimated to be 10^1—10^2 times larger than those at atmospheric pressure.[14],*

Therefore, the remarkable increase in electrical conductivity upon compression, $10^5\sim10^7$ times, must result from the increase in the number of charge carriers, n in $\sigma=ne\mu$; this increment is produced from an unexpected decrease in the band gap. A similar order of decrease in the band gap was also found for some inorganic semiconductors, as is mentioned in Table III.

* The anisotropic compression of some simple organic molecular crystals has been observed by Kabalkina (S. S. Kabalkina, *Fizika Tverdogo Tela.*, **4**, 3124 (1962)). When we applied this finding to the tight-binding approximation roughly, the increase of mobility was estimated to be around $5\times10^1-10^2$ times value for isotropic compression, $1\times10^1-10^2$ times.

TABLE II. THE INTERMOLECULAR DISTANCE (d) OF POLYCYCLIC AROMATIC COMPOUNDS

Compound	Crystal structure	d, Å
Benzene	Orthorhombic	3.6
Anthracene	Monoclinic	3.8
Tetracene	Triclinic	3.68
Pyrene	Monoclinic	3.53
Coronene	Monoclinic	3.4
Quaterrylene	Monoclinic	3.47
Graphite	Hexagonal	3.345

TABLE III. THE DECREASE IN THE ENERGY GAP FOR ORGANIC AND INORGANIC SEMICONDUCTORS

Compound	$(d\Delta\varepsilon/dp)_T$ (in 10^{-6} eV./bar)
Quaterrylene	2.75
Violanthrone A	3.6
Pentacene	8.5
Silicon	2.0[a]
AlSb	1.6[a]

TABLE IV. THE RED-SHIFT OF THE OPTICAL ABSORPTION PEAK FOR VARIOUS POLYCYCLIC AROMATIC COMPOUNDS

Compound	Absorption peak	Applied pressure	Shift per unit of pressure
	cm^{-1}	$\times 10^3$ kg./cm^2	$\times 10^{-6}$ eV./bar
Anthracene	25300	100	4.7
Tetracene	19200*	90	6.8
	19235*	5.2	13.4
	19810	5.2	9.4
Pentacene	15000	55	9.3
Coronene	26810	4.5	13
Perylene	21368	5.2	12.5
Cu-phthalocyanine	16420	55	0.75

* 19200 cm^{-1}, observed by Drickamer, is corresponded to 19235 cm^{-1} band found by the present authors.

On the other hand, we have already determined several characteristic points in the behaviour of the optical properties of aromatic compounds under high pressure; a remarkable increase in Davydov splitting in a tetracene crystal with an increase in the pressure,[15] a strong red-shift of the energy transfer luminescence spectra of the anthracene-tetracene mixed crystal, and a red-shift of the absorption spectra.[16] Table IV shows the red-shift of the absorption peak of aromatic compounds. Generally speaking, the value of the shift is comparable to the contractions of the band gaps; that is to say, both the anomalous changes, electrical and optical, may happen for same reasons.

In the case of a remarkable increase in Davydov splitting, the increase can be explained qualitatively by the following contribution: a decrease in lattice distances and also a rotation of molecules in the lattice points.[15] Under hydrostatic pressure, the crystal lattice may be diminished anisotropically; this is in contrast to the assumption adopted above. Furthermore, the contribution to the intermolecular force from dipole-quadrapole interaction and also quadrapole-quadrapole interaction between adjacent molecules must be considered.

In addition to these theoretical treatments, the accurate experimental values of compressibility in all crystal directions, and also those of electronic mobility under high pressure, which are now being examined, may be introduced as a reasonable explanation for the anomalous change in the electrical and optical properties of aromatic compounds.

The relation between pressure and resistivity above 1×10^5—2×10^5 kg./cm^2 for almost all samples was a leveling off; this parallels the leveling off of the compressibility of organic materials in the pressure range. The curve for tetrathiotetracene is an exceptional one, as is illustrated in Fig. 2-(c). Above 1×10^5 kg./cm^2, the electrical resistance still decreases monotonously.

In the second group, the resistance, after it has been leveling off, gradually increases with time. The change is assumed to be introduced by a chemical reaction between two components of the complexes or by a decomposition of the material itself. After compression, the decomposition of pentacene was confirmed by a detection of the electron spin resonance absorption signal. To the contrary of Drickamer's work, we could not find any "metallic" character of pentacene with a positive temperature coefficient.

The authors wish to thank Dr. Hiroshi Nagasaki for his kind assistance throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 391—395 (1966)

The Synthesis of Some Peptides Related to the Active Site of Enzymes[1]

By Tadao HAYAKAWA,[2] Kaoru HARADA and Sidney W. FOX

Institute of Molecular Evolution, University of Miami, Coral Gables, Florida, U. S. A.; Institute for Space Biosciences and Chemistry Department, The Florida State University, Tallahassee, Florida, U. S. A.

(Received May 10, 1965)

The sequences, α-aspartyl-L-serylglycine and α-glutamyl-L-serylglycine, appear in the "active site" of many esteratic enzymes. The free tripeptides were synthesized in this study. In order to avoid difficulties encountered in more conventional synthetic routes, *N*-carbobenzoxy-L-aspartyl (β-benzyl ester)-*O*-benzyl-L-serylglycine dibenzyl ester and *N*-carbobenzoxy-L-glutamyl (γ-benzyl ester)-*O*-benzyl-L-serylglycine dibenzyl ester were synthesized. These protected peptides were converted to the free tripeptides upon hydrogenolysis, which removed all of the four protecting groups simultaneously. Several derivatives of these tripeptides were also synthesized.

The α-aspartyl-L-serylglycine sequence has been found in many esteratic enzymes in the so-called "active site."[3] The synthesis of this free tripeptide[4] is accordingly of interest for the preparation of derivatives including other peptides of defined constitution, as a standard reference substance in tests of catalytic activity with derivatives, and for investigation as a co-monomer in copolymerizations. For the latter objective, in particular, combination with histidine residues in the same macromolecule would be of interest.

The difficulties of preparation of the free tripeptide posed special requirements. One of these was protection of the unstable seryl residue during the syntheses. Another problem was avoidance of saponification of the ester of β-benzyl *N*-carbobenzoxy-L-aspartate, an intermediate in some projected syntheses. Bernhard et al.[5] found that the saponification of β-benzyl *N*-carbobenzoxy-L-aspartyl residues involved the formation of an imide intermediate. The most rapid reaction, both in the formation of the imide intermediate and its subsequent hydrolysis, was observed with *N*-carbobenzoxyaspartyl (β-benzyl ester)-serinamide. The hydroxyl group of the serine residue was found to be required for the most rapid hydrolysis of this benzyl ester. Bernhard et al. also isolated the intermediate imide compound. These findings suggested that alkaline conditions should be avoided during the synthesis and that protection of the hydroxyl group of the serine residue is desirable.

Attempts in this laboratory to saponify selectively the ethyl ester of *N*-carbobenzoxy-L-aspartyl (β-benzylester)-*O*-benzyl-L-serylglycine were unsuccessful. Hydrogenolysis of the saponified product resulted in hygroscopic peptides composed of aspartic acid, serine, and glycine. These were presumably mixtures of α- and β-aspartyl peptides which could result from saponification of an intermediate imide.

The ethyl esters of glycyl-α-L-aspartyl-L-serylglycine[7] and of L-aspartyl-*O*-acetyl-L-serylglycine[7] have been reported. However, saponification of the ethyl esters and of the *O*-acetate also is difficult to control.

In order to avoid all of the difficulties mentioned, *N*-carbobenzoxy-L-aspartyl-*O*-benzyl-L-serylglycine dibenzyl ester was synthesized because the four protecting groups would presumably be removable by hydrogenolysis, and alkaline treatments during synthetic steps would thus be avoided. A test of this hypothesis showed that the free tripeptide could indeed be prepared in this way. The α-L-glutamyl-L-serylglycine was then similarly prepared. This sequence has also been found in the active site of esteratic enzymes.[3]

Recently, the synthesis of an octapeptide corresponding to a sequence containing the active site of chymotrypsin has been reported.[8]

Experimental

β-Benzyl L-Aspartate.—β-Benzyl L-aspartate was prepared by the sulfuric acid method.[9] m. p. 221°C,

B: Benzyl F: Formyl Z: Carbobenzoxy Et: Ethyl

$[\alpha]_D^{26}$ +24.2° (*c* 1.18, 1 N HCl).

γ-Benzyl L-Glutamate.—γ-Benzyl L-glutamate was also prepared by the sulfuric acid method.[9] m. p. 174°C, $[\alpha]_D^{26}$ +21.8° (*c* 1.87, AcOH).

***O*-Benzyl-L-serine.**—*O*-Benzyl-L-serine was prepared from methyl acrylate by Okawa's method,[10] The *O*-benzyl-DL-serine was acetylated and the resulting *N*-acetyl *O*-benzyl-DL-serine was resolved by Takaacylase, m. p. 219—221°C (decomp.), $[\alpha]_D^{26}$ +5.0° (*c* 1.00, 3 N HCl).

β-Benzyl *N*-Carbobenzoxy-L-aspartate (VII).—β-Benzyl *N*-carbobenzoxy-L-aspartate was prepared by the usual Schotten-Bauman reaction.[11] m. p. 105—106°C, $[\alpha]_D^{27}$ +12.0° (*c* 1.50, AcOH).

γ-Benzyl *N*-Carbobenzoxy-L-glutamate (VIII).—γ-Benzyl *N*-carbobenzoxy-L-glutamate was prepared as described by Hanby et al.[12] m. p. 75—76°C, $[\alpha]_D^{27}$ −22.7° (*c* 1.41, N $KHCO_3$).

β-Benzyl *N*-Formyl-L-aspartate (X).—β-Benzyl L-aspartate, 31.3 g. (0.13 mol.), was dissolved in 200 ml. of 98% formic acid. To this was added dropwise 78 ml. of acetic anhydride at 5—10°C under agitation during a period of 1 hr. After addition was complete, the mixture was stirred for 2 hr. at room temperature. The solution was evaporated to dryness under reduced pressure at 50°C in a water bath. The residue was dried in a vacuum desiccator overnight over sodium hydroxide. The dried residue was dissolved in 150 ml. of acetone and filtered to remove the insoluble material (1.05 g., m. p. 155—160°C). Petroleum ether was added to the acetone solution to crystallize the β-benzyl *N*-formyl-L-aspartate, 28.2 g. (81%), m. p. 122—125°C. This product was recrystallized from acetone and petroleum ether, m. p. 123—125°C, $[\alpha]_D^{25}$ +28.6° (*c* 1.75, ethanol).

Found: N, 5.61. Calcd. for $C_{12}H_{13}O_5N$: N, 5.58%. COOH titration,[13] Found: M=248, Calcd: M=251.2.

γ-Benzyl *N*-Formyl-L-glutamate (XI).—γ-Benzyl *N*-formyl-L-glutamate was synthesized in a way similar to that described above. m. p. 130—131°C, $[\alpha]_D^{25}$ +17.9° (*c* 1.98, ethanol).

Found: N, 5.32. Calcd. for $C_{13}H_{15}O_5N$: N, 5.28%. COOH titration: Found, M=264; Calcd. M=265.3.

***N*-Formyl-*O*-benzyl-L-serine (II).** — *N*-Formyl-*O*-benzyl-L-serine was prepared from *O*-benzyl-L-serine by use of a method similar to that described above. Yield, 78%, m. p. 123—128°C. This was recrystallized from ethyl acetate and petroleum ether, m. p. 129—130°C, $[\alpha]_D^{25}$ +54.8 (*c* 2.75, ethanol).

Found: N, 6.23. Calcd. for $C_{11}H_{13}O_4N$: N, 6.28%. COOH titration, Found: M=223; Calcd. M=223.2.

***N*-Formyl-*O*-benzyl-L-serylglycine Ethyl Ester (IVa).**—*N*-Formyl-*O*-benzyl-L-serine, 6.00 g., was dissolved in 60 ml. of tetrahydrofuran. To this was

13) The carboxyl group was titrated with methanolic sodium methoxide in dimethylformamide or in dioxane by use of thymol blue as the indicator. Elemental Analyses were carried out by Micro-Tech Laboratories, INC., Skokie, Illinois, U. S. A.

added 2.77 g. of freshly distilled glycine ethyl ester (IIIa). To this solution, 5.90 g. of dicyclohexylcarbodiimide (DCCD) in 15 ml. of tetrahydrofuran was added dropwise under cooling with ice water. After 30 min. of cooling, the mixture was allowed to attain room temperature. Precipitated dicyclohexylurea was filtered after 24 hr. of standing, and the filtrate was evaporated under reduced pressure at 40°C. The residue was dissolved in ethyl acetate and filtered to remove dicyclohexylurea. The solvent was evaporated to 25 ml. and petroleum ether was added slowly to precipitate *N*-formyl-*O*-benzyl-L-serylglycine ethyl ester. The mixture was kept in the ice box for 3 hr., then filtered to collect the *N*-acyldipeptide ester, 6.2 g. (75%). This was recrystallized from 10 ml. of ethyl acetate, 15 ml. of ether and 35 ml. of petroleum ether, 5.0 g., m. p. 63—64°C, $[\alpha]_D^{25}$ +4.1° (*c* 2.48, ethanol).

Found: C, 58.44; H, 6.60; N, 9.03. Calcd. for $C_{13}H_{20}O_5N$: C, 58.44; H, 6.55; N, 9.09%.

O-Benzyl-L-serylglycine Ethyl Ester Hydrochloride (Va).—*N*-Formyl-*O*-benzyl-L-serylglycine ethyl ester (IVa), 4.62 g., was dissolved in 18.8 ml. of methanol. To this was added 16.5 ml. of 1 N hydrochloric acid in methanol under cooling (2 ml. of concentrated hydrochloric acid was diluted to 24 ml. with methanol). The solution was allowed to stand at room temperature for 48 hr. The solvent was evaporated under reduced pressure, and the residual syrup was dissolved in 20 ml. of water. The insoluble material was filtered and the filtrate was twice extracted with ether. The aqueous solution was then lyophilized. A slightly yellowish vitreous dipeptide ester hydrochloride was obtained; 4.68 g. (98%). This peptide ester hydrochloride was used for subsequent syntheses without further purification.

N-Carbobenzoxy-L-aspartyl (β-benzyl ester)-O-benzyl-L-serylglycine Ethyl Ester (XIIa).—*O*-Benzyl-L-serylglycine ethyl ester hydrochloride (Va), 14.05 g., was dissolved in 150 ml. of dry dioxane. To this solution, 4.80 g. of triethylamine was added under cooling. The resultant triethylamine hydrochloride was filtered. In this filtrate, 15.85 g. of β-benzyl *N*-carbobenzoxy-L-aspartate was dissolved. To the mixture, a solution of 9.17 g. of DCCD in 50 ml. of dioxane was added slowly under cooling. After 5 min., dicyclohexylurea began to precipitate. The reaction mixture was allowed to stand overnight. Precipitated urea was filtered out and the filtrate was evaporated at 40—45°C under diminished pressure. The residual syrup was dissolved in 180 ml. of ethyl acetate at 45°C and filtered. The filtrate was washed twice with each of the following: 0.3 N hydrochloric acid, 5% sodium hydrogen carbonate, and water. The washed solution was dried over anhydrous sodium sulfate. The ethyl acetate was evaporated to about 80 ml. and then petroleum ether was added solwly to precipitate the protected tripeptide ester. The mixture was kept in the refrigerator overnight. The crystals were filtered and washed with ether and dried; 19.80 g., m. p. 117—120°C. From the mother liquor an additional 1.50 g. of crystals was obtained; yield 78%. This was recrystallized from ethyl acetate, acetone, and petroleum ether; m. p. 121—124°C, $[\alpha]_D^{25}$ −5.6° (*c* 1.51, ethanol).

Found: C, 64.05; H, 6.10; N, 6.79. Calcd. for $C_{37}H_{37}O_9N$: C, 63.96; H, 6.02; N, 6.78%.

N-Carbobenzoxy-L-glutamyl (γ-benzyl ester)-O-benzyl-L-serylglycine Ethyl Ester (XIIIa).—The protected tripeptide ester (XIIIa) was prepared in a way similar to that described above. After washing the ethyl acetate solution with 0.3 N hydrochloric acid, a yield of 10.1 g. (74%) of XIIIa was obtained. This was recrystallized by dissolving in acetone - ethyl acetate mixture and by precipitating with petroleum ether. By this recrystallization procedure, two fractions of different melting points were isolated. One (A), (0.21 g.), has a m. p. 133—134°C and the other (B), (5.10 g.), melted at 147—148°C. The compound A melted at 133—134°C, then solidified, and the solid remelted at 146—147°C. Accordingly, compound A is probably converted to compound B by heating. Elemental analyses of compound A and B each agree with the theoretical value.

Compound A, Found: C, 64.59; H, 6.27; N, 6.81.
Compound B, Found: C, 64.83; H, 6.06; N, 6.68.
Calcd. for $C_{34}H_{39}O_9N_3$: C, 64.54; H, 6.31; N, 6.63%.

N-Formyl-L-aspartyl (β-benzyl ester)-O-benzyl-L-serylglycine Ethyl Ester (XV).—A solution of 23 g. of *O*-benzyl-L-serylglycine ethyl ester hydrochloride (Va) in 200 ml. of dioxane was treated with 11.0 ml. of triethylamine. The free dipeptide ester (VIa) was condensed with 19.1 g. of β-benzyl *N*-formyl-L-aspartate (X) by use of 16.6 g. of DCCD. A yield of 33.0 g. (89%) of protected tripeptide ester (XV) was obtained, m. p. 83—86°C. This was recrystallized from ethyl acetate; m. p. 91—93°C, $[\alpha]_D^{25}$ −5.8° (*c* 1.67, AcOH).

Found: C, 61.52; H, 6.48; N, 7.90. Calcd. for $C_{27}H_{33}O_8N_3$: C, 61.47; H, 6.30; N, 7.97%.

L-Aspartyl (β-benzyl ester)-O-benzyl-L-serylglycine Ethyl Ester Hydrochloride (XVII).—β-Benzyl ester of *N*-formyl-L-aspartyl-L-serylglycine ethyl ester (XV), 16.0 g., was dissolved in 60 ml. of absolute ethanol. To this solution, 40 ml. of 1 N ethanolic hydrogen chloride was added. The mixture was allowed to stand at room temperature for three days. The solvent was evaporated under reduced pressure and the residue was dissolved in 30 ml. of water. The insoluble material was filtered off and the filtrate was extracted with ethyl acetate to remove the unreacted *N*-formyl derivative. The aqueous solution was lyophilized; yield, 3.60 g. (22%).

N-Carbobenzoxy-glycyl-L-aspartyl (β-benzyl ester)-O-benzyl-L-serylglycine Ethyl Ester (XX).—A solution of 2.1 g. of carbobenzoxyglycine (XIX) in 15 ml. of dioxane was added to 50 ml. of acetonitrile solution of L-aspartyl (β-benzyl ester)-*O*-benzyl-L-serylglycine ethyl ester (XVIII) which was prepared from 5.3 g. of L-aspartyl (β-benzyl ester)-*O*-benzyl-L-serylglycine ethyl ester hydrochloride (XVII) and an equimolar amount of triethylamine. The two compounds were condensed by 2.1 g. of DCCD under stirring and cooling. After standing overnight the reaction mixture was treated in the same way as described above. The protected tetrapeptide, 4.0g. (60%), was obtained from ethyl acetate solution by addition of ether, m. p. 68—73°C. This was recrystallized twice from ethyl acetate and ether, m. p. 85—89°C, $[\alpha]_D^{25}$ −13.0° (*c* 2.17, dioxane).

Found: C, 61.55; H, 6.11; N, 8.35. Calcd. for $C_{35}H_{40}O_4N_4$: C, 62.12; H, 5.96; N, 8.28%.

α-Benzyl N-Carbobenzoxy-L-aspartate (IX).—

This compound was prepared by the method of Bergmann et al.[14] The crude product (m. p. 71—78°C) was recrystallized repeatedly from ethyl acetate by petroleum ether. The material which melted at 82—85°C was used for further synthesis, $[\alpha]_D^{25}$ −15.3° (*c* 1.60, ethanol).

Found: N, 3.95. Calcd. for $C_{19}H_{19}O_6N$: N, 3.93%. COOH titration, Found: M=358; Calcd.: M=357.5.

***N*-Carbobenzoxy-L-aspartyl (*α*-benzyl ester)-*O*-benzyl-L-serylglycine Ethyl Ester (XIV).**—Compound Va, 4.00 g., in 30 ml. of tetrahydrofuran, was treated with 1.28 g. of triethylamine. The precipitated amine salt was removed by filtration. To the filtrate, 4.50 g. of *α*-benzyl *N*-carbobenzoxy-L-aspartate (IX) was dissolved. DCCD (2.88 g.), in 10 ml. of tetrahydrofuran, was added slowly to the above mixture while stirring and cooling. The reaction mixture was treated in the same way as described earlier. The product obtained weighed 6.0 g. (77%). This was recrystallized from ethyl acetate (45 ml.) and petroleum ether (40 ml.). Yield, 4.1 g., m. p. 134—136°C (sintering at 128°C).

Found: C, 64.05; H, 6.10; N, 6.76. Calcd. for $C_{33}H_{37}O_9N_3$: C, 63.96; H, 6.02; N, 6.78%.

Glycine Benzyl Ester (IIIb).—The *p*-toluensulfonate of glycine ester was prepared by the method of Zervas, et al.[15] Yield, 80—90%, m. p. 130—132°C. Free glycine benzyl ester was prepared by treating with an excess of anhydrous potassium carbonate and ether while cooling and stirring. The resulting free ester was used for further synthesis without purification.

***N*-Formyl-*O*-benzyl-L-serylglycine Benzyl Ester (IVb).**—To the mixture consisting of 11.2 g. of *N*-formyl-*O*-benzyl-L-serine, 9.1 g. of glycine benzyl ester in 50 ml. of dioxane, 11.0 g. of DCCD in 20 ml. of dioxane was added under cooling. The mixture was allowed to stand overnight. The reaction mixture was treated in the same way as was described earlier. The resultant dipeptide benzyl ester was dissolved in ethyl acetate and precipitated with ether, yield, 15.0 g. (81%), m. p. 89—90°C. The precipitate was further purified by treating it twice with ethyl acetate and ether, 13.0 g., m. p. 91—92°C, $[\alpha]_D^{25}$ +2.2° (*c* 2.43, AcOH), $[\alpha]_D^{25}$ +0.26° (*c* 3.0, ethanol).

Found: C, 65.02; H, 5.92; N, 7.53. Calcd. for $C_{20}H_{22}O_5N_2$: C, 64.85; H, 5.97; N, 7.56%.

***O*-Benyzl-L-serylglycine Benzyl Ester Hydrochloride (Vb).** — *N*-Formyl-*O*-benzyl-L-serylglycine benzyl ester (IVb), 2.0 g., was dissolved in 6.4 ml. of dioxane and 6 ml. of 1 N ethanolic hydrochloric acid. This solution was allowed to stand at room temperature for 3 days. The reaction mixture was evaporated under reduced pressure at 40°C. The resudue was dissolved in water and the insoluble material was filtered off; the filtrate was extracted with ethyl acetate. The aqueous solution was lyophilized. Yield, 1.40 g. (69%). $[\alpha]_D^{27}$ +8.3° (*c* 6.3, water).

***N*-Carbobenzoxy-L-aspartyl-*O*-benzyl-L-serylglycine Dibenzyl Ester (XIIb).**—*β*-Benzyl *N*-carbobenzoxy-L-aspartate (VII), 6.0 g., was mixed with *O*-benzyl-L-serylglycine benzyl ester (VIb) in 60 ml. of dioxane which was prepared from 7.3 g. of its hydrochloride (Vb) and 2.7 ml. of triethylamine. To this mixture, 4.0 g. of DCCD in 10 ml. of dioxane was added under cooling and stirring. The mixture was allowed to stand overnight at room temperature. The reaction mixture was processed in the usual manner. The protected tripeptide ester was crystallized from ethyl acetate and ether. The crystals were washed with petroleum ether and dried, yield, 5.3 g., (41%), m. p. 119—125°C. This was recrystallized from ethyl acetate and ether, m. p. 129—131°C, $[\alpha]_D^{25}$ −4.7° (*c* 1.43, dioxane).

Found: C, 67.41; H, 5.99; N, 6.25. Calcd. for $C_{38}H_{39}O_9N_3$: C, 66.95; H, 5.77; N, 6.16%.

***α*-Aspartyl-L-serylglycine (XXI).** — *N*-Carbobenzoxy-*α*-L-aspartyl-*O*-benzyl-L-serylglycine dibenzyl ester (XIIb), 1.36 g., was dissolved in 60 ml. of methanol and 5 ml. of 0.4 N hydrochloric acid. This solution was mixed with 3.5 g. of 5% palladium on charcoal. Hydrogenolysis of the mixture was carried out at room temperature for 5 hr. After the reaction was completed, the catalyst was filtered and the filtrate was concentrated to dryness under reduced pressure. The residue was dissolved in a small amount of water and filtered. The filtrate was lyophilized. A yield of 550 mg. of material was obtained. The tripeptide hydrochloride was dissolved in absolute alcohol and the insoluble part was filtered off. To the filtrate was added 0.03 ml. of pyridine and the solution was kept in the refrigerator overnight. The precipitated free tripeptide was collected by centrifugation and washed with absolute alcohol and ether and dried. This was recrystallized by dissolving in water and precipitating with absolute ethanol; yield, 250 mg. (45%). The crystals are not hygroscopic. m. p. 174—176°C (decomp.), $[\alpha]_D^{25}$ −7.3° (*c* 1.54, water).

Found: C, 38.93; H, 5.45; N, 15.16. Calcd. for $C_9H_{15}O_7N_3$: C, 38.99; H, 5.45; N, 15.16%.

By paper chromatography in 80% phenol, the peptide showed an R_f=0.17. Amino acid composition analyzed by the Phoenix K 5000 amino acid analyzer showed 97 aspartic acid: 98 serine: 100 glycine.

***N*-Carbobenzoxy-L-glutamyl-*O*-benzyl-L-serylglycine Dibenzyl Ester (XIIIb).**—*O*-Benzyl-L-serylglycine benzyl ester hydrochloride (Vb), 2.36 g. in 20 ml. of dioxane, was treated with 0.66 g. of triethylamine. Precipitated amine hydrochloride was removed by filtration. To the filtrate, 2.50 g. of *γ*-benzyl *N*-carbobenzoxy-L-glutamate (VIII) and 1.45 g. of DCCD in 5 ml. of dioxane were added. The reaction mixture was kept at room temperature overnight. This was treated in the way described earlier. The protected tripeptide ester was crystallized from ethyl acetate and ether, 2.45 g., m. p. 108—111°C. This solid was recrystallized from ethyl acetate, m. p. 109—112°C, $[\alpha]_D^{25}$ −1.83° (*c* 1.81, dioxane).

Found: C, 67.31; H, 5.97; Calcd. for $C_{39}H_{41}O_9N_3$: C, 67.32; H, 5.94%.

***α*-L-Glutamyl-L-seryl-glycine (XXII).**—*N*-Carbobenzoxy-L-glutamyl-*O*-benzyl-L-serylglycine dibenzyl ester (XIIIb), 1.35 g., was dissolved in a mixture of 60 ml. of methanol, 30 ml. of ethanol, 2.15 ml. of 1 N hydrochloric acid, and 3 ml. of water. To this mixture, 3.0 g. of 5% palladium on charcoal was added. Hydrogenolysis was carried out at room temperature for 10 hr. After the reaction was completed, the catalyst

was removed by filtration and the filtrate was evaporated to dryness under reduced pressure at 40°C. The residue was dissolved in a small amount of water. The insoluble material was filtered and the filtrate was lyophilized. The dried residue (tripeptide hydrochloride) was dissolved in 15 ml. of ethanol and 1.4 millimole of pyridine was added slowly. The tripeptide crystallized at once. The crystals were collected by centrifugation, and were washed with ether and dried, yield, 0.25 g. (44%). This solid was recrystallized by dissolving in 2.5 ml. of water and precipitating by 15 ml. of absolute ethanol. Tripeptide, 202 mg., was obtained, m. p. 191—192°C (decomp.), $[\alpha]_D^{27}$ +8.62° (*c* 1.24, water).

Found: C, 41.23; H, 5.93; N, 14.18. Calcd. for $C_{10}H_{17}N_3O_7$: C, 41.23; H, 5.88; N, 14.43%.

The tripeptide is not hygroscopic. By paper chromatography in 80% phenol, the peptide showed an R_f=0.35. The amino acid composition analyzed showed 100 glutamic acid: 98 serine: 99 glycine.

Summary

Syntheses of the free tripeptides found in the active site of various enzymes,[3] α-L-aspartyl-L-serylglycine and α-L-glutamyl-L-serylglycine, are described. Difficulties in the synthesis included the rapid saponification of β-benzyl *N*-carbobenzoxy-L-aspartyl residues.[5] Also, although many protected tri- and tetra-peptide esters were synthesized, attempts to obtain pure products by saponification were unsuccessful.

The synthesis was accomplished by using intermediates protected only with groups that could be simultaneously removed by hydrogenolysis. The intermediates thus employed were the *N*-carbobenzoxy-α-L-aspartyl-*O*-benzyl-L-serylglycine dibenzyl ester (XIIb) and the α-L-glutamyl analog (XIIIb). The syntheses of these two intermediates are also described.

NOTES

Complexing Behavior of Kojic Acid with Metal Ions. III. Infrared Studies of Bivalent Metal-Kojate Chelates*

By Yukito MURAKAMI and Katsumi MERA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Fukuoka

(Received April 19, 1965)

In previous studies, the interaction of bivalent magnesium, manganese and tervalent iron ions with kojic acid in aqueous media has been investigated and the corresponding stability constants evaluated.[1,2] However, the majority of the bivalent first-transition metals do not yield the corresponding soluble kojate chelates in aqueous solutions. Therefore, most of the potentiometric studies aiming to obtain chelate stability constants have been carried out in dioxane-water media.[3,4] The stability of these kojate chelates with respect to the bivalent metals has been found to follow the sequence:

$$Cu(II) > Zn(II) > Ni(II) \sim Mn(II) \sim Co(II)$$

It is interesting to note that a zinc ion forms a much more stable chelate than do nickel, cobalt and manganese ions in the kojate chelate system. In addition, the comparable stability of the manganese chelates with the corresponding nickel and cobalt chelates is rather unexpected.

In order to investigate the structural change in the ligand molecule brought about through its coordination to the metal ions and the correlation of the structural change with the stability sequence, infrared spectral measurements of the kojate chelates of copper(II), zinc(II), nickel(II) and cobalt(II) have been performed in the present study. The absorption peaks of interest for these metal chelates are listed in Table I for the sake of comparison. The absorption spectra obtained for the zinc, nickel and cobalt chelates were almost identical with each other, and slightly different from that for the copper chelate. The most significant difference among these two types of metal chelates (zinc, nickel, cobalt; copper) is the OH-stretching vibration appeared in the region ranging 3200—2400 cm^{-1}. Another difference is observed in the range between 905 and 850 cm^{-1}, where the copper chelate gives three

TABLE I. SIGNIFICANT PEAKS IN THE INFRARED SPECTRA OF SOME METAL-KOJATE CHELATES

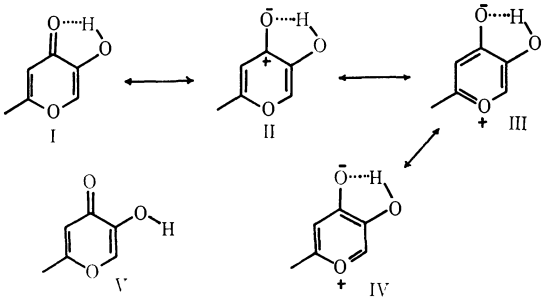
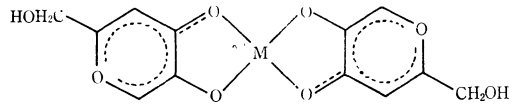
absorption peaks while the other chelates give only one significant peak. In view of the spectral shift of the OH vibrations for the metal chelates from that of the ligand alone, it seems that the stronger hydrogen bonding is secured through metal coordination. In addition, the zinc, nickel and cobalt chelates seem to contain some sorts of hydrogen bonding stronger than that in the corresponding copper chelate, since the former chelate species demonstrated several absorption peaks in the range between 2800 and 2400 cm^{-1}, where the latter chelate does not show any significant peak. Moreover, the nearly-identical spectral behavior among the zinc, nickel and cobalt chelates seems to suggest that these chelates possess coordinate bonds of nearly identical characters.

The following four resonance structures (I—IV) may be drawn for kojic acid:



The absorption bands which appear at 1710 and 1668 cm^{-1} are most likely due to the non-hydrogen-bonded (cf. structure V) and to the hydrogen-bonded carbonyl vibrational modes (cf. structures I—IV) respectively. When kojic acid



VI

forms a complex with a metal ion (as is illustrated by structure VI), the former mode disappears and the latter shifts to lower frequencies. The other significant bands, appearing at 1640, 1621 and 1591 cm^{-1} in the free kojic acid, are assigned to the C=C stretching modes. These bands also were observed to shift to lower frequencies through the formation of metal coordinate bonds. These shifts of C=O and C=C bands to lower frequencies seem to indicate that the contribution of resonance structures of the II, III and IV types, in which a hydrogen atom is replaced by a metal ion, becomes greater as metal coordinate bonds are formed. The resonance interaction involving structures II, III and IV tends to delocalize olefinic and carbonyl π-electrons over both γ-pyron and chelate rings, thus decreasing the double-bond character of olefinic and carbonyl bonds.

The infrared spectral data do not provide any significant correlation with the stability sequence among these bivalent metal kojate chelates. Thus, some further studies are needed to clarify the problems of the stability order.

Experimental

The kojic acid used was a product of the Nutritional Biochemical Corporation, U. S. A., and was purified by sublimation in vacuo: m. p. 156—156.6°C. All the kojate complexes used in this work were prepared by standard methods described in the literature. The analyses are listed in Table II.

Table II. Analyses of metal-kojate chelates

Chelate	Carbon,* %	Hydrogen,* %
$Cu(C_6H_5O_4)_2$	41.19 (41.68)	3.23 (2.92)
$Zn(C_6H_5O_4)_2$	41.04 (41.46)	3.20 (2.90)
$Ni(C_6H_5O_4)_2$	41.08 (42.28)	3.23 (2.96)
$Co(C_6H_5O_4)_2$	41.89 (42.25)	3.03 (2.95)

* Calculated values for the specified formula are given in parentheses.

The infrared spectra of the kojate chelates were measured by the Nujol mull method with a Koken Model DS-301 Spectrophotometer equipped with sodium chloride optics.

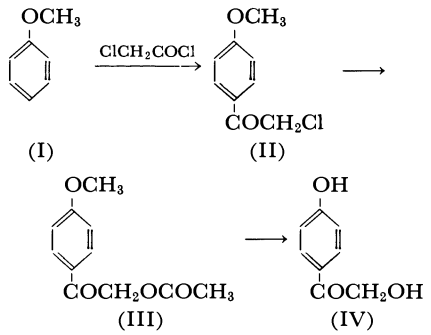
A Modified Method of Preparing of ω, p-Dihydroxyacetophenone

By J. S. CHADHA* and G. K. SHARMA**

Department of Chemistry, Delhi University, Delhi-7, India

(Received May 31, 1965)

The earlier method for the preparation of ω, p-dihydroxyacetophenone (IV)[1,2] needed an improvement because of difficulties encountered in the isolation of the key intermediate, ω-chloro-p-hydroxyacetophenone,[1,3] which in its crude form is extremely lachrymatory. In the present investigation, a modified procedure has been employed to eliminate the use of ω-chloro-p-hydroxyacetophenone.



Chloroacetyl chloride and anisole (I) are condensed in cold in the presence of aluminium chloride[4] to give ω-chloro-p-methoxyacetophenone (II). This compound II, on treatment with anhydrous potassium acetate in absolute ethanol, yields ω-acetoxy-p-methoxyacetophenone[5] (III). This III is then demethylated with aluminium chloride. In the last reaction, deacetylation takes place simultaneously, and thus the final product, ω, p-dihydroxyacetophenone (IV), is directly obtained.

Experimental

ω, p-Dihydroxyacetophenone (IV, obtained by the demethylation and deacetylation of III): ω-Acetoxy-p-methoxyacetophenone (1.30 g.) was dissolved in dry benzene (30 ml.), and anhydrous aluminium chloride (4.0 g.) was added to the solution. The reaction mixture was refluxed for 3 hr., and the solvent removed under reduced pressure. The residual mass was hydrolysed with ice and hydrochloric acid to give a solid, which was extracted with ethyl acetate. The ethyl acetate solution was evaporated and the residual mass crystallised from hot water to yield colourless prisms of the final product, ω, p-dihydroxyacetophenone (0.76 g., 80%); m. p. 177—178°C (sinters at 170°C). (Found: C, 63.2; H, 5.2. Calcd. for $C_8H_8O_3$: C, 63.2; H, 5.2%).

The authors are thankful to Dr. Miss Krishna K. Vashistha, Department of Chemistry, Delhi University, Delhi-7, India, for her valuable help and constant encouragement during this work.

A Study of the Hydration of Calcium Orthoplumbate. IV. The Behavior of Dehydration

By Masumi KOISHI and Kenjiro MEGURO

Department of Applied Chemistry, Faculty of Science, Tokyo College of Science, Kagurazaka, Shinjuku-ku, Tokyo

(Received June 15, 1965)

In the previous papers[1] it was demonstrated that Kissinger's method[2] of differential thermal analysis could be used to analyze the reaction kinetics of the dehydration of calcium orthoplumbate hydrates. That is, the reaction order and the activation energy of dehydration were determined, and the information thus obtained was used to analyze the behavior of the dehydration.

In the present paper, the authors will attempt to confirm the previous conclusion by thermogravimetric analysis. The reaction order and the activation energy of the dehydration will also be examined by Freeman's method[3] of thermogravimetric analysis.

The results of present experiments will support the conclusions of the previous papers.

Experimental Procedure

Material.—*Calcium Orthoplumbate Hydrate-Calcium Hydroxide Mixtures.*—The mixture used in this experiment was prepared by hydrating calcium orthoplumbate. The process of hydration was carried out with the apparatus and procedure previously described.[1] Hydrated mixtures were identified by X-ray diffraction patterns, differential thermal and thermogravimetric curves, and chemical analysis.

Calcium Orthoplumbate Hydrate.—Franke's method[4] was used to remove calcium hydroxide from hydrated mixtures, as has been described before.[1]

The samples employed for thermal analysis are the same as those used in the previous work.

Apparatus and Procedure.—The DTA-TGA unit (Automatic Differential Thermobalance, made by the Rigaku Denki Company, Tokyo), designed for simultaneous differential thermal and thermogravimetric analyses, was used in this work. Specimen holders made of platinum and beryllium oxide were employed. A platinum-rhodium thermocouple was used. The reference material was α-alumina. Each of the eight samples was run in analysis at the rate of 2.5 and 10°C per min. in order to determine the activation energy and the reaction order. The samples were ground enongh to pass them through a 250-mesh sieve. Specimen holders were filled loosely with 400—600 mg. of the sample. The differential temperature variation and the weight change as a function of the time and the temperature were recorded continuously.

Results and Discussion

The continuous tracings of the weight change accompanying the heat treatment of calcium orthoplumbate hydrate and calcium orthoplumbate hydrate - calcium hydroxide mixtures are given in Figs. 1 and 2 respectively. A typical comparison of simultaneously-recorded curves of thermogravimetric and differential thermal analyses is then given in Fig. 3.

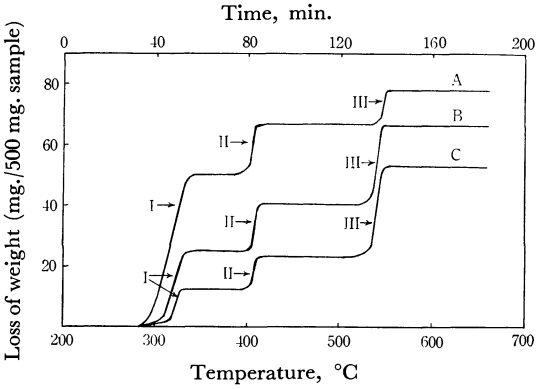

Fig. 1. Thermogravimetric analysis curves for calcium orthoplumbate hydrate - calcium hydroxide mixtures.

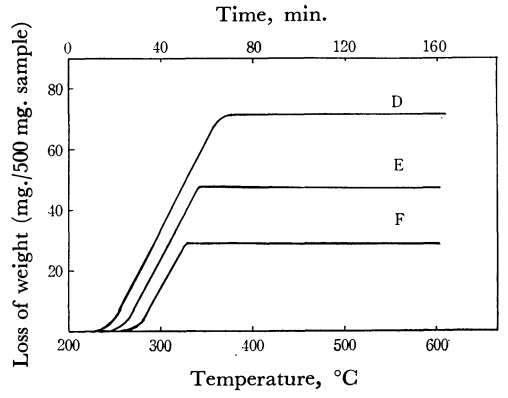

Fig. 2. Thermogravimetric analysis curves for calcium orthoplumbate hydrate.

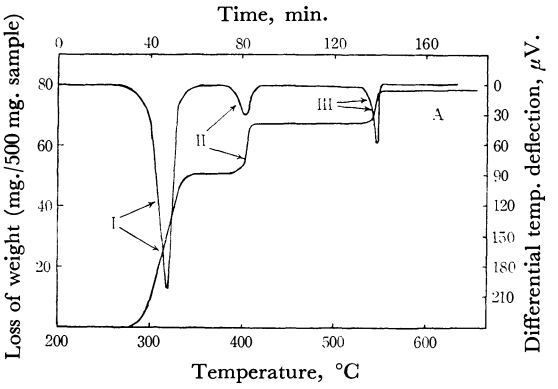

Fig. 3. Comparison of simultaneously recorded thermogravimetric and differential thermal curves.

It is apparent from Figs. 1 and 2 that the dehydration of samples D, E and F proceeds in one stage, while that of samples A, B and C, proceeds in three stages. Stages I and II in Fig. 1 show the first and second stage of the dehydration respectively; Stage III shows the decomposition of calcium hydroxide.

When the thermogravimetric analysis data of Figs. 1 and 2 were plotted according to Freeman's method, straight lines were obtained for each cases, thus enabling us to calculate the activation energy. The results of the thermogravimetric studies in the present work are compared with the values obtained by Kissinger's method based on differential thermal analysis, in Table I.

The value of the reaction order of magnesium hydroxide (1.00) reported in this paper (Table I) differs from those reported by Kissinger and by Gregg and Razouk[2] (0.67), but the agreement with the differential thermal analysis value (0.99) is good. The activation energy (25.0 kcal. per mol.) differs slightly from their values (27.2—31.4 kcal. per mol.) in order of magnitude. This discrepancy may be attributed to the difference in the particle size and in the mineral origin of the samples.

The values of the reaction order derived from the thermogravimetric analysis are nearly equal to unity in the cases of samples A, B and C. While the activation energies of the first dehydration were found to be 20.1, 21.0 and 20.1 kcal. per mol., those of the second dehydration were from 41.0 to 45.7 kcal. per mol. The activation energies for samples D, E and F were found to 11.8, 12.6 and 12.6 kcal. per mol. while their reaction orders were nearly equal to unity.

Table I. Comparison of results with thermogravimetric and differential thermal analysis methods

Material		x TGA	x DTA	E, kcal./mol. TGA	E, kcal./mol. DTA
A	I*1	1.10	1.08	20.1	18.2
	II*2	0.90	—	41.0	—
	III*3	0.70	0.66	32.8	33.0
B	I	1.10	1.10	21.0	18.0
	II	0.90	0.92	43.8	41.0
	III	0.70	0.66	32.8	33.0

H		1.00	0.99	25.0	25.0
I	a)	0.55 to	0.44	31.4	
	b)	0.69		27.2	

*1 First dehydration step.
*2 Second dehydration step.
*3 Dehydration of liberated calcium hydroxide.
a) Kissinger's data[2] by DTA method for Brucite.
b) Kissinger's data[2] by isothermal weight-loss measurements for Brucite.

As was concluded in the previous paper, the difference in activation energy between the first and second dehydration processes indicates that the dehydration is influenced by the inhibitive action of the calcium hydroxide liberated; that is, the elevation of the activation energy of the second dehydration seems to result from the fact that small particles of calcium hydroxide liberated in hydrate mixtures are firmly bonded to the hydrate.

The results of the thermogravimetric studies by Freeman's method in the present work agree well with the values obtained by Kissinger's method which based on the differential thermal analysis. It may be concluded from the results of this kinetic investigation that the method of thermogravimetric analysis can be used to obtain information about the kinetics of simple dehydration reactions.

However, several factors which may influence the patterns have not examined, such as pressure, atmosphere and particle size.

The Syntheses of Substituted 4-Indanyl Phenyl Ketones and Aceanthrenes

By Tosio MORIWAKE

Department of Industrial Chemistry, School of Engineering, Okayama University, Tsushima, Okayama

(Received June 19, 1965)

According to Cook,[1] it appears that the carcinogenic potency of methylcholanthrene cannot be attributed to its special pentacyclic structure. Fieser and Hershberg[2] have suggested that methylcholanthrene owes its high activity to the presence of the 1, 2-benzanthracene ring system with a simple substituent at the 10-position. These facts have prompted the present author to synthesize the derivatives of aceanthrene, which has a structural analogy to cholanthrene but which possesses no carcinogenic activity by itself.

The Elbs reaction[3] has been extensively used for the preparation of polycyclic aromatic hydrocarbons. The syntheses of 1, 2-cyclopentenoaceanthrene and 1, 2-dimethylaceanthrene by this reaction have been reported by Fieser and Hershberg.[2] There are also several other methods[4] for preparing aceanthrene derivatives, but the method using the pyrolysis of substituted 4-indanyl phenyl ketone seems to be the most convenient. This paper will deal with the synthesis and the pyrolysis of some substituted 4-indanyl phenyl ketones.

The condensation of benzonitrile with 4-indanyllithium, which had been prepared by the reaction of 4-bromoindane with lithium in ether, gave 4-indanyl phenyl ketone in a 78% yield, whereas the reaction of benzoyl chloride or benzonitrile with 4-indanylmagnesium bromide, which had been prepared from 4-bromoindane and magnesium in ether, gave 4-indanyl phenyl ketone in yields of 40 and 27% respectively. The author then prepared other 4-indanyl phenyl ketones, which are summarized in Table I, by the condensation of benzonitrile with 4-indanyllithium.

The pyrolysis of 4-indanyl phenyl ketone at 350—355°C for 5 hr. gave a product, which was identified as aceanthrene by a study of its melting point, picrate and spectra, in a 27.2% yield. The pyrolysis of 4-indanyl *p*-tolyl ketone gave 9-methylaceanthrene in a 25.0% yield.

On the other hand, the pyrolysis of 4-indanyl *o*-tolyl ketone gave a viscous material, from which small amount of picrate was then obtained. The analytical data of the picrate agreed well with the values calculated for $C_{17}H_{14}\cdot C_6H_3O_7N_3$. In view of the structure of the ketone, 1, 2-cyclopentenoanthracene or 7-methylaceanthrene might be the pyrolytic product. However, the attempted isolation of hydrocarbon from the picrate failed. The pyrolysis of other ketones failed to give pure substances.

Experimental[5]

4-Indanyl Phenyl Ketone: Method A (from Benzonitrile and 4-Indanyllithium).—A solution of 9.8 g. of 4-bromoindane[6] in 30 ml. of ether was added

to a suspension of 0.8 g. of lithium in 30 ml. of ether at such a rate that moderate refluxing was continued; this refluxing was continued for a further 5 hr. To the resulting solution there was added, with ice-cooling, 5.2 g. of benzonitrile dissolved in a mixture of 20 ml. of ether and 20 ml. of benzene over a 30-min. period. After the mixture had been refluxed for 2 hr., it was decomposed by the addition of 50 ml. of 10% hydrochloric acid. After the organic solvent had been distilled off, 10 ml. of water, 10 ml. of concentrated hydrochloric acid and 5 ml. of acetic acid were added; the mixture was then refluxed for 2 hr. to complete the decomposition of the resulting ketimine. The product was extracted with a mixture of ether and benzene, and the extract was washed with a saturated sodium bicarbonate solution, and with water, dried, concentrated, and distilled to give 8.0 g. (72%) of 4-indanyl phenyl ketone (b. p. 153—155°C/2 mmHg; n^{15} 1.6080). Attempts to prepare the oxime and semicarbazone of the ketone failed.

Found: C, 86.37; H, 6.78. Calcd. for $C_{16}H_{14}O$: C, 86.45; H, 6.35%.

The other indanyl phenyl ketones summarized in Table I were prepared by this method.

Method B (from Benzoyl Chloride and 4-Indanylmagnesium Bromide).—A solution of 9.8 g. of 4-bromoindane in 30 ml. of ether was added under refluxing to 1.2 g. of magnesium covered with 30 ml. of ether over a 10-min. period. Refluxing was then continued for an additional 1.5 hr. to complete the reaction. The mixture was cooled with an ice bath; a solution of 7.0 g. of benzoyl chloride in 30 ml. of ether was then added over a 15-min. period, and the mixture was refluxed for 1 hr. The cooled reaction mixture was decomposed by the addition of 60 ml. of 10% hydrochloric acid, extracted with ether, and treated as usual. Distillation gave 4-indanyl phenyl ketone in a 40% yield.

Method C (from Benzonitrile and 4-Indanylmagnesium Bromide).—To an ethereal solution of 4-indanylmagnesium bromide (prepared from 3.3 g. of 4-bromoindane and 0.4 g. of magnesium in ether) there was added a solution of 2.0 g. of benzonitrile in 20 ml. of ether over a 10-min. period. The resulting mixture was treated with in the same manner as has been described in method A. 4-Indanyl phenyl ketone was obtained in a yield of 27%.

Aceanthrene (The Pyrolysis of 4-Indanyl Phenyl Ketone).—When 2.0 g. of 4-indanyl phenyl ketone was heated at 350—355°C for 5 hr. in a metal-bath and distilled at 2 mmHg, a viscous distillate was obtained, which crystallized on standing. The recrystallization of the resulting yellow crystalline from ethanol gave 0.5 g. (27.2%) of aceanthrene; m. p. 114.5—115.5°C (lit.[3] 113°C); λ_{max}^{EtOH} 254 mμ (ε 13800), 258(115000), 356(3100), 375(6300) and 396(3600); (Found: C, 93.91; H, 5.98%.

The picrate (from ethanol) melted at 120—120.5°C (lit.[3] m. p. 120°C).

9-Methylaceanthrene (The Pyrolysis of 4-Indanyl *p*-Tolyl Ketone).—2.2 g. of 4-indanyl *p*-tolyl ketone was heated at 360—370°C for 4 hr. and distilled at 3 mmHg to give 500 mg. (25.0%) of yellow crystals, m. p. 115—118°C. The recrystallization of this material from ethanol gave an analytically pure sample; m. p. 118—118.5°C; λ_{max}^{EtOH} 259 mμ (ε 113000), 355(3000), 373(6200) and 394(3500).

Found: C, 93.36; H, 6.41. Calcd. for $C_{17}H_{14}$: C, 93.53; H, 6.47%.

The picrate, as fine, dark-red needles, melted at 121—122°C after recrystallization from ethanol.

Found: C, 61.64; H, 3.94. Calcd. for $C_{23}H_{17}O_7N_3$: C, 61.74; H, 3.83%.

The Pyrolysis of 4-Indanyl *o*-Tolyl Ketone.—When 2.0 g. of 4-indanyl *o*-tolyl ketone was heated at 350—360°C for 5 hr. and distilled at 5 mmHg, a reddish oil was obtained. To this distillate there was added a saturated ethanolic solution of picric acid, and the dark-red fine needles which separated were collected. Recrystallizations from ethanol gave a pure picrate, m. p. 123.5—124°C.

Found: C, 61.94; H, 4.04. Calcd. for $C_{23}H_{17}O_7N_3$: C, 61.74; H, 3.83%.

The analytical data agreed well with the values calculated for $C_{17}H_{14}\cdot C_6H_3O_7N_3$, the picrate of 7-methylaceanthrene or 1, 2-cyclopentenoanthracene, but the attempt to isolate the corresponding hydrocarbon from the picrate failed.

The Separation of Selenium(IV) and Selenium(VI) by Solvent Extraction

By Mariko INARIDA

The Institute of Physical and Chemical Research, Komagome, Bunkyo-ku, Tokyo

(Received June 24, 1965)

As a method for the mutual separation of selenium(IV) and selenium(VI), precipitation with sulfur dioxide gas[1] has been used. The present author has now tried to separate them by extraction with TBP (tributyl phosphate) and Na(DDTC) (sodium diethyldithio carbamate). As a result, a more rapid and simple method will be elaborated.

Selenium(IV) forms a yellow compound in hydrochloric acid media with DDTC, this chelate can be extracted by TBP from a 0.05 N—0.1 N hydrochloric acid solution quantitatively, while selenium(VI) does not form DDTC complexes under these conditions. The author has devised the following separation prosedure based on the above properties.

Experimental and Results

The Preparation of the Radioactive Selenium(IV) Solution and the Radioactive Selenium(VI) Solution.—^{75}Se was added to a nitric acid solution (1 : 1) of standard selenium(IV) solution. The solution was then evaporated, dried up, and dissolved with a 0.1 N hydrochloric acid solution. One milliliter of this solution contained 100 μg. of Se*(IV). The radioactive selenium(VI) solution was prepared using radioactive selenium-(IV) by the method of Dennis and Koller.[2]

The Determination of the Distribution Ratios.—The distribution ratios of selenium(IV) and selenium(VI) in the DDTC-HCl-TBP system were studied. The radioactive selenium(IV) solution (or the radioactive selenium(VI) solution) and 0.1 M Na(DDTC) were mixed with 5 ml. of hydrochloric acid in various concentrations and then shaken with an equal volume of TBP(pre-equilibrated with each hydrochloric acid solution). The equilibrium was established within 1 min. The two phases were then separated by centrifuging, and a 1 ml. portion was taken from each phase. The γ-radioactivity was measured with a well-type scintillation counter. The data obtained are shown in Fig. 1, where D is the distribution ratio. It is clear from this figure that the mutual separation of selenium(IV) and selenium(VI) is possible at the acidity of a hydrochloric acid solution of 0.05—0.1 N.

The effects of the ratio of DDTC to selenium were next investigated. The smallest DDTC-to-selenium ratio, giving the highest extraction, was between 4 and 5 to 1 on a molar basis.

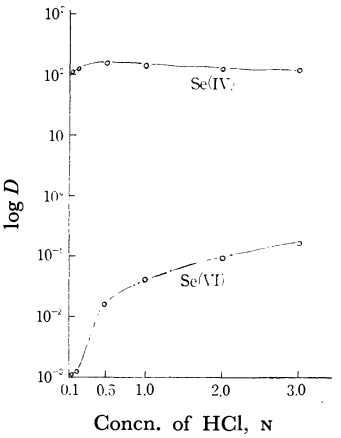

Fig. 1. Distribution of selenium in DDTC-HCl-TBP system.

The Back-Extraction of Selenium(IV).—Selenium(IV) in the TBP phase is back-extracted by shaking for one minute with 20 ml. of a 10% perchloric acid solution and 1 ml. of a hydrogen peroxide solution. More than 99% of the selenium-(IV) was recovered in the aqueous phase by two back extractions.

The Mutual Separation of Selenium(IV) and Selenium(V).—A radioactive (or inactive) selenium(IV) solution and an inactive (or radioactive) selenium(VI) solution were mixed (selenium-(IV): 10 mg., selenium(VI): 10 mg.). The solution was then adjusted to the acidity of a 0.05—0.1 N hydrochloric acid solution. The total volume was 20 ml. After the addition of 2 ml. of a 10% Na(DDTC) solution, the solution was shaken with 5 ml. of TBP in a separating funnel for one minute. The extraction was then repeated two times. After the selenium(IV) has been extracted with TBP, leaving selenium(VI) in the aqueous phase, the selenium(IV) was back-extracted twice as above. Then the aqueous phase was separated. The γ-activity of the aqueous and organic phases was measured with a well-type scintillation counter. By this simple procedure, these ions can be separated quantitatively.

The author is grateful to Dr. Nobufusa Saito, Chief of the Laboratory of Nuclear Chemistry, for his helpful discussions.

SHORT COMMUNICATIONS

The Catalytic Activity of Bis-cyclopentadienyltransitionmetal Compounds for Ethylene Polymerization

By Yoshio TAZIMA and Sadao YUGUCHI

Central Research Laboratory, Toyo Rayon Co., Ltd., Otsu, Shiga

(Received June 24, 1965)

The catalytic activity of the binary sytsem of the biscyclopentadienyltransitionmetal compound and of the organoaluminum compound has been investigated. The transition metal π-complexes used as components of the binary system were biscyclopentadienyltransitionmetal halide, -chromate, -dichromate, -phosphate, -thiocyanate, -tetrathiocyanatodiamminechromate (VI), etc., while the center elements of the π-complexes tried were titanium, vanadium and zirconium.

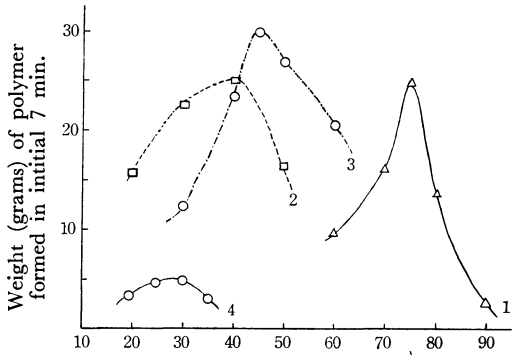

Fig. 1. Catalytic activity of the binary system for echylene polymerization at various temperature.
1. $Cp_2TiCr_2O_7$ - $AlEt_2Cl$
2. $Cp_2TiCr_2O_4$ - $AlEt_2Cl$
3. $Cp_2Ti[C_6H_2(NO_2)_3O]_2$ - $AlEt_2Cl$
4. $Cp_2Ti[(NH_3)_2Cr(SCN)_4]_2$ - $AlEt_2Cl$

Figure 1 shows the relations of the polymerization temperature and the weight of the polymer formed during the initial seven minutes by the binary catalyst systems of 0.1 g. of biscyclopentadienyltitanium compounds and 1 cc. of $AlEt_2Cl$, using 50 cc. of toluene as a solvent under 40 kg./cm^2 of ethylene pressure. The temperature at which the catalyst system showed a maximum activity was 75°C in the $Cp_2TiCr_2O_7$ - $AlEt_2Cl$ system, 50°C in the Cp_2TiCrO_4 - $AlEt_2Cl$ system, and 45°C in the $Cp_2Ti[C_6H_2(NO_2)_3]_2$ - $AlEt_2Cl$ system.

When vanadium or zirconium was the center element instead of titanium, the same tendency was observed.

The results are summarized in Table I and Table II. In Table I the temperature of the maxiumm catalytic acitivity of the system is shown for each center element of titanium, vanadium, zirconium. In Table II the maxium catalytic activity of each binary system (the transitional π-complex - $AlEt_2Cl$) is shown. The catalytic activity is expressed as grams of polymer formed in an hour per gram of transition metal complex under the experimental conditions.

TABLE I. THE TEMPERATURE (°C) OF THE MAXIMUM CATALYTIC ACTIVITY OF THE (Cp_2MX_2 - $AlEt_2Cl$) SYSTEM

M: Ti, V, Zr.

Center element / Anion species	Ti	V	Zr
Cl^- (Br^-)*	25	25	30
$Cr_2O_7^{2-}$	75	75	80
CrO_4^{2-}	40	40	50
$C_6H_2(NO_2)_3O^-$	45	45	50
$[(NH_3)_2Cr(SCN)_4]^-$	30	30	40
PO_4^{3-}	30	30	40

* Cp_2ZrBr_2

TABLE II. THE MAXIMUM CATALYTIC ACTIVITY OF THE SYSTEM

Center element / Anion species	Tt	V	Zr
Cl^- (Br^-)*	31740	130	15
$Cr_2O_7^{2-}$	2180	100	2.2
CrO_4^{2-}	2100	75	4.4
$C_6H_2(NO_2)_3O^-$	2580	8200	2.4
$(NH_3)_2Cr(SCN)_4^-$	330	50	7.2
PO_4^{3-}	40	20	0.9

* Cp_2ZrBr_2

Therefore, the following points were concluded.

1) The activity of the catalyst system depends principally on the nature of the center element of the π-complex, and the order of catalytic activity is conspicious;

$$(Ti \gg V \gg Zr)$$

2) The temperature of the maximum catalytic activity of the binary system depends on the anion species of the π-complex, and it is independent of the center element.

3) Exceptionally, the system of biscyclopentadienylvanadiumpicrate $\simeq$ aluminumdiethylchloride is extraordinarily active at 45°C.

4) As an organoaluminum compound, $AlEt_2Cl$ is better than $AlEt_3$, $AlEtCl_2$, $Al(i\text{-}Bu)_3$, etc.

The Reaction Between Benzylsulfonyl Halide and Phenyllithium

By Yasuhiko SHIROTA, Toshikazu NAGAI and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Higashinoda, Miyakojima-ku, Osaka

(Received November 6, 1965)

When benzylsulfonyl chloride (Ia) was treated with phenyllithium at 20—25°C, lithium benzylsulfinate (I), α-chlorobenzyl phenyl sulfone (II), m. p. 179—180°C, chlorobenzene (III), *trans*-stilbene (IV), m. p. 123°C, α, α-dichlorobenzyl phenyl sulfone (V), m. p. 151—152°C, *trans*-1, 2-diphenyl vinyl phenyl sulfone (VI), m. p. 182.5—183°C, benzyl phenyl sulfone (VII), m. p. 146°C, α-benzylsulfonyl-α'-benzenesulfonyl dibenzyl sulfone (VIII), m. p. 199—201°C and α-benzylsulfonyl-α-benzenesulfonyl toluene (IX), m. p. 237—242°C (decomp.) were obtained and identified.

(I), $C_6H_5CH_2SO_2Li$, was verified by converting it to benzyl methyl sulfone,[1] m. p. 126°C and to Ia. I was the major product; it was obtained in an overwhelming yield. II, IV and VII were identified by means of mixed melting point methods and by the coincidences of the infrared spectra with those of the respective authentic specimens.[2-4] The ields were 9.1, 3.6 and 0.4% respectively. III was identified by the coincidences of the boiling point, the infrared spectrum and the retention time obtained by V. P. C. with those of the standard sample, the yield being 16%.

V, VI and VIII were identified on the basis of elemental analyses, mol. wt. determinations,[5] and infrared, NMR or ultraviolet spectra. The yields were 0.7, 6.0 and 1.6% respectively. (V), $C_6H_5C(Cl_2)SO_2C_6H_5$, IR: ν_{max}^{Nujol} 1330 and 1050 cm^{-1} (SO_2), NMR: τ 2.35 (phenyl protons). Found: C, 51.54; H, 3.06; Cl, 23.75: Calcd. for $C_{13}H_{10}Cl_2O_2S$: C, 51.84: H, 3.34; Cl, 23.54%. (VI), $C_6H_5CH{=}C(C_6H_5)SO_2C_6H_5$, IR: ν_{max}^{Nujol} 1300, 1140 (SO_2), 1620(C=C) and 820 cm^{-1} (tri-substituted ethylene), UV: λ_{max}^{EtOH} 216 mμ (ε 21600) and 275 mμ (ε 18900), NMR: τ 2 (vinyl proton, singlet, 1H) and τ 2.65 (phenyl protons, 15 H). Found: C, 74.64; H, 5.05; S, 10.09; mol. wt., 316, Calcd. for $C_{20}H_{16}O_2S$: C, 74.97; H, 5.03; S, 10.00%; mol. wt., 320.

(VIII), $C_6H_5{-}SO_2{-}CH_D(C_5H_6){-}SO_2{-}CH_C(C_5H_6){-}SO_2{-}C(H_A)(C_5H_6){-}H_B$,
IR: 1340, 1330, 1320, 1150 and 1120 cm^{-1} (SO_2), NMR: τ 5.63 (H_A snd H_B, quartet with J_{AB}= 13.5 c.p.s.), τ 3.3 (H_C singlet), τ 3.08 (H_D, singlet) and τ 2.6 (phenyl protons). The relative areas were 2 : 1 : 1 : 20. Found: C, 60.01; H, 4.54; S, 17.49; mol. wt., 543, Calcd. for $C_{27}H_{24}O_6S_3$: C, 59.98; H, 4.47; S, 17.78%; mol. wt., 541. (IX), IR; ν_{max}^{Nujol} 1320, 1310, 1150 and 1135 cm^{-1} (SO_2), NMR (in DMSO at 100°C): τ 2.6 (phenyl protons), τ 3.5 ($SO_2{-}CH(C_6H_5){-}SO_2$) and τ 5.2 (methylene protons), the relative areas being around 15 : 1 : 1.8. Found: C, 61.99; H, 4.69; S, 16.33; mol. wt., 374. Calcd. for $C_{20}H_{18}O_4S_2$: C, 62.15; H, 4.70; S, 16.59%; mol. wt., 386. Yield: 3.7%.

$C_6H_5CH_2SO_2Cl + C_6H_5Li \rightarrow$

$C_6H_5CH_2SO_2Li$ (I) main product

$C_6H_5CH_2SO_2F + C_6H_5Li \rightarrow$

$C_6H_5{-}SO_2{-}CH(C_6H_5){-}SO_2{-}CH_2(C_6H_5)$ (IX) main product

On the other hand, the similar treatment of benzylsulfonyl fluoride (Ib) with phenyllithium gave the disulfone (IX) with a m. p. of 248—250°C (decomp.) exclusively (60% yield), together with 3.9% of IV, 1.8% of VII, 4.0% of VIII and 3.0% of I. The corresponding fluorocompounds of II, V and VI, however, were not formed.

The results above described indicate that, in the reaction of Ia with phenyllithium, Li–Cl interconversion is the predominant reaction course; it contains both the direct Li–Cl interconversion between Ia and C_6H_5Li and the Li–Cl interconversion after the metalation at the α-position to the sulfone group, whereas the reaction of Ib with phenyllithium takes a different course. The formation of IV and VI suggests the possibility of the intermediacy of a phenylsulfene[6] resulting from α-lithium benzylsulfonyl halide, followed by the β-elimination of LiX. The details, including the the formation of a polysulfone, $(C_6H_5CHSO_2)_n$,[7] at a low temperature (−80°C), will be reported in the near future.

7) It has a higher molecular weight than VIII.

Long Range Interaction between Hydrated Electrons

By Hideo TSUJIKAWA, Kenji FUEKI and Zenichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received November 26, 1965)

The pulse radiolysis technique has made it possible to observe directly the formation and reactivity of the hydrated electron in liquid water. The bimolecular reaction of the hydrated electron has been found to be a fast reaction[1] and a subject for discussion, since it is the reaction of two negative species in which only a repulsive interaction would be expected from a simple classical consideration.

In order to understand this reaction, it is necessary to consider the interaction between hydrated electrons on a theoretical basis. We have, therefore, made a calculation, using the polaron model, of the long range interaction between hydrated electrons.

The interaction energies between two hydrated electrons in the electronic ground state are expressed as follows:

$$E\left\{\begin{matrix}{}^1\Sigma_g^+\\ {}^3\Sigma_u^+\end{matrix}\right\}=\frac{1}{1\pm S^2}\left[-2\beta e^2\left\{\frac{1}{r_0}\int_{r_{b1}\leq r_0}\phi_a^2(1)\mathrm{d}v_1+\int_{r_{b1}\geq r_0}\frac{\phi_a^2(1)}{r_{b1}}\mathrm{d}v_1\pm S\left(\frac{1}{r_0}\int_{r_{b1}\leq r_0}\phi_a(1)\phi_b(1)\mathrm{d}v_1+\int_{r_{b1}\geq r_0}\frac{\phi_a(1)\phi_b(1)}{r_{b1}}\mathrm{d}v_1\right)\right\}+\frac{e^2}{D}\left\{\int\frac{\phi_a^2(1)\phi_b^2(2)}{r_{12}}\mathrm{d}v_1\mathrm{d}v_2\pm\int\frac{\phi_a(1)\phi_b(2)\phi_a(2)\phi_b(1)}{r_{12}}\mathrm{d}v_1\mathrm{d}v_2\right\}\right]$$

where the upper and lower signs on the right-hand side correspond to the ${}^1\Sigma_g^+$ and ${}^3\Sigma_u^+$ states respectively; a and b represent the cavities which are formed by each electron; r_0 is the cavity radius; ϕ_a and ϕ_b are the wave function of the hydrated electron in the cavities a and b respectively; r_{b1} is the distance between the center of the b cavity and the 1 electron; r_{12} is the distance between the electrons; S is the overlap integral between ϕ_a and ϕ_b, and $\beta=(1/D_{op})-(1/D_s)$, D_{op} and D_s being the optical and static dielectric constants of water respectively.

The wave function of the hydrated electron is obtained by the SCF dielectric treatment,[2] while the effective dielectric constant, D, has been estimated in the following way:

$D=D_s$ for $R\geq 12$Å

$D=f(R)$ for $12\text{Å}\geq R\geq 6\text{Å}$

$D=D_{op}$[3] for $6\text{Å}\geq R$

where $f(R)$ is a cubic function with srepect to the distance, R, between the cavities and is connected smoothly with D_{op} at $R=6$Å and with D_s at $R=12$ Å.

Figure 1 shows the interaction energy, E, calculated as a function of R for the different cavity radii, $r_0=0$ and 1.8 Å. The interaction potentials for both the ${}^1\Sigma_g^+$ and ${}^3\Sigma_u^+$ states are attractive rather than repulsive except at short distances. The potential curve for the ground state (${}^1\Sigma_g^+$) has a minimum at 7.5 Å. The increase in the cavity radius lowers the ${}^1\Sigma_g^+$ state slightly and raises the ${}^3\Sigma_u^+$ state to the same extent.

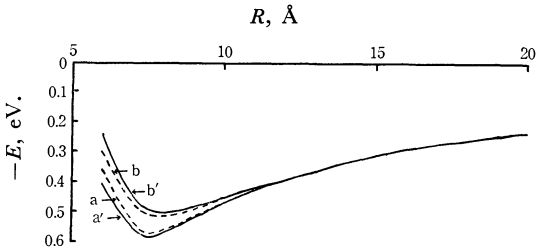

Fig. 1. The interaction energy between hydrated electrons.
a: ${}^1\Sigma_g^+$, $r_0=0$; a′: ${}^1\Sigma_g^+$, $r_0=1.8$Å
b: ${}^3\Sigma_u^+$, $r_0=0$; b′: ${}^3\Sigma_u^+$, $r_0=1.8$Å

The present results suggest that the activation energy for the bimolecular reaction of the hydrated electron arises from a short range interaction when the activation energy for diffusion is properly taken into account, and that it is not justifiable to use a simple electrostatic interaction between hydrated electrons in applying the Debye equation to the second-order rate constant.

Four Isomers of Monobromo-2-stilbazole

By Takumi KATSUMOTO and Akiko HONDA

Faculty of Science, Kwansei Gakuin University, Nishinomiya, Hyogo

(Received November 30, 1965)

Monobromo-2-stilbazole, Ph-(CH=CBr)-Py-2, is expected to have four isomers: *cis*- and *trans*-2-(α-bromostyryl)-pyridine, Ph-CBr=CH-Py-2 and *cis*- and *trans*-2-(β-bromostyryl)-pyridine, Ph-CH=CBr-Py-2. However, only one species (m. p. 74—75°C) has been obtained by the dehydrobromination of 2-stilbazole dibromide,[1-3] its structure had not yet been established. The three other possible but unknown isomers have now been prepared in our laboratory, after which the structures and configurations of all the isomers have been established:

cis-2-(α-bromostyryl)-pyridine,
Ph-CBr=CH-Py-2 (I)

trans-2-(α-bromostyryl)-pyridine,
Ph-CBr=CH-Py-2 (II)

cis-2-(β-bromostyryl)-pyridine,
Ph-CH=CBr-Py-2 (III)

trans-2-(β-bromostyryl)-pyridine,
Ph-CH=CBr-Py-2 (IV)

I was prepared by the dehydrobromination of *threo*-2-stilbazole dibromide. Colorless prisms, m. p. 146.5—147.2°C (Found: Br, 31.08. Calcd. for $C_{13}H_{10}NBr$: Br, 30.73%). UV in heptane: 242 mμ (log ε, 3.90), 290 mμ (3.57). II was prepared either by the action of phosphorus pentabromide upon 2-phenacylpyridine, Ph-CO-CH_2-Py-2, or by hydrogen bromide addition to 2-tolazole, Ph-C≡C-Py-2. Liquid, b. p. 123°C/3 mmHg, n_D^{25} 1.6638. (Found: C, 59.93; H, 3.94; N, 5,50; Br, 30.55. Calcd. for $C_{13}H_{10}NBr$: C, 60.02; H, 3.87; N, 5.38; Br, 30.73%). UV: 220 mμ (4.05), 292 mμ(4.31). III was prepared by the dehydrobromination of *erythro*-2-stilbazole dibromide. Colorless prisms, m. p. 72.7—74.5°C. (Found: C, 60.06; H, 3.98; N, 5.57; Br, 30.69%). UV: 230 mμ (4.12), 286 mμ(3.89). IV was prepared by the action of phosphorus pentabromide upon 2-Pyridyl benzyl ketone, Ph-CH_2-CO-Py-2. Liquid, b. p. 127°C/3 mmHg, n_D^{25} 1.6710. (Found: C, 59.99, H, 4.06; N, 5.34; Br, 30.96%). UV: 223 mμ (4.17), 303 mμ(4.38).

The above-described structures of these isomers were established by the following experiments. (a) The process of preparing II and IV using pentabromide on the -CO-CH_2-group suggests that the bromine atom is combined with α-carbon in II and with β-carbon in IV respectively, and that they are both trans isomers. (b) III is the main product of the dehydrobromination of *erythro*-dibromide in an alcoholic potassium hydroxide solution and is supposed to be cis form as the result of trans elimination. (c) I and III are converted into II and IV respectively when heated at 200°C, while the reverse reactions from II and IV do not occur under the same conditions. (d) All isomers are converted into 2-tolazole by further dehydrobromination. The reactions of I and III are by far slower than those of II and IV. (e) By the reduction of bromine with zinc, II and IV are converted into *trans*-2-stilibazole, Ph-CH=CH-Py-2, almost quantitatively, while I and III are converted into *cis* 2-stilbazole. (f) The bathochromic shifts and remarkable increases in the absorption intensity occur as usual on passing from the cis isomers to the trans isomers.

A cis isomer usually melts at a much lower temperature than a trans isomer does, but in this case the cis isomers are crystal and the trans isomers are liquid. It is also interesting to note that the cis isomer I was the main product obtained from *threo*-dibromide, because the trans elimination of *threo*-dibromide generally gives the trans isomer.

The S_N1 Hydrolysis of α-Phenylethyl Chloride Proceeding with the Retention of the Configuration in Binary Mixtures of Phenol and Water

By Kunio OKAMOTO, Masayuki HAYASHI and Haruo SHINGU

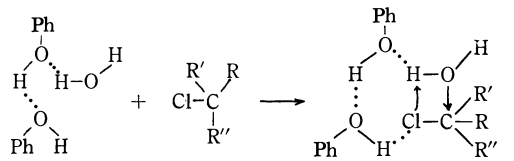
Department of Fuel Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received December 2, 1965)

In recent publications, Goering and his collaborators[1] have reported that the S_N1 hydrolysis (alkyl-oxygen cleavage) of *p*-chlorobenzhydryl *p*-nitrobenzoate proceeds with an excess retention of the configuration in 80—90% aqueous acetone. Despite extensive investigations of the steric course of S_N1 hydrolysis, no other examples which follow the retained steric course are known for such a system without a configuration-retaining group adjacent to the reaction center. The present report is of significance both because it will present another example of hydrolysis with the retention of configuration for a simple secondary carbon system, and because it can throw light on the hitherto elusive nature of the retention mechanism for this system in general.

Solvolyses of optically active α-phenylethyl chloride (0.106 M) were conducted in 75, 80, and 90 wt.% aqueous phenols in the presence of triethylamine (0.114—0.118 M) for ten half-lives at 30.0°C. The products of the competitive phenolysis and hydrolysis were chromatographed over basic alumina and purified by distillation in vacuo. From the rotations of α-phenylethyl alcohol (α_D, $-1.58°$, $-1.64°$ and $+1.16°$ (neat, 0.5 dm.) for the respective solvolyses) and α-phenylethyl phenyl ether (α_D, $+0.62°$, $+0.76°$ and $-1.97°$, neat, 0.5 dm.) thus obtained, it was found that the configurations of the chlorides (α_D, $-27.39°$, $-26.30°$ and $+27.06°$, neat, 0.5 dm.) were retained for both hydrolysis and phenolysis over the entire solvent range examined. The extents of retention[2] were calculated on the basis of the rotaions of the starting chloride to be 16.3, 17.6 and 12.1% for α-phenylethyl alcohol and 6.08, 7.76 and 19.5% for α-phenylethyl phenyl ether for the respective solvolyses. In previous papers,[3] with regard to phenolyses in various mixtures of phenol and organic solvents (e. g.,benzene, cyclohexane, and acetonitrile), we reported that the formation of α-phenylethyl phenyl ether from α-phenylethyl chloride proceeded with a net retention of configuration, and suggested a mechanism involving a S_Ni-like four-center reaction between a molecule of phenol and the ion-pair intermediate.

For the retention of the steric course of the hydrolysis, we have considered two possible explanations. The shielding by a phenol molecule might be operative from the back-side of the S_N1 intermediate; this concept has been used in explaining the decrease in inversion in the hydroxylic solvents of a higher content of such co-solvents as ether, dioxane, nitrobenzene and acetone.[4] However, this possibility is unlikely since the extent of retention for the α-phenylethyl alcohol shows a decreasing tendency, passing through a maximum value in the solvents with the higher phenol contents. It appears that some intermolecular complexes between water and phenol molecules of different degrees of association favor the front-side attack, as is depicted in the case of the 1 : 2 complex as follows:



This may be regarded as a detailed expression of the "polymolecular"[5] attack of hydroxylic molecules on the halogen atom in the S_N1 solvolysis.

The details of this work and descriptions of some further extention experiments with methanolic phenol solvents will be published in the near future.

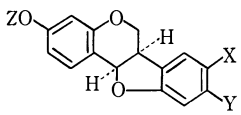
The Absolute and Relative Stereochemical Correlation of Isoflavanone, Sophorol and Naturally-occurring Isoflavan Derivatives

By Hiroshi SUGINOME

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received December 10, 1965)

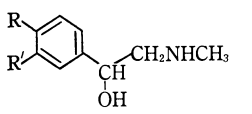
The absolute and relative stereochemical correlations between corresponding asymmetric centers of optically acitve isoflavanone, sophorol[1] and various chromanocoumarans, including (−) homopterocarpin[2a] (I) X=H, Y=OMe, Z=Me, (−) maackiain[2b] (I) X and Y=methylenedioxy, Z=H and (−) trifolirhizin[11,2c] (I) X and Y=methylenedioxy, Z=-D-glucose, have not yet been defined.

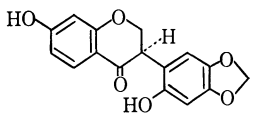


(I)

The optical rotatory-dispersion curves of sophorol, the oxidation product of *O*-methyldihydropterocarpin[3] and *O*-dimethylsophorol, exhibit virtually identical plain positive dispersion curves throughout the spectral range under examination. This result can be taken as conclusive evidence of an identical absolute configuration at C^3 in sophorol and the corresponding asymmetric center[4] of maackiain and the related compounds; it thus confirms previous assumptions.[5] The rotatory-dispersion curves of homopterocarpin, pterocarpin and maackiain all exhibit negative cotton effect curves. In these cases C^3 asymmetric carbon in the chromanocoumaran molecule makes a very weak negative contribution,[6] as is shown in the dispersion curve of dihydro-*O*-methylmaackiain *O*-methylether. Therefore, the relatively strong negative rotation accompanying by the cotton effects in these compounds is probably produced by the C^4 asymmetric center.

Lyle[7] reported that the compounds of the II, III, IV, (I) ephedrine and (−)-ϕ-ephedrine types showed negative cotton effects of a similar shape, and he identified the absolute configuration of (−) halostachine (II) as R on the basis of an unequivocal chemical correlation.[7]





(II) R=R′=H
(III) R=H, R′=OH
(IV) R=R′=OH

(V)

Attention must be drawn to the structural similarity between the asymmetric center of halostachine (II) and the environment of the corresponding asymmetric center of pterocarpin. Although, in the series of compounds in the present case, the aromatic ring is not free to rotate, and the enhancement of the optical activity can be observed,[8] the negative cotton effects by the asymmetric center of the R configuration in halostachine (II) and the C^4 environment of pterocarpin are strong evidence for assuming that the asymmetric centers of these compounds have the same absolute configuration R.

Since the B/C ring junction in pterocarpin is cis,[9] pterocarpin is represented as the C^4R, C^3R, configuration (I). Consequently, all the other chromanocoumarans which have been reported to exhibit negative rotation can be identified as having the C^4R, C^3R, configuration. Since it is apparent from the O. R. D. curve that C^3 in the isoflavan equol[10] and the corresponding asymmetric center of dihydro *O*-methylmaackiain-*O*-methylether have the same absolute configuration, the C^3 center of equol is assigned the R configuration. Therefore, sophojaponicin[11] must have the C^4S, C^3S configuration.

Furthermore, it follows that the absolute configuration of C^3 of sophorol is R (V). The present assignment of the absolute configuration should, however, be examined by an unequivocal chemical correlation.*

Isopyrrolnitrin: A Metabolite from Pseudomonas

By Masashi HASHIMOTO and Kiyoshi HATTORI

Research Laboratories, Fujisawa Pharmaceutical Co. Ltd., Higashi-yodogawa, Osaka

(Received December, 13, 1965)

Pyrrolnitrin (I) was isolated as a metabolite of Pseudomonas and its structure established by Arima and others.[1] During our investigation of metabolites of Pseudomonas, an isomer of pyrrolnitrin was found in the acetone extracts of the bacterial cells. First the existence of isopyrrolnitrin has been recognized by silica-gel thin-layer chromatography: R_f-values, 0.50 for pyrrolnitrin and 0.67 for isopyrrolnitrin, as determined by chloroform developing.

Isopyrrolnitrin has been isolated as yellowish crystals; m. p. 105—108°C, mol. wt. 257 by mass spectrometry.

Found: C, 46.82; H, 2.12; N, 11.27. Calcd. for $C_{10}H_6N_2O_2Cl_2$: C, 46.71; H, 2.35; N, 10.90%.

The infrared spectrum shows the presence of a –NH-group (3460 cm^{-1}) and characteristic absorption bands of the nitro group (1515 and 1349 cm^{-1}); the whole pattern of the spectrum is very similar to that of pyrrolnitrin. A color reaction by the Ehrlich reagent is positive (blue-violet). These data have suggested that isopyrrolnitrin has a structure similar to that of pyrrolnitrin. Conclusive information has been obtained from the NMR spectrum; the α-proton of the pyrrole ring appears at 6.76 p.p.m. as a doublet signal (coupling with the NH-proton of pyrrole), a proton adjacent to the nitro group in the benzen ring appears at 7.90 p.p.m. as a quartet signal, the multiplet signals from three protons appear at 7.3—7.7 p.p.m. of the aromatic proton region, and the proton of the NH-group appears at 8.4 p.p.m. as a broad signal (measured in $CDCl_3$ at 60 M c.p.s.). It follows from these data that the structure of isopyrrolnitrin is *o*-nitrophenyl-dichloropyrrole. The infrared absorption band at 743 cm^{-1} also shows that the compound is of a *o*-nitrophenyl substitution type, and the bands appearing in the region of 700—900 cm^{-1} are of a characteristic absorption which is common in the spectra of 2-substituted derivatives of pyrrolnitrin.

As a result of these studies, it may be supposed that the structure of isopyrrolnitrin is 2, 3-dichloro-4-(2'-nitrophenyl)-pyrrole (II). The correctness of this deduction has been proved by the synthesis.

The details will be published later.

A New Method for the Synthesis of Alkyl Aryl Sulfides

By Hiroshi YOSHIDA, Saburo INOKAWA and Tsuyoshi OGATA

Department of Synthetic Chemistry, Faculty of Technology, Shizuoka University, Oiwake, Hamamatsu

(Received December 15, 1965)

Alkyl aryl sulfides are generally produced by the condensation of alkyl halides with thiophenolates.[1,2] In previous papers,[3,4] the authors have reported that methyl xanthates, $MeOCS_2R$ (R= Me, Et, *n*-Pr), reacted with triethylamine to form the ammonium salts, $Et_3\overset{\oplus}{N}(Me)\overset{\ominus}{S}COSR$, at room temperature and to form dithiolcarbonates at an elevated temperature. In a similar reaction of *S*-phenyl xanthates with triethylamine, alkyl aryl sulfides were obtained in a good yield, this reaction will be described in this communication.

Upon mixing *S*-phenyl methyl xanthate (I, b. p. 100—102°C/2 mmHg, n_D^{14} 1.6304. Found: S, 34.2%. Calcd. for $C_8H_8OS_2$: S, 34.6%) and triethylamine at room temperature, immediate exotherms were observed with the evolution of carbonyl sulfide gas. After several minutes, methyl phenyl sulfide (b. p. 74.5—75°C/15 mmHg, n_D^{13} 1.5918) was produced in a 93% yield, while the amine remained almost unchanged. The equimolar mixture of I and triethylamine gave, at −20°C after 12 hr. in the form of pale yellow hygroscopic crystals needles (m. p. 57—59.5°C) in only a 3% yield by weight. These crystals were decomposed with aqueous hydrochloric acid to thiophenol, carbonyl sulfide and methyltriethylammonium chloride. Thus the structure of these crystals was concluded to be II (R=Et), similar to that of the salts[3] produced from $MeOCS_2R$ (R=Me, Et, *n*-Pr) and triethylamine. I and trimethylamine in benzene gave, at room temperature after 12 hr., white crystals (m. p. 130—134°C); these crystals showed reactions similar to those of II (R=Et) with aqueous hydrochloric acid. II (R=Me, Et) gave methyl or ethyl phenyl sulfide with methyl or ethyl iodide.

Methyl phenyl sulfide was also produced in a good yield by treating I with II (R=Et) at room temperature or with II (R=Me) at 70°C. These reactions may be summarized as follows:

$$MeOCS_2Ph \xrightarrow[(R=Me,\ Et)]{R_3N} \underset{(I)}{} MeSPh + \underset{(II)}{R_3\overset{\oplus}{N}(Me)\overset{\ominus}{S}COSPh} + COS$$

$$MeOCS_2Ph \xrightarrow{II} MeSPh + COS$$

$$R_3\overset{\oplus}{N}(Me)\overset{\ominus}{S}COSPh \xrightarrow[(R'=Me,\ Et)]{R'I} R'SPh + COS + R_3\overset{\oplus}{N}(Me)\overset{\ominus}{I}$$

Similarly, ethyl phenyl sulfide[5] (b. p. 80—81°C/13.5 mmHg, n_D^{13} 1.5669) was obtained by the catalytic decomposition of *S*-phenyl ethyl xanthate[1] (b. p. 95—97°C/1.5 mmHg, $n_D^{17.5}$ 1.6100) with triethylamine at 80°C with only a small amount of oily ammonium salt.

The Sulfuryl Chloride Chlorination of Alkyl Silanes. The Electronic Effect of Some Silyl Groups

By Yoichiro NAGAI, Noboru MACHIDA and Toshihiko MIGITA

Department of Chemistry, Gunma University, Kiryu, Gunma

(Received December, 24, 1965)

The free radical halogenation of alkylsilanes is one of the most convenient methods of introducing functional groups into the organic substituents attached to silicon. While much of the work in this field has been expended for synthetic purposes,[1] relatively little is known about the effect of changes in the structure of the silanes on the reactivities of each position of the alkyl groups.[2]

In order to obtain quantitative data on the effect of silyl groups in directing substitution, the sulfuryl chloride chlorination of ethyltrichloro-, ethylmethyldichloro-, ethyldimethylchloro-, *n*-propyltrichloro- and *n*-butyltrichloro-silane has been studied competitively in the presence of toluene.

Table I lists the relative reactivities per hydrogen atom at each carbon atom of those silanes, the aliphatic hydrogen atom in toluene being taken as unity.

Table I.[a] The relative reactivities of C–H bonds in the sulfuryl chloride chlorination of silanes

CH_3–CH_2SiCl_3		CH_3–$CH_2SiMeCl_2$		CH_3[b]–CH_2SiMe_2Cl
0.17	0.15	0.35	0.41	— 0.82

CH_3–CH_2–CH_2SiCl_3			CH_3–CH_2–CH_2–CH_2SiCl_3			
0.27	0.57	0.19	0.25	1.1	0.49	0.09

a) All the experiments were carried out in carbon tetrachloride at the reflux temperature. Product analyses were made by means of vapor-phase chromatography (QF-1, Silicone Grease).

b) The β-chloroethyl compound has not yet been positively characterized.

It may be seen from the table that the values for the methyl groups of *n*-propyltrichlorosilane and *n*-butyltrichlorosilane are very similar, indicating that the trichlorosilyl group exerts only the slightest influence, if any, on the γ- and δ-carbon atoms. Therefore, it follows that the β-position of ethyltrichlorosilane is less reactive, and that of ethylmethyldichlorosilane is more reactive, than ordinary primary hydrogens. From the electrophilic character of chlorination,[2] it is, then, obvious that the trichlorosilyl group is electron-withdrawing and that the methyldichlorosilyl group is electron-releasing. This seems to be the first comment to have been made concerning the electronic effects of those groups.

Another notable feature of the table is the marked decrease in the reactivity of hydrogens on carbons alpha to silicon. In fact, the reactivity ratio of α-methylene to an ordinary methylene is 0.14 (0.15/1.1), 0.37 (0.47/1.1) and 0.75 (0.82/1.1) for ethyltrichlorosilane, ethylmethyldichlorosilane and ethyldimethylchlorosilane respectively. It should be noted, however, that these methylene groups on silicon have only three adjacent C–H bonds capable of stabilizing the incipient α-radicals by hyperconjugation.

There are indications in the literature that radical formation at the alpha position of alkylsilanes is quite difficult relative to that at the beta position. For example, the chlorination of 1, 1-dichlorosilacyclopentane under radical conditions produces more beta than alpha.[3] Similarly, the sulfuryl chloride chlorination of ethylmethyldichlorosilane yields the chloroethyl compounds only, no substitution occurring at the methyl group alpha to silicon.[4]

The reduced possibilities of alpha radicals for hyperconjugation are apparently responsible for these observations.

Some Reactions of the Glycidyl Esters of Sulfonic Acids

By Nobuo NAKABAYASHI, Eiichi MASUHARA and Yoshio IWAKURA

Research Institute of Dental Materials, Tokyo Medical and Dental University, Yushima, Bunkyo-ku, Tokyo; Department of Synthetic Chemistry, The Faculty of Engineering, The University of Tokyo, Hongo, Tokyo

(Received March 4, 1965)

1-Chloro-2-hydroxypropyl sulfonates are obtained by the reaction of glycidyl sulfonates with hydrochloric acid at room temperature. They are converted into 1, 3-dichloro-2-propanol by the action of hydrochloric acid at 100°C, or into epichlorohydrin by that of bases. The reaction of glycidyl sulfonates and sodium carboxylates affords glycidyl carboxylates. In the preparation of glycidyl carboxylates, glycidyl sulfonates act as a direct alkylation agent for sodium carboxylates. The addition of amines to the epoxide is carried out at first in the reaction of glycidyl sulfonates and amines. The adducts are converted into glycidyl amines by the action of sodium hydroxide, or into *N*-[β-hydroxypropylene(α, γ)]-ammonium sulfonates by the isomerization, by heating them or letting them stand for a long time. The latter is an intermediate used in preparing 1, 4-dioxane derivatives in the presence of sodium hydroxide.

Glycidyl vinylsulfonate, glycidyl allylsulfonate, and glycidyl β-styrenesulfonate have been prepared and copolymerized with acrylonitrile, styrene and methyl methacrylate to obtain reactive polymers containing a glycidyl sulfonate group.[1-3] During our recent study of the reaction of the copolymers with amines, it has been demonstrated that a ring-opening addition of epoxide competes with a carbon-oxygen bond scission of sulfonate. The latter reaction is unfavorable for the purpose of polymer reaction because of the elimination of the reaction site from the polymers.

The present work was undertaken in order to investigate in more detail the reactions of glycidyl sulfonates with hydrochloric acid, sodium carboxylates and amines.

Results and Discussion

The Preparation of Glycidyl Sulfonates and Their Reaction with Hydrochloric Acid.— Glycidyl esters of methane-, allyl-, 2-propane-, butane-, and *p*-toluenesulfonic acid were prepared from glycidol and the corresponding sulfonyl chlorides. The results are shown in Table I.

$$RSO_2Cl + HOCH_2CH(\diagdown O \diagup)CH_2 \rightarrow RSO_2OCH_2CH(\diagdown O \diagup)CH_2$$

Glycidyl sulfonates reacted with hydrochloric acid to give 3-chloro-2-hydroxypropyl sulfonates in a good yield at room temperature. The results are shown in Table II.

$$RSO_2OCH_2CH(\diagdown O \diagup)CH_2 + HCl \rightarrow RSO_2OCH_2CH(OH)CH_2Cl$$

3-Chloro-2-hydroxypropyl sulfonates afforded 1, 3-dichloro-2-propanol in the reaction with hydrochloric acid at 100°C, whereas they formed epichlorohydrin in the presence of sodium hydroxide or triethylamine. This indicates that the scission of the carbon-oxygen bond of sulfonic ester

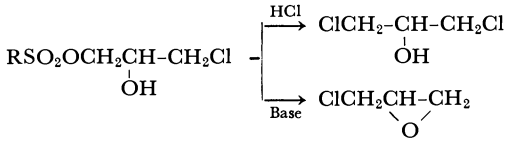
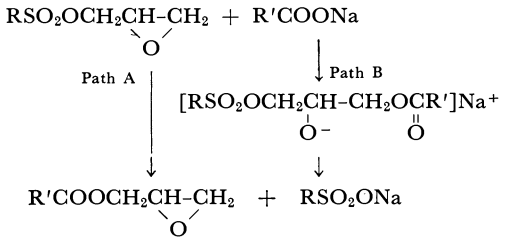
1) Triethylbenzylammonium chloride was not used.
2) Excess GMS was used as a reagent and solvent.
3) The solvent was water and the catalyst was not used.
4) ECH indicates epichlorohydrin. It was used in place of glycidyl sulfonates.

predominates over that of the carbon-chlorine bond.



The Reaction of Glycidyl Sulfonates with Sodium Carboxylates.—Next, the preparations of glycidyl carboxylates by the reactions of sodium acetate or sodium methacrylate and glycidyl sulfonates in the presence of a catalytic amount of triethylbenzylammonium chloride[5,6] were studied (Table III).



As is shown in the above scheme, there can be considered to be two alternative pathways for the formation of glycidyl carboxylates; namely, the direct displacement of sulfonate by carboxylate (Path A), or the attack of the carboxylate ion on the terminal carbon of the epoxide, thus giving rise to an intermediate alkoxide ion, which subsequently reforms the epoxide by the displacement of sulfonate (Path B), similar as in the case of the reaction of epichlorohydrin with sodium carboxylate.[6] It was found that the reaction of n-propyl methanesulfonate with sodium acetate gave n-propyl acetate in the same yield as in the case of glycidyl acetate. In view of this finding, it may be said that the reaction proceeds through Path A.

6) O. Maerker, J. F. Carmichael and W. S. Port, *J. Org. Chem.*, **26**, 2681 (1961).

The Reaction of Glycidyl Sulfonates with Amines.—When glycidyl methanesulfonate (GMS) was allowed to stand with morpholine at 25°C for an hour, the formation of 2-hydroxy-3-(4-morpholinyl)-propyl methanesulfonate (I) was observed by means of a study of the infrared spectrum. The treatment of the reaction mixture (hereafter we will call it the "first stage reaction mixture," which might be composed mainly of I) with sodium hydroxide at 25°C for an hour gave 4-(2, 3-epoxypropyl)-morpholine (III) in a 70% yield. III was also obtained by the reaction of GMS with morpholine in the presence of sodium hydroxide at −5°C for 30 min.

The isomerization of I to 4-[β-hydroxypropylene-(α, γ)]-morpholinium methanesulfonate (II)[4] was observed by the change in the infrared spectrum when the first stage reaction mixture was allowed

1) The reaction was carried out in 0.02 mol. scale.
2) Mo indicates morpholine, Py: pyrrolidine, Pi: piperidine, and Et: diethylamine
3) 1st: First treatment of an aqueous mixture of glycidyl sulfonates and amines.
NaOH: A or B shows that addition of sodium hydroxide to the mixture of glycidyl sulfonates and amines was performed together with 1st or 2nd treatment.
After 1st treatment, 2nd treatment was carried out.
4) III is 1-(2,3-epoxypropyl)-morpholine, IV: 2,5-bis-(4-morpholinylmethyl)-1,4-dioxane, V: 2,5-bis-(1-pyrrolidinylmethyl)-1,4-dioxane, VI: 2,5-bis-(1-piperidinylmethyl)-1,4-dioxane, VII: *N*-(2,3-epoxypropyl)-*N*,*N*-diethylamine, and VIII: 1-(2,3-epoxypropyl)-pyrrolidine.
5) The reaction temperature was raised by the heat of reaction for an instant.
6) A resinous product was obtained.

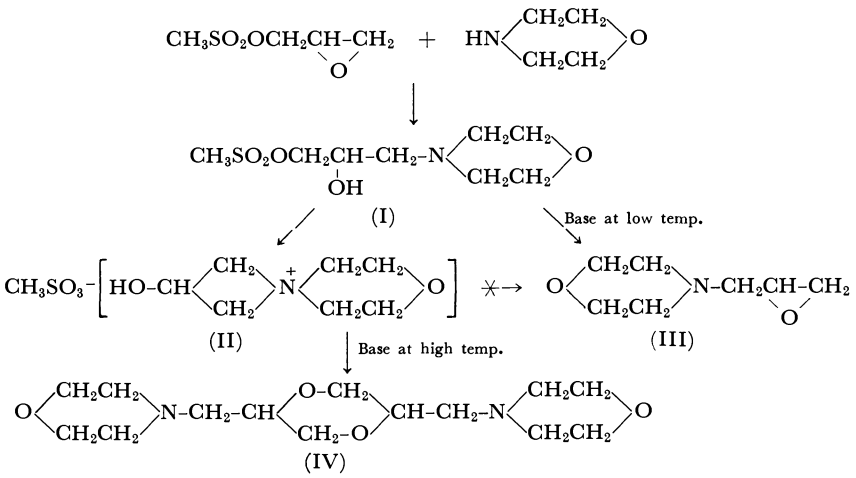

Fig. 1. The process of the reaction of GMS with morpholine.

to stand at 25°C for 45 hr. or at 80°C for 20 min. (we will call the reaction mixture at this stage the "second stage reaction mixture," which might be composed mainly of II). By treating the second stage reaction mixture with sodium hydroxide at 80°C for 20 min., 2, 5-bis-(4-morpholinylmethyl)-1, 4-dioxane (IV) was obtained in a 56% yield. On the other hand, the treatment of the above mixture with sodium hydroxide at 25°C resulted in the formation of a resinous product. The reaction of GMS with morpholine in the presence of sodium hydroxide at 80°C gave a mixture of III (17%) and IV (35%) after 20 min.

Both glycidyl 2-propanesulfonate or glycidyl *p*-toluenesulfonate and morpholine gave IV in a 53% yield when the reaction mixture (after standing at 80°C for 20—30 min.) was treated with sodium hydroxide at 90°C for 15—20 min.

The reaction of piperidine or pyrrolidine with GMS and sodium hydroxide also afforded 2, 5-bis-(1-piperidinylmethyl)-1, 4-dioxane or 1-(2, 3-epoxypropyl)-pyrrolidine and 2, 5-bis-(1-pyrrolidinylmethyl)-1, 4-dioxane, just as in the reaction of piperidine or pyrrolidine with epichlorohydrin.[7,8] By the treatment of GMS with diethylamine and sodium hydroxide, *N*-(2, 3-epoxypropyl)-*N*, *N*-diethylamine was obtained, but no dioxane derivative was detected as was in the reaction of epichlorohydrin with diethylamine and sodium hydroxide.[8,9] The above results are summarized in Table IV.

The process of the reaction of GMS with morpholine may be depicted as Fig. 1.

As the reaction of GMS with morpholine in the presence of sodium hydroxide to give III proceeded faster than that of *n*-propyl methanesulfonate with morpholine to give 4-(*n*-propyl)-morpholine under the same reaction conditions, it seems rational to consider the former reaction to proceed via an intermediate such as I rather than via the direct replacement of the ester group by an amino group. The isomerization of I to II, which was favored in the absence of sodium hydroxide, and the formation of III from I may be considered to be competitive reactions on the basis of the following facts. (1) When the mixture of GMS and morpholine was allowed to stand without sodium hydroxide to afford the second stage reaction mixture, only IV was obtained upon subsequent treatment with sodium hydroxide. (2) On the other hand, when sodium hydroxide was added earlier to the reaction mixture (first stage), III was obtained in a 70% yield. (3) The reaction of GMS with morpholine, carried out in the presence of sodium hydroxide from the beginning at 80°C, gave a mixture of III and IV.

Experimental

Raw Materials.—Methanesulfonyl chloride, 2-propyl bromide, *n*-butyl bromide, sodium sulfite, phosphorus pentachloride, glycidol and *p*-toluenesulfonyl chloride were commercially available. Sodium 2-propanesulfonate,[10] sodium butanesulfonate, 2-propanesulfonyl chloride (b.p. 83°C/25 mm.; lit.[11] 74.5°C/15 mm.), *n*-butanesulfonyl chloride (b. p. 96°C/16 mm.; lit.[12] 93.5°C/15 mmHg), glycidyl methanesulfonate[4] (GMS) and glycidyl *p*-toluenesulfonate[4] (GTS) were prepared by methods reported previously.

Glycidyl 2-Propanesulfonate (GPS).—To a solution of 22.3 g. (0.301 mol.) of glycidol and 30.3 g. (0.300 mol.) of triethylamine in 200 ml. of dry toluene, there was added, drop by drop, a mixture of 40.7 g. (0.286 mol.) of 2-propanesulfonyl chloride and 20 ml. of dry toluene under cooling in an ice-salt bath. The reaction mixture was then stirred for 3 hr. at room temperature. The triethylamine hydrochloride formed was removed by filtration, and the toluene was distilled off in vacuo. The residue was distilled under reduced pressure to give 35.8 g. of GPS boiling at 114—115°C/1 mmHg. The yield was 69.2%.

2-Hydroxy-3-chloropropyl 2-Propanesulfonate.—A mixture of 7.8 g. of GPS and 20 ml. of concentrated hydrochloric acid was occasionally stirred over a 2 hr. period while being kept at room temperature. The fractionation of the residue after the water had been removed gave 8.5 g. (91%) of 2-hydroxy-3-chloropropyl 2-propanesulfonate boiling at 148—150°C/1.5 mmHg.

Glycidyl Acetate from GMS. — a) A mixture of 3.0 g. (0.02 mol.) of GMS, 1.6 g. (0.02 mol.) of sodium acetate, 0.2 g. of triethylbenzylammonium chloride and 20 ml. of dry toluene was refluxed for 0.5 hr. After the precipitate had been removed by filtration and the toluene had been removed by distillation in vacuo, the fractional distillation of the residue afforded 1.2 g. (50%) of glycidyl acetate (b. p. 71°C/17 mmHg) and 0.8 g. (27%) of GMS.

b) A suspension of 15.2 g. (0.10 mol.) of GMS and 1.6 g. (0.02 mol.) of sodium acetate and 0.2 g. of triethylbenzylammonium chloride was stirred for 0.5 hr. at 110°C. After the precipitate had been removed, the residue was fractionated to give 0.6 g. (26% yield based on the sodium acetate charged) of glycidyl acetate and 12.5 g. of GMS.

c) A suspension of 3.0 g. of GMS and 1.6 g. of sodium acetate in 5.0 g. of water was stirred for 11.5 hr. at

10) S. Zuffanti, *J. Am. Chem. Soc.*, **62**, 1044 (1940).
11) F. Asinger, W. Schmidt and F. Ebeneder, *Ber.*, **75**, 34 (1942).
12) F. Asinger, F. Ebeneder and E. Bock, ibid., **75**, 42 (1942).

room temperature. The reaction mixture was then extracted with ether. After the ether had been removed, the distillation of the residue gave 0.3 g. (13%) of glycidyl acetate boiling at 57—59°C/11 mmHg and 2.0 g. (67%) of GMS.

Glycidyl Methacrylate from GMS.—Glycidyl methacrylate was prepared exactly as was glycidyl acetate, except that sodium methacrylate was treated with GMS in place of sodium acetate. From 2.2 g. of sodium methacrylate and 3.0 g. of GMS, 1.2 g. (42%) of glycidyl methacrylate (b. p. 84—85°C/15 mmHg) (lit.[5] 85°C/15 mmHg) was obtained and 0.8 g. (37%) of GMS was recovered.

4-(2, 3-Epoxypropyl)-morpholine (III).—a) Under occasional cooling with a dry-ice methanol bath in order to maintain the reaction temperature below 30°C, there were mixed 3.0 g. (0.02 mol.) of GMS and 1.7 g. (0.02 mol.) of morpholine. After the initial exothermic reaction had subsided, the reaction mixture was allowed to stand for an hour at room temperature. The infrared spectrum of the mixture showed a hydroxyl band at 3390 cm.$^{-1}$ and sulfonic ester bands at 1350 and 1170 cm.$^{-1}$, but no epoxide bands. The mixture was then treated, with occasional stirring, with a solution of 0.9 g. (0.023 mol.) of sodium hydroxide in 2 ml. of water for 1 hr. at room temperature. The solution was extracted with ether continuously. After the ether had been removed, the fractionation of the residue afforded 2.0 g. (70%) of III boiling at 93—97°C/12 mmHg (lit.[8] 93—95°C/12 mmHg).

b) Into 3.0 g. (0.02 mol.) of GMS in an ice-salt bath there was stirred a solution of 1.7 g. (0.02 mol.) of morpholine and 1.0 g. (0.025 mol.) of sodium hydroxide in 5.0 ml. of water at −5°C. The reaction mixture was then allowed to stand for 0.5 hr. at this temperature. The other treatment was same as that described above. The yield of III was 1.5 g. (53%).

2, 5-Bis-(4-morpholinylmethyl)-1, 4-dixoane (IV).—a) GMS (3.0 g., 0.02 mol.) was mixed with a solution of 1.7 g. (0.02 mol.) of morpholine in 5 ml. of water under moderate cooling in order to maintain the temperature below 30°C. The mixture was allowed to stand for 20 min. at 80°C. The infrared spectrum of the mixture obtained showed sulfonate ion bands at 1200 and 1030 cm^{-1} and a hydroxyl band at 3220 cm^{-1}; it was essentially identical with that reported by Ichikawa.[4] The above mixture was then treated with 0.9 g. (0.023 mol.) of sodium hydroxide at 80°C for 20 min. and extracted continuously with ether. After the ether had been removed, 1.6 g. (56%) of IV was obtained as a crystalline product. It was recrystallized from ether. The melting point of IV was 107—108°C (lit.[8] 108—110°C).

b) IV was also prepared by the reaction of GPS or GTS with morpholine in a manner similar to that used with GMS (see above). The yield was 53% in both cases.

2, 5-Bis-(1-pyrrolidinylmethyl)-1, 4-dioxane (V), 2, 5-Bis-(1-piperidinylmethyl)-1, 4-dioxane (VI), *N*-(2, 3-Epoxypropyl)-*N*,*N*-diethylamine (VII) and 1-(2, 3-Epoxypropyl)-pyrrolidine (VIII).—The reaction of GMS with the secondary amines was carried out in a manner similar to that used for GMS with morpholine (III and IV).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 417—422 (1966)

Thermal and Radiation Oxidations of Benzene to Phenol in Aqueous Solutions Containing Metal Ions at Elevated Temperatures. VII. The Mechanisms of Phenol Formation as Studied by Stable Isotopes*

By Hiroshi HOTTA, Nobutake SUZUKI and Toshihiko ABE

Takasaki Radiation Chemistry Research Establishment, Japan Atomic Energy Research Institute, Takasaki, Gunma

(Received April 21, 1965)

When benzene was oxidized to phenol in an oxygen-18 enriched aqueous solution of iron and copper sulfates, the oxygen-18 was much concentrated to phenol. The oxygen-18 content depended on the kind of metal ion and on the temperature. This suggests that the oxygen in the phenol produced is donated not only by the molecular oxygen, but also by the water. Therefore, it is assumed for the termination process that phenol is formed by the ionic reactions. Furthermore, when an equimolar mixture of benzene and benzene-d_6 was oxidized, the isotope effect of hydrogen, k_H/k_D, as estimated from the isotopic composition of the phenol produced, was about 1.2. This value seems to be small for the hydrogen abstraction reaction of radicals. Therefore, when we compare these results with the other facts reported previously, the main reaction of the propagation process may be supposed to be the abstraction reaction of hydrogen by phenyl peroxide. In this experiment, it was also found that phenol exchanges hydrogen with water. The rate constant of the exchange reaction was estimated by Bateman's equation. The rate constant is the highest in the ferric sulfate solution.

* Partly Presented at the 15th Symposium on Organic Reaction Mechanisms, Nagoya, October, 1964.

The effects of metal ions on the autoxidation of benzene to phenol in aqueous solutions of iron and copper sulfates have previously been studied in our laboratory.[1-6] The present paper will describe the results of the studies which were carried out by using stable isotopes, i. e., oxygen-18 enriched water, benzene-d_6 and deuterium oxide, in order to confirm the reaction scheme hitherto assumed. The reactions in the oxygen-18 enriched water solution other than phenol formation will be discussed in the following paper, also in this Bulletin.

Experimental

Oxidation Procedure.—Benzene was oxidized in oxygen-18 enriched aqueous solutions of ferrous, ferric and cupric sulfates by the following procedure, described in a previous paper.[2] These sulfate solutions were prepared by dissolving 0.01 M of metal ion.[1] Oxygen-18 enriched water (1.63 oxygen-18 atom %) was obtained from the Weizman Institute of Science, Israel.

One cubic centimeter of benzene was put on 15 cc. of the aqueous phase in a hard-glass tube in a 50 cc. stainless-steel reactor under an oxygen pressure of 30 atm. This system was then heated by a controlled procedure and kept 30 min. at a given temperature. When it was irradiated, a dose of about 13000 r. of cobalt-60 gamma rays was given for 25 min. Some related experiments were also carried out under other conditions for the sake of reference.

The Analysis of Oxygen-18 in Phenol.—Phenol was separated into 30 cc. of water after ether extraction from the above aqueous phase. It was precipitated as tribromophenol by adding 50 cc. of a 0.1 N bromide solution, a solution of potassium bromate and potassium bromide, and 10 cc. of 12 N hydrogen chloride. The precipitate was purified by sublimation at 100°C using the suction of an aspirator. The oxygen-18 content was analyzed using a mass spectrometer according to the method of Rittenburg and Ponticorvo.[7]

The Experiment on Benzene-d_6.—In order to study the isotope effect of hydrogen at the above oxidation, benzene-d_6 (Merck Sharp & Dohme of Canada, Ltd.) was mixed with benzene in the ratio, $C_6H_6 : C_6D_6 : C_6HD_5 : C_6H_2D_4 : C_6H_3D_3 : C_6H_4D_2 : C_6H_5D = 100 : 93.7 : 4.1 : 0.4 : 0.4 : 0.1 : 0.1 : 0.0$, according to mass spectrometry.[8] This benzene mixture was then oxidized in the solutions of natural water by the above oxidation procedure. This ratio did not change for the unreacted benzene within the range of experimental error after oxidation in the present degree of conversion.

After the phenol produced, which was extracted into ether by the previous method,[2] had been separated by gas chromatographic fractionation using the column of PEG 6000 at 170°C, the abundance ratio between various deuterated phenols in the product (cf. Table III) was determined from the mass spectrum on the following assumption. That is, the ion abundance ratio between $C_6H_5O^+$, $C_6H_5OH^+$ and $^{12}C_5{}^{13}CH_5OH^+$ for the mass spectrum of phenol is 2.06 : 100 : 6.69. Since the formation of these ions is independent of hydrogens of the benzene ring, the ratio between $i-1$., i and $i+1$'th peaks ($i=m/e$ of parent peak) is assumed to be the same for the mass spectrum of various deuterated phenols.

Benzene was also oxidized in the solution of deuterium oxide (99.75%, Showa Denko Co., Tokyo) by the same procedure.

Results

Oxygen-18 in Phenol.—Since the previous papers[1-6] have shown that the yield of phenol in

the oxidation of benzene depends on the kind of metal ions, the impurities in the benzene, irradiation with gamma rays, and so on, the atom percentage of oxygen-18 in the phenol produced was examined in oxygen-18 enriched aqueous solutions at the various conditions listed in Table I. Experiments 3, 7 and 9 were carried out with gamma-ray irradiation. The purified benzene was used for experiments 4, 10, 11 and 12. The purity of the benzene used for the other experiments was the same as was shown in Table I of Part VI.[6] Two grams of copper pieces were added for experiments 11 and 12. Experiment 13 was carried out in an aqueous solution of 0.001 M cupric sulfate. The significance of these conditions is described in the previous paper referred to the last columm of Table I.

For reference, the aqueous solutions of phenol (0.021 M) were also treated by the same procedure as was used in the benzene oxidation under the pressure of either oxygen or nitrogen (30 atm. at 20°C). The results, shown in Table II, show that the content of oxygen-18 in phenol is not changed by the present procedure.

Therefore, the increase in oxygen-18 in Table I is not due to the exchange reaction of oxygen between water and the phenol produced, but to some reaction in the oxidation process of benzene.

Table II. Atom-% of oxygen-18 in treated phenol

No.	Additive	Temp. °C	Atmosphere[a]	Atom-% of ^{18}O
14	None	180	Oxygen	0.21
15	$FeSO_4$	180	Nitrogen	0.21
16	$Fe_2(SO_4)_3$	180	Nitrogen	0.20
17	$Fe_2(SO_4)_3$	180	Oxygen	0.21

a) 30 atm. at 25°C.

This means that some part of the oxygen in the phenol produced does not come from gaseous oxygen but from water during the phenol formation. The percentage of such oxygen given from water, F_w, is estimated by the equation:

$$F_w=\frac{(x-0.20)}{(1.63-0.20)}\times 100 \qquad \text{(i)}$$

as is shown in Table I, where x is the observed value of the atom percentage of oxygen-18 in phenol.

When the results are compared, it may be concluded that 52±3% of oxygen are transferred from water to phenol at 180°C in an aqueous solution of iron sulfates, regardless of ferrous or ferric sulfate, purification of benzene, and irradiation, and that the corresponding percentage is 33±5% at 200°C in an aqueous solution of cupric sulfate.

When experiments 1 and 13 are compared with others, it may be seen that the value of F_w increases with the temperature and with the concentration of metal ions.

Deuterium Distribution in Phenol.—Under the conditions shown in Table III, the benzene mixed with deuterated benzene was oxidized in natural water (experiments 20—32), while benzene without deuterated benzene was oxidized in deuterium oxide (experiments 23—26). For reference, the solution of phenol in deuterium oxide was also treated by the same procedure as was used for the benzene oxidation.

After experimentation, the abundance ratios between various deuterated phenol were determined as to be shown in Table III by the procedure mentioned above. The ratios in experiments 20—22 are quite different from the original benzene mixture. Such deuterium transfer appears to be independent of the oxidation process of benzene, for it also occurs to a considerable extent in the solution of phenol, as is shown for experiments 27—30. The hydroxyl group of phenol formed in deuterium oxide was changed to OH-group during separation of phenol from the aqueous solution, even if it was OD-group (experiments 23—30).

Discussion

Oxygen of the Hydroxyl Group.—It has been assumed that the present autoxidation of benzene is propagated by the abstraction of the hydrogen atom from benzene (reaction 3) as follows:

$$RO_2 + PhH = RO_2H + Ph\cdot \quad (1)$$

$$Ph\cdot + O_2 = PhO_2 \quad (2)$$

$$PhO_2 + PhH = PhO_2H + Ph\cdot \quad (3)$$

$$PhO_2H + M^+ = PhO\cdot + OH^- + M^{2+} \quad (4)$$

$$PhO_2H + M^{2+} = PhO_2 + H^+ + M^+ \quad (5)$$

$$2PhO_2 = 2PhO\cdot + O_2 \quad (6)$$

where M^+ represents a ferrous or cuprous ion, and M^{2+}, a ferric or cupric ion. The initiation process of the peroxide formation (RO_2) is omitted in the present paper.[4]

However, it is not explained in the above reaction scheme how to form phenol from the phenoxy radicals accumulated. The process for it can be interpreted on the basis of the present finding in Table I, by taking the ionic reaction scheme as follows[9,10]:

$$PhO\cdot + M^+ = PhO^{-}\cdot + M^{2+} \quad (7)$$

$$PhO^{-}\cdot + H^+ = PhOH \quad (8)$$

and

$$PhO_2 + M^{2+} = Ph^{+}\cdot + O_2 + M^+ \quad (9)$$

$$Ph^{+}\cdot + O^*H^- = PhO^*H \quad (10)$$

where O* is the oxygen atom from water. The values of F_w in Table I obtained from Eq. i can be interpreted as the result of the competition between reactions 4 and 7 and reactions 5 and 9.

Benzene is not oxidized to phenol in the cupric sulfate solution, even with irradiation at temperatures lower than 180°C, because cuprous ions are immediately oxidized by oxygen if produced by reaction 5.[3,4] The fact suggests that, in the above reaction scheme, the rate of reaction 9 is extremely slow at the lower temperature, because phenol is not formed by the aid of cupric ions, and because reaction 7, another path of phenol formation, can not occur due to the lack of cuprous ions. On the other hand, a considerable amount of phenol is produced at 200°C.[3,4] Therefore, it may be supposed that the rate of reaction 5 is so fast at 200°C that a larger amount of cuprous ions is produced than is consumed by their oxidation. The low value of F_w in Table I suggests that the rate of reaction 9 becomes significant at 200°C, but that it is not so fast as for iron ion to be discussed below.

Since ferrous ions are not oxidized as quickly as cuprous ions,[1] phenol is produced by reaction 7 in the iron sulfate solutions.[2,4] Since the values of F_w in Table I increase between 150°C and 180°C, the rate of reaction 9 is sure to increase in this temtemperature range. This is consistent with the above assumption that the rate of reaction 9 for cupric ions is very dependent on temperature in the same range. Almost all the iron species are ferrous in solutions after the oxidation of benzene.[2] This accumulation of ferrous species is due to the fast rate of reaction 5 and the slow oxidation of ferrous ions rather than to the fast rate of reaction 9. Phenyl peroxides, accumulated by reactions 3 and 5, might be converted to phenoxy radicals by reaction 6, and then to phenol by reaction 7. Therefore, it may be concluded that phenol is mainly produced by reaction 4—7, not by reaction 9, at least at lower temperatures.

The oxygen-18 content in the phenol produced in Table I, is larger in iron sulfate solutions than in a 0.01 M cupric sulfate solution as well as in a 0.001 M cupric sulfate solution. The concentration of iron species in iron sulfate solutions at 180°C (experiments 2, 3, 4, 6 and 7) is about 0.0002 M due to the precipitation of ferric oxides.[1,2] This means that iron ions are much more reactive than copper ions in the present process, and that the rate of reaction 9 for ferric ions is quite different from that for cupric ions.

Recently, Vysotskaya reported that the phenol which was produced by hydrogen peroxide in the presence of ferrous or ferric ions in oxygen-18 enriched water contained some of oxygen-18.[11] Although this is of much interest in relation to the

present study, it must be noted that phenol is produced through the non-chain process at room temperature, not through the chain process as in the present study.

The Isotope Effect of Hydrogen on Benzene Oxidation.—The isotope effect of hydrogen on the oxidation of deuterated benzene might prove the abstraction reaction of the hydrogen atom from benzene by a free radical (reaction 3), because the reactions above-mentioned scheme are independent of the dueterium atom except reaction 3. For this purpose, since the conversion of benzene is very low in the present study, the rate-constant ratio, k_H/k_D, is estimated for experiments 20—22 in Table III by the equation:

$$\frac{k_H}{k_D}=\frac{(C_6H_5OH)}{(C_6H_6)}\times\frac{\sum_{i=1}^{5}(C_6H_iD_{6-i})}{\sum_{i=1}^{4}(C_6H_iD_{5-i}OH)} \qquad \text{(ii)}$$

Although the isotope effect or the rate-constant ratio, k_H/k_D, is usually larger than the values in Table III, i. e., about 1.2, for the hydrogen abstraction reaction by free radicals, the reactions with the smaller activation energy have the smaller isotope effect.[12] The rate of the autoxidations is mainly controlled by the rate of the abstraction reaction by peroxides, as in reaction 3. However, it is very difficult in the present system to obtain an activation energy which is physically meaningful, due to the complexity of the pre-equilibration between reactants related to the reaction in question. At any rate, the temperature-dependent coefficient apparently corresponds to about 10 kcal./mol. between 150°C and 180°C for the oxidation of purified benzene in the aqueous solution of ferrous sulfate, judging from the result reported previously.[4] The value obtained by Terakawa et al. is 6 kcal./mol.[13] Both values are smaller than the value for the autoxidation of parrafins, 15 kcal./mol.[14]

It is confirmed that the formation of phenol in the aqueous solution of benzene at room temperature, by radiation and the Fenton's reagent, is to be attributed to the addition reaction of the hydroxyl radical.[15,16] On the other hand, the present chain autoxidation of benzene at elevated temperatures cannot be understood by the same mechanisms due to the following facts. a) No ferric ions are reduced in the mechanisms of the Fenton's reagent, but almost all the iron species are ferrous after the present experimentation.[2] Especially, in the presence of oxygen, it is very difficult to see how ferric ions are reduced. b) The yield of phenol increases abruptly above 170°C.[4] This fact cannot be interpreted without assumption of reactions 1 and 3, because the yield of the hydroxyl radical cannot increase like the yield of phenol. c) The effect of the impurities in benzene indicates that the initiation of the present process is not the direct reaction between benzene and hydroxyl radical.[4] Therefore, reaction 1 must be assumed at first for the oxidation of benzene.

The Exchange Reaction of Hydrogen.—As has already been shown in the section on "Results," the isotopic composition of the phenol produced in Table III is quite different from that of the original benzene mixture. This is due to the exchange reaction of hydrogen between phenol and water, which is independent of the oxidation process of benzene.

Phenol makes phenolate with ferric ions, not with ferrous or cupric ions, so phenol is usually analyzed qualitatively as ferric phenolate. It has been reported that phenol in deuterium oxide exchanges the hydrogen atom of *o*- and *p*-positions only and hydroxyl group with water.[17] On the other hand, in Table III, the exchange of the hydrogen atom is extremely high in the ferric sulfate solution (experiments 28—30), and the phenol having more than three deuterium atoms is very little. Therefore, it may be concluded that the formation of a Ph-O-M bond (M=metal ion) induces the hydrogen exchange of the *o*- and *p*-positions electronically.

Since the exchange reaction of hydrogen is consecutive, as in:

$$\underset{(N_1)}{C_6H_5OH}\xrightarrow[k_1]{}\underset{(N_2)}{C_6H_4DOH}\xrightarrow[k_2]{}\underset{(N_3)}{C_6H_3D_2OH}\xrightarrow[k_3]{}\underset{(N_4)}{C_6H_2D_3OH}\xrightarrow[k_4]{} \qquad (11)$$

the rate constant of the exchange reaction for the i'th deuterium atom, k_i, can be estimated by Bateman's equation[18]:

$$N_1=N_{01}e^{-k_1t} \qquad \text{(iii)}$$

$$\frac{N_i}{N_{01}}=\frac{k_1k_2k_3\cdots k_{i-1}}{(k_2-k_1)(k_3-k_1)(k_4-k_1)\cdots(k_i-k_1)}e^{-k_1t}+\frac{k_1k_2k_3\cdots k_{i-1}}{(k_1-k_2)(k_3-k_2)\cdots(k_i-k_2)}e^{-k_2t}+\cdots+\frac{k_1k_2k_3\cdots k_{i-1}}{(k_1-k_i)(k_2-k_i)\cdots(k_{i-1}-k_i)}e^{-k_it} \qquad \text{(iv)}$$

where N_i is the number of phenol molecules attacked by the i'th deuterium atom at time $t=t$, which is N_{01} at $t=0$.

The rate constants shown in Table IV are

estimated for experiments 27—30 by the above equations from the observed values listed in Table III on the assumption that the reaction time, t, is 1800 sec. Since the true time should be longer than this time because of some contribution of the reaction during heating and cooling,[1,2] the corrected rate constants would be faster than the present values. This increase would be ten percent at most. Furthermore, since the sulfate solutions containing benzene or phenol become a ferrous and ferric mixture at elevated temperatures, regardless of whether they are ferrous or ferric originally,[2,5] the true rate should be faster for ferric ions and slower for ferrous ions than the present values. For the cupric sulfate solution, the contribution of cuprous ions can be ignored because of their fast autoxidation.[3]

In comparing the rate constants in Table IV, it can be seen that the first rate constants, k_1, are not very different from the second rate constants, k_2, but are larger than the third rate constants, k_3. However, the accuracy of the third rate constants is the lowest.

The Transfer of the Oxygen Atom of Water in an Aqueous Solution of Iron and Copper Sulfates*

By Nobutake SUZUKI, Hiroshi HOTTA and Hitoshi HASHIMOTO

Takasaki Radiation Chemistry Research Establishment, Japan Atomic Energy Research Institute, Takasaki, Gunma

(Received April 21, 1965)

When an oxygen-18 enriched aqueous solution of ferrous, ferric and cupric sulfates was heated between 130 and 200°C, the oxygen-18 content decreased in the order of $Fe^{II} > Fe^{III} > Cu^{II}$ in water; and it increased in the sulfate group and in the molecular oxygen of the gaseous phase. A transfer of oxygen from water to the sulfate group was also observed, even in a nitrogen atmosphere. The oxygen transfer was promoted in all the cases in the presence of molecular oxygen, and it increased further in the presence of benzene. Since the exchange reaction of oxygen does not occur between water and sulfate ions, the above facts may be attributed to the reactions between water and the thermal decomposition products of the sulfate group, and between water and the hydrogen peroxide produced. The peroxy species, produced by the oxidation of the decomposition products, are more reactive in such a transfer of oxygen, since the reaction is promoted in the presence of oxygen. The peroxides in the autoxidation of benzene seem also to be reactive in it.

The oxidation reaction of benzene to phenol in aqueous solutions of ferrous, ferric and cupric sulfates has previously been studied in our laboratory.[1-3] We showed that some of the oxygen atoms of the phenol produced originated in the water, using oxygen-18 enriched water.[4] In connection with this, the phenomena of the oxygen transfer in the oxygen-18 enriched aqueous solutions of these sulfates, which were studied with and without benzene, will be described in the present paper. Some properies of these solutions, studied without benzene under the same conditions as in the benzene oxidation, had already been reported in a previous paper.[5]

Experimental

Procedure.—The solutions of ferrous, ferric and cupric sulfates were prepared by dissolving 0.01 M of

* Thermal and Radiation Oxidations of Benzene to Phenol in Aqueous Solutions Containing Metal Ions at Elevated Temperatures. VIII.

metal ion in oxygen-18 enriched water (1.63 oxygen-18 atom%) obtained from the Weizman Institute of Science, Israel. These solutions were treated by the same procedure as was used in a previous paper.[5] That is, 15 cc. was put in a hard-glass tube in a 50 cc. stainless-steel reactor at an oxygen pressure of 30 atm. This system was then heated by a controlled heater and kept for 30 min. at a given temperature. Some of the experiments were performed under other conditions (see Table I). For example, experiments 44—47 were carried out at a nitrogen pressure of 30 atm., while 1 cc. of benzene was added for experiments 48—50. The experiments for the cupric sulfate solution were carried out only at 200°C under various conditions; experiment 40 was carried out under the standard condition described above; for experiment 40 the 0.001 M solution was used instead of the 0.01 M solution; experiment 42 was carried out in the presence of copper metal pieces alone[2]; and a 0.1 N sulfuric acid solution of 0.01 M cupric sulfate was used for experiment 43.

Although oxygen-18 7.56-atom-% enriched water was used to measure the change in the oxygen-18 content in the gaseous phase, the value in Table I is corrected as measured in 1.63-atom-% enriched water.

Analytical.—The oxygen-18 content in the water was determined as the atom percentage of oxygen-18 by the mass spectrum of carbon dioxide after equilibration with it by shaking it at 30°C for four hours.[6]

The oxygen-18 content in the sulfate group was also determined by the mass spectrum of carbon dioxide according to the method of Rittenburg and Ponticorvo after it was precipitated as barium sulfate and dried in vacumm for 48 hr.[7,8]

Although the observed values for the original enriched water as the standard fluctuated within ± 0.02 atom %, the decrements after experimentation were in good agreement within ± 0.001 atom% between the different runs. Therefore, the decrements or the differences between the values after and before experimentation are shown in the present paper.

Since the decomposition of the sulfate group must be expected at higher temperatures,[5] its concentration in the solutions after the above procedure was determined roughly as the residual ratio of the sulfate group:

$$R = \frac{(BaSO_4)_{treated}}{(BaSO_4)_{untreated}} \times 100 \qquad (i)$$

where $(BaSO_4)_{untreated}$ and $(BaSO_4)_{treated}$ represent the weights of dry barium sulfate precipitated from 50 cc. of the original and treated solutions respectively.

Results

The Decrements of the Oxygen-18 Atom Percentage in Water.—The results are shown in Table I. The decrements in the ferrous sulfate solution mount with increasing temperature (experiments 31—35). The decrements in the ferric sulfate solution are somewhat smaller than in the ferrous solution. When the solution was irradiated by 13000 r. of cobalt-60 gamma rays,[5] the decrements were nearly the same or a little larger than in the unirradiated solutions (experiments 37 and 39). The decrement in the cupric sulfate solution is smaller than in the iron sulfate solutions.

The results in 0.1 N sulfuric acid solutions are not very different from those in aqueous solutions (experiments 34 and 43); the effect of sulfuric acid is considerable in a nitrogen atmosphere (experiment 47).

The results in Table Ib) show that the decrement is appreciable even in a nitrogen atmosphere, although it is smaller than in an oxygen atmosphere. The results in Table Ic) will be discussed later.

Oxygen-18 in the Sulfate Group.—The increments of the oxygen-18 atom percentage in the sulfate group, less by 0.20 than the observed value, are shown in Table I. They are larger in an oxygen atmosphere than in a nitrogen atmosphere, except in the cupric sulfate solution (experiment 46). The value in the presence of benzene is the largest among experiments 40, 46 and 50.

Iron sulfates are precipitated as ferric oxides at temperatures higher than 150°C in aqueous solutions[5] while few precipitates are found in an aqueous solution of cupric sulfate, even at 200°C. However, the concentration of the sulfate group in the iron sulfate solutions does not decrease so much as iron ions are precipitated, as is shown by the residual ratio of Eq. i in Table I.

Discussion

The results in Table Ib) show that there is some exchange reaction of oxygen between water and the sulfate group, independent of the presence of molecular oxygen. Brodsky and Vysotskaya have suggested the following scheme:

$$-X{=}O + H_2O^* \rightarrow -X\begin{matrix}O^*H\\OH\end{matrix} \rightarrow -X{=}O^* + H_2O \qquad (1)$$

for a similar reaction.[9] Since the exchange of the oxygen atom does not occur between water and sulfate ions,[10] the transfer of oxygen may be supposed to be due to the reaction not with the sulfate ion but with the sulfur trioxide produced by the thermal decomposition of the sulfate group; that is, the reaction may be similarly assumed to be:

$$MSO_4 \rightarrow MO + SO_3 \qquad (2)$$

$$\begin{matrix}O\\O\end{matrix}\!\!>\!S{=}O + H_2O^* \rightarrow \begin{matrix}O\\O\end{matrix}\!\!>\!S\!<\!\begin{matrix}O^*H\\OH\end{matrix} \qquad (3)$$

In fact, the increment of the oxygen-18 content in the sulfate group is larger in experiment 45 than in experiment 46 (in the order of the unstability of sulfates) and larger in experiment 47 than in experiment 46 (in the order of the concentration of the sulfate group). It is also explained by reactions 2 and 3 why the concentration of the sulfate group does not decrease in spite of the precipitation of ferric oxides, as is shown by the residual ratio of Eq. i. However, the result of experiment 44 is still obscure.

When the results in the oxygen and nitrogen atmospheres are compared, it may be seen that the transfer of the oxygen atom from water is promoted in the oxygen atmosphere, although the oxygen atom is not necessarily transferred from water to the sulfate group. Although the thermal decomposition of iron sulfates is independent of the presence of the molecular oxygen,[5] the decomposition products from the sulfate group are oxidized to peroxy acids, which are capable of exchanging oxygen with water, in the presence of oxygen.[11-13]

It has been assumed so far that hydrogen peroxide is formed in the oxygenated solution of iron and copper sulfates, as a result of the reaction:[1,14]

$$O_2 + M^+ = O_2^- + M^{2+} \quad (4)$$

Furthermore, it is known that the oxygen exchange reaction between hydrogen peroxide and water is induced in the presence of iron and copper ions (which are represented by M^+):

$$HOOH + M^+ = MOOH + H^+ \quad (5)$$

$$MOOH + H_2O^* = HOO^*H + MOH \quad (6)$$

and that reaction 6 is also induced by sulfur trioxide.[15,16] The oxygen exchange reaction might also occur between water and sulfur peroxides resulting from the oxidation of the decomposition products, in a manner similar to reaction 6.[10,13] These products, labeled by oxygen-18 as the result of these exchange reactions, namely, the labeled hydrogen peroxide and sulfur peroxides, provide not only the labeled sulfate and molecular oxygen, but also various products containing oxygen-18 which were not detected in the present study. In fact, even in experiment 46, the amount of oxygen-18 transferred from water (0.6 mg.) is fairly large in comparison with that transferred to the sulfate group (0.1 mg.); the amount transferred into gaseous oxygen, in experiment 40, is 0.1 mg. at most.

In summarizing the above discussion, the oxygen transfer reactions from water may be classified

into 1) reaction 3 through the thermal decomposition products of the sulfate group, independent of the presence of molecular oxygen; 2) some reactions through peroxy products from the above decomposition products in the presence of oxygen; and 3) reaction 6 through the formation of hydrogen peroxide.

As was pointed out in the foregoing paper,[4] the concentration of iron species in the solution is about 0.0001 M at 180°C and 200°C as a result of the precipitation of ferric oxides.[5] Although this is much smaller than in experiment 41 (0.001 M $CuSO_4$), the observed value of the decrement of the oxygen-18 content in water is much larger in experiments 33 and 38 than in experiment 41. The efficiency for the decrement is in the order of $Fe^{II} > Fe^{III} > Cu^{II}$. This suggests that the oxidation of metal ion, as well as the decomposition of sulfate, plays an important role in the transfer of the oxygen atom from water.

The Effect of Benzene Oxidation.—The results in Table I c) show that the decrement of the oxygen-18 content in water increases in the presence of benzene by 0.007 atom% at 180°C in either ferrous or ferric sulfate, and by 0.004 atom% at 200°C in cupric sulfate, in addition to the decrement when there is no benzene (Table I a), (experiments 33, 38 and 40), and that the increment of the oxygen-18 content in the sulfate group also increases considerably (experiments 40 and 50).

Since phenyl peroxide and its hydroperoxide are accumulated in the chain process of the benzene oxidation,[4] the above effect may be attributed to some reaction with them. For example, phenyl peroxide and its hydroperoxide might exchange oxygen with water in a manner similar to reaction 6:

$$PhOOM + H_2O^* = PhOO^*H + MOH \qquad (7)$$

When M is sulfur trioxide, it may give the labeled sulfate group or its precursor.

When the results in Table I a) are compared with those in the previous papers,[1-3] it may be seen that a large amount of benzene is oxidized to phenol when the decrement of the oxygen-18 content in water is greater than 0.010 atom% in Table I, independent of the other conditions. This suggests that the initiation process of the benzene oxidation is related to one of the oxygen-transfer process discussed above. Especially, the oxidation of benzene above 180°C in the unirradiated ferric and cupric sulfate solutions is considered to be initiated by the decomposition products of the sulfate group and their peroxides, since such decomposition is confirmed by the present study using oxygen-18. It has been reported that various aromatics, as well as benzene, are oxidized by sulfuric acid[17] and aqueous sulfate[18], which are decomposed to oxidizing reagents.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 425—428 (1966)

The Spectrophotometric Determination of Iron(III) with Methylthymol Blue

By Kôichi TONOSAKI

Department of Chemistry, Faculty of Literature and Science, Hirosaki University, Hirosaki, Aomori

(Received May 13, 1965)

The reaction between iron(III) and methylthymol blue has been studied spectrophotometrically in an attempt to establish the optimum conditions for determining small amounts of iron. Depending on the acidities of a solution, iron(III) reacts with methylthymol blue to form one of two complexes. The 1-to-1 complex, which has its maximum absorbance in the acidity range from 0.07 to 1.00 M with respect to perchloric acid, has an absorption maximum at about 580 mμ against a reagent blank. The 1-to-2 (metal-reagent ratio) complex, which has its maximum absorbance in the pH range from 4.5 to 5.5, has an absorption maximum at about 520 mμ against a reagent blank. With either complex, Beer's law is obeyed over the range from 5 to 50 μg. of iron(III) in 25 ml. of complex. The apparent molar extinction coefficients of the two complexes at their absorption maxima were calculated to be 15000 and 14000 respectively (the former, at 0.08 M HClO; the latter, at pH 5). According to Sandell's notation, the sensitivities of the reactions are 0.004 μg. of iron(III) per cm^2 at 580 mμ and 0.005 μg. of iron(III) per cm^2 at 520 mμ respectively. The effect of diverse ions was examined with a solution containing iron(III) and 25 cations.

* This work was presented at the 12th Annual Meeting of the Japan Society for Analytical Chemistry, Kanazawa, October, 1963.

Methylthymol blue was first prepared by Körbl et al.[1] It has since been widely used as a universal metallochromic indicator in complexometric titrations. The color reaction between this reagent and such metal cations as zirconium(IV),[2,3] yttrium(III),[4] lanthanum(III),[4] mercury(II),[5] thorium(IV),[6,7] and gallium(III)[8] has been studied spectrophotometrically in determining these cations.

It has been found that, depending on the acidity of a solution, iron(III) reacts with methylthymol blue to form two complexes, with metal-ligand ratios of 1 to 1 and 1 to 2, and that these reactions are applicable to the spectrophotometric determination of iron. The proposed metho dis very sensitive; it is comparable in sensitivity with the method using xylenol orange,[9] ferron,[10] hydrazinophthalazine,[11] or salicylaldoxime.[12]

Experimental

Reagents.—*The Standard Ferric Perchlorate Solution.*—This was prepared by dissolving the freshly-precipitated ferric hydroxide in hot 4.5 M perchloric acid and then diluting it with water to make the solution about 0.01 M with respect to iron. The solution was standardized by the complexometric titration[13] using α-pyridyl-β-azonaphthol as an indicator. Working solutions of iron were then prepared by diluting the standard solution with distilled water.

Methylthymol Blue Solution.—A 1×10^{-3} M methylthymol blue solution was prepared by dissolving the Dotite MTB reagent (disodium salt), which was used without further purification, in distilled water.

An acetate buffer solution and nitric acid were used for the adjustment of the pH values. Solutions of diverse ions were prepared by dissolving the respective compounds (all reagent-grade chemicals) in distilled water in appropriate concentrations.

Apparatus.—A Hitachi spectrophotometer, model EPV-2, was employed, with 1 cm. cells for all the absorbance measurements. A Hitachi glass-electrode pH meter, model EHP-1, was employed for all the pH determinations.

Results and Discussion

Absorption Curves.—The absorption curves of the solutions containing iron(III) and methylthymol blue at different acidities are shown in Figs. 1 and 2. These curves were obtained by measuring the absorbance of the colored solutions against a reagent blank which contained the same amount of methylthymol blue.

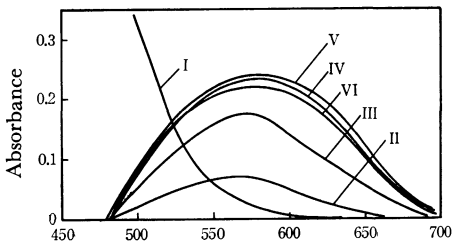

Fig. 1. Absorption curves of methylthymol blue and its iron complex at various acidities.
Iron: 26.8 μg.; MTB: 1.96×10^{-4} M
I: MTB vs. water at pH 0-6; II: Iron complex vs. a reagent blank
$HClO_4$ concn.: II 0.30 M; III 0.20 M; IV 0.15 M; V 0.08 M; VI 0.05 M

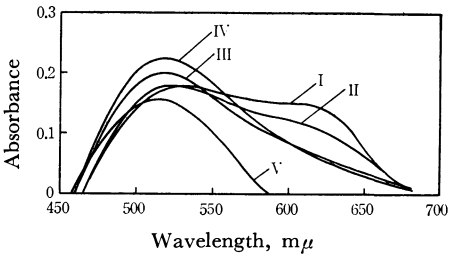

Fig. 2. Absorption curves of the iron-methylthymol blue mixture at various acidities.
Iron: 26.8 μg., Reference: a reagent blank
pH value: I 2.5; II 3.0; III 4.0; IV 4.5—5.5; V 6.5

When the concentration of perchloric acid is 0.05 to 0.20 M, the solutions give essentially identical absorption curves, with an absorption maximum at about 580 mμ. Above pH 2, the position of the maximum absorption shifts toward shorter wavelengths with the increase in the pH value. The curves obtained at pH 2.5 and 3.0 have a shoulder at about 610 mμ. Between pH 3.5 and 6.5, however, the solutions give absorption curves with an absorption maximum at about 520 mμ. Therefore, it may be concluded that, in the presence of an excess of methylthymol blue, two complexes are formed between iron(III) and the reagent.

The Effect of the Acidity.—The effect of the acidity on the absorbance of the solution was examined by measuring, at two wavelengths, 580 and 520 mμ, the absorbance of a solution containing 26.8 μg. of iron and a 5- to 10-fold excess of methylthymol blue. From the curves shown

in Fig. 3, it may be seen that the maximum absorbance is obtained in the acidity range from 0.07 to 0.1 M with respect to perchloric acid when measured at 580 mμ, and in the pH range from 4.5 to 5.5 when measured at 520 mμ.

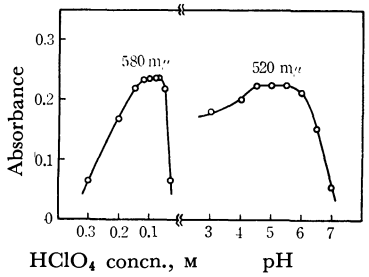

Fig. 3. Effect of acidity.
Iron: 26.8 μg.; MTB: 1.96×10^{-4} M
Reference: a reagent blank

The Stability of the Color.—The color development between iron(III) and the reagent occurs instantaneously at room temperature. The color intensity of the solution remained almost constant for at least 4 hr. after preparation, either at the acidity of 0.08 M or at pH 5.0.

Calibration Curves.—From the foregoing results, two optimum conditions for determining iron were found. The procedure for preparing the calibration curves for iron was as follows: An aliquot of the standard iron(III) solution was pipetted into a 25-ml. volumetric flask. The acidity of the solution was then adjusted to 0.08 M in the final concentration with perchloric acid or to pH 5.0 with an acetate buffer. To the solution, 2.5 to 3.5 ml. of a 1×10^{-3} M methylthymol blue solution was added, and the resulting solution was diluted with water to the mark. After about 30 min., the absorbance of the solution was measured at 580 or 520 mμ against the reagent blank.

The results shown in Fig. 4 indicate that Beer's law is followed by solutions containing up to at least 50 μg. of iron. The sensitivities of the methods

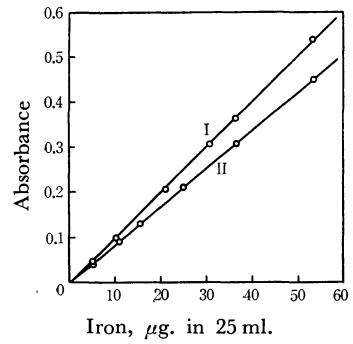

Fig. 4. Calibration curves.
I: MTB 1.15×10^{-4} M; $HClO_4$ 0.08 M; 580 mμ
II: MTB 1.37×10^{-4} M; pH 5.0; 520 mμ

are 0.004 μg. of iron per cm^2 at 580 mμ and 0.005 μg. of iron per cm^2 at 520 mμ.

The Effect of Diverse Ions.—The effect of diverse ions was examined with a solution containing 26.8 μg. of iron and diverse ions. The acid concentration of the solution was adjusted to 0.08 M with perchloric acid. Of the 25 cations tested, such ter- or quadrivalent cations as bismuth, gallium, indium, thallium, thorium, uranium, vanadium, and zirconium gave a positive error, while common divalent cations and some rare earth elements did not interfere. The following anions did not interfere under the conditions described: chloride, nitrate and sulfate up to at least 100 μmol., fluoride up to 5 μmol., tartrate and citrate up to 50 μmol. and phosphate up to 30 μmol. Oxalate, nitrilotriacetate and ethylenediaminetetraacetate, however, inhibit the formation of the complex, even when only trace amounts are present.

The Composition of the Complexes.—*The Complex with an Absorption Maximum at* 580 mμ. —The method described by Frank and Oswalt[14] was applied. This method is effective in the identification of a 1-to-1 complex with a formation constant of less than about 10^4.

An attempt was made with solutions with a given molar concentration of iron at a given perchloric acid concentration, but with varying methylthymol blue concentrations. If only a 1-to-1 complex is formed under the conditions, and if the absorbance of the solution, A, is measured against the reagent blank, the following relationship may be derived:

$$ab/A = (a+b)/(\varepsilon_C - (\varepsilon_O)_H) + 1/(K_1')_H(\varepsilon_C - (\varepsilon_O)_H) \quad (1)$$

where a and b represent the total molar concentration of iron and that of the reagent respectively; ε_C is the molar extinction coefficient of the complex, and $(\varepsilon_O)_H$ is the apparent molar extinction coefficient of the reagent at a given acidity. $(K_1')_H$ is defined as:

$$(K_1')_H = x/(a-x)(b-x) \quad (2)$$

where x represents the equilibrium molar concentration of the complex at a given acidity.

In Fig. 5 ab/A is plotted against $(a+b)$ at 580 mμ. In these solutions, the concentration of iron was 1.92×10^{-5} M, while that of methylthymol blue varied from 1.0×10^{-4} to 1.2×10^{-3} M; the acidity was held constant at 0.02 M with respect to perchloric acid. The good linearity of the plots supports the assumption inherent in Eq. 1, indicating that only a 1-to-1 complex is found under the conditions investigated. The molar extinction coefficient was calculated to be 15000 at 580 mμ, and the value of $(K_1')_H$, to be 8.4×10^3.

14) H. S. Frank and R. L. Oswalt, *J. Am. Chem. Soc.*, **69**, 1321 (1947).

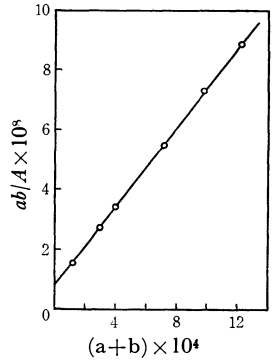

Fig. 5. Plot of ab/A vs. $(a+b)$ at 580 mμ.
a: 1.92×10^{-5} M; b: 1.0×10^{-4}—1.2×10^{-3} M
$HClO_4$: 0.20 M

The Complex with an Absorption Maximum at 520mμ. —The mole ratio of iron to the reagent was confirmed by the mole ratio method at pH 5.5. In this work, each solution was 1.02×10^{-4} M in the total concentration of methylthymol blue. The results are shown in Fig. 6, which indicates that probably a 1-to-2 complex is formed between iron and the reagent. The wavelengths, 540 and 550 mμ, were chosen because the reagent itself has too high an absorbance at 520 mμ. The molar extinction coefficient of this complex was calculated to be about 14000 at 520 mμ.

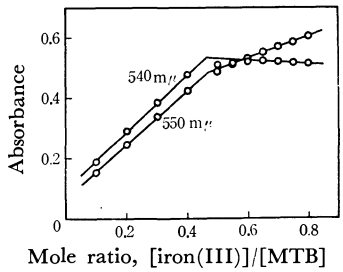

Fig. 6. Mole ratio method.
MTB: 1.02×10^{-4} M, pH: 5.5

The author wishes to thank Mr. Makoto Otomo for his discussion and Mr. Fujio Maeda for his assistance. This investigation was partly supported by a grant from the Ministry of Education.

Studies of Poly-2-vinylpyridine. I. Suspension Polymerization and Molecular Weight Distribution

By Shizuo ARICHI, Seiji MITSUTA, Noriyuki SAKAMOTO and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received May 19, 1965)

2-Vinylpyridine has been polymerized by the suspension method. A stable suspension has been obtained using a mixture of sodium butylnaphthalene sulfonate and gelatine as a stabilizer in the concentration ranges of 0.025—0.75 per cent (for the former) and 0.75—1.0 per cent (for the latter) in water. The molecular weight of polymers thus obtained from this stable suspension system could be controlled by varying the concentration of azo-bis-isobutyronitrile and the temperature. The M_w/M_n ratios of the polymers obtained by the above method are relatively large; from 3.5 to 5. Precipitation fractionation has been carried out for a polymer obtained using ethyl methyl ketone as a solvent and ligroin as a precipitant at a constant temperature. Three kinds of molecular weight distribution curves have been obtained by applying the data of fractionation to (1) Tung's method, (2) exponential-type and (3) logarithmic normal-type molecular weight distribution functions. By comparing the average molecular weights, M_w and M_n calculated from each curve with the experimental values, it was found that the molecular weight distribution of the fraction can be well represented by the function 2 or 3.

Various copolymers[1-4] of 2-vinylpyridine have been extensively studied because of their practical importance. The derivatives of poly-2-vinylpyridine have also fully been investigated from the point of view of polyelectrolytes[5-8] and

polysoaps[9-13] by Fuoss, Strauss and others. One of the present authors has studied this polymer as an emulsifying agent[14] in the polymerization of acrylonitrile in an acidic medium; he has also studied some properties of the aqueous solution of a polysoap[15] derived from poly-2-vinylpyridine. As for poly-2-vinylpyridine itself, however, relatively few investigations have been reported.

It is considered that studies of the polymerization, the fractionation, the relation between the intrinsic viscosity and molecular weight, etc., are important for the practical use of this polymer. In addition, by investigating the solution properties of the polymer, it may be possible to obtain some information about the effect of the polarity of pyridine nitrogen on its solubility and conformation in a solution. Recently, the effect of the tacticity of a polymer on solution behavior has become an interesting subject; data in this field have been collected for many polymers. Isotactic crystalline poly-2-vinylpyridine was first polymerized by Natta and others[16] in 1960 using Grignard's reagent as a catalyst. As both isotactic and atactic poly-2-vinylpyridine are soluble in various solvents at ordinary temperatures, they are considered to be suitable samples for the investigation into the effect of tacticity on the solution properties.

In the present work, the suspension polymerization of 2-vinylpyridine was studied with regard to the effect of the concentrations of the stabilizer and the initiator and to that of the temperature. The results of the study of the molecular weight distribution of the polymer will also be reported here.

Experimental

Materials. — 2-Vinylpyridine monomer (Tokyo Yukigoseikogyo Inc.) was distilled immediately before use under a vacuum with a 100-cm. jacketed column containing Podvielniak single-turn helix packing. A middle portion (b. p. 71°C/32 mmHg) was used for polymerization. All the solvents were purified by the usual procedure. Sodium butylnaphthalene sulfonate (Pelex-NBK, Kao Sekken Inc.) was purified by recrystallization.

Polymerization.—2-Vinylpyridine was polymerized in a sealed glass ampoule under a nitrogen atmosphere by the suspension method. Gelatine and Pelex-NBK were used as stabilizers, and azo-bis-isobutyronitrile (AIBN), as an initiator. An aqueous solution of gelatine and Pelex-NBK and a monomer in which AIBN had been dissolved under cooling were introduced in an ampoule successively. The ampoule was then cooled with a mixture of dry ice and acetone, and the air was replaced by a nitrogen atomsphere. After the ampoule had been sealed, polymerization was performed in a water bath with stirring by the revolution of the ampoule. After the required time, the polymerization was stopped by pouring the suspension into a large amount of water. The supernatant liquid was decanted off after most of polymer particles had precipitated. The particles were washed at least four times with hot water on a No. 2 sintered glass filter.

Intrinsic Viscosity.—A modified Ubbelohde-type viscometer was used for the measurement of the viscosity. The flow time for 92.01 weight per cent ethanol varied from 120 to 300 sec. according to the viscometer used. All the solutions were filtered through a No. 3 sintered glass filter immediately before measurement and were successively diluted in the viscometer. The initial concentration was determined by a weighing method. The intrinsic viscosity $[\eta]$, was obtained according to Eq. 1:

$$\eta_{sp}/c = [\eta] + k'[\eta]^2 c \qquad (1)$$

where η_{sp} is the specific viscosity; c, the concentration of the polymer in g./100 ml., and k', Huggins' constant.

Osmotic Pressure.—The osmotic pressure was measured statically with a Zimm-Myerson-type osmometer (Shibayama Rikagaku Kikai Seizosho) at 25± 0.003°C. Gel cellophane No. 300 (Tokyo Serohanshi Inc.) was used as the membrane after the usual treatment. The leakage of low-molecular-weight polymer through the membrane could not be prevented because all the samples were unfractionated polymers. Thus, the pressure decreased slowly and linearly after the attainment of an apparent equilibrium. Consequently, the measurement was carried on for 5 or 6 days, employing the method of extrapolation to zero time. The number-average molecular weight, M_n, was obtained according to Eq. 2:

$$\pi/c = \boldsymbol{R}T(1/M_n + A_2 c) \qquad (2)$$

where π is the osmotic pressure; $\boldsymbol{R}$, the gas constant; T, the absolute temperature, and A_2, the second virial coefficient.

Light Scattering.—Light scattering was measured with a Brice-type microphotometer (Shimadzu Seisakusho Inc.) with unpolarized and monochromatized incident light (436 mμ) and using the dissymmetry method. The refractive index increment was measured with a Debye-type instrument (Shimadzu Seisakusho Inc.). Data were arranged according to Eq. 3:

$$Kc/R_\theta = 1/\{M_w P(\theta)\} + 2A_2 c \qquad (3)$$

where $K = 2\pi^2 n_0^2 (\mathrm{d}n/\mathrm{d}c)^2/(\lambda^4 \boldsymbol{N})$

and where n_0 is the refractive index of solvent: $\mathrm{d}n/\mathrm{d}c$, the refractive index increment; λ, the wavelength of incident light; $\boldsymbol{N}$, the Avogadro number; R_θ, the reduced intensity of scattered light at an angle of θ, and $1/P(\theta)$, the dissymmetry correction. $[Kc/R_\theta]_0$ was obtained by the extrapolation of the linear line obtained by plotting Kc/R_θ versus c, while $1/P(90)$ was obtained from the dissymmetry, $z=[Kc/R_{135}]_0/[Kc/R_{45}]_0$, using the table

of Doty and Steiner[17] for the unfractionated polymers. The instrument was calibrated with benzene which had been purified by three recrystallizations and distillations, using $R_{90}=48.5\times10^{-6}$ (436 mμ).[18]

Fractionation.—The fractional precipitation method was used. Ethyl methyl ketone and ligroin were used as a pair, as a solvent and a precipitant. The polymer solution (of 1 or 2 weight per cent) was poured into a heart-type flask, and then ligroin was added slowly while the solution was stirred vigorously at 30°C. After the appearance of a proper turbidity, stirring was still continued for 1 or 2 more hours; then the system was allowed to stand overnight. The gel thus obtained was separated from the supernatant liquid by decantation. A solid polymer was obtained by pouring excessive petroleum ether into the gel. The product was washed with petroleum ether and dried in a vacuum dryer.

Results and Discussion

The Effect of Concentrations of Gelatine and Pelex-NBK on the Stability of the Suspension.—The effect of concentrations of gelatine and Pelex-NBK on the stability of the suspension was investigated with a 20 ml. ampoule scale. The polymerization conditions were as follows: water, 10 g.; monomer, 5 g.; AIBN, 0.1 g.; temperature, 45°C and revolution velocity of ampoule, 40 r. p. m. while the concentrations of gelatine and Pelex-NBK varied. After 5 hours' polymerization, the states of suspension were observed and the diameter of particles was measured with a microscope.

Neither gelatine and Pelex-NBK, when used separately, had any dispersion power up to the concentrations of 2.0 and 0.5 weight per cent respectively in water. Even when they were used as a mixture, the stability of the suspension was poor, regardless of the concentration of gelatine, until the concentration of Pelex-NBK was 0.02 per cent. When the concentrations of gelatine and Pelex-NBK exceeded 0.75 and 0.025 per cent respectively, however, the suspension became very stable; the stability showed no remarkable change with the concentrations of gelatine and Pelex-NBK until they were 1 and 0.75 per cent respectively. However, the size of the particle became smaller and the polydispersity decreased wtih the increase in the concentration of gelatine at a constant concentration of Pelex-NBK.

The diameter of most particles was smaller than ca. 0.2 mm. There was also a small amount of very fine particles.

The Effect of the Concentration of AIBN and of the Temperature on the Conversion and the Intrinsic Viscosity of the Polymer.—The polymerization for the preparation of samples was performed in a 400 ml. ampoule. The conditions were as follows; the weight ratio of water to the monomer was 2 : 1; the concentrations of gelatine and Pelex-NBK were 0.75 and 0.025 weight per cent in water respectively; the revolution velocity of ampoule was 40 r.p.m., and the concentrations of AIBN and the temperature varied. The intrinsic viscosity of the polymer solutions in 92.01 weight per cent ethanol was measured at 25±0.01°C.

The results of polymerization are shown in Table I. As may be seen in this table, the conversion is sufficiently high in most cases. When we denote the concentration of AIBN as p (weight per cent with respect to the monomer), the relation between $p^{-1/2}$ and $[\eta]$ at each temperature is

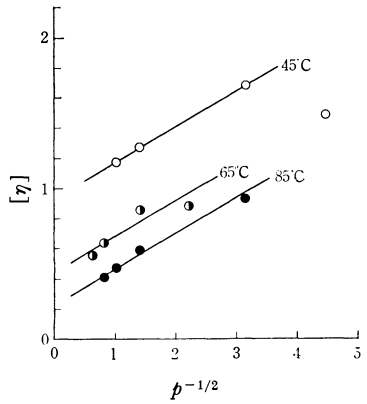

Fig. 1. Effect of AIBN concentration, p (weight per cent with respect to monomer), on the intrinsic viscosity of poly-2-vinylpyridine at constant temperature indicated.

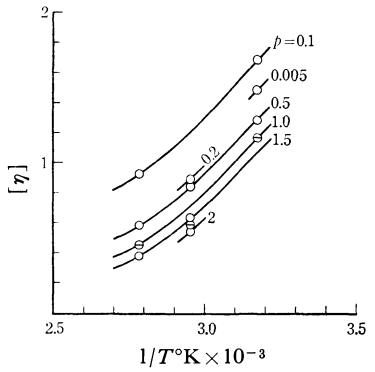

Fig. 2. Effect of temperature on the intrinsic viscosity of poly-2-vinylpyridine at constant concentration of AIBN indicated.

linear except at a very low concentration of catalyst, as may be seen in Fig. 1.

The relation between $1/T°K$ and $[\eta]$ at a constant concentration of AIBN is shown in Fig. 2. The temperature dependence of $[\eta]$ seems to be nearly the same for all the concentrations of AIBN studied. It is apparent that, in the present method of suspension polymerization, it is possible to control the molecular weight of the polymer by varying the concentration of AIBN and the temperature.

The Weight-average and Number-average Molecular Weight of the Polymer.—The M_w and M_n values of several samples were determined by measuring the light scattering of the polymer in methanol and the osmotic pressure of the polymer solution in ethyl methyl ketone respectively. The results are shown in Figs. 3 and 4 and are summarized in Table I. The values of M_w/M_n given in column 9 of the table show that the width of the molecular weight distribution of the polymers is quite large, but the values do not vary very much with polymerization conditions.

In Fig. 5 the intrinsic viscosity in 92.01 weight per cent ethanol is plotted against the M_w and M_n values in double logarithmic scales. Sufficiently exact information has been obtained on the relation between the intrinsic viscosity and the molecular weight of the polymer obtained under the experimental conditions described. The results on the fractionated polymers will be reported in Part III.[19]

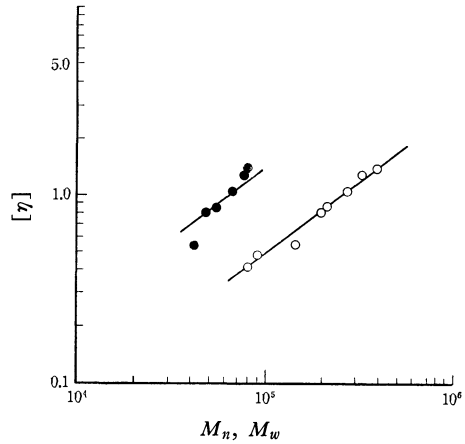

Fig. 5. Log-log plots of $[\eta]$ vs. M_n (-●-) and of $[\eta]$ vs. M_w (-○-) in 92.01 weight per cent ethanol at 25°C for unfractionated poly-2-vinylpyridine.

Results of Fractionation.—Unfractionated poly-2-vinylpyridine (No. 6 listed in Table I) was chosen as the sample for the measurement of the molecular weight distribution. Using the method described previously, 61.6 g. of this polymer was fractionated into five fractions; each of the first four fractions was refractionated into eight or ten subfractions, and the intrinsic viscosity was measured in 92.01 weight per cent ethanol at 25±0.01°C. The results of fractionation are shown in Table II.

The Molecular Weight Distribution (MWD) Curve.—Three kinds of MWD curves were obtained by applying the data in Table II to (1) Tung's method,[20] which is a modification of Schulz',[21] (2) exponential-type[22] and (3) logarithmic normal-type MWD functions[23] respectively.

Schulz-Tung's Method.—According to Tung,[20] the S-shape integral distribution, $I(M)$, was assumed to be given by:

$$I(M) = 1-\exp(-aM^b) \quad (4)$$

If $\log[1/\{1-I(M)\}]$ is plotted against M on a double logarithmic paper, the plots will fall on a straight line with a slope of b and an intercept of $\log(a\log e)$. The differential weight distribution function, $w(M)$, can be obtained from Eq. 4 as follows:

$$w(M) = \mathrm{d}I(M)/\mathrm{d}M = ab\exp(-aM^b)M^{b-1} \quad (5)$$

When the molecular weight, M, is replaced by the intrinsic viscosity, the constants a and b are

21) G. V. Schulz and A. Dinglinger, *Z. physik. Chem.*, **B43**, 47 (1939).
22) G. V. Schulz, ibid., **B30**, 379 (1935); B. H. Zimm, *J. Chem. Phys.*, **16**, 1099 (1948).
23) R. Koningsveld and C. A. F. Tuijnman, *J. Polymer Sci.*, **39**, 445 (1959).

replaced by a' and b'; the relations among them are given[24] by:

$$a' = aK'^{-b/\nu}, \quad b' = b/\nu$$

where K' and ν are the constants in the Mark-Houwink equation, $[\eta]=K'M^{\nu}$.

The Tung plot is shown in Fig. 6. The values of a' and b' obtained from this figure are 0.532 and 1.60 respectively. As will be shown in Part III,[19] the Mark-Houwink equation with fractionated poly-2-vinylpyridine in 92.01 weight per cent ethanol at 25±0.01°C is expressed by $[\eta]=1.22\times10^{-4}M_w^{0.73}$. Using this equation and the values of a' and b' obtained above, the values of a and b are calculated to be 2.95×10^{-7} and 1.17 respectively. The calculated $w(M)$ value is shown in Fig. 7 by curve I.

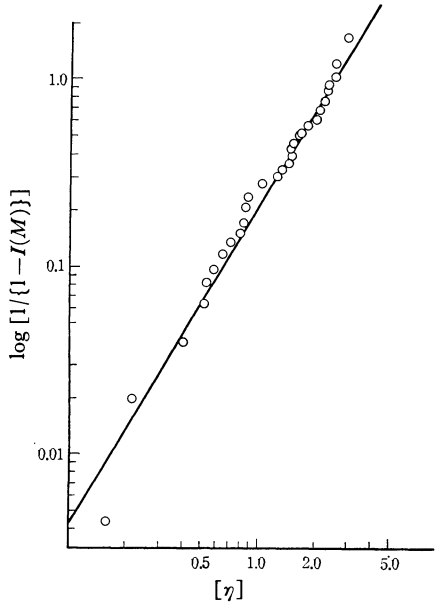

Fig. 6. Fractionation data for poly-2-vinylpyridine (sample, No. 6) arranged by Tung's method.

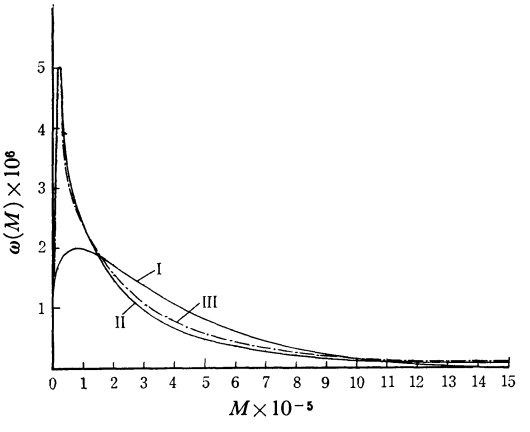

Fig. 7. Differential weight distribution curves of poly-2-vinylpyridine (sample, No. 6).
I Tung's method, II Exponential type, III Logarithmic normal type

The Exponential-type MWD Curve.—The MWD function proposed by Schulz and Zimm[22] and treated by the statistical method of Booth and Beason[25] is expressed by Eqs. 6 and 7:

$$w_i(M)=\{Y_i^{h_i+1}/\Gamma(h_i+1)\}M^{h_i}\exp(-Y_iM) \quad (6)$$

$$w(M)=\sum w_i(M) \quad (7)$$

where $w_i(M)$ and $w(M)$ are differential MWD functions of the ith fraction and the original polymer respectively. Parameters Y_i and h_i are related by Eq. 8 to the molecular weights, M_{wi} and M_{ni} of the ith fraction:

$$Y_i = h_i/M_{ni} = (h_i+1)/M_{wi} \quad (8)$$

In this work, these parameters for each fraction were calculated from the values of M_{wi} and M_{ni} which had been obtained from the Mark-Houwink equation for M_w described above and that for M_n[19]; $[\eta]=2.13\times10^{-4}M_n^{0.73}$. The result for MWD is shown by the curve II in Fig. 7.

The Logarithmic Normal-type MWD Curve.—The logarithmic normal distribution function proposed by Koningsveld and Tuijinman[23] is expressed by Eq. 9:

$$w_i(M) = MA_i\exp\{-p_i^2(\ln M/M_{oi})^2\} \quad (9)$$

where $w_i(M)$ is the differential weight distribution function of the ith fraction and A_i, a parameter normalizing the function to a desired total number of weight; p_i, a parameter related to the width of the distribution; and M_{oi}, the molecular weight at which the function reaches its maximum value. The values of A_i, p_i and M_{oi} can be calculated by the following equations, using the average molecular weights, M_{wi} and M_{ni}, of the ith fraction:

$$A_i = (W_i/M_{wi}M_{ni})\exp(-1/p_i^2)(\pi^{1/2}/p_i) \quad (10)$$

$$M_{wi}/Mn_i = \exp(1/2p_i^2) \quad (11)$$

$$M_{oi} = M_{wi}/\exp(5/4p_i^2) \quad (12)$$

In this work these parameters were again obtained from the values of M_{wi} and M_{ni} which were calculated from the intrinsic viscosity of each fraction. The value of $w(M)$ for the original sample can be calculated by Eq. 13:

$$w(M) = \sum w_i(M) \quad (13)$$

The MWD curve thus obtained is shown by the curve III in Fig. 7.

An Examination of the MWD Curves.—As may be seen in Fig. 7, the MWD curves, II and III, closely resemble each other. Each of them has a maximum at a very low molecular weight and a characteristic long tail in the higher

TABLE III. COMPARISON OF $[\eta]$, M_w AND M_n OF UNFRACTIONATED POLY-2-VINYLPYRIDINE (SAMPLE NO. 6)

	Obs.	Calcd. From data of each fraction	Calcd. From MWD curve I	Calcd. From MWD curve II	Calcd. From MWD curve III
$[\eta]$	1.29	$\frac{\sum W_i[\eta]_i}{\sum W_i}=1.33$	1.33	—	—
$M_w\times10^{-4}$	32.40	$\frac{\sum W_iM_{wi}}{\sum W_i}=34.8$	36.9	29.7	31.3
$M_n\times10^{-4}$	7.73	$\frac{\sum W_i}{\sum(W_i/W_{ni})}=6.7$	11.1	7.6	8.1
M_w/M_n	4.2	5.2	3.3	3.9	3.9

molecular weight range. In contrast to these, the curve I has a lower maximum of $w(M)$ at a higher molecular weight.

To examine the validity of these MWD curves, the M_w, M_n and $[\eta]$ values of the original polymer were calculated from these curves and compared with the experimental values. In the case of Tung's treatment, the values of M_w and $[\eta]$ were calculated by Eqs. 14 and 15[24]:

$$[\eta] = a'^{-1/b'}\Gamma(1+1/b') \tag{14}$$

$$M_w = a^{-1/b}\Gamma(1+1/b) \tag{15}$$

The results are shown in Table III. The values cited in column 3 of this table were calculated by means of the equations in the same column, using the weight, W_i; the intrinsic viscosity, $[\eta]_i$, and the molecular weights, M_{wi} and M_{ni}, which were obtained from $[\eta]_i$. From these values the Mark-Houwink equations described above have been proved to be applicable to the fractions in this study.

In Table III it is noticeable that the values of M_w and M_n from the exponential-type MWD curve, II, and those from the logarithmic normal-type one, III, are in good agreement with the experimental values. On the other hand, those from Tung's method, I, are considerably larger than the experimental values. These results show that the MWD of each fraction is well represented by the above two functions; they also show that the overlapping of various molecular weights in each fraction can not be neglected in reality. These results resemble closely those for isotactic polypropyrene reported by Kotera and others.[26]

Studies of Poly-2-vinylpyridine. II. Solubilities in Various Solvents

By Shizuo ARICHI, Hiroatsu MATSUURA, Yoshio TANIMOTO and Hiromu MURATA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received May 19, 1965)

The viscosity and osmotic pressure of a fraction of poly-2-vinylpyridine have been measured in various solvents, and the parameters concerning the solubility of this polymer, that is, the osmotic second virial coefficient, A_2, the polymer-solvent interaction parameter, μ, and the solubility parameter, δ_2, have been obtained. From the values of these parameters, the following conclusions have been obtained: poly-2-vinylpyridine has a solubility parameter of ca. 10.4 $(\text{cal./cc.})^{1/2}$ and acts as an electron donor. As a result of the specific interaction between a solvent and the pyridine nitrogen of this polymer, the solvent power is greater in an acidic solvent and smaller in a basic than would be expected from the solubility parameter alone. An especially strong interaction between poly-2-vinylpyridine and aliphatic alcohols, chloroform and nitroethane has been observed and its nature has been discussed.

The interaction between a polymer and a solvent is the very important factor which influences the behavior of the polymer in solution.[1,2] The nitrogen atom which is situated at the α-position of pyridine ring of poly-2-vinylpyridine has a lone

2) H. Daoust and M. Rinfret, ibid., **7**, 11 (1952).

electron-pair and, consequently, shows a fairly strong basic character. The solubilities of this polymer in various solvents are much influenced by the basicity and the structural position of nitrogen. In the present study, the viscosity and osmotic pressure of a fraction of poly-2-vinylpyridine was measured in various solvents, and the nature of the polymer-solvent interaction will be discussed using the various solubility parameters obtained by these measurements.

Experimental

Polymer.—A fraction of poly-2-vinylpyridine, our sample number H-2, was used for this investigation. The procedure of the polymerization of this polymer has been described in Part I,[3] while that of the fractionation will be given in Part III.[4]

Solvents.—The solvents used were treated by the usual procedure and distilled before use.

The Viscosity and the Osmotic Pressure.—All parts of the apparatus and all procedures for the measurement of the viscosity and the osmotic pressure were the same as in Part I.[3] In order to measure the intrinsic viscosity of one fraction in various solvents, many viscometers with capillaries of different diameters were used; the correction of kinetic energy could be neglected. The osmotic pressure was measured by the static method with a gel cellophane membrane No. 300.

Results and Discussion

Huggins' Polymer-Solvent Interaction Parameter.—According to Huggins,[5] the partial molar free energy of dilution, ΔF_1, is given by the expression:

$$\Delta F_1 = \boldsymbol{R}T\{\ln(1-v_2) + (1-1/x)v^2 + \mu v_2^2\} \quad (1)$$

where v_2 is the volume fraction of the polymer; x, the ratio of the molar volume of polymer to that of solvent, and μ, a polymer-solvent interaction parameter which is independent of the molecular weight and the concentration of the polymer. The μ value is related to the osmotic second virial coefficient, A_2, by the following equation[6]:

$$A_2 = \bar{v}_2^2/\boldsymbol{N}V_1'(1/2-\mu) \quad (2)$$

where $\bar{v}_2$ is the specific volume of the polymer; $\boldsymbol{N}$, the Avogadro number, and V_1', the molecular volume of the solvent.

The results of osmotic pressure measurements of the H-2 fraction in ethanol, methanol, isopropanol, benzene and ethyl methyl ketone at 25±0.003°C are shown in Fig. 1. The relation between the π/c and c values in each solvent is shown by a linear line, from the slope of which the values of A_2 and μ were calculated by using

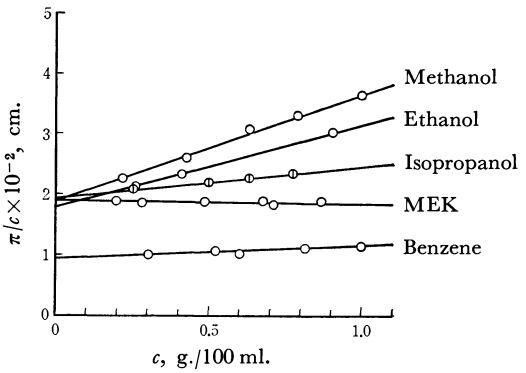

Fig. 1. Plots of reduced osmotic pressure vs. concentration of poly-2-vinylpyridine (fraction H-2) in various solvents at 25°C.

Eq. 2. As for the value of $\bar{v}_2$, the observed value of 0.856 ml./g. was used. The value of π/c in a benzene solution is small over the whole range of concentration. From the observed value of the intrinsic viscosity in benzene, this abnormality of π/c is considered to be caused by the leak of solute molecules through the membrane, and not by such an abnormality of the molecular dispersion state as association[7] in solution. The leak of solute molecules, however, may not influence the value of A_2 very much.[8] The values of A_2 and μ are shown in columns 4 and 5 of Table I.

The value of μ can also be evaluated from the data of the intrinsic viscosity.[9] From the theory of Flory and Fox,[10,11] the relation between the intrinsic viscosity $[\eta]$ in a solvent and the $[\eta]_\theta$ value in a θ-solvent is expressed by Eq. 3 for a homogeneous fraction of the polymer:

$$[\eta] = [\eta]_\theta \alpha^3 \quad (3)$$

where α is the viscosity expansion factor, which can be expressed by Eq. 4:

$$\alpha^5 - \alpha^3 = 2C_m(1/2-\mu)M^{1/2} \quad (4)$$

where C_m is a constant which depends on the specific volume of the polymer, $\bar{v}_2$, and on the molar volume of solvent, V_1; it can be expressed by: $C_m = (27/2^{5/2}\pi^{3/2})(\bar{v}_2^2/\boldsymbol{N}V_1)(\langle L^2\rangle_0/M)^{-3/2}$, where $\langle L^2\rangle_0$ is the mean-square displacement length of the chain in a θ-solvent. By rearranging Eqs. 3 and 4, the following equation can be obtained:

$$(1/2-\mu) = (V_1/2C_m'\Phi_0 M)([\eta]^{5/3}/[\eta]_\theta^{2/3} - [\eta]) \quad (5)$$

where C_m' is a constant expressed by $(27/2^{5/2}\pi^{3/2})(\bar{v}_2^2/\boldsymbol{N})$ and Φ_0, a universal constant.

a) Our sample number, H-2.
b) The values from measurement of osmotic pressure, Eq. 2.
c) The values from measurement of viscosity, Eq. 5.
d) The values of δ_1 are taken from Hildebrand and Scott[14] for most of the solvents and are calculated with the aid of Hildebrand's rule[14] for the rest.

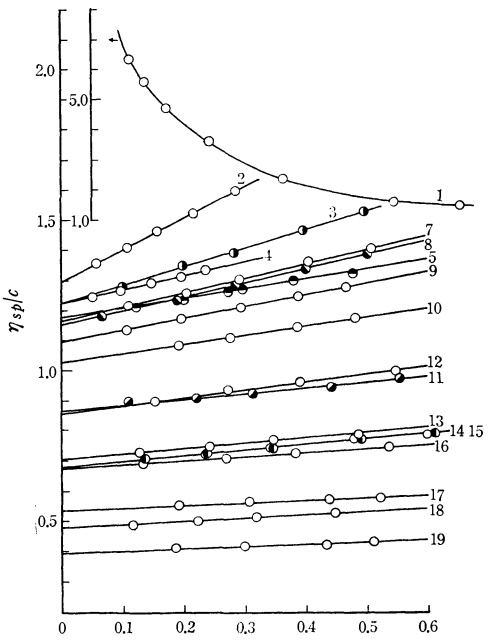

Fig. 2. Plots of reduced viscosity vs. concentration of poly-2-vinylpyridine (fraction H-2) in various solvents at 25°C. The number on each line corresponds to that of solvent cited in Table I.

The value of μ was evaluated by Eq. 5. The results of the viscosity measurements of the H-2 fraction in various solvents at 25±0.01°C are shown in Fig. 2 and are listed in Table I. The value of $[\eta]_\theta$ was evaluated by the following equation of Krigbaum[12]:

$$[\eta] = [\eta]_\theta + 5.0 \times 10^{-3} A_2 M \qquad (6)$$

The values of A_2 and $[\eta]$ are plotted in Fig. 3,

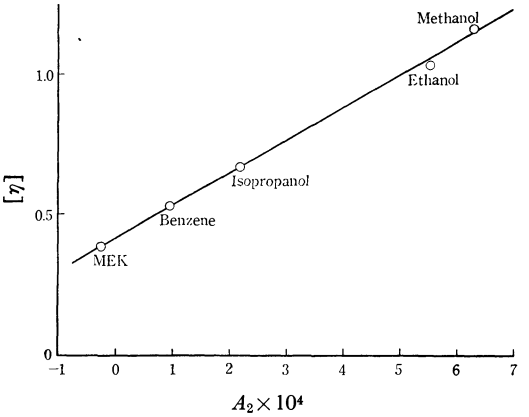

Fig. 3. Plots of intrinsic viscosity vs. osmotic second virial coefficient of poly-2-vinylpyridine (fraction H-2) in various solvents at 25°C.

12) W. R. Krigbaum, *J. Polymer Sci.*, **28**, 213 (1958).

from which the value of $[\eta]_\theta$ can be found to be 0.415. The measurement of the molecular weight, $M_w(30.08\times10^4)$, of this polymer will be described in Part III.[4] The values of μ in various solvents, which were calculated by inserting these data in Eq. 5, are shown in column 6 of Table I.

The values of the intrinsic viscosities, the osmotic second virial coefficients and the interaction parameters cited in Table I show that Lewis bases such as ethyl methyl ketone and dioxane and neutral solvents such as benzene are poor solvents, while Lewis acids such as nitroethane, chloroform and aliphatic alcohols are good solvents.

The Cohesive Energy Density of Poly-2-vinylpyridine.—According to the theory of Huggins,[13] μ can be divided into the term of entropy, μ_s, and that of the heat of mixing, μ_h:

$$\mu = \mu_s + \mu_h \tag{7}$$

When the contribution of μ_h is endothermic, it is related to the solubility parameters of the solvent, δ_1, and to that of the polymer, δ_2, as follows[14]:

$$\mu_h = V_1/\boldsymbol{R}T(\delta_1-\delta_2)^2 \tag{8}$$

where δ_1 and δ_2 are the square roots of the cohesive energy densities of the solvent and the polymer respectively. Equation 8 shows that the closer the value of δ_2 gets to δ_1, the stronger the solvent power becomes. Therefore, δ_2 is a useful key in selecting the solvent for the polymer.[15]

The method for evaluating the δ_2 value for the linear polymer has also been proposed by Bristow and Watson,[16] who obtained the following equation by combining Eqs. 7 and 8:

$$\delta_1^2/\boldsymbol{R}T = \mu/V_1$$
$$= 2(\delta_2/\boldsymbol{R}T)\delta_1 - (\delta_2^2/\boldsymbol{R}T+\mu_s/V_1) \tag{9}$$

$(\delta_1^2/\boldsymbol{R}T-\mu/V_1)$ was plotted against δ_1 in Fig. 4 using the values of μ and δ_1 cited in columns 6 and 7 of Table I. The value of δ_2 evaluated from the slope of the line and that evaluated from the intercept at the ordinate, neglecting the term of μ_s/V_1 are 10.4 and 10.5 $(\text{cal./cc.})^{1/2}$ respectively.

In principle Eq. 8 should be applied to the system in which the heat of mixing, μ_h, is only endothermic. If this is the case for poly-2-vinylpyridine-solvents systems, the solvent which has a value of δ_1 closer to 10.4 $(\text{cal./cc.})^{1/2}$ should have a stronger solvent power. Consequently, the intrinsic viscosities in such solvents must be large.

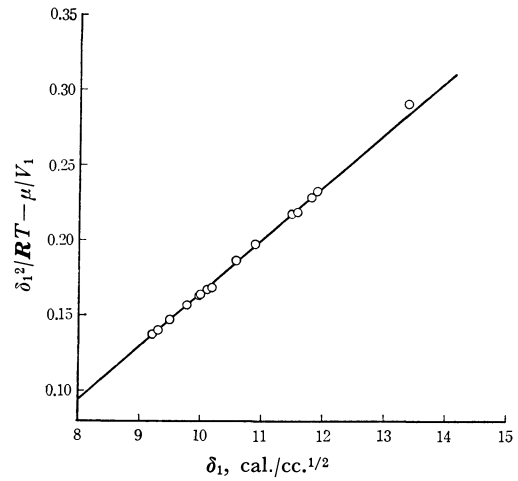

Fig. 4. Plots of $(\delta_1^2/\boldsymbol{R}T-\mu/V_1)$ vs. solubility paremeter of solvents for poly-2-vinylpyridine (fraction H-2).

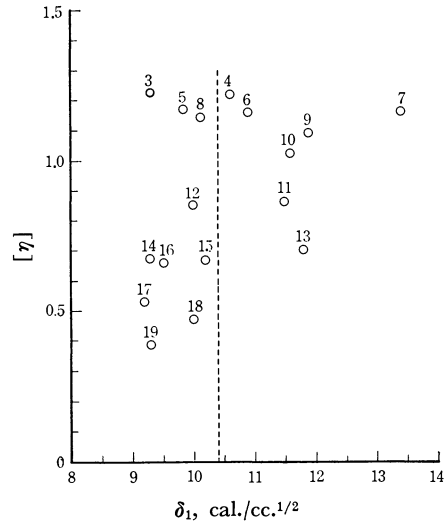

Fig. 5. Plots of intrinsic viscosity vs. solubility parameter of solvents for poly-2-vinylpyridine (fraction H-2). The number on each point corresponds to that of solvent cited in Table I.

In Fig. 5 the intrinsic viscosities in Table I are plotted against the δ_1 values of the corresponding solvents. From this figure no clear correlation can be seen between $[\eta]$ and δ_1. Thus, it may be considered that there exists some exothermic interaction between poly-2-vinylpyridine and some solvents.

Interaction between Poly-2-vinylpyridine and Solvents.—The nature of the specific interaction between poly-2-vinylpyridine and solvents described above was investigated from the viewpoint of Spurlin.[17] The nitrogen atom at the α-position of the pyridine ring has a lone electron-pair and acts as an electron donor, and so poly-2-vinylpyridine is quite a strong base. When a solvent is a Lewis acid or can act as an electron acceptor, its solvent power with regard to the

polymer may be increased because of solvation.

A typical example of such solvents is alcohols. As may be seen in Table I, it is remarkable that all the intrinsic viscosities of the polymer in various aliphatic alcohols are quite high except that in isopropanol. The intrinsic viscosities in methanol, ethanol and *n*-propanol are much higher than those which would be predicted on the basis of their solubility parameters alone. It is known that the lower aliphatic alcohol can act as a Lewis acid.[18,19] Alcohols, as a result, may be solvated to pyridine nitrogen, probably through the hydrogen bond.

The intrinsic viscosity of the H-2 fraction in chloroform, which has an acidic hydrogen atom, is also much higher than that which would be predicted on the basis of its solubility parameter alone. In contrast to this, carbon tetrachloride, which has no hydrogen atom, is nonsolvent of poly-2-vinylpyridine. These facts may be explained by the solvation of chloroform through hydrogen bonding to the polymer. A similar effect of solvated chloroform on the intrinsic viscosity was reported for polymethyl methacrylate.[20]

The existence of the hydrogen bond between the pyridine nitrogen in the polymer and alcohol or chloroform was supported by the following experiments. When the precipitant, *n*-hexane, was added to a poly-2-vinylpyridine solution in isopropanol or chloroform, and also when water was added to the solution in methanol, the lower the temperature, the larger the volume of the precipitant required for the first appearance of turbidity, as may be seen in Table II. Furthermore, the turbid solution thus produced became clear when it was cooled while this clear solution again became cloudy when heated. Obviously the temperature coefficient of the solubility of this polymer in these mixed solvents is negative; this may lead us to the conclusion that the polymer forms a hydrogen bond with the alcohol and chloroform.

Table II. Precipitation measurement of poly-2-vinylpyridine solution[a]

Solvent	Isopropanol		Methanol		Chloroform	
Precipitant	*n*-Hexane		Water		*n*-Hexane	
	Temp. °C	φ[b]	Temp. °C	φ[b]	Temp. °C	φ[b]
	20	40.26	10	53.98	10	55.75
	30	40.19	25	52.47	25	55.04
	40	39.02	40	51.10	35	54.02
	50	37.88			50	52.58

a) Our sample No. 5. Concentration was 1.0 g./100 ml.

b) Volume per cent of precipitant at the time of the first appearance of turbidity.

In the process of hydrogen bonding, it is probable that there is a steric hindrance for the orientation of solvent molecules. The fact that the H-2 fraction is practically insoluble in *t*-butanol is considered to be due to the steric hindrance. Such a steric hindrance may be small in the case of poly-4-vinylpyridine, in which the nitrogen atom is located at the γ-position of the pyridine ring. In fact, poly-4-vinylpyridine dissolves even *t*-butanol, and Strauss[21] has recognized the existence of hydrogen bonding in the poly-4-vinylpyridine-*t*-butanol system because of the negative temperature coefficient of the solubility of this polymer in a *t*-butanol - benzene mixture.

An extreme case of the specific interaction between poly-2-vinylpyridine and an acidic solvent is seen in the results of the viscosity measurement of the H-2 fraction in nitroethane. As may be seen in Fig. 2, the relation between the reduced viscosity and the concentration is similar to that of typical polyelectrolyte.[22] A similar result has been obtained by Cashin[23] in the case of poly-2-vinylpyridine in nitromethane. Nitroalkyl is tautomerized into nitro and acid forms, the latter of which behaves as an acid.[24] Nitroalkyl in the acid form may, therefore, quaternize the pyridine nitrogen. Thus, poly-2-vinylpyridine in nitroalkyl behaves as a polyelectrolyte.

The oxygen of the carbonyl group in ethyl methyl ketone has two lone electron-pairs, and so this solvent can act as a typical Lewis base.[18] Dioxane and nitrobenzene also act as bases to Lewis acid.[18] As may be seen in Fig. 5 the intrinsic viscosities in these solvents are lower than would be predicted on the basis of their solublity parameters alone. These results may also be explained as resulting from the interaction between pyridine

nitrogen and solvents.

The intrinsic viscosity of the H-2 fraction in isopropanol is relatively low in spite of the value of δ_1 being closer to 10.4 (cal./cc.)$^{1/2}$ and in spite of its acidity. This is considered to be due to the steric hindrance to hydrogen-bond formation described previously.

Benzene is a typical neutral solvent, and the viscosity behavior of the polymer in this solvent coincides with that which is to be expected from its solubility parameter.

Huggins' Constant and Spurlin's Constant. —It has generally been recognized that Huggins' constant, k', defined by Eq. 1 in Part I[3] and Spurlin's constant, k_s, the ratio of the slope in the plots of $\log(\eta_{sp}/c)$ against c to the intrinsic viscosity, decrease with solvent power.[20,25] The values of k' and k_s obtained from the measurement of viscosity for the H-2 fraction in various solvents are cited in columns 8 and 9 of Table I and are plotted against the corresponding intrinsic viscosity in Fig. 6, which shows that the general rule described above is applicable to the present results.

Studies of Poly-2-vinylpyridine. III. Intrinsic Viscosity and Molecular Weight

By Shizuo ARICHI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima

(Received May 19, 1965)

The viscosity, osmotic pressure and light-scattering of a series of 14 fractions of poly-2-vinylpyridine in various solvents have been measured. The following results have been obtained: The constants, K_w' and ν, in the Mark-Houwink equation have been determined for the solutions of: (a) 92.01 weight per cent ethanol, (b) methanol, (c) dimethylformamide, (d) benzene and (e) dioxane as follows:

(a) $[\eta] = 1.22\times10^{-4} M_w^{0.73}$ (d) $[\eta] = 1.70\times10^{-4} M_w^{0.64}$
(b) $[\eta] = 1.13\times10^{-4} M_w^{0.73}$ (e) $[\eta] = 3.09\times10^{-4} M_w^{0.58}$
(c) $[\eta] = 1.47\times10^{-4} M_w^{0.67}$

The molecular weight of the polymers ranged from 3.4×10^4 to 93×10^4, while the viscosity was measured at 25±0.01°C. The constant, K', in the Mark-Houwink equation in the case of a homogeneous molecular weight has been calculated assuming the exponential- and logarithmic normal-type molecular weight distribution functions for each fraction. The Flory constant, K, defined as $[\eta]_\theta = KM^{1/2}$ has been found by the method of Fixman and Krigbaum to be: $(8.7\pm1.0)\times10^{-4}$ at 25°C. The K value has also been found to be $(9.1\pm1.1)\times10^{-4}$ by measuring the intrinsic viscosity in benzene at the θ-point, 16.2°C. The short range interactions of this polymer have also been discussed.

The Mark-Houwink viscosity equation and the unperturbed chain dimension of poly-2-vinylpyridine have not been reported in spite of their importance in the investigation of the polymer solution. The Mark-Houwink equation for poly-4-vinylpyridine, which, in chemical structure, closely resembles poly-2-vinylpyridine, has been reported by Strauss[1] and Fuoss[2], and the data concerning to the unperturbed chain dimension of poly-4-vinylpyridine, together with those of many other polymers, have recently been summarized by Kurata and Stockmayer.[3] The Mark-Houwink equation for poly-2-vinylpyridine may not be so much different from that of poly-4-vinylpyridine. However, the solubility characters of these two polymers in certain solvents differ from each other, as has been shown in Part II[4]; so it is considered important to obtain the equation for poly-2-vinylpyridine. In addition, by comparing the unperturbed chain dimension of poly-2-vinylpyridine with those of poly-4-vinylpyridine and polystyrene, it may be possible to obtain information about the effect of the polarity and the structural position of pyridine nitrogen on the conformation of the polymers in solution.

As most polymer samples have a distribution

of molecular weight, corrections for the distribution must be applied to the experimentally obtained parameters, such as the constants, K' in the Mark-Houwink equation and K in the Flory equation. These corrections can be made by means of the proper equation based on a molecular weight distribution function; in this case the M_w/M_n ratio of the sample is always an important factor. In this study, both M_w and M_n were measured for 14 fractions of poly-2-vinylpyridine, and corrected values of the constants in the Mark-Houwink equation in five solvents and the unperturbed dimensions of the polymer were obtained.

Experimental

Polymers.—The polymer samples used in this investigation were prepared by the fractionation of the original polymers, which were described in Part I.[5] The composition of the solvent-precipitant and the technique of the fractionation were similar to those reported previously.[5] Each of the ten original polymers was first divided into 3 or 5 fractions; the fractions whose intrinsic viscosities were close to one another were put together. Thus, 13 fractions were obtained, they were named A, B, C, etc. Each of these fractions was then refractionated into three fractions, which were denoted A-1, A-2, A-3, B-1, etc.; of these, the middle fractions (A-2, B-2, C-2, etc.) were mainly used in this investigation.

In order to obtain the fractions whose molecular weights are higher than those obtained by the above method, the polymerization was performed by the method of Pritchard and others,[6] using potassium persulfate-sodium bisulfite as a redox initiator in an aqueous solution of the monomer acidified with hydrochloric acid at 45°C. The polymer was then fractionated as has been described above. Two of the resultant fractions N-3 and N-4, were used in this study.

Solvents.—The solvents used were guaranteed or first class reagents and were distilled before use, as has been described in Part I.[5]

The Phase Separation Temperature.—The polymer-solvent phase separation temperature was measured using a heart-type flask, to which a reflux condenser, a drying column containing phosphorous pentoxide and a glass stirrer were attached.

Viscosity, Osmotic Pressure and Light-scattering.—All apparatus for the measurement of viscosity, osmotic pressure, light-scattering and the refractive index increment were described in Part I.[5] The viscosities of a series of fractions were mesaured in various solvents at 25±0.01°C by the method of dilution in a viscometer. The correction for kinetic energy was neglected. The osmotic pressure was measured by a static method at 25±0.003°C, using a gel cellophane membrane (No. 300). No leakage of the solute molecule through the membrane was observed except for the sample with the lowest molecular weight (A-2, $M_w = 3.40\times10^4$); within 6 to 12 hr. the pressure reached an equilibrium which showed no change even after 24 hr. The reproducibility was checked by the reduced osmotic pressures, $(\pi/c)_0$, measured three times with the E-2 fraction in methanol, which were 3.41 3.43, and 3.30 ($\times10^2$ cm.).

Light-scattering was measured by a dissymmetry method with unpolarized incident light (436 mμ) at 25±1°C. The instrument was calibrated by using benzene[7] and also by means of a standard scattering plate.[8] The instrumental constants obtained by these two methods agreed with each other within the range of experimental error. The values of the molecular weight of the standard polystyrene, MS-1,[9] determined by using this instrumental constant were 23.7×10^4 and 23.6×10^4; these values were in good agreement with the mean value reported.[9] The solution and solvent were filtered through a cellafilter, "fein" or "mittel" (Membran Geselschaft, Göttingen, Germany). The concentration of the solution was determined by a weighing method. The dissymmetry was determined by the $[Kc/R_{135}]_0/[Kc/R_{45}]_0$ ratio, which was corrected for the back reflection of the incident light.

Results and Discussion

The Intrinsic Viscosity.—The results of the viscosity measurement of a series of fractions in methanol at 25±0.01°C are shown in Fig. 1. The measurements were also carried out for the same fractions in 92.01 weight per cent ethanol, dimethylformamide, benzene and dioxane.

9) The Committee on Molecular Weight and Molecular Weight Distribution, *Rept. Progr. Polymer Phys. Japan*, **4**, 141 (1960).

The Osmotic Pressure.—The results of the measurement of the osmotic pressure of a series of fractions in methanol at 25±0.003°C are shown in Fig. 3. The results for the H-2 fraction in ethanol, methanol, isopropanol, benzene and ethyl methyl ketone were presented earlier, in Part II.[4]

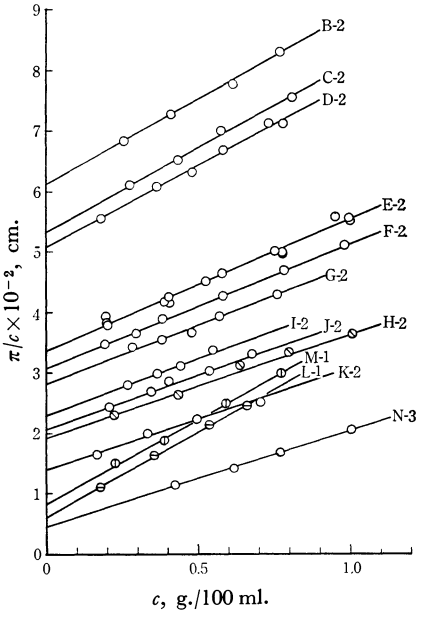

Fig. 2. Plots of reduced osmotic pressure vs. concentration of poly-2-vinylpyridine fractions in methanol at 25°C.

The Light-scattering.—The light-scattering of several of the fractions was measured in methanol, ethanol, isopropanol, ethyl methyl ketone, dioxane and benzene. In spite of the normal behavior shown in R_{90}, the angular distribution of scattered light showed a noticeable abnormality in all solvents; an extremely small dissymmetry (sometimes less than unity) was observed over the whole range of concentrations measured. A typical example is shown in Fig. 3 by the Zimm plot. The same behavior was observed irrespective of whether the incident light was polarized or unpolarized.

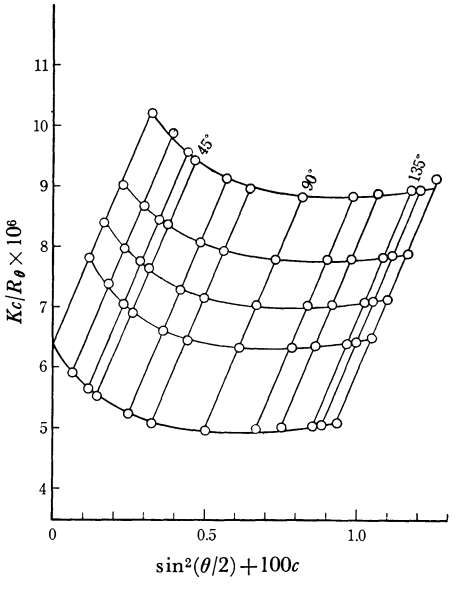

Fig. 3. The Zimm plots of faction G-2 in methanol at 25°C.

An abnormalilty in the angular distribution has also been reported by Miura and others[10] for poly-2-methyl-5-vinylpyridine in methanol. Fuoss and others[2] measured the light scattering of poly-4-vinylpyridine in absolute ethanol containing 0.02 mol. of dry ammonia per 1000 cc. "in order to suppress any possible ionization of pyridine nitrogen." In fact, an abnormal behavior in dissymmetry, which resembles that of a polyelectrolyte in a solution of a low ionic strength, has also been found for poly-2-vinylpyridine in absolute ethanol[11] and in nitromethane.[12]

On the other hand, no abnormality has been reported for poly-4-vinylpyridine in 92.01 weight per cent ethanol[1] or for poly-2-vinylpyridine in methanol[13] or in dioxane[12]. Since the abnormality described above was not observed in the

case of unfractionated poly-2-vinylpyridine[5] it may be possible to explain this phenomenon in terms of the contamination of polymers by some electrolytes in the course of fractionation, but the dissymmetrical behavior in benzene, dioxane and ethyl methyl ketone can not be explained in the same way. This phenomenon may also arise from the optical anisotropy of segments.[14,15]

Although the origin of the abnormality has not yet been clarified, it disappeared when methanol containing 0.02 mol. of dry ammonia per 1000 cc. was used as the solvent.[2] This solvent, therefore, was used in this study for the measurement of light-scattering of a series of poly-2-vinylpyridine fractions. The results are shown in Fig. 4.

The results of the measurements of the viscosity, the osmotic pressure, and the light-scattering are summarized in Table I, where M_n and $(A_2)_{OP}$ are the number average molecular weight and the second-virial coefficient in osmometry, and where M_w, z, $\langle L^2\rangle^{1/2}$ and $(A_2)_{LS}$ are the weight average moleclar weight, the intrinsic dissymmetry, the root mean square displacement length and the second-virial coefficient in turbidimetry respectively.

Relations among A_2, M_w and $\langle L^2\rangle^{1/2}$.—The plots of A_2 versus M_w and of $\langle L^2\rangle^{1/2}$ versus M_w are shown in Figs. 5 and 6 respectively. The expressions obtained from these plots are given in Table II. The relation between A_2 and M_w is almost the same as those obtained with other linear polymer-solvent systems, such as the polystyrene-toluene system.[16]

The exponent in the relation between $\langle L^2\rangle^{1/2}$

Table II. Relations among A_2, M_w and $\langle L^2\rangle^{1/2}$

Solvent	Temp., °C	Formula
Methanol-NH_3	25±1	$(A_2)_{LS} \propto M_w^{-0.22}$
Methanol	25±0.003	$(A_2)_{OP} \propto M_w^{-0.29}$
Methanol-NH_3	25±1	$\langle L^2\rangle^{1/2} \propto M_w^{0.5}$

and M_w seems to be smaller than that which might be expected from the following facts: the relations between M_w and the intrinsic viscosities in pure methanol and methanol containing 0.02 mol. of dry ammonia per 1000 cc. are almost the same for all the fractions measured; moreover, methanol is an extremely good solvent for this polymer.[4]

Relations among M_w, M_n and $[\eta]$.—For polymer samples which are homogeneous with respect to the molecular weight, the relation between the intrinsic viscosity and the molecular weight can be expressed by the Mark-Houwink equation:

$$[\eta] = K_i' M^{\nu} \tag{1}$$

where K_i' and ν are constants independent of the molecular weight. However, it is well known that the empirically determined values of K' in the form of Eq. 1 for heterogeneous samples vary with the kind of average, and also with the width of the distribution of the molecular weight.[17-19]

In such cases, if the molecular weight distribution of the sample is known, a quantitative relation between K' and the degree of homogeneity can be obtained.[20,21] For example, when the molecular weight distribution of each fraction can be represented by the exponential-type function[22]:

$$w(M) = \{Y^{h+1}/\Gamma(h+1)\} M^h \exp(-YM) \tag{2}$$

the following relations are given:

$$[\eta] = K_w' M_w^{\nu} = K_i' \{\Gamma(\nu+h+1)/ \Gamma(h+1)(h+1)^{\nu}\} M_w^{\nu} \tag{3}$$

$$[\eta] = K_n' M_n^{\nu} = K_i' \{\Gamma(\nu+h+1)/ \Gamma(h+1)h^{\nu}\} M_n^{\nu} \tag{4}$$

The parameters in Eq. 2 have the same meaning as in Eq. 6 in Part I,[5] while the constants, K_w' and K_n' in Eqs. 3 and 4 refer to weight and number average respectively.

On the other hand, if we take the logarithmic normal-type distribution function[23]:

$$w(M) = MA \exp\{-p^2(\ln M/M_0)^2\} \tag{5}$$

the relations are given by:

$$[\eta] = K_w' M_w^{\nu} = K_i' (M_w/M_n)^{\nu(\nu-1)/2} M_w^{\nu} \tag{6}$$

$$[\eta] = K_n' M_n^{\nu} = K_i' (M_w/M_n)^{\nu(\nu+1)/2} M_n^{\nu} \tag{7}$$

The parameters in Eq. 5 are the same as in Eq. 9 in Part I.[5]

As the variation in the K_w' value in Eq. 3 or 6 with the change in M_w/M_n is comparatively small, the value of ν can be assumed to be nearly the same as the slope of the linear line in the double logarithmic plots of $[\eta]$ versus M_w for fractionated samples. Thus, the value of K_i' can be calculated by means of the above equations.

The intrinsic viscosities of fourteen fractions in five kinds of solvents and those in methanol are plotted against M_w and M_n respectively in Fig. 7. The plots of $[\eta]$ versus M_n can be expressed by linear lines, whereas the plots of $[\eta]$ versus M_n scatter considerably. This is considered to be due to the heterogeneity of the samples, as is shown by the M_w/M_n values cited in Table I.

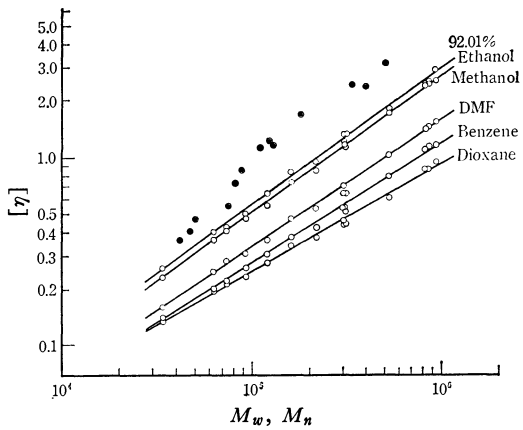

Fig. 7. Log-log plots of $[\eta]$ vs. M_n in methanol (-⊙-) and of $[\eta]$ vs. M_w in various solvents indicated (-○-) for poly-2-vinylpyridine fractions at 25°C.

The constants, ν and K_w', evaluated from the linear lines in Fig. 7 are shown in columns 2 and 3 respectively in Table III. The values of K_n' in column 4 of the table are the mean values of K_n' for all fractions; these values were calculated

from the equation, $[\eta]=K_n'M_n^{\nu}$, the values of ν being assumed to be the same as those for the relation between $[\eta]$ and M_w.

Assuming that the molecular weight distribution of each fraction can be represented by Eqs. 2 and 5, the values of K_i' were evaluated by inserting the values of ν, K_w' and K_n' cited in Table III into Eqs. 3 and 4 and Eqs. 6 and 7. The results are shown in columns 5 and 6 of Table III.

The values of K_i' calculated by assuming the two functions given above are in good agreement with each other. The validity of the values of K_i' and ν is shown with the methanol solution,

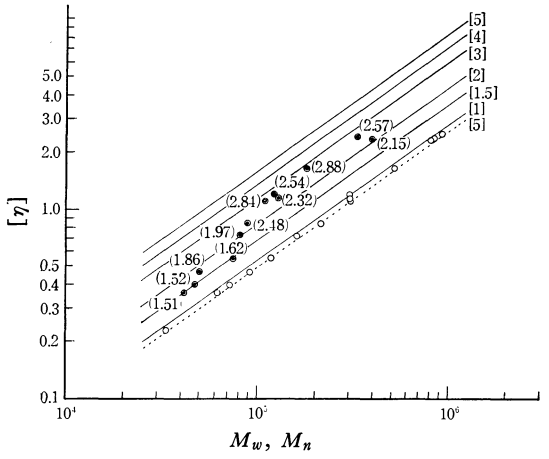

Fig. 8. Log-log plots of $[\eta]$ vs. M_w (---, Eq. 3) and $[\eta]$ vs. M_n (——, Eq. 4) for different M_w/M_n ratios indicated in [ ] assuming $K_i'=1.19\times10^{-4}$ and $\nu=0.73$ in methanol at 25°C. Points show plots of $[\eta]$ vs. M_w (-○-) and $[\eta]$ vs. M_n (-⊙-) for observed values of M_w/M_n indicated in ( ).

as an example, in Fig. 8. The figure in the parenthesis at each point in Fig. 8 shows the observed value of M_w/M_n. The straight lines correspond to the values of K_w' and K_n' which are obtained from Eqs. 3 and 4 by inserting the values of K_i' (1.19×10^{-4}) and ν (0.73) and the voluntarily selected values of M_w/M_n which are shown in the brackets. Almost the same results were obtained from Eqs. 6 and 7.

These results show that the values of K_i' and ν thus obtained are quite reasonable. The relation between the molecular weight and the $[\eta]$ value for sufficiently fractionated samples can be expressed by the Mark-Houwink equation containing the constants, K_i' and ν, cited in Table III.

The direction of the variation in the values of ν with the solvent is the same as the solvent power described in Part II.[4] The constants, K_w' and ν, for poly-2-vinylpyridine in 92.01 weight per cent ethanol at 25°C cited in Table III are almost the same as those for poly-4-vinylpyridine in the same solvent and temperature[1]:

$$[\eta]=1.20\times10^{-4}M_w^{0.73}$$

The Unperturbed Chain Dimension of Poly-2-vinylpyridine.—The intrinsic viscosities of a flexible linear polymer in theta and nontheta solvents are expressed by Eqs. 8 and 9 respectively[24]:

$$[\eta]_\theta = KM^{1/2} \tag{8}$$

$$[\eta] = KM^{1/2}\alpha^3 \tag{9}$$

Here K is a constant for a given polymer independent of the solvent and the molecular weight; it is related to the mean square displacement length of the chain, $\langle L^2\rangle_0^{1/2}$, in an ideal solvent as follows:

$$K=\Phi_0A^3, \qquad A^2=\langle L^2\rangle_0/M \tag{10}$$

where Φ_0 (0.87×10^{21}) is the universal viscosity constant for chain polymers in a theta solvent, while α in Eq. 9 is the viscosity expansion factor. According to a recent perturbation theory,[24-27] α is a function of z, which is defined by:

$$z = (3/2\pi)^{3/2}BA^{-3}M^{1/2} \tag{11}$$

where A is a parameter concerned with the short range interaction of segments defined by Eq. 10, and B, a parameter on the long range interaction of segments which is related to the excluded volume effect. The relation between α and z obtained by Stockmayer and Fixman[24] is:

$$\alpha^3 = 1 + 1.55z \tag{12}$$

From these equations they derived the following expression:

$$[\eta]/M^{1/2} = K + 0.51\Phi_0BM^{1/2} \tag{13}$$

The values of $[\eta]$ and M_w cited in Table I are plotted according to this equation in Fig. 9.

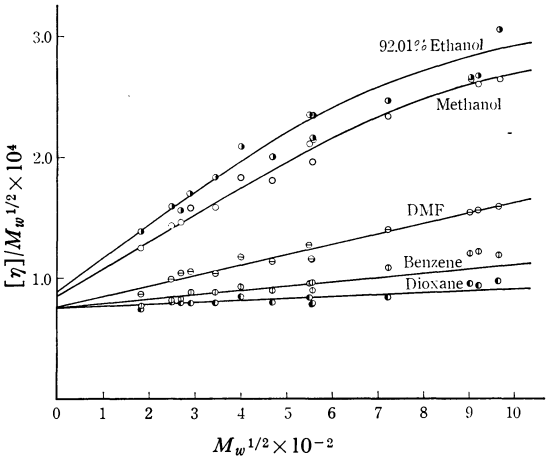

Fig. 9. Plots of $[\eta]/M_w^{1/2}$ vs. $M_w^{1/2}$ for poly-2-vinylpyridine fractions at 25°C.

The lines for the viscosities in the relatively poor solvents, dimethylformamide, benzene and dioxane, pass through the same intercept and are linear, as was to be expected from Eq. 13, whereas the lines for the good solvents, 92.01 weight per cent ethanol and methanol, have an upward curvature and the intercepts are larger than other one. Consequently, the K_w values obtained from these intercepts lie between 7.5×10^{-4} and 8.9×10^{-4}. A similar solvent dependence of the intercept has been reported for polymethyl methacrylate.[3,28,29] In Part II,[4] the existence of the solvation of alcohol molecules to pyridine nitrogen was suggested; therefore, it is of interest to investigate the solvent effect[30] on the unperturbed dimension of the chain. However, the present data seem insufficient for discussing this problem.

The value of K can also be obtained by the following semi-empirical equation of Krigbaum[31]:

$$[\eta] = [\eta]_\theta + 5.0\times10^{-3}A_2M \qquad (14)$$

As has been described in Part II,[4] the relation between $[\eta]$ and A_2 for the H-2 fraction in various solvents at 25°C can be expressed by Eq. 15:

$$[\eta] = 0.415 + 1.10\times10^3A_2 \qquad (15)$$

When the value of M_w, 30.08×10^4, for the H-2 fraction is inserted into Eq. 14, the following equation can be obtained:

$$[\eta] = [\eta]_\theta + 1.50\times10^3A_2 \qquad (16)$$

The difference between the coefficient of A_2 in Eq. 15 and that in Eq. 16 may be due to the molecular weight inhomogeneity and to experimental errors in M_w and A_2. The agreement, however, is satisfactory, and so it is reasonable to take the value of 0.415 for $[\eta]_\theta$. By inserting the values of $[\eta]_\theta$ and M_w for the H-2 fraction in Eq. 8, the value of K_w is found to be 7.6×10^{-4}. The probable error of K_w is $\pm(0.5\times10^{-4})$.

The value of K can be obtained by the more direct method, namely, by measuring the $[\eta]$ value of a fraction of poly-2-vinylpyridine in a θ-solvent. Flory and Shultz[32] have derived the following relation between the critical temperature, $T_c(°K)$, in a binary polymer-solvent system and the number of segments, x or M_w:

$$1/T_c = (1/\theta)\{1 + (1/\psi_1)(1/x^{1/2} + 1/2x)\}$$
$$\cong (1/\theta)(1 + b/M_w^{1/2}) \qquad (17)$$

where θ is the theta-temperature and ψ_1, an entropy parameter.

Benzene was used as the solvent in this experiment, and the critical temperature was determined by the method of Flory[32] for the E-2, J-2, K-2 and N-3 fractions. The results are plotted in Fig. 10 according to Eq. 17. The value of θ obtained from the intercept of the linear line in Fig. 10 is 16.2°C. The intrinsic viscosity of the H-2 fraction in benzene at 16.2°C was found to be 0.465; this, by definition, is the $[\eta]_\theta$ of this fraction. Thus, the value of K_w is calculated by means of Eq. 8 as 8.5×10^{-4} at 16.2°C. The probable error of K_w is $\pm(1.0\times10^{-4})$ in this case.

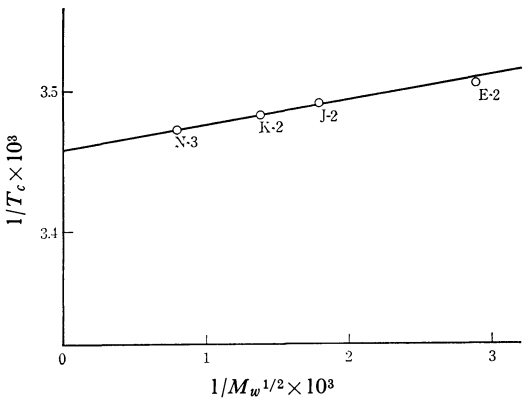

Fig. 10. Plots of reciprocal critical temperature in benzene vs. $1/M_w^{1/2}$ for poly-2-vinylpyridine fractions.

As the values of K_w obtained above were based on the data for samples which are not numerous enough to discuss them as a molecular homogeneous polymer, the correction for the molecular weight distribution was applied to them. Assuming again the exponential function[22] for the distribution of the molecular weight, the K_w values were corrected by the following equations[3]:

$$[\eta]_\theta/M_w^{1/2} = K_w = q_wK \qquad (18)$$

$$q_w = \Gamma(h+1.5)/(h+1)^{1/2}\Gamma(h+1) \qquad (19)$$

As may be seen in Table I, the M_w/M_n ratio for a series of fractions is ca. 2 as a mean value, while the ratio for the H-2 fraction is 2.32. Thus, q_w was calculated by using $h = 1$ for the value of K_w obtained by the Fixman plot and $h = 0.758$ for the values of K_w obtained by the latter two methods. The corrected K values are shown in Table IV.

Table IV. Corrected values of the Flory constant, K

Method	Temp. °C	$K_w\times10^4$	q_w	$K\times10^4$
Fixman (Eq. 13)	25.0	8.2±0.7	0.94	8.7±0.8
Krigbaum (Eq. 14)	25.0	7.6±0.5	0.93	8.2±0.6
Flory (Eq. 17)	16.2	8.5±1.0	0.93	9.1±1.1

The K values obtained by the methods of Fixman and Krigbaum are, as may be seen in Table IV, in good agreement with each other. This implies

TABLE V. UNPERTURBED CHAIN DIMENSION CALCULATED FROM K VALUES

Polymer	Temp. °C	$K\times10^4$	$\left[\frac{\langle L^2\rangle_0}{M}\right]^{1/2}\times10^{11}$	$\left[\frac{\langle L^2\rangle_{0f}}{M}\right]^{1/2}\times10^{11}$	σ	V_x
Polyethylene[3]	ca. 100	23.0±3.0	950±40	582	1.63±0.08	8
Polystyrene[3]	ca. 30	8.2±0.5	670±15	302	2.22±0.05	89
Poly-4-vinylpyridine[3]	25	9.4±1.0	710±30	300	2.37±0.10	81
Poly-2-vinylpyridine	25	8.7±1.0	673±30	300	2.24±0.10	81

that these two methods are closely correlated with each other. In fact, an extremely close resemblance between Fixman's equation (Eq. 13) and a deformation of Krigbaum's equation:

$$[\eta]/M^{1/2} = K + 0.63\Phi_0 Bh(z)M^{1/2} \qquad (20)$$

has been discussed by Stockmayer and Fixman.[24]

Considering that the hindrance to internal rotation about the C–C bond generally decreases with a rise in the temperature,[33] the value of K at 16.2°C is reasonable.

Using the values of $K = (8.7\pm1.0)\times10^{-4}$ and $\Phi_0 = 2.87\times10^{21}$, the value of $[\langle L^2\rangle_0/M]^{1/2}$ for poly-2-vinylpyridine was calculated by means of Eq. 10 as $(673\pm30)\times10^{-11}$ at 25°C.

By denoting the unperturbed root mean square displacement length of the polymer chain in the case of free rotation about C–C bond as $\langle L^2\rangle_{0f}^{1/2}$, and by assuming the C–C bond length and tetrahedral angle to be 1.54 Å and 109.5° respectively, the value of $[\langle L^2\rangle_{0f}/M^{1/2}]$ was found to be 300×10^{-11}.

As a measure of the hindrance to internal rotation, the following factor, σ, was calculated for the polymer using the values of $\langle L^2\rangle_0/M$ and $\langle L^2\rangle_{0f}/M$ described above:

$$\sigma^2 = \langle L^2\rangle_0/\langle L^2\rangle_{0f} \qquad (21)$$

The results are shown in Table V, together with those[3] for polyethylene, polystyrene and poly-4-vinylpyridine. The molar volumes, V_x, of side groups of these polymers, hydrogen, the benzene ring and the pyridine ring, are shown in column 7 of Table V.

When we compare the values of σ for these four polymers, we can find relatively large σ values for the latter three polymers; these are considered to be due to the steric hindrance caused by large groups of atoms in the side chain.[3,33] Further, as the V_x value of pyridine is smaller than that of benzene, the steric hindrance to internal rotation is considered to be somewhat smaller in polyvinylpyridines than in polystyrene. In spite of this difference in the values of V_x, the values of σ for the polyvinylpyridines are, on the other hand, a little larger than that for polystyrene, as may be seen in Table V. This may be interpreted as being due to electrostatic interaction between pyridine rings.

The small difference between the σ values for poly-2-vinylpyridine and poly-4-vinylpyridine may be due to the difference in the degree of short range interactions, for example, the interaction between the nitrogen and the hydrogen in the neighboring pyridine rings or in the main chain.

However, further systematic investigation will be required to clarify this problem, together with the solvent effect on the value of K described previously.

The author wishes to express deep appreciation to Professor Hiromu Murata for making this study possible and for his kind advice, and to Professor Masaji Miura for his encouragement and many valuable discussions throughout this work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 447—452 (1966)

The Rheological Study of Aqueous Solutions of Polyvinyl Alcohol at Ultrasonic Frequencies

By Kiyoshi ARAKAWA and Nobuo TAKENAKA

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received June 3, 1965)

The ultrasonic velocity and the absorption have been measured over the 5—45 Mc./sec. frequency range for aqueous solutions of polyvinyl alcohol by means of an ultrasonic pulse technique which was similar in principle to that used by Pinkerton (*Proc. Phys. Soc.* **B62,** 286 (1949)). The temperature varied over the 3—70°C range. The velocity-versus-temperature curves have been found to be convex upwards, like that of pure water, but the peak shifts upwards and to the lower-temperature side with an increase in the concentration. The ultrasonic absorptions of aqueous solutions of partly-saponified polyvinyl alcohol have been found to be larger than those of perfectly-saponified alcohol at the same concentrations. Two relaxation mechanisms have been found for each sample. For the solutions of the perfectly-saponified sample, the first relaxation frequency, f_1, is 35 Mc./sec. at 12°C, while the second relaxation frequency f_2 is 40 Mc./sec. at 60°C, for example. On the other hand, these values have been found to be nearly equal for the solutions of the partly-saponified sample. The activation energy, ΔH_2, obtained from the temperature dependence of f_2 is about 4 kcal./mol., irrespective of the quantity of resuidal acetate groups, and the ΔH_1 value for f_1 is of the order of 10 kcal./mol.

In a previous paper[1] some results of rheological investigations of concentrated aqueous solutions of polyvinyl alcohol using an ultrasonic pulse technique have been reported; the adiabatic compressibility of polymer molecules in solutions have been discussed elsewhere.[2] However, the previous data concern one ultrasonic frequency in the mega cycle region; therefore, we have attempted in the present experiment to obtain ultrasonic data on the solutions of polyvinyl alcohol over a wider range of frequencies using a newly-constructed apparatus for the measurement of the ultrasonic velocity and the absorption by the pulse method.[1,3]

The oscillational displacement, ξ, in a longitudinal wave through the solution at a distance, x, from a source of sound is:

$$\xi = \xi_0 \exp(-\alpha x) \exp\{i\omega(t - x/c)\} \quad (1)$$

where c is the sound velocity; ω, the angular frequency; ξ_0, the amplitude of oscillation; α, the absorption coefficient, and t, the time. We will here obtain c and α values for various frequencies and temperatures.

Experimental

Apparatus and Procedure.—The apparatus used in this experiment is similar to that reported in the previous paper,[1] but this apparatus can be used for a wider range of frequencies. A block diagram of it is shown in Fig. 1.

A pulse generator supplies an electric pulse of about 5—10 μ sec. duration, and with a repetition rate of 2—5 kc./sec., into a high-frequency oscillator, which operates as an oscillator only during the loading period of the pulse. The oscillator is constructed from three independent parts, each of which is used for each available frequency range between 1—50Mc./sec.; for the measurement in the range of 50—100 Mc./sec., a frequency doubler unit[4] is inserted in a position series to the oscillator. The pulse-modulated high-frequency voltage from the oscillator is led to a transmitter quartz in a cell which contains a sample solution; there it is transduced into an ultrasonic pulse. The pulse which has been propagated through the solution is again transduced into an electric pulse by a receiver quartz and then led to an attenuator. The pulse from the attenuator is amplified and supplied into a vertical axis of a synchroscope.

The velocity of sound, c, is measured according to the procedure described in the previous paper.[1] The amount of attenuation is determined by the compensation method, using the attenuator. That is, the difference in the attenuator reading gives the amount of attenuation for the given path length between the two positions of the movable receiver quartz when attenuator is adjusted so that the pulse pattern in the synchroscope screen has the same height for the two positions of the receiver quartz. The absorption coefficient, α, is determined from the tangent of a linear plot of the amount of attenuation against the length of the ultrasonic path.

Samples.—The two samples, A and B, used were the same as those reported in the preceding paper.[1] The average molecular weight was 8.0×10^4 for the perfectly-saponified P.V.A. sample A and about 9×10^4 for the sample B, which is the partly saponified P. V. A. and which has 12.2 mole % of the residual acetate groups. The preparation procedure of the aqueous solution is similar to that reported previously.[1]

Measurement.—In this experiment the sound velocity and absorption were measured for 5 and 10 wt. % solutions of the two samples. The temperature was varied within the range of 3—70°C. The frequency range used was 5—45 Mc./sec.

Results and Discussion

The Effect of Aging on Ultrasonic Absorption.

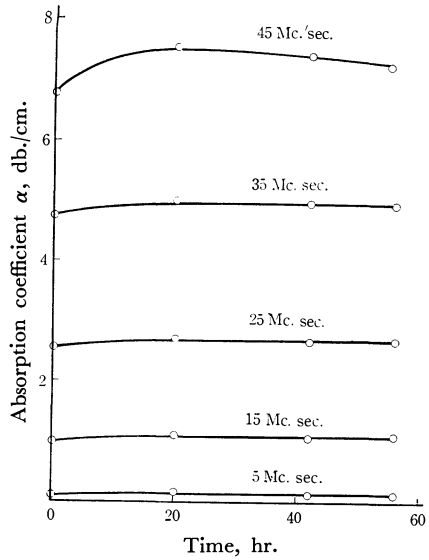

Fig. 2. Aging curve for the 10 wt.% solution of sample A.

—Concentrated polymer solutions are often found to exhibit an aging behavior. In Fig. 2 the absorption coefficient, α, which was measured for the 10 wt.% solution of sample A is plotted against the standing time after the thermal equilibration of the solution has been reached at room temperature. As may clearly be seen in Fig. 2, the

effect of aging is not very large, but it has a tendency to increase with the frequency; the primary effect of aging is confined within 20 hr., while after more than 20 hr. the absorption coefficient is found to reach a constant value. Therefore, in the present experiment the measurements were made after the prepared solution had been allowed to stand at room temperature for more than 20 hr. after its preparation.

Data of Ultrasonic Velocity.—In Figs. 3(a), (b), (c), and (d) the sound velocities obtained for solutions of samples A and B are plotted against the temperature for each concentration; here the frequency dependence is not very clear. All the data for the 5—45 Mc./sec. frequency range are also plotted together against the temperature. Each solid line is one which is obtained by the parallel shift of the velocity vs. the temperature curve for pure water[5] (the amount of the shift is given in each figure). The sound velocity in pure water is found to have a maximum value, 1555.5 m/sec., at 74°C.[5] It may be seen in Fig. 3 that the peak in the velocity vs. the temperature curve shifts toward a temperature lower than that for pure water; it may also be seen that the amount of shift increases with the increase in the concentration.

Data of Sound Absorption.—In Figs. 4(a), (b), (c), and (d) the absorption coefficient, α, is plotted against the temperature; the frequency is varied within the 5—45 Mc./sec. range. It is found that the absorption of aqueous solutions of sample B is larger than that of sample A at the same concentration. It may be seen especially in Figs. 4(c) and (d) that absorption curves have two characters, that is, a peak or shoulder at about the 0—20°C range and a shoulder at about the 30—40°C range; it may also be seen that the two peaks or shoulders shift to a higher temperature region with the increase in frequency.

5) M. Greenspan and C. E. Sschiegg, *J. Res. Natl. Bur. Std.*, **58**, 249 (1957); *J. Acoust. Soc. Am.*, **31**, 75 (1959).

It is well known that the ultrasonic absorption of pure water decreases monotonously with the increase in temperature in this frequency range. Therefore, from these two characteristics we may

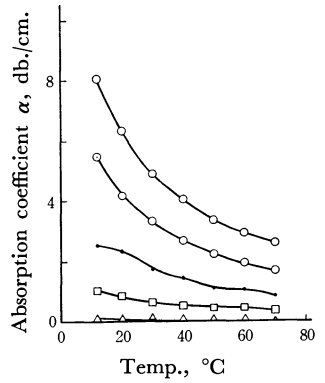

Fig. 4(a). Absorption coefficient, sample A, 5% solution.

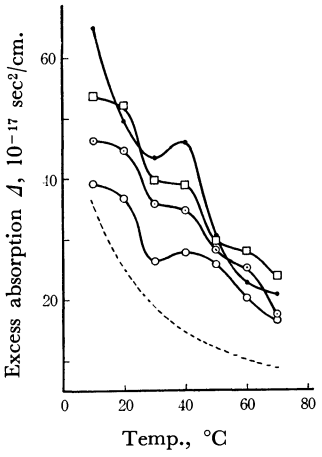

Fig. 5(b). Excess absorption, Sample B, 10%.

say that in this range of temperature and frequency the ultrasonic absorption of aqueous solutions of polyvinyl alcohol is approximately composed of three parts. The first one is, of course, to be attributed to free water, which is the greater part by weight in these solutions. The contribution from this part to the total absorption is, however, not necessarily the greater part of the total absorption. In the case of a 10% solution it is about one-third of the total absorption. The second and the third parts are to be attributed to polymer molecules, including the contribution from hydrated bound water. The second corresponds to the peak or shoulder at about the 0—20°C range, and the third, to the shoulder at about 30—40°C, as has been described above.

In Figs. 5(a) and (b), the excess absorption, Δ, for the 10 wt.% solution;

$$\Delta=\left(\frac{\alpha}{f^2}\right)_{\text{solution}}-0.9\left(\frac{\alpha}{f^2}\right)_{\text{water}} \qquad (2)$$

is plotted against the temperature. The dashed lines are the values (α/f^2) for pure water,[6] which may be, so to speak, regarded as back ground curves in the total absorption. The amount of Δ is the part of the absorption attributed to polymer molecules in solutions, including the excess contribution of hydrated water molecules, that is, the difference between the amount of the absorption of hydrated water molecules and the amount of the absorption of the water molecules when they are allowed to be free. The presence of the two absorption mechanisms may clearly be seen in Figs. 5(a) and (b). Therefore, it may safely be said that the ultrasonic absorption of a polyvinyl alcohol solution in this temperature range is approximately given by the summation of three parts, as is shown in Fig. 6, for example, where, however, the proportion of the absolute amount of each component is, of course, somewhat arbitrary.

Frequency Dependence of Ultrasonic Absorption.—In order to obtain the frequency dependence of the ultrasonic absorption we have given here, in Figs. 7(a) and (b), the α/f^2 vs. f curve, and also the $\alpha\lambda$ vs. f curve in Figs. 8(a) and (b), where λ is the wavelength, obtained from the data shown in Figs. 4(c) and (d).

As has been stated before on the basis of a consideration of the temperature dependence of the absorption, the presence of two relaxation mechanisms may be concluded. They are characterized by two relaxation frequencies, f_1 and f_2, each, which are numbered in order from the low temperature side in the α vs. T curve. For example, in the case of the 10 wt.% solution of the sample A, the value of f_1 and f_2 is determined from the

curves in Fig. 7(a) and Fig. 8(a). In Fig. 8(a) the large peak in the curve at 12°C, which is characterized by the relaxation frequency f_1, is

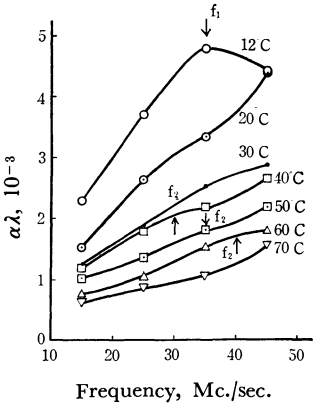

Fig. 8(a). $\alpha\lambda$ vs. f curve for the 10% solution of sample A.

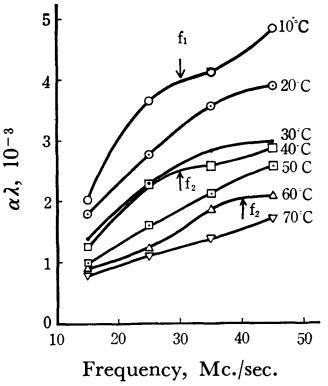

Fig. 8(b). $\alpha\lambda$ vs. f curve for the 10% solution of sample B.

found to correspond to the peak at 0—20°C in Fig. 5(a), while this peak is found to be shifted at the high frequency end at 20°C in Fig. 8(a). The shoulder[7] found at 30 Mc./sec. in the 40°C curve in Fig. 8(a), which corresponds to the shoulder near 40°C in Fig. 5(a), seems to shift gradually to the high frequency side with the increase in temperature; this shoulder is thought to be characterized by the relaxation frequency f_2. A similar consideration holds for the 10 wt.% solution of the sample B.

The value of the activation energy, ΔH_2, may be determined to be 4.2 kcal./mol. for both samples, A and B, from the temperature dependence of f_2. The value of ΔH_1 for f_1 can not be determined, but it may be estimated to be larger than 10 kcal./mol. from the curves in Figs. 8(a) and (b).

In Fig. 7(b) it may be seen that the values of α/f_2 decrease with the decrease in frequency at low temperatures. This may be attributed to the presence of Rayleigh scattering because of the co-existence of some larger colloidal particles;

7) M. Pancholy and S. P. Singal, ibid., **18**, 582 (1963).

this scattering follows the f^4 law. The fact that the decrease in α/f^2 with the decrease in frequency occurs at low temperatures only may be said to support this consideration.* Though the reason why this tendency is stronger for the sample B than for the sample A is not clear at present, it seems that it is to be attributed to the presence of residual acetate groups in the sample B which amount to about 1/8 in the mole fraction.

Longitudinal Wave Modulus.—From the values of the ultrasonic velocity and the absorption coefficient, the real part and imaginary part of the longitudinal wave modulus, M_1 and M_2, are obtained.

$$M_1=\rho c^2\frac{1-(\alpha c/\omega)^2}{\{1+(\alpha c/\omega)^2\}^2} \tag{3}$$

$$M_2=\rho c^2\frac{2(\alpha c/\omega)}{\{1+(\alpha c/\omega)^2\}^2} \tag{4}$$

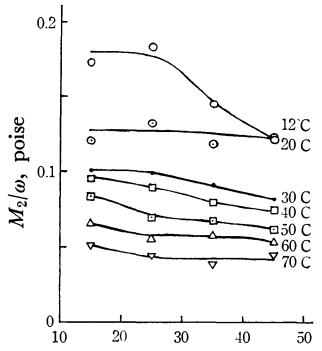

Fig. 9. Values of M_2/ω for the 10% solution of sample A.

* In Fig. 7(b) it may be seen that the curve at 20°C only is flat at low frequencies, in contrast to the above-described behavior of other curves at 10—40°C. This is because, if the Rayleigh dispersion is absent, the 20°C curve may be expected to go down rapidly with an increase in the frequency, while the 10, 30, and 40°C curves are more flat or slowly decrease on this low frequency side with an increase in the frequency.

From the values obtained in this work, the $(\alpha c/\omega)$ value is found to be very small compared with unity; therefore, the following relation is derived:

$$\frac{M_2}{\omega}=2\rho c^3\left(\frac{\alpha}{\omega^2}\right) \tag{5}$$

The M_2/ω quantity has the dimension of viscosity. In the preceding paper[1] it was found that the values of M_2/ω amount to 2—3 poises for the 10 wt.% solutions at 1.4 Mc./sec. From the present data we can determine the M_2/ω values to be of the order of 0.1 poises; these values are given in Fig. 9.

Summary and Conclusions

Data concerning ultrasonic velocity and absorption have been obtained by means of an ultrasonic pulse technique for aqueous solutions of polyvinyl alcohol.

1) The ultrasonic velocity and absorption have been measured over the temperature range of 3—70°C and the frequency range of 5—45 Mc./sec.

2) The ultrasonic absorption of aqueous solutions of partly-saponified polyvinyl alcohol is larger than that of perfectly-saponified polyvinyl alcohol at the same concentration.

3) Two relaxation mechanisms are present; one, which has been obtained from the temperature dependence of the relaxation frequency, is characterized by the activation energy of about 4 kcal./mol., and the other, by the activation energy of the order of 10 kcal./mol.

4) The value of the longitudinal wave modulus, M_2/ω, has been found to be of the order of 0.1 poises.

The authors wish to thank Miss Mitsuko Kobayashi for her cooperation in performing this study.

The Heterogeneous Adsorption of Carbon Dioxide on the Nickel Surface as Studied by the Isotopic Desorption Method

By Yasushi KOBAYASHI and Kozo HIROTA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received June 11, 1965)

Further evidence on the adsorptive heterogeneity of the nickel surface has been presented by the use of the technique described in our previous paper. The results support the conclusion already proposed that more than 20—30% of the surface can adsorb carbon dioxide strongly over the temperature range between −78° and 300°C.

The heterogeneity of the adsorptive power of the nickel surface has often been reported by using various physical techniques, e. g., infrared spectroscopy,[1] measurements of the electric resistance[2] and of the surface potential,[3] and electron microscopy.[4] Nevertheless, the question why the heterogeneous adsorptivity can be observed at all has not yet been answered satisfactorily. Besides, the fractions of the individual nickel surfaces, which differ in their activity, to the total surface have rarely been determined without ambiguity, though their determination is important to an understanding of the occurrence of heterogeneity in the study of adsorption and catalysis.

Several years ago, the present authors[5] applied the isotopic desorption method (or the differential isotopic method) of Roginsky[6] to the present problem; they then found that about 20—30% of the BET area of the nickel surface can adsorb carbon dioxide more strongly over the temperature range from −78°C to 300°C than the other fraction of the surface. Since carbon dioxide is soluble into the nickel bulk with much difficulty, the result is free from any ambiguity of absorption, the disturbing effect of which was confirmed in the application of this method by Takeuchi and Asano, when tritium was used as the tracer.[7] The heterogeneity observed, therefore, may be suggested as being due to the co-existence of various crystal planes rather than to such peculiar sites as lattice defects on the surface. Selwood et al.[8] reported the same conclusion for nickelkieselguhr on the basis of the method of magnetization-volume isotherms; they concluded the coverage of the stronger adsorption to be one-sixteenth. Quinn and Robert[9] and Suhrmann et al.[10] also found heterogeneity in the adsorption of carbon dioxide and carbon monoxide respectively on nickel films. Moreover, recently one of the present authors could explain the poisoning effect of carbon dioxide on the self-hydrogenation of ethylene[11] in terms of the above findings.

Such being the situation, it will be significant to report here some supplementary data obtained since the report mentioned above,[5] which will be denoted hereafter as "Paper I." The object of the investigation is to obtain some knowledge on the physical equilibration of the adsorbed carbon dioxide and also to clarify the adsorbed state, because both points seem to involve some questions, when the previous results are discussed. In the present paper, therefore, two kinds of experiments will be reported, with the desorption time changed on one hand, and with $^{13}CO_2$ and $CO^{18}O$ used as the adsorbate gases on the other.

Experimental

The apparatus and procedure were the same as those adopted in Paper I, except for minor differences to be mentioned below. The reduced nickel powders used as the adsorbent were a different lot from the same source. The weight was 19.8 g., and the BET area, 0.178 cc./g. These powders will be denoted as "Cat. B," if necessary, so as to discriminate them from the "Cat. A" used in Paper I. Heavy carbon dioxide $^{13}CO_2$ (19.7 atom%) was prepared by oxydizing $^{13}CH_4$ which had been given to the authors by Professor S. Horibe.[12] It was enriched

by the thermal diffusion column set at the Titani Laboratory of Tokyo Metropolitan University. $CO^{18}O$ was prepared by the present laboratory; its ^{18}O concentration was high enough to fulfill the object of the present research (ca. 29 or 15 atom%). The mass spectrometer used for isotopic analysis was a Hitachi (model RMB).

It might be mentioned that the desorption of carbon dioxide was always carried out by condensing it at the temperature of liquid nitrogen (−195°C), as was done in Paper I; i. e., desorption was continued until the vapor pressure of the adsorbed carbon dioxide decreased to 10^{-5} mmHg.[13] Special care was always taken in materials and manipulation so that no poison appeared on the nickel surface.

Results and Discussion

Table I summarizes the runs (Nos. 7—10) which were carried out to study the effect of the desorption time after introduction of the second gas. In Table II are shown the runs (Nos. 11 and 12) in which $^{13}CO_2$ was used as the first introduced gas, the desorption time being 120 min. In the tables, V_1 denotes the amount of the first gas introduced; V_1', that of the first gas which remained

13) Landolt-Börnstein, "physik. u. Chem. Tabellen," II band, 2 Teil (1960), p. 54.

after the desorption; V_2, that of the second gas introduced in the adsorption vessel (A), and V_r, the gas remaining after the second desorption at the same temperature. According to the data of Paper I, all the V_1+V_2 values in these runs are enough to form a monolayer of carbon dioxide on the surface.

No. 7 shows that the desorption time after the introduction of the second gas will not affect the result very much because the change in the residual amount on the surface was small, as is shown in Table II. The first residual gases of No. 7, 8, and 9 agree well with that of Paper I; i. e., 0.72 cc./g. was given for No. 8, while 0.67 cc./g. was given for the mean of Nos. 1 and 4, the desorption time of which was the same (120 min.) as that of No. 8. Thus, the desorption time of the second introduced gas, 110 or 120 min., is enough to make possible the conclusion drawn in Paper I. In other words, the present result means that the second portion of the introduced gas reached a physical equilibration after two hours, but that the isotopic equilibration with the first introduced gas was nevertheless not realized in the present system.

Table II shows that the amount of gas strongly adsorbed was practically unchanged at the same temperature, even if carbon dioxide was labelled by carbon instead of oxygen. (Compare Nos. 12 and 11 with Nos. 8 and 10 respectively.) The second point to be mentioned is the production of $^{13}CO^{18}O$ in the first desorbed gas. However, it could not be identified in the portions of the gas desorbed thereafter, for their quantities were too small. This finding tells us that the following exchange reaction (A) proceeds during the adsorption:

$$^{13}CO_2 + CO^{18}O \rightarrow {}^{13}CO^{18}O + CO_2 \qquad (A)$$

In other words, a kind of dissociative adsorption of carbon dioxide occurs. However, the dissociation may mean the formation of CO (ads)+O(ads), but not of C (ads)+2O(ats), considering the findings of Suhrmann et al.[10] as well as the energetic reason.

As Table II shows, it is now evident that the numerical value of the "strong" area, one-third, becomes more reliable and that carbon dioxide strongly adsorbed may exist as a dissociative state, as has been proposed.[5,9] However, there still exists a possibility of exchange without dissociation, similarly to that proposed by Webb and Eischens[14] in the case of exchange reaction (B):

$$^{13}CO + C^{18}O \rightarrow {}^{13}C^{18}O + CO \qquad (B)$$

The possibility of such a reaction without dissociation will be taken up again in the next section.

General Discussion

As has been mentioned above, there are at least two kinds of adsorption sites on the nickel surface. It is possible, however, that the above conclusion is of an apparent nature, considering that the "induced heterogeneity" may be produced as a result of mutual interactions between adsorbed molecules or between them and catalyst atoms. This possibility, which would be useful in explaining the gradual change in the adsorption heat, cannot be applied to the present findings, however, because since the desorption was carried out after the formation of a monolayer of carbon dioxide, it must occur at random if the surface is homogeneous.*

However, it must be admitted that there was gradual change in the adsorptive power of the strong sites now observed, because the fraction of the strongly-adsorbed carbon dioxide, reaching ca. 38% over the temperature range from −78°C—100°C, decreased to ca. 10% at 300°C. The above tendency can be explained in run No. 7 as follows. The residual amount of 1.4 cc. at −78°C decreased only by 9% at 100°C, but by 65% at 300°C, the isotopic concentration of the gas desorbed being that of the first gas. Moreover, the desorption at 300°C for 15 hr. could not make the decrease in the amount of adsorbed gas less than 0.49 cc. Now that the presence of stronger adsorption sites seems very plausible, let us discuss its nature.

As has been suggested in Paper I, the difference in the adsorptive power of each crystal plane may be its cause, judging from the magnitude of the ratio of the strong to the weak sites. The word "heterogeneity" must, however, be understood by a conventional standard, because the "strong" adsorption in this research means that the thermodynamical activity of strongly-adsorbed carbon dioxide is less than that of a carbon dioxide trapped at −195°C. Therefore, the strong adsorption sites could be classified in more detail if the relation between the residual amount of $C^{18}O_2$ (last column in Table I) and the desorption temperature could be analyzed more precisely. Thus, the discrepancy in the magnitude of stronger sites between the value of Selwood[8] and that of the present authors may be explained. However, the problem can not be answered quantitatively by the present method of investigation, because there remains a possibility that the decrease in residual $C^{18}O_2$ can be realized to some degree by the slow isotopic exchange (A) without dissociation between the adsorbed carbon dioxide on strong and weak sites. This possibility, if it does occur, may be small, however, considering

14) A. N. Webb and R. P. Eischens, *J. Am. Chem. Soc.*, **77**, 4710 (1955).

* This argument owes much to the kind suggestion of Professor Tomiyuki Toya, Hokkaido University.

15) Cf. G. Ehrlich, *Advan. Catalysis*, **14**, 255—427 (1963).

that the numerical value of the "strong" area determined by the present research coincides well that obtained by the adsorption measurement.[9]

Besides, the difference in adsorptive power between several crystal planes may also be supported by the adsorption measurements obtained on hydrogen by electron microscopy[4] or by field emission microscopy.[15] The possibility of relating the adsorptive to the catalytic heterogeneity has already been mentioned by one of the present authors[11]; it will be discussed elsewhere* in connection with the self-hydrogenation of ethylene on nickel.

Summary

The so-called adsorptive heterogeneity of the nickel surface has been studied at −78°C and 0°C by the isotopic desorption method, using labeled carbon dioxides ($CO_2{}^{18}$ and $^{13}CO_2$). The following results have been obtained:

(i) The fraction of the nickel surface which can adsorb carbon dioxide "strongly" at −78—300°C has been found to be about 20—30% of the total area, a proportion which is unchanged even when the desorption time is varied after the introduction of the second gas; (ii) When $^{13}CO_2$ and $C^{18}O_2$ are used as the first and second gas respectively, $^{13}CO^{18}O$ can be produced, indicating a dissociation of carbon dioxide on the strong stites of the surface.

These findings seem to offer some new evidence of the surface-heterogeneity which may be brought about by different crystal planes of the nickel surface, judging from the percentage of the area of the strong sites.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 456—459 (1966)

The Photolysis of *cis*-2-Butene and Its Implications for Radiation Chemistry

By Yoshihiko HATANO and Shoji SHIDA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Ookayama, Tokyo

(Received June 14, 1965)

The direct photolysis at 1849 Å and the mercury-photosensitized reaction at 2537 Å of *cis*-2-butene have been studied in the gas phase at room temperature. It may be considered that the excited singlet state of *cis*-2-butene is formed in the former, and that the excited triplet state of *cis*-2-butene is formed in the latter. *trans*-2-Butene is predominantly produced in the latter, while the decomposition products (e. g., hydrogen, methane, ethane, ethylene, propylene, etc.) predominate in the former. The rates of the formation of all the products are pressure-independent in the former, while in the latter those of all products except *trans*-2-butene decrease rapidly with an increase in the initial pressure. The rate of *trans*-2-butene formation in the latter, however, increases gradually with an increase in the initial pressure until it becomes constant above 100 mmHg. By comparing the pressure-dependence and the product-distribution of these two reactions with the results of the radiolysis of liquid *cis*-2-butene, one may conclude that the excited triplet state of *cis*-2-butene contributes chiefly to the formation of *trans*-2-butene in the radiolysis, while the excited singlet state of *cis*-2-butene contributes chiefly to the decomposition products.

There are two ways in which excited molecules can be formed by ionizing radiation. One is from the neutralization of a positive ion by an electron or by a negative ion; the other is the direct excitation by the high-energy radiation itself. It is generally considered that these excited states consist of high levels of the different state manifolds. However, little attention has been paid to the nature of these states.

In a previous paper[1] on the radiolysis of liquid *cis*-2-butene, it was considered that *trans*-2-butene, which may be produced for the most part through the molecular mechanism, is formed not through the excited singlet state but through the excited triplet state. Moreover, on the basis of this inference, the effects of added aromatic hydrocarbons[1] and nitrous oxide[2],* on the radiolysis could be explained consistently.

The present investigation was undertaken in

1) Y. Hatano, S. Shida and S. Sato, This Bulletin, **37**, 1854 (1964).

2) Y. Hatano and S. Shida, The 18th Annual Meeting of the Chemical Society of Japan, Osaka, 1965.

* Nitrous oxide has been considered as an effective electron scavenger: $N_2O + e \rightarrow N_2 + O^-$. The addition of nitrous oxide to liquid *cis*-2-butene has the same effect on the formation of *trans*-2-butene as in the case of benzene as an additive.[1]

an attempt to confirm the above inference experimentally. The excited singlet and triplet states of gaseous *cis*-2-butene were formed photochemically. The former was formed by the direct photoexcitation at 1849 Å, while the latter was formed by the mercury-photosensitization at 2537 Å.

Gary and Pickett[3] investigated the ultraviolet absorption of *cis*-2-butene and reported that *cis*-2-butene has a maximum absorption in the region near 1849 Å. The energy level of the first excited singlet state of *cis*-2-butene has been estimated[4,5] to be a little lower than that of $Hg6^1P_1$, 6.7 eV., corresponding to 1849 Å. Therefore, the excited singlet state of *cis*-2-butene may be formed by the direct photo-excitation at 1849 Å. There has been, to the authors' knowledge, no report dealing with the direct photolysis of *cis*-2-butene.

On the other hand, many works have been done on the mercury-photosensitized reaction of olefins.[6] It is generally considered that olefins are excited by the collision between olefin molecules and excited mercury atoms, $Hg6^3P_1$, formed by the irradiation of light at 2537 Å. These excited olefin molecules return to the ground states through decomposition or collisional deactivation. On the basis of the results of the benzene-photosensitized reaction of *cis*-2-butene[7-9] and other evidence,[4,5] the energy level of the first excited triplet state of *cis*-2-butene is estimated to be about 4 eV. which is lower than that of $Hg6^3P_1$, 4.8 eV. Therefore, the excited triplet state of *cis*-2-butene may be formed by the mercury-photosensitization at 2537 Å. The mercury-photosensitized reaction of 2-butenes, especially the cis-trans isomerization, has been reported by Cundall et al.[10] According to them, the overall reaction can be explained in terms of the formation of the vibrationally-excited triplet state of 2-butene.

In this paper, experiments on the direct photolysis and the mercury-photosensitized reaction of *cis*-2-butene were undertaken in order to get some information about the role of lower excited singlet and triplet states in the radiolysis of *cis*-2-butene.

Experimental

Materials.—Matheson research-grade *cis*-2-butene was used after the usual degassing and bulb-to-bulb distillations. It was found by gas chromatography to contain less than 0.4% *trans*-2-butene.

In the experiments on the direct photolysis of gaseous *cis*-2-butene, it was prepared using the mercury-free vacuum line and was purified using gold foil in a cold trap.

Irradiation.—In the experiments on the direct photolysis at 1849 Å, an ordinary mercury resonance lamp was used as the light source. A cylindrical quartz cell, 50 mm. in diameter and 20 mm. thick, was connected to a mercury-free vacuum line. Moreover, the absence of mercury in the system was confirmed by making sure that the reaction did not take place at all when *cis*-2-butene was irradiated for 30 min. with the light source of 2537 Å.

In the experiments on the mercury-photosensitized reaction at 2537 Å, the light source and the reaction cell were the same as those used in the experiments on the direct photolysis. A droplet of mercury in the reaction cell provided a constant pressure of mercury vapor. The light shorter than 2100 Å was cut off with a filter.

All runs were made statically at room temperature, 25±3°C.

Analysis.—The analytical procedures were almost the same as in the radiolysis.[1]

After irradiation the gases noncondensable at −196°C (hydrogen and methane) were collected and measured by an analysis device composed of a Toepler pump, a McLeod gauge, and a copper oxide furnace. Products condensable at −196°C were analyzed by a home-made reduced-pressure-type gas chromatograph. A benzyl ether column was used mainly at room temperature, for the separation of C_1—C_4 hydrocarbons.

Results and Discussion

Table I shows the amounts of the major products of the direct photolysis of gaseous *cis*-2-butene at 1849 Å, the mercury-photosensitized decomposition of gaseous *cis*-2-butene at 2537 Å, and the γ-radiolysis[1] of liquid *cis*-2-butene. A marked difference between the relative rates of formation for

Table I. Products from the direct photolysis of gaseous *cis*-2-butene at 1849 Å and the mercury-photosensitized reaction of gaseous *cis*-2-butene at 2537 Å and the γ-radiolysis of liquid *cis*-2-butene

these reactions may be noted. In the mercury-photosensitized decomposition, *trans*-2-butene is a major product, but not in the direct photolysis. To compare these reactions more precisely, the dependence of the rates of formation on the irradiation time and the pressure was examined.

The amount of the major products were measured at various irradiation times in the direct photolysis. The initial pressure of *cis*-2-butene was 40 mmHg. Until 3 min. of irradiation every product increased linearly with the time, showing no measurable secondary reaction of the product at this stage of reaction, although it decreased with time after 3 min. Figure 1 shows the rates of the formation of major products at various initial pressures for the irradiation time of 3 min. It may clearly be seen that the rates of the formation of all products are practically constant at pressures between 20 and 120 mmHg. These features agree with the results of the direct photolysis of propylene,[11] 1-butene[12] and cyclopentene[13] at 1849 Å.

The amounts of the major products were also measured at various irradiation times in the mercury-photosensitized reaction. The initial pressure of *cis*-2-butene was again 40 mmHg. Until 5 min. of irradiation every product increased linearly with the time; then it decreased with time after 5 min. Figure 2 shows the rates of the formation of major products at various initial pressures for the irradiation time of 5 min. It may clearly be seen that the rates of the formation of all products except *trans*-2-butene are strongly pressure-dependent. This is remarkably different from the results of the direct photolysis. The rates of the formation of all products except *trans*-2-butene rapidly decrease with an increase in the initial pressure. The rate of *trans*-2-butene formation,

however, increases gradually with an increase in the initial pressure until it becomes constant above 100 mmHg.

On the basis of these data, it seems reasonable to assume that the excited triplet state of *cis*-2-butene is more readily deactivated than the excited singlet state of *cis*-2-butene. In other words, the life-time of the latter is shorter than that of the former, and the latter decomposes with a larger probability before the collisional deactivation. The ratio of the cis-trans isomerization to the decomposition is 60 at the pressure of 100 mmHg in the mercury-photosensitized reaction, while it is 0.07 at the pressure of 120 mmHg in the direct photolysis. Thus, the excited triplet state may contribute much more effectively to the formation of *trans*-2-butene than does the excited singlet state.

These results may reasonably be explained by the following mechanisms.

In the direct photolysis of gaseous *cis*-2-butene at 1849 Å, the excited singlet state of *cis*-2-butene is formed, giving chiefly such decomposition products as C_1, C_2 and C_3 hydrocarbons:

$$\text{Cis} + h\nu \rightarrow \text{Cis}^* \text{ (singlet)} \quad (1)$$

$$\text{Cis}^* \text{ (singlet)} \rightarrow \text{Decomp. products} \quad (2)$$

where Cis and Cis*(singlet) indicate the ground state and the first excited singlet state of *cis*-2-butene respectively.

In the mercury-photosensitized reaction, on the other hand, the overall reaction is explained by

the formation of a vibrationally-excited triplet state of *cis*-2-butene in a fashion similar to that described by Cundall:[10]

$$Hg^1S_0 + h\nu \rightarrow Hg^3P_1 \quad (3)$$

$$Hg^3P_1 \rightarrow Hg^1S_0 + h\nu \quad (4)$$

$$Hg^3P_1 + Cis \rightarrow Cis^{**}\ (triplet) + Hg^1S_0 \quad (5)$$

$$Cis^{**}\ (triplet) + Cis \rightarrow Cis^{*}\ (triplet) + Cis \quad (6)$$

$$Cis^{*}\ (triplet) \rightarrow Trans \quad (7)$$

$$\searrow\ Cis \quad (8)$$

$$Cis^{**}\ (triplet) \rightarrow Decomp.\ products \quad (9)$$

where Cis*(triplet) and Cis**(triplet) indicate the first excited triplet state and the vibrationally-excited triplet state of *cis*-2-butene respectively. The steady-state treatment leads to Eqs. I and II:

$$R_t \simeq \frac{k_7 I}{k_7+k_8} \quad \text{at a higher pressure} \quad (I)$$

$$R_d = \frac{k_5 k_9 IP}{(k_4+k_5P)(k_9+k_6P)} \quad (II)$$

(P=the initial pressure of *cis*-2-butene)

where R_t and R_d indicate the rate of the formation of *trans*-2-butene and that of the decomposition products respectively. From Eq. I, it seems that the rate of the formation of *trans*-2-butene should be pressure-independent at a higher pressure. From Eq. II, it seems that the rate of the formation of decomposition products should become zero at higher pressures.

In view of the fact that the radiolysis of *cis*-2-butene mentioned above[1] is the reaction in the liquid phase, the most reasonable conclusion to be drawn from the above discussion is that the excited triplet state of *cis*-2-butene may contribute chiefly to the formation of *trans*-2-butene in the radiolysis, while the excited singlet state of *cis*-2-butene may contribute chiefly to the decomposition products. Comparing the patterns of the distribution of decomposition products in the three reactions, one may find that the pattern of the distribution in the radiolysis is similar to that in the direct photolysis. Thus, the following mechanism may be proposed for the radiolysis of liquid *cis*-2-butene:

$$\begin{array}{l} \quad\quad\quad\

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 39 460—465 (1966)

The Infrared Spectra of Artificial Coal made from Submerged Wood at Uozu, Toyama Prefecture, Japan

By Hiroshi TSUKASHIMA

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka

(Received June 15, 1965)

The infrared spectra of artificial coal prepared from Submerged Wood were observed and compared with those of lignin and cellulose. The artificial coalification seems to proceed in three stages, characterized by the corresponding infrared spectra, i. e., a cellulose-like spectrum, a lignin-like spectrum, and a spectrum resembling that of natural coal. The infrared spectrum of artificial coal is generally similar to that of natural coal with a little higher carbon content, suggesting that the degree of coalification is more advanced in artificial coal than in natural coal. The background absorption in the infrared spectra of artificial coal of a low coalification is weak, while that in the infrared spectra of artificial coal of a high coalification is strong.

The infrared spectra of coal have frequently been used to investigate its structure.[1] The present report will deal with the mechanism of artificial coalification by observing the infrared spectra of the artificial coal prepared from Submerged Wood at Uozu, Toyama Prefecture, Japan, and by comparing these spectra with those of lignin and cellulose.

Experimental

One series of samples of artificial coal was prepared as follows. Fifty grams of the powdered sample (40—100 mesh) of the Submerged Wood was placed in a stainless steel autoclave of the shaking type (capacity; 1 l.) with 500 ml. of water. This was then heated at 150, 170, 200, 250, 260, 270, 280, 300, 325 and 350°C for 8, 24, 40 and 72 hr. under gas-steam pressure at 4, 13, 25, 50, 58, 65, 80, 105, 154 and 210 atom. (gauge pressure). The artificial coal (AC) thus obtained from the Submerged Wood was separated by filtration, washed with water, and air-dried.

Another series of samples of the artificial coal was prepared as follows. After 50 g. of the powdered sample of the Submerged Wood had been placed in a stainless steel autoclave of the rotating type (capacity; 5 l.) with 700 ml. of water, the air in the autoclave was replaced with nitrogen. Then the powdered sample in the autoclave was heated at 375 and 400°C for 8 and 40 hr. under gas-steam pressure at 210 and 270 atm. (gauge pressure). The artificial coal (AC) thus obtained was separated by filtration, then washed with water and air-dried. The conditions of artificial coalification are shown in Table I, while the elementary analysis and the yield of the artificial coal are given in Table II.

The infrared (IR) spectra of AC free from bitumen, lignins and cellulose were also measured. Powdered filter paper (No. 2) of the Toyoroshi Co., Ltd., was used as a sample of cellulose in measuring the IR spectra.

The lignin samples were prepared as follows. About 20 g. of powdered saw dust (60—100 mesh) from needle-leaved trees (Japanese red pin trees) was treated with a mixed solvent of ethyl alcohol and benzene (1 : 1) in order to extract the resinous matter and then treated with 400 ml. of concentrated hydrochloric acid (42%) and left to stand at room temperature for 24 hr., during which time it was occasionally shaken. Then the mixture was diluted with 3.6 l. of water and heated to boiling. The lignin thus obtained was filtered and thoroughly washed with hot water until the washings were free from chlorine ions. The yield was 13—16 g. of the so-called hydrochloric acid lignin, a light brownish powder.

About 100 ml. of concentrated hydrochloric acid was added to 400 ml. of waste liquor (specific gravity; 1.097 at 14°C) of sodium sulfate pulp made from pine trees and some broad-leaved trees (1 : 3), and then heated on a water bath for 1 hr. The thioalkali lignin thus precipitated was washed with hot water on a Buchner funnel until no chlorine ions were detected in the washings, and then dried at room temperature. The thioalkali lignin (30—40 g.) was thus obtained. The analytical data are listed in Table III.[2]

The IR spectra of the AC, lignins and cellulose were measured on potassium bromide disks in the following way. Five milligrams of the above sample in a small glass tube was dried in a vacuum desiccator with phosphorus pentoxide at 110°C for 6 hr., and then the tube was sealed. At a constant temperature (20°C) and at a constant humidity (35%) the sealed glass tube

Results

The IR spectra of the Submerged Wood, AC, lignins and cellulose were measured. The results are shown in Fig. 1. The IR spectra of lignin and cellulose reported by previous authors are also shown, for the purpose of comparison, in Fig. 1.

Discussion

1) There have been two explanations for the strong background absorption of the IR spectra of coal.[1] One is that it is caused by the size of the particle of the sample. The other is that it is caused by the growth of graphite crystallites as the condensation of the aromatic cluster proceeds. When there is a low degree of the coalification of AC, the background absorption is weak, but it is very strong with a high degree of coalification, especially in the region from 4 μ to 6 μ, possibly because of the growth of graphite crystallites and the abundantly distributed particles of a comparatively large size. The background absorption is stronger in the spectra of AC than in that of natural coal of a similar carbon content. This might be caused by the greater refractivity of AC.

2) The IR spectrum of AC is generally similar to that of natural coal with a little higher carbon content, suggesting that the degree of coalification is more advanced in AC than in natural coal.

3) 3.03 μ (3300 cm^{-1}). The H-bonded OH group. The absorption of the H-bonded OH group increases with an advance in coalification under 200°C and decreases with an advance in coalification above 200°C. Similar results have been reported both in other kinds of AC and in natural coal.[1]

4) 3.25 μ (3000—3100 cm^{-1}). The aromatic CH group. There was no absorption of the aromatic CH group in the AC spectra, but it appears in the spectra of natural coal in which the carbon content is above 80 per cent.[1]

5) 3.43 μ (2800—3000 cm^{-1}). The aliphatic CH (CH_2, CH_3) group. The absorption of the aliphatic CH group appears at a medium intensity and then gradually decreases above 200°C because the aliphatic CH group in AC is broken up.

6) 5.85 μ (1700 cm^{-1}) The carbonyl and carboxyl CO group. There is no absorption of the CO group in the spectra of Submerged Wood and the AC obtained at 150°C; it appears in the spectra of the AC obtained at 200°C and increases in those of the AC obtained at 200—250°C, while it diminishes in the AC obtained above 250°C. The cellulose that contains no CO group vanishes at about 200°C. The remaining lignin that contains a CO group causes the absorption band of the CO group to appear; this gradually increases up to 250°C, possibly because of the oxidations of the lignin,[4] and then decreases above 250°C, possibly because of the conversion of lignin into a coaly matter by dehydration and deoxidation.

7) 6.25 μ (1600 cm^{-1}). Aromatic C–C bond and oxygen-containing groups (H-bonded carbonyl groups). This absorption is mainly due to the C–C double bond in the aromatic structure of coal. On the other hand, it has been reported[1] that the absorption intensity of this C–C vibration is enhanced by oxygen-containing groups and that the H-bonded carbonyl group is responsible for this absorption. It appears at a considerable intensity in the AC spectra and increases with an advance in the coalification of AC. In the spectra of the AC obtained above 280°C, it is weak, possibly because the background absorption has increased.[1]

8) 6.64 μ (1500 cm^{-1}) The aromatic C–C bond. The absorption of the aromatic C–C bond is very strong in the spectra of lignins.[1,5] In the spectra of the AC of a low coalification (obtained under 200°C), the absorption of the aromatic C–C bond at 6.64 μ is stronger than those of the aromatic C–C bond and oxygen-containing groups at 6.25 μ, but in the spectra of the AC of a high coalification (obtained at 200—250°C), the former is weaker than the latter. This shows that the oxidation of lignin in AC occurs at 200—250°C (cf. 6)).

9) 6.85, 7.00, 7.33 μ (1460, 1430, 1360 cm^{-1}). Aliphatic CH_2, CH_3, and cyclic CH_2 groups. The absorption intensities of aliphatic CH and cyclic CH groups decrease with an advance in the coalification.

10) 7.92, 8.30 μ (1260, 1200 cm^{-1}). The aromatic C–O (phenolic OH, aryl ether and methoxyl benzene) bond. The absorption of the aromatic C–O bond increases up to 250—260°C with an advance in the coalification and then decreases above 260°C.

11) 8.66—9.70 μ (1150—1030 cm^{-1}). The carboxyl CO group, the aliphatic ether C–O–C bond and the alcohol OH group. The absorptions of

AC obtained above 200°C.

12) The absorption bands of the aromatic CH groups at 11—14.5 μ (690—900 cm^{-1}) do not appear clearly in the AC spectra.

13) The functional group absorptions in the IR spectrum of material of a complicated structure with a great molecular weight are difficult to discriminate because of the interference of each group with the others. In such a case, a comparison of the figures of the IR spectra of the materials is useful. For instance, the IR spectra of the AC obtained at 150—200°C are similar to that of cellulose between 5.00—6.00 μ, 7.00—7.33 μ and 9.00—9.70 μ. The IR spectra of the AC obtained at 250—260°C are similar to those of lignins between

5.00—6.00 μ, 6.25—7.92 μ and 9.00—9.70 μ. The IR srectra of the AC obtained at 270—280°C are different from those of lignins, and their absorption bands between 9.00—9.70 μ are weak.

14) The remarkable change in the IR spectra and in the results of the rational analyses of AC obtained at 200—250°C shows that a very important change in its chemical structure has occurred in this temperature range.

15) The relation between the carbon content of AC and the optical density of the bands of the functional groups is illustrated in Fig. 2.[6] The percentage transmission near 5.26 μ (1900 cm^{-1}) was chosen for the base line in calculating the optical density. In Fig. 2 there are two clearly discernible turning points at carbon percentages, about 60 and 75. Thus artificial coalification seems to proceed in three stages. In the first stage, at carbon percentages of 60 and less (coalification temperature; 150—200°C), the IR spectra of the AC are similar to that of cellulose. In the second stage, at carbon percentages from 60 to 75 (coalification temperature; 200—250°C), they are similar to those of lignins. In the third stage, at carbon percentages of 75 and more (coalification temperature; above 250°C), they are rather similar to those of natural coal. These results agree with those mentioned above (6, 13 and 14) and with those presented in a previous report by the present author.[2]

The Liquid-Liquid Extraction of Alkali Metals as Their Poly-Iodides

By Ikuko AKAZA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received June 16, 1965)

It has been known that alkali metal ions can be extracted into nitrobenzene as their poly-iodides, but the extraction has not been attempted for various salts of alkali metals except in the case of their iodides. In this research ammonium iodide and elemental iodine were preferentially added to the extraction system in order to convert various alkali metal salts into poly-iodides. Ammonium iodide should be larger than the equivalent amount to an alkali metal present in an aqueous solution. The ratio of free iodine to ammonium iodide is an important factor; when the ratio is more than three, a higher distribution ratio is obtained. The ratio of iodine to iodide in the organic phase after the extraction is estimated to be six; therefore, the extracted species seems to be heptaiodide. The extractability of alkali metals increases in the order: Li–Na–K–Rb–Cs, and the distribution ratio decreases with the increase in the amount of metal ions taken in. Back extraction is achieved by shaking the organic phase with 10 M nitric acid. The separation factor between the metals is too low for them to be separated from one another.

Dawson et al. demonstrated at the turn of the century that alkali metal ions could be extracted into nitrobenzene and other solvents with the poly-iodide anion.[1-3] Later Bock and Hoppe[4] investigated the distribution of alkali poly-iodides between aqueous solutions and various organic solvents, and obtained much valuable information on the liquid-liquid extraction of alkali metal ions and their separability from one another. However, in their experiments, metal iodides and iodine were added to the extraction system, and other alkali salts, such as chloride and sulfate, were left outside their scope. Many problems pertinent to the practical application of the method have remained unsolved, e. g., how to convert the chloride or sulfate into iodide easily in an aqueous solution, what distribution ratio is to be established in the presence of diverse ions, and what are the optimum conditions to be kept during the extraction process. The present author has studied the above subjects using nitrobenzene as an extracting solvent. This paper will describe a device for the conversion of other salts of alkali metals into iodides; ammonium iodide is preferred as the reagent for the conversion. Also described will be the relation of the distribution ratio to the concentrations of various alkali salts in the aqueous phase and of the elemental iodine added to the system. It can be concluded that the metals may be divided into two groups: the first, which has lower distribution ratios in

the nitrobenzene, includes sodium and lithium, while the second, which has higher distribution ratios, consists of potassium, rubidium and cesium. The separation of the metals within each group, even by multiple extraction in the batch system, seems to be difficult because of their low separation factor. The present author aims to accomplish a satisfactory separation of these metals by reversed-phase partition chromatography based on liquid-liquid extraction. The techniques employed and the separability obtained will be described in a following paper.

Experimental

Into a 50-ml. separatory funnel there was put 10 ml. of an aqueous solution containing a known amount of alkali salt and a varying amount of ammonium iodide; then 10 ml. of nitrobenzene was added. After solid iodine in varying amounts had been put into the funnel, the vessel was tightly stoppered and shaken for five minutes with an Iwaki-V-S shaking machine, operating at 230 double strokes per minute. After the phases became disengaged, the lower organic phase was drained into an Erlenmyer flask, from which 5 ml. of the organic phase was then pipetted into a porcelain crucible. The nitrobenzene and free iodine were driven off by heating them with an infrared lamp. When the residue became white, 1 ml. of 5 M sulfuric acid was dropped onto it and heating was continued under the infrared lamp until the white fumes of sulfuric acid ceased to evolve. The crucible was then put in an electric furnace and heated to 750°C in the cases of potassium and sodium and to 600°C in the cases of lithium, rubidium and cesium. The weight of alkali sulfate was determined in order to calculate the distribution ratio as well as the recovery of the metal. However, in the presence of free iodine, the volumes of the aqueous and organic phases after the equilibration both remarkably differed from that taken initially of the aqueous solution and the nitrobenzene; therefore, the distribution ratio of the metal was computed with the volumes which resulted. The composition of the organic phase was estimated as follows: a part of the phase was taken out and the amount of free iodine was titrated with a standard sodium thiosulfate solution using starch as the indicator. The total iodine content was estimated by titration in hydrochloric acid with a standard potassium iodate solution, as has been described in a general text-book.[5]

Results and Discussion

The Formation and Extraction of Poly-iodides.—If alkali chlorides or sulfates only are present in the sample solution, they cannot be extracted with nitrobenzene. Therefore, a method should first be established to convert them into polyiodides. For this purpose a mixture of hydriodic acid and iodine, another of ammonium iodide, sulfuric acid and iodine, and a third of ammonium iodide and iodine were tried separately for the solution containing alkali metal salts. From the results obtained after the extraction in the presence of each mixture, the last one was found to be the best for the conversion of alkali metals into poly-iodides in an aqueous solution, with respect to the stability of the reagents and the ease of maintaining the optimum conditions.

Definite amounts of a potassium sulfate solution and a solution of ammonium iodide, varying in amount from one to five equivalents to the potassium ion, were put into a separatory funnel; the total volume was made 10 ml. Ten milliliters of nitrobenzene were then added, 1.00 to 2.00 g. of solid iodine was thrown into the funnel, and the extraction was attempted according to the standard procedure. As is shown in Table I, the maximum recovery was obtained at the NH_4I : K ratio close to two at a fixed amount of iodine. The recovery of potassium increased with the amount of iodine added and with the ratio of iodine to iodide; when 2 g. of iodine was used the recovery was as high as 93%, while when the iodine was absent scarcely any extraction was accomplished. Thus the extraction seemed to depend upon the amounts of both ammonium iodide and iodine in the system. In other words two variable factors, the NH_4I : K and the I_2 : NH_4I ratios, may be considered to affect the extraction of potassium. Next, the extraction process was carried further, keeping the NH_4I : K ratio at two and varying the I_2 : I^- ratio from unity to five in the reaction system.

In each case 47.1 mg. of potassium was taken as 105.0 mg. of potassium sulfate in 10 ml. of an aqueous phase, and 10 ml. of nitrobenzene was used as an extractant.

5) I. M. Kolthoff and R. Belcher, "Volumetric Analysis," Vol. 3, Interscience Publ., New York (1957), p. 447.

The larger the amount of iodine added, the larger was the recovery of potassium in the organic phase, as is shown in Table II, and it was also found that as large a recovery as 97% was obtained when the $I_2 : I^-$ ratio was 5.0.

Table II. Dependence of recovery on the ratio of free iodine to iodide in the extraction system

$I_2 : I^-$ initially added to system	Recovery of potassium in organic phase %	*D*	$I : I^-$ in org. phase after extn.	Recovery of NH_4^+ in organic phase %	*D*
1.0	64.1	1.73	3.9	9.1	0.09
2.0	86.6	6.16	4.7	32.5	0.45
3.0	96.5	25.60	6.0	48.1	0.87
4.0	96.0	21.67	6.6	57.6	1.23
5.0	97.4	33.33	6.4	58.8	1.28

In each case 47.1 mg. of potassium as 105.0 mg. of sulfate and 400 mg. of ammonium iodide were taken in 10 ml. of an aqueous phase. Free iodine was added to nitrobenzene to make the ratio $I_2 : I^-$ in the system as shown in the first column.

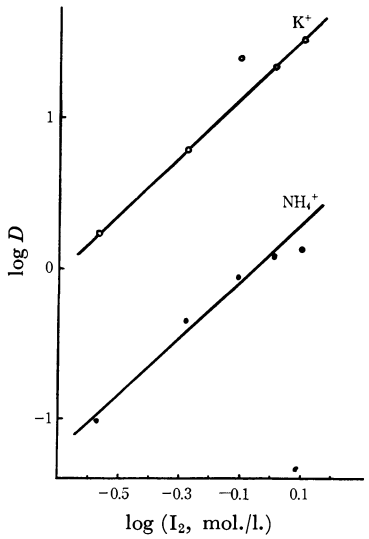

Fig. 1. Relation between distribution ratio and the concentration of iodine added in the system.

In order to examine the composition of the organic phase after the extraction, a part of it was taken out and the amounts of free iodine and iodide were determined volumetrically. From the results shown in the fourth column of Table II, it can be seen that the ratio of iodine to iodide in the organic phase in which the largest recovery of potassium was accomplished was approximately six; therefore, the extracted compound of potassium seemed to be the heptaiodide KI_7, the formation of which has been described by Dawson.[2] In this process the ammonium ion was also extracted into nitrobenzene as its poly-iodide, as is shown in the last column of Table II. Generally, it may be concluded that when the molar ratio of iodine to ammonium iodide exceeds three, a nearly constant distribution ratio is maintained, and the extracted species is the hepta- or a higher poly-iodide of the metal.

In the extraction the relation between the distribution ratio of the metal and the amount of free iodine added to the system may give information as to the composition of the compound extracted as well as the extraction mechanism in the process. In Fig. 1, the relation is shown in a graph of log *D* vs. log (I_2); this relation is a straight line with a slope of 2. Taking the results in Table II and Fig. 1 into account, it can be assumed that potassium and ammonium ions form their triiodides readily in the aqueous phase and that two molecules of free iodine subsequently combine with the triiodide to form the heptaiodide.

In Table III are shown the results of the extraction in which the $I_2 : I^-$ ratio was kept constant while the amount of ammonium iodide was varied. From the results it is clear that if the $I_2 : I^-$ ratio is kept constant at 3.2, the recovery of potassium in the organic phase is also held constant, so the ratio is an important factor, while the amount of ammonium iodide is not. Aqueous solutions containing various amounts of potassium were submitted to extraction by nitrobenzene, as has been described above, at the nearly constant ratio $I_2 : I^-$. The results are shown in Table IV, from which it may be seen that the larger the amount of potassium taken, the lower is the recovery of its poly-iodide; however, the distribution ratio remains constant for a given amount of potassium, even when 20 ml. of the solvent is used. The relation of the distribution ratio to the amount of potassium taken is clearly shown in Fig. 2, in which a straight line with a slope of -1 may be drawn between the distribution ratio and the amount of potassium, both in the logarithmic scale. In these experiments the composition of the organic phase was also examined in the manner shown previously; the extracted species could be identified as potassium heptaiodide, regardless of

Extractions were carried out with potassium taken as sulfate and under the following conditions.

(1) 0.40 g. NH_4I and 2.80 g. I_2 were put into the system.
(2) 1.48 g. NH_4I and 9.08 g. I_2 were put into the system.
(3) 10 ml. of nitrobenzene was used as an extractant.
(4) 20 ml. of nitrobenzene was used as an extractant.

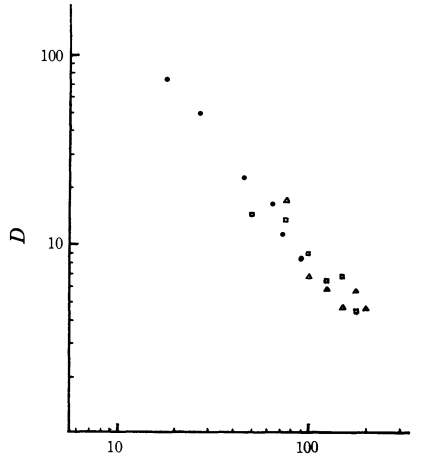

Fig. 2. Dependence of distribution ratio on the amount of potassium taken in the system. Condition of extraction (1), (2), (3) and (4) are shown in Table IV.
• (1) and (3), □ (2) and (3), △ (2) and (4)

the amount of potassium in the original solution.

The extraction procedure was also applied to an aqueous solution containing various kinds of potassium salt, as is shown in Table V; satisfactory recoveries were obtained, even when their amount present was large. Therefore, this procedure must be applicable to solutions containing neutral potassium salts. Other alkali metal ions, lithium, sodium, rubidium and cesium, were subjected to extraction under the same conditions as for potassium, but the detailed results will be

TABLE V. EXTRACTION OF POTASSIUM FROM AQUEOUS SOLUTION CONTAINING VARIOUS KINDS OF POTASSIUM SALT

Potassium salt kind	Potassium salt taken mg.	Potassium taken mg.	Distribution ratio (D)	Recovery of K^+ %
KNO_3	323.0	125.0	6.58	86.8
KSCN	311.0	125.0	7.62	88.4
K_2CO_3	221.0	125.0	8.69	89.7

KBr	381.0	125.0	6.76	87.1
KCl	238.0	125.0	7.39	88.1
KI	531.0	125.0	10.40	91.2
K_2SO_4	279.0	125.0	7.50	88.1

In the above experiment 1.48 g. of NH_4I and 9.08 g. of iodine were added to each extraction system.

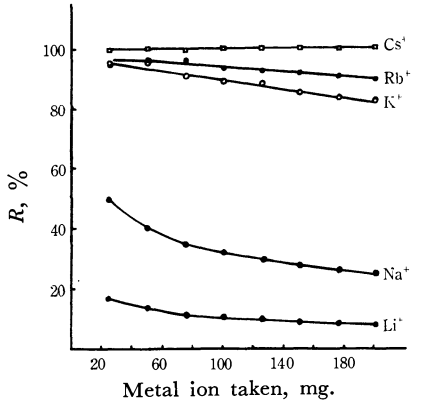

Fig. 3. Recovery of extraction of various metal chlorides as poly-iodides in nitrobenzene. In each case 1.483 g. of NH_4I, 10 ml. of nitrobenzene and 9.09 g. of free iodine were present in the system.

omitted here, since these ions behaved exactly like potassium. The summarization in Fig. 3 shows the behavior of individual metal ions when extracted with nitrobenzene from an aqueous solution containing the corresponding chloride. The same results were obtained for their sulfates. Cesium was the most easily extractable in both cases, followed by rubidium, potassium, sodium, and lithium in that order. Because the distribution ratios of cesium, rubidium and potassium are

approximately equal, these metals may be included in one group, while sodium and lithium may be put in another for the same reason. Because of the marked difference in distribution ratio between potassium and sodium, these ions may be separated from each other by the method of continuous extraction.

The Effect of Acids on the Extraction.—If a free acid is present in the aqueous solution, it may affect the extraction of alkali poly-iodides. As an example, the data found in the case of perchloric acid are given in Table VI. It may be concluded that the stronger the acid, the less satisfactory the extraction.

Table VI. Effect of acids on the extraction

a) Perchloric acid:

$HClO_4$ in aq. phase M	Extraction of Na		Extraction of K	
	D	Recovery %	D	Recovery %
0.00	0.471	32.0	8.90	89.0
0.02	0.429	30.0	11.00	91.7
0.06	0.410	29.1	9.75	90.7
0.10	0.404	28.8	9.53	90.5
0.20	0.412	29.2	9.64	90.6
0.40	0.377	27.4	6.69	78.3
0.50	0.357	26.3	2.01	66.8
1.00	0.280	22.4	0.48	32.8

b) Organic acids:

Acid, 100 mg. equivalent	pH of aqueous phase before extraction	Extraction of Na	
		D	Recovery %
Citric acid	1.95	0.464	31.7
Oxalic acid	0.90	0.477	32.3
Succinic acid	2.32	0.456	31.3
Tartaric acid	1.61	0.473	32.1
Without org. acid	6.18	0.471	32.0

In the above experiment 1.48 g. of ammonium iodide and 9.08 g. of iodine were put into the system, and 100 mg. of sodium or potassium ion was taken in each case.

The Back-extraction of the Metals from the Organic Phase.—The organic phase can be readily stripped, by the following method, of the metal it has taken up. The organic phase separated with a separating funnel was mixed with an equal volume of 10 M nitric acid; the free iodine separating out as a solid by the oxidative action of the acid was then filtered off with a sintered-glass-filter and washed well with water. In the filtrate and washings, two layers of liquid were seen; one of them was nitrobenzene, and the other, a solution of the nitrate of the metal. The organic layer was rejected, and the aqueous phase was evaporated to dryness under an infrared lamp. Thus the alkali metal in the nitrobenzene layer was isolated as its nitrate. The residual iodine on the filter was found to have adsorbed a small quantity of the metal. The yield in the stripping process reached 97.0%.

Summary

The author has described how alkali metal ions in an aqueous solution can be extracted as their hepta- or higher poly-iodides into nitrobenzene in the presence of ammonium iodide in an aqueous solution and in the presence of free iodine in an organic solvent. The extractability of the metals increased in the order; Li–Na–K–Rb–Cs. The equivalence ratio of free iodine to ammonium iodide was an important factor in the satisfactory extraction of the metallic poly-iodide; the ratio had to be kept above three. Acids in the aqueous phase inhibited the extraction, and the removal of metals from the nitrobenzene could be achieved by shaking it with 10 M nitric acid.

The author wishes to express her hearty thanks to Professor Toshiyasu Kiba for his advice and encouragement.

Intramolecular Interaction between Hydroxyl Group and π-Electrons. XIX.[1] Steric Effects on the Interaction in *o*-(1-Alkenyl)phenols

By Michinori Ōki and Hiizu Iwamura

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo

(Received June 17, 1965)

Nine *o*-(1-alkenyl)phenols, *o*-$HOC_6H_4CR^1{=}CR^2R^3$, have been prepared and their ultraviolet absorptions and the O–H stretching bands (ν_{O-H}) in the infrared absorption measured in an effort to explore the effect of the substituents, R^1—R^3, on the strength of the intramolecular interaction between the OH group and the π-electron system. The K-band of the styrene chromophore at 240—250 mμ is lost in the samples involving R^1, which is bulkier than methyl. As the size of R^1 increases from H, by way of Me, Et, and *i*-Pr, to *t*-Bu, the angle of the twist between the planes made by the benzene ring and the ethylenic group must increase; this trend is nearly parallel with the amount of the interacting ν_{O-H} in the infrared spectrum. The phenomenon is interpreted mainly by means of the favorable overlap between the O–H group and π-orbitals. *o*-Isobutenylphenol shows a ν_{O-H} triplet at 3610, 3576 and 3539 cm^{-1}. The latter two bands are assigned to the hydroxyl group interacting with π-electrons on the vinyl group intramolecularly. A tentative explanation has been developed which attributes the two interacting bands to the presence of two interacting conformations. The solvent effect on the ultraviolet absorptions is in accord with this explanation.

o-Vinylphenol shows a doublet O–H stretching vibration (ν_{O-H}) at 3611 and 3557 cm^{-1} in the infrared absorption spectra[2]; the latter band has been assigned to the hydroxyl group taking part in the intramolecular interaction with the π-electrons on the vinyl group. Although the interaction does not involve the lone pair of electrons as a proton acceptor, it has been found to be analogous to the ordinary hydrogen bonding in that the polarizable π-electrons play the role of the electron donor. Thus, in *o*-(*trans*-1-propenyl)-phenol, the electron-releasing methyl substituent on the vinyl group enhances the strength of the interaction, as is visualized by a greater shift of the ν_{O-H} to the lower frequency,[3,4] while in 2-hydroxy-*trans*-stilbene[2] and 2-hydroxy-ω-nitrostyrene,[5] the electron-attracting phenyl and nitro groups diminish and extinguish the interaction[6] respectively. These electronic effects have been fully discussed in a series of 2-hydroxybiphenyls,[7] which are aromatic analogs of *o*-vinylphenols.

Since the strength of the interaction must be sharply dependent on the overlap between the π-orbitals in the electron donor and the electron-accepting O–H orbital, the steric hindrance in the neighborhood of the interacting group may be expected to alter the interaction to a great extent. In the present paper, it will be shown that the substituents in the alkenyl group of *o*-(1-alkenyl)phenols (I—VIII) exert a conspicuous steric effect on the interaction in addition to the expected electronic effect. The steric environment of the phenols will be evaluated as a steric inhibition of the resonance between the benzene ring and the alkenyl group through the ultraviolet absorption spectra.

	R^1	R^2	R^3
I	H	H	H
II	Me	H	H
III	*t*-Bu	H	H
IV	H	Me	Me
IV′	H	Me	Et
V	Me	Me	Me
VI	*i*-Pr	Me	Me
VII	H	Me	H
VIII	Et	Me	H

Experimental

The Measurement of the Absorption Spectra.— The infrared measurements were carried out with a Perkin-Elmer 112 G grating infrared spectrometer, the spectral slit width under the 3 μ region being adjusted to 0.8 cm^{-1}. Samples were dissolved in carbon tetrachloride (redistilled over phosphorus pentoxide) with a

4) A. W. Baker and A. T. Shulgin, *Spectrochimica Acta*, **20**, 153 (1964).
5) The phenol shows a single symmetric band at 3597.5 cm^{-1} which, though shifted to a lower frequency, can be assigned to the free ν_{O-H}.
6) Undoubtedly the planarity of the molecule is unfavorable to the interaction in these compounds, as will be discussed later. However, the presence of the interaction in 2-hydroxy-*trans*-stilbene is an indication of a non-planar conformation, at least to a small extent, in comparison with the absence of the interaction in 1-naphthol.

VII	101/22	1.5562 (22)	104—105/13	1.5600 (30)[15]		
VIII	112—113/17	1.5188 (21)	113—115/19	1.52013 (17)[12]		

concentration of around 0.001 mol./l., unless otherwise stated. Quartz cells 2.0 and 5.0 cm. in optical length were employed in order to obtain the desired absorption intensity. The apparent absorptions were assumed to be expressed by means of the Lorentz curves and separated into the individual absorptions when they are overlapped. Each integrated intensity (A) was computed from the equation[8]:

$$A = K\frac{\pi}{2cl} \times \ln\left(\frac{I_0}{I}\right)_{max} \Delta\nu^a{}_{1/2}$$

where K was put at unity, $\Delta\nu^a{}_{1/2}$ being the apparent half band width.

The ultraviolet absorptions were measured with a Beckman DU spectrophotometer. The concentration of the samples in 95% aqueous ethanol or in *n*-heptane of a spectro-grade was nearly 10^{-5} mol./l. throughout.

The Preparation of the Samples.—*3, 3-Dimethyl-2-(2-hydroxyphenyl)-2-butanol.*—To a Grignard solution prepared from 41 g. (0.5 mol.) of *t*-butyl chloride, 12 g. (0.5 atom) of magnesium and 300 mol. of ether, was added 20.5 g. (0.15 mol.) of *o*-hydroxyacetophenone in 50 ml. of ether with efficient stirring and cooling. The mixture was heated under reflux for 2 hr., and then 600 ml. of anhydrous benzene added. The solvent was removed by distillation until the boiling point was attained (75°C). The remainder was heated for a further 6 hr. and, after cooling, decomposed with 500 ml. of 15% aqueous acetic acid. Stirring was continued throughout the process. The organic layer was separated, and the aqueous layer extracted with benzene. The combined benzene solution was washed with aqueous sodium bicarbonate, dried, and fractionally distilled to give 7.0 g. of recovered *o*-hydroxyacetophenone and 5.0 g. (17%) of the desired product as a highly viscous colorless oil, b. p. 118—120°C/4 mmHg. The oil later solidified and was recrystallized from petroleum ether to give colorless prisms, m. p. 75—77°C.

Found: C, 74.20; H, 9.45. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%.

2, 4-Dimethyl-3-(2-hydroxyphenyl)-3-pentanol.—This was similarly prepared from methyl salicylate and isopropylmagnesium bromide; it was obtained as needles, m. p. 114—116°C, in a 40% yield.

Found: C, 75.36; H, 9.73. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%.

o-(1-t-Butylvinyl)phenol.—3, 3-Dimethyl-2-(2-hydroxyphenyl)-2-butanol (5 g.) and 10 mg. of iodine were heated in vacuo. The dehydration took place at ca. 100°C, and the product distilled at about 150°C (bath temperature). The distillate was taken up in ether, washed with aqueous sodium thiosulfate, and dried. Distillation gave 3 g. (60%) of a colorless oil.
