BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 1—4 (1969)

Study on Fragmentation Process of Thymidine by Mattauch-Herzog Geometry High Resolution Mass Spectrograph

Sukenari TSUNAKAWA*1

Department of Chemistry, Massachusetts Institute of Technology, Cambridge, Massachusetts, U.S.A.

(Received November 27, 1967)

High resolution mass spectra of thymidine were studied by Mattauch-Herzog geometry mass spectrograph. The element map of it was presented and the fragmentation processes were shown by solid or dotted lines on the map. The spectra were measured with higher accelerating voltages (about 0.1 %) in order to obtain many metastable peaks on the photographic plate. By a single focusing mass spectrometer ten metastable peaks were measured and "intentionally defocused" high resolution spectra gave twenty five diffused peaks with slight shifts to the high mass region though no metastable peaks were observed under normal operating conditions.

Recently many remarkable improvements have been made on organic chemical applications of high resolution mass spectrometry.[1,2] It is also a well-developed technique at the present time to use metastable peaks as keys to the determination of the fragmentation process. Various reports have been published on their measurements and assignments.[3-8] In this paper, the author studied on slightly "defocused" high resolution mass spectrum of thymidine with Mattauch-Herzog geometry mass spectrograph so that the "metastable peaks" could be observed on the photographic plate at the same time with the "normal peaks." Barber and his coworkers[8] proposed a method to observe metastable transitions which occur in the field free region between the source and the electrostatic analyser by increasing the accelerating voltage, V, so that the daughter ions are permitted to pass through the analyser. In the studies of thymidine described here, the increment of V was restricted to only about 0.1%. This low increment permits all of the normal ions to be still in focus on the photographic plate together with metastable peaks.

Experimental

Reagent grade thymidine, $C_{10}H_{14}N_2O_5$, was used without further purification. Measurements were carried out with Hitachi RMU-6D 90° magnetic sector type single focusing mass spectrometer and CEC 110 Mattauch-Herzog geometry double focusing mass spectrograph. Sample introduction were made through direct inlet systems. The single focusing type was used in order to compare the results with those obtained double focusing. Ion source temperature was set at 230°C and ionization voltage at 70 eV in both cases.

By the single focusing measurement, a mass spectrum from 1 to 250 *m/e* was recorded within 1 min using an electron multiplier and a Honeywell visicorder.

In double focusing measurement, about 50 μg sample was introduced with the marker (PFK) according to the normal operating condition (accelerating voltage 8 kV), another two exposures were made successively on the same photographic plate with slight increases of accelerating voltage, +9.6 V (condition I), and +16.8 V (condition II) respectively. Accurate masses were determined by Datex comparator connected to the densitometer, and the center of the diffused peak was measured on the paper recorded spectra. Whole results were presented in Biemann's element map system.[9-11]

Results and Discussion

Low Resolution Spectra. Ten metastable peaks were obtained and completely assigned by use of N. Mancuso's computer program by considerations of the products of the intensities of the parent and daughter peaks and their elemental compostions.[7] Fragmentation processes are shown in Table 1 and also in Fig. 1 by solid lines. Assuming that neutral fragments are expelled as one piece, the daughter ions are derived easily without any drastic rearrangement from the thymidine structure, so the investigation of a metastable peak gives very important informations on the structure

12) J. A. McClosky, Ph. D. Thesis, Massachusetts Institute of Technology, Cambridge (1963).

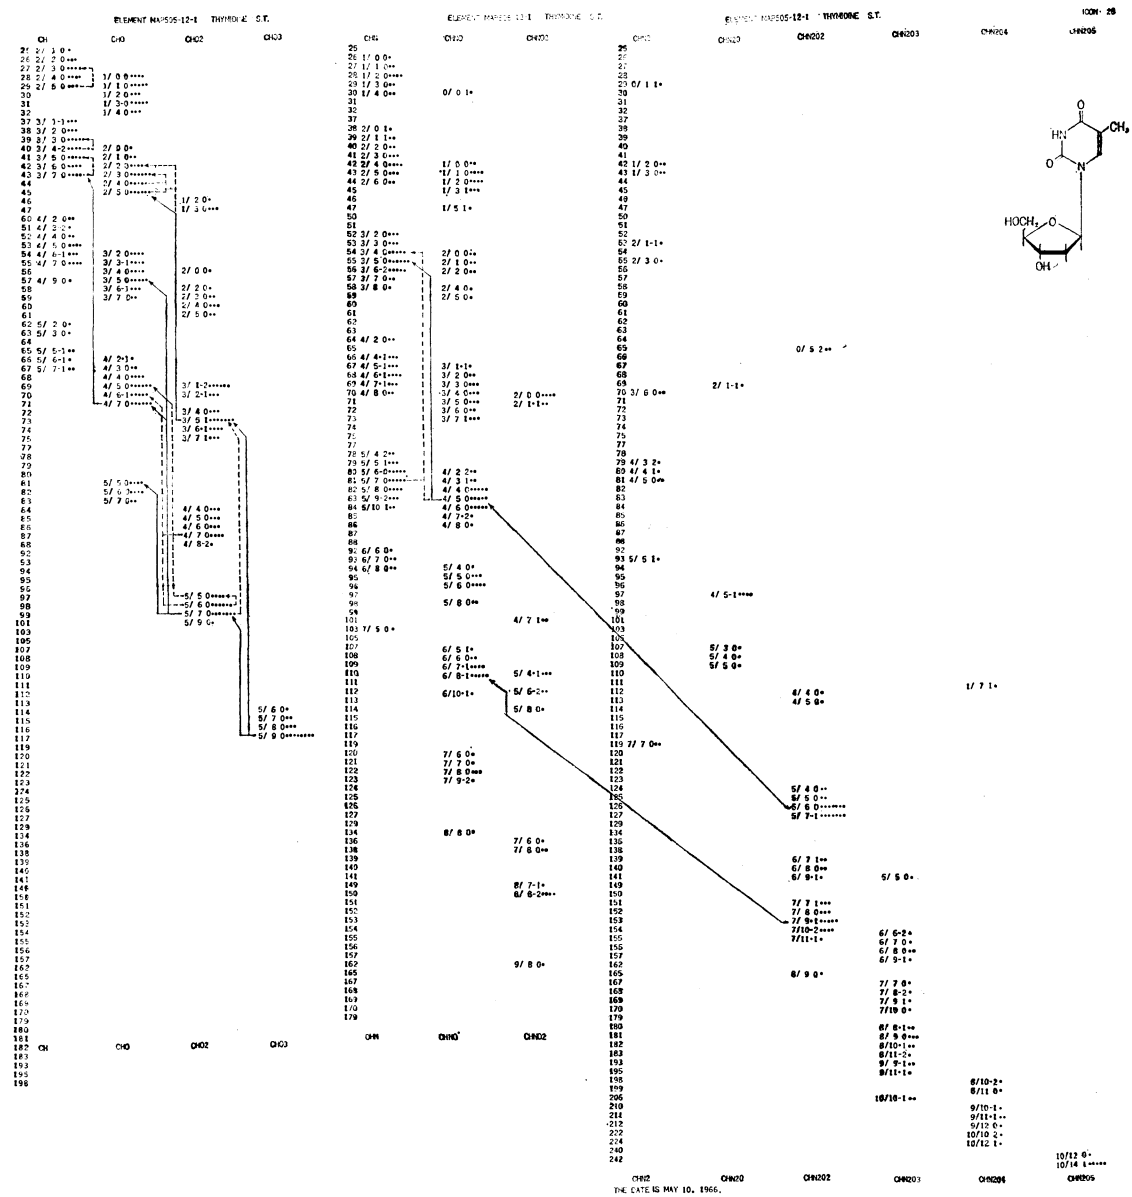

Fig. 1. Element map of thymidine.

of the sample.

Some of these fragmentation processes, for example, from $C_5H_6N_2O_2^+$ to $C_4H_5NO^+$, are well agreed with the previous reports[12,13] on some thymidine type compounds and make it clear that thymidine decomposes in the same manner as thymine.

Mattauch-Herzog Geometry High Resolution Spectra. No metastable peaks were observed under normal measuring conditions, indicating that the thymidine fragmentation is in a sense different from 1-*n*-butylthymine which shows many metastable peaks under usual operation.[7] In the case of thymidine no decomposition occurs in the field free region between electric and magnetic sector. If the fissions are supposed to proceed near the ion source, the daughter ions should be able to reach the detector by increasing the accelerating voltage to $V=m_1 \cdot V_0/m_2$,[4,5] where m_1 and m_2 are the masses of the parent and daughter ions respectively and V_0 is the usual accelerating voltage. Many diffused peaks were observed by "intentionally defocused" measurements (condition I and II). In the case of thymidine some fissions are thought to occur not only in the ionization chamber but also in the electric sector, probably

13) J. M. Rice, G. O. Dudek and M. Barber, *J. Am. Chem. Soc.*, **87**, 4569 (1965).

near the exit slit, because the increase of accelerating voltage, 9.6 or 16.8 V, is too small to carry the daughter ions through the electric sector to the detector. In Table 1, fissions of thymidine are listed in terms of the metastable peaks under condition I with corresponding reaction formulas. Under condition II, normal ion path is deflected more than under condition I, and then relative intensities of metastable peaks increase, accompanied with larger shifts to the high mass direction. It has been known that the diffused peaks of some hydrocarbons shift to the high mass region when the accelerating voltage is increased.[14,15] Then

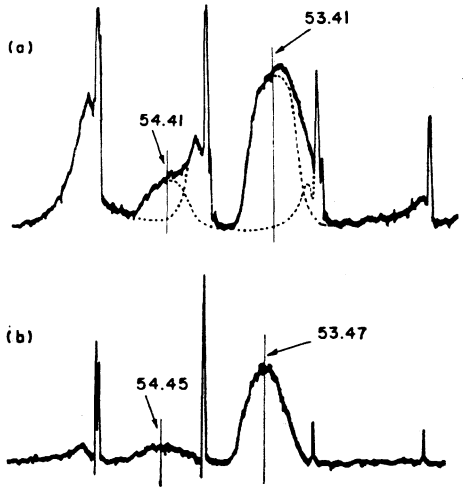

Fig. 2. Metastable peaks in the intentionally defocused thymidine spectra; (a) condition I, 8 kV 9.6 V. (b) condition II, 8 kV 16.8 V. The peaks in (a) show "tailing" on the high mas sides by the "defocusing."

15) Private communications from JEOL mass spectroscopy reaserch group.

it follows that the relative positions of the metastable peaks on the photographic plate must depend upon the regions where the fissions occur. The amount of the displacement of the m^* position differs from peak to peak. This is reasonable bacause it is considered that the shift depends upon the position where the decomposition occurs, the energy loss at the moment of the fission and also upon the mass to charge ratios of the parent and daughter ion. Portions of the spectra measured under condition I and II are shown in Fig. 2 (a) and (b) respectively.

Under the considerations of these facts, the metastable peak assignment was carried out assuming that the theoretical value must have smaller mass to charge ratio, and the limit of the range is 0.7 mass unit in high and 0.4 mass unit in low mass region. The metastable peaks marked with * are those which are measured by single focusing instrument. Among ten reactions measured by single focusing, six are observed also by double focusing. It is worth to notice there are many metastable transitions which are observed only under these "intentionally defocused" conditions and not by the single focusing instrument. Besides the structural data, this method would supply valuable informations on chemical kinetics.

Element Map of Thymidine and Its Fragmentation Process. Figure 1 shows the element map of thymidine. A solid line shows the fission determined by the metastable peak measurement with Hitachi instrument and a dotted line that by intensionally defocused Mattauch-Herzog experiment under condition I.

The encouragement and support of Professor K. Biemann during this work carried out in M. I. T. are gratefully acknowledged. The author also express his thanks to Dr. N. Mancuso for his continuing interest and for giving the computer aided data.

Ultrasonic Relaxation of Water-Dioxane System

Kiyoshi ARAKAWA and Nobuo TAKENAKA

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received January 31, 1968)

Ultrasonic investigations of the water-dioxane system were made by means of an ultrasonic pulse technique. The ultrasonic velocity and absorption of the solutions were measured in the frequency range from 5 to 45 Mc/sec. The temperature was varied from 20 to 60°C. It was observed in the velocity *vs.* concentration curves obtained at various temperatures that all curves converged at 0.03—0.04 mol fraction of dioxane. The ultrasonic absorption of pure dioxane was found to increase with the rise of temperature, which might be ascribed to the vibrational relaxation. From the ultrasonic absorption data obtained for the solutions of the water-dioxane system in various compositions and temperatures it was observed that at 0.3—0.4 mol fraction of dioxane an absorption peak was present in the absorption *vs.* concentration curve, and also that there was no shift of the concentration at the peak with the variation of temperature. Some discussion on the structure of the water-dioxane system was given from the ultrasonic data obtained.

Dioxane is completely miscible with water. The water-dioxane system is of considerable interest, since the dielectric constant of the system varies from the magnitude of about 80 for pure water to the magnitude of about 2 for pure dioxane with the variation of its composition. Also, the strong interactions, which are supposed to consist mainly of hydrogen bonding, are present between dioxane and water molecules, though dioxane molecules have no ability to form hydrogen bonding between themselves.

The physical properties of water and dioxane are similar in several respects. For example, the difference between their boiling points is within 15°C, and that between their freezing points is within 12°C, *etc.* The size and shape of molecules are however, fairly different.

From the view-points described above, the water-dioxane system has long been the object of thermodynamical,[1-5] viscometric,[6] dielectric,[7-9] NMR,[10] spectroscopic,[11] and ultrasonic studies.[12] However, no decisive conclusion has been obtained at present. We have measured the ultrasonic velocity and absorption of the water-dioxane system by means of an ultrasonic pulse technique, and discussed the structure of the solutions.

Experimental

Apparatus and Procedures for Measurements. The ultrasonic velocity and the absorption were measured according to the pulse method developed by Pinkerton[13] and others. The apparatus and the procedures for the measurements were described in the preceding paper.[14] The sound velocity was measured at a fixed frequency of 5 Mc/sec. The absorption was measured over the frequency range of 15—45 Mc/sec. All measurements in this experiment were made in the range of temperature from 20°C to 60°C with 10°C intervals, and the temperature was controlled to within ±0.1°C.

Materials. For the measurements of dioxane-water mixtures, the reagent-grade dioxane, obtained from Wako Pure Chemicals, was mixed with freshly distilled water. In the case of the measurements of pure dioxane the dioxane sample was further purified according to the following procedure:[15] after being treated with hydrochloric acid and thereafter with potassium hydroxide, the dioxane sample was refluxed with metallic

sodium and was fractionally distilled. The fraction in boiling range of 101.3—101.7°C was used for the measurement.

Results

Sound Velocity. The ultrasonic velocity at 5 Mc/sec obtained for the water-dioxane system of various compositions is plotted against temperature in Fig. 1. The accuracy of the data obtained is within 2 m/sec. As is seen in Fig. 1, the sound velocity of water-dioxane mixtures and also that of pure dioxane decrease linearly with the increase in temperature, being in sharp contrast with the increasing trend in the velocity *vs.* temperature curve for pure water which is given for comparison.

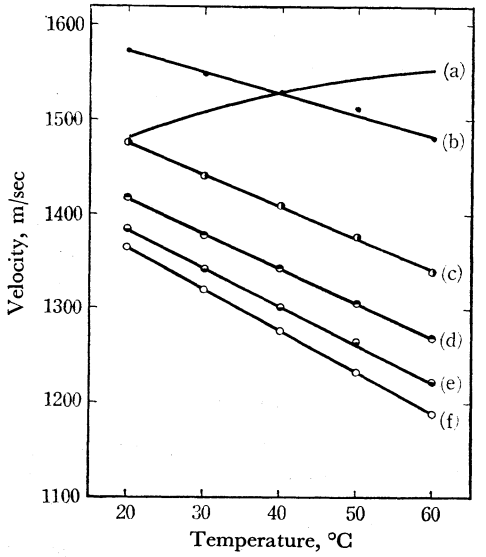

Fig. 1. Temperature dependence of ultrasonic velocity for the dioxane-water system.
dioxane mol%: (a) pure water, (b) 17.5 mol%, (c) 40 mol%, (d) 60 mol%, (e) 80 mol%, (f) pure dioxane

In order to investigate the concentration dependence of ultrasonic velocity, the velocity is plotted against dioxane concentration by mole % for each temperature in Fig. 2. It is seen that at about 3—4 mol% of dioxane (about 15 vol% of dioxane) all curves converge, and that the trend of the temperature dependence of sound velocity is reversed after passing through that concentration.

It is well known that the increasing trend of sound velocity in pure water with the increase of temperature in this temperature range is ascribed to the presence of the "open structure" in liquid water.[16-18] The disappearance of that trend after

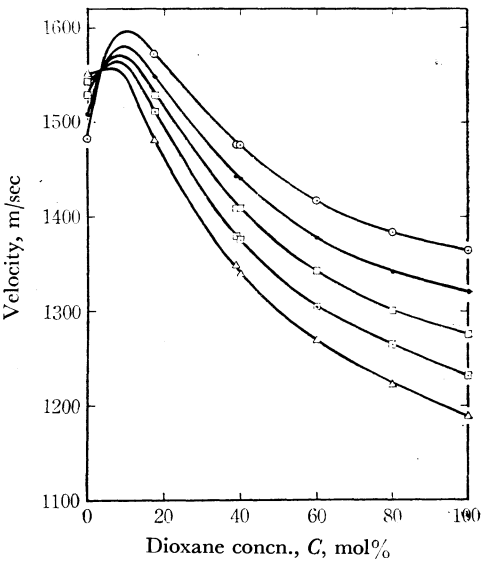

Fig. 2. Concentration dependence of ultrasonic velocity.
⊙ 20°C, ● 30°C, □ 40°C, ⊡ 50°C, △ 60°C

the addition of about 3—4 mol% of dioxane to water is supposed to occur from the strong interaction of dioxane molecules to the structure in water, where dioxane molecules behave as the hydrogen bonding acceptor and water molecules as the hydrogen bonding donor.

Ultrasonic Absorption of Dioxane. The absorption coefficient, α, was measured for the sample of pure dioxane over the frequency range from 15 to 45 Mc/sec. The data obtained are given in Fig. 3, which are plotted against frequency in a logarithmic scale. The accuracy of α obtained is within ±2%. As is clearly seen in Fig. 3, no characteristic relaxation frequency is observed in this frequency range. The magnitude of the absorption is found to increase with the increase of temperature. From these observations the

source of the ultrasonic absorption in dioxane in this frequency range might be ascribed to the vibrational relaxation. The temperature dependence of α is also shown in Fig. 4. The value reported by Heasell and Lamb[19] is also given which is slightly smaller than our data in spite of the fairly large difference in the frequency used. We might say that no characteristic relaxation frequency should be present in the frequency range including the measurement of Heasell *et al.*

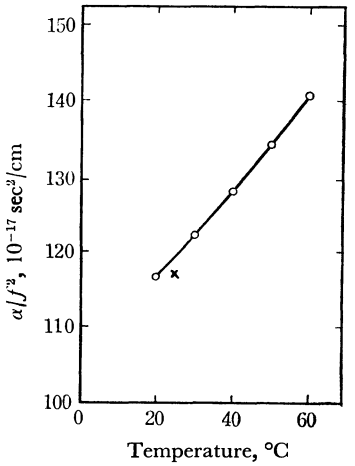

Fig. 4. Temperature dependence of ultrasonic absorption for dioxane.
× Heasell anb Lamb's data[19] at 24.6°C and 104 Mc/sec

Ultrasonic Absorption of Water-Dioxane System. The data of the ultrasonic absorption of the water-dioxane sytem are given in the form of α/f^2 *vs.* $\log f$ relation, where f is frequency, in

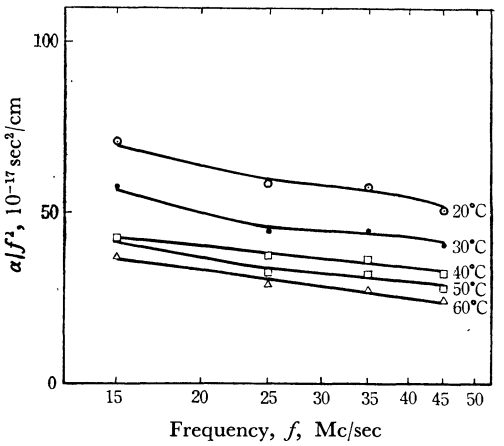

Fig. 5(a). Ultrassonic absorption of the water-dioxane system (17.5 mol% of dioxane).

19) E. L. Heasell and J. Lamb, *Proc. Phys. Soc.*, **B69**, 869 (1956).

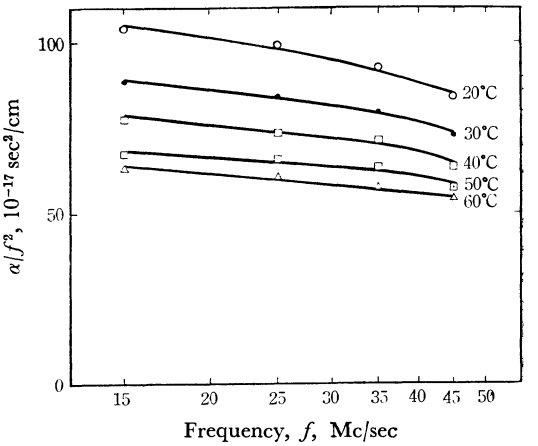

Fig. 5(b). Ultrasonic absorption of the water-dioxane system (40 mol% of dioxane).

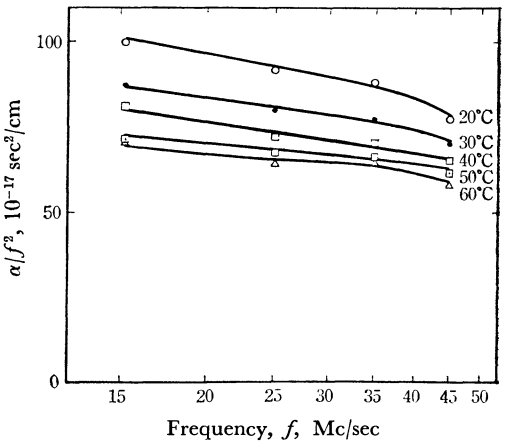

Fig. 5(c). Ultrasonic absorption of the water-dioxane system (60 mol% of dioxane).

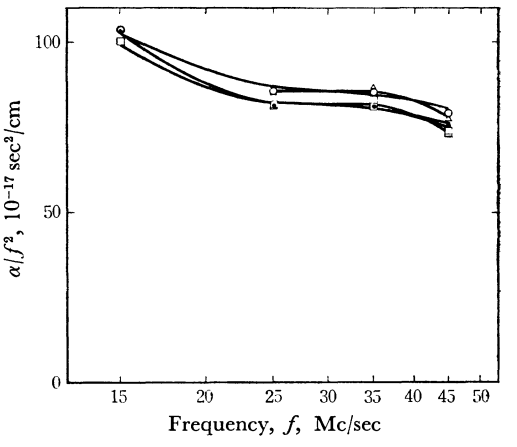

Fig. 5(d). Ultrasonic absorpption of the water-dioxane system (80 mol% of dioxane).
⊙ 20°C, ● 30°C, □ 40°C, ⊡ 50°C, △ 60°C

Fig. 5(a)—(d). The molar concentration of dioxane is 17.5, 40, 60, and 80 mol% respectively. As for the ultrasonic absorption of the water-dioxane system, the data obtained by means of an optical diffraction method was reported previously by Burton.[12] However, Burton's values are much larger than ours.

The concentration dependence of α/f^2 is shown in Fig. 6, where the absorption data for pure water reported by Pinkerton[13] and also our data for the solutions of 75 vol% (38.9 mol%) dioxane are added. A maximum of α/f^2 is seen in Fig. 6 at about 0.4 mol fraction of dioxane at lower temperatures. At higher temperature the maximum is found to deform into a shoulder, but the mole fraction at the shoulder is seen to be constant. The characteristic in the α/f^2 *vs.* mole fraction curve is found to be more discriminate, after the value of α/f^2 obtained according to the proportional calculation to the mole fraction of two components, $(\alpha/f^2)_{lin}$, has been subtracted from the observed value of $(\alpha/f^2)_{obs}$.

The value of the excess absorption,

$$\Delta = (\alpha/f^2)_{obs} - (\alpha/f^2)_{lin}$$

is plotted against the mol% of dioxane in Fig. 7.

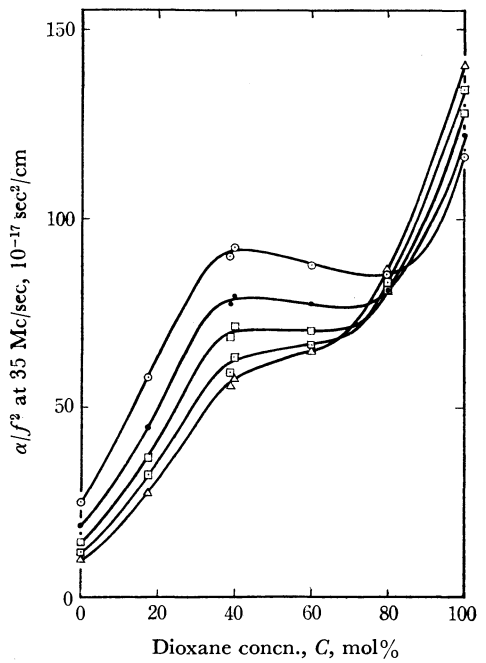

Fig. 6. Concentration dependence of ultrasonic absorption.
⊙ 20°C, ● 30°C, □ 40°C, ⊡ 50°C, △ 60°C

From Fig. 7 it is observed that a maximum of Δ is present always at about 0.35 mol fraction of dioxane irrespective of the variation of temperature though the magnitude of Δ becomes smaller with the increase in temperature.

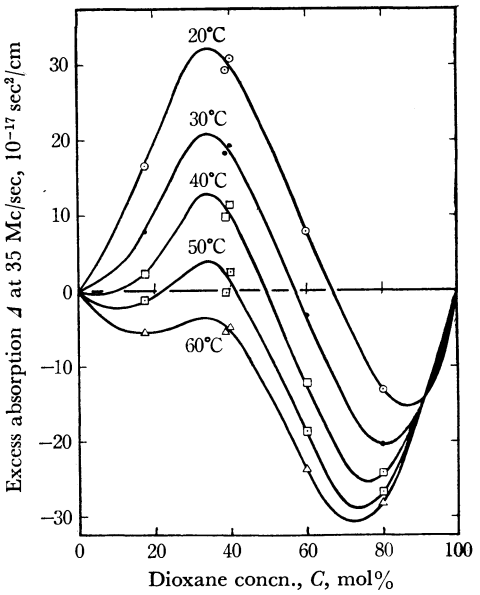

Fig. 7. Concentration dependence of excess absorption.

The temperature dependence of α/f^2 in each solution is shown in Fig. 8. As is clearly seen, the α/f^2 *vs.* temperature curves go downwards with the increase in temperature up to the 60 mol% solutions. In the solution of 80 mol% dioxane

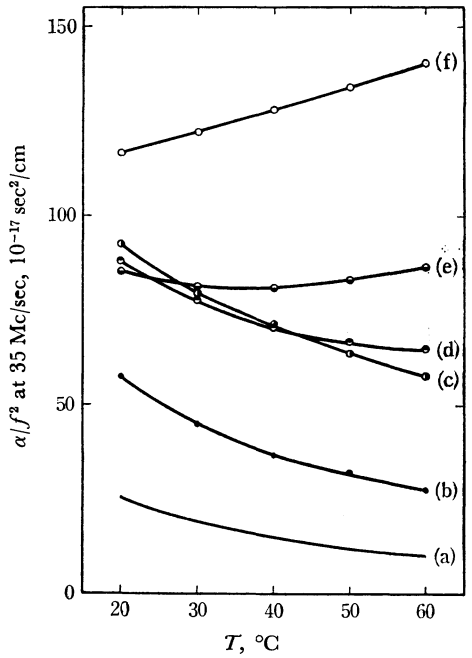

Fig. 8. Temperature dependence of ultrasonic absorption.
Dioxane mol%: (a) pure water, (b) 17.5 mol%, (c) 40 mol%, (d) 60 mol%, (e) 80 mol%, (f) pure dioxane

the cruve has a shallow minimum and is nearly flat.

Discussion

Vibrational Relaxation in Dioxane. As stated from the result given in Fig. 3, the source of ultrasonic absorption in dioxane is ascribed to the vibrational relaxation, which occurs from the time lag of energy transfer from the translational motion to the vibrational motion in dioxane molecules. When water is added to dioxane till the mole ratio of water to dioxane, 1 : 4 (the vol% of water in this composition is as small as about 5% since the dimension of dioxane molecule is larger than that of water molecule), this behavior practically disappears, as is seen in Fig. 8.

In the latter case some structure, which behaves as an energy bridge for the energy transfer from the external degree of freedom to the internal, may be formed in the solution as a result of the strong interaction, perhaps hydrogen bonding, between dioxane and water molecules.

Structure of Water-Dioxane System. It is observed in Fig. 6 and Fig. 7 that at 0.3—0.4 mol fraction of dioxane an absorption peak appears, and that the composition at the maximum absorption remains constant when the temperature is varied. The mole fraction at the maximum or shoulder corresponds to the composition of dioxane dihydrate. From the facts stated above the presence of dioxane dihydrate, which is proposed by Garg and Smyth on the basis of their dielectric measurements,[8] might be suggested.

The excess entropy of mixing, ΔS_E, reported by Vierk,[2] which was obtained from the data of the vapor pressure and the heat of mixing measured on the system, was found to have its maximum in the absolute magnitude at 0.35 mol fraction of dioxane at 20°C. Goates *et al.*[4] also reported from their calorimetric data that $|\Delta S_E|$ was maximum at about 0.3 mol fraction of dioxane at 25°C. According to the dilatometric data of Hovorka *et al.*,[5] the excess volume of mixing, ΔV_E at 25°C also was found to have its maximum value at 0.3—0.4 mol fraction of dioxane in its absolute magnitude at 20—50°C.

This thermodynamic data suggests the presence of some structure between water and dioxane molecules at the 0.3—0.4 mol fraction of dioxane, the composition of which approximately corresponds to dioxane dihydrate.

According to the dielectric relaxation measurements on the water-dioxane mixture reported recently by Garg and Smyth,[8] two relaxation times, τ_1 and τ_2, are present and the longer one, τ_1, which is of the order of 10^{-11} sec has its maximum value at 0.3—0.5 mol fraction of dioxane in the range of temperature, 10—55°C, where the mole fraction at its maximum is found to increase with the rise of temperature. Garg and Smyth have proposed the presence of dioxane dihydrate from their results according to the suggestion of Bak and Hynne.[8]

Geddes[6] proposed the presence of $C_4H_8O_2 \cdot 5H_2O$ from his viscometric results. According to Goates *et al.*[4] a dip in the mixing enthalpy was found at 0.15 mol fraction of dioxane and also in the case of the freezing point curve a sharp dip was found at the same mole fraction, which corresponded to the composition of $C_4H_8O_2 \cdot 6H_2O$. However in our ultrasonic relaxation data no feature is seen in that range of compsotion, and we can not state decisively the presence of hexahydrate or pentahydrate.

Summary and Conclusion

Ultrasonic investigations of the water-dioxane system have been made by the pulse method over the frequency range of 5—45 Mc/sec. The source of the ultrasonic absorption in this frequency range for pure dioxane has been ascribed to the vibrational relaxation. The ultrasonic absorption for the water-dioxane system has been found to have its maximum or shoulder at 0.3—0.4 mol fraction of dioxane and it has also been found that the mole fraction of maximum absorption is maintained to be nearly constant with the variation of temperature. The structure of the water-dioxane system has been discussed concerning the presence of dioxane dihydrate.

The authors wish to thank Miss Yuko Endo for her cooperation in carrying out this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 10—15 (1969)

The $n\rightarrow\pi^*$ Bands of Phenyl Carbonyl Compounds, α-Diketones, and Quinones at Low Temperatures

Akira KUBOYAMA, Ryuichi YAMAZAKI,[*1] Sanae YABE and Yoshio UEHARA[*2]

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received February 20, 1968)

The positions and intensities of the $n\rightarrow\pi^*$ absorption bands in solutions at 77°K (in the rigid glass state) and at 201°K (in the liquid state) have been studied in comparison with those at room temperature. At 201°K the positions and intensities are similar to those at room temperature. At 77°K some distinct facts have been found in EP (ether-isopentane (1:1) mixture) which are different from those which hold in the liquid state: 1) In desoxybenzoin the absorption is remarkably weak in intensity. 2) In some α-diketones and β-naphthoquinone, the $n\rightarrow\pi^*$ bands shift greatly to the blue. 3) In β-naphthoquinone the absorption is remarkably strong in intensity. Discussions of the obtained results have been presented.

Heretofore, the electronic spectra of organic compounds at low temperatures have not been very extensively studied. It is expected that, in some cases, low-temperature electronic spectra may show valuable information about the structural and analytical chemistry because of their sharp vibrational structures and strong solvent effects.

The positions and intensities of $n\rightarrow\pi^*$ absorption bands are, in general, structure- and solvent-sensitive. The $n\rightarrow\pi^*$ bands of phenyl carbonyl compounds, α-diketones, and quinones in solutions at room temperature have been studied by many authors. In this work, the positions and intensities of these $n\rightarrow\pi^*$ bands in solutions at low temperatures have been studied in comparison with those at room temperature.

Experimental

Measurements. The electronic spectra were measured with a Cary recording spectrophotometer, 14 M. The partly-silvered quartz vacuum-flasks and quartz cells used in this work are shown in Fig. 1. A cylindrical cell had a long tube through which a sample solution was introduced into the cell. The cell was immersed in a cooling medium except for a part of the tube. The shaded portions in Fig. 1 were flanges which were attached to the inner windows of the vacuum flask and used in order to support the cell and make bubbles deviate from the optical path. The distance between a window of the cell and an inner window of the vacuum flask was *ca.* 1 mm. Vacuum flasks with cells 1 and 5 cm in optical path were made. The solvents used in this work have shown no absorption in the wave-region studied at 201°K and 77°K, using those at room temperature as references. Therefore, usual cylindrical quartz cells with the same path length as those of the sample cells were used as references in this work. With this apparatus measurements at low temperatures were made easily and precisely. The solvents used in the measurements were an ethyl ether-isopentane (1 : 1) mixture (EP), an methanol-ethanol (1 : 4) mixture (ME), an ethyl ether - isopentane - ethanol (5 : 5 : 2) mixture (EPA), and methylcyclohexane (MCH). The measurements were carried out at the temperature of liquid nitrogen (77°K), at the temperature of dry ice - ethanol (201°K), and at room temperature. At 77°K all the solutions used were transparent in the rigid glass state, while at 201°K they were transparent in the liquid state.

Materials. The reagents used in this work were all of the purest grade commercially available except for the β-naphthoquinone and the *N*-acetylisatin. The acetophenone, isobutyrophenone, and diacetyl of the G. R. grade of the Tokyo Kasei Kogyo Co., and the 1-phenyl-1,2-propanedione of the Eastman grade of

Distillation Products Ind. were used without further purification. The benzophenone, desoxybenzoin, and benzil were purified by recrystallization. The *p*-benzoquinone was purified by sublimation. The 2-methylanthraquinone and camphorquinone were purified by vacuum sublimation. The α-naphthoquinone was purified according to Fieser's method.[1] The β-naphthoquinone was prepared and purified according to Fieser's method.[1] The *N*-acetylisatin was prepared by the *N*-acetylation of isatin and was purified by recrystallization. The *n*-heptane, ethyl ether, and isopentane were purified according to the methods described in our previous papers.[2,3] The methylcyclohexane, methanol, and ethanol were of the same quality as those described in a previous paper.[3]

Results

In order to compare the absorption intensities of the $n\rightarrow\pi^*$ bands at low temperatures with that at room temperature, a ratio of the integrated absorption intensity was obtained. The shift in the wave number of the positions of the $n\rightarrow\pi^*$ bands, ($\Delta\bar{\nu}$), and the ratio of the integrated absorption intensity of the $n\rightarrow\pi^*$ bands, (R.I.), between a low temperature and room temperature, are shown in Tables 1—3. In Tables 1—3, I—XIII are acetophenone, isobutyrophenone, desoxybenzoin, benzophenone, diacetyl, camphorquinone, 1-phenyl-1,2-propanedione, benzil, *N*-acetylisatin, *p*-benzoquinone, α-naphthoquinone, 2-methylanthraquinone, and β-naphthoquinone respectively. As for the $\Delta\bar{\nu}$ and R.I. in these tables, for example, if $\Delta\bar{\nu}$ is positive, the $n\rightarrow\pi^*$ band at a low temperature shifts to the blue relative to that at room temperature, and, for example, if R.I. is larger than one, the integrated absorption intensity of the $n\rightarrow\pi^*$ band at a low temperature is larger than that at room temperature. In order to correct for the volume contraction at a low temperature, the measured absorption intensities at low temperatures were multiplied by factors (0.9 for 201°K and 0.8 for 77°K) chosen in view of the reported data.[4] The results obtained at 77°K for α-naphthoquinone in EPA and desoxybenzoin in EP with 1 cm and 5 cm path cells were the same.

The $n\rightarrow\pi^*$ bands, obtained mainly in EP, are shown in Figs. 2—14. In these figures all the spectra have been corrected for the volume contraction at low temperatures. In quinones there are uncertainties in the R.I. values due to a large overlapping of $\pi\rightarrow\pi^*$ and $n\rightarrow\pi^*$ bands, as may be seen in Figs. 12—14.

Discussion

As is shown in Tables 1—3 and in Figs. 4, 6, and 14, the positions and absorption intensities at 201°K

are in all cases similar to those at room temperature. This fact is thought to be mainly due to the fact that solutions at 201°K are in the liquid state the same as it is at room temperature.

As for the phenyl carbonyl compounds in Table 1, the $n\rightarrow\pi^*$ bands at 77°K shift to the blue relative to those in the liquid state except for that of isobutyrophenone, the shift of which at 77°K relative to that at room temperature is not clear. This blue-shift in EP may be mainly due to a charge transfer (CT) interaction of the n–π type,[5] to be mentioned later, between an oxygen atom in ethyl ether and phenyl carbonyl compounds, while the blue-shift in EPA may be due to hydrogen-bond formation between carbonyl groups and alcohols, both probably stronger than those in the liquid state.

As for the R.I. values in Table 1, a remarkable decrease in the absorption intensity of desoxybenzoin is found in EP and EPA at 77°K, especially in the former, relative to those in the liquid state, as may also be seen in Fig. 4. The strong intensity of the $n \rightarrow \pi^*$ band of benzophenone may be attributed to the mixing of the (n, π^*) state with (π, π^*) states due to the overlapping of the n-orbital of a carbonyl oxygen atom and the π-orbitals of two phenyl groups, because of the non-coplanarity of the benzophenone molecule resulting from steric hindrance between the two phenyl groups. On the other hand, the strong intensity of the $n \rightarrow \pi^*$ band of desoxybenzoin in the liquid state may

be assumed to be mainly attributable to the mixing of the (n, π^*) state with (π, π^*) states of the non-conjugated phenyl group, due to the overlapping of the n-orbital of the carbonyl oxygen atom and the π-orbitals of the non-conjugated phenyl group; this assumption is based on the facts about α-phenylcarbonyl compounds presented by Kumler *et al.*[6] Therfore, the above-mentioned fact about desoxybenzoin at 77°K may be attributed to the decrease in the overlapping of the oxygen n-orbital and the π-orbitals of the non-conjugated phenyl group in the rigid glass state relative to those in the liquid state.

As for the α-diketones in Table 2, it is noticeable that the $n\rightarrow\pi^*$ bands of diacetyl and *N*-acetylisatin in EP at 77°K shift greatly to the blue relative to those in the liquid state, while the $n\rightarrow\pi^*$ bands of camphorquinone and 1-phenyl-1,2-propanedione shift a little to the red, as may also be seen in Figs. 6, 7, 8, and 10. Such a large blue shift is also found in β-naphthoquinone, as may be seen in Table 3 and Fig. 14. In all the three α-diketones in Table 2 except 1-phenyl-1,2-propanedione and benzil, the two carbonyl groups are assumed to be nearly coplanar. This large blue shift is assumed to be due to a strong CT interaction of the n-π type between ethyl ether in EP on one hand, and α-diketones and β-naphthoquinone on the other hand, in the rigid glass state. In a previous work[2] we found that the $n\rightarrow\pi^*$ bands of *o*-quinones in dioxane at room temperature shift greatly to the blue relative to those in *n*-heptane, while those in ethyl ether shift only a little to the blue. In that work this large blue shift in *o*-quinones in dioxane was attributed to the strong CT interaction of the n-π type between dioxane and *o*-quinones, while the small blue shift in ethyl ether was attributed to a weakening of the CT interaction of the n-π type due to steric hindrance caused by the chains of ethyl ether.

It may be concluded from the theoretical considerations that an oxygen atom in dioxane coordinates itself to some point between two adjacent carbonyl carbon atoms in *o*-quinones in the CT interaction of the n-π type. This conclusion is supported by the results obtained by the X-ray crystal analyses of parabanic acid and chloranil.[7] It may be assumed on the basis of these results that the large blue shift in the α-diketones and β-naphthoquinone in EP mentioned above is due to a strong CT interaction of the n-π type between ethyl ether on the one hand, and α-diketones and β-naphthoquinone on the other hand, at 77°K, an interaction similar to that between dioxane and *o*-quinones at room temperature. This strong CT interaction of the n-π type between ethyl ether and α-diketones and β-naphthoquinone at 77°K is assumed to be ascribable to a weakening of the above-mentioned steric hindrance due to a weakening of thermal motion of the chains of ethyl ether, relative to that in the liquid state.

In camphorquinone a similar strong CT interaction cannot be expected, since the close approach of an oxygen atom in ethyl ether to the carbonyl carbon atoms in camphorquinone is prevented by steric hindrance. Therefore, the small red shift in camphorquinone in EP shown in Table 2 may be due to a reinforced van der Waals interaction between camphorquinone and EP at 77°K relative to that at room temperature. In EPA and ME, a hydrogen bond between camphorquinone and alcohols is assumed to be formed at 77°K as well as in the liquid state. Therefore, the effect of the hydrogen-bond formation on the shift of the $n\rightarrow\pi^*$ band at 77°K in camphorquinone is contrary to that in the phenyl carbonyl compounds shown in Table 1 and may be characteristic of camphorquinone.

As for 1-phenyl-1,2-propanedione and benzil, the molecules are assumed to be greatly twisted about the (O=)C–C(=O) bond due to the strong steric hindrance.[8] Therefore, any CT interaction of the n-π type between EP and 1-phenyl-1,2-propanedione and benzil may be weak. The twisting angles in these molecules in the rigid glass state may be somewhat different from those in the liquid state. At this stage further discussions about their $n\rightarrow\pi^*$ bands cannot be undertaken.

As for the quinones in Table 3, the blue shift at 77°K in α-naphthoquinone and 2-methylanthraquinone may be interpreted in the same manner as that in Table 1, while the red shift at 77°K in *p*-benzoquinone is rather puzzling. In the $n\rightarrow\pi^*$ band of β-naphthoquinone, a large blue shift and a large enhancement of its absorption intensity at 77°K relative to those in the liquid state are found, as is shown in Table 3 and Fig. 14. The former fact has already been discussed together with the situation in α-diketones. The latter fact may be due to the increased mixing of the (n, π^*) state with the low-energy (π, π^*) state at 77°K, where the both states are energetically closer to each other relative to those in the liquid state, as is shown in Fig. 14, because of the large blue shift of the $n\rightarrow\pi^*$ band mentioned before and the red shift of the $\pi\rightarrow\pi^*$ band at the longer wavelengths (the tail of which band may be seen in the figure) at 77°K relative to those in the liquid state.

Transition Energy Diagram for Solvated Electrons and Its Application to the Interpretation of Their Absorption Spectra

Syozi NODA, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received February 29, 1968)

The energy levels of solvated electrons have been calculated as a function of the static dielectric constant and of the cavity radius on the basis of a continuous dielectric model with an adiabatic approximation, and a contour diagram has been drawn up for the transition energy of solvated electrons. Using this diagram and the observed absorption spectra, the quantities on solvated electrons in alcohols have been estimated. The cavity radius, R, ranges from 0.9 to 1.6 Å, the charge distribution for the ground state, from 2.4 to 3.2 Å, and the variation in cavity radius, from 0.50 to 0.60 Å, at room temperature. From the calculations of the temperature dependence, $d(h\nu)/dt$, of the transition energy, it can be said that, for solvated electrons in alcohols, the contribution to $d(h\nu)/dt$ of the change in R with the temperature is rather more dominant than the change in the static dielectric constant with the temperature. It has also been found that there exists a correlation between the dR/dt value and the ratio of the number of the OH bond to the total number of bonds involved in each alcohol.

The formation of the solvated electron by the action of ionizing radiations on some polar media has been well established in recent years. The electronic absorption spectra of solvated electrons in alcohols and the effect of the temperature on their absorption spectra have been observed by the pulse radiolysis technique.[1,2] The experimental results suggest a simple relationship between the optical transition energy of solvated electrons and the dielectric constant of the medium within a series of alcohols.

On the other hand, the theory of solvated electrons has been developed on the basis of the continuous dielectric model[3] and applied with considerable success to the interpretation of the optical properties of solvated electrons in metal-ammonia solutions,[4] hydrated electrons,[5] and trapped electrons in an organic glass.[6,7]

For the present paper, we have calculated the energy levels of solvated electrons as a function of the static dielectric constant of solvents and of the radius of a cavity in which an electron is located on the basis of a continuous dielectric model with an adiabatic approximation, we have then drawn up a contour diagram for the transition energy of solvated electrons.

Using this diagram and the observed absorption spectra, we have estimated the charge distribution, the cavity radius, and the range of the cavity radii of solvated electrons in alcohols. We have also examined the factors which may be responsible for the temperature dependence of their absorption spectra.

Method of Calculation

Transition Energy of a Solvated Electron. The solvated electron interacts with the polarization filed of the dielectric medium, and the interaction energy is determined by the long-range interaction. The potential function, $V(r)$, in which an electron is bound, is expressed as follows:

$$\left.\begin{aligned} V(r) &= -\beta e^2/r \quad \text{for } r > R, \\ V(r) &= -\beta e^2/R \quad \text{for } r < R, \end{aligned}\right\} \qquad (1)$$

where $\beta = (1/D_{op}) - (1/D_s)$, D_s and D_{op} are the static and optical dielectric constants, and where R is the cavity radius. The reference state is that of a non-polarizing electron located in the medium at an infinite distance from the cavity.

The calculations were carried out using the variation method. The one-parameter wave function used for the ground state was of this form:

$$\psi_{1s} = (\mu^3/\pi)^{1/2} \exp(-\mu r) \qquad (2)$$

The energy of the ground state can be presented by:

1) M. C. Sauer, Jr., S. Arai and L. M. Dorfman, *J. Chem. Phys.*, **42**, 708 (1965).
2) S. Arai and M. C. Sauer, Jr., *J. Chem. Phys.*, **44**, 2297 (1966).
3) J. Jortner, *Mol. Phys.*, **5**, 257 (1962).
4) J. Jortner, *J. Chem. Phys.*, **30**, 859 (1959).
5) J. Jortner, *Radiation Res., Suppl.*, **4**, 24 (1964).
6) K. Fueki, *J. Chem. Phys.*, **44**, 3140 (1966).
7) M. J. Blandamer, L. Shields and M. C. R. Symons, *J. Chem. Soc.*, **1965**, 1127.

$$W_{1s} = \int_v \psi_{1s}[-\hbar^2/8\pi^2 m\nabla^2 + V(r)]\psi_{1s}dv, \quad (3)$$

where ∇^2 is the Laplacian operator.

For a given value of R and β, W_{1s} is obtained as a function of μ. The best value of μ is given by the condition $\partial W_{1s}/\partial\mu=0$. The substitution of this value of μ into (2) and (3) yields the wave function and the energy for the 1s state respectively. The mean radius for the 1s state is given by $r_{1s}=3/2\mu$. The 2p state can be treated in a manner similar to that used for the ground state.

According to the Franck-Condon principle, the value for R and the form of the potential selected for the 2p state are the same as those for the ground state. The energy of the 2p state was calculated using the one-parameter wave function:

$$\psi_{2p} = (\alpha^5/\pi)^{1/2} r\cos\theta\exp(-\alpha r) \quad (4)$$

The mean radius for the 2p state can be presented by $r_{2p}=5/2\alpha$. The electronic polarization energies for the 1s and 2p states are approximately given by:

$$\left.\begin{aligned} S_{1s} &= -(e^2\mu/3)(1-1/D_{op}),\\ S_{2p} &= -(e^2\alpha/5)(1-1/D_{op}). \end{aligned}\right\} \quad (5)$$

Thus, the total energy is obtained as:

and:

$$\left.\begin{aligned} E_{1s} &= W_{1s} + S_{1s},\\ E_{2p} &= W_{2p} + S_{2p}. \end{aligned}\right\} \quad (6)$$

The energy for the 1s→2p transition is given by:

$$h\nu = E_{2p} - E_{1s}, \quad (7)$$

which corresponds to the excitation energy at the absorption maximum.

Temperature Dependence of the Transition Energy. The energy shift presents the difference between the change in the energy of the ground and excited states:

$$d(h\nu)/dt = dE_{2p}/dt - dE_{1s}/dt, \quad (8)$$

where t is the temperature.

The temperature coefficient of the 1s state is obtained in the form:

$$\frac{dE_{1s}}{dt} = \left[\frac{\partial E_{1s}}{\partial\beta} - \left(\frac{\partial S_{1s}}{\partial\mu}\right)\left(\frac{\partial^2 W_{1s}/\partial\beta\partial\mu}{\partial^2 W_{1s}/\partial\mu^2}\right)\right]\left(\frac{d\beta}{dt}\right) + \left[\frac{\partial E_{1s}}{\partial R} - \left(\frac{\partial S_{1s}}{\partial\mu}\right)\left(\frac{\partial^2 W_{1s}/\partial R\partial\mu}{\partial^2 W_{1s}/\partial\mu^2}\right)\right]\left(\frac{dR}{dt}\right) \quad (9)$$

The temperature coefficient for the 2p state is given by Eq. (9) with E_{2p} substituted for E_{1s}, S_{2p} substituted for S_{1s}, and α substituted for μ. For a given value of R and β, dE_{1s}/dt and dE_{2p}/dt are presented by:

$$dE_{1s}/dt = a_1(d\beta/dt) + b_1(dR/dt), \quad (10)$$

and:

$$dE_{2p}/dt = a_2(d\beta/dt) + b_2(dR/dt), \quad (11)$$

where E is expressed in eV, where R is expressed in Å, and where a_1, b_1 and a_2, b_2 are defined by Eq. (9) and the corresponding equation for the 2p state respectively. From Eq. (8) we obtained:

$$d(h\nu)/dt = a(d\beta/dt) - b(dR/dt), \quad (12)$$

where $a=a_2-a_1$ and where $b=b_2-b_1$.

The temperature dependence of the energy levels and of the transition energy may thus be attributed to the temperature dependence of the properties of the dielectric medium which are roughly expressed by the temperature dependence of D_s and D_{op}, and to the temperature dependence of the mean cavity radius.

Results and Discussion

Transition Energy Diagram. The transition energy, $h\nu$, of a solvated electron is dependent on β and R. Since the optical dielectric constant, D_{op}, of any substance is not different from 2, we use a constant value, 2, for D_{op} in the calculation of $h\nu$, so that we may deal with the problem in a systematic way. Thus, we can construct a transition energy diagram by calculating $h\nu$ as a function of D_s and R.

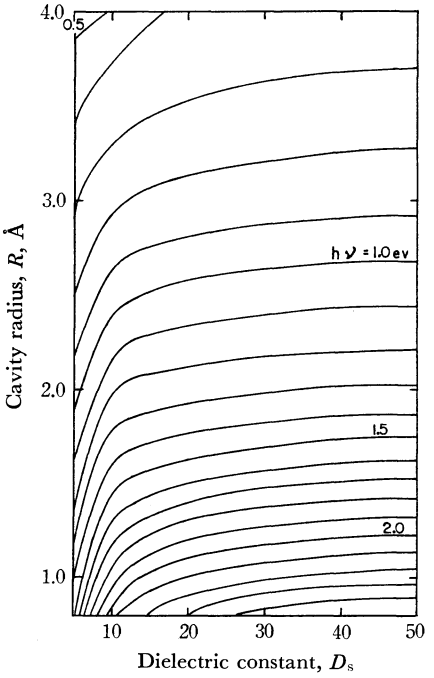

Fig. 1. Transition energy diagram for solvated electrons.

Figure 1 shows the calculated transition energy diagram, in which the contour lines for $h\nu$ are drawn every 0.1 eV, and where D_s the values range from 5 to 50 and the R values, from 0.8 to 4 Å. The results for high D_s values and the very small R values are not included in the diagram because the adiabatic approximation is less satisfactory for these cases. The adiabatic approximation is more

satisfactory for low D_s values and large R values because the binding energy of a solvated electron is small in such cases.

Solvated Electrons in Alcohols. From the transition energy diagram and the observed absorption spectra, the quantities of solvated electrons in alcohols at room temperature are obtained; they are given in Table 1.

Table 1. Charge distribution, the mean cavity radius, and the range of cavity radius of solvated electrons in alcohols at room temperature

Substance	$D_s^{25°C}$	$h\nu_{max}$ [1,2] (eV) (obs.)	$\bar{r}_{1s}$ (Å)	$\bar{r}_{2p}$ (Å)	R (Å)	$\pm\Delta R$ (Å)
Methanol	32.6	1.97	2.65	5.75	1.15	0.53
Ethanol	24.4	1.77	2.88	5.95	1.32	0.60

Glycerol	42.5	2.35	2.40	5.62	0.90	0.50

* 20°C

In Table 1, $\bar{r}_{1s}$ and $\bar{r}_{2p}$ are the mean radii for the 1s and 2p states respectively, R is the mean cavity radius, and ΔR is the range of the cavity radius, which will be discussed below.

Transition Energy and Cavity Radius. It can be seen from Table 1 that the mean cavity radius for solvated electrons in alcohols is 0.9—1.6 Å*1 and that the mean radius of the solvated electron orbitals for the ground state is 2.4—3.2 Å.

The mean cavity radius is plotted against the transition energy in Fig. 2. It may be seen that there is a correlation between the cavity radius and the transition energy. The transition energy increases with a decrease in the cavity radius. The cavity radius decreases with an increase in the static dielectric constant for all these alcohols except *n*-butanol (Fig. 3).

Absorption-band Width and the Range of the Cavity Radius. It is well known that the solvated electron exhibits a braod absorption spectrum. The high-energy side of the absorption band may be interpreted in terms of the transition of the solvated electron to higher excited states and an energy continuum as well as in terms of the broadening of the band due to variations in cavity size. On the other hand, the side with an energy lower than the band maximum is explicable only in terms of the broadening of the band due to various cavity sizes as long as the band maximum is interpreted as arising from the 1s→2p transition.

Table 2. Absorption band width and the range of cavity radius of solvated electrons at different temperatures

Temp.	Substance	$h\nu_{max}$ [1,2,7] (eV) (obs.)	$\Delta(h\nu)$ [1,2,7] (eV) (obs.)	R (Å)	$\pm\Delta R$ (Å)
25°C	Methanol	1.97	0.45	1.15	0.53
	Ethanol	1.77	0.45	1.32	0.60
	n-Butanol	1.80	0.44	1.20	0.60
− 78°C	Methanol	2.17	0.41	1.07	0.38
	Ethanol	2.18	0.50	1.05	0.47
	n-Butanol	2.28	0.53	0.90	0.50
−196°C	Methanol	2.41	0.27	0.89	0.23
	Ethanol	2.41	0.35	0.88	0.35
	n-Butanol	2.47	0.48	0.83	0.48

*1 It should be noted that, since the optical dielectric constants of methanol and ethanol are lower than 2 by about 10% the cavity radii for these alcohols will be found to be larger by about the same degree than those in Table 1 if the exact optical dielectric constants are used in these calculations.

TABLE 3. TEMPERATURE EFFECT ON THE TRANSITION ENERGY OF SOLVATED ELECTRONS IN ALCOHOLS

Substance	$d(h\nu)/dt$ (eV/deg) (obsd)[2]	$[d(h\nu)/dt]_I$ (eV/deg) (calcd)	$[d(h\nu)/dt]_{II}$* (eV/deg) (calcd)	dR/dt (Å/deg)	$\frac{[d(h\nu)/dt]_I}{d(h\nu)/dt}$
Methanol	-2.2×10^{-3}	-0.44×10^{-3}	-1.76×10^{-3}	1.5×10^{-3}	0.20
Ethanol	-3.4×10^{-3}	-0.41×10^{-3}	-2.99×10^{-3}	2.9×10^{-3}	0.12
Isopropanol	-3.5×10^{-3}	-0.60×10^{-3}	-2.90×10^{-3}	3.3×10^{-3}	0.18
n-Butanol	-4.5×10^{-3}	-0.77×10^{-3}	-3.73×10^{-3}	3.4×10^{-3}	0.17

* $[d(h\nu)/dt]_{II} = d(h\nu)/dt - [d(h\nu)/dt]_I$

Thus, the absorption-band width can be related to the cavity radius, which may be represented by the half-height width, ΔR, measured towards the low-energy side.

The values of ΔR for solvated electrons in alcohols at room temperature are given in Table 1. The effect of the temperature on ΔR is shown in Table 2. It can be seen from Table 2 that the range of the cavity radius decreases with a decrease in the temperature. It can also be seen that ΔR increases as the alkyl group in alcohols becomes bulky; this tendency is most clearly manifested at -196°C.*2

If the broadening of the absorption band towards the low-energy side is ascribed to the transition of solvated electrons in larger cavities, the photobleaching of these electrons by light with a selected energy limit will result in the blue shift of the absorption spectrum. Further experimental studies along this line are needed to substantiate such an interpretation.

Effect of Temperature on the Transition Energy. The calculated temperature dependence of the transition energies of solvated electrons in alcohols is given in Table 3, together with the observed one.

In these calculations the temperature dependence of β is presented approximately by $d\beta/dt = (1/D_s)\, d(\ln D_s)/dt$, since the temperature dependence of D_{op} is much smaller than that of D_s. The temperature coefficient of D_s is taken from the experimental data.

*2 Since there are no available data on D_s at -196°C, we have used the values of D_s at -78°C in the calculations at -196°C. This approximation is possible because the transition energy is relatively insensitive to the value of D_s for high D_s values (see Fig. 1) and because D_s is high enough to satisfy this requirement for alcohols at -78°C.

In Table 3, $[d(h\nu)/dt]_I$ and $[d(h\nu)/dt]_{II}$ represent the contribution to $d(h\nu)/dt$ of the changes in D_s and in the mean cavity radius with the temperature respectively. The contribution of the former to $d(h\nu)/dt$ is 20% at most, as is shown in the last column of the table. The calculated dR/dt is also given in Table 3. In Fig. 4 the value of dR/dt is plotted against the ratio of the number of the OH bond to the total number of bonds involved in each alcohol. There is a correlation

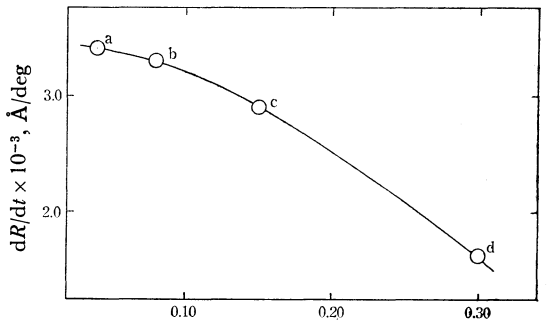

Fig. 4. Dependence of dR/dt on the ratio of the number of the OH bond to the number of bonds involved in each alcohol.
a: *n*-butanol, b: isopropanol, c: ethanol, d: methanol.

between these quantities, probably indicating a relation between the expansion of a cavity and the strength of such intermolecular interactions as hydrogen bonding.

It may be concluded that the temperature dependence of the transition energy of solvated electrons in alcohols is mainly attributable to the change in the cavity size with the temperature.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 20—24 (1969)

Studies of the Precipitation of Humic Acid by Cationic Polyelectrolytes

Hiroshi KUMANOMIDO

Resources Research Institute, Kotobuki-cho, Kawaguchi-shi, Saitama

(Received March 13, 1968)

In order to elucidate the mechanism of the precipitation of humic acid by two cationic polyelectrolytes, the *n*-butylamine-epichlorohydrin condensation polymer (BECP) and the cyclohexylamine-epichlorohydrin condensation polymer (CECP), electrophoresis and conductometric titration were made in conjunction with precipitation experiments in various concentrations of humic acid with an optimum dosage of cationic polyelectrolyte. The results of these experiments indicated that a cationic polyelectrolyte precipitates the humic acid by combining stoichiometrically with the negatively-charged groups of the humic acid. A possible mechanism for the precipitation was proposed schematically on the basis of the experimental results obtained.

Many previous studies[1-7] of the interaction between surface active agents and proteins have shown that precipitation takes place when they are oppositely charged. Thus, the electrostatic force between their opposite charges is considered to be responsible for the precipitation. However, only a few studies[8,9] have been reported on the interaction between polyelectrolytes with opposite charges.

Previously the present author[10] studied the precipitation of humic acid by cationic polyelectrolytes and found that some cationic polyelectrolytes are excellent precipitants for humic acid, and that the characteristics for the precipitation of humic acid with these cationic polyelectrolytes quite differ from those observed with inorganic salts($BaCl_2$, $Al_2(SO_4)_3$, *etc.*) or with a low-molecular-weight organic cation (*e. g.*, *p*-toluidine hydrochloride).

The present study intends to clarify the mechanism of the precipitation of humic acid with two cationic polyelectrolytes, the *n*-butylamine-epichlorohydrin condensation polymer (BECP) and the cyclohexylamine-epichlorohydrin condensation polymer (CECP).

The relationship between the humic acid concentration and the cationic polyelectrolyte dosage in the precipitation region is investigated in terms of conductometric titration and electrophoresis as well as the transmittance of the test solution.

Experimental

Humic Acid. To 500 g of −149 μ-size Nakayama-lignite, containing 7.92% ash and 10.09% moisture, 1*l* of a 5% aqueous solution of hydrogen peroxide was added; the mixture was then allowed to stand at room temperature (about 20°C). After 24 hr, the lignite was filtered, washed with distilled water, and dried at 107°C for 5 hr. Humic acids prepared by the oxidation of lignite were extracted by the digestion of the oxidized lignite with 5% ammonia water. The aqueous alkali extracts were filtered and boiled in a water bath in order to remove the excess ammonia, and then purified by the use of electrodialysis. The humic acid thus purified was filtered, dried, and dissolved in a sodium hydroxide solution. The aqueous solution of sodium humate of 2 g/*l* in a concentration of pH 7 was prepared as a stock solution and was used throughout the present studies.

The relationship between the concentration and the transmittance of the aqueous solution of sodium humate at pH 7 is illustrated in Fig. 1. The transmittance was measured using a photoelectric colorimeter (Model 7A of the Tokyo Photo-Electric Co., Ltd.) with an 18-mm light path and a 420-mμ filter.

The analyses of purified humic acid are shown in Table 1. The COOH equivalent and the phenolic-OH equivalent of humic acid were determined according to the methods of Higuchi and Shibutani.[11]

Cationic Polymers. As cationic polymers, BECP and CECP were synthesized. The reactions between amines and epichlorohydrin have been studied exten-

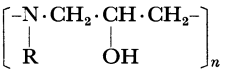
sively,[12-18] and it is widely recognized that the structure of monoamine-epichlorohydrin condensation polymers can be represented as follows:



R: butyl or cyclohexyl radical

One mole of epichlorohydrin was poured slowly, with vigorous stirring, into a 200-m*l* flask containing 1 mol of *n*-butylamine or cyclohexylamine and 25 g of water. The mixture was then heated under reflux in a boiling-water bath. After 5 hr of heating, 1 mol of an aqueous solution of sodium hydroxide was added to the mixture, after which heating was continued for an additional 5 hr. The condensation polymer isolated from the reaction mixture by adding sodium hydroxide was washed with hot water, dissolved in benzene, and then washed with water until free from chloride ions; finally, the benzene was evaporated off.

The two condensation polymers obtained were dissolved in a stoichiometric hydrochloric acid solution to a concentration of 50 g/*l*.

18) D. L. Heywood and B. Phillips, *J. Am. Chem. Soc.*, **80**, 1257 (1958).

The molecular weights of the polymers, determined by means of the cryoscopic method using a benzene solution, were 3080 for BECP and 1720 for CECP.

Nonionic and Anionic Polymers. The following nonionic and anionic polymers were used:

Nonionic polymers: Polyacrylamide, Polyvinylpyrrolidone, Polyvinyl alcohol, Polyethyleneglycol.

Anionic polymers: Polyacrylic acid, Urea-formaldehyde condensation polymer.

The analytical grades of these samples were satisfactory for use as delivered.

Precipitation Procedure. A calculated amount of an aqueous polymer solution was poured into an aqueous solution (20 m*l*) of sodium humate placed in a test tube. Immediately after the addition, the test tube was turned upside-down twenty times at equal time intervals. After it had then been left to stand for 30 min, the solution was filtered through No. 5C filter paper; then the transmittance of the filtrate was measured by the photoelectric colorimeter described above.

The transmittance of the filtrate was utilized as a convenient measure for representing the precipitation of humic acid, because the precipitate, which increases the transmittance of the filtrate, could be removed by filtration.

The dispersing power of cationic polymers for the humic acid precipitated was studied as follows:
An appropriate amount of an aqueous solution of the cationic polymer was added to the humic acid precipitate obtained with an optimum dosage of the cationic polymer. The mixture in a test tube was violently shaken, left to stand for 30 min, and filtered, and the transmittance of the filtrate was measured.

Conductometric Titration. The change in the electric conductivity of the aqueous solution (100 m*l*) of 1 g/*l* sodium humate upon the drop-by-drop addition of a cationic polymer solution (50 g/*l* in concentration) was measured with a conductometric titrator (Model CT-2 of the Shimadzu Seisakusho, Ltd.); at the same time, the precipitation curve of the humic acid - cationic polymer system was determined in a way previously described.

Electrophoresis. A calculated amount of an aqueous polymer solution was poured into an aqueous solution (100 m*l*) of 0.5 g/*l* sodium humate placed in a measuring cylinder. Immediately after the addition, the cylinder was turned upside-down thirty times and then left to stand for 30 min. The electrophoresis of the humic acid in the mixture was qualitatively observed using a U-tube. At the same time, a part of the mixture was filtered, and the transmittance of the filtrate was measured by means of the photoelectric colorimeter described above.

Results and Discussion

The Precipitation of Humic Acid with Water-soluble Polymers. It was found that the precipitation of humic acid occurs only by means of cationic polymers, not by means of nonionic or anionic polymers. The results obtained with two cationic polymers, BECP and CECP, are illustrated in Fig. 2. It is seen that the precipitation of humic acid occurs only within a particular range of concentration of cationic polymers; that

Concn. of humic acid: —○— 20 mg/*l*, —●— 50 mg/*l*, —△— 100 mg/*l*, —▲— 200 mg/*l*

is, a sharp decrease in precipitating efficiency is observed with excess dosages of cationic polymers. The humic acids once precipitated with cationic polymers were not dispersed by an excess of cationic polymers.

The characteristics of precipitation in the system of humic acid-water soluble polymers are similar to those observed in the system of proteins-surface active agents, except that the proteins precipitated with surface active agents are dispersed by the addition of more of those surface active agents. Also, we know various systems of colloid-water-soluble polymers in which coagulation takes place in a way similar to that observed in the present experiment.

It may be suggested that the precipitation of humic acid with cationic polymers is caused, as in the other examples of colloidal coagulation, by electrostatic interaction between anionic sites of humic acid and cationic sites of cationic polymers. The following experimental results give further support to this idea.

Relation between Initial Humic Acid Concentration and Optimum Cationic Polymer Dosage. The effect of a variation in the cationic polymer dose on the precipitation of a given amount of humic acid was studied at four different humic-acid concentrations (20, 50, 100, and 200 mg/*l*) at room temperature.

The results obtained are illustrated in Figs. 3 and 4. The abscissa in Figs. 3 and 4 represent the weight-mixing ratio of the cationic polymer to humic acid. The following characteristics may be observed in these figures (Figs. 3 and 4).

(1) Precipitation occurs only over a narrow weight-ratio range of humic acid and cationic polymers, and the range seems to be independent of the initial concentration of humic acid studied; that is, the precipitation of humic acid with a cationic polymer is stoichiometric.

(2) The precipitation of humic acid by BECP occurs in the range of the weight-mixing ratio between 0.35 and 0.55, as is shown in Fig. 3. Since the ratio of the cationic group equivalent (g/equiv.) of BECP to the carboxyl group equivalent (g/equiv.) of humic acid is 0.45, we may infer that the midpoint of the precipitation range corresponds to the point where the number of the cationic group is equal to that of the carboxylic group in the solution. Similar results are observed with CECP. These facts imply that cationic polymers act to precipitate humic acid by combining stoichiometrically with the negatively-charged carboxyl groups of humic acid.

Conductometric Titration. The results obtained with BECP and with CECP are illustrated in Figs. 5 and 6 respectively. It may be noted in Figs. 5 and 6 that there is a break point in the titration curves, the composition of which nearly coincides with that of the optimum precipitation.

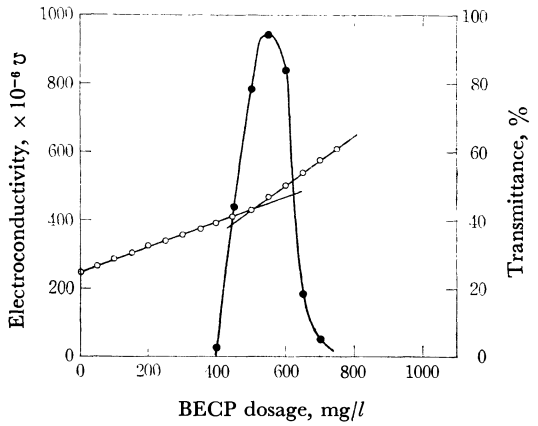

Fig. 5. Relationship between electroconductivity and precipitation in the system humic acid-BECP.
Concn. of humic acid: 1 g/l
—○— electroconductivity
—●— transmittance

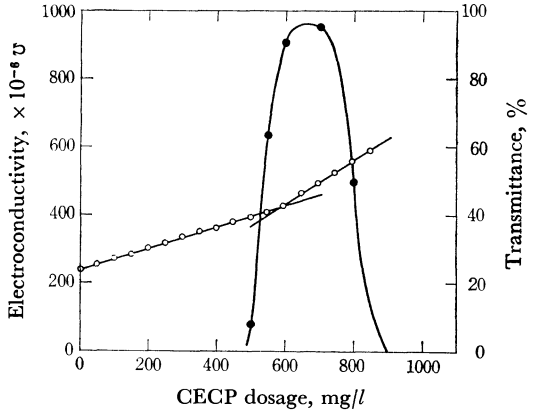

Fig. 6. Relationship between electroconductivity and precipitation in the system humic acid-CECP.
Concn. of humic acid: 1 g/l
—○— electroconductivity
—●— transmittance

The results suggest that the precipitation of humic acid occurs as a result of the neutralization of carboxyl groups with a cationic polymer, with a consequent loss of the charge of binding sites.

Electrophoresis. The results obtained with BECP and CECP are summarized in Tables 2 and 3. It is apparent from these tables that the humic acid is negatively charged in the absence of a cationic polymer, that a reversal of charge occurs when the latter reaches a certain concentration, and that optimum precipitation occurs in the narrow range in which the charge of humic acid changes from negative to positive. The decrease in the precipitating efficiency for excess dosages of cationic polymers is caused by a reversal of the charge of humic acid, leading to an increase in the hydrophilic property of humic acid (humic acid-cationic polymer complexes). The phenomena described above in the humic acid-cationic polymer system may be the same as the flocculation-dispersion phenomena in the colloid-polyelectrolyte system, which has opposite charges.

The Mechanism of Precipitation

Humic acids and cationic polymers possess a number of ionized sites on the molecule; for example, the number of cationic groups per molecule

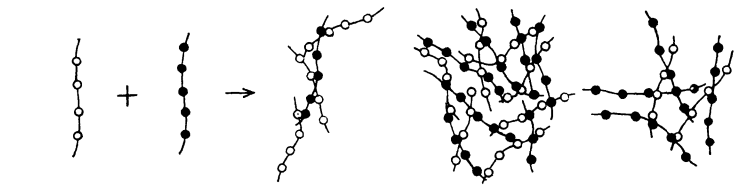

Fig. 7. The precipitation of humic acid by cationic polyelectrolyte.

of BECP is about 24 when the molecular weight is 3080, and that of CECP is about 11 when the molecular weight is 1720. Therefore, it appears to be general true that humic acids may be bridged together by cationic polymers as a result of electrostatic interaction between the carboxyl groups of a humic acid and the cationic groups of a cationic polymer; that is, precipitation is caused by the formation of hydrophobic complexes by a bridging mechanism similar to the polymer-bridging mechanism[19-21] for the flocculation of colloidal suspensions.

Consideration of all of the results obtained in this study leads to the conclusion that the precipitation of humic acid by a cationic polymer is caused by electrostatic and stoichiometric interaction between the anionic sites of humic acid and the cationic sites of the cationic polymer, leading to the formation of salt-like complexes by means of a bridging mechanism. Thus, the precipitation of humic acid by a cationic polymer may be represented schematically as is shown in Fig. 7.

The author wishes to express his gratitude to Professor Tsunetaka Sasaki of Tokyo Metropolitan University and Professor Rhohei Matsuura of Kyushu University for their many valuable discussions. The author also wishes to thank Dr. Michihiro Noda of this Institute for his many valuable discussions and for the help given during the course of this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 25—35 (1969)

Studies of the Transient Intermediates of a Thiopyronine Aqueous Solution under Flash Excitation

Masaharu MORITA*1 and Shunji KATO

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

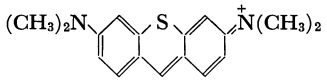
(Received March 18, 1968)

Flash photolytic studies of the transient intermediates produced in the flash excitation of an aqueous buffered solution of the photosensitizing dye "thiopyronine" were undertaken in order to obtain direct insight into the reaction mechanism of the photosensitizing action of the dye. As had been expected from the structural similarity to a well-known photosensitizer, methylene blue, previously reported on, the flash excitation of thiopyronine, in a deaerated buffered solution at pH 7.4 without any substrate, produced three transient intermediates: a triplet-state (D^t), a half-oxidized form (Oxd), and a half-reduced form or semiquinone (Red) of the dye. Red and Oxd were generated simultaneously through electron tansfer reactions, *i. e.*, $D^t + D^t \rightarrow Red + Oxd$ and $D^t + D \rightarrow Red + Oxd$, where D is the dye in the ground state. Thiopyronine solutions containing some reducing and oxidizing agents were studied in order to identify the intermediates. The absorption spectra of these intermediates were identified, and their reaction mechanism studied. The rate constants of some elementary processes obtained are:

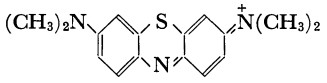
$$\begin{aligned}
D^t &\longrightarrow k_1 = 2.3_6 \times 10^3\ sec^{-1} \\
D^t + D^t &\longrightarrow k' = 7.6_9 \times 10^8\ M^{-1}sec^{-1} \\
D^t + D &\longrightarrow k'' = 7.6_9 \times 10^8\ M^{-1}sec^{-1} \\
Red + Red &\longrightarrow k_6 = (1—2) \times 10^9\ M^{-1}sec^{-1} \\
Oxd &\longrightarrow k_7 = (1—3) \times 10^3\ sec^{-1} \\
D^t + EDTA &\longrightarrow k_8 = 1.6 \times 10^7\ M^{-1}sec^{-1} \\
D^t + ATU &\longrightarrow k_9 \approx \text{small} \\
Oxd + ATU &\longrightarrow k_{10} = (2—5) \times 10^6\ M^{-1}sec^{-1}.
\end{aligned}$$

The high efficiency of thiopyronine in its photodynamic effect was discussed in connection with the high quantum yield of triplet-state production and the high reversibility of the photochemical redox reaction of the dye.

Thiopyronine (I) is an efficient photosensitizing dye; it has a structure similar to that of the well-known photosensitizer, methylene blue (II).



(I)



(II)

Recently, investigations of the photodynamic effect of thiopyronine, as a photosensitizer, on various systems, such as bacterium, virus, nucleic acids, and their base components, have been reported by several authors, and the reaction mechanisms have been discussed.[1] However, all these investigations have been performed by steady-light illumination and were concerned only with the product analysis of the reaction or with physicochemical changes in the irradiated systems.

A more direct investigation of the intermediates is now necessary in order to elucidate the reaction mechanism.

Flash photolytic studies of the transient intermediates in the photoreduction of methylene blue

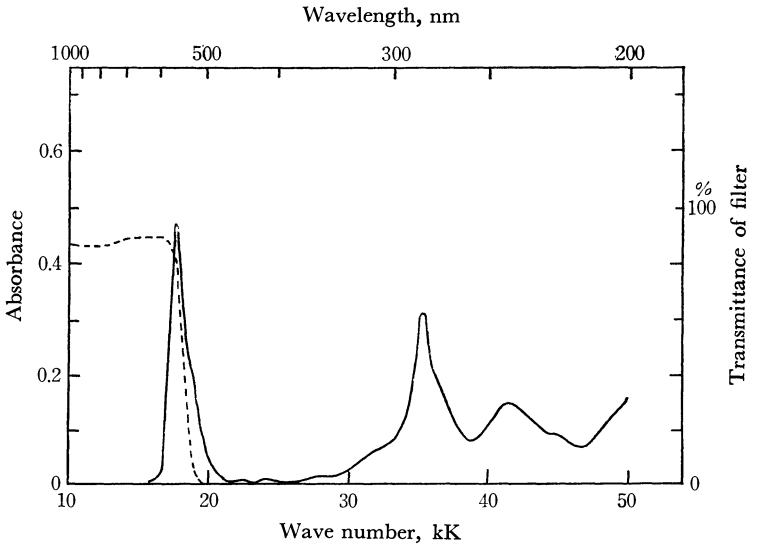

Fig. 1. Absorption spectrum of thiopyronine in buffered solution at pH 7.4; Dye concn. 6.4 μM. Optical path 1.0 cm. Broken line: Transmittance of the orange glass filter (Hoya Crystal Co., 0-54) used.

and thionine have been reported previously by the present authors.[2] That paper reported that the triplet-state of methylene blue produced by flash excitation interacts with the ground-state dye, producing semiquinone and a half-oxidized form.

This is an essential process in the photoreduction of methylene blue in a deaerated phosphate buffered solution in the absence of any reducing agent. A similar result obtained for thionine shows that the photochemical self redox reactions of these dyes take place readily.[3]

The photosensitizing efficiency of dyes has been discussed in connection with their photochemical redox reversibility.[4]

It will be interesting to investigate the correlation between the photosensitizing ability and the photochemical redox properties of these dyes from the point of view described above.

Also, it is expected that thiopyronine has a photochemical redox property similar to that of methylene blue, for the molecular structures are similar, and both have high photosensitizing powers. Thus, the flash photolytic investigation of thiopyronine was undertaken in order to clarify the reaction mechanism of the dye-sensitized photochemistry.

Some results have already been reported in a short form.[5] The aim of the present paper is to report in detail the spectroscopic and kinetic behavior of the transient intermediates of thiopyronine in an aqueous solution with or without substrate.

Experimental

Chemicals. The thiopyronine was synthesized in the way described by Biehringer and Topaloff.[6]

The results of an elementary analysis of the synthesized dye as a zinc double salt were in good agreement with the calculated values. (Found: C, 51.02; H, 4.97; N, 7.00%. Calcd for $C_{17}H_{19}N_2S \cdot \frac{1}{2}ZnCl_2$: C, 52.70; H, 4.95; N, 7.24%.)

After the zinc had been removed by adding ammonia, the dye was recrystallized, in the form of golden-green needles, from concentrated hydrochloric acid as the dichloride ($C_{17}H_{19}N_2SCl \cdot HCl$) which was then recrystallized three times from concentrated hydrochloric acid and desiccated over calcium oxide and concentrated sulfuric acid. The purity was checked by paper chromatography. The solvent used was a mixture of butanol (4), acetic acid (1), and water (4). The chromatogram showed only one distinct single R_f value, 0.61_4. The absorption spectrum of thiopyronine in a buffered solution at pH 7.4 is shown in Fig. 1. The molar extinction coefficient is $7.4 \times 10^4 M^{-1} cm^{-1}$ at 564 nm.

The *p*-benzoquinone (Wako Junyaku Co., G.R.-grade reagent) was recrystallized from ethanol. The hydroquinone (Wako Junyaku Co., G.R.-grade reagent),

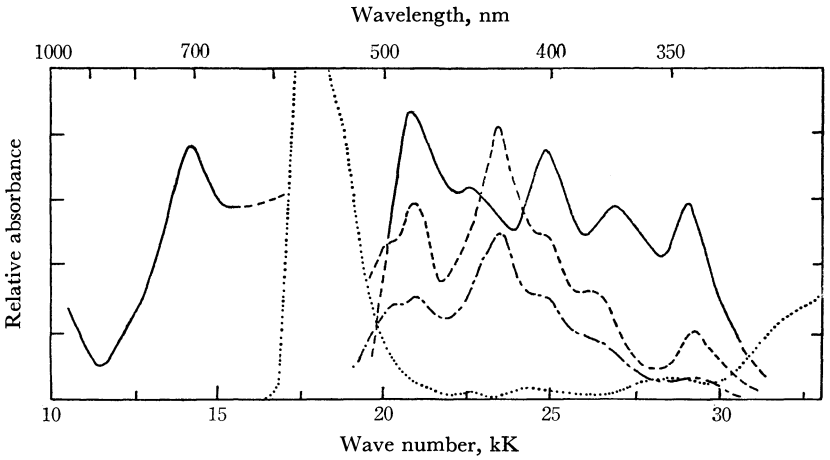

Fig. 2. Transient absorption spectra of thiopyronine in phosphate buffered solution at pH 7.4; Dye concn. 6.5 μM.
—— 22 μsec; – – – 130 μsec; —·— 200 μsec after flashing. The absorption spectrum in near-infrared region was constructed by an extrapolation of the decay curves measured at a series of wavelengths to zero time flashing. The absorption spectrum of thiopyronine is shown for the sake of comparison ·····.

allylthiourea (ATU) (Tokyo Kasei Co., G.R.-grade), and potassium dihydrogen phosphate (Wako Junyaku Co., G.R.-grade) were recrystallized three times from redistilled water. The sodium hydroxide solutions were prepared from a saturated solution of Wako Junyaku Co., G.R.-grade reagent. The disodium ethylene diamine tetraacetate (EDTA) and potassium persulfate, both Wako Junyaku Co., G.R.-grade reagent, were used without further treatment.

Preparation of Sample Solutions. The sample solutions were prepared from a stock thiopyronine solution of 5×10^{-4} M; the pH values were controlled with a 1/25 M KH_2PO_4-NaOH buffered solution and measured with a Hitachi-Horiba M-5 pH meter.

The solution was deaerated by more than five cycles of freezing-pumping-thawing. The absorption spectra before and after flashing were measured by means of a Shimadzu QB50 spectrophotometer or a Shimadzu multipurpose, auto-recording spectrophotometer (MPS-50).

Every measurement of flash photolysis was made with a fresh sample, even when the permanent change resulted from a single flash was negligibly small.

Apparatus. For photolysis, two quartz flash lamps filled with xenon (Ushio Electric Co., UF-693) were powered by a 4-μF capacitor charged up to 10 kV, if not otherwise mentioned. The duration time of photolysis lamps was 15 μsec.

A capillary flash lamp filled with argon was employed as a light source for the spectrophotography; it was worked at 3 kV with a 10-μF capacitor. The transient spectra were taken on Fuji Neopan plates, Fuji Neopan SS films, or Sakura Infrared 750 films by means of a Nalumi RM-23 grating spectrograph, which could also be used as a monochromator by turning a reflecting mirror. A triggering circuit controlled the time interval between the photolysis and the spectro flash from 10 μsec to 800 msec. Some measurements of the transient spectra were photographed by a double-beam flash apparatus described elswhere.[7]

The decays of the transient absorption spectra were measured with a xenon short-arc lamp (Ushio Electric Co., UXL-150D), photomultipliers (RCA 1P28 for the UV and visible region and 7102, Hamamatsu TV Co., for the red to near-infrared region), the monochromator described above, and a Hitachi V-116 synchroscope working through a cathode follower. The photolysis cells were glass tubes 10 cm long and 8 mm in inner diameter, to both ends of which were cemented quartz plane plates.

Hoya 0-54 orange glass cut-off filters were inserted between the photolysis flash lamps and the photolysis cell so as to exclude any light shorter than 540 nm, as is shown in Fig. 1, where the absorption spectrum of the dye is also depicted.

Results and Discussion

A. Transient Intermediates in the System Without Any Substrate. A deaerated, plain, aqueous solution and a buffered solution of the dye were almost completely decolorized transiently just after irradiation by a 200 J flash. The permanent bleaching by a single flash was, however, less than 2%.

The transient absorption spectrum has rather complex feature, as is shown in Fig. 2. It has many peaks which behave in different ways.

The absorption around 350 nm and those in the near-infrared region decay rapidly, while the peak at 425 nm increases after flashing and the

7) S. Kato, "Zikken Kagaku Koza, Zoku 11, Denshisupekutoru (Handbook of Experimental Chemistry, Continued Vol. 11)," ed. by S. Nagakura, Maruzen Inc., Tokyo (1965).

peak at 475—500 nm decays slowly.

From this kinetical difference, it is clear that the overall spectrum consists of several bands of different natures, overlapping with each other.

The absorption decays measured at 340 and 690 nm were analyzed according to the first-order rate formura, as is shown in Fig. 3; the same rate constant was obtained for both wavelengths.

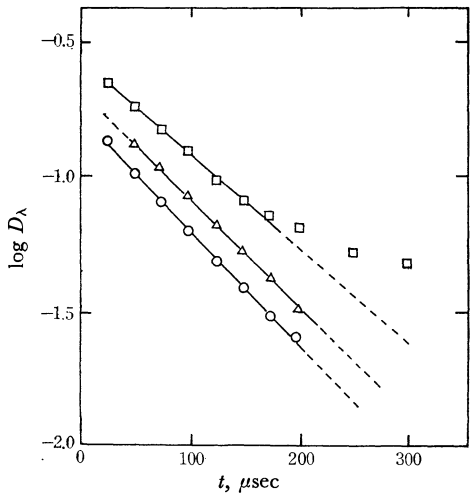

Fig. 3. First-order decay of the triplet state of the dye.
Dye concn. 8.8 μM. pH 7.4.
Wavelengths: ○ 340 nm, □ 375 nm, △ 690 nm

The plot for the first order at 375 nm is also nearly parallel, in the first part, to the other lines.

The coincidence of the rate constants make it possible to attribute these peaks to a single species, which may be assigned to the triplet-state of the dye. This assignment is strongly supported by the good correlation of the peaks with the energies for the triplet-triplet transition caluculated by means of the LCAO-MO-SCF method based on a variable *beta* approximation.[8)]

Every single run for the decay at 340 or 690 nm can be well described as a first-order process, but the observed rate constant increases linearly with the initial dye concentration, as is shown in Fig. 4, which gives the following relation:

$$k_{obs} = k_1 + k(D).$$

On the other hand, the rate constant are quite independent of the flash intensity, whether it is high enough to make a complete transient decoloralization or is so low as to make a 20% conversion (see Fig. 5).

These results can be explained only by a postulating that the triplet-state and the ground-state of the dye make the same contribution to the decay

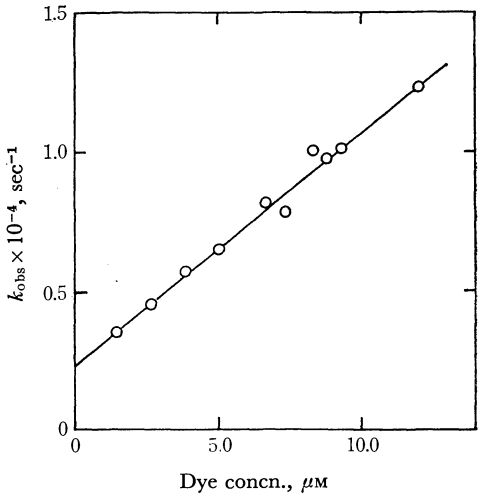

Fig. 4. Concentration dependence of the decay rate of the thiopyronine triplet in a phosphate buffered soultion at pH 7.4 measured at 340 nm.

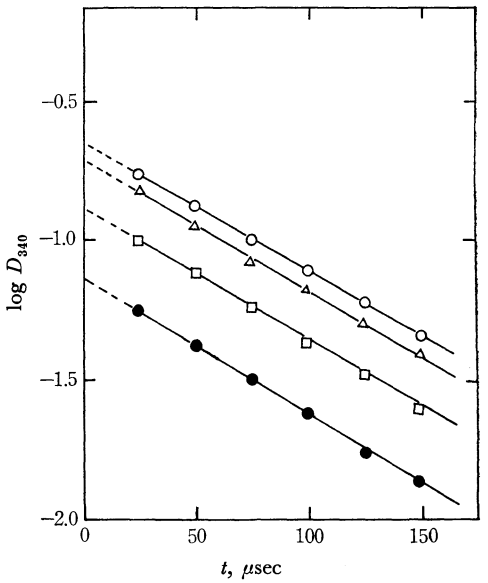

Fig. 5. The effect of the flash-light intensity (as a function of the input electric energy) on the decay rate of the triplet state measured at 340 nm.

○ 200J, △ 180J, □ 72J, ● 32J

of the triplet-state:

$$D^t \longrightarrow k_1$$
$$D^t + D^t \longrightarrow k'$$
$$D^t + D \longrightarrow k''.$$

The peaks at 425 and 475—500 nm have distinctly longer lives than the triplet state, but the kinetical behavior is rather too complex for quantitative analysis. This means that at least two species have absorption bands, greatly overlapping, in

8) M. Morita, S. Kato, K. Nishimoto and L. S. Forster, to be published.

this spectral region. Qualitatively speaking, there exist at least two species, one of which decays in the first-order with a lifetime of less than 100 μsec, and while the other decays in the second order.

From the experimental evidence presented above, and also analogously with the results for methylene blue,[2] it is conceivable to attribute these long-living peaks to the half-oxidized form (475—500 nm) and the half-reduced form or semiquinone (425 nm) of the dye. This assignment was confirmed by the experiments to be described later.

The following reaction mechanism may, then, be proposed for the primary processes of thiopyronine in a buffered solution (pH 7.4) without any substrate:

$$\begin{aligned}
D + h\nu &\longrightarrow D^* \\
D^* &\longrightarrow D^t \\
D^t &\longrightarrow D & k_1 \quad (1)\\
D^t + D &\longrightarrow 2D & k_2 \quad (2)\\
D^t + D^t &\longrightarrow D^t + D & k_3 \quad (3)\\
D^t + D &\longrightarrow \text{Red} + \text{Oxd} & k_4 \quad (4)\\
D^t + D^t &\longrightarrow \text{Red} + \text{Oxd} & k_5 \quad (5)
\end{aligned}$$

where D, D*, D^t, Red, and Oxd are the ground state, the first excited singlet state, the triplet-state, the half-reduced form, and the half-oxidized form of the dye respectively.

The decay of the triplet-state can now be represented as:

$$-d(D^t)/dt = k_1(D^t) + k_2(D^t)(D) + k_3(D^t)^2 + k_4(D^t)(D) + 2k_5(D^t)^2.$$

When (k_2+k_4) is assumed to be equal to (k_3+2k_5), the above equation turns into the following:

$$-d(D^t)/dt = k_1(D^t) + (k_3 + 2k_5)(D_0)(D^t),$$

where $(D_0) = (D^t) + (D)$,

and where (D_0) is the initial dye concentration. The integration of the simplified equation yields:

$$-d\ln(D^t)/dt = k_{obs} = k_1 + (k_3 + 2k_5)(D_0).$$

This also holds in the case of eosine.[9]

Using the values obtained from Fig. 4, one obtains:

$$k_1 = 2.3_6 \times 10^3 \text{ sec}^{-1}$$
$$k_3 + 2k_5 = 7.6_9 \times 10^8 \text{ M}^{-1}\text{sec}^{-1}$$
$$k_2 + k_4 = 7.6_9 \times 10^8 \text{ M}^{-1}\text{sec}^{-1}.$$

B. Transient Intermediates in the Systems Containing Oxidants. *Potassium Persulfate* ($K_2S_2O_8$). In the presence of $K_2S_2O_8$ added as an oxidant, a partial fading of the dye gradually took place in a deaerated solution, even in the dark. When the solution containing 5×10^{-4} M $K_2S_2O_8$ at pH 6.9 was flashed, there appeared only one absorption band, between 450 and 510 nm, as is shown in Fig. 6, and a permanent bleaching of the dye was observed.

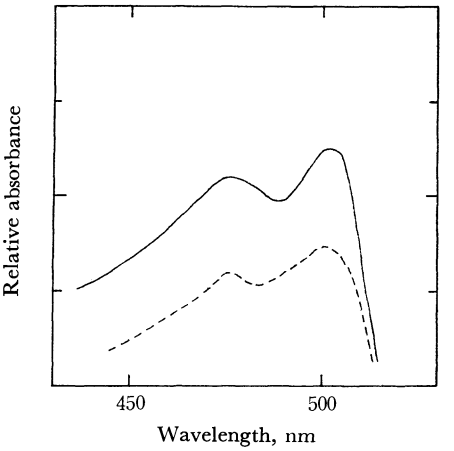

Fig. 6. Absorption spectra of transient species in a buffered solution at pH 6.9 containing 5×10^{-4} M $K_2S_2O_8$.
Dye concn. 3 μM
—— 40 μsec; – – – 105 μsec after flashing.

The absorption spectrum of the product has no distinct band, except for some rise in the shorter wavelength region.

p-Benzoquinone. In the case of the addition of *p*-benzoquinone as an oxidizing agent, two different transient absorption spectra were observed by flash excitation. Figure 7 shows the transient absorption spectra in this system.

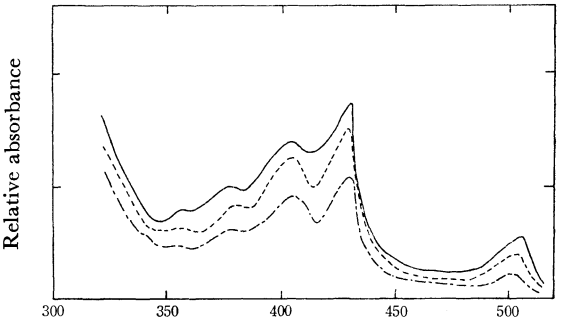

Fig. 7. Transient absorption spectra of thiopyronine phosphate buffered solution containing 5×10^{-4} M *p*-benzoquinone at pH 7.4.
Dye concn. 8 μM
—— 85 μsec; – – – 200 μsec; —·— 440 μsec after flashing.

One has four peaks, at 355, 375, 405, and 432 nm, and the other has one peak, at 500—505 nm. The former agrees with the absorption spectrum of the *p*-benzosemiquinone ion reported by several authors.[10]

9) T. Ohno, S. Kato and M. Koizumi, This Bulletin, **39**, 232 (1966).

10) H. Diebler, M. Eigen and P. Matthies, *Z. Elektrochem.*, **65**, 634 (1961); G. E. Adams and B. D. Michael, *Trans. Faraday Soc.*, **63**, 1171 (1967).

Also, some kinetic studies undertaken at 430 and 370 nm show that these transient species decay according to the second-order rate formula, as is shown in Fig. 8; the slopes of the decay curves give the rate constant of $1.7_3\times10^8$ M^{-1} sec^{-1} at 430 nm and of $1.8_2\times10^8$ M^{-1} sec^{-1} at 370 nm, using $\varepsilon_{430}=7.3\times10^3$ M^{-1} cm^{-1} and $\varepsilon_{370}=4.6\times10^3$ M^{-1}·cm^{-1} as the extinction coefficients of the *p*-benzosemiquinone ion at 430 and 370 nm respectively.

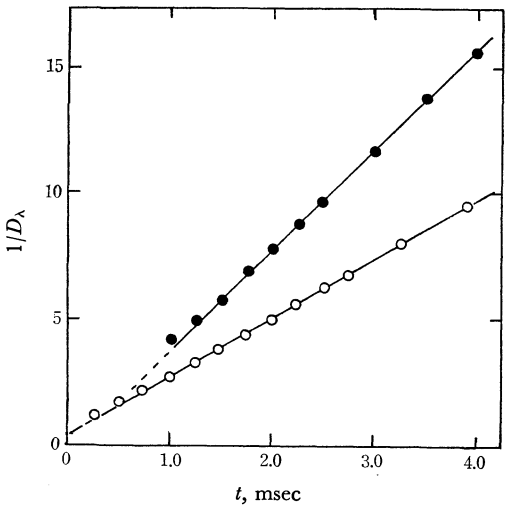

Fig. 8. Second-order decay of the *p*-benzosemiquinone ion.
Dye concn. 8.0 μM. *p*-Benzoquinone concn. 5×10^{-4}M. pH 7.4. Wavelengths: ● 370 nm, ○ 430 mn

These rate constants agree with the value for the dismutation process of the *p*-benzosemiquinone ion previously reported by Diebler, Eigen, and Matthies if one takes into account the temperature difference in the measurements.[10]

Thus, it is very likely that the *p*-benzosemiquinone ion decays through its own dismutation process, without interaction with a dye or any other intermediates.

The transient species, the absorption spectrum of which appeared in the region from 480 to 510 nm, with the peak at 500—505 nm may be identified as the half-oxidized form of the dye on the basis of a comparison with the case of $K_2S_2O_8$. There is no doubt that this intermediate is produced by the following reaction:

$$D^t + Q \longrightarrow Oxd + Q^-$$

where Q and Q^- indicate *p*-benzoquinone and its semiquinone ion respectively. The transient decay kinetics at 490 nm gave the first-order decay rate constant of 1×10^3 sec^{-1}. This evidence confirms conclusively that the transient species with an absorption around 500 nm is not due to the semiquinnoe ion of *p*-benzoquinone, but to the half-oxidized form of the dye.

Aerated Buffered Solution. When an aerated solution of the dye was subjected to flash excitation, only a weak transient absorption spectrum appeared during irradiation; it was in the region from 450 to 510 nm, with two peaks, at 475 and 505 nm. The other transient absorption had completely vanished.

This shows that the transient intermediates which appear in a deaerated solution are due to oxygen sensitive species, *i. e.*, the triplet-state of the dye and the intermediates with longer lifetimes produced from the triplet state. This finding confirms the assignment presented above.

The intermediate with the weak absorption around 450—510 nm may be produced by the reaction between the triplet state of the dye and oxygen. However, a large portion of the triplet state of the dye is likely to be quenched physically with oxygen, thus regenerating the ground-state dye. It seems that only a small portion of the triplet-state dye reacts to give the transient species *via* the following process:

$$D^t + O_2 \longrightarrow Oxd + O_2^-.$$

Thus, the transient intermediate with an absorption around 450—510 nm may be assigned to the half-oxidized form of the dye.

C. Transient Intermediates in the Systems Containing Reductants. *Hydroquinone.* In the presence of 5×10^{-4} M hydroquinone added as a reducing agent, upon flash excitation, there appeared a very intense transient absorption spectrum, with 343, 370, 405, and 428 nm peaks as is shown in Fig. 9.

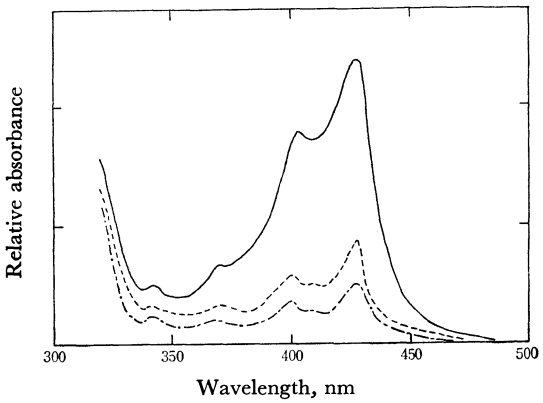

Fig. 9. Transient absorption spectra of a thiopyronine phosphate buffered solution at pH 7.4 containing 5×10^{-4} M benzohydroquinone.
Dye concn. 7.2 μM
—— 55 μsec; - - - 250 μsec; —·— 550 μsec after flashing.

The spectra obtained at 250 μsec and at 550 μsec have almost the same structure as that shown in Fig. 7 in the region from 350 to 450 nm. There is no doubt that these spectra are due to the *p*-

benzosemiquinone ion. On the other hand, the spectrum at 55 μsec is similar to the others in its peak positions, but different in the relative intensities. These results lead to the conclusion that an absorption band of another transient species is superposed in this spectral region; this species is certainly a semiquinone of the dye and has a shorter lifetime. In the case of methylene blue, the superposition of the transient absorptions due to the corresponding semiquinone in this wavelength region has been reported previously.[11] It may be noted that the transient absorption band from 470 to 510 nm which appeared in the dye-*p*-benzoquinone system completely vanishes in this system. Thus, there is scarcely any doubt that the electron transfer or hydrogen transfer occurs from the hydroquinone to the triplet state of the dye. Decay kinetics were undertaken at 430 and 370 nm. As is shown in Fig. 10, decay curves plotted on the second-order rate formula give the rate constants of $1.8_7\times10^8$ M^{-1} sec^{-1} at 430 nm and of $1.6_2\times10^8$ M^{-1} sec^{-1} at 370 nm, using the values of extinction coefficient for each wavelength presented above.

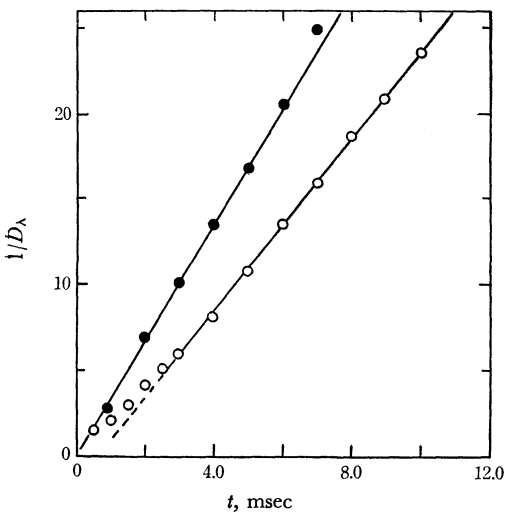

Fig. 10. Second-order decay of the *p*-benzosemiquinone ion.
Dye concn. 7.2 μM
Hydroquinone concn. 5×10^{-4} M. pH 7.4.
Wavelengths: ● 370 nm, ○ 430 nm

These values are in very good agreement with that of the dismutation rate constant of the *p*-benzoquinone ion obtained in the dye-*p*-benzoquinone system. This finding leads to the conclusion that the *p*-benzosemiquinone ion mainly disappears through its own dismutation process in any system examined. Meanwhile, the dye-hydroquinone solution became almost completely transparent at 205 nm, which is within the absorption region of the original dye, immediately after flashing, and then it turned back to become perfectly opaque in 200 μsec. The ground-state dye recovers according to the first-order rate formula. As regards the recovery process of the ground-state dye, such reactions as follows may be supposed:

$$\text{Red} + \text{Red} \longrightarrow \text{D} + \text{Leuco}$$

or:

$$\text{Red} + \text{Q}^- \longrightarrow \text{D} + \text{QH}_2$$

where Q^- and QH_2 are the *p*-benzosemiquinone ion and hydroquinone. If such is the case, the recovery of the ground-state dye should be analyzed according to the second-order rate formula. Thus, this rapid recovery of the ground-state dye is likely to take place directly from an intermediate with a shorter lifetime, an intermediate which is certainly the triplet-state.

Disodium Ethylene Diamine Tetraacetate (EDTA). EDTA has been used as a reducing agent for the photochemical reduction of various classes of dyes.[12] When a deaerated thiopyronine solution containing 5×10^{-3} M EDTA was flashed, more than 50% of the dye was permanently bleached by a single flash.

The completely photobleached solution has a rather diffuse absorption spectrum in the UV region, as is shown in Fig. 11, in contrast to those of methylene blue and thionine.[13]

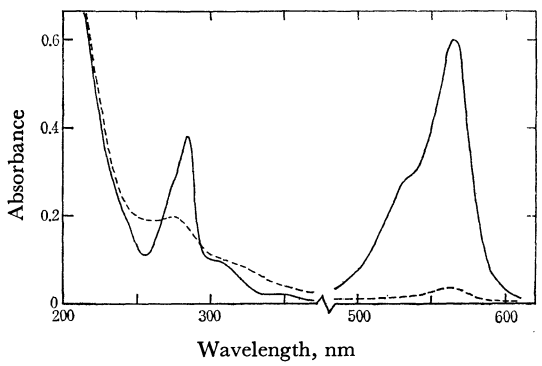

Fig. 11. Absorption spectrum of the photoproduct of thiopyronine containing 5×10^{-3} M EDTA as a reductant.
Dye concn. 8.1 μM
—— before flashing; - - - after flashing (photoproduct)

With the help of light, the photobleached solutions recover their color up to 60% or more of the original

color upon the introduction of air. This shows that the major part of the photoproduct is the leuco dye. However, color recovery does not take place in dark, unlike the case of methylene blue and thionine.[14] When a buffered solution of thiopyronine at pH 7.4 containing 5×10^{-3} M EDTA was flashed, the absorption of the dye disappeared and a transient absorption spectrum with a peak at 426 nm appeared, as is shown in Fig. 12.

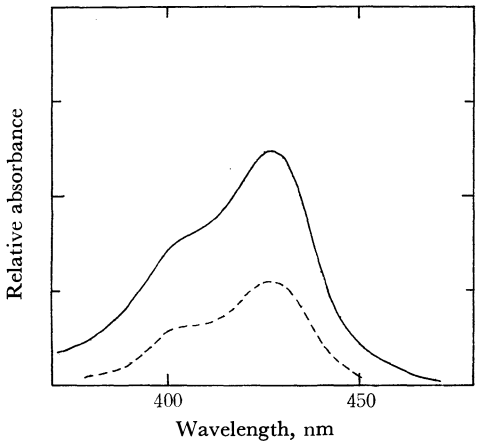

Fig. 12. Transient absorption spectrum of thiopyronine containing 5×10^{-3} M EDTA. pH 7.4.
Dye concn. 8.2 μM
—— 60 μsec; - - - 260 μsec after flashing.

On the other hand, at lower concentrations of EDTA, transient spectra similar to those in the case of the plain aqueous solution and a buffered solution appeared at the initial stage, and then the 426 nm peak increased and the other peaks simultaneously decreased. At 200 μsec after flashing, the 426 nm peak alone survived. The general features of the photobleaching described above and the following kinetic investigations strongly suggest that this intermediate is due to the half-reduced form or the semiquinone of the dye.

The decay of the triplet state of the dye was accelerated by the addition of EDTA, as has been stated above. From the dependence of the decay-rate constant on the EDTA concentration, one can obtain the bimolecular rate constants for the following processes:

$$D^t + EDTA \longrightarrow Red + EDTA_{oxd} \quad k_r$$
$$\searrow D + EDTA \quad k_d.$$

From the slope of the plot of the decay rate constant *vs.* the concentration of EDTA, the quenching constant k_q was obtained:

$$k_q = k_r + k_d = 1.6\times10^7\ M^{-1}sec^{-1}.$$

This value is comparable with that of methylene blue-EDTA, $k_r = k_d = 1.2\times10^7\ M^{-1}\ sec^{-1}$.[15]

15) N. Kosui, K. Uchida and M. Koizumi, *ibid.*, **38**, 1958 (1965).

The decay of the semiquinone, measured at 430 nm, is second order, as is shown in Fig. 13.

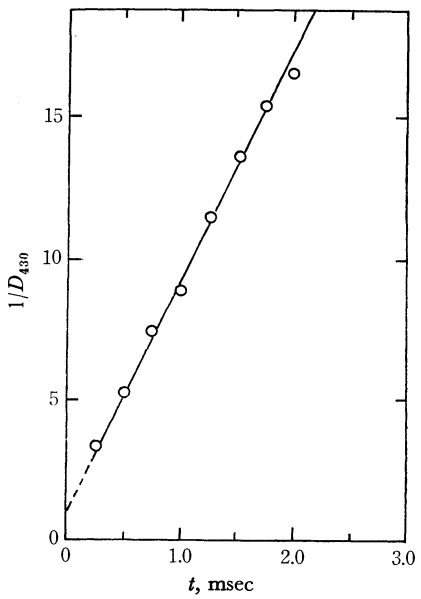

Fig. 13. Second-order decay of the semiquinone of thiopyronine.
Dye concn. 8.0 μM. EDTA concn. 5×10^{-3} M.
pH 7.4
Monitored wavelengths: 430 nm

The slope of the line gives $k/\varepsilon_{430}d$, where k, ε_{430}, and d are the second-order rate constant, the extinction coefficient of the semiquinone at 430 nm, and the optical depth of the reaction cell respectively. It is not easy to determine the absolute value of k since ε_{430} is not certain. However, if it is assumed that the permanent photobleaching, or the production of leuco dye, takes place only through the dismutation process of the semiquinone:

$$Red + Red \longrightarrow D + Leuco,$$

and if no other absorption band overlaps at this wavelength, (this is a reasonable assumption at a high EDTA concentration because it may effectively

consume the triplet-state, a state of which otherwise interferes with the measurement at this wavelength), ε_{430} can be estimated to be 1.0×10^4 M^{-1}cm^{-1} from the amount of the permanent bleaching and the transient increase in the absorbance at 430 nm.

The rate constants for the similar processes of rhodamine B, thionine, and methylene blue are illustrated in Table 2 for the sake of comparison, though the experimental conditions are not alike. The values for thiopyronine and methylene blue are as large as can be expected for a diffusion-controlled process.

TABLE 2. THE SECOND-ORDER RATE CONSTANTS FOR THE DECAY OF SEMIQUINONES OF CATIONIC DYES

Allylthiourea (ATU). ATU has also been used as a reducing agent for the photoreductions of several dyes;[19] however, it is milder in reducing power than EDTA.

Thiopyronine solutions containing ATU were photobleached by steady-light irradiation as well as by flash excitation, but the rate of the bleaching is slower than for EDTA by the factor of ten. For a thiopyronine solution containing 5×10^{-3} M ATU, only about 5% of the original dye was photobleached by a single flash. The absorption spectrum of the photoproduct has no distinct band, as in the case of the EDTA system. After almost complete bleaching with steady illumination, the introduction of air into the reaction cell and the irradiation of UV light recovered about 20% of the original dye, without any shift of the absorption peak at 564 nm. This definite recovery of the original dye confirms that a considerable fraction of the photoproduct is leuco dye.

The transient spectrum of this system, as is shown in Fig. 14, consists of all the characteristic bands of the triplet state (340, 370, and 400 nm), the half-oxidized form (475 nm), and the semiquinone (430 nm) of the dye, which appeared in the plain aqueous solution and the buffered solution.

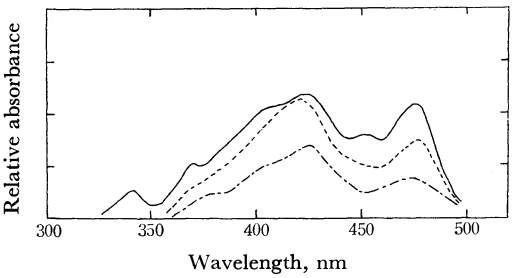

Fig. 14. Transient absorption spectrum of a thiopyronine buffered solution containing 5.0×10^{-3} M ATU. pH 7.6.
Dye concn. 10 μM
—— 45 μsec; - - - 110 μsec; —·— 255 μsec after flashing.

Kinetic investigations were undertaken at 430 nm for Red and at 480—500 nm for Oxd. Red decays according to the second-order rate formula, as is shown in Fig. 15.

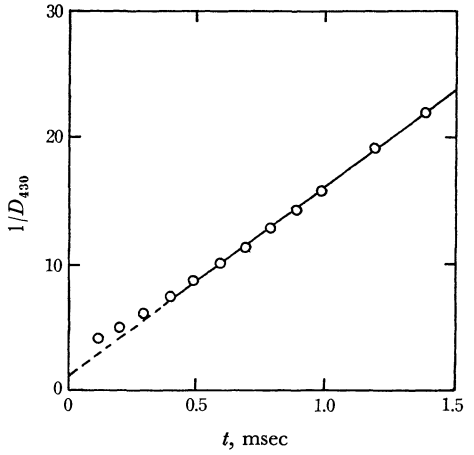

Fig. 15. Second-order decay of semiquinone of the thiopyronine.
Dye concn. 7.2 μM. ATU concn. 5×10^{-3} M.
pH 7.6.
Monitored wavelength: 430 nm

The slope of this line gives 1.5×10^9 M^{-1}sec^{-1} for the second-order rate constant, using the value, $\varepsilon_{430}=1.0\times10^4$ M^{-1}cm^{-1}, estimated above. This rate constant is independent of the concentration of ATU added to the solution.

On the other hand, the half-oxidized form of the dye follows a pseudo first-order decay kinetics, the rate constant of which depends linearly on the concentration of the added ATU. From this relation, one obtains the rate constant for the following reaction:

$$\text{Oxd} + \text{ATU} \longrightarrow$$

to be $(2—5)\times10^6$ M^{-1}sec^{-1}.

Photochemically, ATU is not such a strong reducing agent as EDTA to the triplet-state of the

17) C. G. Hatchard and C. A. Parker, *Trans. Faraday Soc.*, **57**, 1093 (1961).
18) C. A. Parker, *J. Phys. Chem.*, **63**, 26 (1959).
19) M. Pestemer, *Z. Elektrochem.*, **58**, 121 (1954); G. Oster and A. H. Adelman, *J. Am. Chem. Soc.*, **78**, 913 (1956); F. Millich and G. Oster, *ibid.*, **81**, 1357 (1959); K. Kikuchi and M. Koizumi, This Bulletin, **40**, 736 (1967).

dye. Because of this characteristics, the electron transfer between a dye molecule in the triplet-state and another in the ground-state or in the triplet-state predominates over the reaction between a dye molecule in the triplet-state and ATU.

Thus, the formation of the semiquinone and the half-oxidized form of the dye through dye-dye interaction is much more important than the direct attack of ATU on the triplet-state. Accordingly, ATU acts as a reductant mainly in the reaction with the half-oxidized form of the dye:

$$\text{Oxd} + \text{ATU} \longrightarrow \text{D} + \text{ATU}_{\text{oxd}}$$

where ATU_{oxd} is a one electron-oxidized form of ATU. This process takes place in the photoreduction of thiazine dyes, methylene blue and thionine. Koizumi and his co-workers have discussed this mechanism.[20]

If the photoreduction proceeds through this mechanism, the rate formula of the photoreduction by steady-illumination can be expected to be analyzed approximately by the second order with regard to the dye, as Koizumi *et al.* suggested. From this point of view, the steady-light photoreduction of thiopyronine was studied in our laboratory; this relation was confirmed in the case of ATU.

In general, two kinds of reaction

$$\text{D}^t + \text{D or D}^t \longrightarrow$$

and

$$\text{D}^t + \text{Reductant or Oxidant} \longrightarrow$$

compete with each other; the fraction of each path depends both on the reactivity of the added reagent and on its concentration relative to that of the dye.

This has been clearly demonstrated in the steady-light photoreduction of methylene blue reported by Kosui, Uchida, and Koizumi.[15]

The general features of the photochemical reactions of thiopyronine are very much like those of thiazine dyes.

To summarizing the results obtained in the present investigation, the elementary reactions of thiopyronine are as follows:

$$\text{D} + h\nu \longrightarrow \text{D}^*$$

$$\text{D}^* \longrightarrow \text{D} + h\nu_f$$

$$\text{D}^* \longrightarrow \text{D} + \text{heat}$$

$$\text{D}^* \longrightarrow \text{D}^t$$

$$\text{D}^t \longrightarrow \text{D} \qquad k_1 = 2.3_6 \times 10^3\ \text{sec}^{-1} \qquad (1)$$

$$\text{D}^t + \text{D} \longrightarrow 2\text{D} \qquad k_2 \qquad (2)$$

$$\text{D}^t + \text{D}^t \longrightarrow \text{D}^t + \text{D} \quad k_3 \qquad (3)$$

$$\searrow \quad 2\text{D}$$

$$\text{D}^t + \text{D} \longrightarrow \text{Red} + \text{Oxd} \quad k_4 \qquad (4)$$

Lindqvist gave weight to the reversible photochemical redox property of dye in the photosensitizing activity in his extensive investigations of the flash photolysis of xanthene dyes.[4] The efficient photosensitizing power of thiopyronine as well as of methylene blue can be well understood in the light of this photochemical redox reversibility.

By the way, pyronine G, with a structure similar to that of thiopyronine, was studied by the flash method, but no transient absorption appeared under our experimental conditions.

In order to examine the concentration change in the dye in the ground-state, further studies were undertaken by the fluorescence method, which makes it possible to evaluate the amount of the transient bleaching of the dye by measuring the change in fluorescence intensity during flash excitation.[21]

These results showed that the transient bleaching did not take place in the phosphate buffered solution of pyronine G at pH 7.4.

On the other hand, in the case of thiopyronine, it was found that 90% or more of the ground state of the dye was converted to the triplet-state or to intermediate species with long lives during 200 J flash excitation. In the case of rhodamine B, with a structure similar to that of pyronine G, it has been reported that no transient absorption was observed in an aqueous solution.[16]

At any rate, these results are in good agreement with the fact that pyronine G has little photodynamic effect.

The failure to find any intermediates for pyronine G might be due either to their short lifetimes under our experimental conditions, or to the low extinction coefficient of the transient species in the spectral region available. However, this latter seems not to be the case, because our theoretical studies of these photosensitizing dyes predict that they will have very similar electronic structures.[8] Therefore, thiopyronine and pyronine G may be expected to exhibit similar spectroscopic behavior.

An alternative interpretation of this different situation between thiopyronine and pyronine G may be made in terms of the heteroatom effect.

21) A. Kira and S. Kato, *Sci. Rep. Tohoku Univ., Ser. 1*, **158**, 142 (1965).

It is well known that the introduction of a heteroatom into an aromatic system facilitates intersystem crossing.[22]

Nurmukhametov and Gobov have studied the phosphorescence of a series of compounds, *i. e.*, fluorenone, diphenylene oxide, diphenylene sulfide, and carbazole.[23]

They have found that the presence of a nitrogen atom or, more especially, a sulfur atom in an aromatic system appreciably increases the probability of the S*–T intersystem crossing. This was observed as an increase of the phosphorescence yield.

Since the intersystem crossing competes successfully with fluorescence, a decreased fluorescence quantum yield should result. This was confirmed experimentally in the series of compounds mentioned above.[24]

As to pyronine G, there seem no such experimental results. However, comparing the fluorescence quantum yield of pyronine G with that of rhodamine B, a high quantum yield of fluorescence of pyronine G may be anticipated from the structural similarity of these dyes.[25]

On the other hand, the fluorescence quantum yield, Φ_f, and the quantum yield of the triplet-state production, Φ_{S^*-T}, of thiopyronine were determined experimentally in our laboratory to be $\Phi_f = 0.20$ and $\Phi_{S^*-T} = 0.67$.[26]

Thus, the difference in photochemical properties between thiopyronine and pyronine G can be well understood in terms of the difference in the quantum yield of the triplet-state production of the dyes.

Conclusion

The flash excitation of a deaerated buffered solution of thiopyronine without any substrate leads to three transient intermediates: the triplet-state (D^t), the half-oxidized form (Oxd), and the half-reduced or the semiquinone (Red) of the dye.

Red and Oxd were generated simultaneously through the electron-transfer reactions between D^t and D^t and between D^t and D.

It has been established that the high efficiency of thiopyronine in the photodynamic effect is due to the high quantum yield of the triplet-state production and to the high photochemical redox reversibility of the dye.

Thanks are due to Professor H. Tsubomura of the Faculty of Engineering Science, Osaka University, for his permission to use the microphotodensitometer. The authors wish also to thank the Ministry of Education for its Scientific Research Grant-in-Aid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 35—40 (1969)

Heat of Mixing for Binary Mixtures: Pyridine Derivatives+Benzene, and +Cyclohexane Systems

Takeshi MURAKAMI, Sachio MURAKAMI and Ryoichi FUJISHIRO

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received March 19, 1968)

The heat of mixing was measured for binary mixtures of pyridine derivatives (α-picoline, β-picoline, γ-picoline, and 2,6-lutidine) with benzene or cyclohexane at 25.0±0.01°C, and for a binary mixture of pyridine with benzene, or cyclohexane, at 30.0±0.01°C. The small values of the heat of mixing for pyridine derivatives-a benzene system were interpreted as an indication of strong specific interactions between pyridine derivatives and benzene. By treating the results in the manner described in a previous paper (*Bull. Chem. Soc. Japan*, **39**, 720 (1966)), the specific interaction energies of pyridine derivatives with benzene were estimated. The strengths of the molecular interaction energy were in the order: γ-picoline>pyridine>β-picoline>α-picoline> 2,6-lutidine; the order was discussed in terms of the molecular complexes.

Recently extensive studies of the formation of molecular compounds have been made by various techiques, but only a little information has been obtained by direct calorimetry measurements, which

seem to give the most reliable data on molecular interaction energy. In a previous paper,[1] we measured the heat of mixing for binary solutions and estimated the interaction energies of donor-accepter type complexes. Morcom *et al.* have measured the heat of mixing of pyridine derivatives+the carbon tetrachloride system and have discussed the specific interaction in terms of a possible donor-accepter interaction. In our experiment, we measured the heat of mixing for binary solutions of pyridine derivatives [pyridine (py), α-picoline (α-pi), β-picoline (β-pi), γ-picoline (γ-pi), and 2,6-lutidine (2,6-lut)]with benzene or cyclohexane. The small values of the heat of mixing for pyridine derivatives with benzene indicate the estimate of a specific interaction similar to that between pyridine derivatives and carbon tetrachloride. We will estimate the specific molecular energy between pyridine derivatives and benzene in a cyclohexane solution by using the enthalpy cycle, and will discuss the molecular interaction in terms of various types of molecular complexes.

Experimental

The calorimeter for measuring the heat of mixing was described in the previous paper,[1] but we made an improvement in the mixing cell. The mixing cell was made of glass instead of stainless steel, and its shape was similar to that used by Larkin and McGlashan[2] and by Amaya[3]. The experimental procedure was the same as before.

The technique of thermal compensation[1] was used for almost all the experiments. The pyridine was purified by a method described in the literature.[4] The methyl pyridines were supplied by the Tanabe Pharmaceutical Co., Ltd. All these samples except β-picoline were fractionally distilled over P_2O_5 and then under reduced pressure in a nitrogen atmosphere before use. The β-picoline was used without further purification, since no impurity was detected by gas chromatography.

The cyclohexane was treated with a concentrated sulfuric-nitric acid mixture, and then shaken with a

sodium hydroxide aqueous solution and with distilled water. Then it was twice passed through about 1 m silica gel column. The benzene was shaken with concentrated sulfuric acid, a sodium hydroxide aqeuous solution, and distilled water. The cyclohexane and benzene were shaken with mercury and distilled over metal sodium respectively. Gas-chromatographic analysis showed only a single peak for each sample.

Results and Discussion

The results obtained for eleven systems are given in Tables 1-1—1-11, where x_i and n_i ($i=1$ or 2) are the mole fraction and the number of the mole of the i component, respectively. Q is the quantity of heat produced during the mixing process, while ΔH_{x_i} and $\Delta H^M_{x_i}$ are the heats of mixing per mole of the 1 component and per mole of the mixture

respectively. For the mixtures with lower mole fractions, the heat of mixing was measured by diluting a solution, the heat of mixing of which was known from a previous run, with the other component. In eleven systems, for pyridine+cyclohexane or +benzene, and benzene+cyclohexane systems, the heat of mixing was measured at 30.0°C, while for the other systems it was measured at 25.0°C. The heat of mixing for benzene with cyclohexane agrees with that of the literature.[5] Our results for the pyridine+benzene system were endothermic over the whole concentration range, though they were almost zero; Amaya[3,6] found that this system at 25.0°C changed from endothermic to exothermic in the neighborhood of an equimolar composition, though the absolute values will be very small. The heat of mixing at 30°C, $\Delta H^{M}_{x_i}(30°C)$, is related to that at 25°C, $\Delta H^{M}_{x_i}(25°C)$, as follows: $\Delta H^{M}_{x_i}(30°C) = \Delta H^{M}_{x_i}(25°C) + (30-25)C^{E}_{p}$, where C^{E}_{p} is the excess heat capacity. According to Morcom and Travers,[7] C^{E}_{p} for the pyridine-benzene system is positive. Therefore, our data seem to be consistent with those obtained by Amaya.

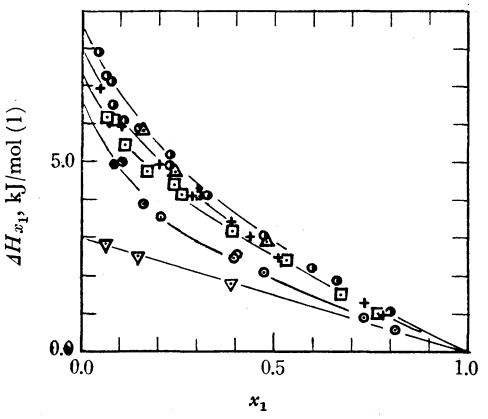

Fig. 1. Heat of mixing for pyridine derivative with cyclohexane.
◐ pyridine, ⊡ α-picoline, + β-picoline, △ γ-picoline, ⊙ 2,6-lutidine, and ▽ benzene with cyclohexane

The experimental data for ΔH_{x_i} have been plotted against the mole fraction in Figs. 1 and 2. By smoothing and extrapolating the curves to an infinite dilution for each system, we can obtain the heat of mixing per mole of the pyridine derivatives at an infinite dilution ($\lim_{x_i \to 0} \Delta H_{x_i}$). These values are given in Table 2.

The values of $\lim_{x_i \to 0} \Delta H_{x_i}$ correspond to the energy changes from the pure pyridine derivatives state to that in which each pyridine derivative molecule is surrounded by a large amount of the solvent medium. As may be seen in Table 2, the values of $\lim_{x_i \to 0} \Delta H_{x_i}$ in benzene are cosiderably smaller than the corresponding values in cyclohexane. This may suggest that a pyridine derivative molecule exists more stably in a benzene solution, by making a specific interaction or by forming a complex with a benzene molecule, than in a cyclohexane solution. The possibility of such a complex formation is supported by the NMR[8] measurements for the pyridine-benzene system. Further, according to Ott *et al.*,[9] the positive excess heat capacity in the binary mixture shows the existence of a specific interaction, or the formation of a complex between the solvent and solute molecules, and the pyridine-benzene solution is a system in which the excess heat capacity is positive.

In order to estimate the interaction energy between a pyridine derivative and benzene molecules, we carried out a treatment described in the

previous paper.[1] In the enthalpy cycle shown in Fig. 3, ΔH_a is the energy of breaking up all the interaction between pure pyridine deriatives by adding a large quantity of cyclohexane; ΔH_b is equal to the value of $\lim_{x_i \to 0} \Delta H_{x_i}$ for the benzene-cyclohexane system, and ΔH_c is the energy change produced by the dilution of pure pyridine derivative with x mol of benzene, where $x \gg 1$: these enthalpy changes were also measured in the present work. ΔH_d consists of two parts; one is equal to $(x+1) \cdot \Delta H_b$, while the other is due to the enthalpy change from the state in which pyridine-benzene associated complexes are surrounded by benzene to that in which they are surrounded by cyclohexane. The latter part of ΔH_d may be put at zero, or even neglected because the two media have almost equal dielectric constants and the dipole stabilization energies of a complex in the two media are considered to be nearly equal.[10]

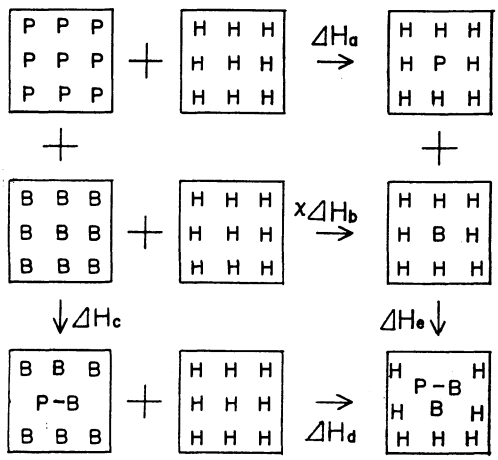

Fig. 3. Enthalpy cycle.[1]

The energies of the specific interaction between a pyridine derivative and benzene in the cyclohexane solution thus obtained from the enthalpy cycle:

$$\Delta H_e = \Delta H_c + \Delta H_d - \Delta H_a - \Delta H_b$$

are tablated in Table 3. Morcom *et al.*[7] measured the heats of mixing for the binary mixtures of carbon tetrachloride with pyridine derivatives; they found that there exists a specific interaction between carbon tetrahcloride and a pyridine derivative. Using their data,[7,11] and following the method of treatment described above, we calculated the specific interaction energies between pyridine derivatives and cabon tetrachloride; they are listed in Table 3. The strength of the specific interaction between

β-Picoline	−5.1	
γ-Picoline	−5.4	−8.3
2,6-Lutidine	−3.2	−7.2

pyridine derivatives and benzene in cyclohexane is in the order of; γ-pi>py>β-pi>α-pi>2,6-lut, while the specific interactions between pyridine derivatives and carbon tetrachloride in cyclohexane solutions are in the order: γ-pi>α-pi≃py≃2,6-lut.

A pyridine molecule has nonbonding lone pair electrons and π-electrons; these n- and π-electrons may be expected to play an important role in complex formation with other molecules. Therefore, the complex formation between pyridine derivatives and benzene may be considered to take place between n- or π-electrons in pyridine derivatives and between π-electrons in benzene. First, we will take up the n–π complex formation. The strength of the complex formation depends upon the ease with which n-electron can be released, and is measured by the pK_a value.[12] According to the pK_a value in Table 4, the strengths of the complexes

Table 4. The values of pK_a[12] and heat of reaction[13] for pyridine derivative with BF_3, ½ B_2H_6, and CH_3SO_3H

	pK_a	BF_3 kcal·mol^{-1}	½B_2H_6 kcal·mol^{-1}	CH_3SO_3H kcal·mol^{-1}

2,6-Lutidine	5.14	−25.0	−17.9	−17.1

will be in the following order: 2,6-lut>α-pi>γ-pi>β-pi>py. In fact, the measurement[13] of the heats of reaction of pyridine derivatives with CH_3SO_3H shows that the absolute values of the heat of reaction increase with the pK_a value of pyridines, in accordance with the order mentioned above. However, our data obtained for the specific interaction of pyridine derivatives with benzene result in the opposite order except for γ-picoline. This inversion is not particularly surprising, however, since it has been known that

because of the steric hindrance of the methyl group of 2,6-lutidine or α-picoline, the heat of the reaction[10] of the pyridine derivative with BF_3, or $(1/2)B_2H_6$ is in the order of: py$>\alpha$-pi$>$2,6-lut.

Thus, it seems that the methyl group of 2,6-lutidine or α-picoline offers steric hindrance to the approach of the benzene molecule; this results in a corresponding decrease in the strength of the molecular interaction. We can qualitatively explain our result in terms of the n–π interaction. On the other hand, in the pyridine derivative-carbon tetrachloride systems we can find only a small change in the strength of the molecular interaction, as shown in Table 3. This may be illustrated as follows. Provided that the carbon tetrachloride molecule interacts with the nitrogen of the pyridine derivative, we know that the carbon tetrachloride molecule is not sterically interfered with so much as the benzene molecule by the methyl group of the pyridine derivative. The strengths of the interaction of pyridine, α-picoline, and 2,6-lutidine with carbon tetrachloride are nearly equal to each other as a result of the cancellation of the inductive effect of the electron-releasing by the methyl group and the effect of the steric hindrance.

On the other hand, the molecular interaction of the π-electrons of the pyridine derivative with the π-electron of the benzene molecule can be shown to be highly plausible. Comparing the ionization potential, or the electron affinity of the pyridine derivatives with that of benzene, it seems reasonable to regard the benzene molecule as a donor. In this case, it seems that the strengths of the interaction are in the order of: py$>\beta$-pi$>$ α-pi$>\gamma$-pi$>$2,6-lut. Our results show the same trend except for γ-pi.

Then, it seems reasonable to explain the specific interaction of pyridine derivatives with benzene in terms of a n–π interaction. On the basis of a thermochemical study alone, however, it can not be decided whether the specific interaction of pyridine derivatives with benzene is an n–π or π–π interaction.

Anomalous Magnetic Properties of Stable Crystalline Phenoxyl Radicals

Kazuo MUKAI*1

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received April 13, 1968)

The results of static magnetic susceptibility measurements in the 1.8—300°K temperature range are reported on powder samples of the stable aromatic free radicals: 2,6-di-*t*-butyl-4(3,5-di-*t*-butyl-4-oxocyclohexa-2,5-dienylidene methyl) phenoxyl (Galvinoxyl) and 2,6-di-*t*-butyl-4(3,5-di-*t*-butyl-4-oxocyclohexa-2,5-dienylidene amino) phenoxyl (BIP) radicals. The susceptibility of Galvinoxyl follows the Curie-Weiss law above $T_c=81\pm1$°K, depending on the sample, with a Weiss constant of 11 ± 3°K. However, at $T_c=81$°K, χ_p rapidly decreases, and below 66°K the susceptibility again increases, with different spin concentrations for independently-prepared samples as the temperature is lowered. A maximum at 81°K was also found by the EPR measurements; the anomaly of the susceptibility at this temperature is probably due to a first-order phase transition induced magnetically, accompanying the pairing of magnetic spins, judging from the results of differential thermal analysis and the magnetic susceptibility measurements. On the other hand, the magnetic susceptibility of the BIP radical exhibits a broad maximum at 54 ± 2°K. This susceptibility can be explained approximately using a model which consists of a singlet ground state and a triplet state lying slightly above the ground state.

2,6-Di-*t*-butyl-4-R-substituted-phenols produce the corresponding phenoxyl radicals upon oxidation with lead peroxide or, preferably, with an alkaline solution of potassium ferricyanide in various organic solvents. The magnetic properties of these phenoxyls in solution have been studied by a number of investigators with the aid of the electron paramagnetic resonance (EPR) spectra.[1-3]

Solvent-free solids of the phenoxyls produced with such oxidations were studied by Müller *et al.*

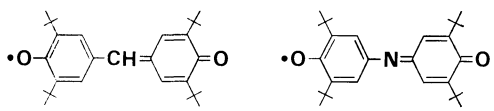
at room temperature[4,5] and, in some cases, at the temperature of liquid nitrogen[6]; they ascertained the absolute paramagnetic contribution to the susceptibility by using Pascal's constants to estimate the diamagnetic correction, χ_d, thus estimating the concentration of the radicals. However, it has not been clear whether or not the observed susceptibility generally follows the Curie-Weiss law.

In a previous paper[7] we have reported an anomaly in the magnetic susceptibility of the Galvinoxyl radical at 82.5°K from the results of the susceptibility measurements between 63°K and 289°K, and have suggested that this radical may have similarities with the well-known anomaly in the magnetic susceptibility of Wurster's blue perchlorate (WB) at 186°K,[8-11] which is explained by the orthorhombic-monoclinic phase transition in which Wurster's blue cations pair up to form dimers with ground singlet states and excited triplet states.[12] Recently, another explanation has been proposed by G. T. Pott *et al.* for the mechanism of the above transition.[13]

In the present paper, first, in order to obtain further information about the transition of Galvinoxyl and the general nature of these neutral radical solids, we have measured the temperature dependence of the magnetic susceptibilities of the solid radicals of a similar molecular structure, including 2,6-di-*t*-butyl-4(3,5-di-*t*-butyl-4-oxocyclohexa-2,5-dienylidene methyl) phenoxyl (Galvinoxyl) and 2,6-di-*t*-butyl-4(3,5-di-*t*-butyl-4-oxocyclohexa-2,5-dienylidene amino) phenoxyl (Bisindophenoxyl; BIP) radical, between 1.8°K and 300°K; these radicals are known to be thermally stable and to be inert to oxygen. Secondly, the measurements of the electron paramagnetic resonance of Galvinoxyl and the differential thermal analyses of the phenoxyl radical and the corresponding phenol were undertaken in order to investigate the properties of the transition.



Galvinoxyl BIP

† : tBu

Extensive work, has been performed on other free radical solids,[14-17] especially tetracyanoquinodimethane (TCNQ) salts, in which the electrons interact to form singlet-triplet pairs. The present evidence indicates that such pairing is also present in the BIP radical hindered by tertiary butyl groups, but in the case of Galvinoxyl the susceptibility below the transition point can not be explained by the hypothesis of a simple pairing such as was observed in Wurster's blue perchlorate.

Experimental

Preparation of Specimens. Galvinoxyl, mp 151.5—153.0°C, was prepared from 2,6-di-*t*-butylphenol according to the method of Kharash and Joshi[18] or Coppinger.[19] After condensation with formaldehyde, the product was oxidized with lead peroxide in ether. A very dark blue crystalline compound was isolated from the ethereal solution.

The BIP radical, mp 155°C, was synthesized following the method of Coppinger[20] and then recrystallized from isooctane under nitrogen gas in a freezer. This melting point is higher than that (132—133°C) of the corresponding phenol. The samples were stored in the dark at a cool ambient temperature under a vacuum.

Measurements. The susceptibility measurements were carried out in the continuous temperature range between 1.8°K and 300°K using a magnetic torsion balance on powder samples of about 100 mg in a heterogeneous magnetic field up to about 10 koe. The details of the apparatus were described previously.[21] After loading the samples in an open quartz bucket into the apparatus, the sample chamber was evacuated to about 10^{-5} mmHg and a small amount of helium was admitted to the apparatus to act as a heat-transfer gas. The temperature of the sample was determined by a AuCo-Chromel thermocouple for the higher temperatures and by a carbon resistance thermometer for the low temperatures, with a supplement of Mn-tutton salt.

The data have been corrected for diamagnetism using the Pascal's constants.[22] The diamagnetic contribution to Galvinoxyl was calculated to be $-276\times$

10^{-6} emu/mol, a value which agrees well with the measured value of -265×10^{-6} emu/mol for the corresponding phenol. The diamagnetic correction for BIP was also obtained from the Pascal's constants and/or from the measured values for the corresponding phenol. The absolute susceptibilities were determined using Mn-tutton salt or Mohr's salt as standards. The relative data were estimated to be reliable to within about ±3% over the entire temperature range, while the absolute susceptibilities were estimated to be correct to within ±5%.

All the EPR measurements were taken with a JEOL 3BX spectrometer, with a 100-kc-field modulation and equipped with a field dial and a variable temperature-control unit. Highly-diluted crystals such as Mn^{2+} in CdS were used as standards. The first derivative of the absorption was observed, and the relative magnetic susceptibility was taken as proportional to the product of the height times the square of the peak-to-peak linewidth of the first derivative.

Results and Discussion

Galvinoxyl. The magnetic susceptibilities obtained for three independently-prepared Galvinoxyl radicals (denoted as Sample Nos. 1, 2 and 3) are shown in Fig. 1 as a function of the temperature. These have been corrected for the diamagnetic contribution of $\chi_{dia}=-276\times10^{-6}$ emu/mol calculated by the Pascal's method. This value agrees well with the measured value of $\chi_{dia}=-265\times10^{-6}$ emu/mol for the corresponding phenol. When the temperature of the radical sample is lowered from room temperature, χ_p increases following the Curie-Weiss law, $\chi_p=C/(T-\theta)$, with the same C_H and θ_H values within the range of experimental errors, reaching a maximum at about $T_c=81$°K, depending on the sample. After passing through the maximum, within about three degrees χ_p decreases rapidly by about 80 percent of its maximum value, and afterward falls off gradually till 66°K. However, below 66°K the susceptibilities increase again as the temperature is lowered. The radical spins in the low-temperature region (5—50°K) obey only the Curie-Weiss law, as is apparent from the $1/\chi_p$-T curve shown in Fig. 2. On the other hand, the spin concentrations differ individually for each sample. The different values of C_L and θ_L obtained for three samples are listed in Table 1, where the subscripts, L and H, refer to the low- and high-temperature regions respectively. These values of C_L are from about three to ten times smaller than that in the high-temperature section (83—300°K). At still lower temperatures (1.8—5°K) the susceptibility again deviates from the Curie-Weiss law. Further, two independent runs about the sample 3 were examined, resulting in a considerable accordance (denotd as 3′ in Fig. 2).

EPR measurements were done with a polycrystalline Galvinoxyl radical in the temperature range between room temperature and the temperature of liquid nitrogen, using a microwave

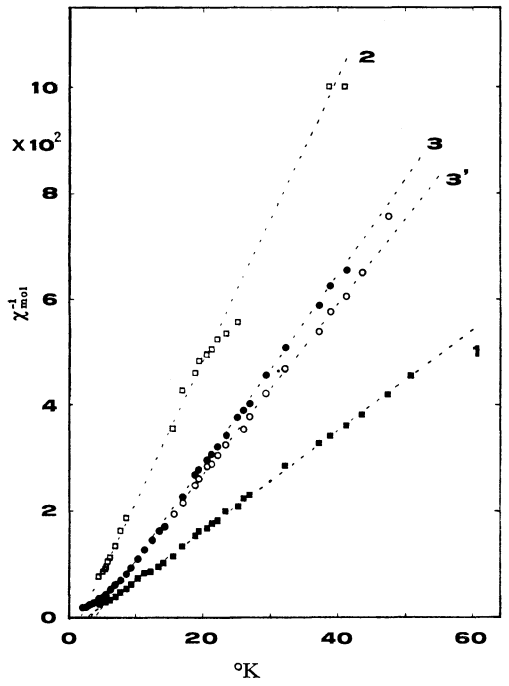

Fig. 2. Inverse molar susceptibilities of the Galvinoxyl radicals *versus* temperature (1.8—50°K). Sample numbers 1, 2, 3 and 3′ are denoted in the figure as ■, □, ● and ○, respectively.

frequency of about 9300 Mc/sec, in order to ascertain the anomaly in the magnetic susceptibility. The paramagnetic absorption spectrum of the Galvinoxyl exhibits one asymmetric line, with a line width of about 5 gauss; this can usually be attributed to the presence of an anisotropic g-value. The line-width is temperature-independent within the range of experimental error from 77°K to room temperature. Since a transition has been found by measuring the static magnetic susceptibility, the absorption was carefully examined above and below $T_c=81$°K. However, no appreciable change in the position and shape of the absorption line could be found in this temperature range. Since the line-width of the magnetic-resonance absorption curve of this radical is approximately constant, the height of the derivative is proportional to the susceptibility. This relative magnetic susceptibility. I_{EPR}, of Galvinoxyl as a function of the temperature is shown in Fig. 3; the maximum of the static susceptibility at 81°K was also found by measuring the electron paramagnetic resonance. The value of the Curie-Weiss constant obtained from the $1/I_{EPR}$-T curve, shown in Fig. 3, $\theta=1\pm5$°K, shows a qualitative agreement with the value, $\theta=11\pm3$°K, obtained from the static magnetic measurements.

If the sudden decrease in magnetic susceptibility is due to the first-order phase transition, the maximum should be found by differential thermal analysis (DTA). In fact, the DTA curve of powdered Galvinoxyl shows a peak around 82°K. On the other hand, the DTA for the corresponding phenol does not show any anomaly at the transition

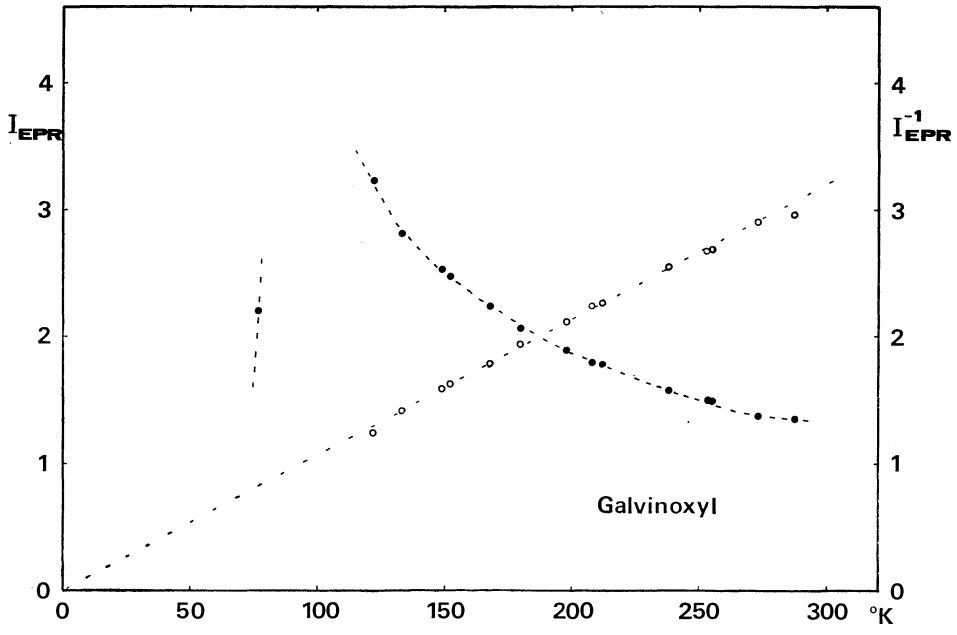

Fig. 3. (a) Relative intensity (full circle, ●) and (b) relative inverse intensity(open circle, ○) of the EPR absorption of the Galvinoxyl radical.

temperature.[23] The high-temperature structure of the Galvinoxyl radical can be understood simply as a molecular crystal composed of unpaired neutral radicals, showing a spin concentration of about 106% as $S=1/2$, following the Curie-Weiss law. Therefore, it is highly probable that the transition found by measuring magnetic susceptibility and the electron paramagnetic resonance absorption for Galvinoxyl is due to the first-order phase transition induced magnetically, accompanied by a pairing of the magnetic spins. This magnetically-induced phase transition of Galvinoxyl differs from that of WB, which can be explained remarkably well in terms of an elementary theory of non-interacting triplet excitons, judging from the results of the pressure dependence of the exchange-narrowed magnetic resonance.[24]

The anomalies in magnetic susceptibility and DTA observed for the Galvinoxyl radical may be characteristic of the hindered phenoxyl radical solids. For example, the rotation of the tertiary butyl group or the intermolecular bonding between oxygen atoms may be responsible for the anomaly. Thus, we have measured the magnetic susceptibility of the BIP radical between 1.8°K and 300°K, for this radical has a molecular structure similar to that of the Galvinoxyl radical. The magnetic susceptibility of the BIP radical, the –CH= group situated at the center of the Galvinoxyl replaced with the –N= group, shows a broad maximum around 54°K, as will be described below. This experimental fact shows that the transition in Galvinoxyl is presumably related to the –CH= group.

Since the anomaly in Galvinoxyl is thought to be the transition accompanied by a pairing of the magnetic spins at the position of the –CH= group, and since the magnetic susceptibilities in the low-temperature region (5—50°K) obey the Curie-Weiss law, with different spin concentrations for the three samples, the low-temperature susceptibilities are probably due to the residual unpaired Galvinoxyl radicals with a spin of 1/2, radicals which will be randomly located in the lattice. Their concentrations, which can be calculated from the C_L values in Table 1, have been found to vary from about 10 to 30 mol%. This explanation can be supported by assuming that the magnetic spins are mostly clustered in groups of two in the crystals and that the exchange interactions between radical spins are large.

Another possible explanation is that the increase in susceptibility at low temperatures may be caused by the linear Ising rings, consisting of odd numbers of the radical molecules. When the phase transition induced by a coupling of magnetic spins leaves an odd number of coupled electrons in a segment, one electron spin will remain unpaired as the spins couple antiferromagnetically at a low temperature.

On the other hand, the values of θ in Table 1 are positive in both the high- and low-temperature regions of Galvinoxyl. This is unlike the negative values of θ obtained from most other organic radical solids, including several phenoxyl radicals.[25] This fact shows a possibility of weak ferromagnetism. The question about the observed ferromagnetic Weiss constants will be discussed elsewhere.

Bisindophenoxyl. The results of the susceptibility measurements on BIP are presented in Fig. 4, where the data have been corrected for a calculated diamagnetism of -268×10^{-6} emu/mol. This diamagnetism value also accords well with the measured value of $\chi_{dia}=-258\times10^{-6}$ emu/mol for the corresponding phenol.

The data were corrected for the presence of paramagnetic impurities by using the low-temperature measurements to determine their concentrations. In the region from 1.8—10.1°K, the Curie-Weiss law was observed corresponding to a spin concentration of 3.6% and a Weiss constant of -1.6 ± 0.1°K. When this low-temperature impurity curve is extrapolated to higher temperatures and subtracted from the experimental curve observed there, the corrected curve shown in Fig. 5 is obtained. The experimental curve has a general appearance very similar to that observed for such crystalline organic radicals as TCNQ salts,[15] picryl amino carbazyl (PAC),[16] and biphenyl-potassium salts.[17] In the case of the BIP radical. the unpaired electrons on the

23) Motivated with these findings, we now proceed to measure the low temperature heat capacities of Galvinoxyl and the phenol from 13 to 300°K. There is a sharp rise in the heat capacity of Galvinoxyl at 81.5°K. Details will be published in this Bulletin by S. Seki, H. Suga, A. Kosaki, Y. Deguchi and the author.

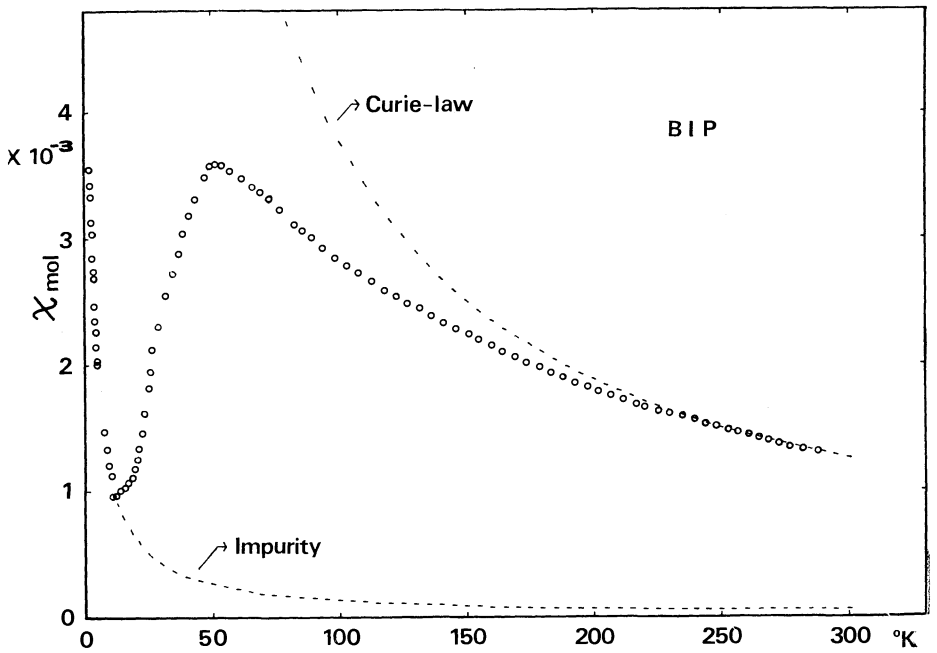

Fig. 4. Molar susceptibility of the BIP radical *versus* temperature (1.8—300°K). The "impurity curve" is an extrapolation of the low-temperature Curie-Weiss data.

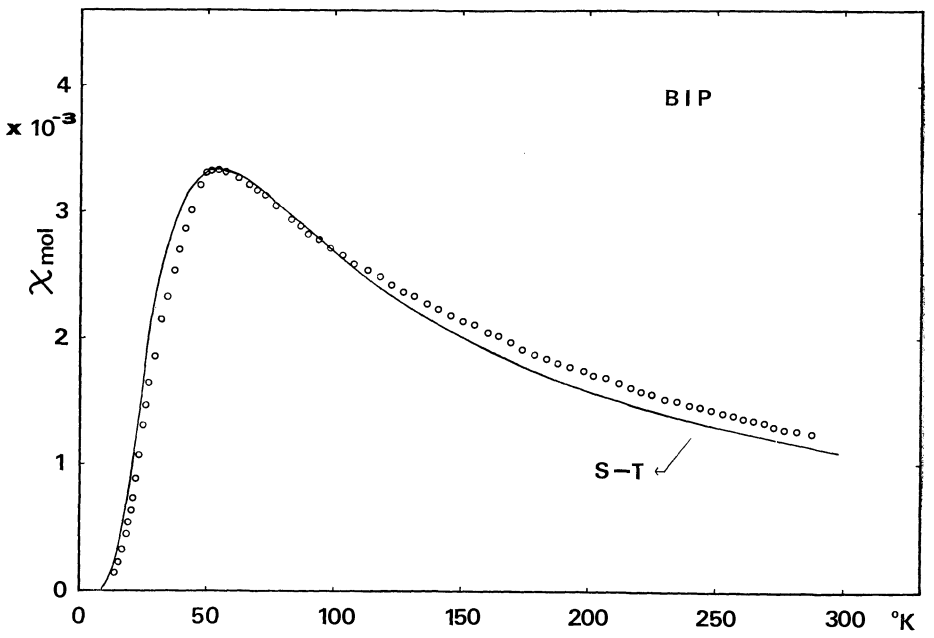

Fig. 5. Subtracted molar susceptibility of the BIP radical *versus* temperature (1.8—300°K). The solid curve is theoretical fits as explained in the text.

BIP molecules also appear to be paired up by an exchange interaction in quasimolecular states. The paramagnetic contribution to the susceptibility of BIP can be fitted approximately to the expression:

$$\chi_p = \frac{2Ng^2\beta^2}{kT} \cdot \frac{1}{3+e^{\delta/kT}} \qquad (1)$$

which corresponds to an assembly of N quasi-molecules with a singlet ground state and a triplet state lying by an energy, δ, above the ground state. If the temperature at which the susceptibility shows a maximum is defined as T_{max}, one can determine the singlet-triplet separation (δ) by using the relation $\delta = 1.61kT_{max}$. The theoreti-

cal curves require multiplication by a constant p to match the experimental data. Thus, with $\delta/k=87$ and $p=0.964$, the theoretical curves can be fitted to the experimental data, assuming that N is equal to one half of the number of BIP radicals and that $g=2.00$. The agreement between theory and experiment in the case of BIP is enough to conclude that the BIP radical forms radical dimers. The singlet-triplet separation can be estimated to be $\delta=60.5\ cm^{-1}$, using the value for $T_{max}(54\pm2°K)$ determined from the experiment.

In order to obtain further information about the magnetic property of the above radical, EPR measurements were made. The EPR spectrum of BIP shows one sharp, asymmetric line, with a line width of 3 gauss, which is temperature-independent between 77°K and room temperature. The expected zero-field splittings for the BIP entities in the triplet states are not observed over the accessible temperature range, although the magnetic susceptibility of BIP follows Eq. (1). This is probably because the zero-field splittings for BIP are collapsed into a single sharp line by the exchange-narrowing effect arising from the high concentration of triplet-state entities in this temperature range.

The crystalline organic free radicals, such as Wurster's blue perchlorate (WB),[12] TCNQ salts,[14,15] and PAC,[16] in which the electrons interact to form singlet-triplet pairs, are thought to be plate-like molecules and to be stacked face-to-face to form alternating chains. In the case of BIP, each phenyl ring (π-ring) being masked by the tertiary butyl groups, the oxygen atoms in BIP may play an important role in the above pairing. However, we could not observe any broad maxima for the other hindered phenoxyl radical solids.[25] Thus, the present evidence indicates that no such pairing is present in hinderd phenoxyl radicals.

EPR measurements of the photodissociation-products of tetraphenyl-hydrazine in a rigid solution at 77°K have indicated that the principal product of this dissociation is the dimer of the diphenyl amino (DPA) radical; this has been established by observing the half-field signal and the computer simulation of the EPR spectra.[26] It was proposed that, in the DPA radical dimer, a configuration of minimal repulsion, that is, with the planes each containing two nitrogens and the axes of the phenyl rings at right angles to each other, might be favored, particularly at low temperatures. The BIP radical dimer may have a configuration similar to that of the diphenyl amino radical dimer. However, until the crystal structure analyses are worked out in sufficient detail to give the exact relative positions of the magnetic molecules, they are of dubious value for our understanding of the exchange interactions in these compounds.

On the other hand, the theoretical value of the susceptibility at T_{max} exhibits a good agreement with the experimental value, as is shown in Fig. 5. However, the experimental susceptibility for BIP was observed to fall a little more rapidly than the theoretical susceptibility at temperatures below T_{max}, while above T_{max} the reverse is preferably true. It is well known that the exchange interaction, J, is strongly dependent on the intermolecular distance, and that the physical systems of interest are those in which the molecular entities are really supermolecules, that is, aggregates of weakly-bound molecules. Therefore, the exchange interaction between the BIP radicals, $|J|$ $(=\delta/2)$, may show temperature-dependence. In fact, the values for $|J|$ calculated from the magnitude of the susceptibility at 20, 30, 40, 54, 72.6, 98.5, 127, 160, 202, 240, and 288°K were 33.2, 32.2, 31.9, 30.2, 30.4, 30.0, 25.4, 18.0, 11.1, 4.1, and 1.0 cm^{-1} respectively.

Such deviations from normal behavior have also been found by, for example, magnetic susceptibility measurements[15] or the anomalous exchange-narrowing results in the EPR spectra[27] of some TCNQ salts. Chesnut[28] has suggested that the presence of an attractive interaction between the excitons may be responsible for the experimentally-observed decreases in J with the temperature. However, a self consistent-field treatment by Soos[29] of a linear antiferromagnetic lattice of any degree of alternation also predicts a decrease in the energy gap, δ, with an increase in the temperature. In addition, other explanations,[30,31] opposite to the model of interacting triplet excitons, have been proposed. Consequently, better theoretical and experimental studies will be required before the temperature dependence of the exchange interaction on the BIP radical can be fully interpreted.

This study was largely carried out under the guidance of Professor Hideo Takaki and Professor Yasuo Deguchi. The author is also indebted to Drs. Mamoru Mekata and Hiroaki Nishiguchi for their helpful discussions. Moreover, he is greatly indebted to Professor Syuzo Seki, Professor Hiroshi Suga, and Mr. Akio Kosaki of Osaka University for the differential thermal analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 47—52 (1969)

Molecular Orbital Treatment of Nitric Oxide Radicals. I. Electronic Structure and Spectrum of the H_2NO Radical

Osamu KIKUCHI

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo

(Received April 16, 1968)

A theoretical treatment of the H_2NO radical is presented. In the calculation, the approximate SCF method of Longuet-Higgins and Pople for open-shell molecules is applied to the valence electron system, the CNDO/2 approximation is adopted, and the molecular excited states are approximated by linear combinations of some doublet Slater determinants constructed by means of the SCF MO for the ground state. The results thus obtained for the electronic structure of the H_2NO radical are discussed. The calculated spectrum for the H_2NO radical shows that the longest wavelength band has the $n\rightarrow\pi^*$ character, and the $\pi\rightarrow\pi^*$ transition energy is smaller than that for the $n\rightarrow\sigma^*$ transition. The $\pi\rightarrow\pi^*$ transition energy, 5.77 eV, calculated by the method in which only the π-electrons were explicitly considered, indicated that the $\pi\rightarrow\pi^*$ band falls into the area near 240 mμ. From the calculated results for the H_2NO radical and the solvent effect on the absorption bands of aliphatic nitric oxide radicals, two bands, at 450 mμ, and 240 mμ, characteristic of the latter radicals have been assigned to the $n\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ transitions respectively.

Nitric oxide radicals are among the most typical organic radicals and have been widely investigated by maens of the ESR method.[1,2] Briere, Lemaire, and Rassat have studied the electronic structures of various stable nitric oxide radicals by the IR, UV, and ESR methods.[2] They have synthesized some aliphatic nitric oxide radicals and measured their electronic absorption spectra and ESR spectra; they found that two electronic absorption bands appear, at 450 mμ and 240 mμ, and that the nitrogen hyperfine splitting constant and the g value are 15—16 gauss and 2.0055 respectively. Since, in these nitric oxide radicals, an odd electron is almost completely localized on the $2p\pi$ orbitals of nitrogen and oxygen, the above characteristic properties can be expected to be understood on the basis of the electronic structure of the N-O group.

In theoretical treatment attempting to determine the electronic structure of open-shell systems such as aliphatic nitric oxide radicals, it is necessary to treat not only π-electrons, but also σ-electrons at the same time. An approximate method to obtain the LCAO-SCF-MO for the π-electron system of open-shell molecules was proposed by Longuet-Higgins and Pople[3] and was later applied to a theoretical treatment of the π-electronic structures of organic radicals.[4] An approximate method for obtaining SCF molecular orbitals for all valence electrons in closed-shell molecules was presented by Pople, Santry, and Segal.[5] They found that completely neglecting the differential overlap (CNDO) approximation in electron-repulsion integrals leads to results which are invariant to simple transformations of the atomic orbital basis set when these integrals satisfy a further restrictive relationship. This approximate method with CNDO was later modified in some ways; the new method was denoted the "CNDO/2 approximation".[5] They used this CNDO/2 method to calculate molecular orbitals for the valence electrons of some closed-shell molecules and have obtained reasonable theoretical results for some electronic properties of molecules.[5]

As the first step of the molecular orbital treatment of nitric oxide radicals, the present investigation intends to obtain information about the electronic

structure of aliphatic nitric oxide radicals and to assign the two characteristic absorption bands at 450 mμ and 240 mμ. For this purpose, we will use the H_2NO radical, which is the simplest nitric oxide radical and the ESR spectrum of which has been obtained.[6] The approximate SCF method of Longuet-Higgins and Pople will be applied to the valence electron system with the CNDO/2 approximation, and the electronic structure and spectrum of the H_2NO radical will be discussed.

Theoretical

The Hamiltonian operator, $\mathcal{H}$, is expressed in the form:

$$\mathcal{H} = \sum_i H_{\text{core}}(i) + \sum_{i>j} e^2/r_{ij} \tag{1}$$

where $H_{core}(i)$ is the sum of the kinetic energy operator for the valence electron, i (the 1s electron for hydrogen and the 2s and 2p electrons for carbon, nitrogen, and oxygen atoms), and the potential energy operator in the core field (nucleus and inner electrons).

The ground configuration of the free radical is doublet, and its antisymmetrized wave function is described by:

$$\Psi_g = |\, \phi_1\bar{\phi}_1 \cdots \phi_{m-1}\bar{\phi}_{m-1}\phi_m \,| \tag{2}$$

where the number of valence electrons is $2m-1$. The excited doublet configurations considered are of the following four types:

$$\left.\begin{aligned}
\Psi_{m\to k} &= |\, \phi_1\bar{\phi}_1 \cdots \phi_{m-1}\bar{\phi}_{m-1}\phi_k \,| \\
\Psi_{i\to m} &= |\, \phi_1\bar{\phi}_1 \cdots \phi_i\bar{\phi}_m \cdots \phi_{m-1}\bar{\phi}_{m-1}\phi_m \,| \\
\Psi_{i\to k}(\mathrm{I}) &= \frac{1}{\sqrt{2}}\{|\, \phi_1\bar{\phi}_1 \cdots \phi_i\bar{\phi}_k \cdots \phi_{m-1}\bar{\phi}_{m-1}\phi_m \,| \\
&\quad + |\, \phi_1\bar{\phi}_1 \cdots \phi_k\bar{\phi}_i \cdots \phi_{m-1}\bar{\phi}_{m-1}\phi_m \,|\} \\
\Psi_{i\to k}(\mathrm{II}) &= \frac{1}{\sqrt{6}}\{|\, \phi_1\bar{\phi}_1 \cdots \phi_i\bar{\phi}_k \cdots \phi_{m-1}\bar{\phi}_{m-1}\phi_m \,| \\
&\quad - |\, \phi_1\bar{\phi}_1 \cdots \phi_k\bar{\phi}_i \cdots \phi_{m-1}\bar{\phi}_{m-1}\phi_m| \,\} \\
&\quad - 2|\, \phi_1\bar{\phi}_1 \cdots \phi_i\phi_k \cdots \phi_{m-1}\bar{\phi}_{m-1}\bar{\phi}_m \,|
\end{aligned}\right\} \tag{3}$$

where i and k are labeled as the doubly-occupied and the unoccupied orbitals respectively in the ground configuration. In the present treatment, the electronic wave functions for ground and excited doublet states are approximated by linear combinations of the above configurations:

$$\Phi = \sum_i A_i\Psi_i \tag{4}$$

For the open-shell molecules, an approximate method for obtaining self-consistent molecular orbitals for π-electrons was proposed by Longuet-Higgins and Pople.[3] We applied their method to the valence electron system using the CNDO/2 approximation. The valence electrons are assigned to LCAO molecular orbitals:

$$\phi_i = \sum_r C_{ri}\chi_r \tag{5}$$

where χ_r are valence atomic orbitals. The molecular orbital energies and LCAO coefficients are obtained by:

$$\sum_s (F_{rs} - \delta_{rs}\varepsilon)C_{si} = 0 \tag{6}$$

and the matrix elements are given by:

$$\left.\begin{aligned}
F_{rr} &= U_{rr} + \left(P_{AA} - \frac{1}{2}P_{rr}\right)\gamma_{AA} + \sum_{B(\neq A)}(P_{BB} - \zeta_B)\gamma_{AB} \\
F_{rs} &= \frac{1}{2}(\beta_A + \beta_B)S_{rs} - \frac{1}{2}P_{rs}\gamma_{AB} \quad (r \neq s)
\end{aligned}\right\} \tag{7}$$

where the electron-density and bond-order matrix, P_{rs}, is given by:

$$P_{rs} = \sum_{i=1}^{m-1} 2C_{ri}C_{si} + C_{rm}C_{sm} \tag{8}$$

and where the other notations are the same as those given by Pople *et al.*[5] The choice of all the parameters except the bonding parameters are entirely based on them; the bonding parameters, β_A, are determined by the method to be described in the next section.

An initial calculation of the molecular orbital coefficients is carried out by a Hückel-type calculation; iterations are then performed until self-consistency is achieved on all orbital energies with a tolerance of 0.00005 eV. All the present calculations were carried out with the HIPAC 103 computer of Tokyo Kyoiku University.

Results and Discussion

At first the values of bonding parameters, β_A, were reexamined. Pople *et al.* have determined the values of bonding parameters empirically so that the CNDO calculations give the best over-all fit with the accurate LCAO-SCF calculations on diatomic molecules.[5] For the orbital energy intervals, the bonding parameters listed in their article reproduce almost well those obtained by the full LCAO-SCF calculations. However their results also show that the orbital energy intervals $(\varepsilon_j - \varepsilon_i)$ are not satisfactory for π-orbitals; the discrepancy from the results obtained by the full LCAO-SCF calculations is about 3.5 eV for some diatomic molecules. Therefore, their values will not be the best ones to discuss all the kinds of electronic transitions, such as $n\to\pi^*$, $n\to\sigma^*$, and $\pi\to\pi^*$, at the same time. To obtain bonding parameters appropriate to the present calculations, the formaldehyde molecule was chosen as an example; for it the $n\to\pi^*$, $n\to\sigma^*$, and $\pi\to\pi^*$

*1 Reference 7.

*2 A symbol "$n\rightarrow\pi^*$" is used when the excited state wave function is mainly consist of the configurations in which one electron in the ground configuration is excited from n(non-bonding)-orbital to π^*(π-anti-bonding)-orbital, and the transition from the ground state to this state is $n\rightarrow\pi^*$ transition.

absorptions are confirmed experimentally.[7] In the calculation of the H_2CO molecule, the C–H and C–O bond lengths were assumed to be 1.09 Å and 1.21 Å respectively,[8] and all the bond angles, to be 120°. We also assumed a planar structure with a C_{2v} symmetry for the ground and excited states. The SCF equations for closed-shell molecules derived by Pople *et al.* were used, and after the usual configurational interaction calculation for excited singlet states, the electronic transition energies for the H_2CO molecule were obtained. The values of β_H, β_C, and β_O were determined to be −8, −14, and −25 eV respectively. These values well reproduce the experimental $n\rightarrow\sigma^*$ and $\pi\rightarrow\pi^*$ transition energies, while for the $n\rightarrow\pi^*$ transition, the calculated energy was somewhat lower than the experimental one. The calculated SCF molecular orbitals are shown in Table 1, and the results of the configulation interaction treatment are shown in Table 2. By a number of calculations for the H_2CO molecule, the following results were also obtained: (1) the bonding parameter for the hydrogen atom does not change the calculated excitation energies so much as those of the carbon and oxygen atoms, (2) the parameters obtained, $\beta_H=-8$ eV, $\beta_C=-14$ eV, and $\beta_O=-25$ eV, almost completely reproduce the bond-order and electron-density matrix calculated by the parameters listed by Pople *et al.* but give a better agreement with the experimental transition energies than their parameters.

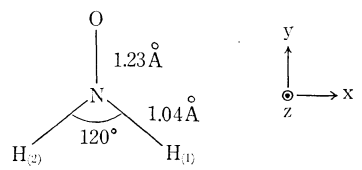

Fig. 1. Assumed structure of the H_2NO radical.[9]

The electronic structure of the H_2NO radical has been calculated assuming the planar configuration shown in Fig. 1. The bonding parameters obtained by calibration from the formaldehyde was used; for the bonding parameter of the nitrongen

atom, β_N, the value of −20 eV was used for no particular reason. This value is between those for carbon and oxygen atoms; the effect of the variation in β_N on the results will be examined below. The orbital energies and LCAO coefficients obtained are listed in Table 3, and the bond-order and electron-density matrix, in Table 4. These tables show the following features of the electronic structure of the H_2NO radical:

(1) The ground-state electron configuration is:

$$(1a_1)^2(2a_1)^2(1b_2)^2(3a_1)^2(1b_1)^2(2b_2)^2(2b_1)^1$$

where the orbitals, $3a_1$, $1b_1$, $2b_2$, and $2b_1$, are understood to be the N-O σ-bonding orbital (by the $2p_y$ atomic orbitals of the nitrogen and oxygen atoms), the π-bonding orbital (by the $2p_z$ orbitals of the nitrogen and oxygen atoms), the non-bonding orbital of the oxygen atom, and the π-anti-bonding orbital respectively. This electron configuration show that the odd electron occupies the anti-bonding π-orbital, that the non-bonding orbital ($2p_x$(O)) is the highest doubly-occupied orbital, and that this makes the nitric oxide radical have a large g_{yy} tensor in the ESR spectra.[10]

(2) The spin density on the oxygen atom is larger than that on the nitrogen atom. When only the π-system of the N-O group is considered, however, this difference is very small (Table 6).

(3) The coefficients for $2p_x$(O) show that the lone-pair orbital on the oxygen atom partially distributes on the hydrogen atoms through the pseudo-π-orbital constructed by two 1s orbitals of the hydrogen atoms and the $2p_x$ orbitals of the nitrogen and oxygen atoms.

In the configurational interaction treatment for the H_2NO radical, all singly-excited configurations of the form in Eq. (3) were considered. The energy levels and the configurations contributing to each state are tabulated in Table 5. The ground state has a B_1 symmetry, and the excited states are of 4 types, A_1, A_2, B_1, and B_2. The intensities are expected to be small for the transitions to A_1 and B_2 states because the basis set of the π-orbital is different from that of the non-bonding orbital or the σ-orbitals.*1 The $B_1 \rightarrow A_2$ ($n \rightarrow \sigma^*$) and the $B_1 \rightarrow B_1$ ($\pi \rightarrow \pi^*$) transitions will have strong intensities, but for the $n \rightarrow \sigma^*$ transitons it must be noted that the electronic oscillator strength is

10) O. H. Griffith, D. W. Cornell and H. M. McConnell, *J. Chem. Phys.*, **43**, 2909 (1965).

*1 The predicted intensity of the $B_1 \rightarrow B_2$ transition will be zero for the electric-dipole radiation, and for the $B_1 \rightarrow A_1$ transition the transition moment will be finite as a result of the 2s atomic orbitals in the LCAO σ-orbital, but the intensity will not be strong.

small for the $\Phi_G\rightarrow\Phi_{E3}$ transition because of the porperties of the two electronic wave functions, Φ_G and Φ_{E3}.*2 The calculated results indicate that the longest wavelength band corresponds to the $n\rightarrow\pi^*$ transition and that the two transitions at 6.00 eV and at 6.78 eV have strong intensities. As has been described before, Briere *et al.*[2] have reported the characteristic bands for aliphatic nitric oxide radicals, 2.76 eV (450 mμ, $\varepsilon=10$) and 5.17 eV (240 mμ, $\varepsilon=3000$). They assigned the band at 450 mμ to the $n\rightarrow\pi^*$ transition on the basis of its weak intensity and the facts that this band is sensitive to the polarity of the solvent and shifts to the shorter wavelength region in the polar solvent. The calculated energy for the $n\rightarrow\pi^*$ transition is lower than the experimental value by about 1 eV; this tendency also appeared in the calculation of the formaldehyde by the present calculation method. For the band at 240 mμ, from its intensity, they supposed it to be a $\pi\rightarrow\pi^*$ or $n\rightarrow\sigma^*$ transition. Their experimental results have also shown that this band is not sensitive to the polarity of the solvent and may be assigned to the $\pi\rightarrow\pi^*$ transition. The present calculated energy for the $\pi\rightarrow\pi^*$ is lower than that for the $n\rightarrow\sigma^*$ transition ($\Phi_G\rightarrow\Phi_{E8}$); this indicates that the band at 240 mμ corresponds to the $\pi\rightarrow\pi^*$ transition. A number of calculations for the H_2NO radical have shown that the above results for the H_2NO radical were consistent even with variations in the bonding parameter for the nitrogen atom (-15 —— -23 eV) and in the N-O bond length (1.20—1.30 Å). Namely, the longest wavelength band has the $n\rightarrow\pi^*$ character, the transition energy for the $\pi\rightarrow\pi^*$ is always lower than that for $n\rightarrow\sigma^*$ ($\Phi_G\rightarrow\Phi_{E8}$ in Table 5), and some weak band exist in the ultraviolet and visible regions.

The $\pi\rightarrow\pi^*$ transition energy for the H_2NO radical, calculated by the method in which only the π-electrons were explicitly considered, is shown in Table 6. The calculation method and semi-empirical parameters used were the same as those reported elsewhere.[11] This result supports the assignment that the band at 240 mμ is the $\pi\rightarrow\pi^*$ transition.

Table 6. Energy levels and wave-functions of H_2NO radical*1

0.00	$\Phi_G = 0.999\lvert\phi_1\bar{\phi}_1\phi_2\rvert + 0.035\lvert\phi_1\bar{\phi}_2\phi_2\rvert$
5.77	$\Phi_E = 0.035\lvert\phi_1\bar{\phi}_1\phi_2\rvert - 0.999\lvert\phi_1\bar{\phi}_2\phi_2\rvert$

*1 π-electrons only were explicitly considered. The calculation method were same as that in Ref. 11.
*2 LCAO MO's are
$\phi_1 = 0.706$: $2p_z(N) + 0.708$: $2p_z(O)$
$\phi_2 = 0.708$: $2p_z(N) - 0.706$: $2p_z(O)$

The results for the $(CH_3)_2NO$ radical are added. The experimental values used in this paper are those for aliphatic nitric oxide radicals, and so the present calculations of the H_2NO radical do not strictly correspond to them. Therefore, the substituent effect on the results obtained above was examined. The results were parallel to those for the H_2NO radical; the calculated transition energies for the $(CH_3)_2NO$ radical corresponding to the $n\rightarrow\pi^*$, $\pi\rightarrow\pi^*$, and $n\rightarrow\sigma^*$ transitions of the H_2NO radical are 2.00, 6.77, and 8.33 eV respectively.

Some unsatisfactory points remain in this study: (1) In spite of the trial calculation for the H_2CO molecule, it is uncertain whether the method with CNDO approximation gives the proper results for the electronic transition energy of free radicals; (2) The molecular structure in the excited state was assumed to be the same as that of the ground state. In this study, the effect of these defects on the calculated results was not estimated and so some uncertainty may remain as to the assignment of

*2 $\langle\Psi_g\lvert\sum_n er_u\rvert\Psi_{i\rightarrow k}(\mathrm{II})\rangle = 0$ (See Table 5).

Photochemistry of Acetanilide. II. The Primary Processes in the Photochemical Reaction

Haruo SHIZUKA[1)]

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 10, 1968)

The photochemical primary processes of acetanilide have been discussed on the basis of the quantum yields in various solvents, the dependences of the quantum yields on the excitation wavelength, and the emission spectra. The quantum yields of the products (*o*-aminoacetophenone and *p*-aminoacetophenone) at 2537 Å decreased greatly in polar solvents. A non-linear relationship between the quantum yield and the fraction of hydrogen-bonded acetanilide in the cyclohexane-ethanol solution was obtained. No variation in the quantum yield was observed upon the change of the excitation from 2537 to 2740 Å. These results indicate the occurrence of a radiationless internal conversion, $S_1(\pi\pi^*) \leftarrow S_2(\pi\pi^*)$. The relative fluorescence intensity in a polar solvent was larger than that in a nonpolar solvent. On the basis of these studies, it can reasonably be considered that the primary process in the photochemical reaction of acetanilide involves predissociation.

In a previous paper[2)] on the photochemical reaction of acetanilide, it has been shown that the quantum yields under various conditions and the kinetic data of benzene photosensitization indicate a mechanism *via* the lowest excited singlet state, $S_1(\pi\pi^*)$, not the triplet state, $T_1(\pi\pi^*)$.

The excitation of acetanilide at 2537 Å occurs from the ground state, S_0, to the secondary excited singlet state, $S_2(\pi\pi^*)$. The occurrence of a non-radiative internal conversion, $S_1(\pi\pi^*) \leftarrow S_2(\pi\pi^*)$, is to be expected. Since acetanilide has a carbonyl group involving non-bonding electrons, it is also interesting to consider the role of $S_1(n\pi^*)$ or $T_1(n\pi^*)$ in the photochemical primary processes. Measurements of fluorescence and phosphorescence spectra are useful for obtaining knowledge of electronic excited states in acetanilide. The purpose of the present work is to clarify the mechanism of photochemical primary processes in acetanilide.

This paper will report on the measurements of quantum yields in various solvents, the relationship between the quantum yield and the fraction of hydrogen-bonded acetanilide, the effect of the excitation wavelength of the quantum yield, measurements of emission spectra, and a theoretical estimation of the n-π^* energy level relative to the π-π^* energy levels by means of the intramolecular charge transfer theory.[3)] It will also include a discussion of the primary processes in this photochemical reaction.

Experimental

The experimental procedure and reagents were similar to those previously described.[2)] A low-pressure mercury lamp was used as the 2537 Å radiation source with a Vycor glass filter, while a high-pressure mercury lamp was used in the 2740 Å range with an interference filter UV-D-25. The fluorescence and phosphorescence spectra were observed by means of a Hitachi MPF-2 Spectrophotofluorometer and an Aminco Bowman Spectrophotofluorometer respectively. In these measurements, the concentrations of the solutions were adjusted so that the values of optical density were 0.600 at 2537 Å. The methylcyclohexane, ether, and ethanol were Tokyo Kasei Co. G. R.-grade products, while the methylcyclohexane was purified by passing it through silica-gel and by distillation.

Experimental Results

1) Effect of Solvent. The quantum yields in various solvents were measured in a manner similar to that described in a preceding paper.[2] The results are shown in Table 1.

Table 1. Quantum yields of the products in various solvents at 2537 Å

Solvent	Quantum yield (Φ)	
	Φ_o	Φ_p
Cyclohexane[2]	7×10^{-2}	6×10^{-2}
Ether	4.3×10^{-2}	3.7×10^{-2}
Ethanol	1.7×10^{-2}	1.4×10^{-2}
H_2O	4.8×10^{-3}	1.8×10^{-3}

Φ_o: Φ of *o*-aminoacetophenone
Φ_p: Φ of *p*-aminoacetophenone

Polar solvents decreased the quantum yields. The dependence of quantum yields on the solvents was examined by means of the method reported by Shinzawa and Tanaka.[4] The ultraviolet spectra of acetanilide in an ethanol - cyclohexane solution varied with the composition of the solvents, as is shown in Fig. 1. The concentrations of ethanol were about 100 times greater than those of acetanilide.

Acetanilide has been revealed, by means of a study of its ultraviolet spectra, to form hydrogen bonds with dioxane and cyclohexanone as proton acceptors.[5] Assuming a hydrogen bond between

acetanilide and ethanol in the present study, the equilibrium constant, K, of the bond formation was calculated by the method obtained by Baba and Nagakura.[6] The value of K obtained from Fig. 2 was ~6.5 l/mol.

In order to ascertain the relation between the quantum yield and hydrogen-bond formation, the quantum yields are plotted in Fig. 3 against the fractions of the hydrogen-bonded molecules calculated from the K value.

A non-linear relationship was obtained, as is shown in Fig. 3.

2) Effect of Excitation Wavelength. A high-pressure mercury lamp was used for the 2740 Å

range, which corresponds to the lowest excited singlet state, $S_1(\pi\pi^*)$,[7] with an interference filter, UV-D-25. The quantum yields of *o*-aminoacetophenone and *p*-aminoacetophenone by irradiation with a 2740 Å range light were 0.07 and 0.06 respectively in a cyclohexane solution. No effect of excitation wavelength on the quantum yields was observed from 2537 to 2740 Å.

3) Emission Spectra. In order to study the behavior of acetanilide in electronically-excited states, the emission spectra were measured. Figure 4 shows the fluorescence spectra of acetanilide in ethanol and cyclohexane solutions.

These data are summarized in Table 2.

Table 2. Fluorescence and phosphorescence spectra of acetanilide at 2537 Å.

Solvent	Fluorescence at room temperature		Phosphorescence at 77°K	
	λ_{max} (mμ)	I^F_{rel}	λ_{max} (mμ)	I^P_{rel}
Cyclohexane	317	13		
Methylcyclohexane			373	1
Ethanol	356	47	388	30

The concentrations were adjusted so that the optical densities at 2537 Å were 0.600.

I^F_{rel} and I^P_{rel} are the relative intensities of the fluorescence and phosphorescence maxima respectively.

In view of its red shift in a polar solvent, it is reasonable to assume that the fluorescence was the emission from $S_1(\pi\pi^*)$ to S_0. The phosphorescence can be assigned to the emission from the triplet state, $T_1(\pi\pi^*)$, to S_0, since the lifetime of the phosphorescence was a few seconds at 77°K. The natural radiative lifetime, τ_0, was calculated from Eq. (1):

$$\tau_0 = \frac{3.47\times10^8}{(\bar{\nu}_{max})^2\int\varepsilon(\bar{\nu})d\bar{\nu}} = 1.12\times10^{-7}\text{sec} \quad (1)$$

where $\bar{\nu}_{max}$ is the wave number of Absorption Band I,[7] which corresponds to $S_1(\pi\pi^*)$, $3.65\times10^4\text{cm}^{-1}$, and where $\int\varepsilon(\bar{\nu})d\bar{\nu}$ is the experimental extinction coefficient integrated over the width of Band I, 2.32×10^6 cm/mmol. The fluorescence lifetime is given by:

$$\tau_F = \tau_0\cdot Q_F = \sim10^{-10}\text{sec} \quad (2)$$

where Q_F is the fluorescence quantum yield of acetanilide in a cyclohexane solution, and where the order of magnitude is $\sim10^{-3}$, a value which was obtained by comparison with the relative fluorescence intensity of carbazole, whose fluorescence quantum yield is 0.35.[8]

Discussion

It has been reported that, in the nitrone→oxazirane photoisomerization, the lifetime of the excited nitrone molecule should be shorter than the relaxation time ($\sim10^{-11}$ sec)[9] of the arrangement between solute and solvent, since the linear relationship between the decrease in the quantum yield of the nitrone in anet hanol-cyclohexane solution and the fraction of hydrogen-bonded nitron molecules indicates that no rearrangement of solvent surrounding the excited nitrone molecule occurs before the photochemical reaction of the nitrone takes place.[4] In constrat to this, a non-linear relationship between the decrease in the quantum yield of acetanilide in an ethanol-cyclohexane solution and the fraction of hydrogen-bonded acetanilide was obtained, as is shown in Fig. 3. It is a possible explanation that the lifetime of an excited acetanilide molecule is longer than the relaxation time ($\sim10^{-11}$ sec)[9] of the arrangement of solute and solvent, and that therefore the radiationless internal conversion, $S_1(\pi\pi^*)\leftarrow S_2(\pi\pi^*)$, may occur.

In addition to this, no variation in the quantum yield was observed upon the change of excitation wavelength from 2537 to 2740 Å. This finding supports the occurrence of an internal conversion, $S_1(\pi\pi^*)\leftarrow S_2(\pi\pi^*)$, and of a Boltzmann distribution in $S_1(\pi\pi^*)$.

The n–π^* absorption band in acetanilide could not be observed, even at high concentrations ($\sim3\times10^{-3}$ mol/*l*). It is known that n–π^* transition in the molecules with a carbonyl group adjacent to the electron-donating group result in a large blue shift.[10] These phenomena have been theoretically explained by Nagakura *et al.*[3] and by Baba.[10] A theoretical estimation of the n–π^* energy level relative to π–π^* levels was carried out by means of the intramolecular charge transfer theory.[3]

The highest occupied (H_B, H_S) and the lowest vacant levels (V_B, V_S) were determined by means

CH_3COCH_3	2790
CH_3COCl	2345
CH_3COOH	2040
CH_3CONH_2	2050

of aniline and acetone, using experimental knowledge of their ionization potentials[11] and their near-UV absorption spectra. The highest occupied orbital of aniline (H_B) interacts with the lowest vacant orbital (V_B) of the substituent group (carbonyl group). Consequently, two new levels, W_n and W_e, result, as is shown in Fig. 5.

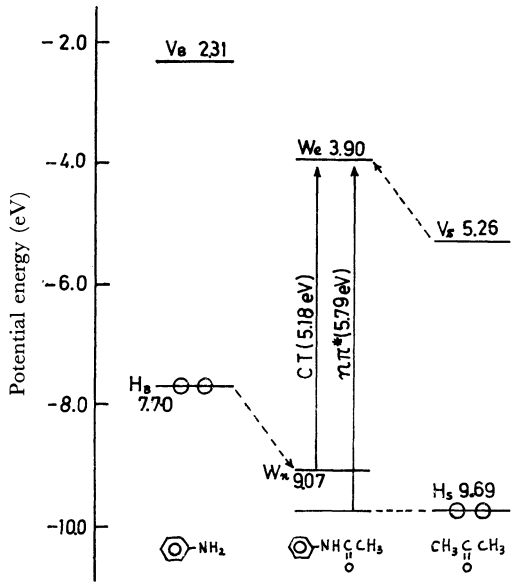

Fig. 5. Estimation of n–π^* transition in acetanilide

Their wave functions, Ψ, and energy levels, W_n and W_e can be represented as follows:

$$\Psi = a\varphi_B + b\varphi_S \quad (3)$$

$$W_n = \frac{1}{2}[H_B + V_S - \{(H_B - V_S)^2 + 4\beta^2\}^{1/2}] \quad (4)$$

$$W_e = \frac{1}{2}[H_B + V_S + \{(H_B - V_S)^2 + 4\beta^2\}^{1/2}] \quad (5)$$

where φ_B and φ_S are the wave functions for the H_B and V_S levels respectively and where β is the exchange integral.

Baba and Suzuki have reported that the lower excited singlet states in acetanilide consist of $S_1(\pi\pi^*)$ ($^1B_2$, 4.532 eV) and $S_2(\pi\pi^*)$ ($^1A_1$, 5.183 eV).[7] The $W_e \leftarrow W_n$ excitation corresponds to the $^1A_1 \leftarrow {}^1A_1$ transition and has a polarization of the transition dipole along the long axis.[7] Therefore, this transition is assigned to $S_2(\pi\pi^*) \leftarrow S_0$. The $S_1(n\pi^*)$ transition energy in acetanilide can then be estimated as 5.79 eV, as is shown in Fig. 5. The n–π^* transition energy is larger than that of $S_2(\pi\pi^*)$. Considering the energy levels as shown in Fig. 5, the photochemical reaction of acetanilide can not occur through the n–π^* state.

It has also been shown that $S_1(\pi\pi^*)$ in acetanilide is the lowest excited singlet state from the fluorescence spectra. The energy difference, ΔE, between $h\nu$ and $h\nu'$ can be calculated from the experimental data of absorption[12] and the emission spectra:

$$\left.\begin{aligned}(\Delta E)_{CH} &= 4900\ \text{cm}^{-1}\\ (\Delta E)_{EtOH} &= 8500\ \text{cm}^{-1}\end{aligned}\right\} \quad (6)$$

ΔE was larger in the polar solvent than in the nonpolar solvent. This indicates that the potential curve of the lowest excited singlet state, $S_1(\pi\pi^*)$, in the polar solvent lines below that in the nonpolar solvent. The repulsive potential curve of $^3\sigma_0$(N–C) may be approximately the same in polar and nonpolar solvents, since, in general, the triplet energy level is scarcely affected at all by a poar solvent. As has been described above, excited acetanilide molecules in $S_1(\pi\pi^*)$ are distributed according to the Boltzmann law. Therefore, the potential barrier which corresponds to the energy difference between their crossing point and the zero point energy level in $S_1(\pi\pi^*)$ may be larger in polar solvents. The effect of polar solvents on the quantum yield was very large, and the quantum yield decreased significantly in polar solvents, as is shown in Table 1. Moreover, the fluorescence intensity in a polar solvent was larger than that in a nonpolar solvent, as Table 2 shows.

It is reasonable to assume the intersystem crossing

between $S_1(\pi\pi^*)$ and $^3\sigma_0$(N–C) repulsive state. Figure 6 shows a schematic potential energy diagram.

It has also been found that the quantum yield for the predissociation is dependent on the temperature and that this temperature dependency is affected by the polarity of a solvent.[13] Thus, the deactivation processes ($k_S+k_F+k_C$; see below) become more important than the nonpolar solvents. The primary processes in the photochemical reaction at 2537 Å can be represented by the following equations:

$$S_0 \xrightarrow{h\nu} S_2(\pi\pi^*) \quad (8)$$

$$S_2(\pi\pi^*) \xrightarrow{k_{ic}} S_1(\pi\pi^*) \quad (9)$$

$$S_1(\pi\pi^*) \xrightarrow{k_S} S_0 \quad (10)$$

$$S_1(\pi\pi^*) \xrightarrow{k_F} S_0 + h\nu' \quad (11)$$

$$S_1(\pi\pi^*) \xrightarrow{k_c} T_1(\pi\pi^*) \quad (12)$$

$$S_1(\pi\pi^*) \xrightarrow{k_{dis}} \phi\text{-NH}\cdot + \cdot\text{COCH}_3 \quad (13)$$

$$T_1(\pi\pi^*) \xrightarrow{k_T} S_0 \quad (14)$$

$$T_1(\pi\pi^*) \xrightarrow{k_p} S_0 + h\nu'' \quad (15)$$

Although this singlet-triplet transition, $^3\sigma_0$(N–C)$\leftarrow S_1(\pi\pi^*)$, is spin-forbidden, it must have a high transition probability to compete with the other deactivation processes for the lowest excited singlet state, $S_1(\pi\pi^*)$, in acetanilide. The probability of the $^3\sigma_0$(N–C)$\leftarrow S_1(\pi\pi^*)$ transition may result from the vibronic coupling between $S_1(\pi\pi^*)$ and $T_1(n\pi^*)$.

In conclusion, the photochemical reaction of acetanilide occurred from the lowest excited singelt state, $S_1(\pi\pi^*)$. The $S_1(\pi\pi^*)$ state might cross over to the $^3\sigma_0$(N–C) repulsive state, resulting in the fission of the N–C bond and the liberation of the ϕ-NH and $COCH_3$ radicals in their doublet ground states. It is reasonable to consider that the primary processes in this photochemical reaction involve the predissociation of the N–C bond.

The author is greatly indebted to Professor Ikuzo Tanaka and Associate Professor Yuji Miro of the Tokyo Institute of Technology for their generous and very helpful discussions of this paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 57—65 (1969)

Photochemistry of Acetanilide. III. The Secondary Processes in the Photochemical Reaction

Haruo SHIZUKA[1)]

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 18, 1968)

The photochemical secondary processes of acetanilide have been studied. The photochemical reaction of *p*-methylacetanilide at 2537 Å did not produce the *p*-rearrangement product, but the *o*-rearrangement one. The quantum yields of the *o*-rearrangement and of the disappearance of *p*-methylacetanilide were 0.09_2 and 0.12 respectively. Comparing the quantum yields of acetanilide with those of *p*-methylacetanilide, the values of the quantum yields for the predissociation of the N-C bond, the back reaction, and the recombination ratio were estimated to be 0.25, 0.10, and 0.9 respectively. These results indicate that the recombination reaction between the pair radicals formed by the predissociation of the N–C bond occur efficiently in a solvent cage. The rate constants of the back reaction, the *o*-rearrangement, and the *p*-rearrangement were proportional to the odd π electron densities of the anilino radical. No intermediate was observed by the flash photolysis. The small dependence of the quantum yields of acetanilide on the temperature supports the predissociation mechanism previously described.[2)] On the basis of these studies, the mechanism of the photochemical reaction of acetanilide in the liquid phase has been proposed.

In the second paper of this series,[2)] it has been shown that the photochemical primary process of acetanilide involves the predissociation caused by intersystem crossing, ${}^3\sigma_0(\mathrm{N\text{–}C}) \leftarrow s_1(\pi\pi^*)$. It is expected that, in the liquid phase, the recombination between the pair radicals formed by the predisso-

1) Present address: Department of Chemistry, Faculty of Engineering, Gunma University, Tenjin-cho, Kiryu, Gunma.

2) H. Shizuka, This Bulletin, **42**, 52 (1969).

ciation will occur with a high probability; this is the so-called "cage effect".[3] Many investigations of the cage effect have been reported by Noyes and by others.[4–10]

In order to determine the photochemical secondary processes of acetanilide, it is necessary to obtain the values of the quantum yields for the predissociation of the N–C bond, Φ_{dis}, the back reaction, Φ_B, and the recombination ratio, β. Considering their UV absorption spectra, the electronically-excited states in acetanilide and *p*-methylacetanilide are the same in a first approximation. Therefore, the photochemical primary process of *p*-methylacetanilide would be the same as that of acetanilide. However, the photochemical reaction of *p*-methylacetanilide at 2537 Å did not produce the *p*-rearrangement product but, rather, the *o*-rearrangement product, because its *p*-position is blocked by the methyl group.

The values of Φ_{dis} and Φ_B may be estimated by comparing the quantum yields of acetanilide with those of *p*-methylacetanilide.

On the other hand, flash photolysis is useful in detecting some intermediates, and the effect of the temperature on the quantum yield is also useful in discussing the mechanism of the photochemical reaction of acetanilide. This paper will report on the photochemical reactions of *p*-substituted acetanilide at 2537 Å, the dependence of the quantum yield on the temperature, the data of flash photolysis, and the estimations of Φ_{dis}, Φ_B, and β, it will also include a discussion of the photochemical secondary processes of acetanilide.

Experimental

The experimental technique was similar to that previously described.[2,11] The flash apparatus was an ordinary one. The excitation flash lamp with 150 mmHg of xenon gas, was made of quartz. The condenser for the excitation flash lamp with a capacity of 25μF was charged to 4 kV; the energy corresponded to 200 J. The pulse had a half-value width of about 50μsec. The flash lamp for spectroscopy, with 150 mmHg of xenon, was made of quartz. The condenser for the spectral flash lamp with a capacity of 8μF was charged to 4 kV; the energy corresponded to 64 J. The pulse had a half-value width of about 20μsec.

p-Methyl-, *p*-chloro-, *p*-bromo-, *p*-iodo-, and *p*-nitroacetanilides were prepared by treating reagent-grade products of *p*-substituted anilines with glacial anhydride and were purified by repeated recrystallizations from water. *p*-Amino- and *p*-hydroxyacetanilides were Tokyo Kasei Co. reagent-grade products and were purified by recrystallization from water.

Results and Discussion

1) Irradiation of *p*-Substituted Acetanilides at 2537 Å. The absorption spectra of the solutions of *p*-substituted acetanilides were similar to that of acetanilide, except in the case of *p*-nitroacetanilide.[12] The spectra of all the solutions of *p*-substituted acetanilides except *p*-nitroacetanilide changed markedly by upon irradiation with a 2537 Å light. The photochemical reactions of *p*-substituted acetanilides may be classified into the following four types.

a) Photochemical Reactions of p-Methyl- and p-Chloroacetanilides. Figure 1(a) shows the spectral change in a cyclohexane solution of *p*-methylacetanilide at 2537 Å. The absorption Band II (243 mμ) decreased and new bands appeared with maxima of 228 and 363 mμ as the irradiation time increased; there were three isosbestic points at 213, 235, and 260 mμ. The product which had absorption peaks at 228. and 363 mμ was assigned to 2-amino-5-methylacetophenone (*o*-rearrangement product) by gas chromatography. A similar spectral change was observed in the case of *p*-chloroacetanilide, as is shown in Fig. 1(b).
The quantum yields were obtained spectrophotometrically in cyclohexane.*1 The disappearance quantum yields of *p*-methyl- and *p*-chloroacetanilides were 0.12 and 0.13 respectively at 20°C. The quantum yields of 2-amino-5-methyl- and 2-amino-5-chloroacetophenones were 0.09_2 and 0.09_7 respectively. These photochemical reactions are analogous to those reported by Kobsa for *p-t*-butylphenylacetate derivatives,[13] as is shown in Eqs. (1) and (2):

(2)

where Ar represents a phenyl substituent.

b) Photochemical Reactions of p-Bromo- and p-Iodo-Acetanilides. Figure 2(a) shows the spectral change in the solution of *p*-bromoacetanilide. The Absorption Band II (250 mμ) decreased and new bands with the maxima of 225, 290, and 365 mμ appeared, but with no clear isosbestic point such as those in the cases of *p*-methyl- and *p*-chloroacetanilides. The appearance of the 290 mμ peak probably indicates that *p*-aminoacetophenone was also produced by the irradiation with 2537 Å.[11] A similar spectral change was observed in the case of *p*-iodoacetanilide, as is shown in Fig. 2(b). In the photochemical reactions of *p*-bromo- and *p*-iodoacetanilides, it is reasonable to assume that the predissociation at the C–Br or at the C–I bond was caused by irradiation, resulting in acetanilide. Therefore, the *p*-rearrangement at 2537 Å might occur as well as the *o*-rearrangement.

(a) degassed (b) aerated

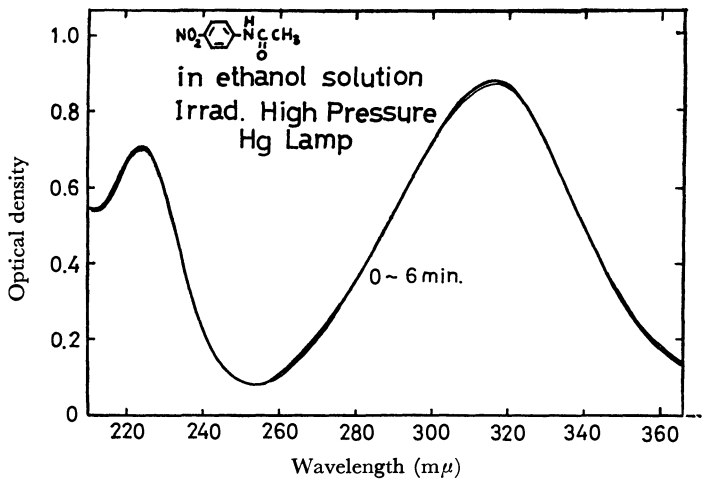

Fig. 4. The spectral change of ethanol solution of *p*-nitroacetanilide by irradiation with a high pressure mercury lamp.

c) *Photochemical Reactions of p-Amino- and p-Hydroxyacetanilides.* *p*-Amino- and *p*-hydroxyacetanilides had very poor solubilities in cyclohexane at room temperature. Therefore, ether was used as the solvent. Figure 3(a) shows the spectral change in a degassed ether solution of *p*-aminoacetanilide at 2537 Å. The Absorption Band II (262 mμ) decreased and new bands with the maxima of 237 and 395 mμ appeared, as well as those of *p*-methyl- and *p*-chloroacetanilides. However, in an aerated ether solution, the spectral change was different from that in a degassed solution, as is shown in Fig. 3(b).

In the case of an aerated ether solution, the Absorption Band II (262 mμ) decreased and new peaks appeared at 237, 243, 254, 263, 322, and 378 mμ. The increase in the 237 mμ peak corresponds to the *o*-rearrangement. The appearance of peaks at 243, 254, and 263 mμ in an aerated solution of *p*-aminoacetanilide was similar to that in an aerated solution of *p*-phenylenediamine at 2537 Å found by Hinohara.[14] Similar results were observed in the cases of degassed and aerated ether solutions of *p*-hydroxyacetanilide at 2537 Å.

It may be considered that, in the presence of dissolved oxygen, 2,5-diaminoacetophenone (the *o*-rearrangement product) was oxidised to the corresponding imine.

d) *Phntochemical Reaction of p-Nitroacetanilide.* Scarcely no spectral change was observed in an aerated ethanol solution of *p*-nitroacetanilide upon irradiation with a high-pressure mercury lamp, as is shown in Fig. 4.

The quenching mechanism by the substitution of

14) T. Hinohara, Presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967.

the nitro group has been explained by Tanaka *et al.*[15]; internal quenching is caused by the atomic rearrangement of the nitro group (especially the oxygen atom) in the excited Franck-Condon state. Kokubun and Kobayashi supported this quenching mechanism on the basis of their investigation of the fluorescence quantum yield and the lifetime of *m*-nitrodimethylaniline.[16]

2) Estimation of Dissociation and Back-reaction Quantum Yields. The quantum yields for *p*-X substituted acetanilides at 2537 Å are summarized in Table 1. By *p*-methyl or *p*-chloro substitution, the disappearance quantum yields decreased, the quantum yields of the *o*-rearrangement increased, and the *p*-rearrangement did not occur.

TABLE 1. QUANTUM YIELDS FOR *p*-X SUBSTITUTED ACETANILIDE AT 2537 Å

X	Quantum yield (Φ)					
	Observed			Calculated		
	Φ_o	Φ_p	Φ_{dec}	Φ_N	Φ_B	Φ_{dis}
H[a]	0.07	0.06	0.15	0.02	0.10	0.25
CH_3	0.09_2	0	0.12	0.02_8	0.13	0.25
Cl	0.09_7	0	0.13	0.03_3	0.14	0.27

a) See Footnote 11.

Φ_o and Φ_p are the quantum yields of *o*- and *p*-rearrangements respectively; Φ_{dec}, the decrease quantum yield of acetanilide; Φ_N, the quantum yield of *p*-X substituted aniline; Φ_B, the quantum yield of the back reaction, and Φ_{dis}, the dissociation quantum yield for the N–C bond.

In the present work, aniline could not be observed by the spectrophotometric method.[11] Elad reported the formation of aniline as well as of *o*- and *p*-aminoacetophenones in the photochemical reaction of acetanilide.[17] Therefore, the quantum yields of *p*-X aniline (Φ_N) may be evaluated approximately by Eq. (3):

$$\Phi_N \approx \Phi_{dec} - (\Phi_o + \Phi_p) \tag{3}$$

The electronically excited states in acetanilide and *p*-methylacetanilide are the same in a first approximation, since the shapes of their UV absorption spectra are about the same. Therefore, it is reasonable to assume that these photochemical reactions can occur through the same primary processes; the dissociation quantum yields for the N–C bond have the same value, as is shown in Eq. (4):

$$\Phi^{H}_{dis} \approx \Phi^{CH_3}_{dis} \tag{4}$$

On the other hand, the observed quantum yields, Φ_o, Φ_p, and Φ_{dec}, of *p*-methylacetanilide differ from those of acetanilide, as is shown in Table 1. These differences can be explained as follows. In the photochemical primary process, anilino and acetyl radicals are produced by the intersystem crossing, ${}^3\sigma_0(\text{N–C}) \leftarrow S_1(\pi\pi^*)$.[2] The *p*-position being blocked in the anilino radical by the methyl group, the acetyl radical can not move to the *p*-position. Therefore, the acetyl radical which is expected to rearrange at the *p*-position follows this course:

1) recombination with the anilino radical at the *o*-position, which causes an increase in the Φ_o.

2) recombination with the anilino radical at the nitrogen dot; this is the back reaction, which decreases the Φ_{dec} and increases the Φ_B.

3) abstraction reaction, resulting in *p*-X-aniline formation, which in turn increases the Φ_N.

In order to estimate the dissociation and back-reaction quantum yields, the ratio of Φ_B to 1/2 Φ_o was obtained as follows:

$$\Delta\Phi_o = \Phi^{CH_3}_o - \Phi^{H}_o = 0.022 \tag{5}$$

$$\Delta\Phi_B = \Phi^{CH_3}_B - \Phi^{H}_B = \Phi^{H}_{dec} - \Phi^{CH_3}_{dec} = 0.03 \tag{6}$$

where:

$$\Phi^{H}_{dis} = \Phi^{H}_B + \Phi^{H}_{dec}, \quad \Phi^{CH_3}_{dis} = \Phi^{CH_3}_B + \Phi^{CH_3}_{dec}$$

and $$\Phi^{H}_{dis} = \Phi^{CH_3}_{dis}$$

$$\frac{\Delta\Phi_B}{\frac{1}{2}\Delta\Phi_o} = 2.9 \tag{7}$$

$$\frac{\Phi_B}{\frac{1}{2}\Phi_o} \approx \frac{\Delta\Phi_B}{\frac{1}{2}\Delta\Phi_o} = 2.9 \tag{7'}$$

The rate of the back reaction was 2.9 times that of the *o*-rearrangement. Thus, the values of $\Phi^{CH_3}_B$, Φ^{H}_B, $\Phi^{CH_3}_{dis}$, and Φ^{H}_{dis} are given by:

$$\Phi^{CH_3}_B = \frac{1}{2}\Phi^{CH_3}_o \times 2.9 = 0.13 \tag{8}$$

$$\Phi^{CH_3}_{dis} = \Phi^{CH_3}_B + \Phi^{CH_3}_{dec} = 0.25 \tag{9}$$

$$\Phi^{H}_B = \frac{1}{2}\Phi^{H}_o \times 2.9 = 0.10 \tag{10}$$

$$\Phi^{H}_{dis} = \Phi^{H}_B + \Phi^{H}_{dec} = 0.25 \tag{11}$$

The values of Φ^{Cl}_B and Φ^{Cl}_{dis} were also estimated:

$$\Phi^{Cl}_B = \frac{1}{2}\Phi^{Cl}_o \times 2.9 = 0.14 \tag{12}$$

$$\Phi^{Cl}_{dis} = \Phi^{Cl}_B + \Phi^{Cl}_{dec} = 0.27 \tag{13}$$

As has previously been described,[2] the fluorescence lifetime, τ_F, is of the order of magnitude of $\sim 10^{-10}$ sec. The dissociation rate constant, k_{dis}, can be evaluated as follows:

15) I. Tanaka, Y. Mori *et al.*, Presented at the Symposium on Electronic state, Osaka, Oct., 1966.

16) H. Kokubun and M. Kobayashi, Presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967.

17) D. Elad, *Tetrahedron Letters*, **1963**, 873. D. Elad, D. V. Rao and V. I. Stenberg, *J. Org. Chem.*, **30**, 3252 (1965).

$$\left.\begin{aligned} S_1(\pi\pi^*) &\xrightarrow{k_s} S_0 \\ S_1(\pi\pi^*) &\xrightarrow{k_F} S_0 + h\nu' \\ S_1(\pi\pi^*) &\xrightarrow{k_c} T_1(\pi\pi^*) \\ S_1(\pi\pi^*) &\xrightarrow{k_{dis}} \phi\text{-NH} + \text{CCH}_3 \\ & \qquad\qquad\quad \| \\ & \qquad\qquad\quad \text{O} \end{aligned}\right\} \quad (14)^{b)}$$

b) See Footnote 2.

$$\Phi^{H}_{dis} = \frac{k_{dis}}{k_s + k_F + k_c + k_{dis}} = 0.25 \quad (15)$$

$$k_{dis} = \frac{0.25}{\tau_F} = \sim 10^9\ \text{sec}^{-1} \quad (16)$$

3) Secondary Processes. The photochemical rearrangement of acetanilide was an intramolecular reaction, since no effect of the quantum yield on the concentration has been observed.[11] It is interesting to note that the value of the high recombination ratio (β) between anilino and acetyl radicals in the liquid phase is quite high, as is shown in Eq. (17):

$$\left.\begin{aligned} \beta_H &= \frac{\Phi^H_o + \Phi^H_p + \Phi^H_B}{\Phi^H_{dis}} = 0.92 \\ \beta_{CH_3} &= \frac{\Phi^{CH_3}_o + \Phi^{CH_3}_B}{\Phi^{CH_3}_{dis}} = 0.89 \\ \beta_{Cl} &= \frac{\Phi^{Cl}_o + \Phi^{Cl}_B}{\Phi^{Cl}_{dis}} = 0.88 \end{aligned}\right\} \quad (17)$$

These results indicate that the recombination reaction between pair radicals occurs efficiently in a solvent cage. The little hydrogen-atom abstraction from the solvent may be caused by the anilino or the acetyl radical. Figure 5 shows the reaction model in a solvent cage.

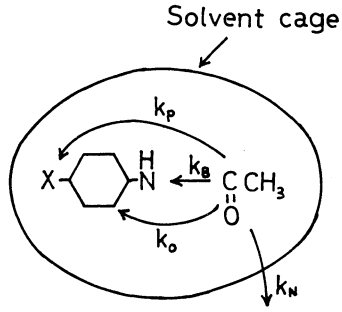

Fig. 5. Reaction model in a solvent cage.

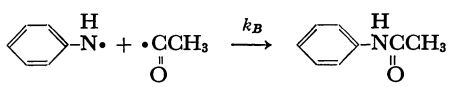
The photochemical secondary processes of acetanilide can be represented as in the following equations:

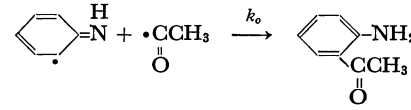
Recombination Reactions.

a) Back reaction:



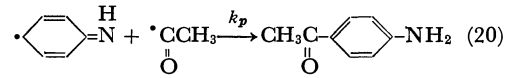
(18)

b) *o*-Rearrangement:



(19)

c) *p*-Rearrangement:



(20)

where k_B, k_o, and k_p are the rate constants of the back reaction, the *o*-rearrangement, and the *p*-rearrangement respectively. In the recombination reaction between the pair radicals, the correlation between the rate constants (k_B, k_o, and k_p) and the odd π electron densities (ρ_7, ρ_2, and ρ_4) was obtained as follows. To the first approximation,the odd π electron densities of the anilino radical were obtained from a semiempirical ASMO-CI calculation on aniline,[18] as is shown in Fig. 6.

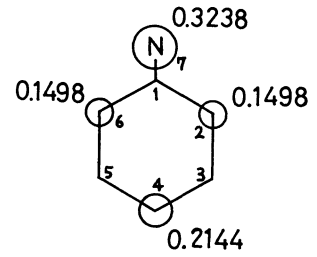


Fig. 6. Odd π electron densities of anilino radical.[18]

$$k_B : k_o : k_p = \Phi_B : \frac{1}{2}\Phi_o : \Phi_p = 1 : 0.35 : 0.6 \quad (21)$$

$$\rho_7 : \rho_2 : \rho_4 = 1 : 0.46 : 0.66 \quad (22)$$

$$k_B : k_o : k_p \approx \rho_7 : \rho_2 : \rho_4 \quad (23)$$

The rate constants, k_B, k_o, and k_p, were proportional to the odd π electron desities, ρ_7, ρ_2, and ρ_4 respectively. These results lend some support to the radical mechanism for the photochemical secondary processes in acetanilide. The recombination between the pair radicals in a solvent cage may occur within several collisions, since k_B, k_o, and k_p are all larger than k_N. It is assumed that these recombination rate constants are of the order of magnitude of 10^{11}—10^{12} sec^{-1}, considering the number of collisions between solute and solvent to be about 10^{13} sec^{-1}.[19]

No intermediate could be observed by the flash

18) H. Baba, This Bulletin, **34**, 76 (1961); N. Mataga, *ibid.*, **36**, 1607 (1963). The highest occupied molecular orbital of aniline ϕ_4:

$$\phi_4 = 0.356\chi_1 + 0.387(\chi_2 + \chi_6) - 0.133(\chi_3 + \chi_5) - 0.463\chi_4 - 0.569\chi_7$$

Odd electron densities were obtained from the square of the coefficient of atomic orbital χ_i in ϕ_4

19) *E. g.*, M. Tamura, "Kokagaku," Shibundo, Tokyo (1947), p. 160; M. Koizumi, "Kokagaku-gairon," Asakurashoten, Tokyo (1963), p. 78.

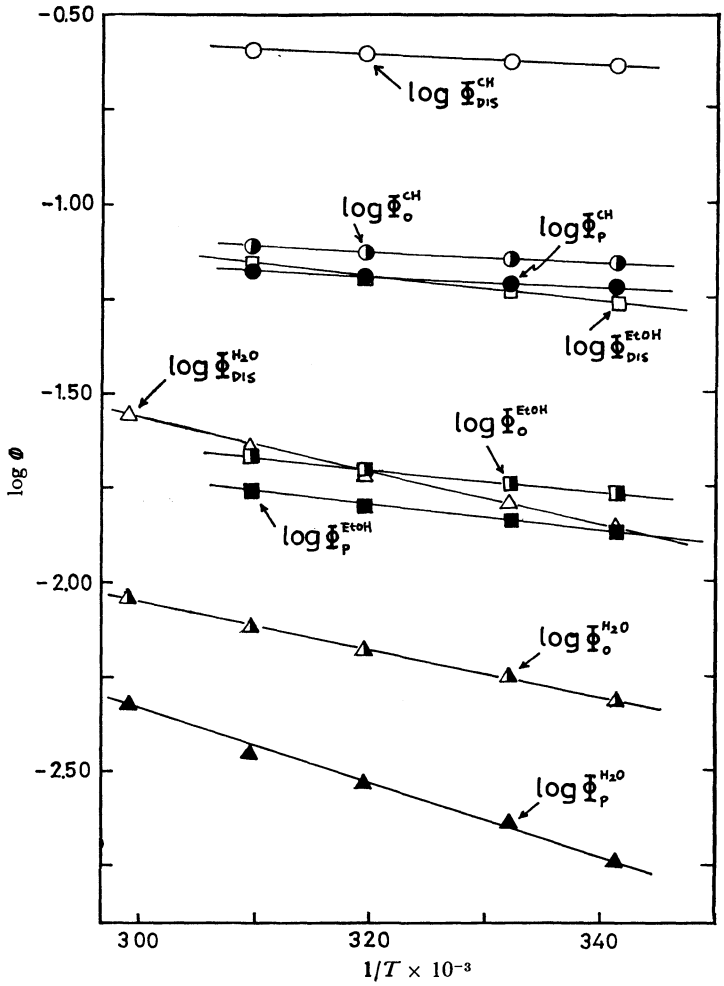

Fig. 7. Plots of logarithm of quantum yields against reciprocal of temperature.

technique. The absorption of the products appeared within the shortest delay time (20 μsec) observed.

4) Dependence of the Quantum Yield on the Temperature. The quantum yields (Φ) in various solvents were measured while varying the temperature in the range from 20 to 70°C. The quantum yields depended on the temperature; plots of log Φ against $1/T$ fell on a straight line, as is shown in Fig. 7. Moreover, a linear relationship was obtained between log Φ_{dis}*2 and $1/T$.
The activation energies in the photochemical rearrangement of acetanilide were calculated to be as shown in Table 2.

The values of the activation energies in polar solvents were larger than those in nonpolar solvents. However, even these values were very low in comparison with those of the hydrogen-atom abstraction reaction by radicals.[20] These results also suggest that hydrogen-atom abstraction reactions are not involved in the *o*- and *p*-rearrangements:

Table 2. Activation energies in the photochemical reaction of acetanilide

Solvent	Activation energy, kcal/mol		
	E_o	E_p	E_{dis}
Cyclohexane	0.6_0	0.6_1	0.6
Ethanol	1.4_5	1.6_0	1.5
Water	2.8_2	4.1_5	3.0

E_o, E_p, and E_{dis} are the activation energies of the *o*-rearrangement, the *p*-rearrangement, and the dissociation for the N-C bond respectively.

*2 The Φ_{dis} values were estimated as follows:

$$\Phi_{dis} \approx \Phi_B + \Phi_o + \Phi_p \approx 2.43\,\Phi_o + \Phi_p$$

20) *E. g.*, M. H. J. Wijnen, *J. Am. Chem. Soc.*, **80**, 2394 (1958).

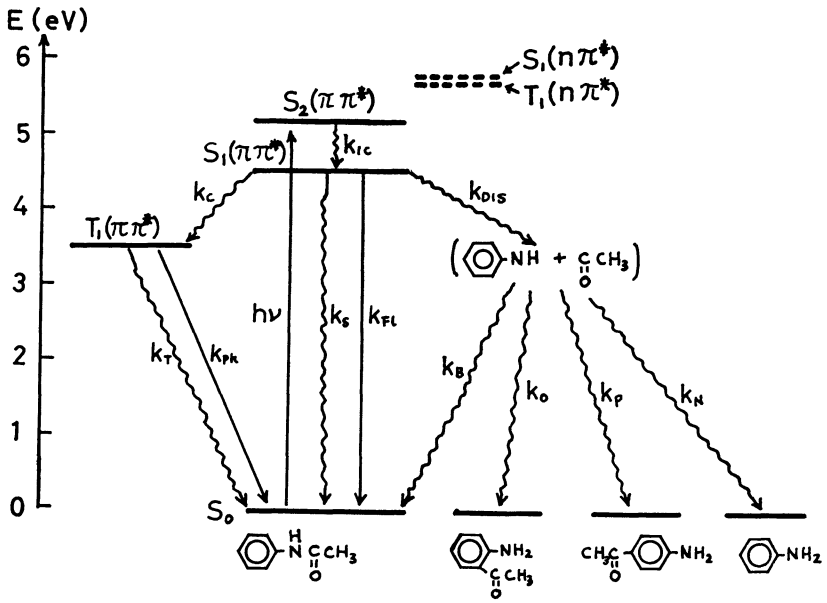

Fig. 8. Energy state diagram for acetanilide.

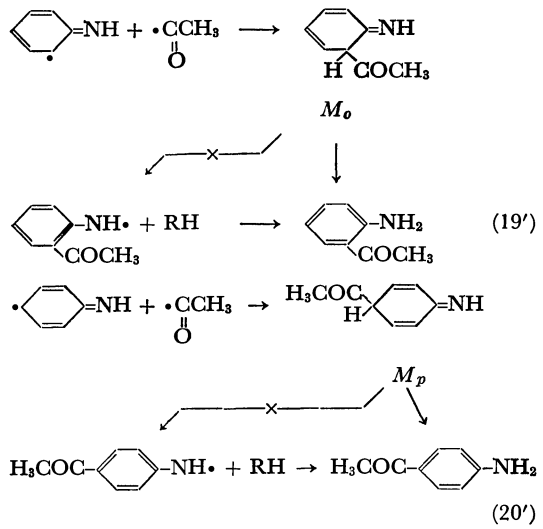


Since the M_o and M_p intermediates might have highly vibrational and rotational energies when a pair of radicals recombine, the values of their lifetimes would be very short; probably one may assume an order of magnitude of $\sim 10^{-12}$ sec. In fact, no intermediate could be observed by means of the flash technique, as has been mentioned above. It is more reasonable to consider that the rearrangements occurred immeadiately, as is shown in Eqs. (19) and (20).

The results regarding the activation energies for the dissociation quantum yields E_{dis}, lend some support to a photochemical primary process[2] which involves the predissociation of the N-C bond in acetanilide.

Conclusion

From these studies, the reaction scheme of acetanilide at 2537 Å can be written as is shown in Fig. 8.

The mechanism of the photochemical reaction of acetanilide involves the lowest excited singlet state, $S_1(\pi\pi^*)$; the predissociation by intersystem crossing, ${}^3\sigma_0(\text{N-C}) \leftarrow S_1(\pi\pi^*)$, and the recombination reaction between the pair radicals in a solvent cage.

The author is greatly indebted to Professor Ikuzo Tanaka and Associate Professor Yuji Mori of the Tokyo Institute of Technology for their generous and very helpful discussion of this paper.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 66—70 (1969)

Mechanism of a Stereospecific, Photosensitized, Cyclization Reaction of 3-Methylene-1,5-heptadiene

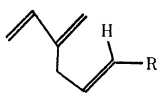
Sin-ichiro KITA*1 and Ken-ichi FUKUI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto

(Received May 30, 1968)

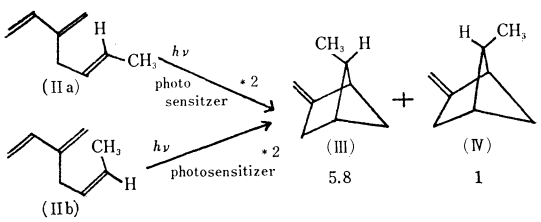
In order to understand the mechanism of the photosensitized, stereospecific cyclization of 3-methylene-1,5-heptadiene, we calculated the electronic state of two intermediates (13 imaginary conformations) by the extended Hückel molecular orbital method and discussed its rotation angle dependency. We obtained the following conclusions. 1) In the two intermediates, the second model (we suppose this to be more like a real intermediate) has lower energy than the first model (we suppose this to be an initial intermediate) both in the ground state and the excited state. 2) If it is necessary for this cyclization that an overlap stabilization exists between two carbon atoms to be bonded and the intermediate has lower energy in that state, the intermediate seems to cyclize after the transition to the ground state singlet. 3) The overlap stabilization between two carbon atoms mentioned above is mainly defined by the interaction between 2p electrons in the highest occupied orbital. This fact coincides with the consequence of the frontier electron theory. 4) The existence of the overlap stabilization between 2p electrons mentioend above corresponds to the fact that the special valence atomic orbital of that two carbon atoms has the same symmetry. This fact is in line with the Woodward-Hoffmann rule on "electrocyclic reactions."

The photosensitized bicyclization reaction of 3-methylene-1,5-hexadiene derivatives (I) has been reported by Charton *et al.*[1], Liu,[2] and Liu *et al.*[3]



(I)

In their reports,[2,3] Liu has shown that either *trans* or *cis* 3-methylene-1,5-heptadiene (IIa or IIb) gave an identical product mixture of two products (III and IV) in a ratio of 5.8 to 1 (in this point this reaction is stereospecific) and regardless of the initial composition of the triene mixture the relative amounts of the two products remained unchanged throughout the reaction and at the same time the relative amounts of the starting materials were found unchanged.



From the fact mentioned above and other facts, he has considered the presence of long lived intermediate (V)*3 in these reactions.

In this report, we calculated the electronic state of an intermediate (V) by Hoffmann's extended

*1 Present address: Ohe Work, Sumitomo Chemical Industry Co. Ltd., Ohe, Niihama, Ehime, Japan.

1) J. L. Charlton, P. de Mayo and L. Skattebol, *Tetrahedron Letters*, **1965**, 4679.

2) R. S. H. Liu, *ibid.*, **1966**, 2159.

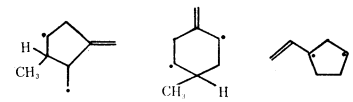
*2 β-Acetonaphthone, triphenylene, benzophenone or fluorenone.

*3 As intermediates, one can also consider the followings.



(VI) (VII) (VIII)

Liu has considered that VI is an unlikely intermediate in these reaction on the grounds of energy considerations.[2] As regards VII and VIII, we found that the following experimental rule exists in these reactions. "In the cyclization of an excited triplet state, intermediates which contain two unpaired electrons in one ring structure, such as VII and VIII, can not exist, while in the cyclization of an excited singlet state the restriction mentioned above does not exist." This rule was justified in the case of the photocyclization of 1,5-hexadiene,[4] 1,6-heptadiene,[5] myrcene,[6] 1,5-cyclooctadiene[7] and neryl acetate.[8]

(V)

Hückel molecular orbital (MO) method[9] and discussed the mechanism of its stereospecific cyclization.

The Parameters used and the Coordinates

The MO's to describe this system are represented by a linear combination of valence atomic orbitals (AO); that is, the 1s orbital of the hydrogen atom and the 2s, 2px, 2py, 2pz orbitals of the carbon atom. The Coulomb integrals of these AO's, H_{pp}, are given as follows.

$$H_{pp}\ (1s, H) = -13.60\ eV$$
$$H_{pp}\ (2s, C) = -21.43\ eV$$
$$H_{pp}\ (2p, C) = -11.42\ eV$$

The resonance integral between ith and jth AO's, H_{pq}, is calculated by the equation

$$H_{pq} = 0.875(H_{pp} + H_{qq})S_{pq}$$

where S_{pq} is the overlap integral.[9] The effective nuclear charges for these atoms are $\mathcal{Z}_H = 1.00$, $\mathcal{Z}_C = 3.25$.

The bond distances, the bond angles and the coordinates of models used in this paper are presented in Table 1 and Fig. 1.

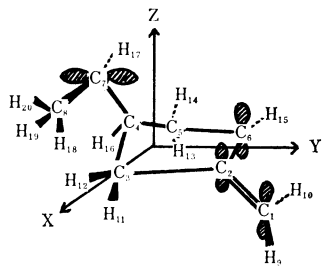

Fig. 1. Coordinates of the model.

Results and Discussion

In cyclopentane, the ring is nearly planar[10] and the intermediate (V) is considered as a long lived one.[2,3] Therefore, it is supposed that the 5-membered ring of the intermediate (V) is planar. The first model refers to this case. Next, if the intermediate (V) cyclizes to III or IV, C_6 and C_7 which are to become bonded in this reaction must approach nearer than in the case of the first model. The second model refers to one of these cases.

Figure 2 shows the θ dependence of the total energy in the first model and in the second model. θ is the angle between the C_8, C_7, C_4-plane and the C_7, C_4, H_{16}-plane and is measured from the C_2, C_3, C_5, C_6-plane side of the former plane to the direction of a C_2–C_1 double bond. From Fig. 2, it can be seen that the second model has lower energy than the first model both in the ground state and the excited state. Therefore, it can be supposed that the cyclization of intermediate (V) proceeds *via* the route from the first model to the second model.

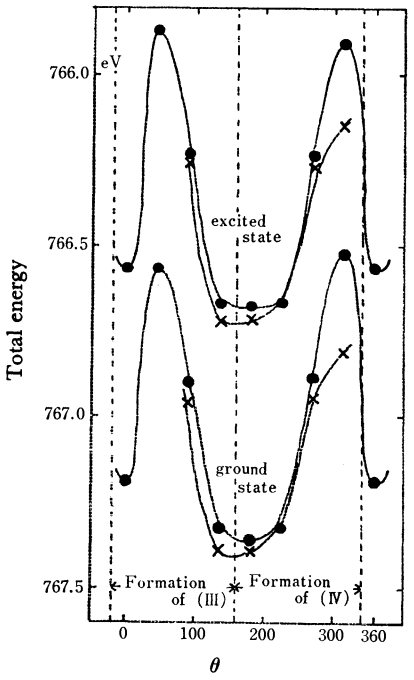

Fig. 2. θ dependence of total energy.
● first model × second model

In the following discussion, we discuss mainly using the first model only for the convenience of calculations and qualitatively one can obtain the same conclusion even if one uses the second model.

Here we suppose that it is necessary for this cyclization that an overlap stabilization[12] exists between C_6 and C_7. Figure 3 shows the θ dependence of the bond energy*5 between C_6 and C_7. In the case of the ground state of the first model, C_6 and C_7 are "bonding" in two θ ranges, the one corresponding to the formation of III, and the other to the formation of IV. If one considers the total energy of these two "bonding" θ ranges, it is apparent that the energy of the fomrer range

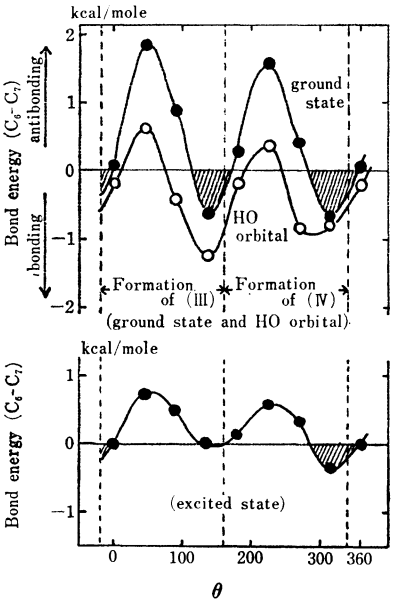

Fig. 3. θ dependence of bond energy (first model).

is lower than that of the latter range. This relation holds also in the second model. In the case of the excited state, C_6 and C_7 are "bonding" in one θ range only, which corresponds to the formation of IV. From the experimental data,[2,3] it is seen that III occurs more than IV. Therefore, the intermediate (V) (excited triplet) seems to cyclize after the transition to the ground state singlet.

Furthermore, let us consider the reason why C_6 and C_7 is "bonding" in the special θ ranges only. Figure 3 also shows the bond energy between C_6 and C_7 in the HO orbital. From Fig. 3, it is apparent that the "bonding" in the ground state corresponds to that in the HO orbital. This fact is interesting, because it coincides with the theoretical consequence of the frontier electron theory.[13] From Table 3, it can be seen that the interaction of 2p electrons contributes mainly to this "bonding." Figure 4 shows the atomic bond population and the AO bond population of the ground state and the HO orbital. From Fig. 4, it is apparent that the main reason of the "bonding" is the interaction between $6\,C_{2pz}$ and $7\,C_{2py}$ and this interaction corresponds to that in the HO orbital. Therefore, the phenomenon that C_6 and C_7 is "bonding" is mainly defined by the fact that $6\,C_{2pz}$ and $7\,C_{2py}$ is "bonding."

Next, let us consider the reason why the AO bond population between $6C_{2pz}$ and $7C_{2py}$ in the HO orbital has positive values in the special θ ranges. Figure 5 shows the θ dependence of the coefficients of $6C_{2pz}$ and $7C_{2py}$ in the HO orbital.

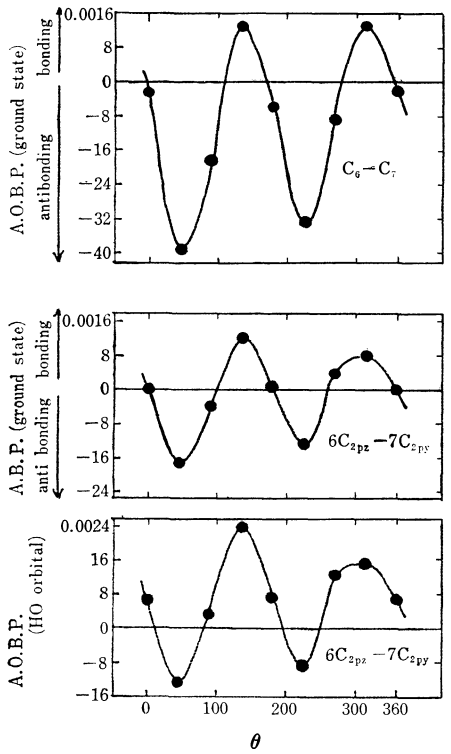

Fig. 4. θ dependence of atomic bond population and atomic orbital bond population.

From Fig. 5, it is apparent that the phenomenon mentioned above is due to the fact that the coefficients of $6C_{2pz}$ and $7C_{2py}$ have the same sign, in other words, the valence AO of $6C_{2pz}$ and $7C_{2py}$ have the same symmetry in the θ range

mentioned above. This fact is interesting, because it is in line with the Woodward-Hoffmann rule on electrocyclic reactions.[14]

The calculations have been carried out on an HITAC 5020 computer at Tokyo University. One of the authors (S.K.) is grateful to Mr. R. Kuroda, Dr. O. Saheki and Dr. T. Irie for their interest in this work. He also wishes to thank the Sumitomo Chemical Industry Co. Ltd. for permission to publish this paper.

Electronic Spectra of Crystalline TCNQ Anion Radical Salts. I. Simple Salts*1

Yôichi IIDA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received May 31, 1968)

The present paper deals with crystalline TCNQ anion radical "simple" salts of M^+ $TCNQ^-$, where M^+ represents a diamagnetic counter cation. Their crystalline electronic spectra were measured in the range between 4.0 and 30.8 kK by means of diffuse reflectance. The crystalline spectra thus obtained were quite different from that of the TCNQ radical anion monomer and exhibited a broad and intense low-energy band around 9 kK in the low-conductivity compounds and at 4.3 kK in the high-conductivity compound. These bands were ascribed to inter-radical charge-transfer in the solid state. The crystalline spectra were found to be closely correlated to their unusual electrical and magnetic properties. It was concluded that these physical properties were based on a unique TCNQ molecular arrangement in groups of several or an infinite number of face-to-face molecular systems.

In a previous paper,[1] it has been shown that Würster's salts exhibit characteristic electronic and magnetic properties in the solid state. These properties result from charge-transfer interaction between the cation radicals. Unusual low-energy bands in the diffuse reflectance spectra have been identified as inter-radical charge-transfer bands. In connection with them, the magnetic properties of the salts have been speculated on on the basis of antiferromagnetic interaction between ion radicals. Charge-transfer interaction might make a significant contribution to the stabilization of the antiferromagnetic interaction.

However, these interesting physical properties may not be restricted to Würster's salts, but may be regarded as of the nature of ion (cation and anion) radical salts. In ion radical salts, the unpaired electrons play a predominant role in causing these properties. Along this line, measurements of the magnetic susceptibility and ESR have been powerful tools for clarifying the solid-state interactions among unpaired electrons.[2-8] However, the study of the crystalline electronic spectra may still provide us with useful information concerning these interaction mechanisms. With this hope, we will deal with the anion radical salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ).[9] TCNQ is a well-known strong electron acceptor which forms stable crystalline anion radical "simple" salts of the M^+ $TCNQ^-$ type and new classes of "complex" salts of $(M^+)_2(TCNQ)_3^{--}$ and $M^+(TCNQ)_2^-$, which contain the formally neutral TCNQ and the anion radical $TCNQ^-$. The advantage in dealing with TCNQ salts is that their salts are easily obtained as stable single crystals and that, consequently, their electrical and magnetic properties have been extensively studied.[5-11] Thus, their crystalline electronic spectra can be studied in connection with these properties. The purpose of the present paper is to clarify the crystalline electronic spectra of TCNQ anion radical simple salts by means of diffuse reflectance and to discuss the solid-state interactions among unpaired electrons.

Experimental

Materials. The ten TCNQ simple salts under investigation are Li^+TCNQ^-, Na^+TCNQ^-, K^+TCNQ^-, NH_4^+ $TCNQ^-$, Triethylammonium$^+$ $TCNQ^-$, Methyltriphenylphosphonium$^+TCNQ^-$, Methyltriphenylarsonium$^+TCNQ^-$, Morpholinium$^+TCNQ^-$, *N*-Methylquinolinium$^+TCNQ^-$, and *N*-Methylphenazinium$^+TCNQ^-$.

Li^+TCNQ^-, Na^+TCNQ^-, K^+TCNQ^-, NH_4^+ $TCNQ^-$, and Morpholinium$^+TCNQ^-$ were prepared

by a direct reaction between TCNQ and the iodides in acetonitrile.[9] The other compounds were prepared by the metatheses of the corresponding cation sources with Li^+TCNQ^-.[9,11]

Measurements. The electronic absorption spectra in acetonitrile were measured in concentrations of the order of 10^{-5} mol/*l* at room temperature, using a Beckman DK-2A spectrometer.

The crystalline electronic spectra were measured in the range between 4.0 and 30.8 kK by means of diffuse reflectance at room temperature. The electronic absorption spectra were reproduced employing the Kubelka-Munk function $f(R)=(1-R)^2/2R$, where R is the reflectance. The experimental details are the same as those described in a previous paper.[1] Potassium bromide, sodium chloride, and naphthalene were used as solid diluents and also as references.

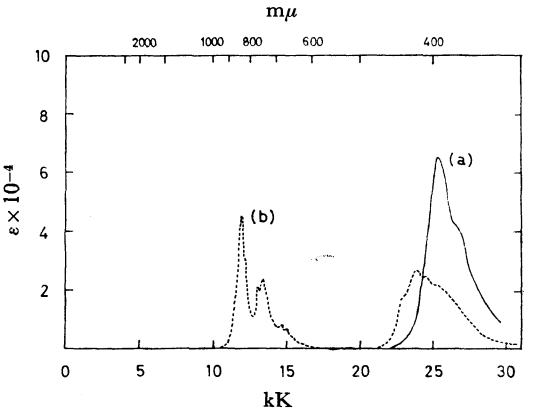

Fig. 1. Absorption spectra of TCNQ (Curve a) and K^+TCNQ^- (Curve b) in acetonitrile solution.

Results and Discussion

The absorption spectra of neutral TCNQ and anion radical $TCNQ^-$ in acetonitrile are illustrated in Fig. 1, Curve a and Curve b respectively. The absorption spectrum of TCNQ has a peak at 25.3 kK with a molar extinction coefficient (ε) of 65000, while that of $TCNQ^-$ shows $\varepsilon=21500$ at 25.3 kK and $\varepsilon=45000$ at 11.9 kK. The natures of these absorption bands have been investigated by Lowitz by the molecular orbital method.[12] The reversible dimerization of $TCNQ^-$ in an aqueous solution has been noted by Boyd and Phillips.[13] According to them, the dimer spectrum exhibits new absorption peaks around 15.6 and 27.0 kK.

In discussing the experimental results, the crystalline $TCNQ^-$ simple salts can be divided into two classes: those with low electrical conductivity and those with high conductivity.[10] These two classes are not well-defined, but this classification facilitates the presentation of the results and the discussion.

Low-conductivity Compounds. All of the simple salts except the *N*-methylphenazinium salt belong to this group. These compounds have conductivities of 10^{-4} $\Omega^{-1}cm^{-1}$ or less and activation energies as high as 0.3 eV.[9,10] As for the magnetic properties, they are diamagnetic at low temperatures, and at higher temperatures are still diamagnetic or exhibit a small paramagnetic contribution to the susceptibility, which increases with an increase in the temperature. This phenomenon has been tentatively interpreted in terms of a ground singlet and an excited triplet equilibrium with a relatively high energy separation.[8] If this is the case, the weak paramagnetic contribution is due to the population in the thermally-accessible triplet state. The paramagnetic contribution (χ) to the susceptibility is written as:

$$\chi = \frac{2\mathcal{N}g^2\beta^2}{kT[3+\exp(J/kT)]} \qquad (1)$$

where $\mathcal{N}$ is the number of spin-coupled pairs and J, the singlet-triplet energy separation.

In the following paragraphs, the results of experiments on sample low-conductivity compounds will be presented and discussed.

K^+TCNQ^-. According to Anderson and Fritchie,[14] this salt crystallizes in a monoclinic system. The crystal structure consists of columns of $TCNQ^-$ with face-to-face stacking parallel to the *a* axis; the molecular axes normal to the molecular plane nearly coincide with the column axis. It is not clear whether or not there is an alternation in the inter-radical spacings within the column. Unless one assumes such an alternation, the inter-radical spacing is 3.4—3.5 Å.

The absorption spectrum in acetonitrile has already been illustrated in Fig. 1, Curve b. The crystalline spectrum (Fig. 2, Curve a) shows a similarity to that of the $TCNQ^-$ dimer in an aqueous solution.[13] The crystalline spectrum has peaks at 8.5, 16.4, and 27.8 kK. The latter two peaks almost agree with the 15.6 and 27.0 kK peaks respectively in the dimer spectrum. The nature of these bands in the solid state is not clear, but the bands should be assigned to the shifted bands of the $TCNQ^-$ monomer. The low-energy band at 8.5 kK observed in the solid state should correspond to the charge-transfer transition between the anion radicals. If this is the case, its electronic transiton will be allowed with the polarization out

of the molecular plane (*i. e.*, along the *a* crystal axis). Anderson and Fritchie have confirmed this prediction experimentally using a near-normal incident reflection.[14] The corresponding charge-transfer band of the dimer in the solution has not yet been obtained, presumably because of the absorption of the solvent. The present question is whether the system of the linear chain column of $TCNQ^-$ with molecular spacing as relatively long, as 3.4—3.5 Å should exhibit a spectral resemblance to the dimer. The electronic state of the isolated ion radical dimer has been examined by Hausser and Murrell.[15] If the spacings are strongly alternate in such a solid, the electronic state might appear to be similar to that in the dimer. However, even if we accept the assumption, the charge-transfer energy in such an ionic crystal should be appreciably different from that in an isolated dimer. Accordingly, the charge-transfer band observed at 8.5 kK is regarded as "crystalline." Nevertheless, because of the experimental similarity of the crystalline spectrum to that of the dimer in the region of high-energy bands, it must be emphasized that all the crystalline electronic state except for the charge-transfer process may be described approximately in terms of the dimer. The approximation might become probable by assuming one of the two possibilities, namely, that ion radicals are equally spaced and weakly coupled with two neighbors each or that ion radicals are alternatingly spaced and rather strongly coupled with one neighbor each. That the molecular spacing, 3.4—3.5 Å, in the case of equally-spaced ion radicals is regarded as relatively long compared with that of a high-conductivity compound (see below) affords evidence for the "weakly-coupled" nature in the former case. The finding that this salt has a low electrical conductivity and a high activation energy[10] supports both possibilities. On the other hand, its almost diamagnetic susceptibility (-1.3×10^{-4} emu/mol at 300°K)[16] has been tentatively described by Eq. (1) with $J\sim0.2$ eV.[8] This description may imply a strong alternation in $TCNQ^-$ stacking, which will support the latter assumption. Under these circumstances, further, detailed study of the crystal structure analysis is necessary to distinguish these two possibilities. At any rate, at the present time, its magnetic property is regarded as based on a non-alternating or alternating linear-chain Heisenberg antiferromagnet, which should produce its almost diamagnetic susceptibility, as is almost the case with certain Würster's salts.[1] Again in TCNQ salts, the contribution of the charge-transfer interaction to the antiferromagnetic interaction is important.

Morpholinium$^+$ TCNQ$^-$. According to Maréchal and McConnell,[17] this substance crystallizes with triclinic symmetry. Its absorption spectrum in acetonitrile is the same as that of the potassium salt. The crystalline spectrum (Fig. 2, Curve b) also exhibits a similarity to that of the dimer. The band peaks are located at 9.5, 16.3, and 27.7 kK. The band at 9.5 kK corresponds to the charge-transfer transition. The latter two bands should be identified as shifted bands of the $TCNQ^-$ monomer.

Here, in this salt, the magnetic property has been well described by Eq. (1) with $J=0.41$ eV.[5] The triplet-state spin-Hamiltonian is written as:

$$\mathcal{H} = \beta \boldsymbol{H}\cdot g\cdot \boldsymbol{S} + DS_z^2 + E(S_x^2 - S_y^2) \qquad (2)$$

where D and E are zero-field splitting parameters. It has been found by ESR study[17] that the z and x axes of the fine-structure Hamiltonian are approximately coincident with the (111) and ($1\bar{1}0$) axes respectively. Here, one assumes a $TCNQ^-$ dimer with a D_{2h} symmetry of face-to-face stacking, where the z and x axes are normal to and along the short axis of the molecules respectively. Theoretical values of D and E can be calculated approximately in terms of magnetic dipole-dipole interaction between unpaired electrons in the dimer. If one uses the spin densities of free $TCNQ^-$ given by Rieger and Fraenkel[18] and the molecular structure given by Hanson,[19] the D and E *versus* inter-planar spacing (z) of the dimer shown in Fig. 3 can be obtained.*2 In order to coincide with the experimental results of $|D|_{obs}=450.2\pm0.4$ and $|E|_{obs}=$

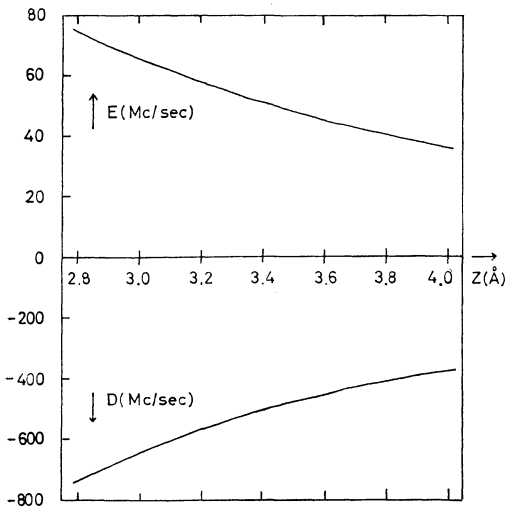

Fig. 3. Calculated zero-field splitting parameters (D and E) in the triplet state of $TCNQ^-$ dimer in Eq. (2) *versus* intermolecular spacing (z).

53.82±0.12 Mc/sec by Marechal and McConnell,[17] z should be 3.4—3.5 Å. Although the crystal structure is not yet available in detail, the estimated value of z is quite reasonable compared to the 3.4—3.5 Å in the potassium salt. Therefore, it may be concluded that $TCNQ^-$ molecules in the morpholinium salt pair up to produce a dimer with an almost D_{2h} symmetry. Its crystalline spectrum supports this conclusion.

Although there exists a rough resemblance of the crystalline spectra and even an exact agreement in high-energy bands between the potassium and the morpholinium salts, their low-energy charge-transfer band peaks show a shift of 1.0 kK; this shift is considered to be due to the difference in the modes of $TCNQ^-$ stacking and/or to that in the sizes of the cations between these two salts. In addition, the finding of a remarkable difference in their electrical conductivities at 23°C between the potassium salt (1×10^{-4} $\Omega^{-1}cm^{-1}$)[10] and the morpholinium salt (1×10^{-9} $\Omega^{-1}cm^{-1}$)[10] may also indicate the importance of the difference in $TCNQ^-$ stacking modes between them.

In connection with the calculations of D and E, it should be mentioned that the lowest triplet wave-function cannot be mixed theoretically with the charge-transfer configuration conceived, because the charge-transfer configuration is a singlet and mixing is forbidden by the spin multiplicity. Thus, the triplet state is probably repulsive.[15] This concept implies that the spin densities in the triplet state of the dimer may be approximately described in terms of the individual doublet spin densities. This speculation is strongly supported by the finding that the observed D and E values in the triplet state are well represented by the magnetic dipole-dipole interaction between a pair of anion radicals with doublet spin densities.

The Other Compounds. All of the other compounds with low conductivity exhibit, more or less, a spectral resemblance to the spectra of the potassium or the morpholinium salt. The three band peaks of their crystalline spectra listed in Table 1 are designated as CT-, α-, and β-bands in the order of increasing energy. Apparently, the locations of the corresponding bands, especially the low-energy charge-transfer (CT) bands, in these compounds depend on the kind of cation. The main reason for the band shifts is also the difference in the modes of $TCNQ^-$ stacking in the crystal and/or that in the sizes of the cations. Nonetheless, all of them have relatively weak interactions among unpaired electrons, producing the rough resemblance of the spectra to that of the dimer.

Table 1. The data for three band peaks in the crystalline electronic spectra of the low-conductivity compounds

Compound	CT-Band (kK)	α-Band (kK)	β-Band (kK)

$NH_4^+TCNQ^-$	8.9	16.3	27.8
Triethylammonium$^+$ $TCNQ^-$	8.7	16.4	27.6
Methyltriphenyl-phosphonium$^+TCNQ^-$	10.3	15.3	26.7
Methyltriphenyl-arsonium$^+TCNQ^-$	10.3	15.2	26.3
Morpholinium$^+TCNQ^-$	9.5	16.3	27.7
N-Methylquinolinium$^+$ $TCNQ^-$	9.4	16.1	27.0

In Li^+TCNQ^- the slight but distinct peak at 11.9 kK in the crystalline spectrum (Fig. 2, Curve c) must be noted. It probably arises from the $TCNQ^-$ monomer in some kinds of defects, because in this salt an appreciable ionic conduction, presumably due to the defect, has been found to contribute to its electrical conductivity.[20]

High-conductivity Compound. *N*-Methylphenazinium$^+$ $TCNQ^-$ is the only example exhibiting an electrical conductivity as high as $1.4\times10^2\Omega^{-1}cm^{-1}$. According to Fritchie,[21] it crystallizes as blue-black needles with triclinic symmetry. $TCNQ^-$ molecules form a charge-transfer-bonded, regular, linear chain column parallel to the a crystal axis, with interplanar spacing of 3.26 Å and without any interplanar distance alternation. It is noteworthy that this interplanar spacing is relatively short compared with the 3.4—3.5 Å in the low-conductivity compounds.

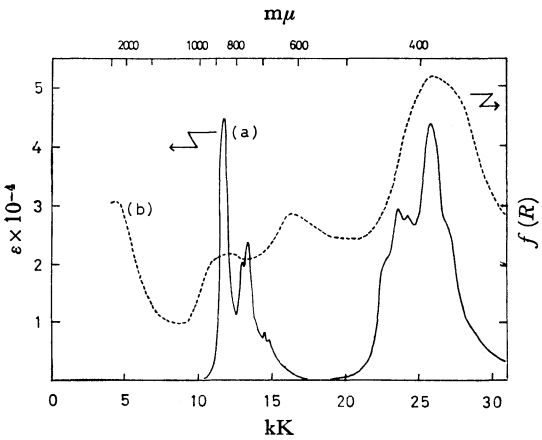

Fig. 4. Absorption spectrum in acetonitrile solution (Curve a) and crystalline electronic spectrum (Curve b) of *N*-Methylphenazinium$^+$ TCNQ$^-$.

The absorption spectrum of the *N*-methylphenazinium salt in acetonitrile, shown in Fig. 4, Curve a, is essentially the same as that of the potassium salt, with the addition of the cation spectrum peak at 25.8 kK. The crystalline spectrum, shown in Fig. 4, Curve b, has peaks at 4.3, 11.8, 16.4, and 25.8 kK. In the previous section the low-conductivity compounds have been found to exhibit approximately the dimer spectrum, whereas the spectrum of the *N*-methylphenazinium salt bears no resemblance to those of the low-conductivity compounds. This must be due to the difference in the manners of TCNQ$^-$ intermolecular interactions in the solid state. It has been demonstrated that some Würster's salts with more-than-pairwise and strong intermolecular interaction exhibit spectra different from either the monomer or dimer spectrum and extending to the lower-energy region.[1] Furthermore, Würster's red bromide has two charge-transfer bands in the low-energy region.[1] Being similar to these salts, the *N*-methylphenazinium salt is characterized by a "strongly-coupled" linear chain system, in which the lowest-energy band observed, at 4.3 kK, may be regarded as an inter-radical charge-transfer absorption. There is a possibility that the band at 11.8 kK is due to the second charge-transfer band or to the shifted band of the TCNQ$^-$ monomer; this point, not yet clear, may be distinguished by means of the polarized spectrum. Although the natures of the bands at 16.4 and 25.8 kK may be similar to those of the α- and β-bands in the low-conductivity compounds respectively, the band at 25.8 kK should comprise that of the cation spectrum, too. However, it must be noted that the elctronic absorption bands in the *N*-methylphenazinium salt are appreciably diffused and continuously overlap with each other. In addition, the facts that the *N*-methylphenazinium salt is the most highly electrically conductive organic compound[11] and that the ions are arranged as a "strongly-coupled" linear chain[21] would imply the delocalization of the unpaired electrons, probably leading to the establishment of a band model for the electrical conduction. It is likely that the lowest-energy band, at 4.3 kK, identified as an inter-radical charge-transfer band, may be associated with the transition from the valence band to the conduction band.[22] Although further work is necessary to explain the relation fully, this speculation is supported by the finding that highly conductive "complex" salts of TCNQ also show a strong low-energy band with an absorption peak around 2—3 kK (see Ref. 23).

Summary

We have divided TCNQ$^-$ simple salts into low- and high-conductivity compounds.

Although the mode of TCNQ$^-$ stacking in the low-conductivity compounds is the dimer (*e. g.*, the morpholinium salt) or the infinite linear chain with equally-spaced ion radicals (*e g.*, one with the assumed model for the potassium salt), the molecular spacings are regarded as being as large as 3.4—3.5 Å in these systems. This gives rise to a relatively small overlap integral of unpaired-electron molecular orbitals between the nearest-neighbor ion radicals. Their crystalline spectra resemble that of the dimer in an aqueous solution, exhibiting the charge-transfer band around 9 kK. Charge-transfer interaction should contribute significantly to the stabilization of antiferromagnetic interaction, resulting in their almost diamagnetic susceptibilities and, in some cases, a singlet-triplet equilibrium for the dimer. The relatively small overlap integral still produces their low electrical conductivities and high activation energies. The relations between the overlap integral and these physical properties remain to be elucidated.

The mode of TCNQ$^-$ stacking in the *N*-methylphenazinium salt is an infinite linear chain column with molecular spacing as little as 3.26 Å. Therefore, the overlap integral of unpaired-electron molecular orbitals is regarded as large. The crystalline spectrum bears no resemblance to those of the low-conductivity compounds and has a low-energy charge-transfer band at 4.3 kK; the reason for this is probably related to its unusually high electrical conductivity.

The author would like to express his appreciation to Professor Yoshio Matsunaga for his generous support to this work and to Mr. Nobuhiko Miyajima for his technical assistance.

Electronic Structure of Lone Pairs. I. Azine Compounds and Quinones*1

Teijiro YONEZAWA, Hiroko YAMABE and Hiroshi KATO

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received June 6, 1968)

Molecular orbital investigations of the electronic structures of lone pairs of some azine compounds and quinones are carried out by the Hückel method and the extended Hückel method for σ and π electron systems. The delocalization and the s–p mixing of lone pairs are investigated. Qualitative discussions of the splitting of the lone-pair levels and the calculated n–π^* transitions of these compounds are made. It is revealed that the Hückel method, which does not include direct interactions, gives an incorrect prediction for the symmetry of the energy levels of pyridazine. After comparative discussions, it is concluded that the lone paris couple with each other directly "through-space" as well as "through-bond."

Many theoretical investigations[1] of the electronic structures of such azine compounds as pyridine, diazines and triazine have been carried out in order to discuss the n–π^* transitions in these compounds.

Since the theoretical procedure for treating the lone pair has never been settled, there exist few theoretical approaches to the problems of the delocalization of the lone pair, its hybridization, and the mode of interaction between two lone pairs in a molecule.

Recently, however, Hoffmann[2] proposed an extended Hückel calculation in which all the valence electrons were taken into account and established the delocalization of the lone pair whose 2s character is less than 10%.

These conclusions were further confirmed by Lipscomb[3] and his co-workers on the basis of a more rigorous SCF MO treatment. They concluded that an accurate quantitative work should take into account the appreciable amount of delocalization and the smaller 2s participation of the nitrogen lone pair than one would predict on the basis of an sp^2 hybridization.

In the present paper, we make use mainly of two alternative MO methods in order to investigate the problems stated above in azine compounds and some quinones. The first method is the Hückel treatment for σ electronic systems proposed by Sandorfy and Yosizumi[4] and developed by some of the present authors.[5] This will be abbreviated hereafter to as the H method. Since the resonance integrals between non-adjacent AO's are neglected, this method may be considered to treat the delocalized lone pair with the through-bond interaction.*2 The second method is the extended Hückel method, to be referred to as the E-H method. This method is suitable for discussing the electronic structure of two lone-pair couplings, "through-bond" as well as "through-space."*2

By comparative discussions, the following conclusions are obtained. The delocalization of lone-pair electrons and the appropriate mutual interaction between them must be taken into account in arriving at a better interpretation of the n–π^* transitions.

The electron distribution and the splitting of the lone-pair levels due to mutual interaction as calculated by the Hückel method for σ electron systems seems to be adequate. However, as the direct interaction (through-space interaction) of the lone pair is not taken into account in this method, it gives an incorrect prediction for the symmetry of the energy levels, as in the case of pyridazine. Therefore, for a more accurate discussion of, for instance, the 2s participation in the lone pair and the interaction of two separate lone pairs, it seems better to use the extended Hückel method.

Theoretical

The parameters used in the Hückel method for σ electron systems are tabulated in Table 1.

Table 1. Parameters in Hückel calculation for σ electron systems

Coulomb integrals for σ system		Resonance integrals for σ systems	
C (sp^2)	α	C–C	β
N (sp^2)	$\alpha+0.2\beta$	C (sp^2)	0.38β*
H	$\alpha-0.2\beta$	C–N	β
O	$\alpha+0.3\beta$	N–N	β
		N (sp^2)	0.4β*
		C–H	0.94β
		C–O	1.2β
		O	0.3β*

* Resonance integrals between two σ orbitals belonging to the same atom.

The resonance integrals between non adjacent AO's are ignored, as is usual with the Hückel method.[5] In the extended Hückel calculations, the resonance integral, H_{rs}, is evaluated by $H_{rs}=\frac{K}{2}S_{rs}(H_{rr}+H_{ss})$, putting $K=1.75$, where S_{rs} is the overlap integral between the atomic orbitals, χ_r and χ_s. The Coulomb integral, H_{rr}, for which the valence state ionization potential is usually used, is modified to improve the overestimated electron distribution in this calculation and to obtain a more reasonable energy for the lone-pair orbital. For this purpose, we refer to the results of the application of the ω_A-technique[6] in the extended Hückel method. These H_{rr} values are listed in Table 2. The bond lengths and angles employed are shown in Fig. 1. These values are

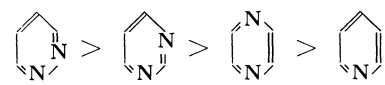
Results and Discussion

Delocalization of Lone Pair. Since the Hückel calculation needs the values of the hybridization of constituent atoms in order to estimate the Coulomb and resonance integrals of a lone-pair AO, an sp^2 hybridization for the nitrogen atom in azine compounds is assumed.

It may be noted that, in the Hückel calculation, the highest occupied σ orbitals in azine compounds are, without exception, remarkably localized on the lone-pair AO of the nitrogen atom. These MO's will be referred as lone-pair MO's hereafter in the present paper.

The electron distributions of these lone-pair MO's as obtained by the Hückel calculation are given in Fig. 2. For the diazines, the distribution is obtained by summing two lone-pair MO's, the highest occupied MO and the next highest occupied MO. For triazine and tetrazine, three and four lone-pair MO's are summed respectively. In view of the partial electron density at the lone-pair AO, about 80%—90% of the lone-pair electrons are localized on that orbital and the electron density increases with a decrease in the distance between nitrogen atoms in diazine compounds. It can also be seen that these partial electron densities run parallel with the observed pK values[8] and also with the blue shifts of the n–π* bands,[8] accompanied by the change in solvent from cyclohexane to an aqueous solution except in the case of pyridine.

Figure 3 lists the total σ electron densities obtained by the Hückel calculation in these compounds. These electron distributions may also indicate the extent of lone-pair delocalization. Namely, the total electron density at the lone-pair AO is always less than 2, and about a 20%—30% delocalization of lone-pair electrons is observed. The total electron densities of the lone-pair AO in four heteroaromatic compounds decrease in the order:



This order is parallel with the order obtained by the partial electron densities of the lone-pair MO.

Next, for the sake of comparison, let us discuss the electron distribution of the azine compounds obtained by the extended Hückel calculation. The atomic population and the atomic orbital population of lone-pair MO's at the nitrogen atom are shown in Table 3, together with the values obtained by the Hückel calculation.

There exists a definite parallelism between the π-electron densities of the nitrogen atom obtained by the Hückel calculation and the atomic orbital populations of the p_z orbital of the nitrogen atoms in azine compounds. Namely, they decrease in the order:

s-Tetrazine	1.4729	0.9315	1.7401	0.8773	5.0218	5.1158	3.9715	1.1443

* q^{π}; Total π electron density of the nitrogen atom N.

$\sum_r^{\text{on N}} q_r^{\sigma}$; Summation of the σ electron density of AO's belonging to the nitrogen atom

$$\sum_r^{\text{on N}} q_r = q_r^{\pi} + q_r^{\sigma}$$

An agreement is also observed between the atom population and the total density obtained by summing all the σ electron densities and the π electron density around the nitrogen atom in the Hückel calculation.

However, it should be noted that the parallelism between the sum of the AO populations of s, p_x, and p_y and the summed σ electron density around the nitrogen atom, $\sum_r^{\text{on N}} q_r^{\sigma}$, obtained by the H-method does not hold.

Electron Distribution of Some Quinones. The lone-pair electron densities of *p*- and *o*-benzoquinones, 1,4-naphthoquinone, and 9,10-anthraquinone have been calculated by the H method and E-H method. In the H calculation a lone pair of the 2p type is assumed on the oxygen atom.[*3] The highest occupied and the next highest occupied σ orbitals obtained are considerably localized on the lone-pair AO of the oxygen atom of these quinones.

The total and partial lone-pair electron densities on the oxygen atoms of quinones are shown in Fig. 4. The partial electron densities in the lone-pair MO's are shown by the parentheses. About 98% of the lone-pair electrons are localized on the lone-pair AO of the oxygen atom; this magnitude is larger than that of the nitrogen atom of azines.

Both the total and partial electron densities at

*3 This assumption is made with reference to the conclusion on the s nature of the lone-pair orbital at the oxygen atom to be presented below.

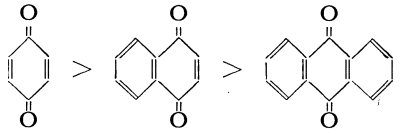
the lone-pair AO of the oxygen atom decrease in the order:



Moreover, the electron density at the lone-pair AO runs parallel with the observed pK values[9] cited in Fig. 4 for *p*-benzoquinone and 1,4-naphthoquinone.

The electron distributions of these compounds as obtained by the H and E-H calculations are given in Table 4 In the E-H calculation, the highest and next highest occupied σ orbitals of the quinones are lone-pair MO's, as in the H calculation. The atomic orbital populations of p_x and $s+p_x$ of the oxygen atom, which would correspond to the population of the lone-pair AO, increase in an order reverse to that of the H calculation.

However, a parallelism is observed between the π-electron densities of the oxygen atom of quinones obtained by the H calculation for π electron systems and the AO population of p_z of the oxygen atom obtained by the E-H calculation. Furthermore, in the 6th and 7th columns, there is a parallelism between the atom population obtained by the E-H calculation and the total density obtained by summing all the σ and π electron densities around the oxygen atom in the H calculation.

2s Participation in the Lone-pair MO. Since the hybridizations of the atoms are assumed *a priori*, the Hückel calculation is not applicable to a discussion of the s contribution of the nitrogen atom to the lone-pair orbital. Hence, the extended Hückel treatment is adopted for investigating the hybridizations of the nitrogen and oxygen atoms. The molecular orbital coefficients of the lone-pair MO's of pyrazine and *p*-benzoquinone are listed in Table 5.

In pyrazine, the lone-pair MO's consist of only 2s and $2p_y$ AO's of the nitrogen atom. This indicates that the nitrogen atom has a sp^n-type hybridization. On the other hand, in the lone-pair MO's of *p*-benzoquinone, only the $2p_x$ orbital of the oxygen atom is involved in the highest and the next highest occupied MO's. Therefore, the lone pairs of the diazine and *p*-benzoquinone may be referred to as a hybridized-type and a *p*-type lone pair respectively. Hence, it can be pointed out that the lone pairs of azine compounds, ammonia, and hydrogen cyanide belong to the former type, while those of aldehydes, quinones, and alcoholes belong to the latter type.

To estimate the s character of these compounds, the oscillator strength of n-π^* transition, which depends mainly on the s character of the lone pair is calculated.

9) M. E. Peover, *J. Chem. Soc.*, **1962**, 4540.

Some of the oscillator strengths calculated by the three different methods are listed in Table 6. In the table, the values in the last column are the results obtained by combining the ordinary Hückel procedure for π electrons with the Hückel treatment based upon a completely-localized sp^2 hybridized lone-pair model. The results are in a poor agreement with the experimental results, so further improvement is required to make a quantitative discussion. However, it may be generally remarked that the results calculated by three methods decrease in the order:

$$\text{HD method} > \text{H method} > \text{E-H method}$$

This order is parallel with the decrease in the s contribution of the lone pair in the three methods and also with the increase in the delocalization of lone-pair electrons.

In these circumstances, it can easily be understood that, since the magnitude of the oscillator strength depends on the 2s contribution, the n-π^* transitions due to the pure p-type lone pair has an approximately zero or a very small oscillator strength, in accordance with the experimental results.*4

Interaction between Lone Pairs. In the molecules in which more than two lone-pair AO's are involved, the interaction between these lone-pair AO's should be taken into account. The mode of the interaction between two lone-pair AO's has, however, never been studied comprehensively. In the present paper this problem is studied by the three different methods described above.

The characteristics of the three methods are illustrated in Fig. 5. In the HD method, only the direct interaction of the lone pair is considered, as it is based upon the localized model. In the Hückel approach, only the through-bond interaction is taken into account. In the extended Hückel method, however, both interactions, through bond and through space (direct), are considered.

An energy-level diagram of the lone pair as determined by the H calculation is shown in Fig. 6. In the figure, the orbital symmetries, the observed n-π^* transition energies[8] (in cm^{-1}), the splitting of the lone-pair levels as estimated by Mason[8] (written in parentheses in cm^{-1}), and the observed ionization potentials[10] are cited. The Hückel approximation does not include electronic interactions explicity; therefore, only a qualitative discussion is possible. For diazines a rough linear

*4 Nagakura (*Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **74**, 499 (1953)) and Sidman (*J. Am. Chem. Soc.*, **78**, 2363, 4567 (1956)) reported values of 10—100 for the molar extinction coefficient of the n-π^* transitions of *o*- and *p*-benzoquinones, 1,4- and 1,2-naphthoquinones, and 9,10-anthraquinone.

relation is obtained between the highest occupied level and the ionization potential. From Fig. 6, it can be seen that the splitting of lone-pair levels becomes larger with a decrease in the mutual distance of two nitrogen atoms; this is in accordance with Mason's estimation.[8] These results suggest an interpretation of the long-wavelength n–π^* band. In the case of pyridazine, however, the symmetry of the two lone-pair orbitals is inverse to the experimental suggestion[8] that the highest occupied must be B_2, and the next one, A_1. This is probably because the allowed transition of pyridazine is $n(B_2) \rightarrow \pi^*(A_2)$ and because its absorption band is at the longest wavelength among these azines. This discrepancy seems to be a defect of the method, in which the direct interaction of the adjacent lone pairs of the nitrogen atom, which may have sizable overlaps,*5 is not taken into account. These circumstances are shown in Fig. 5. "Circle" denotes the agreement of the level sequence obtained by the experiment and by calculation, while "Cross" denotes their disagreement. In the E-H method the higher one is B_2, and the lower one is A_1, they agree with the experimental suggestions, in contrast to the results of H calculation. However, the trend of the splitting expected from the experiment, that is a small splitting for pyrazine, a large one for pyridazine, and an intermediate one for pyrimidine, can not be interpreted. The splittings calculated by the E-H method are pyrazine (1.38 eV), pyrimidine (0.63 eV), and pyridazine (0.66 eV). In the localized model, as is shown in Fig. 5, the higher one is B, the antibonding orbital of two lone pairs, and the lower one is A, the bonding orbital, for all the azines; these results contradict the experimental suggestions regarding pyrazine.*6

Summarizing these discussions, it may be concluded that the lone-pairs interact directly through space as well as through bond. When two lone pairs lie in close proximity to each other, as in pyridazine, the through-space interaction should not be neglected. On the other hand, when two lone pairs are separated by several bonds,

*5 It is estimated as 0.08β by the use of tables (R. S. Mulliken and C. A. Rieke, D. Orloff and H. Orloff, *J. Chem. Phys.*, **17**, 1248 (1949)) for the sp^2-type lone-pair orbitals of pyridazine.

*6 Mason mentioned (Ref. 8) in his localized model, in which the through-bond interaction is not considered, that the higher-energy lone-pair molecular orbital of pyrazine is b_{1u} in D_{2h} and that the lower one is a_g.

as in pyrazine, the through-bond interaction should not be neglected.

The Direct Interaction. In the preceding section we mentioned that the H method, which does not include direct interactions among lone-pair orbitals, gives incorrect level sequences for the symmetry of pyridazine. In order to test the effect of the direct interaction, we modified the H calculation by including that of the neighboring lone pairs of pyridazine. Though interactions among all the non-bonding orbitals should be taken into account, we picked up only one interaction, that between lone-pairs, as the most important direct interaction that affects the lone-pair levels. The calculated lone-pair levels of two methods are illustrated in Fig. 7. In method I, the direct interaction is not considered. In the method II, a direct interaction of 0.2β is assumed. It may be noted that the lower level of method I becomes the upper one of method II and coincides with the orbital sequence obtained by the E-H method, as had been anticipated. On the other hand, the sequence of the other occupied levels is not changed.

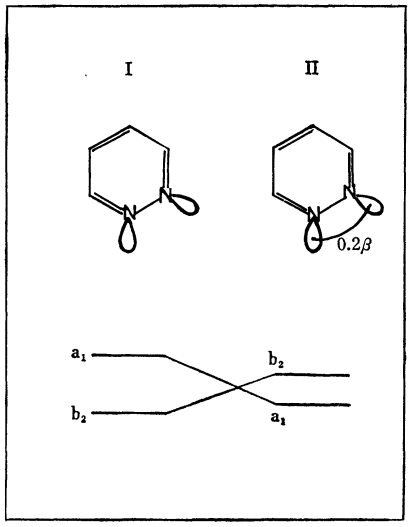

Fig. 7. Direct interaction of lone-pairs of pyridazine.

The electron distribution of method II is shown in Fig. 8. When it is compared with the electron distribution of method I in Fig. 3, it is noted that the value, 1.7910, of the lone-pair electron density in Fig. 8. deviates conspicuously from the value in the series of diazines shown in Fig. 3. When the direct interaction of lone pairs is included, the Coulomb and resonance integrals should be evaluated newly, taking into account the main direct interactions among orbitals other than lone pairs.

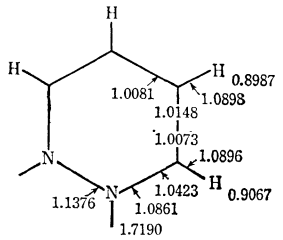

Fig. 8. Total σ electron density of pyridazine in including the direct interaction of 0.2β.

The calculations have been carried out on an IBM 7090 computer at the Japan IBM CO., with the permission of the UNICON committee, and on an HITAC 5020 computer at the Computation Center of the University of Tokyo.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 84—91 (1969)

Thermodynamic Properties of Neopentane from 4°K to the Melting Point and Comparison with Spectroscopic Data*1

Hisae ENOKIDO,*2 Takako SHINODA and Yo-ichiro MASHIKO

Government Chemical Industrial Research Institute, Tokyo, Shibuya-ku, Tokyo

(Received June 4, 1968)

Heat capacities, latent heats and vapor pressures of solid and liquid neopentane were measured and the following values were obtained; heat of transition = 628.7±0.3 cal/mol, T(trans. pt.) = 140.498±0.05°K, heat of fusion = 740.0±0.3 cal/mol, T(triple pt.) = 256.750°K, and P(triple pt.) = 268.47±0.13 Torr. The amount of impurity in the sample after purification was estimated from a plot of the equilibrium temperature against the reciprocal of the fraction melted. From the result the impurity present was found to be 0.003_2 mol%. Despite of high purity, C_p value in the region below the melting point increases unexpectedly with temperature. This is interpreted as an effect of formation of vacancies in the crystals. The enthalpy required to form vacancies was estimated to be 3240±220 cal/mol from the analysis of the heat capacity curve in the region below the melting point. The molal entropy of the ideal gas at the boiling point, calculated from the calorimetric data, was 71.24±0.3 *e. u.* To bring this value into agreement with the value calculated from the infrared and Raman frequencies and the moments of inertia, requires the assumption of three equal potential energy maxima of 4.4 kcal/mol for hindered internal rotation of the methyl groups.

Non-polar tetrahedral molecules are grouped into two classes: one which undergoes phase transition in the solid state, and the other which does not.[1] Probably, this can be mainly accounted for by interaction between molecular octupoles. We have treated neopentane first in a series of structural thermodynamic studies of tetrahedral molecular crystals.

Neopentane crystal is known to have a transition below its melting point, which was confirmed from the measurement of heat capacity by Aston *et al.*[2] Also X-ray structural study of neopentane crystal[3] shows that its unit cell is face-centered cubic with four molecules at −50±5°C, and tetragonal at −150±5°C. But no information about the orientations of the molecular axes in the unit cell is given yet. Aston *et al.* measured heat capacity of neopentane from 13.22°K to the boiling point, the amount of impurity in their specimen used being 0.727 mol%. And the premelting phenomenon observed was ascribed to the impurities involved in the specimen.

The present paper will describe some results of the measurement of the thermodynamic properties of highly purified neopentane from 4 to 260°K.

The heat capacity curve in the region below the melting point was analyzed so as to study the premelting phenomenon of neopentane crystal. And a comparison of the entropy calculated from spectroscopic data with calorimetric data was made based on the third law of thermodynamics.

Experimental

Material. A chemically pure-grade reagent neopentane obtained from Philips Co., Ltd. (purity; 99.52 mol%[4]) was further purified by means of the "Spinning band fractional distillation column" SB618 (effective height of column is 3 m and the number of theoretical plates is 180) developed by Tokyo Kagaku Seiki Co., Ltd. and a Molecular Sieve 5A adsorption column. The resulting material was twice distilled, at dry ice temperature, through pyrex glass fractionating bulb A (Fig. 1), in which fractionation could be carried out in the absence of air in a vacuum system. The middle fraction was collected in the sample bulb B with a cock connected to the vacuum line by a pyrex glass joint. This sample was cooled to liquid nitrogen temperature and pumped out to less than 5×10^{-4} Torr, melted, cooled again and repumped to remove the trace of air from the sample. The cock attached to the sample bulb was closed and the weight of the sample together with the bulb was measured. For introduction of the sample into the calorimeter, the sample bulb

weighed was attached again to the filling line which was evacuated to less than 10^{-5} Torr. After condensing the neopentane into the calorimeter vessel, the neopentane left in the vacuum line was collected in the sample bulb cooled to liquid nitrogen temperature and weighed together with the bulb. The weight of the actual specimen was estimated by subtracting the leavings from the weight measured first. A schematic diagram of the calorimeter filling system which attaches to the vapor pressure measurement and purification apparatus is shown in Fig. 1. As grease of cock a particular 'Phynal' which is soluble in water was employed instead of silicone grease, since the latter is

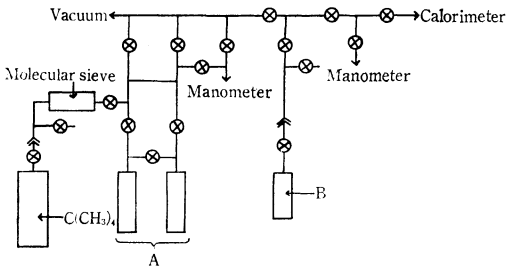

Fig. 1. Schematic diagram of the calorimeter filling system which attaches to the vapor pressure measurement and purification apparatus.

dissolved by hydrocarbon liquid and vapor.

The amount of impurity in the specimen was determined from measurements of the melting point range.

Apparatus. The cryostat and the calorimeter vessel were the same as described previously.[5] The heat input and the resistances of the thermometers were recorded on a Hitachi recorder and a Rubicon six-dial double microvolt potentiometer as a function of time, respectively. The monitoring and control of the adiabatic conditions were automatically made. For this purpose, the highly sensitive *d. c.* amplifier which was possible to detect $\pm 2 \times 10^{-9}$ V was designed and constructed. When the thermocouple signaled, the current in the heater circuit was regulated so as to be proportional to the temperature difference between the calorimeter and the adiabatic shield. All adjusting operations of the intercept and slope of the proportion were carried out according to the conditions of measurement. These adiabatic controls were separately adjusted in three parts of the shield. The controlling operations for measurement below 15°K were carried out manually, since the temperature difference thermocouple tended to lose its sensitivity rapidly at low temperatures.

The working thermometer for $T<13.5$°K was a germanium resistor (Minneapolis-Honeywell Reg. Co.) calibrated by thermodynamic temperature scale. We shall describe below the procedure by which the temperature scales were fixed.

Measurement for the calibration was reported previously.[5] Recently Plumb *et al.*[6] attempted to fit the resistance-temperature data for germanium resistors to a polynomial of the form

$$\log_{10} R = \sum_{n=0}^{m} A_n (\log_{10} T)^n \qquad (1)$$

where the upper limit of m is varied from 3 to 8 depending on individual resistor. Owing to the difficulty of computation we attempted to find four formulas which would fit separately to the regions; 12.00—15.00°, 9.75—12.00°, 6.36—9.75° and 1.50—6.36°. The formulas are given in the following:

$$\log_{10} R = (-K)/(\log_{10} R) + A + (B/T'),$$
$$T - T' = a(T-b)(T-c)(T-d)(T-e) + f. \qquad (2)$$

Coefficients determined are given in Table 1. The deviations of the observed values from the calculated curve, by using the formulas Eq. (2) are within ±0.01° as shown in Fig. 2.

Table 1. Coefficients determined by fitting Eq. (1) to the calibration data of Ge-resistor

Results and Discussion

Heat Capacity of $C(CH_3)_4$. The calorimeter contained 7.4675 g (=0.10350 mol) in measurement series I and 14.4073 g (=0.19968 mol) in measurement series II. Series I and II were taken from separate filling from the same sample. The measured values of the heat capacity in the region of 4 to 260°K are listed in Table 2. The second virial coefficient of gaseous neopentane has not been determined experimentally below 300°K. Therefore its value at low temperatures was estimated by extrapolation of high temperature results using

the (7, 28) Lennard-Jones potential.[7] The heat capacity of gaseous neopentane used was those estimated from experimental equation obtained by Spencer *et al.*[8] The density taken for the liquid was given by Whitmore *et al.*,[9] and that for the solid was ascertained by the reference data of X-ray analysis.[3] The value of heat of vaporization was that obtained by Aston *et al.*[2] Corrections were made for curvature where necessary.

The results of measurements of the heat capacity are plotted in Fig. 3 along with those given by Aston *et al.*[2] Their results deviate considerably from ours, particularly in the ranges of melting point and transition point. This is probably due to the fact that the higher amount of impurity was involved in the specimen employed by them.

The time required for the calorimeter system to reach equilibrium after heating was a few seconds at $4<T<6$°K, a few minutes at $10<T<20$°K and about ten minutes at $T>60$°K. But in the middle point of the transition and the melting duration, the time for equilibration after heating became about an hour and 20—30 min, respectively.

The transition, the maximum of which is at 140.498 ± 0.05°K, should in principle be second-

order as was shown in Fig. 3, but actually nearly first-order. We observed no dependence of the heat capacity anomaly of the sample on its thermal history.

The Triple Point and Purity Determination. The equilibrium temperature and pressure of the system were observed during the fusion. The results are given in Table 3. The triple point of pure neopentane, given as 256.756°K, was estimated from a plot of the equilibrium temperature against the reciprocal of the fraction melted. The amount of impurity present in the specimen was also found to be 0.003_2 mol% from the plot.

The present result for the triple point temperature of neopentane deviates considerably from the other results except from that of Aston *et al.* as shown in Table 3. This is also interpreted as an effect induced by impurities.

The Heats of Fusion and of Transition. Two measurements of the heat of fusion are summarized in Table 4, and the average result is compared with that obtained by Aston *et al.* In spite of their correction for premelting, their average result deviates remarkably from the present result.

Aston *et al.* treated the abnormal rise in the heat capacity curve at about 140°K as an isothermal transition. However, we obtained that the transition may be in principle second-order type, with very high heat capacity (*i. e.* 34.58 cal/mol at 141.715°K) over a narrow temperature range. As to the heat of transition, two determinations of the heat supplied to the specimen in the region between 140 and 142°K were made, and the results are also given in Table 4. This average value is to be compared with the heat of transition of 615.9±0.6 cal/mol reported by Aston *et al.*

Heat Capacities in the Premelting Range. Using highly purified neopentane we reexamined the existence of premelting effect found by Aston *et al.* The measurements of the heat capacity in the vicinity of the melting point were made several times with various temperature rise (0.5—1°C) to determine the detailed shape of the heat capacity curve in this region. The result is plotted in Fig. 4, and analysed by ascribing to it several causes.

In the region far below the melting point the data of C_p (normal) can be expressed with sufficient accuracy in the form $A+BT$. Thus, we first attempted to find a formula which would fit to the observed values of heat capacity in the region from 195 to 215°K. The formula obtained is the following:

$$C_p(\text{normal}) = 14.369 + (0.068327)T, \qquad (3)$$

and the plots of C_p(normal) *versus* T as determined from the formula (3) in the region below the melting point are shown with small open circles connected with solid line in Fig. 4.

We, then, estimated[10] the effect on the heat capacity induced by impurities that we determined in the previous section, and the results are shown by the dashed curve in Fig. 4, which is still below the observed values.

We assumed finally, that the excess heat capacity

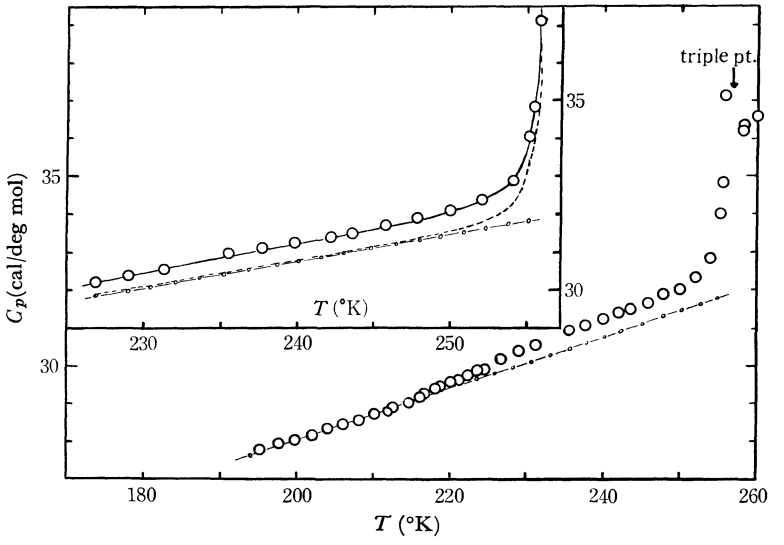

Fig. 4. Heat capacity in the premelting range.
○ : C_p(obs.)
———: C_p(normal) + C_p(impurity) + C_p(vac.)
—o—o—: C_p(normal) = 14.369 + 0.068327T
– – – –: C_p(normal) + C_p(impurity)

10) Y. Mashiko, *Japan Analyst*, **15**, 1151 (1966).

remained in subtracting C_p(normal) and C_p (impurity) from the total is caused by the thermal creation of imperfections, asssuming such as the Schottky-type vacancies. The assumption may be supported by the facts that neopentane crystal transforms to a plastic crystal phase below its melting point, and self-diffusion was observed by the experiment of proton T_1(spin lattice relaxation time) in this phase.[11]

The enthalpy to form the vacancies was calculated from the theory of Schottky vacancy. $\log_{10}(\Delta C_p \times T^2)$ was plotted against $1/T$, where $\Delta C_p = C_p$ (obs.) $- C_p$(normal) $- C_p$(impurity), and a straight line was obtained as shown in Fig. 5. By using the information contained in the intercept and slope of its line, we obtained the following expression:

$$n/N = 4 \times \exp\left[\frac{-3240(\pm 220)}{RT}\right], \qquad (4)$$

where n is the number of vacancies, and N Avogadro's number. The value of 3240 ± 220 cal/mol is the enthalpy of formation of vacancies obtained from the plot. Using the Eq. (4) it is calculated the vacancies of $(n/N)_{T.P.} = 0.69\%$ are to be formed in the crystal at the tiple point.

If the excess heat capacity due to vacancy formation is denoted by C_p(vac.), the plots of C_p (normal) $+ C_p$(impurity) $+ C_p$(vac.) *versus* T are shown by the solid cruve in Fig. 4. The observed values (open circles) of heat capacity for $C(CH_3)_4$

may be found to be in excellent agreement with the calculated values. Although there is no example of the creation of vacancies in molecular crystals except for inert gas crystals investigated by Morrison *et al.*,[12] the consideration of lattice vacancies seems to be important in treating premelting phenomenon as shown in this experiment.

The Vapor Pressure Measurements. The measurements were made in the region of 194 to 260°K as already described,[5] and the results are listed in Table 5.

An attempt was made to find coefficients which would fit the equation based on the theory of ideal gas, liquid and crystal to the observed values. The final equations are given in the following:

i) 194°K$<T<$triple point

$$\log_{10} P + 2(\log_{10} T) + \exp(-g_s/RT) = -1672.65/T + 13.76190, \quad (5)$$

where the third term on the left hand side is the contribution due to the creation of vacancies described in the previous section, and g_s is the Gibbs energy of formation of the vacancies.

ii) $T>$triple point

$$\log_{10} P + 2(\log_{10} T) = -(1517.19)/T + 13.15766. \quad (6)$$

The deviations of the calculated values (horizontal line), using Eqs. (5) and (6), from the observed one are shown by the open circles in Fig. 6. Also in Fig. 6 are illustrated the deviations between the pressures observed by Whitmore *et al.*[9] and by Aston *et al.* and those calculated. The other results show strong deviation from the present results, and this may arise from the facts that the sample used in the measurements by Aston *et al.* was stated to be 99.273 mol% pure, but the amount of impurity in the sample used by Whitmore *et al.* was not reported.

Total	78.89	78.68
Calorimetric	71.71	71.24
$(S_f - S) \times 4$ (difference from the value for free rotation)	7.18	7.44

4°K was estimated by using the values of Debye characteristic temperature obtained from the extrapolation of plots of Debye temperature *versus* T. The entropy from 260°K to the boiling point was estimated by using the thermal data observed by Aston *et al.*

The spectroscopic entropy of neopentane gas at the boiling point calculated from its infrared and Raman spectra[13] and the moment of inertia ($I=186.2\times10^{-40}$ g·cm^2), are given in Table 6 along with that obtained by Aston *et al.* The difference of the vibrational entropy between the present result and their one is due to the difference of the spectroscopic data used in the calculations; in their calculation earlier data by Rank *et al.*[14] were employed.

To bring the calorimetric value into agreement with the spectroscopic, requires the assumption of three equal potential energy maxima of 4.4 kcal/mol for hindered internal rotation of the methyl groups (moment of inertia $I_{Me}=5.14\times10^{-40}$ g·cm^2). This value of hindering potential is reasonable in comparison with the observed value of 5.2 kcal/mol, for solid neopentane obtained by cold neutron scattering.[15]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 91—101 (1969)

The Crystal Structure of Two Crystalline Polymorphs of *N*-(*p*-Methoxyphenyl-3-propyl)-*p*-bromobenzamide

Noritake YASUOKA, Nobutami KASAI and Masao KAKUDO

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka

(Received June 6, 1968)

The crystal structure analysis of *N*-(*p*-methoxyphenyl-3-propyl)-*p*-bromobenzamide was carried out by means of X-rays. This compound crystallizes in two crystalline polymorphs, both belonging to the monoclinic system.

α-form: $a = 14.59_2$, $b = 9.57_2$, $c = 11.24_2$ Å, $\beta = 94.2_6°$; $Z = 4$; space group $P2_1/c$.

β-form: $a = 11.94_0$, $b = 10.01_9$, $c = 6.57_7$ Å, $\beta = 90.5_6°$; $Z = 2$; space group $P2_1$.

A little difference in structure is observed between the molecules in the two polymorphs, while the conformations of the carbon-carbon bonds in the 3-aminopropyl group are of the *trans* form. In both forms, belts of molecules parallel to the *b* axis are formed by hydrogen bonds between the amide groups of the molecules related by the twofold screw axis. These belts are packed anti-parallel in the α-form, but parallel in the β-form.

The first step in the interpretation of an X-ray fiber diagram is, generally, to build up a plausible model which accounts for the observed fiber period.

In the X-ray structure analysis of a series of polyamides prepared by the condensation of 1,2-bis-[*p*-(3-aminopropyl)phenoxy]ethane and adipic acid or its homologues,[1] the fiber periods of all these polyamides have been observed to be shorter by 3—4 Å than the calculated values, assuming the ordinary bond lengths and bond angles in the calculation, and the *trans* conformations for all the single bonds in the polymer chains. This "shortening" of the observed fiber periods suggests the presence of conformations other than *trans*, or of bond lengths or angles different from the normal ones.

These polyamides, $[NHCH_2CH_2CH_2C_6H_4O(CH_2)_nOC_6H_4CH_2CH_2CH_2NHCO(CH_2)_mCO]_p$ ($n=1,2,3,4,5,6$ $m=4,8$), have very complicated repeating units. In addition, these polyamides are poorly crystalline and the diffraction data available from these fibers are not sufficient to build up a model of a molecular skeleton which accounts for the "shortening" of the observed fiber periods. In these cases it is effective to carry out the complete crystal structure analysis of some simple compounds containing the important parts of the polymer chain and to deduce the chain structure of the polymer on the basis of the determined conformations of the parts along the chain.

1) T. Ando, N. Yasuoka and S. Kuribayashi, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **87**, 536 (1966).

From these considerations, we undertook crystal structure analyses of a series of compounds with the formula of $XC_6H_4O(CH_2)_nOC_6H_4X$ ($n=2,3$ or 4, X=H, Cl or Br) to determine the conformation of methylene groups between phenoxy groups. The structures of *p,p'*-dichlorodiphenoxy-1,2-ethane ($n=2$ and X=Cl) and 1,2-diphenoxyethane ($n=2$ and X=H) have already been determined and reported,[2,3] and it has been found that the OCH_2-CH_2O groups are of the *gauche* form.

Next, the crystal structure analysis of *N*-(*p*-methoxyphenyl-3-propyl)-*p*-bromobenzamide was carried out in order to determine what the detailed structure of the $-C_6H_4CH_2CH_2CH_2NH-$ group is in the crystalline state. In addition, the finding of the polymorphism of this substance prompted us to make a complete crystal structure analysis and to ascertain what the difference is between two polymorphic forms.

Experimental

The two crystalline polymorphs of *N*-(*p*-methoxyphenyl-3-aminopropyl)-*p*-bromobenzamide were found to be stable at room temperature. Preliminary X-ray work revealed that both forms belong to the monoclinic system, but to different space groups: one is $P2_1/c$ and the other $P2_1$. The crystal of the $P2_1/c$ space group is named the *α*-form, and that of the $P2_1$ space group, the *β*-form. The crystal data of both polymorphs are summarized in Table 1.

TABLE 1. CRYSTAL DATA OF *N*-(*p*-METHOXYPHENYL-3-PROPYL)-*p*-BROMOBENZAMIDE

Br–C$_6$H$_4$–CO–NH–CH$_2$–CH$_2$–CH$_2$–C$_6$H$_4$–O–CH$_3$

	α-form	*β*-form
a =	14.592 ± 0.007	11.940 ± 0.007 Å
b =	9.572 ± 0.005	10.019 ± 0.006 Å
c =	11.242 ± 0.006	6.557 ± 0.004 Å
β =	94.26 ± 0.03	90.56 ± 0.03°
V =	1565.9	784.4 Å^3
Z =	4	2
D_x =	1.476	1.474 g cm^{-3}
	$P2_1/c$	$P2_1$

Crystals of the *α*-form were obtained by slowly evaporating an ethanol solution saturated with this substance. After the *α*-form crystals had been picked up, the mother liquor was left to vaporize. When it was dried up, crystals of a different behavior from those of the *α*-form were obtained, these were later found to be the *β*-form.

The unit cell dimensions and reflection intensities were measured with a General Electric XRD-5 goniostat using zirconium-filtered Mo*Kα* radiation within a range of $\sin\theta/\lambda$ less than 0.59 ($2\theta=50°$). Each independenet reflection intensity was measured by the stationary-crystal stationary-counter technique at a counting time of 20 sec. 2743 reflections were collected in the case of the *α*-form and 1474 in the case of the *β*-form. The crystals used had the dimensions of $0.10\times0.15\times0.15$ mm^3 and $0.10\times0.15\times0.20$ mm^3 for the *α*- and *β*-forms respectively. No correction was made for the absorption, while the corrections for Lorentz and polarization factors were made in the usual way.

The infrared absorption spectra were measured in a KBr disk with a Hitachi EPI-1 spectrometer.

Structure Determination

α-Form. The three-dimensional Patterson function was synthesized, and the position of the bromine atom was easily obtained from it. Then the structure was solved by the minimum function method by superposing four sets of three-dimensional Patterson maps with coordinates of the bromine atoms at the four equivalent positions of the $P2_1/c$ space group. Significant peaks appeared on the minimum function map, and the coordinates of all the atoms except hydrogen could be read off. The structure factors were calculated with these atoms, and the three-dimensional electron density distribution was computed. The peak height of each atom was reasonable considering the chemical constitution of this compound.

Then the structure was subjected to least-squares refinement using the block-diagonal matrix approximation. After six cycles the discrepancy index decreased from 0.313 to 0.136. In the refinement, 2743 measured reflections were used. At this stage, the difference Fourier function was synthesized. Several residual peaks with heights of from 0.4 to 0.8 e.Å^{-3} appeared, most of them were found at sites where hydrogen atoms were expected to be present. All the hydrogen atoms with isotropic temperature factors were included in the refinement thereafter. The final discrepancy index is 0.124 for 2421 non-zero reflections, and 0.143 for all reflections.

The atomic scattering factors used in the calculations were taken from those of Hanson and his co-workers.[4] In the least-squares refinement the weight assigned for each reflections was 1.00 for most of them, but 0.25 for the few weakest ones. The computations throughout this work were done on a NEAC 2200 computer in this University and on a HITAC 5020 computer in the University of Tokyo, using programs written by Dr. Tamaichi Ashida of the Institute for Protein Research of this University.

The final atomic and thermal parameters are listed in Table 2. Tables of the observed and

three-dimensional electron density distribution was then computed using all the observed reflections, with phases assigned by the bromine atom only. Atoms of the benzene ring to which the bromine atom attached and those of the amide group could be found easily, but it did not seem possible to assign those of the *p*-methoxyphenylpropyl group without error. The second Fourier synthesis was carried out on the basis of phases assigned by the Br, C(1) to C(7), N, and O(1) atoms. The coordinates of other non-hydrogen atoms could thus be obtained.

The atomic parameters were then refined by the least-squares method. The refinement was carried out with all the measured reflections. After 7 cycles the discrepancy factor was reduced from 0.233 to 0.081. The difference Fourier function was synthesized. Several peaks were found at sites where hydrogen atoms were expected to be present. All the hydrogen atoms with isotropic temperature factors were then included in the refinement. After two cycles, some hydrogen atoms were shifted in such a way that the bond distances to the attached atoms were rather long. The parameters of these shifted atoms were, therefore, restored to their original positions, after which two cycles of refinements were carried out with hydrogen atoms fixed in their original positions. The final discrepancy index is 0.070 for 1332 non-zero reflections, and 0.089 for all reflections.

The final atomic and thermal parameters are listed in Table 3. Tables of the observed and calculated structure factors are preserved by the Chemical Society of Japan. The three-dimensional electron density map is shown in Fig. 2.

Discussion

The bond lengths and bond angles in the molecules of the α- and β-form calculated from the final atomic coordinates are shown in Figs. 3 and 4 respectively. The estimated standard deviations of the bond lengths are from 0.010 to 0.015 Å in the α-form and from 0.012 to 0.030 Å in the β-form. Those of the bond angles are from 0.73 to 0.82°

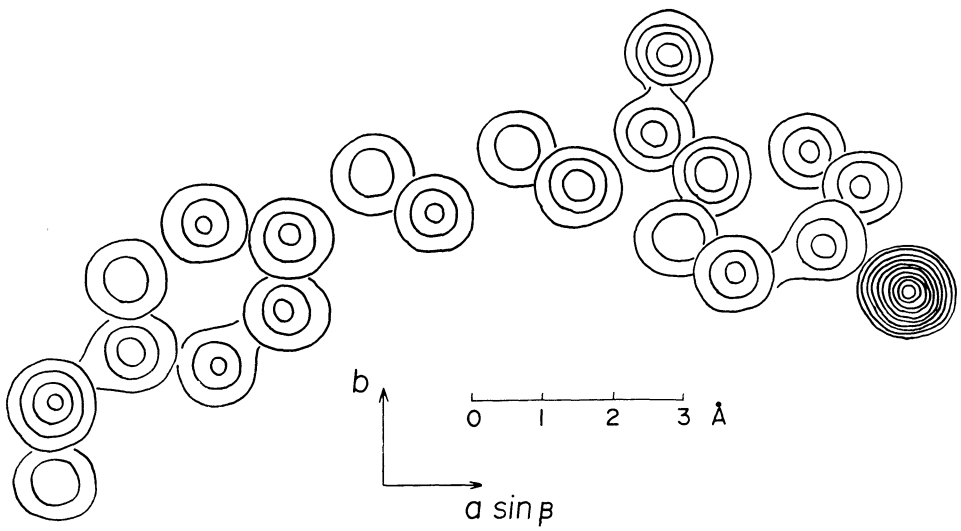

Fig. 1. The final electron density distribution of α-form. Composite diagram of sections parallel to (001) plane. Contours are at intervals of 2 e.Å^{-3}, beginning with the 2 e.Å^{-3} contour. For Br, contours are at intervals of 5 e.Å^{-3} beginning with 10 e.Å^{-3}.

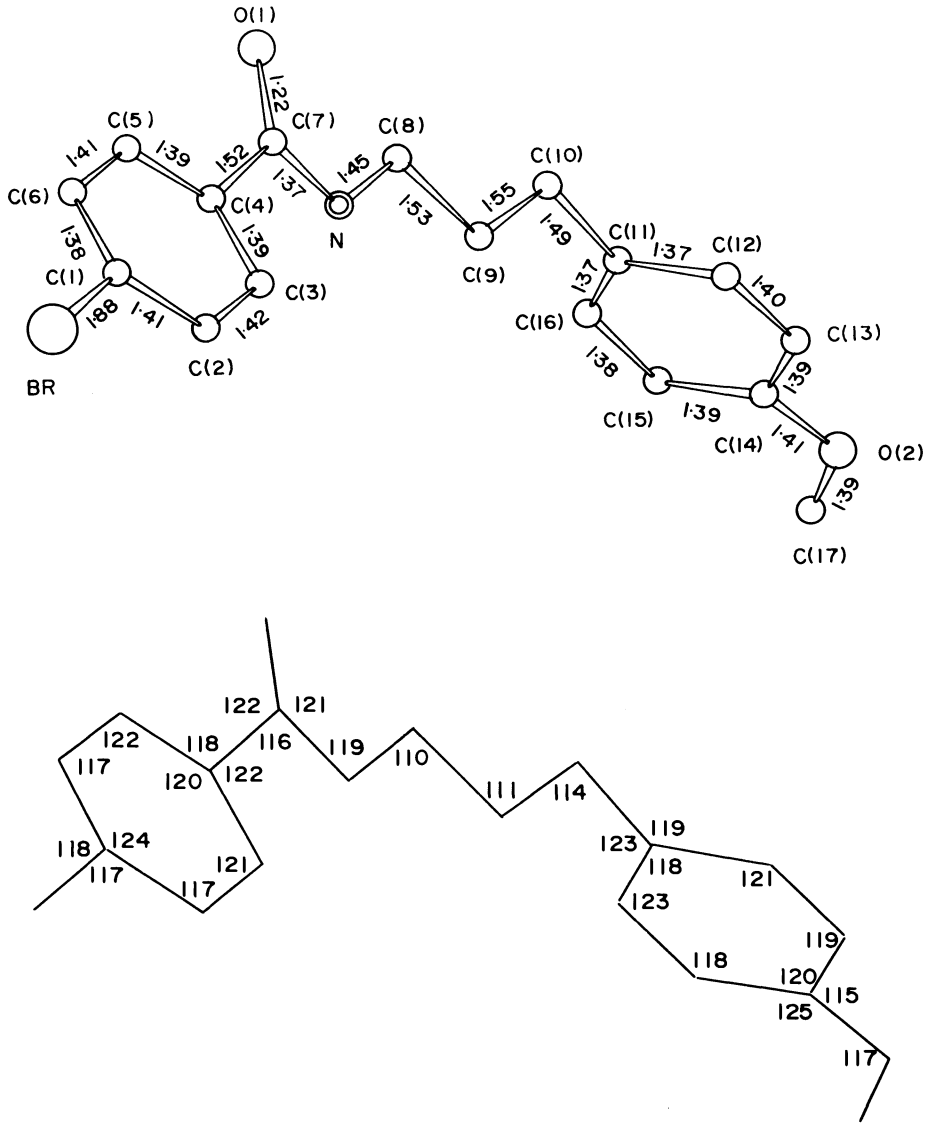

Fig. 4. The molecular shape viewed along the c axis, and bond lengths (Å) and bond angels (°) of β-form.

and from 1.01 to 1.81° in the α- and β-forms respectively. The smaller values of the estimated standard deviations in the α-form than in the β-form are considered to be due to the greater quantity of reflection data (2743 to 1474).

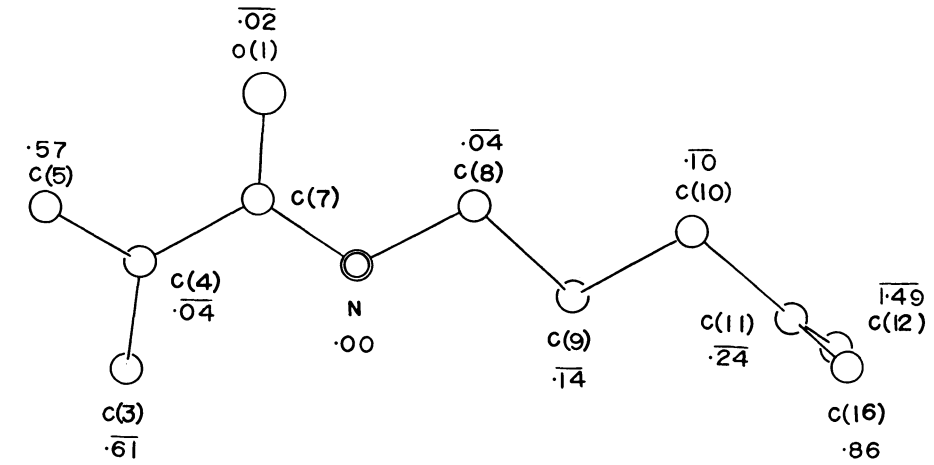
The atomic distances of the corrresponding bonds in the molecules of the two forms give very similar values. The differences of 0.05 Å in C(12)–C(13) and of 0.06 Å in C(17)–O(2) are not significant.

Concerning the 3-aminipropyl group, however, the internal rotation angles are slightly different from each other. Figure 5 illustrates a part of the molecule of each form projected on the best plane of the amide group. The values of the internal rotation angles are listed in Table 4. In

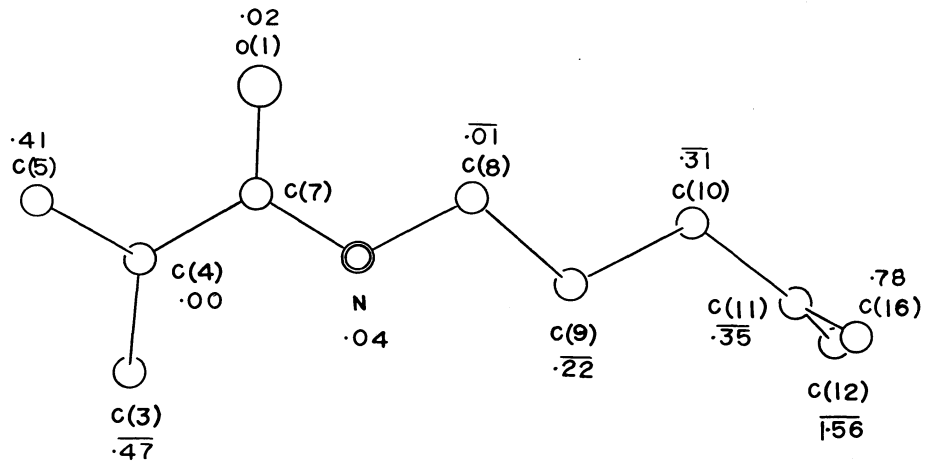
Table 4. Internal rotation angles

	C(4)—C(7)—N	C(7)—N—C(8)	N—C(8)—C(9)	C(8)—C(9)—C(10)	C(9)—C(10)—C(11)
α-form	29.4	−3.4	− 4.2	−3.2	−2.0	89.6
β-form	21.3	2.3	−10.6	1.4	7.4	88.0

Table 4, the internal rotation angles for a bond are defined as follows: looking from the right atom to the left, the clockwise rotation is taken as + and exact *trans* conformation, as 0°. The conformations of the propyl group in two forms are all *trans* in principle, but they show slight differences. First, the internal rotation angles about the C(4)–C(7) bond show a difference of 8.1°, the different inclination angle of the benzene ring to the amide plane



(a)



(b)

Fig. 5. The parts of the molecule projected on the best plane of the amide group.
(a) α-form; (b) β-form.
The figures on the names of atoms show the deviations from the plane.

results from this. Secondly, those about the N–C(8) and C(8)–C(9) bonds are different by some degrees. Therefore, the deviation of C(10) from the amide plane is different, as may be seen in Fig. 5. The angle about the C(9)–C(10) bond is different by 9.4° and somewhat releases the difference in the deviation of C(11) from the amide plane. Such a difference in the conformations of the two forms is considered to be due to interactions between adjacent molecules in the crystal.

The crystal structures of both forms projected along the *b* and *c* axes are shown in Figs. 6 and 7 respectively. In both forms the amide group of a molecule forms the hydrogen bond with that of the molecule related by the twofold screw axis parallel to the *b* axis. Thus, the belts of the molecules are formed by the hydrogen bonds. In the β-form the belts are packed together parallel to the *b* axis, but in the α-form the belts are packed antiparallel in the *b* direction. This difference is

Equiv. 8	$1+x, y, 1+z$	

due to the absence or presence of the glide plane normal to the *b* axis in the β-form or α-form crystal respectively. The intermolecular approaches less than 4 Å are summarized in Table 5. These values are shown as the distances from the original molecule (x, y, z) to the equivalent molecule (*e. g.*, $\bar{x}, \bar{y}, \bar{z}$) related by the space group symmetry. The intermolecular contacts shown as Equiv. 2 in Table 5 are those between molecules related by the twofold screw axis (Fig. 7). The corresponding distances are all shown. Very similar contact distances are seen in two polymorphic forms.

The hydrogen bond distances are listed in Table 6 with estimated standard deviations and also

TABLE 6. NH STRETCHING FREQUENCY AND HYDROGEN BOND DISTANCE

	ν(NH)	N···O distance
α-form	3323 cm^{-1}	2.988 ± 0.011 Å
β-form	3345 cm^{-1}	3.026 ± 0.014 Å

with infrared absorption frequencies of the NH stretching band. It is well established that the stretching frequencies are lowered by the presence of hydrogen bonds and that the frequency shift is monotonic and approximately a linear function of the hydrogen bond distance. Though the difference between the two hydrogen bond distance is not fully significant, the lower frequency of the α-form corresponds to the shorter hydrogen bond distance, and *vice versa* in the β-form. This is in good agreement with Nakamoto's results.[5]

On the basis of the conformations of the 3-aminopropyl group determined above, and of those of the $-OCH_2CH_2O-$ group already reported,[2,3] a possible chain structure of the polyamide obtained by the condensation of 1,2-bis-[*p*-(3-aminipropyl)-phenoxy]ethane and adipic acid has been proposed.[6] The fiber period per repeating unit of this structure model is 26.4 Å, a value which agrees well with the observed value of 26.3 Å.

The authors wish to express their deep thanks to Dr. Tadanao Ando for supplying the samples. They are also grateful to Dr. Tamaichi Ashida and Dr. Tatzuo Ueki, who supplied their computer programs.

(Received June 6, 1968)

Infrared absorptions have been observed in the 1800—700 cm^{-1} region of four purified amino-acid transfer ribonucleic acids (tRNA's): alanine tRNA and valine-I tRNA from *Torulopsis utilis* (torula yeast) and methionine tRNA and tyrosine tRNA from *Escherichia coli* in their deuterated film. Spectral features in the 1550—1750 cm^{-1} region of the valine, methionine, and tyrosine tRNA's indicate that each of these tRNA's has an amount of base-pairs, which is in accord with the "clover leaf" structure previously proposed. The relative amounts of the paired and unpaired cytosine residues are estimated on the assumption that the intensity ratio of the 1523 and 1500 cm^{-1} bands is 0.18 for the paired cytosine residue and 0.84 for the unpaired cytosine residue. The results are also compatible with the "clover leaf" structure.

This is a preliminary report of our infrared absorption measurements of four purified amino-acid transfer ribonucleic acids (tRNA's). Our aim of such measurements is to obtain an information of the secondary structure of a tRNA and of its change caused by a change of the environment. Here we describe only the results obtained of the deuterated films of these tRNA's, from which a piece of the desired information has been obtained.

Abbreviations used in this paper are AMP=adenosine-5′-monophosphate, UMP=uridine-5′-monophosphate, GMP=guanosine-5′-monophosphate, CMP=cytidine-5′-monophosphate, A=unpaired adenosine, U=unpaired uridine, G=unpaired guanosine, C=unpaired cytidine, AU=adenine-uracil base pair, and GC=guanine-cytosine base pair, Ψ=pseudouridine, DiHU=5,6-dihydrouridine.

Experimental

Four tRNA samples were used: (1) alanine-specific tRNA from *Torulopsis utilis* (torula yeast), (2) one of the two valine-specific tRNA's (named "valine-I tRNA") from *T. utilis*, (3) methionine-specific tRNA from *Escherichia coli*, and (4) tyrosine-specific tRNA from *E. coli*. The former two were prepared as has been described by Takemura *et al.*[1,2] and the latter two as has been described by Nishimura *et al.*[3] The first two samples were precipitated by ethanol, washed by ether, and dried in vacuum. Each of the last two samples (about 1 mg) was brought into a concentrated aqueous solution. This was dialysed against a 0.01 M $MgCl_2$ solution to remove polyatomic anions and then lyophilized. A film of each sample was prepared on a AgCl plate. The control of the humidity of the air over the sample film and deuteration of the sample were made by the method described by Sutherland and Tsuboi.[4]

Results and Interpretation

1) General Feature. In Fig. 1, whole the spectrum of the 700—1750 cm^{-1} region observed of alanine tRNA is illustrated. Here, the recorded transmission-wavenumber curve is converted into an absorbance-wave number curve, because one of our aims is to conduct a quantitative analysis (as to the amounts of nucleotide residues located at different intramolecular environments).

In many respects, the spectral features of the four tRNA's are similar to one another, to that of double-helical RNA from rice dwarf virus,[5] and to that of ribosomal RNA from rat liver.[6] All of the four tRNA's (deuterated) give strong absorptions in the 1070—1100 cm^{-1} region, 1220—1260 cm^{-1} region, and 1640—1700 cm^{-1} region. These are attributable respectively to the PO_2^- symmetric

stretching, PO_2^- antisymmetric stretching + D_2O deformation, and in-plane stretching vibrations of the base residues.[4] There are moderately strong absorption bands at 1575 and 1500 cm^{-1} assignable respectively to the guanine and cytosine residues.[7,7a] The absorption bands at 1125 and 810 cm^{-1} are characteristic of RNA and are assigned to $\begin{matrix}C\\C\end{matrix}\rangle$C-O degenerate and symmetric stretching vibrations around the 2'C in the ribose residue.[8]

The details of the spectrum in the 1400—1750 cm^{-1} and 760—840 cm^{-1} regions, on the other hand, are somewhat different for different RNA's. The absorption curves of the four tRNA's in these spectral regions are shown in Figs. 2—6.

2) The 1550—1750 cm^{-1} Region. Recently, Thomas[9] described a method for evaluating of the fractions of AU and GC base pairs contributing to the secondary structure of a given RNA from its infrared absorption spectrum in the 1550—1750 cm^{-1} region. For such an evaluation, he presented a catalog of infrared absorption spectra

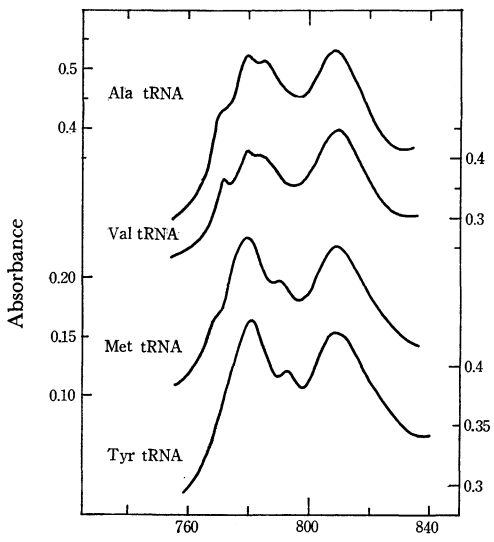

Fig. 6. Infrared absorption curves (760—840 cm^{-1} region) of deuterated films of alanine tRNA, valine-I tRNA, methionine tRNA, and tyrosine tRNA.

of poly(A+U), poly(G+C), AMP, UMP, GMP, and CMP in their D_2O solutions. We have been attempting similar base analyses, and what we observed of poly(A+U) and poly(G+C) in D_2O

are found to be in accord with what Thomas independently observed. We have not yet determined, however, the molar extinction coefficient for each point in the absorption curve, as Thomas did. In addition, we have been using the absorption curves of adenosine, uridine, guanosine, and cytidine in D_2O[10] which may be slightly less suitable than the curves of AMP, UMP, GMP, and CMP as the standard curves for evaluating the amounts of unpaired bases. Let us use, therefore, the standard curves presented by Thomas in our present infrared analyses.

The infrared base-analyses of tRNA's have an additional difficulty: we have no standard spectra of minor bases in tRNA. In the present preliminary analyses, we neglect their contribution. It is true that the total amount of the minor bases in each tRNA is not small at all. For example, valine-I tRNA molecule has altogether 12 minor base residues in the total 75 base residues. They consist, however, of smaller numbers of several different minor bases, and the contribution of each base is different from another and is rather small.

The observed absorption curve of our alanine tRNA (Fig. 2,A) indicates that some of the base residues in it are hydrogen-bonded (paired) and others are unpaired; the absorption peak at 1690 cm^{-1} is caused mainly by the AU and GC base pairs, whereas absorptions at 1655 and 1625 cm^{-1} are mainly attributable to the unpaired bases.[9,11] The determination of the chemical structure of alanine tRNA from torula yeast is not yet completed. For alanine tRNA from baker's yeast, however, the nucleotide sequence was determined by Holley *et al.*[12] On the basis of this sequence, Holley[13] suggested a "clover leaf" model,[13a] which contains 2 AU pairs, 17 GC pairs, and 6A, 9U, 8G, and 6C unpaired. On the basis of this base-pair composition, a synthetic spectrum in the 1550—1750 cm^{-1} region was calculated by the use of Thomas' standard curves. The result is given in Fig. 2, B. As another trial, a calculated curve (Fig. 2, C) was obtained for a "clover-leaf" model in which the so-called "DiHU arm.[14] has only three GC pairs instead of four (most of other "clover-leaf" models so far presented have only three base pairs in the "DiHU arm"). A comparison of the curves A, B, and C in Fig. 2 indicates that the structure of alanine tRNA of torula yeast is somewhat different from what was proposed of baker's yeast. It is suggested that the former has more base pairs or less unpaired bases than the latter, because the relative intensity of the 1690 cm^{-1} peak is found to be greater in the observed spectrum than that in the calculated spectra. In some respects, however, the alanine tRNA in question seems to be similar to the "clover-leaf" model of alanine tRNA of baker's yeast. For example, the relative intensity of the 1623 cm^{-1} peak is lower in the alanine tRNA in question than in the other three tRNA's examined (Figs. 3—5). This fact indicates that the number of unpaired A is relatively small in this tRNA. This is the case also in the "clover-leaf" model of alanine tRNA of baker's yeasts; there are only 6 A's, whereas in most of the "clover-leaf" models of other tRNA, there are more than 10 A's.

Valine-I tRNA should have 5AU, 12GC, 1AΨ, and 2GU base pairs and 8A, 4U, 4G, and 8C unpaired, if the "clover-leaf" model is adopted.[15] Because we do not yet know the standard curves for AΨ and GU pairs, let us assume for trial that there are 7AU and 13GC in obtaining the synthetic spectrum. The result is given in Fig. 3, B. Figure 3, C is a calculated spectrum for a structure which is obtained from the "clover-leaf" model by breaking the three base pairs (two GC and one GU) in the "DiHU arm"[14] and one GU pair in the "amino-acid arm."[14] (This may be the structure obtained in the first stage of the melting process of the "clover-structure). Figure 3, D is a calculated spectrum which is expected for the completely denatured form. Among these three calculated spectra (B, C, and D), spectrum B is in the best agreement with the observed spectrum (Fig. 3, A). Therefore, it may be concluded that valine-I tRNA now in question has base pairing contents which are almost equal to those in its "clover-leaf" model.

Similar examinations were made also for methionine and tyrosine tRNA's from *E. coli*. In each case, the calculated spectrum on the basis of the "clover-leaf" model[16,17] is in a good agreement with the observed spectrum (see Figs. 4 and 5). Both of these two tRNA's show relatively strong

13 a) The "clover leaf" model is what was proposed by Holley[13] as one of possible models of the secondary structure of alanine-tRNA from baker's yeast. It has four arms named[14] "amino-acid arm," "T, Ψ arm," "anticodon arm," and "DiHU arm," which have seven, five, five and four base-pairs respectively. Nucleotide sequences determined later for a number of amino-acid specific tRNA molecules indicated that a similar model is reached when each tRNA molecule is folded so that the number of intramolecular Watson-Crick base-pairs is a maximum.

1650 and 1623 cm^{-1} peaks. This fact indicates that the relative amounts of the GC pair and unpaired A are great in these tRNA. These amounts are certainly great if their "clover-leaf" models are valid: 17GC and 13A in methionine tRNA and 17GC and 11A in tyrosine tRNA.

3) The 1400—1550 cm^{-1} Region. The moderately strong band at 1500 cm^{-1} is assigned to the cytosine residue.[7,7a] This band seems to appear irrespective of whether the cytosine residue is hydrogen-bonded or not. Another band attributable to the cytosine residue at 1523 cm^{-1}, on the other hand, is strong only when the residue is unpaired. The intensity ratio of the 1523 to 1500 cm^{-1} bands, $I(1523\ cm^{-1})/I(1500\ cm^{-1})$ is about 0.84 in completely heat denatured DNA in D_2O solution.[18] It has about the same value in cytidine and in CMP in D_2O solutions. While, the $I(1523\ cm^{-1})/I(1500\ cm^{-1})$ value is 0.18 in native double-helical DNA in D_2O. It has almost the same value for double-helical RNA.[5] Fortunately, there are almost no disturbing bands of other base residues in this spectral region, and therefore these two bands are useful in estimating the relative amounts of paired and unpaired cytosine residues. It is assumed that the mole ratio r of the paired cytosine *versus* total cytosine residues is given by

$$r = 1.27 - 1.52\ I(1523\ cm^{-1})/I(1500\ cm^{-1}) \quad (1)$$

so that $r=0$ when $I(1523\ cm^{-1})/I(1500\ cm^{-1}) = 0.84$, and $r=1$ when $I(1523\ cm^{-1})/I(1500\ cm^{-1}) = 0.18$. $I(1523\ cm^{-1})/I(1500\ cm^{-1})$ is found to be 0.30, 0.43, 0.39, and 0.45 respectively for alanine, valine-I, methionine, and tyrosine tRNA's. By the use of Eq. (1), r is calculated to be 0.79, 0.62, 0.68, and 0.59. The paired C/total C values determined from the infrared data for valine-I, methionine, and tyrosine tRNA's (0.62, 0.68, and 0.59, respectively) are in accord with what are expected on the "clover-leaf" models (0.60, 0.68, and 0.63, respectively) within the experimental error which would be about ± 0.05. The paired C/total C values determined from the infrared data of alanine tRNA of torula yeast (0.79) is not greatly different from what is expected on the "clover-leaf" model of alanine tRNA of baker's yeast (0.74).

In the spectral region of 1450—1480 cm^{-1}, poly(G+C) gives no absorptions, while polyAU- (copolymer with adenylic acid and uridylic acid in the alternating sequence) gives two bands here: a weaker band at 1480 cm^{-1} and a stronger band at 1460 cm^{-1}.[18] Therefore, from the spectral features of tRNA's in this spectral region an information on the content of the AU pair may be drawn. This is, however, yet to be done.

4) The 760—840 cm^{-1} Region. The absorptions in the 770 − 790 cm^{-1} region are assignable to out-of-plane vibrations of the base residues.[7] Poly (G+C) gives a strong band at 780 cm^{-1}, whose absorption intensity is more than three times of that of the 810 cm^{-1} band (skeletal stretching vibration around the 2'COH group of the ribose residue).[18] While, polyAU gives much weaker bands at 790 and 770 cm^{-1}.[18] The spectral features of the four tRNA's examined are somewhat different from one another (see Fig. 6). Thus, the spectrosopy in this region is also considered to be useful for an base analysis of tRNA's. This again is yet to be done.

(Received June 10, 1968)

Deuteron quadrupole coupling tensors in $Co(ND_3)_6Cl_3$ were determined at various temperatures. The observed quadrupole coupling shows that $Co(ND_3)_6^{3+}$ ions execute a rapid isotropic reorientation at high temperatures (above 320°K for one of the sites (the 4f sites) and above 190°K for another (the 2e sites)), while at low temperatures (below 190°K for the 4f sites, and 170°K for the 2e sites), only a C_3 axis reorientation of the ligand ND_3 groups is present. The deuteron resonance spectra clearly show that $Co(ND_3)_6^{3+}$ ions in the 4f sites begin to reorient about one of the three C_4 axes at intermediate temperatures (about 240°K). On the basis of the orientation of quadrupole tensors, probable orientations of $Co(ND_3)_6^{3+}$ ions in the 4f sites in the crystal are proposed. Additional measurements of the proton resonance on a single crystal of $Co(NH_3)_6Cl_3$ support the results obtained from the deuteron resonance. To obtain the reorientation rates and the activation energies of these reorientational motions, the deuteron resonance line width at the 4f sites is measured at various temperatures and at various crystal orientations. From the temperature dependence of the line width, the presence of two cations with slightly different rates at the 4f sites is suggested. However, because of the limits set by the various experimental conditions, reliable values of the reorientation rates and activation energies could not be obtained.

Structure and molecular motions in the hexamminecobalt(III) chloride crystal have been studied by several authors by measurements of the line shape and of the second moment of the proton magnetic resonance. Murray and Waugh[1] investigated the $Co(NH_3)_6X_3$-type compounds and found that the protons of the NH_3 ligand reorient about its C_3 axis at the temperature of liquid nitrogen. They also found that these complex salts show unusual and very broad line-width transitions in the cases of X=Cl, Br, I, and NO_3. They explained these phenomena in terms of over-all reorientations of complex cations occupying two nonequivalent crystal sites. Dharmatti, Saraswati, and Vijayaraghavan[2] confirmed the existence of two kinds of crystal sites in cobalt atoms by observing the ^{59}Co NMR line, which splits into two components at a static magnetic field of 3 k gauss. Kim[3] measured the proton second moment of $Co(NH_3)_6Cl_3$ at very low temperatures and showed that the reorientation of ammonia molecules about their C_3 axes does not freeze, even at the temperature of liquid helium. In order to obtain detailed information about the structure and motions in this crystal, we measured the deuteron magnetic resonance on single crystals of deuterated hexamminecobalt(III) chloride.

In a nucleus with a nuclear spin greater than 1/2, the NMR spectrum exhibits quadrupole splitting, which is often strongly affected by nuclear motions. It is well known that if two nuclei at different sites exchange positions at a rate much greater than the separation between the lines of the two sites, the field gradient at the nucleus is averaged and the absorption line is observed at the averaged position of the two lines.[4]

In the present case, the field gradient of the deuteron is averaged by the C_3 axis reorientation of ND_3 in a $Co(ND_3)_6^{3+}$ ion because this motion is sufficiently rapid. Assuming an axially symmetric field gradient in the direction of the N–D bond, the direction of the maximum principal component of the averaged field gradient, q_{zz}, can be assumed to be parallel to the Co–N bond direction. Since the $Co(ND_3)_6^{3+}$ ion possesses an approximate O_h symmetry, three types of over-all reorientational motions may be considered——the reorientations about three C_4 axes, those about four C_3 axes, and those about six C_2 axes. If the reorientation about one of the C_4 or C_2 axes is sufficiently rapid, two

of the three axially-symmetric q-tensors in the three N-Co-N directions average to a new axially-symmetric q-tensor, one which has $-(1/2)$ the original value and which is parallel to the third. On the other hand, if the reorientation about any one of the C_3 axes is rapid, the field gradient becomes nearly zero. If the reorientations about various axes occur simultaneously (isotropic reorientation), so that all the six ligand molecules can exchange their positions, the field gradient also becomes nearly zero. Therefore, by deuteron resonance study, we can expect to find out what type of motion is present in the crystal.

Experimental

The sample was prepared by the usual method.[5] Deuteration was easily performed by the successive isotope exchange of $Co(NH_3)_6Cl_3$ with D_2O. A single crystal was obtained by slowly cooling a saturated heavy-water solution. The over-all dimensions of a typical sample used in the present experiment are about $10\times 7\times 7$ mm^3. The measurements were carried out at 10 Mc/sec using a Robinson-type detector. The output signal of the spectrometer was amplified by a narrow-band 'lock-in' amplifier, and the derivative of the absorption line was recorded. Temperature control was accomplished by using an electric heater wound outside the probe or by passing through cooled nitrogen gas obtained by boiling liquid nitrogen. Temperature control within ± 1°C was attained by this method. For the deuteron, the nuclear spin $I=1$; therefore, the quadrupole interaction gives a pair of lines ($m=1\leftrightarrow 0$ and $0\leftrightarrow -1$). In order to eliminate the second-order effect of quadrupole interaction and the error due to field drift, the frequency separation between the pair of lines ($2\Delta\nu$) was measured instead of the separation of each sideband from the Larmor frequency. The angular dependence of the quadrupole splitting is given by:

$$2\Delta\mu = \frac{3}{4h}e^2Q\left\{-q_{zz}+(q_{xx}-q_{yy})\cos 2\theta_z + 2q_{xy}\sin 2\theta_z\right\} \quad (1)$$

where q_{ij} is the ij element of the field gradient tensor, where x, y, and z are the coordinates fixed to the probe head, z being along the axis of rotation, and where θ_z is the angle of rotation of H_0 measured from the x axis. From the measurements of rotation patterns about three mutually orthogonal axes, all the components of the p-tensor can be determined.[6] Since the crystal structure of $Co(NH_3)_6Cl_3$ is monoclinic ($\beta=91°19'$),[7] we measured the rotation patterns about the b axis, c axis, and the a* axis (perpendicular to the b and c axes).

Results

The observed spectra are strongly dependent on the temperature. At 320°K, a single broad line at the Larmor frequency (denoted by line 1) and a pair of sharp lines with a separation of several gauss (lines 2) are observed. The intensity of line 1 decreases as the temperature is lowered,

In this pattern, the lines 1b′ (A) and 1b″ (B) or 1b″ (A) and 1b′ (B) overlap each other.

until it almost fades out at 305°K. New weak lines begin to appear at this temperature. These lines are clearly distinguished as pairs of lines (1a and 1b) at 240°K. At 190°K, the line 1b further splits into two lines (1b′ and 1b″). The lines 2 become weak as the temperature is lowered and almost fade out at 170°K. Eight or nine pairs of lines are observed at the temperature of liquid nitrogen.

a) Lines 1 and 2. The spectrum at 320°K consists of lines 1 and 2. The rotation patterns are shown in Fig. 1. Line 1 has no angular dependence, but at a particular angle a small splitting is observed when the modulation width is decreased. The analysis of the two rotation patterns, 1 and 2 gives $e^2qQ/h \fallingdotseq 0$ for line 1 and $e^2qQ/h = 5.6 \pm 0.5$ kc/sec, $\eta = 0.45$ for line 2. The principal axes, z, y, and x, of the field gradient tensor of the deuteron for line 2 are nearly parallel to the a, b, and c axes respectively. The spectrum at room temperature consists of lines 2 and lines 1a and 1b. Lines 1a and 1b are broad and weak. The lines 2 at room temperature are identical to that at 320°K within the limits of experimental error.

b) Lines 1a, 1b, 1b′, and 1b″. At 240°K, the lines 1a and 1b are observed in addition to the lines 2. In the b axis rotation pattern, the lines 1a and 1b consist of four pairs of lines (1a(A), 1a(B), 1b(A), and 1b(B)), while in the c axis and the a* axis rotation patterns these lines consist of two pairs ([1a(A), 1a(B)] and [1b(A), 1b(B)]).*1 The rotation patterns at 240°K are shown in Figs. 2, 3, and 4 by solid circles.

At 190°K, the lines 1b split into 1b′ and 1b″ but 1a remains unchanged. In the a* axis rotation pattern, the spectra consist of three pairs of lines ([1a(A), 1a(B)], [1b′(A), 1b′(B)], and [1b″(A), 1b″(B)]). In the b axis rotation pattern, the spectra consist of four pairs (1a(A), 1a(B), [1b′(A), 1b″(A)], and [1b′(B), 1b″(B)]). In the c axis rotation pattern, the spectra consist of three pairs ([1a(A), 1a(B)], [1b′(A), 1b″(B)], and [1b″(A), 1b′(B)]). The rotation patterns at this temperature are shown in Figs. 2, 3, and 4 by open circles. In Figs. 2, 3, and 4, the lines 2 are omitted because they are almost identical to those at 320°K. The field gradient tensors derived from the analysis of the rotation patterns at 240°K and 190°K are shown in Table 1. The quadrupole coupling constants corresponding to the lines 1a(A), 1a(B), 1b′(A), 1b′(B), 1b″(A), and 1b″(B) are the same (about 63 kc/sec) within the limits of experimental error. Similarly, the coupling constants corresponding to the lines 1b(A) and 1b(B) are nearly the same

*1 [1a(A), 1a(B)] signifies that lines 1a(A) and 1a(B) are observed as a single line because they approximately overlap.

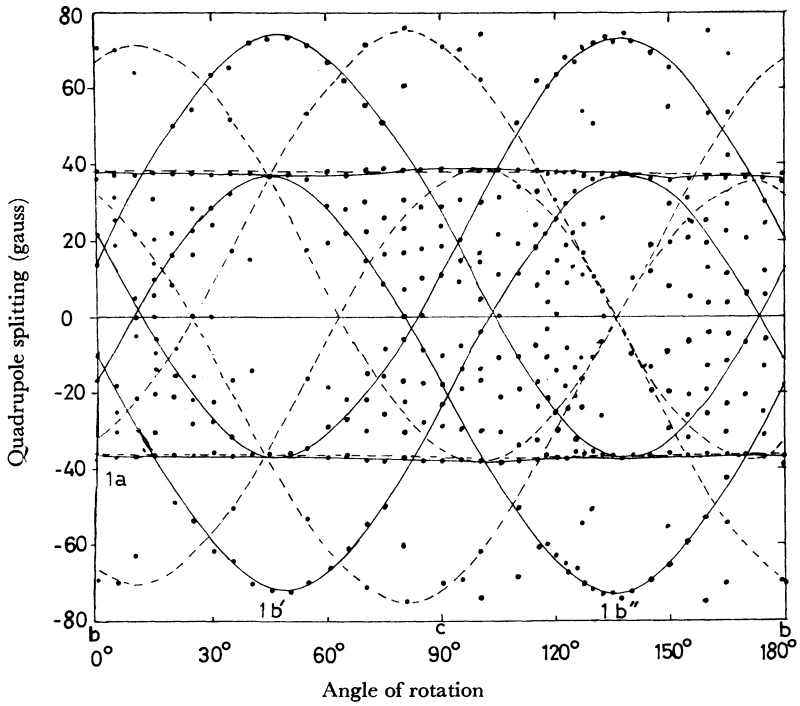

Fig. 5. a* Axis rotation pattern of deuteron resonance in $Co(ND_3)_6Cl_3$ at 77°K.

Table 1. Observed deuteron quadrupole interactions in $Co(ND_3)_6Cl_3$

Temperature		240°K			
Absorption line		1a A	1a B	1b A	1b B
e^2qQ/h (±1 kc)		62.7	63.6	32.2	32.6
η (±0.05)		0.02	0.01	0.02	0.02
Direction of q_{zz} axis* (±3°)	θ	3°	7°	3°	7°
	φ	180°	0°	180°	0°

Temperature		190°K					
Absorption line		1a A	1a B	1b' A	1b' B	1b'' A	1b'' B
e^2qQ/h (±1 kc)		62.7	63.0	64.0	63.8	63.5	63.5
η (±0.05)		0.04	0.00	0.02	0.03	0.00	0.05
Direction of q_{zz} axis* (±3°)	θ	3°	4°	86°	93°	94°	86°
	φ	180°	0°	45°	45°	−45°	−45°

* θ is the polar angle with respect to the a* axis.
ϕ is the azimuthal angle measured from the b axis.

(about 32 kc/sec). The latter value is approximately one half the former value. The asymmetry parameter, η, is nearly zero in all cases.

c) Spectra at the Temperature of Liquid Nitrogen. The spectra at the temperature of liquid nitrogen are very complicated. Although the lines 1a, 1b', and 1b'' are still recognizable, many other lines appear over the range of about 150 gauss. Therefore, it is almost impossible to get each curve of the rotation pattern separately. The a* axis rotation pattern is shown in Fig. 5 as an example.

Discussion

Waugh and Murray[1] reported that the crystal structure of the hexamminecobalt(III) chloride is monoclinic, containing three cobalt atoms in a unit cell, and that these three atoms are at two different crystallographic sites in a relative abundance of 2 : 1. However, Giménez-Hugget[8] recently reported that the space group for this compound is $P2_1/m$ and that a unit cell contains twelve cobalt atoms at two 4f sites and two 2e sites. He also concluded that the nitrogen atoms of four NH_3 groups lie on a (010) plane and that of the other two NH_3 groups, one lies above and one below this plane. The integrated intensity ratio of lines 1 and 2 at 320°K at the angle of maximum separation is approximately 2 : 1. Therefore, the lines 1 and 2 are assigned to the signals from the ions at the 4f and 2e sites respectively. The temperatures at which these lines disappear (260—320°K for the lines 1, and 170—190°K for the lines 2) are in good agreement with the proton line-width transition temperatures, 260—330°K and 150—230°K respectively.[1] Since the quadrupole splittings of the lines 1 and 2 are both very small, it is confirmed that a rapid isotropic reorientation

8) M. Giménez-Hugnet, *Dissertation Abstr.*, **22**, 2209 (1962), Thesis, Purdue Univ. (1961).

occurs in the complex cations at both sites above room temperature. The small quadrupole coupling may be due to the distortion of a $Co(ND_3)_6^{3+}$ ion from the O_h symmetry and the effect of the external crystal field, a situation similar to that in the case of the rapidly reorienting ND_4^+ ion in some ammonium salts.

Lines 1a, 1b, 1b′, and 1b″ seem to originate from the complex cations belonging to the 4f sites, because on cooling they appear after line 1 has faded out. On the basis of knowledge obtained from proton resonance studies, NH_3 ligands can be said to reorient rapidly about their C_3 axes throughout the temperature range of our experiment. Therefore, at 190°K, the maximum principal axis of the field gradient tensor of the deuteron is found to be approximately parallel to the Co–N bond direction by motional averaging. If the D–N–D angles of a coordinated ammonia molecule are tetrahedral, the motionally-averaged deuteron quadrupole coupling constant will be one-third that of the rigid molecule, assuming an axially symmetric field gradient in the direction of the N–D bond. From the known deuteron quadrupole coupling constants for the rigid ND_4^+ ion[9,10] (179.9 kc/sec, 180.0 kc/sec, and 174 kc/sec in ND_4Cl, ND_4Br, and $(ND_4)_2SO_4$ respectively), the quadrupole coupling averaged by the C_3 axis reorientation of ND_3 can be estimated to be about 60 kc/sec. This is in good agreement with the observed quadrupole coupling constants in $Co(ND_3)_6Cl_3$ at 190°K, about 63 kc/sec. Therefore, the lines 1a, 1b′, and 1b″ at 190°K are assigned to signals from ND_3 groups of the three different Co–N bond directions of a $Co(ND_3)_6^{3+}$ ion. The fact that absorption lines due to ND_3 groups corresponding to three Co–N bond directions are separately observed indicates that the complex cations at 4f sites are stationary at 190°K. From the directions of the field gradient tensors, the following conclusions concerning the orientations of $Co(ND_3)_6^{3+}$ ions at the 4f sites can be reached: (1) $Co(ND_3)_6^{3+}$ ions at the 4f sites have two different orientations, shown as A and B in Fig. 6 (A and B each seem to correspond to one of the two 4f sites). (2) One of the Co–N bond directions in a $Co(ND_3)_6^{3+}$ ion (1–2 in Fig. 6) is about 5° away from the a* axis on the a*c plane, while the other two Co–N bond directions (3–4 and 5–6) make angles of about 45° with the b axis, where deuterons at 1 and 2 give lines 1a, deuterons at 3 and 4 give lines 1b′, and deuterons at 5 and 6 give lines 1b″. These conclusions are not in accord with Giménez-Hugget's findings that four NH_3 are here placed in a (010) plane and that all $Co(NH_3)_6^{3+}$ ions have the same orientation. However, since the deuteron resonance spectra clearly show more than one orientation of $Co(ND_3)_6^{3+}$ ions, his conclusion concerning the nitrogen positions does not seem to be correct.

At 240°K, the lines 1b appear at the averaged positions of the lines 1b′ and 1b″, which have already faded out by this temperature, while the lines 1a remain the same as those at 190°K. This can be explained by a uniaxial reorientation of the $Co(ND_3)_6^{3+}$ ion about the axis 1—2 of Fig. 6, one of its C_4 axes. Since this motion gives rise to an exchange between the 3 and 4, and 5 and 6, positions of Fig. 6, the lines 1b′ and 1b″ are averaged. The reorientation about the C_2 axis perpendicular to the 1—2 direction will also have the same effect. However, in this case, all the ligands must change their positions, so the potential barrier to this motion may be much higher than that to the reorientation about the C_4 axis. Therefore, the reorientation about the C_2 axes is unlikely. Although we have assumed in the above discussion that the motion at a high temperature is an isotropic one, there remains an alternative possibility that this motion is a uniaxial reorientation about any one of the four C_3 axes, because the averaged field

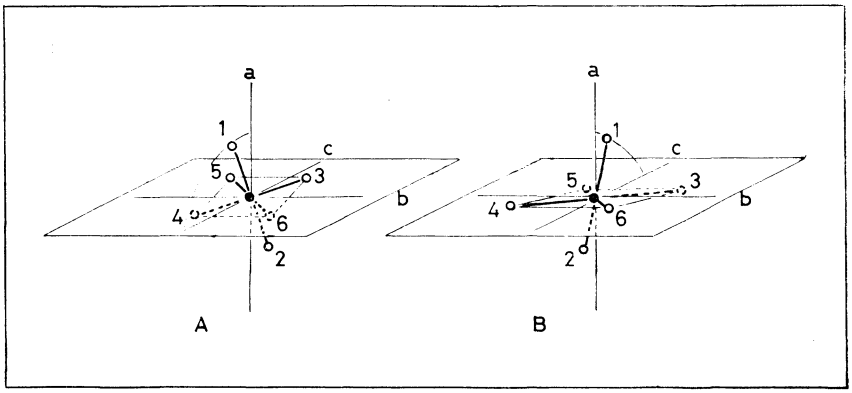

Fig. 6. Two possible orientations of $Co(ND_3)_6^{3+}$ ions at 4f sites.

10) D. E. O'Reilly and T. Tsang, *J. Chem. Phys.*, **46**, 1291 (1967).

gradient by such a motion is nearly zero. However, since the reorientation about the C_4 axis has already been excited at lower temperatures, it is unlikely that the motion at a high temperature is an over-all reorientation about the C_3 axis only.

At about 190°K, the lines 2 are sharp lines with a small separation, indicating an isotropic reorientation of the complex cations at the 2e sites down to this temperature. At the temperature of liquid nitrogen the over-all motions of all the complex cations must be frozen, for the absorption lines are split into many components. The spectra are so complicated that the orientation of $Co(ND_3)_6^{3+}$ ions at the 2e sites could not be determined. For the same reason the possibility of a uniaxial motion of this ion at the intermediate temperatures could not be ascertained. However, because the maximum splitting is observed when H_0 is nearly parallel to the a*, b, or c axis in the rotation patterns at the temperature of liquid nitrogen, the three Co–N bond directions in a $Co(ND_3)_6^{3+}$ ion in the 2e sites are probably nearly parallel to the a*, b, and c axes.

The proton resonance on a single crystal of $Co(NH_3)_6Cl_3$ was also measured. The resonance line exhibits a structure characteristic of a rotating three-spin system.[11] When the reorientation axis is perpendicular to the plane of the spin triangle, the spectrum is a triplet line with a peak separation of $C(3\cos^2\theta-1)$, where C is a constant determined from the proton-proton distance, and θ is the angle between H_0 and the reorientation axis. When H_0 is applied parallel to the a* axis, the spectrum at 200°K consists of two pairs of peaks with a strong center line. When H_0 is applied parallel to the b axis, only a single line with unresolved shoulders appears.

These spectra can be interpreted as follows. In the case of the H_0//a* axis, one of the reorientation axes of NH_3 is parallel to $H_0(\theta=0)$ and the other two are perpendicular to it ($\theta=\pi/2$), so that the spectral lines consist of a triplet line with a peak separation of $2C$ and that with a peak separation of $-C$. Thus, the spectrum will be a central line with two pairs of peaks. The observed peak separation, $2C$, is about 20 gauss. Assuming the H–H distance of NH_3 to be 1.67 Å,[1] the theoretical value for the rotating three-spin system is 18.4 gauss, which is in reasonable agreement with the observed value. In the case of the H_0//b axis, one of the reorientation axes is perpendicular to H_0 and the other two make an angle of 45° with H_0, so that the spectrum consists of triplet lines with a peak separation of $-C$ and those with a peak separation of $(1/2)C$. Since the total spread of the line is small, the spectrum may be seen as a broad line with unresolved shoulders. When H_0 is applied in the direction 45° from the b axis in the bc plane, the line with two pairs of peaks was observed at 200°K, while the line with unresolved shoulders was observed at 240°K. In this case, one of the reorientation axes of NH_3 (3–4 in Fig. 6) is parallel to H_0, and the other two (5–6 and 1–2) are perpendicular to it. Since the uniaxial motion about the axis 1–2 gives rise to exchange between the 3 and 4, and 5 and 6, positions, the spectrum at 240°K consists of triplet lines, one with a separation of $-C$ (a line that originates from 1 and 2), one with a separation of $(1/2)C$ which is produced by averaging the triplet lines, one with separation of $2C$ (a line originating from 3 and 4), and one with a separation of $-C$ (a line originating from 5 and 6). Although the effect of uniaxial motion on the second moment of a powdered sample is not clear,[1] single crystal spectra show the occurrence of this motion in $Co(NH_3)_6Cl_3$. At 77°K, the proton line is a single broad line exhibiting no structure. If there are several orientations for $Co(NH_3)_6^{3+}$ ions, as suggested by the deuteron resonance, this can be understood as a single broad line resulting from the superposition of several triplet lines with various separations.

The rate of the motion can be estimated from the width of spectral lines. In the present case, the line widths at the limits of slow and rapid exchange rates can be derived from the general formula[4] as follows:

(I) Uniaxial motion

slow exchange limit ($\Omega \ll \delta$):

$$\Delta\nu_{motion} = \Omega/2\pi \tag{2}$$

rapid exchange limit ($\Omega \gg \delta$):

$$\Delta\nu_{motion} = \pi\delta^2/\Omega \tag{3}$$

(II) Isotropic motion

slow exchange limit ($\Omega \ll \delta$)

parallel to rotation axis:

$$\Delta\nu_{motion} = \Omega/\pi \tag{4}$$

perpendicular to rotation axis:

$$\Delta\nu_{motion} = \Omega/2\pi \tag{5}$$

rapid exchange limit ($\Omega \gg \delta$):

$$\Delta\nu_{motion} = \left(\frac{16}{27}\right)\pi\delta^2/\Omega \tag{6}$$

$\Delta\nu_{motion}$ is the line width due to the motion, Ω is the rate of the motion, and 2δ is the frequency separation of the two sites. The rate of the motion can be calculated from the observed line width due to the motion. However, in solid samples it is difficult to estimate $\Delta\nu_{motion}$ because the signal-to-noise ratio for the broadened lines is generally poor and the absorption lines possess a dipolar width. For the $Co(ND_3)_6^{3+}$ ions at the 4f sites for which the stationary orientation has been well determined, the $\Delta\nu_{motion}$ is estimated from the observed line

11) E. R. Andrew and R. Bersohn, *J. Chem Phys.*, **18**, 159 (1950).

width by an approximate procedure,[12] from which Ω is derived using Eqs. (2)—(6). The results are shown in Fig. 7. One can immediately

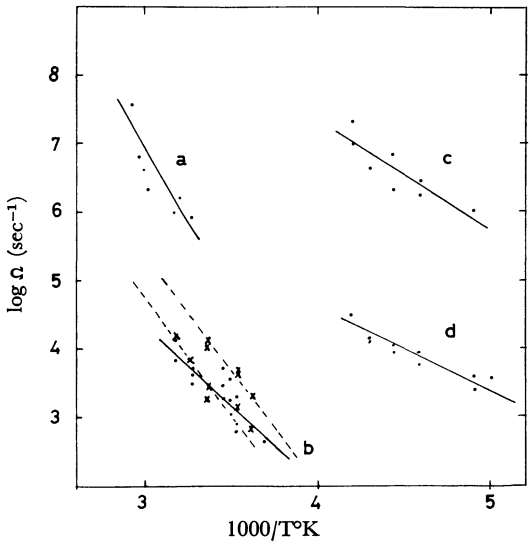

Fig. 7. Temperature dependence of reorientation rates of a $Co(ND_3)_6^{3+}$ ion.

a) Isotropic motion (rapid limit)
b) Isotropic motion (slow limit)
c) Uniaxial motion (rapid limit)
d) Uniaxial motion (slow limit)

notice that there is a vast disagreement between the line connecting points of Ω from the rapid exchange limit and the line connecting points of Ω from the slow exchange limit. As will be described below, this discrepancy originates from the presence of two crystallographically-nonequivalent 4f sites for $Co(NH_3)_6^{3+}$ ions, ions which have approximately the same orientation but which are subject to a slightly different barrier hindering reorientation.

As can clearly be seen in the typical example of line broadening given in Fig. 8, the lines corresponding to the stationary ions (slow-limit spectrum) and their motionally-averaged lines (rapid-limit spectrum) are simultaneously observed at some temperatures. The theory of motional averaging predicts no such spectra (the coexistence of a spectrum of a slow exchange limit and that of a fast exchange limit) in the intermediate temperature range. In tracing the motional broadening of deuteron resonance lines, there is commonly a range of temperature where the spectrum is completely washed out and unobservable between the two limiting ranges. The rather peculiar phenomenon in the present experiment can be explained by assuming that the complex cations at the two 4f sites (A and B in Fig. 6) have slightly different

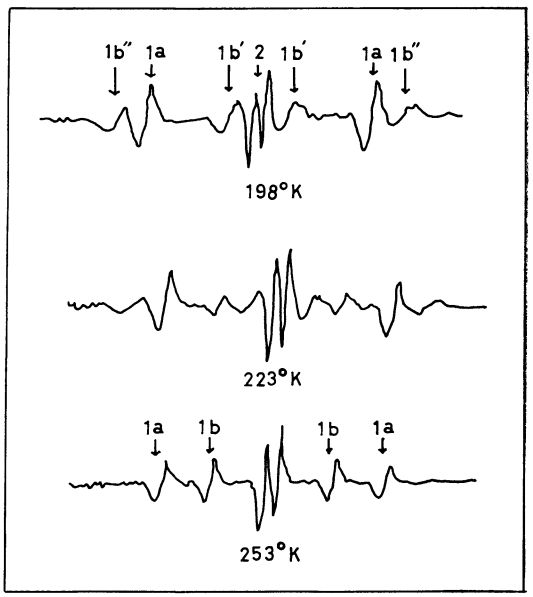

Fig. 8. Shapes of spectral lines. $H_0//15°$ from c axis in the bc plane.

Upper: At low temperature range (198°K), the lines 1a, 1b′ and 1b″ corresponding to the stationary ion are observed.
Lower: At high temperature range (253°K), the lines 1a and 1b corresponding to rapid reorienting ion are observed.
Middle: At intermediate temperature range (223° K), the lines 1b are observed together with the lines 1a, 1b′ and 1b″.

environments, and that, as a consequence, the cations at the two different 4f sites begin to reorient at different temperatures. The broadening process of the lines for the A and B of 4f sites cannot be observed separately except for the slow-exchange limit of the isotropic motion, because they overlap with each other in most of the crystal orientations. The presence of two 4f sites with different rates is verified by the b axis rotation spectrum, where the lines corresponding to the A and B of the 4f sites can be observed separately. The line broadening, in fact, takes place at different temperatures for the A and B sites: the lines 1a(A) and 1b(A) fade out at a lower temperature than do the lines 1a(B) and 1b(B). The rates obtained individually from these observations are also shown in Fig. 7 (by × marks). The apparent reorientation rates obtained here from the broadening of the spectrum such as that shown in Fig. 8 may, therefore, be considered to be subject to the effect of motions at the two sites, A and B. In the spectrum at 223°K of Fig. 8, the slow-limit lines (1b′ and 1b″) originate from the site with the slower exchange rate (site B),*2 while the central rapid-limit line originates from the site with the faster exchange

12) T. Chiba and Y. Kakiuchi, This Bulletin, **41**, 828 (1968).

rate (site A).*2 Therefore, the rate derived from the slow limit may be predominantly of the site B, and the rate derived from the rapid limit may be predominantly of the site A. This is in qualitative agreement with the results shown in Fig. 7.

Limited as they are by various experimental conditions, the exchange rates derived in this experiment are not sufficient for the determination of potential barriers hindering the reorientations. However, we believe that the qualitative features of the motions in this crystal are rather well defined.

One of the authors (T. I.) would like to thank Professor Hiroshi Kobayashi for his encouragement throughout this work.

*2 The site with the larger exchange rate for the isotropic motion is A. Although the rate for the uniaxial reorientation has not been determined for each site separately, it may be reasonable to assume that for this motion the ions at the site A have also a greater exchange rate than those at the site B.

Effect of Additives in the Radiolysis of Gaseous Ammonia at High Densities

Masaru NISHIKAWA, Kazufumi KURODA and Niro MATSUURA

Department of Pure and Applied Sciences, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received June 17, 1968)

The effect of additives and density on the radiolysis of ammonia at 140°C was studied over the density range 0.07 to 0.13 g/cc. The observation of a sharp decrease of G values in the radiolysis of pure ammonia at $d\sim0.1$ g/cc confirmed the result reported by Toi *et al.* (*Radiation Res.*, **17**, 399 (1962)). The yield of hydrogen in the presence of ~1.5 mol% C_3H_6 was practically independent of density at $G=0.65$ over the density range studied. $G(H_2)$ in the presence of C_3H_8, estimated by extrapolation to zero propane concentration, was also constant at $G\simeq5.7$ at $d\simeq0.07$ and 0.13 g/cc. These observations were discussed in relation to the mechanism for depression of G values in the radiolysis of pure ammonia at higher densities.

The radiolysis of gaseous ammonia at high densities above the critical temperature has been investigated by Toi *et al.*[1] They observed a sharp depression in $G(H_2)$ and $G(N_2)$ at a density near 0.1 g/cc and concluded that such a decrease is consistent with the formation of ion clusters. Cluster formation in the irradiated ammonia has in fact observed in the high-pressure mass spectrometer,[2] apparently in support of their conclusion. However, the fact that observed ionic species are only clusters of $NH_4^+\cdot(NH_3)_n$ type, with n as large as 20 at 200 Torr, implies that, if the ion clustering is to be invoked as the process responsible for the decrease, neutralization of charge in such a density region involves ion-ion recombination, since the neutralization of NH_4^+ whether clustered or unclustered is bound to end up in hydrogen formation as long as it occurs by way of ion-electron recombination. One such possibility as the mechanism at high densities has been proposed in a previous publication in terms of the neutralization between NH_4^+ and NH_2^-.[3] In an attempt to provide further informations as to the processes occuring at a high density, the effect of additives such as propylene and propane, which act as hydrogen atom scavengers, was investigated over the density range of 0.065 to 0.13 g/cc at 140±1°C.

Experimental

Purification of materials was described.[3] Gas chromatographic analysis of propane indicated that no organic impurities were present at levels exceeding 10^{-3} mol%.

Irradiations were carried out in glass cells of about 2 m*l* made of a glass tubing of 7 mm in outer diameter and 5 mm in inner diameter without a break-seal placed in a stainless steel autoclave in which a known volume of ammonia was introduced in order to balance the pressure in- and outside of glass cells. During irradiation in a source of approximately 1000 Ci of ^{60}Co, temperature was kept constant at 140±1°C by a heater with thermostat.

The absorbed dose in ammonia (E_a) was calculated from that determined by Fricke dosimetry on the basis

of electron density ratios. It was previously shown by Toi *et al.*[1] that the calculation is permissible in the density range $d \gtrsim 0.07$ g/cc. The dose absorbed in propane (E_p) was calculated from E_a using the ratio of stopping powers obtained by Meisels.[4] The dose rate in ammonia at $d=0.10$ g/cc was 2.34×10^{13} eV/ml/sec.

The products non-condensable at 77°K were analyzed by combustion over cupric oxide in a furnace heated at $\gtrsim$350°C.

Results and Discussion

Figure 1 shows the dependence on density of the yield of hydrogen from pure ammonia, ammonia mixed with propylene, and with propane. The concentration of propylene (~1.5 mol%) was

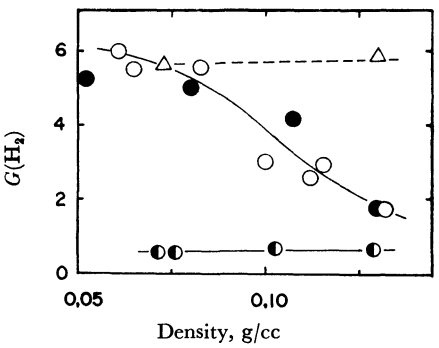

Fig. 1. Effect of density on $G(H_2)$ in the radiolysis of ammonia at 140°C.
○, from pure ammonia (this work); ●, (Toi *et al.*[1]); △, with propane (the intercept of Fig. 2); ◐, with propylene.

indicated to be sufficient as the H atom scavenger by a previous study.[3] The yield of hydrogen in the presence of propylene is demonstrated to be practically independent of density at $G(H_2)=$ 0.61—0.69, which is in agreement with $G_{H_2}=0.74$ determined previously at 50 cmHg and 22°C,[3] and also with $G(H_2)=0.70$ cited as a lower limit for G_{H_2} in liquid ammonia at 20°C.[5],*1 The dependence of $G(H_2)$ on the propane concentration is essentially the same as that observed at the ammonia pressure ~50 cmHg and 22°C. Since hydrogen is one of the main products of propane radiolysis, correction is necessary for determining the yield of hydrogen from the ammonia fraction *via* the reaction

$$H + C_3H_8 \rightarrow H_2 + C_3H_7 \qquad (1)$$

and *via* the processes leading to molecular hydrogen.

The estimate of the contribution of propane fraction to hydrogen production was made by plotting G-values of the total hydrogen ($G(H_2)_t$) calculated for the total energy absorbed by the mixture ($E_t = E_a + E_p$) against the fraction of energy absorbed by propane ($f_p = E_p/E_t$). The plot is based on the equation which is applicable only in the region where energy transfer between the components of the mixture is negligible;

$$G(H_2)_t = G(H_2)^\circ_a \cdot f_a + G(H_2)^\circ_p \cdot f_p$$

where G°_a and G°_p are those due to energy deposited in ammonia and in propane, respectively, and f_a and f_p are the fraction of energy deposited, *i. e.*, $f_a + f_p = 1$. Figure 2 shows that $G(H_2)_t$ at high densities lies, within the experimental error, on the same straight line obtained at ~50 cmHg

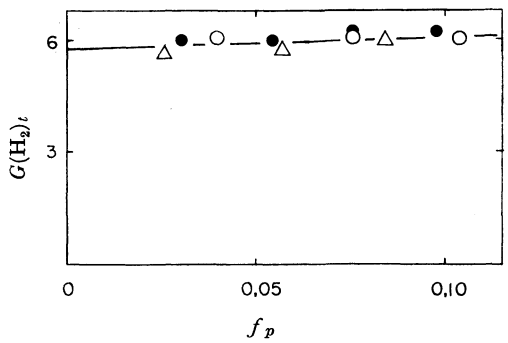

Fig. 2. Dependence of $G(H_2)_t$ from $NH_3 + C_3H_8$ mixtures at 140°C on the fraction of energy absorbed by C_3H_8 ($f_p = E_p/E_t$).
○, $d \cong 0.13$ g/cc; △, $d \cong 0.07$ g/cc;
●, $d \cong 0.0005$g/cc (~50 cmHg) at 22°C

and 22°C. Extrapolation to $f_p=0$, by the least square method over the points including those for ~50 cmHg, yields $G(H_2)^\circ_a = 5.74 \pm 0.13$, which should be a measure of $G_H + G_{H_2}$ of ammonia radiolysis. $G_H=5.1$ thus determined is significantly lower than the values hitherto reported.[7,8] The disagreement in the value of G_H will be discussed elsewhere.[6]

The observed yield of hydrogen in the presence of propylene and of propane appears to indicate that G_H and G_{H_2} are independent of temperature and density. "Molecular" hydrogen seems less likely to be associated with the observed depression in the yield at $d \cong 0.1$ g/cc as it is relatively unimportant at the lower density region. It is, therefore, the behavior of G_H that is playing the major role in the observed phenomenon. The finding that G_H is apparently constant at $d \cong 0.07$ and at 0.13 g/cc

may be interpreted at least in two ways in this regard. First the yield of hydrogen atoms is really independent of density; it follows that the processes responsible for the depression must be those in which hydrogen atoms disappear with the precursor for nitrogen. Secondly the apparent constancy of G_H is due to alterations in the reaction paths caused by the addition of propane, and that in pure ammonia G_H itself is influenced by the density change. For the former case, one of the most probable processes is the geminate recombination of radical pairs

$$H + NH_2 \xrightarrow{M} NH_3 \qquad (2)$$

whose specific rate is estimated to be 1.2×10^{10} M^{-1}·sec^{-1} at 1 atm.[9] This reaction appears to be favored by higher density because of the track effect leading to relatively high local concentration of radicals. However, Toi *et al.* noted that the track effect is not sufficiently sensitive to density to account for the sudden decrease in the yield. Furthermore, the specific rate for the reaction

$$H + NH_3 \longrightarrow NH_2 + H_2 \qquad (3)$$

is of the order of 10^4 M^{-1}·sec^{-1} at 140°C,[10] so that it is expected to compete successfully with (2) in the bulk ammonia. The extent of "cage" effect $d \sim 0.1$ g/cc and 140°C would not be large enough for reaction (2) to be efficient. Then, the latter seems to be more likely.

$G(N_2)$ in the presence of 1—3 mol% propane is 0.6 at $d=0.07$ and 0.13 g/cc, which is markedly lower than $G(N_2)=1.7$ in the pure ammonia at $d=0.07$ g/cc, but about equal at $d=0.13$ g/cc. The depression of $G(N_2)$ by propane suggests the occurrence of the reaction

$$NH_2 + C_3H_8 \longrightarrow NH_3 + C_3H_7 \qquad (4)$$

If reaction (4) proceeds faster at 140°C than the reaction

$$NH_2 + e^- \longrightarrow NH_2^- \qquad (5)$$

which was included in the mechanism proposed to explain the depression of G values in pure ammonia at $d \sim 0.1$ g/cc, the apparent independence of $G(H_2)$ on density observed in the $NH_3+C_3H_8$ mixtures is compatible with the mechanism; namely, in pure ammonia at high densities, the presence of large clusters lowers the electrostatic field of NH_4^+ to such an extent that reaction (5) can compete for electrons, and the neutralization NH_4^+(clustered)$+NH_2^-$(clustered)$\rightarrow 2NH_3$ reduces both $G(H_2)$ and $G(N_2)$, while in the presence of propane the neutralization $NH_4^+ + e^- \rightarrow H + NH_3$ takes place, which followed by reaction (1) keeps the yield of hydrogen constant. The difference in $G(H_2)$ of pure ammonia at $d=0.07$ and at 0.13 g/cc, $\Delta G(H_2) \simeq 4.5$, is somewhat larger than the value of $100/W$ ($W=26.5$ eV[4]), which is expected if it is to be related to the change in the neutralization process. This apparently excessive decrease might also be explained by the depletion of NH_2 *via* reaction (5) which inhibits processes leading to additional hydrogen formation from precursors other than H atoms. The observation that at 1 atm $G(H_2)$ from pure ammonia at $\gtrsim$100°C is significantly larger than $G(H_2)$ in the presence of propane at the same temperature[8] suggests the occurrence of such processes as a mode of hydrogen formation at a higher temperature, since all the H atoms are expected to be converted into H_2 by reaction (1) in the presence of propane, and by reaction (3) in pure ammonia. This mechanism has the desired sensitivity to density, since it is based on the presence of large clusters. The observation that N_2O has little effect on $G(H_2)$ in liquid ammonia[5] appears to support the mechanism in which it suggests the neutralization in the liquid phase is occurring mostly by $NH_4^+ + NH_2^-$. It is desirable to test the effect of electron scavengers in this density range to see if there is change in the importance of ionic processes. However, most of the compounds used for such a purpose act as hydrogen atom scavenger as well at 140°C, and since the addition of propane has the possibility of changing the reaction paths, neither the use of electron scavengers together with propane can be expected to yield useful informations in this regard. At this stage,the present study could not confirm the proposed mechanism, but appears, at least, to be consistent with it.

We should like to thank Professor M. Takahashi of this department and Dr. K. Fueki of Nagoya University for valuable discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 119—126 (1969)

The Optical Resolution and Circular Dichroism of Cobalt(III) Complexes of the $[Co(O-O)_2(O-N)]^{2-}$ Type

Kiyoshi YAMASAKI, Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received January 31, 1968)

Four cobalt(III) complexes of the tris-chelate type containing two dicarboxylate anions and one aminocarboxylate anion have been newly prepared and separated into their optical isomers by a chemical resolution method: they are bismalonatoglycinato-, bismalonato(L-alaninato)-, bisoxalato(L-alaninato)- and bisoxalato(β-alaninato)-cobalt(III) complexes. The diastereomeric isomers of bisoxalato(L-alaninato)cobalt(III) complex have also been separated by the solubility difference between their barium salts. The absorption spectra, circular dichroism spectra and rotatory dispersion of these complexes have been measured and discussed in relation to the splitting of the d-d transition bands. The absolute configurations of the complexes have been inferred from their circular dichroism spectra. The additivity of configurational and vicinal contributions to the optical activity has been substantiated for the bisoxalato- and bismalonato-(L-alaninato)-cobalt(III) complexes, and some considerations concerning the less stereospecific formation of the L-alaninato diastereomeric isomers have been made in relation to the additivity.

The splitting of the d-d transition bands has been studied for many types of complexes on the basis of their CD (circular dichroism) spectra and their RD (rotatory dispersion) curves.[1-6] It seems, however, that the splitting trend of the first absorption band for a bis(dicarboxylato)mono(aminocarboxylato)cobalt(III) type complex is not completely clear at the present time, because the bisoxalatoglycinatocobalt(III) complex is the only known example.[4]

Bürer pointed out that cobalt(III) complexes containing three six-membered chelate rings differ from those with three five-membered chelate rings in CD behavior of the first absorption band.[7] However, this type of problem has still not been solved. Thus it was thought desirable to study the CD spectra of complexes containing six- and five-membered chelate rings mixed.

In the present paper, the preparations and optical resolutions of four new tris-chelate complexes of the $[Co(O-O)_2(O-N)]^{2-}$ type*1 will be reported. The CD spectra of the complexes will be compared with one another, and their absolute configurations inferred from their CD spectra. The additivity of configurational and vicinal contributions to the optical activity will be substantiated for the two L-alaninato complexes, and considered in relation to the formation ratio of the diastereomeric isomers. The solubility difference between the diastereomers containing these cobalt(III) complex ions will be briefly considered.

Experimental

Preparations of Malonato Complexes. The malonato complexes were prepared using a dark-green solution containing $[Co(mal)_3]^{3-}$.

1) $Ba[Co(mal)_2(gly)]\cdot 1.5H_2O$: To a solution containing 7.9 g of malonic acid and 11.1 g of sodium malonate in 30 m*l* of water were added 12.0 g of cobalt(II) acetate tetrahydrate, 6 m*l* of 50% acetic acid and 10 g of lead dioxide. The resulting mixture was cooled in an ice bath and mechanically stirred for about one hour. After the color of solution had changed from dark-red to dark-green, 3.7 g of glycine was added. The color of the solution gradually changed to dark-

blue when the resulting mixture was stirred at about 60°C for about 40 min. The dark-blue solution was placed in an ice bath for an hour, and then most insoluble material filtered off. To the filtrate, 4 m*l* of 30% aqueous solution of barium perchlorate was added, and the barium malonate deposited removed by filtration. The blue complex desired began to crystallize out when an additional 50 m*l* of barium perchlorate solution was added to the filtrate. After the solution had been cooled in an ice bath for an hour, the crude complex was filtered and washed with water, then methanol, and dried in air. 11 g.

The purification of this complex was performed as follows. Seven grams of the crude complex was added to a solution of 2.4 g of anhydrous sodium sulfate in 50 m*l* of water, and then the barium sulfate which precipitated out was filtered off. To the filtrate was added a solution of 8 g of barium perchlorate in 10 m*l* of water. After a small amount of the barium malonate deposited had been filtered off, the filtrate was kept in a refrigerator overnight. The complex which separated out was filtered and washed with an appropriate amount of water, then methanol, and dried in a vacuum desiccator over phosphorus pentoxide.

Found: C, 19.34; H, 2.21; N, 2.75%. Calcd for $Ba[Co(C_3H_2O_4)_2(C_2H_4NO_2)]\cdot 1.5H_2O$: C, 19.14; H, 2.20; N, 2.80%.

2) Ba[Co(mal)$_2$(L-ala)]: This complex was obtained by a procedure similar to that in 1) using L-alanine instead of glycine. The dark-green solution, containing 4.4 g of L-alanine, was kept at 60°C on a water bath with stirring for 40 min. After the mixture had been cooled to room temperature, most insoluble material was removed by filtration. Twenty grams of barium perchlorate was dissolved in the filtrate, and then the barium malonate which precipitated out was filtered off. An additional precipitate, which deposited upon adding 50 m*l* of methanol to the filtrate, was removed by filtration. The desired complex was precipitated out by adding 100 m*l* of a methanol-ethanol mixture (1 : 1) to the filtrate, and was filtered, washed with methanol and dried in a vacuum desiccator. 10 g.

The crude complex was dissolved in 40 m*l* of water, and to this solution was added 40 m*l* of methanol. After a small amount of the resulting insoluble material had been removed, 5 g of barium perchlorate was dissolved in the filtrate and 60 m*l* of methanol added to it with stirring. The fine bluish-violet crystals which deposited were filtered off, washed with methanol and dried in a vacuum desiccator over phosphorus pentoxide.

Found: C, 22.14; H, 2.16; N, 2.71%. Calcd for $Ba[Co(C_3H_2O_4)_2(C_3H_6NO_2)]$: C, 22.13; H, 2.07; N, 2.87%. $[M]_{546}=-400°$, $[M]_{589}=+50°$.

Preparations of Oxalato Complexes. The oxalato complexes were prepared in the following two ways. In the first one, the binuclear complex, $Na_4[(ox)_2Co(OH)_2Co(ox)_2]\cdot 5H_2O$,[8] was used as starting material. In another one, a solution containing cobalt(II) chloride, potassium oxalate and amino acid (1 : 2 : 1) was oxidized with lead dioxide.

1) Ba[Co(ox)$_2$(gly)]·0.5H$_2$O: The preparation of this complex was reported by Dwyer *et al.*[4] In the present work, however, two different methods were attempted.

1-a). To a solution of 7.0 g of $Na_4[Co_2(ox)_4(OH)_2]\cdot 5H_2O$ and 1.5 g of glycine in 20 m*l* of water were added 3 g of lead dioxide and 6 m*l* of 25% acetic acid. The resulting mixture was kept on a water bath at 65°C with stirring for 20 min. After the color of solution had changed from dark-green to dark-blue, the mixture was cooled to room temperature and then lead dioxide removed by filtration. One gram of barium perchlorate was added to the filtrate, and then a small amount of the insoluble material which appeared filtered off. A further 8 g of barium perchlorate was dissolved in the filtrate and the solution cooled in an ice bath for an hour. The blue complex desired precipitated out and was filtered and dried in air. 3.4 g. The crude complex was purified as described in 1) of Preparation of Malonato Complexes.

Found: C, 15.82; H, 1.19; N, 3.00%. Calcd for $Ba[Co(C_2O_4)_2(C_2H_4NO_2)]\cdot 0.5H_2O$: C, 15.79; H, 1.11; N, 3.07%.

1-b). Twenty grams of potassium oxalate monohydrate and 4.3 g of glycine were dissolved in 40 m*l* of hot water. To the solution was added a solution containing 12.0 g of cobalt(II) chloride hexahydrate in 15 m*l* of hot water. The mixture was kept at 70°C on a water bath and 20 g of lead dioxide added, little by little. The color of solution gradually changed to dark bluish-violet within one hour. After the mixture had been cooled to room temperature, a large amount of the insoluble material which precipitated out was filtered off. The filtrate was kept in a refrigerator overnight. Additional insoluble material which deposited was filtered off, and a small amount of ethanol added to the filtrate. The blue precipitate was removed, and then the potassium salt of the desired blue complex was obtained by adding a large amount of ethanol to the filtrate. The crude product was recrystallized from water by the addition of ethanol. The crystals were filtered, washed with ethanol and ether and dried in a vacuum desiccator over phosphorus pentoxide.

Found: C, 18.87; H, 1.10; N, 3.72%. Calcd for $K_2[Co(C_2O_4)_2(C_2H_4NO_2)]\cdot 3H_2O$: C, 18.61; H, 1.04; N, 3.61%.

The potassium salt can be easily changed to the barium salt with barium acetate monohydrate.

2) K$_2$[Co(ox)$_2$(L-ala)]: In the preparation of this complex, the same procedure as described in 1-a) was employed, but with 1.7 g of L-alanine instead of 1.5 g of glycine. After the lead dioxide had been removed, 4 g of potassium acetate was dissolved in the filtrate. To the solution was added 70 m*l* of methanol, and the slurry precipitate removed by filtration. The blue complex desired was obtained by adding a further 100 m*l* of methanol to the filtrate. Recrystallization was carried out from water by the addition of methanol. The crystals deposited were filtered, washed with methanol and acetone and dried in a vacuum desiccator over phosphorus pentoxide.

Found: C, 21.18; H, 1.81; N, 3.54%. Calcd for $K_2[Co(C_2O_4)_2(C_3H_6NO_2)]$: C, 20.94; H, 1.50; N, 3.48%. $[M]_{546}=-80°$, $[M]_{589}=+440°$.

3) Ba[Co(ox)$_2$(β-ala)]: The β-alaninato complex was prepared using 1.7 g of β-alanine instead of 1.5 g of glycine as in 1-a). After the lead dioxide had been removed, 8 g of barium perchlorate was dissolved in the filtrate and the solution cooled in an ice bath. A small

8) H. F. Holtzclaw, Jr., "Inorganic Syntheses," Vol. VIII, p. 204 (1966).

amount of the colorless insoluble material which precipitated out was filtered off, and then 10 m*l* of methanol added to the filtrate. After a small amount of the slurry precipitate which resulted had been removed, a further 30 m*l* of methanol was added to the filtrate with stirring. The barium salt of the desired blue complex which precipitated out was filtered off, washed with a water-methanol mixture(1 : 1), acetone and then ether, and dried in a desiccator. 4.7 g.

The crude complex was recrystallized two times from water by adding methanol. The crystals obtained were dried in a vacuum desiccator over phosphorus pentoxide.

Found: C, 18.14; H, 1.70; N, 3.02%. Calcd for $Ba[Co(C_2O_4)_2(C_3H_6NO_2)]$: C, 18.28; H, 1.31; N, 3.04%.

Optical Resolutions. The five complexes described above were resolved using strychnium sulfate and $(+)_{546}$- or $(-)_{546}$-$[Co(ox)(en)_2]I$ as resolving agents. The optical isomers of $[Co(ox)_2(L\text{-ala})]^{2-}$ were also separated without resolving agent.

i) Bismalonatoglycinatocobalt(III) Complex: *i-a) With Strychnium Sulfate.* Seven grams of strychnium sulfate pentahydrate was suspended in 40 m*l* of water and 4.0 g of $Ba[Co(mal)_2(gly)]\cdot 1.5H_2O$ added. The mixture was vigorously shaken and barium sulfate which precipitated out was removed. When the filtrate was cooled in an ice bath and the vessle scrubbed with a glass rod, a pale blue diastereomer began to crystallize out. After the solution had been cooled in an ice bath for a while, the less soluble diastereomer which precipitated out was filtered off and washed with a little ice water. The diastereomer was dissolved in 5 m*l* of water and an excess of sodium perchlorate added to the solution. Then the strychnium perchlorate which precipitated out was removed. When an excess of barium perchlorate was dissolved in the filtrate and 5 m*l* of methanol added to it, the optically active barium salt of the complex crystallized out. The complex was filtered, washed with a little ice water, methanol and then acetone, and dried in a vacuum desiccator over phosphorus pentoxide.

Found: C, 18.54; H, 2.32; N, 2.66%. Calcd for $Ba[Co(C_3H_2O_4)_2(C_2H_4NO_2)]\cdot 2.5H_2O$: C, 18.50; H,2.51; N, 2.70%. $[M]_{546}=-2400°$, $[M]_{589}=-4600°$.

i-b) By $(-)_{546}$-[Co(ox)(en)$_2$]I. To a solution containing 1.2 g of anhydrous sodium sulfate in 15 m*l* of hot water was added 4.0 g of $Ba[Co(mal)_2(gly)]\cdot 1.5H_2O$. Then the barium sulfate which deposited was filtered off and washed with 5 m*l* of water. The washing was combined with the filtrate (solution "a"). Silver acetate (1.3 g) and $(-)_{546}$-$[Co(ox)(en)_2]I$ (3.6 g) were shaken well in 15 m*l* of water, and the silver iodide which precipitated out was filtered off and washed with 5 m*l* of water. The washing was combined with the filtrate (solution "b"). To solution "a" was added solution "b", and the resultant solution concentrated in a vacuum desiccator over phosphorus pentoxide until the red-brown diastereomer appeared. The diastereomer was filtered off, washed with a water-methanol mixture (2 : 1) and then acetone, and dried in a vacuum desiccator over phosphorus pentoxide. The less soluble diastereomer, $(-)_{546}$-$[Co(ox)(en)_2]_2\cdot(-)_{546}$-$[Co(mal)_2$-$(gly)]\cdot 2H_2O$, was recrystallized from water by the addition of a methanol-ethanol mixture(1 : 1).

Found: C, 26.12; H, 4.63; N, 13.89%. Calcd for $[Co(C_2O_4)(C_2H_8N_2)_2]_2\cdot[Co(C_3H_2O_4)_2(C_2H_4NO_2)]\cdot 2H_2O$: C, 26.48; H, 4.89; N, 13.90%. $[M]_{546}=-10270°$, $[M]_{589}=-10390°$.

The diastereomer was suspended in a small amount of water, and a slight excess of sodium iodide added to the suspension. After the mixture had been stirred well, $(-)_{546}$-$[Co(ox)(en)_2]I$ which precipitated out was filtered off and an excess of barium perchlorate dissolved in the filtrate. The barium salt of the optically active complex was obtained by adding methanol to the solution and cooling it in an ice bath. This was filtered, washed with a water-methanol mixture (1 : 1), methanol and then acetone, and dried in a vacuum desiccator over phosphorus pentoxide. $[M]_{546}=-2550°$, $[M]_{589}=-4700°$.

ii) Bismalonato(L-alaninato)cobalt(III) Complex: *ii-a) With Strychnium Sulfate.* A small excess of strychnium sulfate pentahydrate (4.5 g) was added to a solution containing 2.5 g of unresolved $Ba[Co(mal)_2(L\text{-ala})]$ in 15 m*l* of water. The diastereomer obtained by a procedure similar to that of i-a) was filtered off and washed with a methanol-ether mixture (1 : 1). Recrystallization was carried out from methanol by the addition of ether. When the recrystallized diastereomer was dissolved in a small amount of water and treated with an excess of barium perchlorate, strychnium perchlorate deposited out. After it had been removed, the configurationally optically active barium salt of the complex was obtained by the addition of methanol and ether to the filtrate. The complex was filtered, washed with a methanol-ether mixture (1 : 1) and dried in a vacuum desiccator over phosphorus pentoxide.

Found: C, 22.26; H, 2.32; N, 2.87%. Calcd for $Ba[Co(C_3H_2O_4)_2(C_3H_6NO_2)]$: C, 22.13; H, 2.07; N, 2.87%. $[M]_{546}=+1300°$, $[M]_{589}=+3200°$.

ii-b) By $(+)_{546}$- or $(-)_{546}$-[Co(ox)(en)$_2$]I. Solution "a", containing the sodium salt of the complex (obtained from 4.9 g of unresolved $Ba[Co(mal)_2(L\text{-ala})]$, 1.4 g of anhydrous sodium sulfate and 15 m*l* of water), and solution "b", containing the acetate of $(+)_{546}$-$[Co(ox)$-$(en)_2]^+$ (obtained from 7.9 g of $(+)_{546}$-$[Co(ox)(en)_2]I$, 3.3 g of silver acetate and 20 m*l* of water), were mixed together. When the mixed solution was cooled in an ice bath, the less soluble diastereomer, $(+)_{546}$-$[Co(ox)$-$(en)_2]_2\cdot(-)_{546}$-$[Co(mal)_2(L\text{-ala})]\cdot H_2O$, crystallized out. The diastereomer was recrystallized from water by the addition of methanol. The crystals were filtered, washed with methanol and then acetone, and dried in a vacuum desiccator over phosphorus pentoxide.

Found: C, 27.90; H, 5.05; N, 13.37%. Calcd for $[Co(C_2O_4)(C_2H_8N_2)_2]_2\cdot[Co(C_3H_2O_4)_2(C_3H_6NO_2)]\cdot H_2O$: C, 27.93; H, 4.91; N, 13.96%. $[M]_{546}=+5450°$, $[M]_{589}=+1460°$.

The configurationally optically active barium salt was obtained by the same method as in i-b). It was recrystallized from water by adding a methanol-ethanol mixture (1 : 1). The fine crystals obtained were filtered, washed with methanol and then acetone, and dried in a vacuum desiccator over phosphorus pentoxide.

Found: C, 22.56; H, 1.93; N, 2.83%. Calcd for $Ba[Co(C_3H_2O_4)_2(C_3H_6NO_2)]$: C, 22.13; H, 2.07; N, 2.87%. $[M]_{546}=-2800°$, $[M]_{589}=-4400°$.

When $(-)_{546}$-$[Co(ox)(en)_2]I$ was used instead of $(+)_{546}$-$[Co(ox)(en)_2]I$ in the above procedure, the less soluble diastereomer obtained was $(-)_{546}$-$[Co(ox)$-$(en)_2]_2\cdot(-)_{546}$-$[Co(mal)_2(L\text{-ala})]\cdot 1.5H_2O$.

Found: C, 27.74; H, 4.86; N, 13.54%. Calcd

for $[Co(C_2O_4)(C_2H_8N_2)_2]_2\cdot[Co(C_3H_2O_4)_2(C_3H_6NO_2)]\cdot 1.5H_2O$: C, 27.65; H, 4.97; N, 13.82%. $[M]_{546}=-9100°$, $[M]_{589}=-7140°$.

iii) Bisoxalatoglycinatocobalt(III) Complex: This complex has been resolved by Dwyer *et al.*[4] A slightly modified method was employed in the present study. Namely, a solution containing the sodium salt of the complex (obtained from $Ba[Co(ox)_2(gly)]\cdot 0.5H_2O$, sodium sulfate and water in the same way as in i-b)) was used instead of $Na_2[Co(ox)_2(gly)]\cdot 1.5H_2O$ as in the reported procedure. The barium salt of the $(-)_{546}$-isomer, which was obtained from the less soluble diastereomer with $(+)_{546}$-$[Co(ox)(en)_2]^+$, was dried in a vacuum desiccator over phosphorus pentoxide.

Found: C, 14.87; H, 1.77; N, 2.99%. Calcd for $Ba[Co(C_2O_4)_2(C_2H_4NO_2)]\cdot 2H_2O$: C, 14.94; H, 1.66; N, 2.90%. $[M]_{546}=-8100°$, $[M]_{589}=-1300°$.

iv) Bisoxalato(L-alaninato)cobalt(III) Complex: *iv-a) Without Resolving Agent.* Eight grams of barium perchlorate was dissolved in a solution containing the sodium salt of the complex as described in 2) of Preparation of Oxalato Complexes, and the less soluble diastereomer of the barium salt, $(+)_{546}$-$Ba[Co(ox)_2(L\text{-}ala)]\cdot 0.5H_2O$, crystallized out. After the mixture had been cooled in an ice bath for one hour, the barium salt was filtered, washed with water, methanol and then acetone, and dried in a vacuum desiccator over phosphorus pentoxide.

Found: C, 18.05; H, 1.53; N, 2.98%. Calcd for $Ba[Co(C_2O_4)_2(C_3H_6NO_2)]\cdot 0.5H_2O$: C, 17.93; H, 1.50; N, 2.99%. $[M]_{546}=+7100°$, $[M]_{589}=+1300°$.

iv-b) By $(+)_{546}$- or $(-)_{546}$-[Co(ox)(en)$_2$]I. This method is almost the same as i-b). A solution of 4.0 g of $K_2[Co(ox)_2(L\text{-}ala)]$ in 25 m*l* of water was used instead of solution "a" containing $Na_2[Co(mal)_2(gly)]$ in i-b). The less soluble diastereomer formed by using $(+)_{546}$-$[Co(ox)(en)_2]I$ was $(+)_{546}$-$[Co(ox)(en)_2]_2\cdot(-)_{546}$-$[Co(ox)_2(L\text{-}ala)]\cdot H_2O$.

Found: C, 26.03; H, 4.64; N, 14.40%. Calcd for $[Co(C_2O_4)(C_2H_8N_2)_2]_2\cdot[Co(C_2O_4)_2(C_3H_6NO_2)]\cdot H_2O$: C, 26.06; H, 4.57; N, 14.40%. $[M]_{546}=0°$, $[M]_{589}=+5100°$.

By the same method as in i-b), the barium salt of the $(-)_{546}$-isomer was obtained from the diastereomer.

Found: C, 17.54; H, 1.40; N, 2.68%. Calcd for $Ba[Co(C_2O_4)_2(C_3H_6NO_2)]\cdot H_2O$: C, 17.57; H, 1.67; N, 2.93%. $[M]_{546}=-7050°$, $[M]_{589}=-500°$.

When $(-)_{546}$-$[Co(ox)(en)_2]I$ was used as a resolving agent, the less soluble diastereomer obtained was $(-)_{546}$-$[Co(ox)(en)_2]_2\cdot(+)_{546}$-$[Co(ox)_2(L\text{-}ala)]\cdot 0.5H_2O$.

Found: C, 26.44; H, 4.83; N, 14.12%. Calcd for $[Co(C_2O_4)(C_2H_8N_2)_2]_2\cdot[Co(C_2O_4)_2(C_3H_6NO_2)]\cdot 0.5H_2O$: C, 26.35; H, 4.54; N, 14.56%. $[M]_{546}=-6560°$, $[M]_{589}=-5280°$.

The barium salt of the $(+)_{546}$-isomer was obtained from the diastereomer. $[M]_{546}=+7100°$, $[M]_{589}=+1300°$.

v) Bisoxalato(β-alaninato)cobalt(III) Complex: Similar to the method of i-b), a mixed solution containing the sodium salt of the complex and the acetate of $(-)_{546}$-$[Co(ox)(en)_2]^+$ was cooled in an ice bath for one hour. The less soluble diastereomer deposited, $(-)_{546}$-$[Co(ox)(en)_2]_2\cdot(-)_{546}$-$[Co(ox)_2(\beta\text{-ala})]$, was filtered, washed with a little ice water and dried in air. Recrystallization was carried out from hot water by adding methanol and cooling in an ice bath. The crystals deposited were filtered, washed with a small amount of water, methanol and then acetone, and dried in a vacuum desiccator over phosphorus pentoxide.

Found: C, 26.76; H, 4.72; N, 14.35%. Calcd for $[Co(C_2O_4)(C_2H_8N_2)_2]_2\cdot[Co(C_2O_4)_2(C_3H_6NO_2)]$: C, 26.60; H, 4.43; N, 14.40%. $[M]_{546}=-1200°$, $[M]_{589}=-9700°$.

The optically active barium salt of the complex was obtained from the diastereomer by the same method as in i-b).

Found: C, 18.86; H, 1.32; N, 3.18%. Calcd for $Ba[Co(C_2O_4)_2(C_3H_6NO_2)]$: C, 18.28; H, 1.32; N, 3.04%. $[M]_{546}=-4900°$, $[M]_{589}=-3300°$.

Measurements. Electronic absorption spectra were measured with a Beckman DU spectrophotomer. CD spectra were recorded with a Roussel-Jouan Dichrographe and RD curves with a Yanagimoto recording spectropolarimeter, Model-185. All measurements were made in aqueous solutions at room temperature.

Results and Discussion

The d–d Transition Bands. The absorption, CD and RD curves of $(-)_{546}$-$[Co(ox)_2(gly)]^{2-}$, $(-)_{546}$-$[Co(ox)_2(\beta\text{-ala})]^{2-}$ and $(-)_{546}$-$[Co(mal)_2(gly)]^{2-}$ are shown in Figs. 1 and 2, and those of the unresolved L-alaninato complexes, $K_2[Co(ox)_2(L\text{-ala})]$ and $Ba[Co(mal)_2(L\text{-ala})]$, in Fig. 3. The

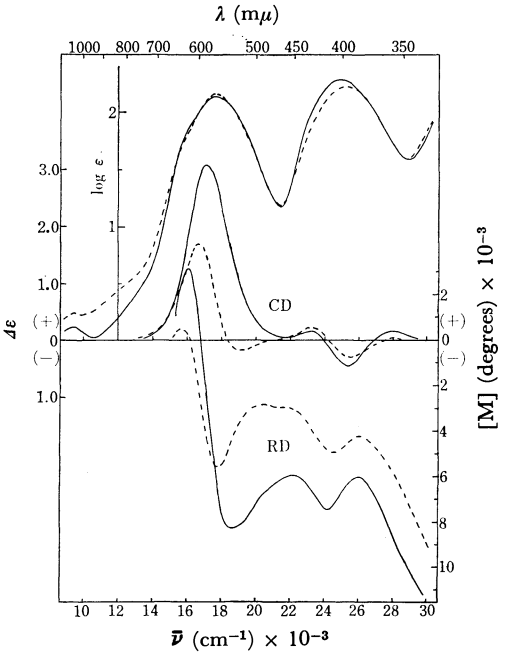

Fig. 1. Absorption, CD, and RD curves of $(-)_{546}$-$Ba[Co(ox)_2(gly)]\cdot 2H_2O$ (——) and $(-)_{546}$-$Ba[Co(ox)_2(\beta\text{-ala})]$ (------).

first absorption bands of the complexes show a vague shoulder (at about 640 mμ) at the lower energy side of the main peak. This absorption behavior coincides with the result expected from

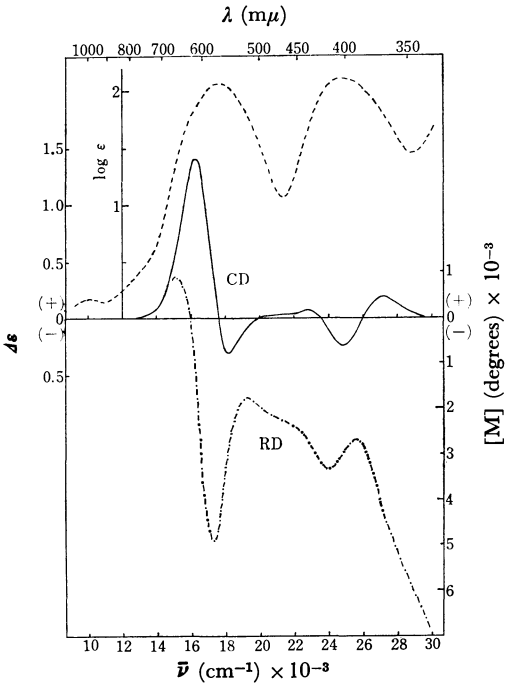

Fig. 2. Absorption (------), CD (——), and RD (—·—·—) curves of $(-)_{546}$-$Ba[Co(mal)_2(gly)]\cdot 2.5H_2O$.

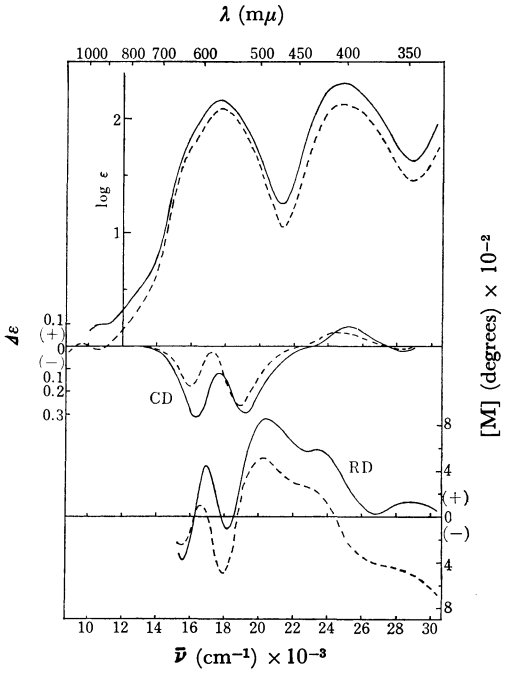

Fig. 3. Absorption, CD, and RD curves of unresolved $K_2[Co(ox)_2$(L-ala)] (——) and $Ba[Co(mal)_2$(L-ala)] (------).

a theory based on the approximation that the effective symmetry of the complexes is C_{4v}.[9] In the corresponding region, the CD cruve of $(-)_{546}$-$[Co(ox)_2(gly)]^{2-}$ shows a positive band, while the CD curves of $(-)_{546}$-$[Co(ox)_2(\beta\text{-ala})]^{2-}$ and $(-)_{546}$-$[Co(mal)_2(gly)]^{2-}$ show two bands (+ and −, listing from the lower energy side), as is seen in Figs. 1 and 2. It is noted, however, that the shape of the CD band of $(-)_{546}$-$[Co(ox)_2(gly)]^{2-}$ is not symmetrical. This trend may indicate that another weak CD band located on the higher energy side is overlapped by the main CD band at 584 mμ. This suggestion is supported by a comparison of the CD behavior with that of $(-)_{546}$-$[Co(ox)_2(\beta\text{-ala})]^{2-}$ or $(-)_{546}$-$[Co(mal)_2(gly)]^{2-}$. Moreover, the unresolved L-alaninato complexes also show two CD bands (− and −) in the corresponding region, as shown in Fig. 3. A similar consideration of the relationship between the CD and the first absorption band has been reported for aminocarboxylatobisethylenediaminecobalt(III) complexes,[2] which also belong to the same symmetry, C_1, as the present complexes. From these facts, it is indicated that all complexes treated in the present paper have at least two CD bands in the first absorption band region.

The second absorption bands of the complexes do not appear to have any splitting. However, the CD spectra of the $(-)_{546}$-isomers have three CD bands (+, − and +) in the corresponding region, though their intensities are somewhat different from one another, as seen in Figs. 1 and 2 and Table 1. From this fact, it might be thought that these three CD bands correspond to three A components under C_1 symmetry, because the true symmetry of the present complexes is C_1.

The absolute configuration Δ (left-handed screw along the pseudo-C_3 axis) has been assigned for $(-)_{546}$-$[Co(ox)_2(gly)]^{2-}$ by Dwyer *et al.*, on the basis of the CD behavior in the first absorption band region.[4] From a comparison of the net sign[10] of the CD bands in the first absorption band region with that of the CD bands of Δ-$(+)_{589}$-$[Co(en)_3]^{3+}$, the Δ configuration can be assigned to all the $(-)_{546}$-isomers in this paper, including those of the two L-alaninato complexes, and the Λ configuration to the $(+)_{546}$-isomers. The absolute configurations of the optical isomers, which formed the less soluble diastereomers with strychnium cation or optically active $[Co(ox)(en)_2]^+$, are summarized in Table 2. It is not surprising that the $(-)_{546}$-isomer of $[Co(mal)_2$(L-ala)$]^{2-}$ forms the less soluble diastereomer with both $(-)_{546}$- and $(+)_{546}$-$[Co(ox)(en)_2]^+$, because $(+)_{546}$- and $(-)_{546}$-$[Co(mal)_2$(L-ala)$]^{2-}$ are not antipodal with each other.

TABLE 2. OPTICAL ISOMER FORMING THE LESS SOLUBLE DIASTEREOMER WITH CATION OF RESOLVING AGENT

Complex anion	Cation of the resolving agent		
	$(-)_{546}$-$[Co(ox)(en)_2]^+$	$(+)_{546}$-$[Co(ox)(en)_2]^+$	Strychnium cation
$[Co(ox)_2(gly)]^{2-}$	Λ-$(+)_{546}$	Δ-$(-)_{546}$	#
$[Co(ox)_2$(L-ala)$]^{2-}$*	Λ-$(+)_{546}$	Δ-$(-)_{546}$	#
$[Co(ox)_2(\beta$-ala)$]^{2-}$	Δ-$(-)_{546}$	Λ-$(+)_{546}$	#
$[Co(mal)_2(gly)]^{2-}$	Δ-$(-)_{546}$	Λ-$(+)_{546}$	Δ-$(-)_{546}$
$[Co(mal)_2$(L-ala)$]^{2-}$	Δ-$(-)_{546}$	Δ-$(-)_{546}$	Λ-$(+)_{546}$

* The isomer of this complex forming the less soluble barium salt is the Λ-$(+)_{546}$-isomer.
\# The resolution has not been tried.

The configurationally optically active isomers, Δ- and Λ-$[Co-(OO)_2(L\text{-ala})]^{2-}$, are not antipodal, but diastereomeric to each other, as mentioned above. It is expected, therefore, that separation of the isomers due to the solubility difference between them is possible as in the case of *trans(N)*-oxalatobis(L-alaninato)cobalt(III) complex[6] or tris-(L-alaninato)cobalt(III) complexes.[11,12] In fact, the diastereomeric barium salts, Δ- and Λ-$Ba[Co(ox)_2(L\text{-ala})]$, were completely separated only by crystallization, as described in the Experimental section, though it was unsuccessful in the case of the potassium salts. From this fact, it is pointed out that even only one asymmetric carbon atom of a ligand is effective for separation of the diastereomers, and that the possibility of separation depends merely on the solubilities of the salts employed.

Additivity of Configurational and Vicinal Effects. The CD and RD curves of Δ-$(-)_{546}$- and Λ-$(+)_{546}$-$[Co(ox)_2(L\text{-ala})]^{2-}$ are shown in Fig. 4. The two isomers are not antipodal, but

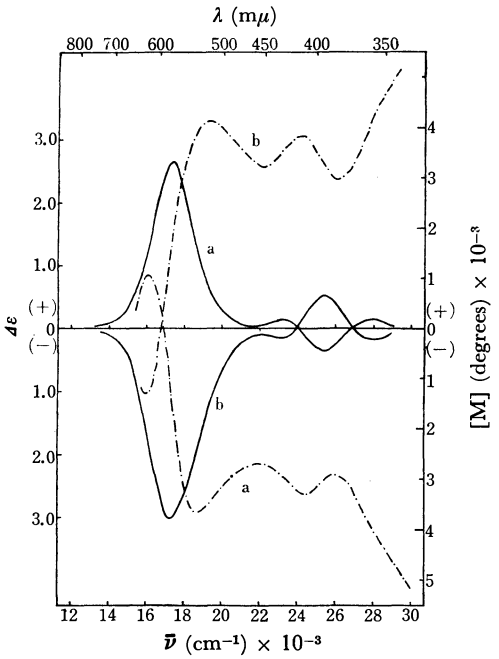

Fig. 4. CD (——) and RD (—·—) curves of Δ-$(-)_{546}$-$Ba[Co(ox)_2(L\text{-ala})]\cdot H_2O$ (a) and Λ-$(-)_{546}$-$Ba[Co(ox)_2(L\text{-ala})]\cdot 0.5H_2O$ (b).

diastereomeric to each other. It was reported for some cobalt(III) complexes that the configurational and vicinal contributions to CD are almost separable and additive.[2,12,13] If this is also true for $[Co(ox)_2(L\text{-ala})]^{2-}$, the following relationships will hold

$$\Delta\varepsilon(L) = \frac{1}{2}\left\{\Delta\varepsilon(\Delta_L) + \Delta\varepsilon(\Lambda_L)\right\} \quad (1)$$

$$\Delta\varepsilon(\Delta) = \frac{1}{2}\left\{\Delta\varepsilon(\Delta_L) - \Delta\varepsilon(\Lambda_L)\right\} \quad (2)$$

$$\Delta\varepsilon(\Delta) + \Delta\varepsilon(\Lambda) = 0 \quad (3)$$

The vicinal CD due to the coordinated L-alaninate, $\Delta\varepsilon(L)$, and the configurational CD, $\Delta\varepsilon(\Delta)$ or $\Delta\varepsilon(\Lambda)$, can be calculated by applying the relationships (1)—(3) to the observed CD cruves for Δ-$[Co(ox)_2(L\text{-ala})]^{2-}$ and Λ-$[Co(ox)_2(L\text{-ala})]^{2-}$, namely $\Delta\varepsilon(\Delta_L)$ and $\Delta\varepsilon(\Lambda_L)$. The calculated cruves are shown with the observed cruves of Δ-$[Co(ox)_2(gly)]^{2-}$ (configurational effect without vicinal) and the unresolved $[Co(ox)_2(L\text{-ala})]^{2-}$(vicinal effect without configurational) in Fig. 5. The good agreement

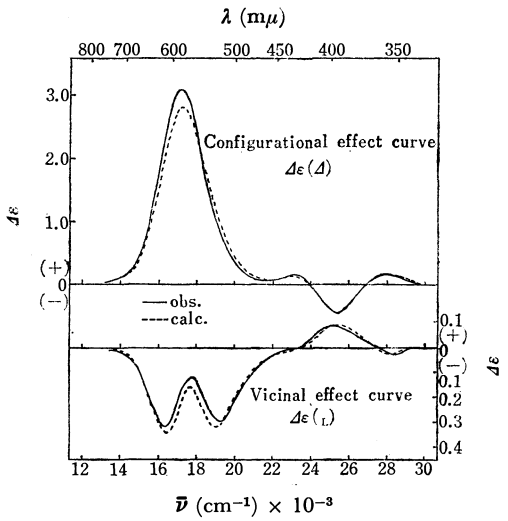

Fig. 5. Upper: The observed CD curve of Δ-$(-)_{546}$-$Ba[Co(ox)_2(gly)]\cdot 2H_2O$ and the configurational effect curve for $[Co(ox)_2(L\text{-ala})]^{2-}$ calculated from the cuves in Fig. 4.
Lower: The observed CD curve of unresolved $K_2[Co(ox)_2(L\text{-ala})]$ and the vicinal effect curve calculated from the curves in Fig. 4.

between the calculated curves and the observed ones substantiate the additivity, and indicate that the unresolved complex is the (1 : 1) mixture of Δ_L- and Λ_L-isomers. Furthermore, the observed CD curve of the reacted solution of $[Co_2(ox)_4(OH)_2]^{4-}$ with L-alanine coincides with that of the unresolved complex which was isolated from the solution. It is concluded, therefore, that this reaction is not stereospecific; in other words, equal amounts of the two diastereomers were produced in this reaction.

The CD and RD curves of Δ- and Λ-$[Co(mal)_2(L\text{-ala})]^{2-}$ are shown in Fig. 6. They are also a couple of diastereomeric isomers. The curves concerning the additivity are shown in Fig. 7. In this case, however, the calculated cruves of Δ- and Λ-$[Co(mal)_2(L\text{-ala})]^{2-}$ were derived from

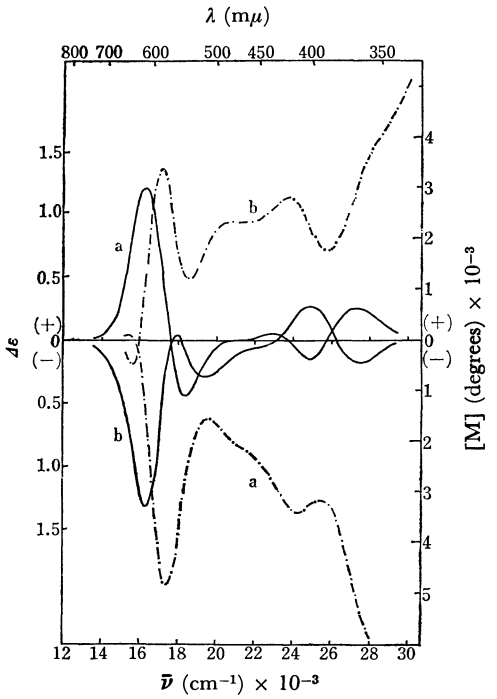

Fig. 6. CD (——) and RD (— · —) curves of Δ-(−)$_{546}$-Ba[Co(mal)$_2$(L-ala)] (a) and Λ-(+)$_{546}$-Ba-[Co(mal)$_2$(L-ala)] (b).

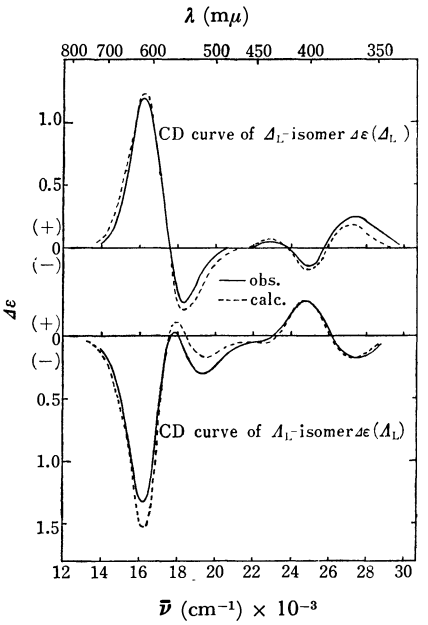

Fig. 7. Upper: The observed CD cruve of Δ-(−)$_{546}$-Ba[Co(mal)$_2$(L-ala)] and the calculated one from the curves of unresolved Ba[Co(mal)$_2$-(L-ala)] and Δ-(−)$_{546}$-Ba[Co(mal)$_2$(gly)]·2.5H$_2$O. Lower: The observed CD curve of Λ-(+)$_{546}$-Ba-[Co(mal)$_2$(L-ala)] and the calculated one.

the curves of Δ-[Co(mal)$_2$(gly)]$^{2-}$ (configurational effect without vicinal) and the unresolved [Co(mal)$_2$-(L-ala)]$^{2-}$ (vicinal effect without configurational). The result was achieved by applying the relationships (3), (4) and (5).

$$\Delta\varepsilon(\Delta_L) = \Delta\varepsilon(\Delta) + \Delta\varepsilon(L) \quad (4)$$

$$\Delta\varepsilon(\Lambda_L) = \Delta\varepsilon(\Lambda) + \Delta\varepsilon(L) \quad (5)$$

The calculated cruves agree quite well with the observed ones of Δ- and Λ-[Co(mal)$_2$(L-ala)]$^{2-}$. From this result and the experimental fact that the CD curve of the reacted solution of [Co(mal)$_3$]$^{3-}$ with L-alanine coincided well with that of the unresolved complex isolated as crystals, it is pointed out that in this reaction Δ- and Λ-[Co(mal)$_2$(L-ala)]$^{2-}$ were produced in almost equal amounts, as in the case of [Co(ox)$_2$(L-ala)]$^{2-}$.

From these facts, it may be concluded that in the oxalato and malonato complexes, the coordinated L-alaninate does not have a notable stereospecific effect. This conclusion can be easily understood for the oxalato complexes, because the oxalate chelate rings are planar. This consideration is supported by the fact that almost equal amounts of Δ- and Λ-[Co(ox)$_2${(−)-pn}]$^-$ ions occur in equilibrium.[14] In the malonate system, the chelate ring of the dicarboxylate is not planar. It is expected, however, that the L-alaninate chelate ring is near-planar and hence the interaction of the CH_3 group with the two malonates in the one configuration is not so different from that in the other configuration. As a result, it is reasonable to consider that the energy difference between the Δ- and Λ-isomers is very small, as in the case of [Co(ox)$_2$(L-ala)]$^{2-}$. A similar result has recently been reported for the [Co(en)$_2$(L-ala)]$^{2+}$ system,[15] in which two gauche ethylenediamines are coordinated to cobalt(III) instead of the two non-planar malonates of the present complexes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 127—131 (1969)

On the Presence of Tetrafluoroborate Ions in Natural Waters[1)]

Tomio ONISHI

The College of Liberal Arts, Kagoshima University, Kamoike-cho, Kagoshima

(Received February 27, 1968)

Tetrafluoroborate ions (BF_4^-) can be formed only in a strongly acid solution. Certain acid thermal waters and volcanic gases in the active volcanic zone can be expected to be the media of BF_4^- formation. When BF_4^- is supplied to natural waters, its rate of hydrolysis is relatively low, suggesting the possibility of the occurrence of BF_4^- in natural waters. The contents of BF_4^- have been determined in various thermal water samples from a volcano in Satsuma Iwo-jima, and the presence of BF_4^- confirmed. The BF_4^- content in the condensed water of volcanic gas from a fumarole with the high temperature of 745°C is 304 mg/*l*, which is 26% of the total F, and 79% of the total B content. The BF_4^- content in a sample of water from Kitabira Spa (pH 1.1) is 8.0 mg/*l*, which is about 50% of the total F or B. However, the presence of BF_4^- can not be confirmed in ordinary natural waters such as land and sea waters.

Ducret[2)] reported a colorimetric method of analysis for B which consisted of the addition of a solution consisting of HF and NH_4F to a sample of water containing B, turning B into BF_4^-, and extracting the complex thus formed by the addition of methylene blue (MB) with 1,2-dichloroethane (DCE). Pasztor[3)] and Utsumi *et al.*[4,5)] have reported improved versions of this method. A series of these analytical methods aimed at determining the quantity of B by utilizing BF_4^- formation. Hosokawa and Morinaga,[6)] and Muto,[7)] taking the advantage of this method, attempted to make the complex of BF_4^- with MB directly, and to extract the BF_4^--MB complex with DCE. Hosokawa and Morinaga, and also Muto, then announced the presence of BF_4^- in sea and river waters and in hot spring water respectively.

On the other hand, in a preliminary study of natural water, a considerable quantity of material forming complexes with MB was extracted by the present author.[8)] However, these complexes might consist of materials other than BF_4^-, such as alkylbenzenesulfonate ions (ABS^-) in river water and Cl^- in sea water. For this reason, the presence of BF_4^- in ordinary natural water is strongly suspected.

BF_4^- can be formed only in a strongly acid solution containing an amount of F larger than that of B.[1,2,4)] If BF_4^- existed in ordinary natural waters, it could not have been formed in the present sea water, nor in land water. Certain acid thermal waters and volcanic gases in the active volcanic zone may be expected to have been the media of BF_4^- formation.

Actually, the formation of Avogadrite (K,Rb)BF_4 had been reported shortly after the eruption of Vesuvius in 1906.[9)] Even if BF_4^- originatin in such volcanoes could exist in a stable state in natural waters, the presence of BF_4^- would be confirmed only in special areas. For the purpose of examining the survival of BF_4^-, KBF_4 was added to various kinds of natural waters, and its rate of hydrolysis was measured. It was found that BF_4^- was relatively stable in an aqueous solution. If there is any source of BF_4^-, BF_4^- may be expected to exist in natural waters under favorable conditions.

Volcanic gases from the volcano in Satsuma Iwo-jima contain a large quantity of the F compound. Large amounts of the H_3BO_3 sublimate were found around some fumaroles,[10,11)] satisfying the requirements for the formation medium of

BF_4^-. The BF_4^- contents have been determined in various samples from this volcano, and the presence of BF_4^- has been confirmed in all of these samples.

Experimental

Analysis of BF_4^-. When the MB complex method was directly applied to natural water in the presence of many interfering materials, the effects of those materials, particularly Cl^-, Br^-, I^-, and ABS^-, posed a problem. Utsumi *et al.*[5] removed the ABS^- in advance with DCE, and also removed the Cl^- by washing with a Ag_2SO_4 solution when the colorimetric method was adopted for the determination of the B in the water. The present author aimed at the direct determination of BF_4^-, but since considerable quantities of ABS^- and Cl^- were considered to exist in river and in sea waters respectively, the quantity of BF_4^- was determined by first extracting ABS^- with DCE only, adding MB to the sample water after removing the ABS^-, extracting the complexes with DCE, and backwashing the complex of F^- extracted with water, backwashing it again with a Ag_2SO_4 solution, and separating the halogen ions other than F^-. Further, it was found that BO_3^{3-} did not interfere because it did not form a complex with MB.

Procedure. A sample solution (20 m*l*) was taken in a polyethylene separating funnel, to which 10 m*l* of DCE was added, after the funnel had been shaken for 1 min, the organic phase was separated. Five milliliters of 0.001 M MB and 10 m*l* of DCE were then added to the water phase, and the mixture was shaken for 1 min. After it had then been left for 10 min, the organic phase was separated, washed with 5 m*l* of water and again with 5 m*l* of 0.01 M Ag_2SO_4, and then transferred into a glass-stoppered test tube. Then about 0.2 g of anhydrous Na_2SO_4 was added to the organic phase, and the mixture was shaken in order to remove the water completely. The optical absorbance of the organic phase was measured at the wavelength of 660 mμ using a blank test solution as a reference. The calibration curve is shown in Fig. 1.

Sensitivity of BF_4^- in the Method of Analyzing F. Various methods of analyzing F which have been widely used do not pay any attention to the presence of BF_4^--type F. However, if BF_4^--type F exists in natural waters, attention should be paid to the behavior

Table 1. Recovery test of F in various states

Sample	Given (μg as F)	Found (μg as F)	Recovery (%)

Table 2. Necessary information on sample waters

Sample water	Sampling date	pH	F (mg/l)	B (mg/l)	Locality
Rain	May 16 '64	6.2	0.100	0.06	Kagoshima city
River	Aug. 2 '65	6.7	0.060	0.05	Kotsuki-gawa
Well	Aug. 4 '65	7.0	0.101	0.13	Kagoshima city
Sea	July 29 '55	8.2	1.42	4.7	Okinoerabu Is.

respect to the optical absorbance of BF_4^- is only 15% of those of F^- and SiF_6^{2-}. Therefore, if BF_4^--type F exists in rain or river water, the conventional colorimetric method for F will give only a part of the F content.

On the other hand, in the case of samples containing much co-existing material, F is usually subjected to distillation in a strongly acid solution prior to the colorimetric determination to separate it from interfering materials. However, if BF_4^- is present in the water sample, or if B is also present, there is a question as to whether the complete recovery of F can be secured by means of distillation. To answer this question, the recovery test of F was conducted by distillation in the presence of interfering materials. The results are given in Table 1. As is shown in Table 1, BF_4^--type F could be sufficiently recovered and did not interfere with the analysis of F at all.

Stability of BF_4^-. The precious reports on hydrolysis have mentioned only its susceptibility to the decomposition of BF_4^-.[7,14] Thus, the experiment was conducted by adding freshly-prepared KBF_4 in pure water and various kinds of natural waters, immediately after the addition, the solutions in a polyethylene bottle were left in a bath with a constant temperature of 20°C. The rate of the decomposition of BF_4^- was traced by both the MB method and the indirect method using F formed through the decomposition of BF_4^-.

The necessary information on the water sample for the stability test of BF_4^- is given in Table 2, while the test results are shown in Fig. 3.

The results shown in Fig. 3 may be summarized as follows:

A. BF_4^- was relatively stable when left in an aqueous solution for one year at room temperature. Twenty percent of it remained in pure water, 25% in river water, and 30% in sea water. With respect the natural water, the higher the salt concentration, the more stable BF_4^- is.

B. As the concentration of BF_4^- increased, the stability also increased. An increase in the temperature of the solution from 5°C to 50°C caused a great increase in the rate of decomposition.

C. When BF_4^- was added to a solution of NaOH with the pH of 12, it was almost completely decomposed in 20 hr. Therefore, generally speaking, as the pH increased, the rate of decomposition increased.

Results and Discussion

Confirmation of the Presence of BF_4^- in the Active Volcano Zone. The volcanic gases of Satsuma Iwo-jima contain a large amount of F compound, sometimes as much as 16.5% HF in vol% of gas excluding water vapor. Also, sublimates of B were found around the crater of the volcano. Thus, the BF_4^- contents were determined in various water samples from a volcano on Iwo-jima. The results are given in Table 3.

Condensed water from volcanic gas (No. 1) was collected on July 26, 1961, because of its high temperature (745°C), it was collected by means of quartz tubing instead of Teflon tubing. The cooling parts and sampling apparatus used were made of glass. There is a possibility of the contamination of B as well as of the reaction of BF_4^- with SiO_2 in galss, and also the possibility of a change in the state of the chemical species in the gas. To eliminate these defects, quartz tubing was inserted in a fumarole in the sampling of No. 2, and the gas was conducted through quartz tubing into chilled water in a polyethylene bottle. Here again, the reaction of BF_4^- with SiO_2 is possible. The No. 3 sample was obtained by using Teflon tubing since

Table 3. Contents of BF_4^- in samples from Iwo-zima

the temperature of the fumarole was below 250°C; we thus avoided mixing the B compound in the solid form and conducting the gas into water.

In very case, BF_4^- was detected; the ratio of the BF_4^--type B against the total B was 77—90%, while that of the BF_4^--type F against the total F was 19—26%. In the subsurface part of fumaroles, no liquid phase is expected to exist. Therefore, the presence of BF_4^- in the condensed water indicates that most of the B is present in the form of BF_3 in the gas phase. The $BF_3(aq.)+F^- \rightarrow BF_4^-$ reaction may be responsible for the formation of BF_4^- in

the liquid phase. The K_p (4×10^{11}, at 25°C) of this reaction indicates that this is highly probable.

A "unique sublimate"*1 (No. 7) was obtained beneath the Kamanokuchi fumarole area. Yoshida *et al.*[10] reported that this material contained a strongly acid aqueous solution consisting mostly of halogen compounds inside, and that its total F content reached 11.6%. If trace amounts of B are embodied in such a sublimate, the most suitable environment for the formation of BF_4^- is realized. The test results indicated that all of the B was present in the BF_4^- form.

BF_4^- was confirmed to exist also in some acid thermal waters near the volcano, such as Kitabira hot spring water (No. 4), with a pH of 1.1, and Higashi hot spring water (No. 5), with pH of 1.6. The change in the BF_4^- content during the storage of hot spring water in a bottle at room temperature for 1 year was pursued. There was no change at all for the No. 4 sample, but No. 5 indicated a 70% decrease in the BF_4^- content over a 10-day period. This may be attributed to the difference in stability caused by the difference in pH.

Sea water (No. 6) was a special sample, a mixture of hot spring water (No. 5) with coastal sea water; its pH was 4.0. There was formed a white suspension composed of amorphous $Al_2O_3\cdot xH_2O$ and $SiO_2\cdot xH_2O$ produced by hydrolysis. The filtrate was analyzed after the precipitates separated, and the presence of BF_4^-, though only a trace, was confirmed. However, sea water like this is extraordinary.

Presence of BF_4^- in Normal Natural Waters. For the purpose of ascertaining the presence of BF_4^-, normal natural water was also analyzed. The results are given in Table 4.

The presence of BF_4^- was not confirmed within the 0.00 mg/*l* detection limits of sea, river, and rain water. Although considerable quantities of F and B exist in sea water, these cannot be expected in the formation of BF_4^- because of the higher pH values of the water sample.*2

The author wishes to thank Dr. M. Kamada of Kagoshima University, Dr. I. Iwasaki, Dr. T. Ozawa and Dr. M. Yoshida of the Tokyo Institute of Technology, Dr. S. Utsumi of Nihon University, and Dr. T. Koh of Tokai University, for their many helpful discussions and suggestions during this work. Thanks are also due Mr. H. Sakamoto for his assistance in the experimental work.

*1 Yoshida *et al.*[10] have reported on the general chemical properties and formation mechanism of this sublimate.

*2 Utsumi and Isozaki[5] suspected the presence of BF_4^- while using the indirect method in analyzing the B in sea water.

Nickel(II) and Copper(II) Complexes of *C,N*-Disubstituted Salicylideneimines with Steric Hindrance

Shoichiro YAMADA, Akira TAKEUCHI, Kuniko YAMANOUCHI and Katsumoto IWASAKI

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received May 21, 1968)

Many new nickel(II) and copper(II) complexes (abbreviated as $M(X\text{-sal.}R)_2$) of Schiff bases were obtained from *C*-substituted salicylaldehydes and 2,6-dimethyl- and 2,6-diethyl-aniline, where X denotes 5-Br, 5-Cl, 5,6-benzo, 5-NO_2 and 3-CH_3O. For X = 5-Cl, the corresponding nickel(II) complex with R = 2,6-dichlorophenyl was also synthesized. All these nickel(II) complexes consist of square-planar molecules in the solid state and in non-donor solvents. The nickel(II) complexes, when dissolved in pyridine, either take up two pyridine molecules to form six-coordinated complexes or retain the original planar configuration. The configuration in pyridine depends upon the nature of X, demonstrating that the effect of X on the electronic state of the ligand may also be important, besides the steric factor, in determining the configuration of the nickel(II) complexes. The corresponding copper(II) complexes, which are square-planar in the solid state and in non-donor solvents, combine with one or two pyridine molecules, when dissolved in pyridine.

Numerous papers have been published about nickel(II) and copper(II) complexes of Schiff bases obtained from *C*-substituted salicylaldehydes (Fig. 1).*1 It is expected, however, that a com-

*1 These metal complexes are abbreviated as $M(X\text{-sal.}R)_2$ in this paper.

plication may occur with these complexes, when steric hindrance is considerable. For R=2,6-$(CH_3)_2$Ph and 2,6-$(C_2H_5)_2$Ph,*2 for example, where steric hindrance is large, complexes of the

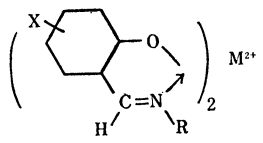

Fig. 1. M(X-sal.R)$_2$.

Ni(X-sal.R)$_2$ type are known to behave differently from the complexes of a similar type with R= phenyl or monosubstituted phenyl showing little or no steric hindrance.[1-3] The behavior of these complexes may also depend upon the nature of X, since the electronic state of the oxygen and the nitrogen atom of these ligands, X-sal.R, may be expected to change in a delicate way on changing X. In order to see the possible effect of the substituent X on the stereochemistry of the metal complexes and to explore a possibility of finding 5-coordinated complexes, the nickel(II) complexes of the Ni(X-sal.R)$_2$ type have been synthesized in the present work with 2,6-$(CH_3)_2$Ph and 2,6-$(C_2H_5)_2$Ph for R. A similar study has also been carried out about the corresponding copper(II) complexes for comparison with the nickel(II) complexes.

Experimental

Materials. Bis(*N*-aryl-*C*-substituted salicylideneiminato)nickel(II) complexes were prepared by a method similar to that previously reported either by reaction of a bis(*C*-substituted salicylaldehydato)nickel(II) with an amine or by reaction of nickel(II) acetate with a mixture of a *C*-substituted salicylaldehyde and an amine.[1,4] Pure crystals of the compounds were obtained by recrystallization of crude product using suitable organic solvents like ethanol, acetone and ethyl ether. Elemental analyses of the new nickel(II) compounds are given in Table 1. They are all green.

Bis(*N*-aryl-*C*-substituted salicylideneiminato)copper-(II) complexes were also prepared by a method similar to that previously reported.[1,2,4] Purification of the complexes was carried out by recrystallization of crude product from suitable organic solvents like ethanol, chloroform and ethyl ether. Elemental analyses of the new copper(II) complexes are given in Table 2.

Measurements. The electronic absorption spectra of the metal complexes in solution and reflection spectra of the solid were determined with a Shimadzu QR-50 spectrophotometer and a Shimadzu MPS-50L spectrophotometer. Pyridine for a solvent was purified, whenever necessary, by distillation after having been dried with potassium carbonate.

The magnetic measurements were carried out by the Gouy method at room temperature using $CoHg(SCN)_4$ as a standard.

Results and Discussion

The Nickel(II) Complexes of *N*-Aryl-*C*-Substituted Salicylideneimines. Many new nickel(II) complexes of the Ni(X-sal.R)$_2$ type have been prepared in the present work (Table 1). The result that all these nickel(II) complexes are diamagnetic in the solid state indicates the planar configuration of these complexes. They afford examples of the green nickel(II) complexes which are diamagnetic and planar.

It is well known that the electronic spectrum of a nickel(II) complex varies remarkably according as the nickel(II) complex is square-planar, tetrahedral, five-coordinated, or octahedral.[1-3] The present work shows that the electronic spectra of Ni(X-sal.2,6-$(CH_3)_2Ph)_2$ and Ni(X-sal.2,6-)$C_2H_5)_2$-$Ph)_2$ in non-donor solvents are typical of the square-planar nickel(II) complex (Fig. 2 and Table 3), and similar to the spectra of Ni(H-sal.2,6-$(CH_3)_2Ph)_2$ and Ni(H-sal.2,6-$(C_2H_5)_2Ph)_2$, which were previously concluded to be square-planar.[2] These complexes show no absorption band at about 900—1000 mμ, where the tetrahedral or the octahedral nickel(II) complexes are expected to absorb. Hence, both the presence of the monomeric, tetrahedral species and the association of the square-planar complexes may be excluded near room temperature. It is known[6,7] that bis(*N*-monosubstituted phenylsalicylideneiminato)nickel-(II) complexes in non-donor solvents consist of the square-planar monomer, the associated polymer with the six-coordinated nickel(II), and the tetrahedral monomer, the former two being in equilibrium with each other near room temperature. The difference in this respect between the *N*-monosubstituted phenyl- and the *N*-2,6-disub-

stituted phenyl-salicylideneiminato-nickel(II) complexes was ascribed mainly to the steric condition.[2] The same explanation applies to Ni(X-sal.2,6-$(CH_3)_2$Ph)$_2$ and Ni(X-sal.2,6-$(C_2H_5)_2$Ph)$_2$, which have been concluded to be square-planar in the solid state and in non-donor solvents.

The configuration of these nickel(II) complexes in pyridine, however, remarkably depends upon the substituent X. Electronic absorption spectra (Fig. 3 and Table 3) clearly show that, for X=5,6-benzo and 5-Br and R=2,6-$(CH_3)_2$Ph and 2,6-$(C_2H_5)_2$Ph, the complexes of the Ni(X-sal.R)$_2$ type bind no additional pyridine molecule, the original square-planar configuration being retained in pyridine. This result, which is the same as that for X=H, is considered to be due mainly to the steric hindrance arising from the two alkyl groups.

* R=2,6-Y_2Ph ** ν, 10^3 cm^{-1}

It is found from the spectra (Fig. 3 and Table 3) that for X=5-NO_2 and 3-CH_3O, the complexes of the Ni(X-sal.2,6-$(CH_3)_2$Ph)$_2$ and Ni(X-sal.2,6-$(C_2H_5)_2$Ph)$_2$ type, when dissolved in pyridine, exist as the six-coordinated pyridine solvates of the Ni(X-sal.2,6-Y_2Ph)$_2$(py)$_2$ type,*3 which show electronic spectra typical of octahedral, six-coordinated nickel(II) complexes. The absorption maxima of these pyridine solvates at about 10 and 16 kK may be assigned as $^3T_{2g} \leftarrow {}^3A_{2g}$ and $^3T_{1g}(F) \leftarrow {}^3A_{2g}$ in the scheme of the O_h ligand field symmetry.

Since Beer's law was obeyed, no equilibrium between the octahedral complex and another species may be likely. This difference between the two types of the substituent for X, which is not considered to be due to the steric factor, indicates that, although steric hindrance in these nickel(II) complexes seems to be more or less effective, it does not absolutely exclude the coordination number exceeding four. This result may be interpreted in terms of the difference in the electronic factor due to various X groups.

For X=5-Cl, anomalous behavior was observed. For example, the Ni(X-sal.2,6-$(CH_3)_2$Ph)$_2$ in pyridine exists as a six-coordinated complex, Ni(X-sal.R)$_2$(py)$_2$, as clearly seen from the electronic spectrum (Fig. 3 and Table 3). On the contrary, Ni(5-Cl.sal.2,6-$(C_2H_5)_2$Ph)$_2$ in pyridine retains the planar configuration. The difference between the complexes with X=5-Cl and with X=5-Br on one hand and between the complexes with R=2,6-$(CH_3)_2$Ph and with R=2,6-$(C_2H_5)_2$Ph for X=5-Cl on the other may also be due to the electronic factor. This fact seems to be in agreement with the fact that the band maximum and consequently the ligand field strength for X=5-Cl and R=2,6-$(CH_3)_2$Ph is slightly lower than the maximum for X=5-Cl and R=2,6-$(C_2H_5)_2$Ph.

It is significant that there is a remarkable difference between the two types of substituents for X. One includes 5-Br and 5,6-benzo, in addition to X=H, and the other 5-NO_2 and 3-CH_3O. The

result of the examination in this work about the configuration of these nickel(II) complexes in pyridine is summarized in Table 4.

In the case of the corresponding cobalt(II) complexes, five-coordinated pyridine solvates of the Co(X-sal.2,6-Y_2Ph)$_2$(py) type were often formed.[8,9] Comparison of the results in the present work with that of the cobalt(II) complexes shows that the stability of the five-coordinated species *vis-a-vis* the four- and the six-coordinated ones is lower for the nickel(II) complexes than for the cobalt(II) complexes.

The Copper(II) Complexes of *N*-Aryl-*C*-substitutued Salicylideneimines. Many new copper(II) complexes of the *C*-substituted salicylideneimines, which are shown in Table 2, have been prepared in the present work. The planar configuration is most likely for these copper(II) complexes, since the tendency of the copper(II) complexes to take the square-planar configuration is known to be very high for the ligands of this series. The square-planar configuration may also be most likely even for 2,6-disubstituted phenyl derivatives in spite of the steric condition, since the corresponding nickel(II) complexes as well as the corresponding copper(II) complexes of salicylideneimines[2] have also been found to be square-planar. This presumption is supported by the present finding that the complexes of the Cu(X-sal.2,6-Y_2Ph)$_2$ type show ligand field bands at frequencies nearly identical with those of Cu(X-sal.YPh)$_2$, which were previously concluded to be planar.[2] It was also concluded previously that the ligand field band was shifted toward a considerably lower frequency when the copper(II) complex was distorted appreciably from the square-planar configuration.[4,6]

The spectral change in the ligand field band region of these copper(II) complexes on going from a non-donor solvent to pyridine (Figs. 4 and 5) is similar to the change observed previously when the four-coordinated complex of copper(II) takes up one or two additional ligands to form a five- or a six-coordinated complex.[2,10] It may be concluded, therefore, that all the copper(II) complexes examined in the present work combine with one or two pyridine molecules in the pyridine solution. This result is the same as the previous conclusion[2] with Cu(H-sal.2,6-Y_2Ph)$_2$, Y_2 being $(CH_3)_2$ and $(C_2H_5)_2$. It is, however, difficult at the moment to determine from the spectrum alone whether the pyridine solvate is five- or six-coordinated.

It is interesting to point out that the behaviour of Cu(X-sal.2,6-Y_2Ph)$_2$ in pyridine is different

from that of the corresponding nickel(II) complexes when X denotes H, 5-Cl, 5-Br and 5,6-benzo. This may also be considered to be an example showing that the coordination number larger than four in copper(II) complexes occurs at a slightly weaker ligand field than in the corresponding nickel(II) complexes.[2,11] This difference between the nickel(II) and the copper(II) complexes may be discussed in terms of the bonding nature of the metal ions and the steric condition arising from the two alkyl groups.[2]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 136—140 (1969)

Trimethylenediamine Complexes. I. Some Trimethylenediamine Complexes Derived from *trans*-[$CoCl_2tn_2$]Cl in Methanol

Hiroshi KAWAGUCHI, Naomichi YANO and Shinichi KAWAGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received May 24, 1968)

Several diacidobis(trimethylenediamine)cobalt(III) complexes including nitrate, nitrite and thiocyanate ions as ligands have been prepared by ligand substitution reactions of *trans*-dichlorobis(trimethylenediamine)cobalt(III) chloride in methanol. All these compounds were assumed to have the trans configuration according to the Baldwin's criterion based on the CH_2 rocking vibration. Isomeric pairs of chloronitro and chloronitrito complexes were also characterized by means of infrared data.

The metal complexes of ethylenediamine have been extensively studied in various aspects, but the investigations on the corresponding trimethylenediamine complexes have been quite limited. The X-ray analysis of *trans*-[$CoCl_2tn_2$]Cl·HCl·$2H_2O$ has been performed by Matsumoto, Ooi and

Kuroya. It was reported[1] that the six-membered chelate ring has a chair form and the bond angles around cobalt and nitrogen atoms are all larger than those in the corresponding ethylenediamine complex. The difference in stabilities of five- and six-membered chelate rings may be reflected in the labilities of ethylenediamine and trimethylenediamine complexes.

The preliminary data by Pearson, Boston and Basolo[2] show that *trans*-$CoCl_2tn_2^+$ hydrolyzes rapidly although the rate of hydrolysis of the mixed complex *trans*-$CoCl_2entn^+$ is only ten times as large as that of *trans*-$CoCl_2en_2^+$. However the rate of carbonate exchange of $CoCO_3tn_2^+$ was reported to be much smaller than that of $CoCO_3en_2^+$ ion.[3] Thus it seems quite necessary to compare the chemistry of trimethylenediamine complexes with that of the corresponding ethylenediamine complexes in more detailed fashion. This paper reports several compounds derived from *trans*-dichlorobis(trimethylenediamine)cobalt(III) chloride by the ligand substitution reactions in methanol.

Experimental

The starting material *trans*-[$CoCl_2tn_2$]Cl was synthesized according to the methods by Bailar and Work,[4] and Werner.[5] The latter method *via* [$Co(NO_2)_2tn_2$]NO_2 is preferable.

Found: C, 23.11; H, 6.59; N, 17.42; Cl, 34.44; Co, 18.97%. Calcd for $C_6H_{20}N_4Cl_3Co$=[$CoCl_2tn_2$]Cl: C, 23.00; H, 6.38; N, 17.87; Cl, 33.94; Co, 18.83%.

1) Nitrato Complexes. A methanol solution of silver nitrate (0.65 g, 3.8 mmol) in 15 m*l* was added to a methanol solution of *trans*-[$CoCl_2tn_2$]Cl (1.2 g, 3.8 mmol) in 120 m*l*. Silver chloride produced was warmed and filtered off during hot. The filtrate was evaporated up to about 50 m*l* and kept standing overnight at room temperature. Bright green leaflet crystals deposited, which were filtered, washed with methanol and dried in air. Yield: 1.1 g. The same compound was also produced by the reaction between *trans*-[$CoCl_2tn_2$]Cl and potassium nitrate in hot methanol.

Found: C, 21.45; H, 6.02; N, 21.14%. Calcd for $C_6H_{20}N_5O_3Cl_2Co$=[$CoCl_2tn_2$]NO_3: C, 21.19; H, 5.93; N, 20.59%.

When 1.3 g (7.6 mmol) or more than 2.0 g (11.8 mmol) of silver nitrate was employed in the above reaction, dark green crystals of [$CoCl(NO_3)tn_2$]NO_3 or russety plates of [$Co(NO_3)_2tn_2$]NO_3 were obtained, respectively.

Found: C, 19.87; H, 5.75; N, 22.68%. Calcd for $C_6H_{20}N_6O_6ClCo$=[$CoCl(NO_3)tn_2$]NO_3: C, 19.66; H, 5.50; N, 22.92%.

Found: C, 18.70; H, 5.11; N, 25.14; Co, 14.96%. Calcd for $C_6H_{20}N_7O_9Co$=[$Co(NO_3)_2tn_2$]NO_3: C, 18.33; H, 5.13; N, 24.94; Co, 14.99%.

2) Isothiocyanato Complexes. A methanol solution of potassium thiocyanate (1.5 g, 15.4 mmol) in 50 m*l* was added gradually into a methanol solution of *trans*-[$CoCl_2tn_2$]Cl (1.0 g) in 140 m*l*. The mixture was cooled with ice and salt for several hours. Deposited green needles were separated, washed with methanol and dried in air. Yield: 0.9 g.

Found: C, 25.28; H, 6.65; N, 20.15%. Calcd for $C_7H_{20}N_5SCl_2Co$=[$CoCl_2tn_2$]SCN: C, 25.16; H, 6.03; N, 20.95%.

To a hot solution of *trans*-[$CoCl_2tn_2$]Cl (1.0 g, 3.1 mmol) in 200 m*l* of methanol was added 0.3 g (3.1 mmol) of solid potassium thiocyanate. The solution was heated for about 5 min and then kept standing overnight at room temperature. Purple crystals of [CoCl(NCS)tn_2]Cl were obtained. Yield: 0.8 g. The same compound was also produced when 1.0 g of *trans*-[$CoCl_2tn_2$]SCN was dissolved in about 200 m*l* of hot methanol, and the solution was heated for about 5 min, concentrated to about 50 m*l* under reduced pressure and cooled in ice overnight. Yield: 0.6 g. In this experiment a prolonged heating should be avoided since a disproportionation to dichloro- and dithiocyanato-complexes occurs.

Found: C, 25.03; H, 6.26; N, 20.36%.

When twice as many moles or large excess of potassium thiocyanate was employed against the starting dichloro-complex in the above experiment, purple crystals of [$Co(NCS)_2tn_2$]Cl (yield 0.85 g) or dark purple crystals of [$Co(NCS)_2tn_2$]SCN (yield 0.7 g) were obtained, respectively.

Found: C, 27.17; H, 5.79; N, 23.30%. Calcd for $C_8H_{20}N_6S_2ClCo$=[$Co(NCS)_2tn_2$]Cl: C, 26.78; H, 5.62; N, 23.42%.

Found: C, 28.50; H, 5.42; N, 25.66%. Calcd for $C_9H_{20}N_7S_3Co$=[$Co(NCS)_2tn_2$]SCN: C, 28.34; H, 5.28; N, 25.71%.

If solid potassium thiocyanate is added in excess to a methanol solution of [CoCl(NCS)tn_2]Cl or [$Co(NCS)_2$-tn_2]Cl, and the solution is cooled, the respective thiocyanate is obtained, [CoCl(NCS)tn_2]SCN appearing as grayish blue needles.

Found: C, 27.43; H, 6.04; N, 22.68%.

3) Nitro Complexes. A cold methanol solution of sodium nitrite (0.30 g, 4.37 mmol) was added gradually to a cold solution of *trans*-[$CoCl_2tn_2$]Cl (1.37 g, 4.37 mmol) in 200 m*l* methanol under vigorous agitation. The solution was evaporated up to about 150 m*l* under reduced pressure at room temperature and then cooled for a few hours with ice and salt. Orange red powder was obtained. Yield: 0.35 g.

Found: C, 22.27; H, 6.29; N, 20.20%. Calcd for $C_6H_{20}N_5O_2Cl_2Co$=[$CoCl(NO_2)tn_2$]Cl: C, 22.23; H, 6.22; N, 21.61%.

If the above reaction mixture is heated for a while, evaporated on a hot water bath, and then cooled in ice, brown crystals were obtained. Yield: 0.97 g. Results of the elemental analysis are quite the same with the above compound.

Found: C, 21.90; H, 6.28; N, 19.85%.

Solid sodium nitrite (1.5 g, 21.7 mmol) was added to a hot solution of *trans*-[$CoCl_2tn_2$]Cl (1.0 g) in about 100 ml of methanol, and heated for a while. The solution changed from green to yellow, and was kept standing overnight at room temperature. Lustrous yellow crystals were separated. The filtrate was evaporated to about half the volume, and further quantity of crystals were obtained. All crystals were joined, washed with methanol and dried in air.

Found: C, 20.33; H, 5.91; N, 27.22%. Calcd for $C_6H_{20}N_7O_6Co$=[$Co(NO_2)_2tn_2$]NO_2: C, 20.88; H, 5.84; N, 28.40%.

Results and Discussion

The infrared absorption spectrum of dinitrobis(trimethylenediamine)cobalt (III) nitrite derived from *trans*-[$CoCl_2tn_2$]Cl in methanol completely coincides with that of *trans*-[$Cc(NO_2)_2tn_2$]NO_2 which was synthesized by the reaction between potassium hexanitrocobaltate(III) and trimethylenediamine in water according to the Werner's direction.[5] The other compounds now obtained are all new compounds and their structures are very interesting.

Several attempts have been made to distinguish between geometrical isomers of cobalt (III) bis(ethylenediamine) complexes by means of the infrared absorption data.[6] Baldwin[7] suggested that the most consistent variation between the spectra of cis and trans isomers is found in the CH_2 rocking region (900—870 cm^{-1}), cis isomers showing two peaks while trans isomers only one, and that these bands are insensitive to natures of A, B and X in complexes of the type [$CoABen_2$]X.

TABLE 1. THE CH_2 ROCKING FREQUENCIES OF [$CoABtn_2$]X COMPLEXES DERIVED FROM *trans*-[$CoCl_2tn_2$]Cl IN METHANOL

Compound	Frequency, cm^{-1}
trans-[$CoCl_2tn_2$]Cl*	889
[$CoCl_2tn_2$]NO_3	887

[$Co(NCS)_2tn_2$]Cl	889, 895
[$Co(NCS)_2tn_2$]SCN	890
[$CoCl(NO_2)tn_2$]Cl (red)	896
[$CoCl(NO_2)tn_2$]Cl (brown)	895
trans-[$Co(NO_2)_2tn_2$]NO_2	899

* Starting material

As shown in Table 1 these diacidobis(trimethylenediamine)cobalt(III) complexes, except [$Co(NCS)_2tn_2$]Cl, show a single peak respectively in the CH_2 rocking region. If Baldwin's empirical rule can be applied to these trimethylenediamine complexes, all these compounds are considered to be trans isomers. Diisothiocyanatobis(trimethylenediamine)cobalt(III) chloride shows two distinct peaks at 889 and 895 cm^{-1}. Therefore it should be assigned the cis configuration according to this criterion. It is not conceivable, however, that only this compound is a cis isomer while the corresponding thiocyanate [$Co(NCS)_2tn_2$]SCN assumes the trans configuration. Baldwin's rule must be concluded not to hold in this case. The X-ray analysis of [$Co(NO_3)_2tn_2$]NO_3 is now being performed by Komiyama and his coworkers. According to their preliminary report[8] crystals are monoclinic and the cobalt atom lies at the center of symmetry, certifying the trans configuration of this complex ion.

It is well known that methanol is much more favorable than water for the trans form of dichlorobis(ethylenediamine)cobalt(III) complex.[9] Such a solvent effect is considered to be due to the lesser power than water of stabilizing the cis form by solvation, and will also apply to the diacidobis(trimethylenediamine)cobalt(III) complexes. On the contrary water will be suitable in synthesizing the corresponding cis compounds.

Two compounds, orange red and brown crystals, were obtained whose analytical data both correspond to the formula [$CoCl(NO_2)tn_2$]Cl, suggesting that they are isomeric. The red form is unstable and easily transformed by heat to the brown form. The frequencies of CH_2 rocking vibration of these compounds indicate that both of them have the trans configuration. The other possibility to be considered is the linkage isomerism. It has been reported[10] that nitropentaamminecobalt(III) shows the NO_2 symmetric stretching peak at 1310 cm^{-1} but nitritopentaamminecobalt(III) at 1065 cm^{-1}. In the present case the less stable red form of this compound shows a very strong peak at 1170 cm^{-1}, but the brown form does not have such a peak. Thus the red isomer can safely be concluded to be a nitrito complex, [$CoCl(ONO)tn_2$]Cl.

Formation of nitritopentaamminecobalt(III) complex by the reaction between aquopentaamminecobalt(III) and nitrous acid in water is believed to

proceed as a nitrosation reaction keeping the Co–O bond intact.[11] In the present case, however, the chloronitrito complex was obtained by the reaction between the dichloro complex and sodium nitrite in methanol. It is not certain whether the overall reaction proceeds *via* the solvolysis process or not, but some novel reaction pathway might be passed through. Kinetic and tracer studies will soon be undertaken to clarify the reaction mechanism.

Absorption spectra of several trimethylenediamine complexes are shown in Figs. 1—3. The first band of $CoClXtn_2^+$ shifts to the shorter wavelength side progressively as the acido group X is substituted from Cl^- to NO_3^-, NCS^- and NO_2^- in accordance with the widely accepted order in the spectrochemical series.[12] Comparison of absorption data of these *trans*-diacidobis(trimethylenediamine)cobalt(III) complexes with corresponding bis(ethylenediamine) complexes as shown in Table 2 clearly indicates that trimethylenediamine is a weaker field ligand than ethylenediamine.

Aquation reactions were examined preliminarily. Dichloro complexes hydrolyze quickly, and the

half time of about 6 min was observed at 0°C in either case. Chloronitrato and dinitrato complexes react more rapidly and the half time was about 1 min. On the other hand diisothiocyanato and dinitro complexes are quite inert, whose absorption spectra in aqueous solutions do not change even after 24 hr at room temperature. Detailed features of these reactions must await further investigations.

Polarographic Studies of Dissolved Oxygen in DMSO-Water Mixtures

Taitiro FUJINAGA, Kosuke IZUTSU and Takeo ADACHI

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received May 29, 1968)

The solubility and polarographic behavior of dissolved oxygen have been investigated in air-saturated DMSO-water mixtures at 25°C and 45°C. The first oxygen wave, which corresponds to one-electron reduction to superoxide ions in water-poor DMSO solutions of 0.1 M Et_4NClO_4, changes to a two-electron process in the range of water content between 10 and 30% because of the protonation reaction due to water. The rate of protonation is potential-dependent. The rate also depends on the species and the concentrations of the supporting electrolytes. The temperature effect is small. Using the solubility and polarographic data obtained, the polarographic diffusion coefficients of oxygen in the mixed solvent have been calculated.

The polarographic reduction of dissolved oxygen has been studied by a number of authors using different electrodes and solvents (for a survey, see Ref. 1). At tha dropping mercury electrode, dissolved oxygen in an aqueous solution usually gives two waves, each corresponding to a two-electron reduction. Recently, however, several authors have found that the reduction of oxygen in dipolar aprotic solvents occurs in two steps, and that the first wave is a one-electron process involving

1) K. J. Vetter, "Elektrochemische Kinetik," Springer Verlag, Berlin (1961), p. 518; R. Takahashi, *Talanta*, **12**, 1211 (1965).

the formation of superoxide anion radicals.[2-7] The effects of acids[2,3,5] and metal cations[4,7] on oxygen waves in aprotic solvents have been studied, but a detailed investigation of the effect of water on the polarographic behavior of dissolved oxygen does not seem to have been undertaken yet. In the present work, we studied the behavior of oxygen in the mixed solvent of DMSO and water.

Apparatus and Reagents

Dc and ac polarograms were recorded with a Yanagimoto Polarograph, PA-102. The constant current source for chronopotentiometry was constructed from a high dc voltage source (225V) with large resistors. Potential-time curves were measured using a Shimadzu pH meter as a high input-impedance preamplifier and a Varicorder VR-100G as a voltage recorder. An H-type cell with a fine porosity sintered glass disk between the two compartments was used, except in the determination of the solubility of dissolved oxygen. In measurement, a sample solution was put in both compartments of the cell and aqueous SCE with a tip of fine porosity sintered glass disk was inserted in the reference compartment. Contamination from the aqueous SCE into the sample compartment of the H-type cell was negligible during measurement. The characteristics of the DME were $m=0.73$ mg/sec and $t=4.0$ sec at -0.4 V *vs.* SCE in a 0.1 M Et_4NClO_4 aqueous solution at 25°C. For the chronopotentiometric measurement, a glassy carbon disk electrode 3 mm in diameter was used. A mercury-coated rotating disk electrode with a diameter of 0.5 mm was prepared by plating gold on the surface of the platinum disk electrode and by amalgamating it. The electrode was rotated at 800 rpm in measuring the current-potential curves. The viscosity of the mixed solvent was measured with a Ostwald viscometer. Experiments were carried out at 25 ± 0.1°C or at 45 ± 0.1°C.

Dimethyl sulfoxide (DMSO) obtained from the Katayama Chemicals Co. was vacuum distilled twice. The water content just after distillation was less than 0.05%, as determined through a Karl Fischer titration. *n*-Bu_4NClO_4 was prepared from an aqueous solution of *n*-Bu_4NBr by adding an equivalent amount of concentrated perchloric acid, and was purified by recrystallization from ethanol solutions. *n*-Bu_4NBr was prepared by refluxing acetonitrile solutions of tri-*n*-butylamine and *n*-butyl bromide for 36 hr.[8] After evaporation of acetonitrile, *n*-Bu_4NBr was recrystallized several times from ethyl acetate. *n*-Pr_4NClO_4 was prepared by neutralizing 10% solutions of *n*-Pr_4NOH, obtained from the Wako Pure Chemicals Industries, Ltd., with perchloric acid and was purified by recrystallization from ethanol. Et_4NClO_4 was prepared by adding an equivalent amount of perchloric acid to Et_4NI in water and was recrystallized from water. Anhydrous $KClO_4$ was of analytical reagent grade and was used without further purification.

Results and Discussion

Solubility of Oxygen in DMSO-Water Mixtures. The concentration of dissolved oxygen in air-saturated DMSO-water mixtures was determined polarographically, because the application of the Winkler method was difficult for systems containing 0.1 M Et_4NClO_4. The dissolved oxygen in the air-saturated 0.1 M Et_4NClO_4 solution of $(100-x)$% DMSO - x%water mixture was determined as follows: In a 100 m*l* tall beaker, thermostated at 25°C or 45°C, 40.0 m*l* of 0.1 N NaOH, 5.0 m*l* of x% DMSO - $(100-x)$% water mixture and a magnetic stirrer were taken. The beaker was closed with a silicon rubber stopper with holes through which DME and aqueous SCE were passed, and with inlets and outlets for nitrogen and an inlet for the sample solution. After the solution was deaerated with nitrogen, the residual current was recorded between -0.3 and -0.5 V *vs.* SCE. Then, while the solution in the beaker was being stirred with a magnetic stirrer and nitrogen gas passed over the solution, 5.00 m*l* of the sample solution of 0.1 M Et_4NClO_4 in a $(100-x)$% DMSO - x% water mixture, which has been saturated with air in a thermostat controlled at 25°C or 45°C, was put with a pipette into the bottom of the beaker. After the solution has been sufficiently mixed, stirring was stopped and the current recorded between -0.3 and -0.5 V *vs.* SCE. By comparing the

diffusion currents obtained for sample solutions of various values of x, the relative solubilities of oxygen in the air-saturated DMSO-water mixtures could be determined. The absolute solubilities could be calculated by measuring the diffusion current for a sample of air-saturated pure water and by assuming the solubilities of oxygen in the air-saturated pure water to be 0.254 mM at 25°C and 0.193 mM at 45°C, respectively.[9] The results are shown in Fig. 1 and Table 1. The reproducibility of the results was within ±2%. The solubility of oxygen at 25°C became minimum in the range 40 to 50% water. In a water-free, 0.1 M Et_4NClO_4 DMSO solution, the solubility was 0.44 mM, which is in agreement with the result of Sawyer and Roberts.[5] At 45°C, the solubility of oxygen was approximately constant over a water content of 50 to 100%. With a smaller water content, the solubility increased rapidly, as in the case at 25°C.

D and $D\eta$ in water-free DMSO solution were determined from the height of the first wave.

The viscosities of DMSO-water mixtures containing 0.1 M Et_4NClO_4 were measured with an Ostwald viscometer at 25°C and 45°C. The results were almost in agreement with those of Cowie and Toporowski[10] determined for Et_4NClO_4-free mixed solvents.

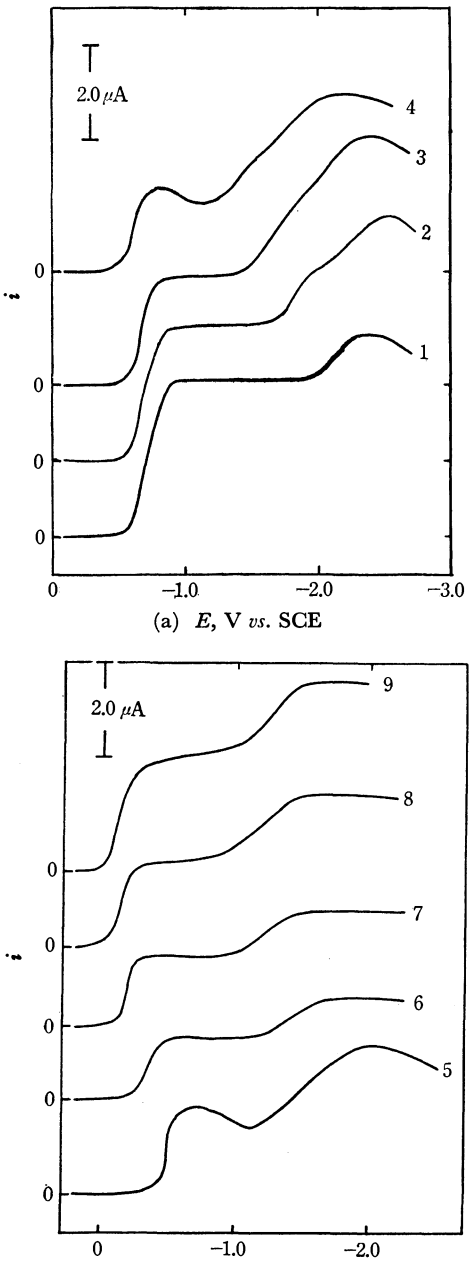

Fig. 2. Oxygen waves in air-saturated DMSO-water mixtures containing 0.1M Et_4NClO_4 at 25°C.

Polarographic Behavior of Oxygen in Mixed Solvents. The curves in Fig. 2 are polarograms of dissolved oxygen in air-saturated 0.1 M Et_4NClO_4 solutions in DMSO-water mixtures. In a water-free solution, two waves were obtained at -0.77 and -2.2 V, respectively. The first wave corresponded to a one-electron reduction to superoxide anion radicals and the second wave to the formation of peroxide anions.[2-7] As reported in the literature,[4] the height of the second wave is smaller than that of the first, even after correction for change in drop-time. The second wave was very sensitive to a small amount of water and, in the presence of more than 0.1% water, the wave shifted to more positive potentials and the wave height was much increased. Increase in the second wave height occurred because peroxide ions were further reduced to hydroxyl ions. The effects of water on the half-wave potential of the first wave and on the potential at which the second wave began to occur are given in Fig. 3. When the water content was 6%, the

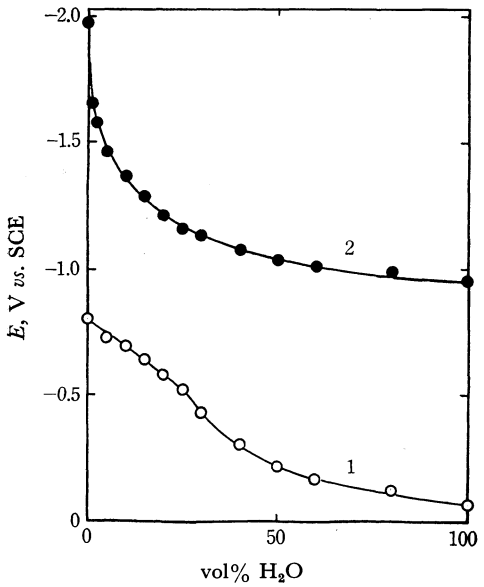

Fig. 3. Half-wave potential of the first wave (curve 1) and the potential at the beginning of the second wave (curve 2) of oxygen in air-saturated DMSO-water mixtures containing 0.1M Et_4NClO_4 at 25°C.

first wave still corresponded to a one-electron reduction, but the total wave approximately to a four-electron reduction (formation of hydroxyl ions). If the water content became greater than 10%, the current at the beginning of the plateau of the first wave increased because some superoxide ions became protonated by water and were further reduced to peroxide ions. Thus, between a water content of 15 and 30%, a distinct minimum was obtained just before the second wave. When the water content was greater than 35%, the minimum disappeared and the first and the second waves became approximately equal in height, both corresponding to two-electron reductions. A similar minimum to that obtained in a 0.1M Et_4NClO_4 solution containing water between 15 and 30% was observed even in solutions containing other supporting electrolytes, such as 0.1M n-Bu_4NClO_4, 0.1M n-Pr_4NClO_4 and 0.1M $KClO_4$. The addition of surface active substances, halide ions and hydroxyl ions did not influence the shape of the oxygen wave. Moreover, such a minimum was obtained even at a mercury-coated disk electrode rotating at 800 rpm. This is probably due to the fact that the rate of the protonation reaction of superoxide ions is potential dependent, and the reaction is faster at more positive potentials. This potential dependence of the protonation reaction may be caused by a change in the surface concentration of superoxide anions with electrode potential: when the potential becomes more negative, negatively charged superoxide ions will be repelled more strongly from the electrode and the surface concentration will become smaller.

The ratio of the total wave height $(i_d)_t$ to that of the first wave $(i_d)_1$ was calculated after correction for change in drop time. A simple Ilkovic equation was assumed for this correction. The results are shown in Fig. 4. Curve 1 was obtained by measuring the height of the first wave at the potential at which the current became maximum, and curve 2 at the potential at which the current became minimum. From these curves, it is apparent that the total wave, which is approximately a two-

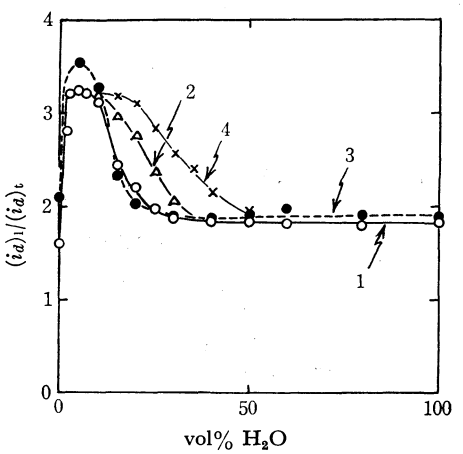

Fig. 4. Ratio of the total wave height to that of the first wave of dissolved oxygen in air-saturated 0.1M (curves 1, 2 and 3) and 0.01M (curve 4) Et_4NClO_4 solutions. Curves 1, 2 and 4 are at 25°C and curve 3 at 45°C. Curves 1 and 3 were obtained by measuring the maximum current of the first wave and curves 2 and 4 the minimum current.

electron reduction in water-free DMSO solution, approaches a four-electron reduction by the addition of several percents of water. The ratio does not become four and is much smaller, probably due to the fact that the drop time at the second wave is so small compared to that at the first wave that the diffusion current may significantly deviate from that given by the Ilkovic equation. The first wave, on the other hand, changed from a one- to a two-electron process between a water content of about 10 and 30%, both at 25°C (curves 1 and 2) and at 45°C (curve 3). The temperature effect was not large. The water content necessary to convert the first wave from a one-electron reduction to a two-electron reduction changed considerably with species and concentrations of supporting electrolytes. When the concentration of the supporting electrolyte decreased, the necessary water content increased, as in curve 4, Fig. 4. The necessary water content also increased with the species of supproting electrolyte in the following order (Fig. 5):

$$KClO_4 < Et_4NClO_4 < n\text{-}Pr_4NClO_4 < n\text{-}Bu_4NClO_4$$

The larger the ionic radius of the cation of the supporting electrolyte, the more water was necessary for the first wave to change from a one-electron process to a two-electron one.

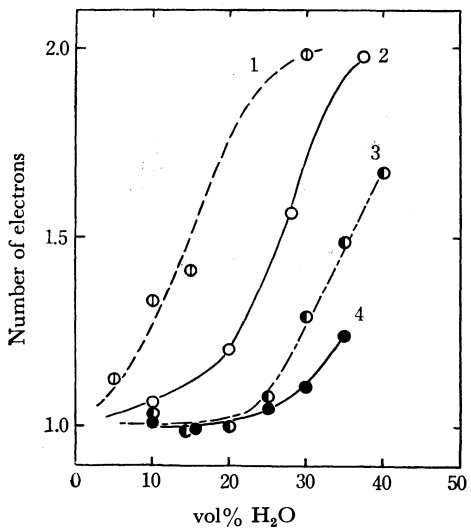

Fig. 5. Number of electrons taking part in the first wave of oxygen in various supporting electrolytes at 25°C.
Supporting electrolytes are: 1, 0.1M $KClO_4$; 2, 0.1M Et_4NClO_4; 3, 0.1M n-Pr_4NClO_4; and 4, 0.1M n-Bu_4NClO_4. Estimated from the current at the minimum of the first wave.

The addition of Et_4NOH to the solution containing water between 15 and 30% did not influence the behavior of the oxygen wave, though a big increase in pH was expected due to hydroxyl ions. From this result, the protonation reaction seems to occur as a reaction between a superoxide anion and a water molecule, and not through a reaction between a superoxide anion and a proton produced by the dissociation of water.

The first wave of oxygen in water-free dipolar aprotic solvents has been reported to be very reversible ac polarographically.[2,6] In an aqueous, unbuffered neutral solution, on the other hand, only a small ac wave can be obtained.[11] In this report, ac polarograms were measured in DMSO-water mixtures and the values of $i_{ac}/i_{dc}\cdot t^{1/2}$ were calculated as a measure of the reversibility of the first oxygen wave. The results are shown in Fig. 6.

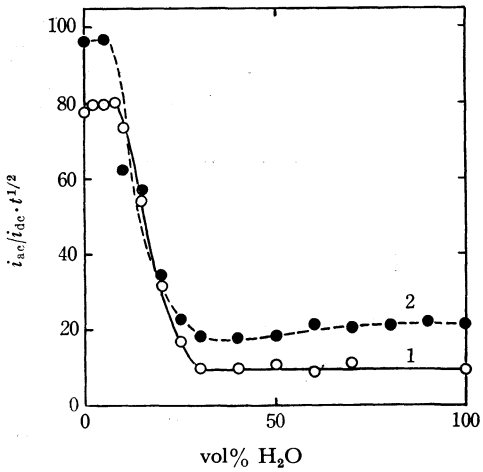

Fig. 6. $i_{ac}/i_{dc}\cdot t^{1/2}$ values for the first wave of oxygen in 0.1M Et_4NClO_4 solutions at 25°C (curve 1) and at 45°C (curve 2).

In solutions at 25°C with a water concentration below 8%, fairly high ac waves with values of $i_{ac}/i_{dc}\cdot t^{1/2}$ of about 80 were obtained. In the range of water concentration between 10 and 30%, in which the first dc wave changed from a one-electron to a two-electron process, the value of $i_{ac}/i_{dc}\cdot t^{1/2}$ decreased gradually, showing a decrease in the reversibility of the electrode reaction. At a water content above 30%, it was almost constant at 10. The ac polarographic behavior at 45°C was approximately similar to that at 25°C.

Reverse chronopotentiometry at the glassy carbon electrode seems to provide, though qualitatively, knowledge concerning the lifetime of superoxide anion radicals. In oxygen-saturated DMSO-water mixtures, potential-time curves for the reduction of oxygen at constant current were measured. Before the transition time of the first wave was attained, the direction of the current was reversed and the potential-time curves for the re-oxidation of the superoxide ions were recorded. From the chronopotentiograms obtained, the time intervals

11) S. Hacobian, *Australian. J. Chem.*, **6**, 211 (1953).

for the reduction (τ_{red}) and the transition time for the re-oxidation (τ_{ox}) were measured. In Fig. 7,

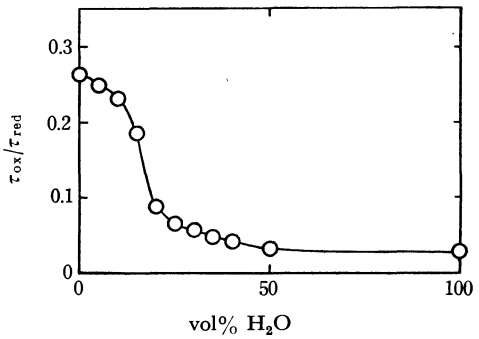

Fig. 7. Ratio of τ_{ox}/τ_{red} obtained by reverse chronopotentiometry at the glassy carbon electrode in oxygen-saturated 0.1M Et_4NClO_4 solutions. τ_{red} = 30 sec.

the values τ_{ox}/τ_{red} are plotted for the case in which $\tau_{red}=30$ sec. Because the mechanisms of further reductions of superoxide anion radicals at the glassy carbon electrode are still unestablished and are probably somewhat different from those at the dropping mercury electrode, the results cannot be analysed theoretically to determine the lifetime of the radical anions. The value of τ_{ox}/τ_{red} for a water concentration below 10%, however, seems to show that the superoxide anions are fairly stable chronopotentiometrically. The rapid decrease of the ratio between 10 and 30% water indicates that superoxide ions disappear rapidly in water-rich solutions in agreement with the results of dc and ac polarography at the dropping mercury electrode.

Polarographic Diffusion Coefficients of Dissolved Oxygen in Mixed Solvents. From the oxygen waves in DMSO-water mixtures, the polarographic diffusion coefficients was calculated using the modified Ilkovic equation:

$$i_d = 607nD^{1/2}Cm^{2/3}t^{1/6}(1 + AD^{1/2}m^{-1/3}t^{1/6}),$$

where the value of A was assumed to be 25. The limiting currents used in the calculation of these diffusion coefficients were confirmed to be diffusion-controlled by the linear proportionality of the currents to the oxygen concentration, and also to the square root of the height of the mercury reservoir. The results are shown in Fig. 8 and Table 1. Curves 1, 2 and 3 are the results at 25°C, and curve 1′ at 45°C. Curves 1 and 1′ were calculated using the total wave heights (assuming four-electron reduction), whereas curves 2 and 3 were calculated from the heights of the first wave. Here, the first wave was supposed to be a one-electron process at a water content below 5% (curve 2) and to be a two-electron process at a water content above

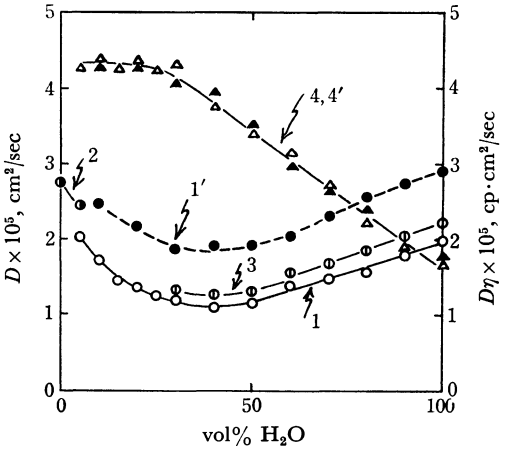

Fig. 8. Diffusion coefficient, D, of oxygen (curves 1, 2, 3 and 1′) and the product, $D\eta$, of the diffusion coefficient and the viscosity (curves 4 and 4′) of the solution containing 0.1M Et_4NClO_4. Curves 1, 2, 3 nd 4 are at 25°C and curves 1′ and 4′ at 45°C. Curves 1 and 1′ were obtained from the total wave heights, curves 2 and 3 from the first wave heights and curves 4 and 4′ were calculated using the values of curves 1 and 1′.

30% (curve 3). In these curves, the diffusion coefficients obtained by measuring the first wave are always larger than the values calculated from the total wave heights. This may be due to several reasons, such as the incompleteness of the diffusion current equation used, the occurrence of the reduction of a small amount of hydrogen peroxide at the potential at which the first wave height was measured, and the depletion effect of the depolarizer which is more pronounced at the potential of the total wave height because of the absence of appropriate maximum suppressors.[12] Moreover, when the water content is small (5% to 15%), the accuracy of the diffusion coefficients obtained from the total wave heights may decrease to some extent because the drop time is very small. Though the polarographic diffusion coefficients suffer from these limitations, they provide sufficient knowledge concerning their variation with composition of mixed solvent. From Fig. 8, the diffusion coefficient becomes a minimum at a water concentration between 30 and 50%, both at 25°C and 45°C. Curves 4 and 4′ are the products $D\eta$ of the diffusion coefficient and the viscosity of the solvent. Both at 25°C and 45°C, when the water content is greater than 30%, the value of $D\eta$ is not constant and increases almost linearly with decrease in water content, but below 30%, it is approximately constant.

Spectroscopic Studies of Polynuclear Complexes. I. Preparations and Circular Dichroisms of Tetrakis(*l*-propylenediamine)-dicobalt(III) Complexes Containing μ-Amido Group

Yoichi SASAKI, Junnosuke FUJITA and Kazuo SAITO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received June 5, 1968)

New binuclear cobalt(III) complexes, $(-)_D$-$[(l\text{-pn})_2Co(\mu\text{-}NH_2,O_2)Co(l\text{-pn})_2](NO_3)_4\cdot 3H_2O$, $(+)_D$-$[(l\text{-pn})_2Co(\mu\text{-}NH_2,O_2)Co(l\text{-pn})_2]I_3\cdot 6H_2O$, $(+)_D$-$[(l\text{-pn})_2Co(\mu\text{-}NH_2,NO_2)Co(l\text{-pn})_2]Br_4\cdot 6H_2O$, $(+)_D$-$[(l\text{-pn})_2Co(\mu\text{-}NH_2,OH)Co(l\text{-pn})_2](NO_3)_4\cdot 2H_2O$ and $(-)_D$-$[(l\text{-pn})_2Co(\mu\text{-}NH_2,SO_4)Co(l\text{-pn})_2](NO_3)_3$ were prepared and their absolute configurations determined to be $\Lambda\Lambda$ on the consideration of the stereospecific coordination of *l*-propylenediamine (*l*-pn) to the metal ion. On the basis of these identifications, absolute configurations of the corresponding ethylenediamine-(en) complex ions were assigned. The nature of the d–d bands of these polynuclear complexes seems to be very similar to those of uninuclear cobalt(III) complexes. One of the two central cobalt(III) ions is regarded as a member of an asymmetric chelate ligand to the other cobalt ion, and the CD corresponding to the d–d bands appears to depend mainly on the strength of vicinal effect due to such a chelate ring.

Since the resolution of several binuclear complexes of the type, $[(en)_2Co(\mu\text{-}NH_2,a)Co(en)_2]^{n+}$,[1] and two quadrinuclear hexol complexes, $[Co\{(\mu\text{-}OH,OH)Co(NH_3)_4\}_3]^{6+}$ and $[Co\{(\mu\text{-}OH,OH)Co(en)_2\}_3]^{6+}$ [2] by Werner, there has been little work reported[3–6] on the preparation and optical properties of polynuclear cobalt(III) complexes. In 1938, Mathieu[3] measured the circular dichroism (CD) spectra of some of Werner's binuclear complexes, and concluded that the absolute configuration of the polynuclear complexes could not be assigned from their CD behavior.

As a first step of studying the structure and optical properties of such complexes, we have attempted to prepare new binuclear complexes, of which the absolute configuration can be assigned by a consideration of the stereospecific coordination of an optically active ligand to the metal ion. In this paper we report the preparation and the absolute configuration of new optically active binuclear complexes of the type, $[(l\text{-pn})_2Co(\mu\text{-}NH_2,a)Co(l\text{-pn})_2]^{n+}$ *1 (a = O_2^-, O_2^{2-}, NO_2^-, OH^-, and "SO_4^{2-}"*2) and compare their optical properties with those of corresponding Werner's ethylenediamine complexes.

Experimental

Preparations of the Complexes. *(1) Octaammine-μ-amido-μ-superoxo-dicobalt(III)**3 *Nitrate.* $[(NH_3)_4Co(\mu\text{-}NH_2,O_2)Co(NH_3)_4](NO_3)_4$ was prepared and purified by Mori, Weil and Ishiguro's new method[7] with concentrated nitric acid at 20—30°C as oxidizing agent instead of diammonium hexanitratocerate(IV). From 50 g of cobalt nitrate hexahydrate, 10 g of the complex was obtained.

*(2) $(+)_D$*4*-Tetrakis(ethylenediamine)μ-amido-μ-hydroxo-dicobalt(III) Nitrate.* $(+)_D$-$[(en)_2Co(\mu\text{-}NH_2,OH)Co(en)_2](NO_3)_4$was prepared by a new method from "$(+)_D$-$[(en)_2Co(\mu\text{-}NH_2,SO_4)Co(en)_2](NO_3)_3\cdot 2H_2O$". The starting complex (500 mg) was dissolved in 0.1 N sodium hydroxide (10 ml), set aside for 1 day at room tempera-

*4 $(+)_D$ and $(-)_D$ refer to the signs of the optical rotation at sodium D-line (589 mμ).

ture, and cooled in an ice bath. The red crystals were filtered off, dissolved in a little water and a small quantity of barium nitrate was added. The barium sulfate was removed and the filtrate concentrated till the crystals appeared and cooled to 0°C. The orangered crystals were recrystallized from hot water. Yield 200 mg.

Found: C, 15.27; H, 6.03; N, 28.43%. Calcd for $C_8H_{35}N_{13}O_{13}Co_2$: C, 15.03; H, 5.52; N, 28.48%.

(3) (−)D-Tetrakis(l-propylenediamine) μ-amido-μ-superoxo-dicobalt(III) Nitrate Trihydrate, (−)D-[(l-pn)$_2$Co(μ-NH_2,O_2)Co(l-pn)$_2$]$(NO_3)_4\cdot 3H_2O$. [$(NH_3)_4$Co(μ-NH_2,O_2)Co$(NH_3)_4$]$(NO_3)_4$ (20 g) in 5% aqueous l-propylenediamine (300 ml) was warmed at about 55°C on a water bath for about 5 hr, then cooled to room temperature, the brown solution treated with concentrated nitric acid until the color changed to green, and then with a large volume of ethanol. Green hygroscopic precipitate was filtered. When the filtrate was green, ethanol was added to obtain further aliquot. The product was recrystallized from 0.1 N nitric acid. The circular dichroism curve of the green fine needles remained unchanged on further recrystallization. Yield 5–7 g. The product seems to consist of only one of the optical isomers.

Found: C, 18.80; H, 6.28; N, 23.64%. Calcd for $C_{12}H_{48}N_{13}O_{17}Co_2$: C, 18.85; H, 6.33; N, 23.83%.

(4) (+)D-Tetrakis(l-propylenediamine) μ-amido-μ-peroxo-dicobalt(III) Iodide Hexahydrate, (+)D-[(l-pn)$_2$Co(μ-NH_2,O_2)Co(l-pn)$_2$]$I_3\cdot 6H_2O$. (−)D-[(l-pn)$_2$Co(μ-NH_2,O_2)Co(l-pn)$_2$]$(NO_3)_4\cdot 3H_2O$ (500 mg) was dissolved in 28% aqueous ammonia (3 ml). To this solution an excess of ammonium iodide was added. The brown precipitate was recrystallized from 15% aqueous ammonia by adding excessive ammonium iodide. Brown powder, yield 100 mg.

Found: C, 15.07; H, 5.40; N, 13.16%. Calcd for $C_{12}H_{54}N_9O_8I_3Co_2$: C, 15.15; H, 5.72; N, 13.25%.

(5) (+)D-Tetrakis(l-propylenediamine) μ-amido-μ-nitrito-dicobalt(III) Bromide Hexahydrate, (+)D-[(l-pn)$_2$Co(μ-NH_2,NO_2)Co(l-pn)$_2$]$Br_4\cdot 6H_2O$. (−)D-[(l-pn)$_2$Co(μ-NH_2,O_2)-Co(l-pn)$_2$]$(NO_3)_4\cdot 3H_2O$ (1 g) was dissolved in 5 ml of water, and treated with sodium nitrate (1 g). The color of the solution gradually changed from green to dark brown. The solution was kept at room temperature for 1 hr, then cooled in an ice bath and treated with concentrated hydrobromic acid (3 ml) slowly and carefully with stirring. The reddish orange crystals were filtered off and recrystallized from water. Yield 300 mg.

Found: C, 15.89; H, 5.49; N, 15.39%. Calcd for $C_{12}H_{54}N_{10}O_8Br_4Co_2$: C, 15.94; H, 5.80; N, 15.49%.

(6) (−)D-Tetrakis(l-propylendiamine) μ-amido-μ-"sulfato"-dicobalt(III) Nitrate, (−)L-[(l-pn)$_2$Co(μ-NH_2,SO_4)-Co(l-pn)$_2$]$(NO_3)_3$·(−)D-[(l-pn)$_2$Co(μ-NH_2,O_2)Co(l-pn)$_2$]$(NO_3)_4\cdot 3H_2O$ (1 g) was suspended in water (2 ml) saturated with sulfur dioxide, warmed on a water bath (60—70°C) for a few minutes and kept in an ice bath. The dark red crystals were filtered off, treated with water (2 ml) saturated with sulfur dioxide, and finally recrystallized from hot water. Reddish violet crystals, yield 400 mg.

Found: C, 20.57; H, 6.01; N, 23.60%. Calcd for $C_{12}H_{42}N_{12}O_{13}S_1Co_2$: C, 20.23; H, 5.94; N, 23.59%. The structure will be discussed in the following section.

(7) (+)D-Tetrakis(l-propylenediamine) μ-amido-μ-hydoxo-dicobalt(III) Nitrate Dihydrate. (+)D-[(l-pn)$_2$Co(μ-NH_2,OH)Co(l-pn$_2$](NO$_3$)$_4\cdot 2H_2O$ was prepared from "(−)D-[(l-pn)$_2$Co(μ-NH_2,SO_4)Co(l-pn)$_2$]$(NO_3)_3$" by a similar method to that for (+)D-[(en)$_2$Co(μ-NH_2,OH)Co(en)$_2$]-$(NO_3)_4$. From 500 mg of the starting material, 200 mg of the complex was obtained. Found: C, 19.58; H, 6.86; N, 24.79%. Calcd for $C_{12}H_{47}N_{13}O_{15}Co_2$: C, 19.71; H, 6.48; N, 24.89%.

Resolution of Tetrakis(ethylenediamine)-μ-amido-μ-superoxo-dicobalt(III) Ion. This was resolved by Werner's method[1] with silver d-bromcamphorsulfonate. Yield, 2 g of nitrate of (−)D form and 3 g of (+)D form from 35 g of [(en)$_2$Co(μ-NH_2,O_2)Co(en)$_2$]Br_4.

Measurements. Absorption and circular dichroism spectra were measured with Hitachi 124 Spectrophotometer and JASCO Model ORD/UV-5 recorder with CD attachment respectively in water at room temperature. All the complexes were stable in water.

Results and Discussion

Stereospecificity of l-Propylenediamine for Binuclear Complexes. It is known that the stable conformation of the chelated l-(D)-propylenediamine will be a λ-form with equatorial methyl group.[8] In tris complexes of l-propylenediamine, the two diastereoisomers, *Δ* and *Λ*[*5] have the "ob" and the "lel" structure, respectively. The lel isomer is estimated to be more stable than the ob isomer.[8] In fact, the products obtained on the reaction between cobalt and l-propylenediamine always consist mostly of *Λ*-[Co(l-pn)$_3$]$^{3+}$ with the lel structure.[9]

The energy difference between the ob and the lel isomer is said to be small for *cis*-bis-(l-propylenediamine) complexes. As stated before, however, the reaction of [$(NH_3)_4$Co(μ-NH_2,O_2)Co$(NH_3)_4$]$^{4+}$ and l-propylenediamine in an aqueous solution seemed to yield only one of the three possible optical isomers of [(l-pn)$_2$Co(μ-NH_2,O_2)Co(l-pn)$_2$]$^{4+}$. We ignore the geometrical isomers depending on the position of the methyl groups, since they would have structurally similar stabilization energies with one another, and could not be separated by usual chemical methods. The pure crystalline isomer exhibits a strong CD, indicating that it is one of the two diastereoisomers *ΔΔ* and *ΛΛ*, and not *ΔΛ* (so-called "meso" form). The isomer, (−)D-[(l-pn)$_2$Co(μ-NH_2,O_2)Co(l-pn)$_2$]$^{4+}$, could be assigned reasonably to the *ΛΛ* configuration, when the stereospecific coordination of l-propylenediamine mentioned above is considered.

No indication of the formation of the other isomers was observed from the CD measurements of many samples obtained at different stages of recrystallization. Studies with molecular models

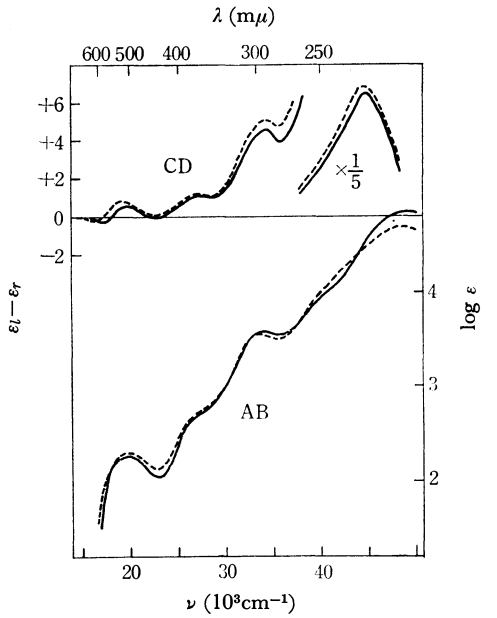

Fig. 4. The absorption (AB) and CD spectra of $(+)_D$-$[(en)_2Co(\mu\text{-}NH_2,OH)Co(en)_2](NO_3)_4$ (——) and $(+)_D$-$[(l\text{-}pn)_2Co(\mu\text{-}NH_2,OH)Co(l\text{-}pn)_2]$-$(NO_3)_4$ (------) in water.

of the isomers show that the repulsion between the amino groups of *l*-propylenediamines around the bridging region seems to be less in the *ΔΔ* and the *ΛΛ* form than in the *ΔΛ* form.

Four complexes, $(+)_D$-$[(l\text{-}pn)_2Co(\mu\text{-}NH_2,O_2)Co(l\text{-}pn)_2]^{3+}$, $(+)_D$-$[(l\text{-}pn)_2Co(\mu\text{-}NH_2,NO_2)Co(l\text{-}pn)_2]^{4+}$, $(-)_D$-$[(l\text{-}pn)_2Co(\mu\text{-}NH_2,SO_4)Co(l\text{-}pn)_2]^{3+}$ and $(+)_D$-$[(l\text{-}pn)_2Co(\mu\text{-}NH_2,OH)Co(l\text{-}pn)_2]^{4+}$, which were derived from the *ΛΛ*-$[(l\text{-}pn)_2Co(\mu\text{-}NH_2,O_2)$-$Co(l\text{-}pn)_2]^{4+}$, would be concluded to have the same *ΛΛ* configuration too, from their CD measurement, as discussed later. Complete inversion to the *ΔΔ* form during their syntheses from the *ΛΛ* isomers seems to be very improbable for these

binuclear complexes.

With these *l*-propylenediamine complexes as standard, the absolute configurations of the corresponding ethylenediamine complexes could be assigned safely from their CD spectra. As Fig. 1 shows, the CD spectra of the two $(-)_D$-μ-amido-μ-superoxo-dicobalt complexes of ethylenediamine and *l*-propylenediamine are very similar to each other. Therefore, we conclude that the isomer, $(-)_D$-$[(en)_2Co(\mu\text{-}NH_2,O_2)Co(en)_2]^{4+}$ has the $\Lambda\Lambda$ configuration. The following complex ions prepared from this isomer would be assigned to the $\Lambda\Lambda$ configuration; $(-)_D$-$[(en)_2Co(\mu\text{-}NH_2,O_2)Co(en)_2]^{3+}$, $(+)_D$-$[(en)_2Co(\mu\text{-}NH_2,NO_2)Co(en)_2]^{4+}$, $(+)_D$-$[(en)_2Co(\mu\text{-}NH_2,SO_4)Co(en)_2]^{3+}$ and $(+)_D$-$[(en)_2Co(\mu\text{-}NH_2,OH)Co(en)_2]^{4+}$.

The assignment for the ethylenediamine complexes coincides with that by Garbett and Gillard.[10] They obtained the uninuclear complexes of the known absolute configuration Λ by decomposing $(+)_D$-$[(en)_2NH_3Co(\mu\text{-}NH_2)CoNH_3(en)_2]^{5+}$, derived from $(-)_D$-$[(en)_2Co(\mu\text{-}NH_2,O_2)Co(en)_2]^{4+}$, which was assigned to have $\Lambda\Lambda$ configuration as stated above.

Absorption and Circular Dichroism Spectra. Absorption spectra of the present binuclear complexes exhibit a similar pattern in essential to that of uninuclear complexes, indicating that no strong metal-metal interaction will exist in them. Fairly strong absorptions at *ca.* 30000 to 35000 cm^{-1} known as "the polynuclear band" seem probably to owe to charge transfer transitions between the metal ions and the bridging ligand groups, although the origin is still uncertain.[11]

Medium intensity bands in the visible region seem to be the so called "first" band, corresponding approximately to the d–d transitions ($^1A_1$–$^1T_1$),

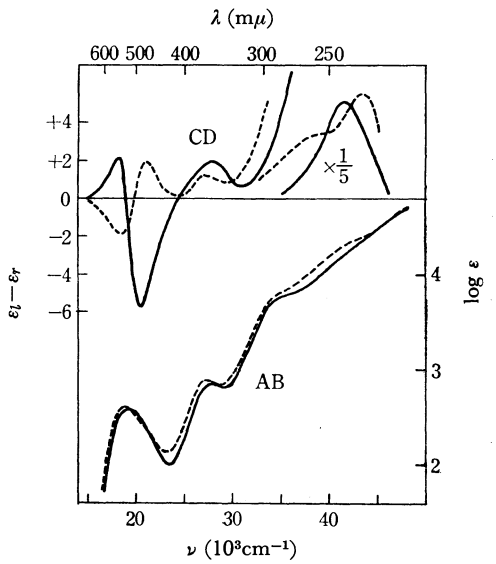

Fig. 5. The absorption (AB) and CD spectra of "$(+)_D$-$[(en)_2(\mu\text{-}NH_2,SO_4)Co(en)_2](NO_3)_3$" (——) and "$(-)_D$-$[(l\text{-}pn)_2Co(\mu\text{-}NH_2,SO_4)Co(l\text{-}pn)_2](NO_3)_3$" (------) in water.

of uninuclear complexes. Table 1 shows that the shifts of these bands can be interpreted by the spectrochemical series,[12] although the field strength of a ligand seems to increase somewhat upon bridging coordination. A similar observation was made by Brubaker and Douglas[6] in their new trinuclear complexes.

Ammine complexes with the superoxo bridge have a characteristic absorption band at *ca.* 14500 cm^{-1} with a medium intensity. Linhard and Weigel[13] assigned such a band in the complex, $[(NH_3)_5Co(O_2)Co(NH_3)_5]^{5+}$ to a split component

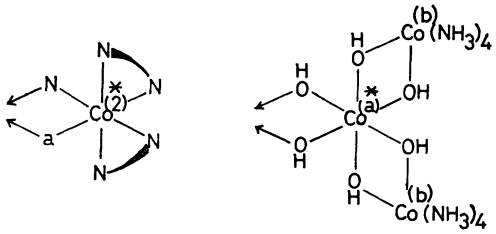
of the first band (I_a). However, this band would be more appropriately assinged to a spin-forbidden d–d transition or to a charge transfer between the superoxo group and the metal ion, since the present μ-amido-μ-superoxo complexes do not show distinct CD in this band region. Split components of the magnetically allowed first band should be optically active. Ohkawa *et al.*[14] detected no CD band in the region of the strong spin-forbidden band of the $(-)_{546}$-*cis*-$[Co(I)(CN)(en)_2]^+$ ion.

The CD spectra corresponding to the d–d transitions ($^1A_1$–$^1T_1$) of the $\Lambda\Lambda$-$[(diamine)_2Co(\mu\text{-}NH_2,a)Co(diamine)_2]^{n+}$ exhibit various appearances depending on the kinds of substituent a, as pointed out by Mathieu.[3] Such a variety could be interpreted by considering "a kind of vicinal effect" of the chelate ring involving an optically active cobalt ion. For example, when we designate the cobalt(III) ions in the binuclear complex as $Co^{(1)}$ and $Co^{(2)}$, the $Co^{(1)}$ is considered to be coordinated with two diamines and a chelate ligand involving an asymmetric $Co^{(2)}$ ion (Fig. 6a). Such an optically active chelate ligand might give a significant vicinal effect more or less to the bands due to $Co^{(1)}$ ion.

The CD of the $(-)_D$-$[Co^{(a)}\{(\mu\text{-}OH,OH)Co^{(b)}(NH_3)_4\}_3]^{6+}$ in the d–d transition ($^1A_1$–$^1T_1$)



(a) (b)

Fig. 6. Bidentate ligands involving asymmetric cobalt ion(s).

region[4] would be interpreted by considering this vicinal effect (Fig. 7). The two absorption peaks at *ca.* 16000 and 20000 cm^{-1} of this complex may correspond approximately to the $^1A_1$–$^1T_1$ transition of the $Co^{(a)}$ and the $Co^{(b)}$ ion, respectively. The higher energy band exhibits a distinct CD, although the terminal $Co^{(b)}$ ions have no asymmetry around themselves. The optical activity of this band will be considered to be introduced by the vicinal effect of the chelate ring involving the optically active $Co^{(a)}$ ion (Fig. 6b). Mason and Wood[4] assigned the $(-)_D$-isomer of this complex to the Δ configuration, since the main CD component corresponding to the band at *ca.* 16000 cm^{-1} (d–d transition of $Co^{(a)}$) has a plus sign. These results suggest that in polynuclear complexes, the vicinal effect of asymmetric cobalt ion with a Δ configura-

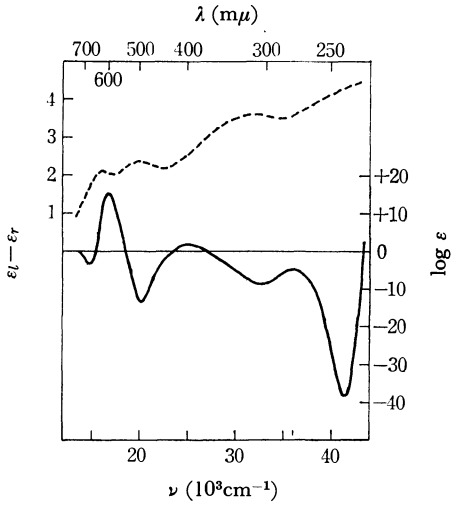

Fig. 7. The absorption (------) and CD spectra (——) of (−)-[Co{(μ-OH,OH)Co(NH$_3$)$_4$}$_3$]$^{6+}$ ion in water. (Ref. 4)

tion gives a negative CD sign for the d–d band ($^1A_1$–$^1T_1$) of the other cobalt ions.

The present binuclear complexes, *ΔΔ*-[(diamine)$_2$Co(μ-NH$_2$,a)Co(diamine)$_2$]$^{n+}$, should show strong negative CD bands in their first band region, if such a vicinal effect were very weak. This will be the case for the μ-superoxo complexes, as is seen in Fig. 1. The other μ-NO$_2$ and μ-hydroxo complexes, on the other hand, exhibit very weak CD bands in this region. Strong negative CD components corresponding to each *Δ*-cobalt ion would be compensated by the positive CD bands resulting from the vicinal effect of each of other asymmetric cobalt ion with the same configuration.

Such an interpretation would be supported by examining the vicinal effect curve of *l*-propylenediamine. In general, the vicinal effect curve of *l*-propylenediamine in cobalt(III) complexes shows one medium strong positive and one small negative peak from longer to shorter wavelength in the region of the first band.[15] The vicinal effect curve of the *l*-propylenediamine for the binuclear complexes could be obtained by subtracting the CD curve of the ethylenediamine complex from that of the corresponding *l*-propylenediamine complex. Both contributions from the configurational and the vicinal effect of the asymmetric cobalt ions would be eliminated from these curves so far as these effects are additive. As Fig. 8 shows, the curves thus obtained show similar appearances to those of uninuclear complexes of *l*-propylenediamine. These results seem to indicate the following conclusions; the nature of the d–d bands of polynuclear cobalt(III) complexes are very similar to those of uninuclear cobalt(III) complexes, and therefore, the CD behavior corresponding to these bands depends mainly on the strength of the vicinal effect of asymmetric cobalt(III) ion.

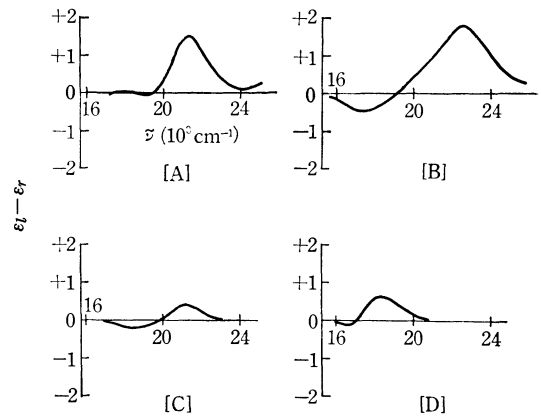

Fig. 8. The vicinal effect curves of four chelated *l*-propylenediamine in the complexes, [(*l*-pn)$_2$Co(μ-NH$_2$,a)Co(*l*-pn)$_2$]$^{n+}$.
(A) a=O$_2^-$ (B) a=O$_2^{2-}$ (C) a=NO$_2^-$ (D) a=OH$^-$
(obtained by subtracting the CD of *ΔΔ*-[(en)$_2$Co(μ-NH$_2$,a)Co(en)$_2$]$^{n+}$ from that of *ΔΔ*-[(*l*-pn)$_2$Co(μ-NH$_2$,a)Co(*l*-pn)$_2$]$^{n+}$.)

Weak CD bands were observed in the region of the other d–d band ($^1A_1$–$^1T_2$), but their behavior has not been made clear.

Corresponding to the so-called polynuclear band at *ca.* 30000 to 35000 cm^{-1} region, the *ΔΔ* complexes exhibit fairly strong CD bands with a positive sign. Although the origin of these bands is uncertain, the fact that the CD sign is always positive as that of the CD for strong charge transfer bands at *ca.* 40000 cm^{-1} indicates that these bands would have also a charge transfer character.

Concerning the CD of charge transfer bands in tris-diamine[16] and tris-aminoalcohol[17] cobalt(III) complexes, it has been suggested that their sign depends mainly on the absolute configuration around the metal ion, and that it will be positive for a *Δ*-type complex and negative for a *Λ*-type complex. Although a positive CD component due to the vicinal effect of the chelated diamines with *λ*-form[16] may be involved in these CD bands, their positive sign seems to support the previous conclusion that all the complexes have the *ΔΔ* configuration.

"μ-Sulfato" Complexes. All the *l*-propylenediamine complexes except for the "μ-amido-μ-sulfato" complex give very similar absorption and CD curves to those of the corresponding ethyl-

enediamine complexes. However, the CD curves of the two "μ-sulfato" complexes appear almost enantiomeric with each other in the d–d transition band region. Such a difference might be originated in a difference between the bonding structure of the bridging sulfato ligands in these two complexes, since both the complexes would have the same $\Lambda\Lambda$ configuration. The aqueous solutions of these complexes decompose gradually to give the $\Lambda\Lambda$-μ-amido-μ-hydroxo complexes.[3,18] Furthermore, addition of barium ions to these solutions results in only a slow precipitation of barium sulfate upon warming, to indicate that the sulfate ions coordinate to the metal ions, and are not the outer sphere ions. Detailed studies about these problems are now in progress, and will be published later.

We express our sincere thanks to the Ministry of Education for Grant-in-Aid.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 152—156 (1969)

The Oxovanadium(IV) Complexes of Schiff Bases Obtained from Substituted Salicylaldehydes and Alkyl Amines*1

Shoichiro YAMADA and Yoshio KUGE*2

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received June 5, 1968)

Many new oxovanadium(IV) complexes (abbreviated as $VO(X\text{-sal.R})_2$) of Schiff bases obtained from substituted salicylaldehydes and alkylamines have been synthesized as crystals, where X=H and 3-CH_3O and R=CH_3, C_2H_5, *n*-C_3H_7, *n*-C_4H_9, *iso*-C_3H_7, $CH(CH_3)(C_2H_5)$, $CH_2CH(CH_3)_2$ and cyclohexyl. Since all these complexes show similar electronic spectra, it is considered that they take an essentially similar configuration, that is, a square-pyramidal one in the solid state and in chloroform, even for $R=\alpha$-branched alkyls. This result is different from that of the copper (II) complexes. It is also concluded that these oxovanadium(IV) complexes, when dissolved in pyridine, take up one pyridine molecule to form a six-coordinated species. The configuration of the pyridine solvate depends upon R.

In previous papers from this laboratory,[1-3] Schiff base complexes of various transition metal ions were described and their stereochemistry was discussed. As an extension of these studies, the oxovanadium(IV) complexes of these Schiff bases have been studied in the present work. The oxovanadium(IV) ion has an electronic configuration d^1, so that its complexes are expected to be somewhat similar to the complexes of copper(II) having a configuration d^9.

Some of the oxovanadium(IV) complexes of this series were previously reported,[4,5] but a systematic study seems to be insufficient. The present paper describes the results of the investigations about the oxovanadium(IV) complexes of the Schiff bases obtained from substituted salicylaldehydes and alkyl amines (Fig. 1).*3

*3 The complexes of this type are abbreviated in this paper as $VO(X\text{-sal.R})_2$.

type, where X=H and 3-CH_3O, were synthesized by a method similar to that previously reported for complexes of other metal ions.[1] One of the typical examples of the syntheses is given below for VO(3-CH_3O-sal.CH_3)$_2$. To a solution of oxovanadium (IV) chloride (0.01 mol) in ethanol were added 3-methoxysalicylaldehyde (0.02 mol), a 40% aqueous solution of methyl amine (0.02 mol) and sodium acetate (0.02 mol). The solution was heated with stirring on a water-bath at about 60°C for about three hours. The solution was allowed to stand overnight, and the precipitate was collected by filtration. Recrystallization from ethanol yielded green crystals of VO(3-CH_3O-sal.CH_3)$_2$.

All the complexes were purified by recrystallization of the crude product from ethanol. Ethanol containing a small amount of pyridine was occasionally used for the recrystallization of the less soluble compounds like VO(H-sal.C_2H_5)$_2$.

The salicylideneiminato-complexes are grey-brownish green, and the 3-methoxysalicylideneiminato-complexes are green. They are soluble in chloroform and dichloromethane, but less soluble in methanol, ethanol and benzene. The complexes of the VO(H-sal.R)$_2$ type are less soluble in common organic solvents than the complexes of the VO(3-CH_3O-sal.R)$_2$ type. Analytical data of the complexes are given in Tables 1 and 2.

Cu(H-sal.*iso*-C_3H_7)$_2$ was prepared as previously reported.[6]

Measurements. The electronic absorption spectra of the compounds in solution and the reflection spectra of the solid were determined with a Shimadzu QR-50 spectrophotometer and a Shimadzu MPS-50L spectrophotometer.

Results and Discussion

The Oxovanadium(IV) Complexes of *N*-*n*-Alkyl-substituted Schiff Bases. Numerous new oxovanadium(IV) complexes of the Schiff bases have been synthesized in the present work. All these complexes are considered to consist of penta-coordinated molecules.[4,5] When R denotes an *n*-alkyl group, there is no or very little steric hindrance, so that the complexes of the VO(X-sal.R)$_2$ type are expected to be square-pyramidal, with the two groups of X-sal.R most probably taking a nearly trans-planar configuration.[5]

Electronic spectra of these complexes in non-donor solvents are essentially similar to the spectra of the same complexes in the solid state (Figs. 2 and 3, and Tables 3 and 4).*4 It is, therefore, most likely that their configuration in such a non-donor solvent as chloroform is similar to that in the solid state, the solvent molecule not being bound with the vanadium(IV) ion. It is also concluded that all these complexes take a similar configuration, that is, a square-pyramidal one, regardless of the substituent, R, since they show similar spectra. The main features of the spectra of these complexes are in agreement with those for the related complexes.[5]

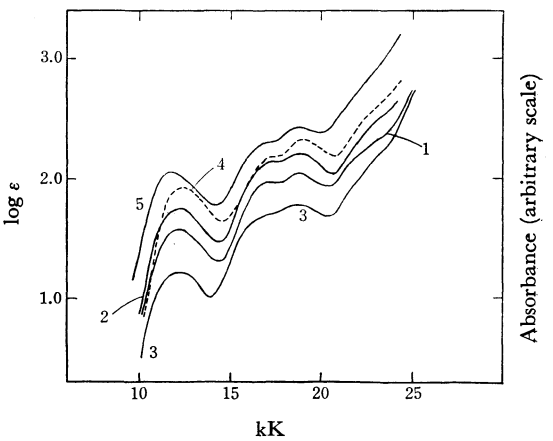

Fig. 2. Electronic absorption spectra of VO(H-sal.R)$_2$: 1, R=C_2H_5, solid; 2, R=*n*-C_4H_9, solid; 3, R=$CH_2CH(CH_3)_2$, in chloroform; 4, R=CH_2-$CH(CH_3)_2$, solid; 5, R=$CH(CH_3)(C_2H_5)$, solid.

6) S. Yamada and H. Nishikawa, This Bulletin, **36**, 755 (1963).

*4 Solubility of these complexes is rather low in common organic solvents other than chloroform and dichloromethane. In this work, the spectra were measured mostly using chloroform as a solvent. Measurements were also carried out with some of the complexes in dichloromethane, but the spectra were found to be essentially similar to the spectra of the chloroform solution.

It is interesting to note that three band maxima are observed in the region of *d–d* bands for these complexes. About an unambiguous assignment of the *d–d* absorption bands of the oxovanadium(IV) complexes there still seems to remain some dipute.[4,7] The three bands at about 12 kK,

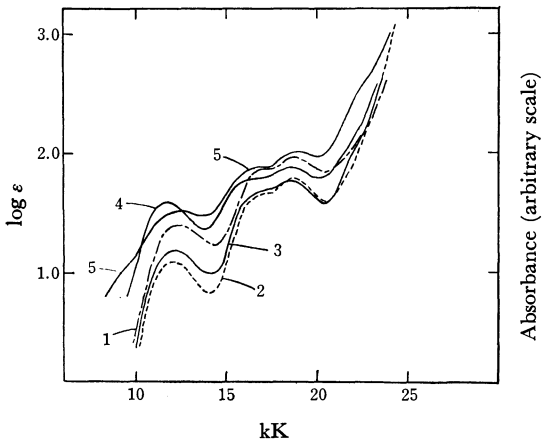

Fig. 3. Electronic absorption spectra of VO-(3-CH_3O-sal.R)$_2$: 1, R=CH_3, solid; 2, R=CH_3, in chloroform; 3, R=n-C_4H_9, in chloroform; 4, R=iso-C_3H_7, solid; 5, R=$CH(CH_3)(C_2H_5)$, in dichloromethane.

16—17 kK and 18.5—19 kK may tentatively be assinged as transitions $d(xz)$, $d(yz)\leftarrow d(xy)$, $d(x^2-y^2)\leftarrow d(xy)$ and $d(z^2)\leftarrow d(xy)$, respectively, on the basis of the "clustered levels" scheme.[5,7]

These complexes in pyridine show electronic spectra, which are different from the spectra of the same complexes in the solid state and in chloroform (Figs. 4 and 5, and Tables 3 and 4). The change in the spectrum on going from a non-donor solvent to pyridine is not very large, but quite characteristic. This fact seems to indicate that the oxovanadium(IV) complexes, when dissolved in pyridine, combine with one molecule of pyridine to form six-coordinated solvates. It is to be noted that for the pyridine solution there appears a shoulder at about 12 kK, in addition to the peak at about 13—14 kK and two other peaks. The two peaks at the lower frequencies may tentatively be assigned as the transitions $d(xz)\leftarrow d(xy)$ and $d(yz)\leftarrow d(xy)$.

R=2-methylpropyl, there is no serious steric hindrance to the planar coordination of the two ligands around the vanadium(IV) ion. For R= isopropyl, 1-methylpropyl and cyclohexyl, however, there may be more or less remarkable steric hindrance to the planar coordination, since the corresponding copper(II) complexes of the Cu(X-sal.R)$_2$ type were found to be planar or distorted from the planar configuration, depending upon the nature of X.[6,8] On the contrary, the complexes of the VO(X-sal.R)$_2$ type for R=α-branched alkyls in chloroform and in the solid state show electronic absorption spectra quite similar to the corresponding complexes with R=*n*-alkyl groups. It is, therefore, most likely that for all these oxovanadium(IV) complexes the coordination of the two ligand groups may be nearly planar. This difference between the oxovanadium(IV) complexes and the corresponding copper(II) complexes indicates that the configuration distorted from the planar one is destabilized to a more or lesser extent for the oxovanadium(IV) ion, as compared with the copper(II) ion. This may be due, at least partly, to the steric effect of the oxygen atom bound to the vanadium(IV) ion, in addition to the difference in the bonding nature of the metal ions. It is, however, to be noted that the intensity of the *d–d* bands, particularly that of the band at the lowest frequency, becomes higher on going from R=*n*-alkyl to R=α-branched alkyl or cyclohexyl for X=3-CH_3O, as shown in Fig. 5 and Table 4. The change is not quite large but definite, and it is most likely that the coordination of the two Schiff bases to the vanadium(IV) ion may be distorted from the planar one to an only small extent.

For R=α-branched alkyl groups, the electronic spectra of VO(3-CH_3O-sal.R)$_2$ in pyridine are clearly different from the spectra of the same complexes in the solid state and in chloroform, as shown in Fig. 5 and Table 4. This fact indicates that the oxovanadium(IV) complexes of this series, when dissolved in pyridine, take up a pyridine molecule. Since, for R=α-branched alkyl groups as well as 2-methylpropyl, the change in the spectra of VO(3-CH_3O-sal.R)$_2$ on going from a non-donor solvent to pyridine is essentially similar to that of VO(3-CH_3O-sal.*n*-alkyl)$_2$, the configuration of the pyridine solvates for these substituents, R, may be similar to the corresponding solvates for R=*n*-alkyl groups.

On the contrary, for R=α-branched alkyl groups or cyclohexyl, the electronic spectra of VO(H-sal.R)$_2$ in pyridine are quite different from the spectra of the same complexes in chloroform and in the solid state (Fig. 4 and Table 3). The *d–d* bands at the lowest frequencies of these complexes are found to become much broader, extending into a considerably lower frequency region on going from chloroform to pyridine. This result is different from that for VO(H-sal.*n*-alkyl)$_2$ and VO(3-CH_3O-sal.alkyl)$_2$. It is most likely that this anomalous change of spectra in VO(H-sal.α-branched alkyl)$_2$ may be due to the steric hindrance leading to a distorted configuration for the pyridine solvates.

For R=α-branched alkyl groups, it is thus found that the behavior of VO(H-sal. R)$_2$ is different from that of VO(3-CH_3O-sal.R)$_2$. This difference provides one of the examples showing that a small difference in the electronic factor due to the substituent X may cause a drastic change in the stereochemistry of the Schiff base metal complexes.

It is also interesting to compare VO(H-sal.*iso*-C_3H_7)$_2$, for example, with the corresponding copper(II) complexes, Cu(H-sal.*iso*-C_3H_7)$_2$. This copper(II) complex, which takes a distorted tetrahedral configuration in non-donor solvents,[6,8] retains the same configuration in pyridine, since its electronic spectrum in pyridine is essentially similar to the spectrum in non-donor solvents. This is another example showing that the distorted tetrahedral configuration is more stable in the copper(II) complex than in the oxovanadium(IV) complex.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 157—162 (1969)

Reactions of Nickel(II), Copper(II) and Palladium(II) Complexes of Bis(acetylacetone)ethylenediimine with Nitric Oxide

Isao MASUDA, Motonori TAMAKI and Koichiro SHINRA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada, Suita, Osaka

(Received June 6, 1968)

Through reaction with nitric oxide, divalent Ni, Cu, and Pd complexes of bis(acetylacetone)-ethylenediimine have been shown to yield fine crystalline compounds of the general formula $M(C_{12}H_{17}N_3O_3)$, where M=Ni or Cu, and of $M(C_{12}H_{16}N_4O_4)$ where M=Ni, Cu or Pd, depending on experimental conditions. They are insoluble in water. The former compounds are rather soluble in common organic solvents, but the latter are sparingly soluble, except in pyridine. On the basis of analytical data and IR-spectral analyses, they are thought not to be nitrosyl metal-complexes but oxime type complexes.

It is well known that the γ-H of metal acetylacetonates can be replaced by halogens or nitro groups.[1] However, the reactivity of chelate complexes, such as acetylacetonate, towards nitric oxide is not yet clarified. In this connection, only a few examples are found in the following studies. Djordjenič *et al.*[2] reported that through reaction with nitrosyl chloride in benzene, platinum(II) acetylacetonate yields a γ-chlorosubstituted compelx, whereas nickel(II) complex yields a compound which is thought to be either an oxime or a nitroso compound. By reaction with nitrite ions in the presence of ammonia, nickel(II) and palladium(II) complexes of acetylacetone yield a compound thought to be a γ-nitroso substituted complex, as shown in Fig. 1. On the other hand, it was shown by Nast *et al.*[3] that cobalt(II) acetylacetonate reacts with nitric oxide to yield a nitrosyl complex, CoA_2*1(NO), in which nitric oxide is bonded to the central metal.

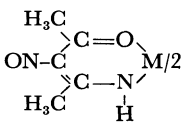

Fig. 1. M=Ni(II); Pd(II)

In the present work, nickel(II), copper(II) and palladium(II) complexes of bis(acetylacetone)ethylenediimine, which have metal-chelate rings analogous to that of acetylacetonate are reported to react with nitric oxide in organic solvents to form new complexes which are thought to have the structures shown in Figs. 2 and 3.

Experimental

Materials. Metal complexes of bis(acetylacetone)-ethylenediimine used in the reactions with nitric oxide were prepared according to McCarthy *et al.*[4] NiAE*2 was purified by recrystallization from an 80% aqueous acetone solution, then dried at 100°C, obtaining reddish brown crystals. CuAE, recrystallized from acetone, was dried at 100°C, yielding dark violet crystals. PdAE, recrystallized from benzene, was dried at 100°C, yielding yellow crystals.

Nitric oxide was generated by the reaction of copper with aqueous nitric acid, and purified by passage through aqueous sodium hydroxide and a tower containing pellets of sodium hydroxide.

Reactions with Nitric Oxide. NiAE: 2.0 g of NiAE was dissolved in 100 m*l* of chloroform, and nitric oxide bubbled through the ice-cooled solution for about fifty minutes until the reddish-brown color of the solution turned to red. Then, the nitric oxide in the solution was driven off by bubbling nitrogen gas through the solution. The orange precipitate was filtered off, and the filtrate evaporated *in vacuo* to leave a red solid. The precipitate was recrystallized from methanol or toluene to give fine red crystals (complex I). The results of elementary analysis, given in Table 1, correspond to the formula shown in Fig. 2. The molecular weight determined with an ebulliometer in toluene for a 0.02 M solution was 298, showing the complex to be monomeric.

Using dichloromethane as a solvent, and bubbling nitric oxide through the solution for 30—40 min, an orange complex precipitated. The precipitate was recrystallized by dissolving it in a large volume of boiling dichloromethane and then cooling the solution. Fine orange crystals (complex II) were obtained. The results of elementary analysis, given in Table 1, correspond to the formula shown in Fig. 3. The orange complex differed from the red complex that was obtained through reaction in chloroform and was only slightly soluble in most organic solvents. It is stable in pyridine, and the complex that was obtained from pyridine solution after the solution was boiled for three hours gave the same infrared spectrum as that of the original orange complex.

CuAE: Two grams of CuAE were dissolved in 100 m*l* of chloroform, and air expelled from the solution and reaction flask by bubbling in nitrogen. Then the ice-cooled solution was saturated with nitric oxide by passing the gas through it for about 20 min. Stirring the solution in air for 20—30 min changed its color from violet to dark red-violet. The solution was evaporated *in vacuo*, leaving a precipitate, which was washed with ether to remove unreacted CuAE. It was recrystallized by dissolution in 50 m*l* of hot methanol and then cooling. Dark red-violet crystals (complex III) were obtained. The analytical results given in Table 1 indicate the formula shown in Fig. 2.

When nitrogen oxide was bubbled through the chloroform solution of CuAE in a similar way as mentioned above, for about two hours, a brown colored complex precipitated. The precipitate was filtered off, washed with chloroform and air-dried. It was recrystallized from methanol to give yellowish-brown crystals (complex IV). The complex was less soluble in most organic solvents than the red complex; analysis indicates the formula shown in Fig. 3.

PdAE: 0.2 g of PdAE dissolved in 50 m*l* of benzene was reacted with nitrogen oxide in the same way as above. After bubbling in nitric oxide for 30—50 min, the solution changed in color from yellow to orange, and an orange complex precipitated. The precipitate was filtered off and washed with benzene and then ether. Recrystallization from dichlorobenzene or pyridine gave fine orange crystals (complex V). Elementary analysis indicated the formula shown in Fig. 3.

Infrared Spectra. Infrared spectra were measured in KBr using a Shimadzu IR-27C spectrometer in the 650—4000 cm^{-1} region. Spectra in the 250—700 cm^{-1} region were obtained in KBr with an Hitachi EPI-L spectrometer.

Results and Discussion

Elementary analyses show that complexes II, IV and V have compositions which correspond to compounds with metal-AE : NO molecular ratios of 1 : 2. As for complexes I and III, analysis indicates a metal-AE: NO molecular ratio of 1 : 1. The solubilities of the complexes, their being insoluble in water and soluble in common organic solvents, suggest that they are non-ionic.

In order to formulate the complexes, their infrared spectra were examined. As is seen in Figs. 6—8, complexes II, IV and V display quite similar spectra, indicating similar structures.

It is well known that metal complexes of AE[5] or β-ketoamine,[6] which have unsaturated, six-membered metal chelate rings, such as shown in Fig. 4, are characterized by two or three absorption

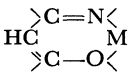

Fig. 4

bands with strong intensities in the 1500—1600 cm^{-1} region, and the band due to π_{C-H} at about 760 cm^{-1}. Compared with this, the spectra of complexes II, IV and V are conspicuous by the absence of strong bands in the 1500—1600 cm^{-1} region and the band due to π_{C-H} (Figs. 6—8). However, the complexes exhibit strong bands in

5) K. Ueno and A. E. Martell, *J. Am. Chem. Soc.*, **59**, 998 (1955).

6) H. F. Holtzclaw, J. P. Collman and R. M. Alire, *ibid.*, **80**, 1100 (1958); R. D. Archer, *Inorg. Chem.*, **2**, 292 (1963).

a higher wave number region, 1660—1689 cm^{-1}. The new bands are attributed to the stretching frequencies of N=O, C=O or C=N from general considerations of their positions and intensities. But in the case of these complexes, the absence of the strong bands in the 1500—1600 cm^{-1} region is thought to eliminate a formula where an N=O group is bound to the γ-C (Fig. 4) on the chelate rings of the original metal-AE, though the π_{C-H} band apparently disappeared. Since in the spectra of metal acetylacetonates, bands analogous to those of metal-AE in the 1500—1600 cm^{-1} region are known not to vanish by substitution on γ-C of an unsaturated group such as nitro-, phenyl- or formyl-groups.[7] A nitrosyl type of structure is also discarded for the following reason. Nitrosyls of nickel, copper and cobalt complexes with AE, where the NO group is bound to the central metal,

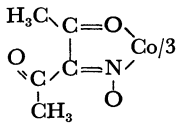

Fig. 5

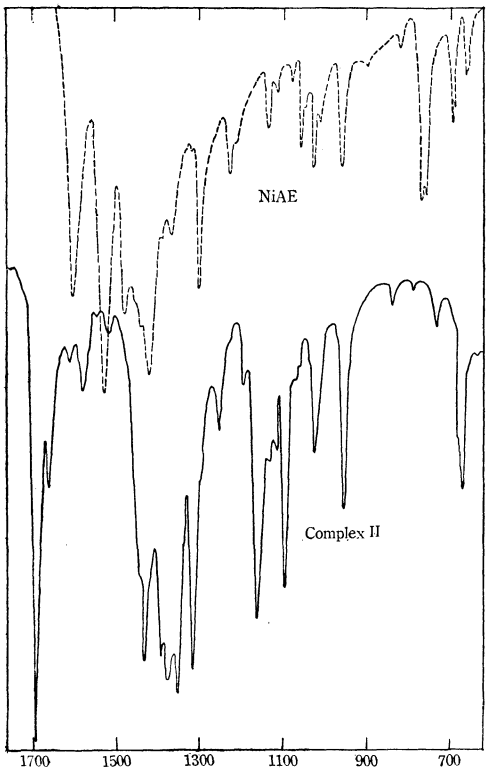

Wave number, cm^{-1}

Fig. 6. IR spectra of NiAE and complex II.

were synthesized by another method.[8] Their spectra show strong bands at about 1680 cm^{-1}, which resemble in position the bands at 1660—1689 cm^{-1} obtained for complexes II, IV and V. However, in the case of these nitrosyls, they still retain the strong 1500—1600 cm^{-1} bands that are diagnostic of the parent metal-AE, and also retain the π_{C-H} band at about 760 cm^{-1}.

Thus, the evidences described above reject the most probable structures containing NO groups in the complexes. A considerably different skeleton for the structures of the complexes from that of the original metal-AE is then proposed. The spectrum of tris(isonitrosoacetylacetonato)Co(III) was inspected and compared with that of the complexes. $Co(INA)_3$*3 has been formulated as shown in Fig. 5,[9] and its spectrum given in Fig. 9 has no strong band in the 1500—1600 cm^{-1} region except

for a band at 1520 cm^{-1}. This band can be assigned to the stretching frequency of C=O that is coordinated to the cobalt atom; the corresponding bands are not observed for complexes II, IV and V (Figs. 6—8). The stretching frequency of non-coordianted C=O to the metal in $Co(IAN)_3$ appeared at 1660 cm^{-1}.

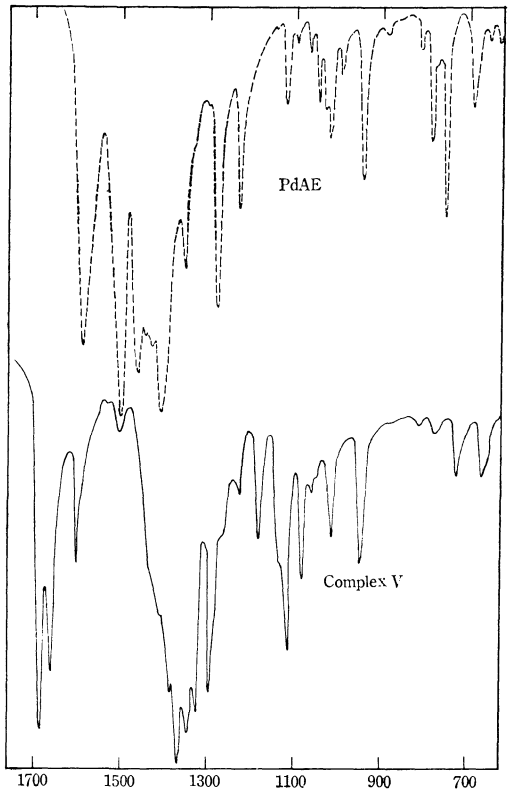

Fig. 8. IR spectra of PdAE and complex V.

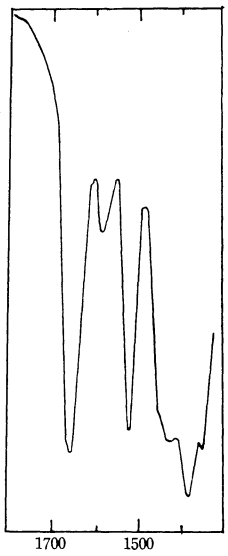

Fig. 9. IR spectra of $Co(INA)_3$.

On the basis of the spectrum of $Co(INA)_3$, the spectra of complexes II, IV and V may be reasonably explained by proposing the structures shown in Fig. 3. Assignments are listed in Table 2. The band at 1682—1689 cm^{-1} has been assinged to the stretching frequency of C=O that is not bound to the central metal atom. As for the subsidiary peak at a lower wave number (1660—1662), it is discussed later and is ascribed to the freqnency of the imine type C=N stretching in the porposed structure (Fig. 3).

Complex I shows interesting spectral features in that it possesses essentially the same frequencies of both complex II and the original NiAE. For example, as shown in Fig. 10 and Table 2, it exhibits bands at 1685 and 1652 cm^{-1}, corresponding to

TABLE 2. CHARACTERISTIC IR ABSORPTIONS OF THE COMPLEXES

a) imine type C=N in chelate, b) C=O in chelate.

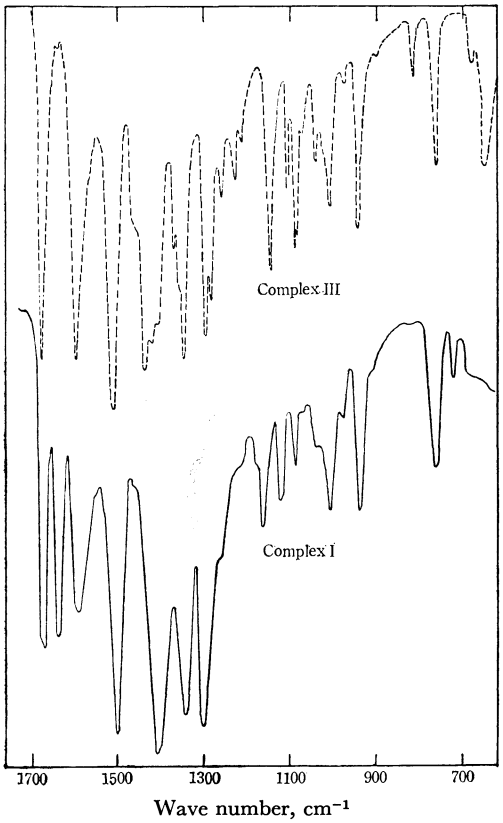

Fig. 10. IR spectra of complex I and complex III.

those at 1689 and 1660 cm^{-1} for complex II, and frequencies at 1605 and 1520 cm^{-1} corresponding to those at 1598 and 1522 cm^{-1} for NiAE. This peculiar feature of the spectrum is found over the 1700—300 cm^{-1} region (Figs. 10 and 11). In addition, complex I still shows the π_{C-H} band at 778 cm^{-1}. Cu complex III also has a rather similar spectrum to complex I (Figs. 10 and 12), indicating similar structures.

This fact may make one suspect complex I to be a mixed crystal of NiAE and complex II. However, from a chloroform solution of NiAE and complex II in a 1 : 1 molar ratio, a red crystal of complex I was not successfully crystallized. Complex I is shown to be monomeric in toluene by a molecular weight measurement. Thus, without presuming a structure such as shown in Fig. 2, the spectral features of complex I, described above, could hardly be understood.

Presuming this structure (Fig. 2), the bands at 1685 and 1520 cm^{-1} for complex I can be assigned to the stretching vibrations of the non-coordinated and coordinated C=O groups, respectively. The band at 1652 cm^{-1} is likely to be due to the stretching vibration of the imine type C=N groups in the complex (Fig. 2).

A chloroform solution of complex I has two peaks at 1685 and 1652 cm^{-1}, as in KBr. These two peaks do not change in intensity ratio with concentration of the complex. This fact indicates that the band at 1652 cm^{-1} can not be attributed to the associated C=O group, although the association of C=O is known to gives rise to a subsidiary peak at a lower wave number than the main peak of the unassociated C=O, as is seen in the case of a 1,2-diketonemonoxime such as diacetylmonoxime.[10] The value, 1652 cm^{-1}, is thought to be considerably higher than that of the C=N stretching frequency of the oxime group in a complex. Usually the frequency of the oxime type C=N stretching in a conjugate system is observed[10] at about 1630 cm^{-1}, and it can be expected to absorb below 1600 cm^{-1} in an unsaturated metal chelate such as shown in Fig. 2, judging from infrared evidence on metal - dimethylglyoximato complexes.[11] The band at 1652 cm^{-1} for complex

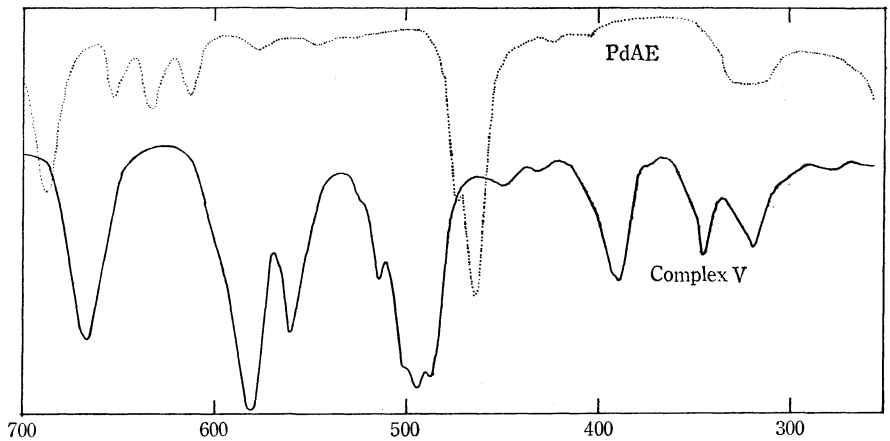

Fig. 13. IR spectra of PdAE and complex V.

I has therefore been ascribed to the stretching of the imine type C=N in the five-membered metal-chelate ring (Fig. 2).

In the spectra of Cu complexes III and IV (Figs. 7 and 10, and Table 2), the band due to the imine type C=N is not observed in the corresponding wave number region. In these cases, the absorption of C=O probably obscures the C=N absorption, whose frequency would be shifted toward higher wave numbers than for the other complexes.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 163—168 (1969)

Kinetics of Multidentate Ligand Substitution Reactions. IV. Substitution Reactions of BT with Cobalt(II) and Nickel(II) Chelates of 1,2-Diaminocyclohexanetetraacetic Acid and Diethylenetriaminepentaacetic Acid

Mutsuo KODAMA, Chifumi SASAKI and Katsumi MIYAMOTO

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received June 8, 1968)

The substitution reactions of Eriochrom Black T (BT) with cobalt(II) and nickel(II) chelates of 1,2-diaminocyclohexanetetraacetic acid (CyDTA) and of diethylenetriaminepentaacetic acid (DTPA) were studied spectrophotometrically. The reactions of BT with CyDTA and DTPA chelates of these metal(II) ions were found to have the same reaction mechanism as the reactions with EDTA chelates did, but to be considerably slower than the latter reactions. On the basis of a comparison of the observed rate constants with those calculated on the basis of the proposed reaction mechanism (glycinate intermediate), the steric effect due to the cyclohexane ring in the CyDTA or $-CH_2-CH_2-N(CH_2-COO^-)-CH_2-CH_2-N(CH_2-COO^-)_2$ group in DTPA on the reaction rate was discussed in a quantitative manner. The effect due to the former group was estimated to be smaller than that due to the latter group.

We have studied a series of substitution reactions of Eriochrom Black T (BT) with cobalt(II)- and nickel(II)-polyaminocarboxylate chelates.[1-3] The reactions were invariably first-order in BT and first-order in the metal(II)-polyaminocarboxylate chelate.

In the present paper, the kinetics of the substitution reactions of BT with cobalt(II) and nickel(II) chelates of 1,2-diaminocyclohexanetetraacetic acid (CyDTA) and of diethylenetriaminepentaacetic acid (DTPA) are dealt with spectrophotometrically. On the basis of a comparison of the rate constants of the substitution reactions of CyDTA and DTPA chelates with those of EDTA chelates, the steric effect of the cyclohexane ring in the CyDTA or $-CH_2-CH_2-N(CH_2-COO^-)-CH_2-CH_2-N(CH_2-COO^-)_2$ group in DTPA on the rate of the substitution reaction is discussed.

Experimental

Reagents. The preparation and the standardization of solutions of cobalt(II) and nickel(II) perchlorates have been described in previous papers.[1,2] Reagent-grade CyDTA and DTPA recrystallized from water were used. The concentration of the CyDTA solution was standardized against the standard lead(II) solution by a volumetric titration, using BT as an indicator.[4] The concentration of DTPA was determined by the same procedure as has been proposed for the EDTA titration of copper(II).[5] The other reagents were of a guaranteed reagent grade and were used without further purification.

Apparatus and Procedure. The apparatus and the experimental procedure were the same as have been described in a previous paper.[1] In this study, all the measurements were conducted on solutions with an ionic strength of 0.30 ($NaClO_4$), and no buffer reagent was used, because free CyDTA and DTPA have enough buffer capacity to maintain the pH values of solutions constant in the pH range from 9.50 to 10.50 in which the present study was conducted.

Results and Discussion

All the exchange reactions were studied in solutions with pH values from 9.50 to 10.50 containing large excesses of complexed and uncomplexed CyDTA or DTPA. Therefore, the exchange reactions can be treated as pseudo first-odrer reactions. In the cases of the reactions of BT with cobalt(II) and nickel(II) chelates of EDTA,[1,2] EDTA-OH[3] and GEDTA,[3] the apparent rate constants of the pseudo first-order reactions could be determined from the slope of the linear relation

between $\log(A_D/(A-A_{MD}))$ and time, t. Here, A_D, A, and A_{MD} have the same meanings as were used previously.[2,3] However, in the reactions of BT with CyDTA and DTPA chelates of these metal(II) ions, the concentration of uncomplexed BT at equilibrium, $[BT]_e$, can not be neglected as compared with that at t, $[BT]_f$, and the initial concentration of BT, $[BT]_0$, because the stability constants of cobalt(II) and nickel(II) chelates of CyDTA and DTPA are comparable to those of corresponding BT chelates. Therefore, in the present substitution reactions, the apparent rate constants should be estimated from the slope of the linear relation between $\log([A_D-A_e]/[A-A_e])$ and t. Here A_e denotes the absorbance at equilibrium and $[A_D-A_e]/[A-A_e]$ can be equated with $([BT]_0-[BT]_e)/([BT]_f-[BT]_e)$ in the Eq. (7) in Ref. (1). Hence, the slope of the linear relation of $\log([A_D-A_e]/[A-A_e])$ and t can be exactly expressed as:

$$\text{slope} = k^+\left(1+\frac{[MZ^{2-m}]}{K_h[Z]_f}\right)\cdot\frac{1}{2.303} \qquad (1)$$

where k^+ corresponds to the apparent rate constant of the pseudo first-order reaction (2),[1-3] where $[MZ^{2-m}]$ and $[Z]_f$ are the concentrations of complexed and uncomplexed CyDTA or DTPA, and where $K_h=K_{MD}\cdot(\alpha_H)_Z/K_{MZ}\cdot(\alpha_H)_{BT}=k^+\cdot(Z)_f/k^-\cdot[MZ^{2-m}]$.

$$\begin{cases} HD^{2-} \\ \uparrow\downarrow \\ D^{3-} \end{cases} \overset{k^+}{\underset{k^-}{\rightleftarrows}} MD^- \qquad (2)$$

The other notation definitions used here are as follows. HD^{2-} and D^{3-} mean doubly- and completely-deprotonated BT anions respectively, and MD^-, the metal(II)-BT chelate. K_{MD} and K_{MZ} are stability constants of the metal(II)-BT chelate and the -CyDTA or -DTPA chelate respectively. $(\alpha_H)_Z$ and $(\alpha_H)_{BT}$ have the same meanings as previously.[3]

k^+ in Eq. (1) can also be determined from the apparent initial rate of the reaction, $(-\Delta[BT]/\Delta t)_0$, with the aid of Eq. (3):

$$\left(-\frac{\Delta[BT]}{\Delta t}\right)_0 = k^+\left(1+\frac{[MZ^{2-m}]}{K_h[Z]_f}\right)[BT]_0 \qquad (3)$$

where $(-\Delta[BT]/\Delta t)_0$ and $[BT]_0$ can be equated with $(-\Delta A/\Delta t\cdot\varepsilon_{BT})_0$ and A_D/ε_{BT},[2] respectively.

In the case of the reactions of BT with nickel(II) chelates of CyDTA and DTPA, the absorbance decreases almost linearly with the time. Therefore, the apparent rate constant was determined from the initial slope of the absorbance *versus* time curve. On the other hand, in the case of the reactions of BT with cobalt(II) chelates, the apparent rate constant, k^+, was calculated from the slope of the linear relation between $\log[(A_D-A_e)/(A-A_e)]$ and t. The A_e*1 value used in the log-

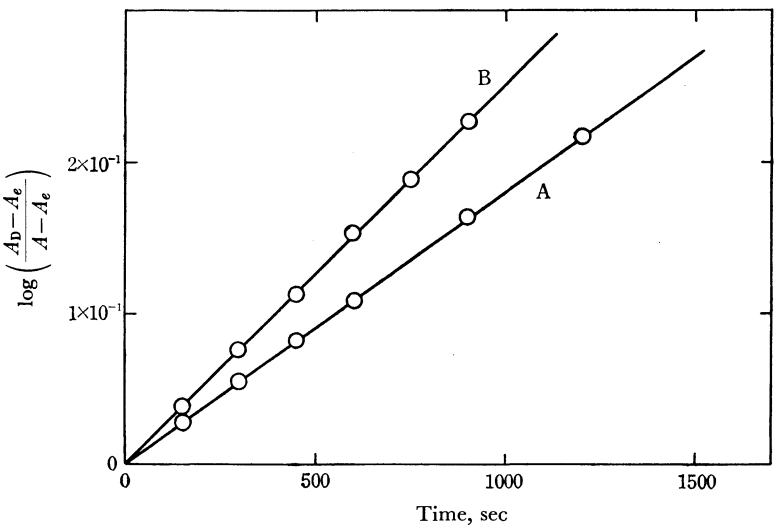

Fig. 1. The plot of $\log[(A_D-A_e)/(A-A_e)]$ against t.
$\mu = 0.30$, $\lambda = 630$ mμ
Initial concentration of BT = 2.5×10^{-5} M
A: Concentration of cobalt(II)-CyDTA chelate = 10.0 mM
Concentration of uncomplexes CyDTA = 10.0 mM
pH = 9.95
B: Concentration of cobalt(II)-DTPA chelate = 7.13 mM
Concetration of uncomplexed DTPA = 10.0 mM
pH = 10.40

*1 The calculated A_e value agreed well with the observed value.

plot examination was calculated by using K_{MD} and K_{MZ} values. Typical linear relations between $\log[(A_D-A_e)/(A-A_e)]$ and t are shown in Fig. 1.

In all the substitution reactions of BT studied in this paper, we found the following experimental facts with regard to the apparent rate constant, k^+:

i) In solutions of a given pH, a given concentration of the metal(II) chelate of CyDTA or DTPA, and a given initial concentration of BT, k^+ is independent of the concentration of the uncomplexed chelating agent (CyDTA or DTPA) (Table 1).

Table 1. Dependence of k^+ on the concentration of uncomplexed chelating agent
$\mu = 0.30$, $\lambda = 630$ mμ

i) Cobalt(II)-CyDTA system		
Concentration of CyDTA, mM	k^+ M^{-1} sec^{-1}	
5.0	1.79×10^{-4}	pH = 9.95
10.0	1.78×10^{-4}	$[BT]_0 = 2.5\times10^{-5}$ M
15.0	1.78×10^{-4}	$[CoZ^{2-}] = 10.0$ mM
ii) Nickel(II)-CyDTA system		
Concentration of CyDTA, mM	k^+ M^{-1} sec^{-1}	
5.0	7.12×10^{-5}	pH = 10.00
10.0	7.13×10^{-5}	$[BT]_0 = 2.5\times10^{-5}$ M
30.0	7.14×10^{-5}	$[NiZ^{2-}] = 8.25_5$ mM
iii) Cobalt(II)-DTPA system		
Concentration of DTPA, mM	k^+ M^{-1} sec^{-1}	
5.0	2.00×10^{-4}	pH = 10.30
10.0	2.00×10^{-4}	$[BT]_0 = 2.5\times10^{-5}$ M
20.0	2.02×10^{-4}	$[CoZ^{3-}] = 7.13$ mM
iv) Nickel(II)-DTPA system		
Concentration of DTPA, mM	k^+ M^{-1} sec^{-1}	
5.0	1.27×10^{-5}	pH = 10.12
10.0	1.30×10^{-5}	$[BT]_0 = 2.0\times10^{-5}$ M
20.0	1.29×10^{-5}	$[NiZ^{3-}] = 10.45$ mM

ii) In solutions of a given pH and given concentrations of uncomplexed and complexed chelating agents CyDTA or DTPA, k^+ is independent of the initial concentration of BT, $[BT]_0$ (Table 2).

iii) In solutions of a given pH, a given concentration of a chelating agent (CyDTA or DTPA), and a given initial concentration of BT, k^+ is exactly proportional to the concentration of the metal(II) chelate of CyDTA or DTPA (Table 3).

iv) As is shown by the curves in Fig. 2, in solutions of a given initial concentration of BT and given concentrations of a free chelating agent (CyDTA or DTPA) and its metal(II) chelate, k^+ is a linear function of the reciprocal of the concentration of hydrogen ions and is given by:

Table 2. Dependence of k^+ on the initial concentration of BT
$\mu = 0.30$, $\lambda = 630$ mμ

i) Cobalt(II)-CyDTA system		
Concentration of BT, M	k^+ M^{-1} sec^{-1}	
1.0×10^{-5}	1.76×10^{-4}	pH = 9.95

3.75×10^{-5}	7.15×10^{-5}	$[Z]_f = 10.0$ mM
iii) Cobalt(II)-DTPA system		
Concentration of BT, M	k^+ M^{-1} sec^{-1}	
2.5×10^{-5}	2.36×10^{-4}	pH = 10.39
3.5×10^{-5}	2.32×10^{-4}	$[CoZ^{3-}] = 7.13$ mM
5.0×10^{-5}	2.40×10^{-4}	$[Z]_f = 10.0$ mM
iv) Nickel(II)-DTPA system		
Concentration of BT, M	k^+ M^{-1} sec^{-1}	
2.0×10^{-5}	1.32×10^{-5}	pH = 10.12
4.0×10^{-5}	1.30×10^{-5}	$[NiZ^{3-}] = 10.45$ mM
6.0×10^{-5}	1.33×10^{-5}	$[Z]_f = 10.0$ mM

$$k^+ = k_\alpha + k_\beta/[H^+] \quad (4)$$

As in the case of the exchange reactions of BT with cobalt(II) and nickel(II) chelates of EDTA,[1,2] these facts clearly indicate that the present reactions also proceed through the following two simultaneous reaction paths:

$$\text{i)}\quad HD^{2-} + MZ^{2-m} \underset{k_1^-}{\overset{k_1^+}{\rightleftarrows}} MD^- + HZ^{1-m}$$

$$\text{ii)}\quad HD^{2-} \overset{\text{rapid}}{\rightleftarrows} H^+ + D^{3-}$$

$$D^{3-} + MZ^{2-m} \underset{k_2^-}{\overset{k_2^+}{\rightleftarrows}} MD^- + Z^{m-}$$

rate-determining step

where HZ^{1-m} and Z^{m-} mean incompletely- and completely-deprotonated CyDTA or DTPA anions, and MZ^{2-m} the metal(II) chelate of CyDTA or DTPA.

Consequently, k^+ should be given by:

$$k^+ = (k_1^+ + k_2^+ \cdot k_2/[H^+])[MZ^{2-m}] \quad (5)$$

where k_2 refers to the dissociation constant of the second phenolic group of BT.[6]

From the slopes of the linear relation between $k^+/[MZ^{2-m}]$ and $1/[H^+]$ and the intercepts, the k_1^+ and k_2^+ values were estimated. These values

* These values are less accurate.

with a copper(II)-CyDTA chelate, the cyclohexane ring in CyDTA does not change the general reaction mechanism (glycinate intermediate mechanism), but does affect the exchange rate considerably. Generally, if two exchange reactions involving metal chelate have the same reaction mechanism, the reaction with the stable chelate will be slower than that with a less stable chelate, because the stable reactant, as compared with the less stable one, often corresponds to the less stable transition state, and hence, to the diminished reactivity.

In the exchange reactions of BT with cobalt(II) and nickel(II) chelates of CyDTA have the same reaction mechanism as those with EDTA chelates (glycinate mechanism), we can estimate the relative rate constants as was done previously.[3] Hence, from a comparison of the observed rate constant with the theoretically-calculated one, we can probably estimate the steric effect of the cyclohexane ring on the exchange reaction of BT in a quantitative manner. Relative rate constants calculated with the aid of Eq. (5) of Ref. 3 by using the numerical values listed in Table 5 are given in

TABLE 5. STABILITY CONSTANTS*

1) EDTA chelates
$K_{CoY} = 10^{15.71}$[10], $K_{NiY} = 10^{18.02}$[10]
$K_{CuY} = 10^{18.70}$[15]**
2) CyDTA chelates
$K_{CoZ} = 10^{18.32}$[10], $K_{NiZ} = 10^{18.80}$[11]
$K_{CuZ} = 10^{21.96}$[16]**
3) DTPA chelates[12]
$K_{CoZ} = 10^{18.17}$, $K_{NiZ} = 10^{19.38}$
4) α-Amino-α-methylpropionate[13]
$K_{CoX} = 10^{3.51}$, $K_{NiX} = 10^{4.56}$
$K_{CuX} = 10^{8.26}$**
5) 1-Aminocyclohexanecarboxylate[14]
$K_{CoX} = 10^{3.87}$, $K_{NiX} = 10^{4.90}$
$K_{CuX} = 10^{8.59}$**

* These values are calculated from the relevant stability constants in solutions of ionic strength 0.10 and the activity constants of the ions calculated by means of Davies equation.[17]
** Values at $\mu = 0.10$.

Table 6, together with the observed values.*2 Here, the calculation was carried out by choosing both α-amino-α-methylpropionate and 1-aminocyclohexanecarboxylate as models; the statistical factor and the stabilization due to the electrostatic attraction[8] were also taken into consideration. The results clearly show that in the reactions of BT with both cobalt(II) and nickel(II) chelates of CyDTA, the steric effect due to the cyclohexane ring is surprisingly small. A small steric effect of the cyclohexane ring on the oxidation reaction of the iron(II)-CyDTA chelate by dissolved oxygen was also mentioned by Kurimura *et al.*[9] The

above explanation, that the diminished activity of CyDTA chelates observed can be ascribed to the steric hindrance due to the cyclohexane ring, is also supported by the fact that ratio between the k^+ ratio calculated and that observed, R, was almost constant, irrespective of the metal(II) ion (Table 6).

In the case of the reaction of copper(II) chelates with polyamine, the ratio between the observed rate constant and the one theoretically predicted on the basis of the glycinate intermediate was calculated to be about 1 : 50. The smaller steric effect of the cyclohexane ring on the reaction of BT can probably ascribed to the planar configuration of the BT anion in the mixed ligand intermediate.

In a similar way, by using the numerical values in Table 5, the relative rate constants for the reactions of BT with DTPA chelates were calculated on the basis of the glycinate mechanism; they are compared with the observed values in Table 6. The results may indicate that the $-CH_2-CH_2-N(CH_2-COO^-)-CH_2-CH_2-N(CH_2-COO^-)_2$ group of DTPA has a larger steric effect on the exchange reactions of BT than does the cyclohexane ring in CyDTA.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 168—177 (1969)

Metal Complexes with Amino Acid Amides. II. Preparations and Circular Dichroism Behavior of the Copper(II) Complexes

Takashi KOMORITA, Jinsai HIDAKA and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka

(Received June 10, 1968)

Planar bis-type complexes of copper(II) with L-leucine-, L-valine-, L-phenylalanine- and L-proline-amidate ligands have been newly synthesized and characterized mainly spectroscopically together with the known complexes with glycine- and L-alanine-amidates. The geometrical structures of these $[Cu(N)_4]$-type complexes have been tentatively determined. The blue colored complexes, $Cu(glycine\text{-}amide)_2SO_4$ and its L-alanine amide analogue, have been isolated, too. The circular dichroism spectra of the complexes containing optically active ligands have been measured in various solvents and discussed in comparison with the available data for square planar d^8-complexes or for amino acidato complexes. A number of interesting relations were observed among the circular dichroism spectra of the copper(II) and the square planar d^8 complexes with optically active bidentate ligands.

It has been well known that most of copper(II) complexes have tetragonally distorted octahedral structures.[1] Since the degree of the distortion, which has been called tetragonality, seems to vary continuously up to the limit of a square planar structure,[2] there are some difficulties in studying the structures of copper(II) complexes in solution. Jørgensen has marked out the tetragonalities of various copper(II) complexes in solution by comparing their electronic spectra with those of the corresponding nickel(II) complexes which have essentially octahedral symmetry.[2] This method, however, cannot be applied to a group of the copper(II) complexes, to which diamagnetic square planar, not octahedral, nickel(II) complexes correspond.

Yasui *et al.*[3] have ascertained experimentally the possibility to resolve the ligand field bands of copper(II) complexes in solution into their split components by means of the circular dichroism (CD), and Wellman *et al.*[4] have suggested a relationship between the signs (and the magnitudes also) of the Cotton effects and the chelate ring conformations of the amino acidato copper(II) complexes. This suggestion has been somewhat modified by Martin *et al.*[5] In these circumstances, it is thought to be desirable to apply a CD study to the copper(II) complexes to which diamagnetic planar nickel(II) complexes correspond.

In the first paper of this series,[6] the two types of nickel(II) complexes, Ni(α-amino-acid-amide)$_2$-$SO_4 \cdot xH_2O$ and Ni(α-amino-acid-amidate)$_2 \cdot xH_2O$, have been reported. The copper(II) complexes (R-type)[7] corresponding to the latter type of nickel(II) complexes with glycine-, L-alanine- or D,L-leucine-amidate have been already prepared,[8] but none of them has been studied concerning their electronic spectra.

In the present paper, we report the preparations of some new complexes of R-type with L-leucine-, L-valine-, L-phenylalanine- or L-proline-amidate and of another new type (B-type)[7] of the copper-(II) complexes, $Cu(glyaH)_2SO_4$ and Cu(L-alaaH)$_2$-$SO_4 \cdot H_2O$,[9] which corresponds to the former type of nickel(II) complexes cited above. The electronic absorption and CD spectral data of all these complexes obtained are discussed in relation to their structures.

Experimental

Preparation. *1) Amino Acid Amides.*[9] The following six amino acid amides used as ligands were derived from the corresponding amino acids by the similar method as described in literature.[10]

glyaH (from chloroform); mp 67.5—68.5°C.

L-alaaH (from chloroform); mp 83—84°C; $[\alpha]_{589} = +11.1°$.

L-leuaH (from benzene); mp 103—104°C; $[\alpha]_{589} = +7.3°$.

Found: N, 21.60%. Calcd for $C_6H_{14}N_2O$: N, 21.52%.

L-valaH (from benzene); mp 87—89°C; $[\alpha]_{589} = +12.2°$.

Found: N, 24.27%. Calcd for $C_5H_{12}N_2O$: N, 24.33%.

L-phalaaH (from benzene); mp 95—96°C; $[\alpha]_{589} = +17.8°$.

Found: N, 17.14%. Calcd for $C_9H_{12}N_2O$: N, 17.06%.

L-proaH (from benzene); mp 106.5—107.5°C; $[\alpha]_{589} = -79.3°$.

Found: N, 24.56%. Calcd for $C_5H_{10}N_2O$: N, 24.54%.

The measurements of the specific rotations were made for the aqueous solutions ($c = 10$) at room temperature (19—21°C). All the melting points were uncorrected.

2) Bis(amino-acid-amidato)copper(II) Complexes. The general preparation procedure of these complexes are as follows. Eleven milliformoles (mF) of amino acid amide was dissolved in 5—30 m*l* of water and the solution was added to the solution containing 1.0 g (5 mF) of copper(II) acetate monohydrate in 15 m*l* of water. Then 5—10 m*l* of the aqueous solution containing 0.40 g (10 mF) of sodium hydroxide was added dropwise to the bluish violet solution with mechanical stirring. The desired complex was crystallized out from the resulted reddish violet solution[11] (filtered if necessary) by an appropriate procedure of the followings, namely, vacuum concentration below 35°C, addition of ethanol (or methanol) and then of ether, or the combined procedure.

Freshly prepared copper(II) hydroxide was also good starting material, which could be used in place of copper(II) acetate monohydrate and sodium hydroxide in the above procedure. All the complexes in this category were obtained in good yields, and only one kind of crystals[12] could be isolated for each of the ligands. Recrystallization was made by one of the following procedures: (I) ethanol and then ether were added to the concentrated aqueous solution, (II) ether was added to the concentrated methanolic solution, (III) the aqueous solution was concentrated *in vacuo*, or (IV) the methanolic solution was concentrated by evaporating in air.

Bis(glycine-amidato)copper(II) Monohydrate: $Cu(glya)_2 \cdot H_2O$. Recrystallized by I.

Found: C, 21.31; H, 5.44; N, 24.65%. Calcd for $C_4H_{12}N_4O_3Cu$: C, 21.08; H, 5.31; N, 24.61%.

Bis(L-alanine-amidato)copper(II): Cu(L-alaa)$_2$. Recrystallized by I.

Found: C, 30.22; H, 5.37; N, 23.63%. Calcd for $C_6H_{14}N_4O_2Cu$: C, 30.31; H, 5.94; N, 23.57%.

Bis(L-leucine-amidato)copper(II): Cu(L-leua)$_2$. Recrystallized by IV and dried over calcium chloride; pink needles; soluble in methanol and moderately soluble in water and ethanol. The raw product was the mixture of the two forms of crystals, the needle and the plate: infrared spectra in NaCl region, however, showed no difference between them.

Found: C, 44.40; H, 8.07; N, 17.19%. Calcd for $C_{12}H_{26}N_4O_2Cu$: C, 44.78; H, 8.14; N, 17.40%.

Bis(L-valine-amidato)copper(II) Dihydrate: Cu(L-vala)$_2 \cdot 2H_2O$. Recrystallized by (IV) and dried in air; violet plates; soluble in water, methanol and ethanol to give reddish violet solutions.

Found: C, 36.48; H, 7.58; N, 16.79%. Calcd for $C_{10}H_{26}N_4O_4Cu$: C, 36.41; H, 7.94; N, 16.98%.

Bis(L-phenylalanine-amidato)copper(II) Dihydrate and Anhydrate: Cu(L-phalaa)$_2 \cdot 2H_2O$ and Cu(L-phalaa)$_2$.

Dihydrate: recrystallized by (III) and dried in air; reddish violet plates; soluble in water, methanol and ethanol.

Found: C, 50.69; H, 6.12; N, 13.13%. Calcd for $C_{18}H_{26}N_4O_4Cu$: C, 50.75; H, 6.15; N, 13.15%.

Anhydrate: derived from the dihydrate by drying *in vacuo* over phosphorus pentoxide overnight; pink solid.

Found: C, 55.15; H, 5.74; N, 14.26%. Calcd for

7) R-type: red colored Cu(II) complex, B-type: blue colored Cu(II) complex.

8) P. Bergell and T. Brugsch, *Z. physiol. Chem.*, **67**, 97 (1910); M. M. Rising and P. S. Yang, *J. Biol. Chem.*, **99**, 755 (1933).

9) The following abbreviations are used for ligands: glyaH=glycine amide, alaaH=alanine amide, leuaH=leucine amide, valaH=valine amide, phalaaH=phenylalanine amide, proaH=proline amide, glyH=glycine, alaH=alanine, leuH=leucine, valH=valine, proH=proline, hyproH=hydroxyproline, piaH=α-picoline amide, $biuH_2$=biuret and $glyglyH_2$=glycylglycine.

10) P. S. Yang and M. M. Rising, *J. Am. Chem. Soc.*, **53**, 3183 (1931); G. Hillmann, *Z. Naturforsch.*, **1**, 682 (1946).

11) When L-leuaH or L-phalaaH was used as the ligand, the desired crystals separated out at this stage.

12) As for the L-leucine amidato complex, see below.

$C_{18}H_{22}N_4O_2Cu$: C, 55.44; H, 5.69; N, 14.37%.

Bis(L-proline-amidato)copper(II) Dihydrate: Cu(L-proa)$_2$·2H$_2$O. Recrystallized by (II) and dried *in vacuo* over calcium chloride; pink needles; soluble in water, methanol, ethanol and *N*,*N*-dimethylformamide, and slightly soluble in pyridine.

Found: C, 36.85; H, 6.83; N, 17.10%. Calcd for $C_{10}H_{22}N_4O_4Cu$: C, 36.86; H, 6.81; N, 17.19%.

3) Bis(amino-acid-amide)copper(II) Sulfates. Bis(glycine-amide)copper(II) Sulfate: Cu(glyaH)$_2$SO$_4$. Copper(II) sulfate pentahydrate (0.84 g) and 0.50 g of glycine amide were dissolved in 5 m*l* of water. After stirring the solution for several min, the blue crystals were obtained by adding a small amount of methanol to the blue solution. This complex was recrystallized from the aqueous solution by adding a small amount of methanol, washed with methanol and then with ether, and dried *in vacuo* over phosphorus pentoxide overnight; very soluble in water but insoluble in methanol and ethanol.

Found: C, 15.34; H, 4.00; N, 17.51%. Calcd for $C_4H_{12}N_4O_6SCu$: C, 15.61; H, 3.93; N, 18.21%.

Bis(L-alanine-amide)copper(II) Sulfate Monohydrate: Cu(L-alaaH)$_2$SO$_4$·H$_2$O. Preparation and purification of this complex was carried out in the same way as given for the corresponding complex with glycine amide. The yield was almost quantitative. Shiny blue plates; very soluble in water but insoluble in methanol and ethanol.

Found: C, 20.70; H, 4.77; N, 15.11; H$_2$O, 4.94%. Calcd for $C_6H_{18}N_4O_7SCu$: C, 20.37; H, 5.13; N, 15.83; H$_2$O, 5.09%.

The water of crystallization was analyzed by the weight loss under aspirator pressure at 60°C.

4) Glycinato(glycine-amidato)copper(II) Monohydrate: Cu(gly)(glya)·H$_2$O. Bis(glycine-amidato)copper(II) in aqueous solution undergoes stepwise hydrolysis of the ligands during several weeks at room temperature and finally changes into bis(glycinato)copper(II). Glycinato-(glycine-amidato)copper(II) monohydrate, an intermediate of the hydrolysis, separated out when a concentrated aqueous solution of Cu(glya)$_2$·H$_2$O was allowed to stand on a warm water bath for several hours. This intermediate complex was also obtained easily by concentrating rapidly the aqueous solution containing Cu(gly)$_2$·H$_2$O and Cu(glya)$_2$·H$_2$O (1 : 1). Recrystallization was made by adding methanol to the aqueous solution of the complex. Shiny violet plates; soluble in water, slightly soluble in methanol and insoluble in ethanol.

Found: C, 21.16; H, 4.90; N, 18.34%. Calcd for $C_4H_{11}N_3O_4Cu$: C, 21.01; H, 4.85; N, 18.37%.

5) *Bis(amino-acid-amide)copper(II) Sulfate Solutions.* The five and ten milliformoles per liter aqueous solutions of bis(amino-acid-amide)copper(II) sulfate were prepared for the absorption and CD spectral measurements, respectively: one (or two) milliliter(s) of the 100 mF $CuSO_4$ and 0.2 mF (or 0.4 mF) of the ligand (L-leuaH, L-valaH, L-phalaaH or L-proaH) were dissolved in water, and the total volume was adjusted to 20 m*l*. Copper (II) sulfate pentahydrate used was a Special Grade reagent produced by Wako Pure Chemical Industries, Ltd.

Measurements. The absorption, diffuse reflectance and CD measurements were made by a Beckman DU spectrophotometer, a Hitachi EPU-2A spectrophotometer and a Roussel-Jouan dichrographe, respectively, at room temperature. Ethanol and methanol used for these measurements as the solvents were dehydrated by refluxing with corresponding magnesium alkoxide and distilled. The solvent *N*,*N*-dimethylformamide was a commercial Spectro Grade one produced by Dojindo & Co., Ltd. No significant change of the spectra was found during every measurement.

Results and Discussion

Amino Acid Amides. In Table 1, the electronic absorption data of the B-type complexes are summarized with some referable data. It has been concluded in the former paper[6] that α-amino acid amide chelates through an amide oxygen and an amino nitrogen to a central metal ion in the bis-(amino-acid-amide)nickel(II) complexes. The N-O coordination is also inferred for the corresponding B-type copper(II) complexes, $Cu(glyaH)_2SO_4$ and $Cu(L\text{-}alaaH)_2SO_4\cdot H_2O$, in the solutions and in the solid states from their electronic spectra. Another support for the common type of coordination between the bis(amino-acid-amide)-copper(II) and -nickel(II) complexes is furnished from the infrared (IR) spectra. The IR spectra of all these complexes show two very strong bands, which are very specific to this type of complexes, in each of their 6μ regions.[15] It may be possible to suggest that the $[Cu(L\text{-amino-acid-amide})_2(OH_2)_2]^{2+}$ ion is only the probable species in the solution.[16]

The electronic absorption and reflectance data of the R-type complexes are summarized with some references in Table 2. The $K_2[Cu(biu)_2]\cdot 4H_2O$[18] and $K_2Cu(glygly)_2\cdot 6H_2O$[20] have been known to have planar $Cu(N)_4$ structure. From the comparison with the electronic spectral data in the solutions and in the solid states and the referable data, it may be concluded that the amino acid amidato ligands in the R-type complexes have the N-N coordination through an amino nitrogen and an amidato nitrogen. The same conclusion has been previously applied for the corresponding nickel(II) and palladium(II) complexes.[6]

2) Solvation and Geometrical Isomerism. The following factors may be inferred to influence considerably the ligand field bands of both the B- and R-type complexes: (a) interaction between copper(II) ion and solvent molecules along with the normal of the coordination square, (b) geometrical isomerism of the complexes, and (c) electronic and structural characteristics of the ligands.

With respect to the five R-type complexes with the L-amino acid amidato ligands, the absorption maxima (ν_{max}) are distributed within the ranges 19000—19500 in water and 19900—20100 cm^{-1} in ethanol respectively, as shown in Table 2. This fact reveals that the effect of the factor (c) is relatively small among the five L-amino acid amidates. The solvent dependence of ν_{max}, derived from the factor (a), is clearly larger than the effect (c). For instance, the difference of ν_{max}'s between the aqueous and the dimethylformamide solutions of $Cu(L\text{-}proa)_2$ is 1200 cm^{-1} and the one between the aqueous and the chloroform solutions of $Cu(pia)_2$, 1800 cm^{-1} (Table 2). The difference of ν_{max}'s between *trans*- and *cis*-$Cu(gly)_2\cdot H_2O$, derived from the factor (b), is only 600 cm^{-1} (Table 1). However, the factor (b) may probably be intensified in the R-type complexes because of the increased covalency in the coordination square.

Now, the ν_{max}'s of the ligand field bands of the R-type complexes shift to lower wave number's and the apparent band widths (δ) decrease in the following order of solvents (or condition): solid→dimethylformamide→ethanol→methanol→water, except for $Cu(L\text{-}vala)_2\cdot 2H_2O$ and $Cu(L\text{-}phalaa)_2\cdot 2H_2O$ in the solid states (Table 2). This spectral behavior including the case of $Cu(L\text{-}phalaa)_2\cdot 2H_2O$ may be understood on the basis of the donor properties of the solvent molecules, that is, of the factor (a). The ν_{max} value of $Cu(L\text{-}vala)_2\cdot 2H_2O$ in only the solid state exceedingly deviates from the above sequence and, in fact, is lower by as much as 1000 cm^{-1} than the value in the aqueous solution (Table 2). This cannot be explained by the coordination of water, that is, factor (a), and the factor (b) should be taken into account. Judging from the facts that most of the copper(II) bis-chelated complexes, the structures of which have been known, have trans ones[16] and that the ν_{max} of *cis*-$Cu(gly)_2\cdot H_2O$ is lower than that of the corresponding trans complex (Table 1), the geometrical structure of $Cu(L\text{-}vala)_2\cdot 2H_2O$ may be tentatively assigned to cis in the solid state and, on the contrary, to trans in the aqueous and the alcoholic solutions. Another support to the trans structure in solution may be furnished by the following observation: when a methanolic solution containing the crystals was rapidly concentrated *in vacuo*, a small amount of red crystals, which may presumably be trans, was found mixed together with the ordinary violet crystals. The other five complexes of R-type may be tentatively considered to have trans structures

both in the solid states and in the solutions from the above discussion.

The ν_{max}'s of $Cu(glya)_2 \cdot H_2O$ both in the solid state and in the solutions considerably shift to lower wave number's than those in the corresponding conditions of the other R-type complexes, which are considered to be trans (Table 2). Similar shift is also observed for $Cu(glyaH)_2SO_4$ compared with the other B-type complexes (Table 1). These behavior should be attributed to the combined effect of the factors (a) and (c).

More quantitative informations about the factor (a) in these complexes may be supplied by comparing their ν_{max}'s with those of the corresponding nickel(II) complexes.[6,15] As far as the B-type is concerned, the tetragonality ratios can be obtained by Jørgensen's definition[2] as shown in Table 3; these values are very close to the value, 1.60, for bis(glycinato)copper(II). Now, concerning the R-type, the corresponding nickel(II) complexes are diamagnetic square planar ones. Neverthless we applied the ratio, ν_{Cu}/ν_{Ni}, also to these complexes, using the ligand field ν_{max}'s of the planar nickel(II) complexes (Table 3). Bis(biuretato)-cuprate(II) and -nickolate(II) may be regarded as "true" square planar complexes, since each the complex reveals the same ν_{max} value between in the aqueous solution and in the solid state. Therefore, the value, 0.91, may be considered to suggest that the nickel(II) complex has larger tetragonality than the copper(II) complex. (This value could be expected to be larger than 1 for a certain tetragonality, or for a certain octahedral field splitting (Δ), after taking the interelectronic repulsion of d^8-configuration into account.) This consideration is compatible with the theory that one electron

and none, respectively, is accommodated in the σ-antibonding (x^2-y^2)-orbital in the ground state of the copper(II) and nickel(II) complexes. The R-type copper(II) complexes seem to be more extensively influenced by the factor (a) than the corresponding nickel(II) complexes. However, it may be reasonable to regard the R-type complexes, including even the glycine amidato one, as "square planar" complexes since their ν_{Cu}/ν_{Ni} values distribute continuously in a rather narrow range, 0.81—0.88, and the minimum is comparable with 0.82 for the bis(picoline-amidato) complexes in "chloroform." It may be worthwhile to note that the ν_{max}'s of the B-type complexes shift to

higher wave number's and the δ's increase with changing the condition from the solid states to the aqueous solutions, in contrast with those of the R-type.

3) CD of the Complexes. In general, the negative CD components are dominant in the ligand field band region of the B- and the R-type complexes with the L-optically active ligands (Table 4 and Figs. 1—3); the CD behavior of Cu(L-proaH)$_2$SO$_4$ in the aqueous solution is only the exception. It has been reported[3] that bis(L-α-amino-acidato)copper(II) complexes also exhibit ligand field CD bands, the negative components of which are dominant, too, except for those of the L-prolinato and the L-hydroxyprolinato complexes. Wellman *et al.*[4] have explained the negative Cotton effect in this region on the assumption of the puckered conformation of amino acidato chelate ring as of ethylenediamine one (Fig. 4c).

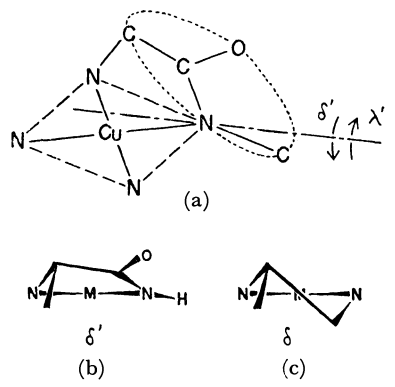

Fig. 4. Conformations of chelate rings of (a) glygly$^-$ in $K_2Cu(glygly)_2\cdot 6H_2O$ (Arrows: the C–CO–N–C plane is inclined), (b) L-amino acid amidate and (c) (+)-propylenediamine.

Informations about the conformation of α-amino acidato or α-amino acid amidato ligand will be obtained from the X-ray analytical data for *cis*-

$Cu(gly)_2 \cdot H_2O$[21] or $K_2Cu(glygly)_2 \cdot 6H_2O$.[20] In the latter complex, both the $Cu(N)_4$ square and the C–CO–N–C moiety of the ligand have good planarity respectively, but these two planes are inclined to each other, intersecting along the axis which passes through the amidato nitrogen and nearly bisects the Cu–N(amino) bond as shown in Fig. 4a. The conformation of the glycinato chelate ring in *cis*-$Cu(gly)_2 \cdot H_2O$ seems to be very similar to that of the glycylglycinato chelate ring mentioned above, and is considerably different, especially around the coordinated oxygen, from that assumed by Wellman *et al.* as shown in Figs. 4b and 4c. Now, two oppositely twisted forms are denoted by δ' and λ' as shown in Fig. 4a. Of course, it is not necessary for the explanation of the optical activity of complexes with optically active ligands to take into account any puckering of chelate rings.[22] However, dissymmetric electron distributions around the coordinated atoms, if present, could be the main origins of ligand field Cotton effects as in the treatment of the simple molecular orbital theory.[23] Since the equatorial conformations of the C_α-substituents are considered to be the preferred forms from the observations in propylenediamine chelate rings (Fig. 4c), δ'-conformation may be assigned to the predominant form in both the chelate rings of L-α-amino acid-amide and -amidate in the complexes in solution as shown in Fig. 4b.

The ligand field CD bands of the bis(L-α-amino-acid-amidato) complexes of copper(II), nickel(II) and palladium(II) have predominantly negative sign over-all.[6,15] Such a CD spectral correspondence between d^8 spin paired and d^9 complexes of bis-chelated square planar structure may be also inferred from Liehr's theory.[23] However, a possibility of direct interactions between the C_α-substituents and the metal chromophores as a source of the Cotton effects cannot be ruled out. Recently, it has been reported[24] that the mono- and bis-type complexes of palladium(II), platinum(II) and gold(III) with (−)-propylenediamine and (−)-cyclohexanediamine reveal predominantly positive CD components in the ligand field band regions, where the ligands coordinate in λ-conformations. Thus, L-α-amino acidate, L-α-amino acid-amide and -amidate and (+)-propylenediamine as bidentate ligands seem to generally give the same sign to the Cotton effects caused by a particular d–d transition.

Now, whether (α) the puckerings of chelate rings or (β) the dispositions of C_α-substituents are the main origins of the Cotton effects? As shown in Figs. 5a and 5b, Wellman *et al.*[4] and Martin

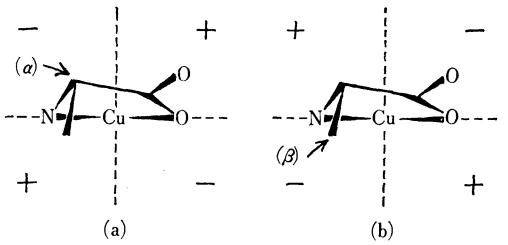

Fig. 5. (a) Wellman's and (b) Martin's spaces applied to the proposed model of L-amino acidato complex.
The signs are given to the front octants or sectors which contain the ligand. (α) and (β) indicate the supposed origins for the negative Cotton effects.

et al.[5] have applied oppositely signed spaces to L-α-amino acidato copper(II) complexes and explained their Cotton effects. This contradiction is resulted from the fact that they have simply regarded the different origin, (α) or (β), as the main source of the Cotton effects. Both explanations could revive even when each of the two spaces is applied to the models of the complexes with δ'- or λ'-conformations. It is to be noted, however, that the visible absorption band of any of these copper(II) complexes would possibly be the overlap of four components, that different origins would possibly be effective to different CD components, and consequently that such an alternately (+)- and (−)-signed space as the octant one for the n–π^* transition of ketones should be determined for a particular transition rather than for a particular geometry of the molecules. Indeed, it is in question whether the main positive CD components of the copper(II) complexes with L-prolinate, L-proline-amide and -amidate, and L-histidine amide[15] and the main negative ones of the corresponding copper-(II) complexes with the other simple L-α-amino acid derivatives (like L-alanine derivatives) might be assigned to the same d–d transition or not. More investigations seem to be necessary to answer these questions.

The CD spectra of the R-type complexes are considerably influenced by changing the solvent. However, a general pattern of the curve for each the complex is well retained as may be seen in Figs. 2 and 3. This fact may point out that the change of solvent gives rise to little changes in the equilibria between the chelate ring conformations (inclined to δ') and between the geometrical isomers (presumably inclined to trans).

21) H. C. Freeman, M. R. Snow, I. Nitta and K. Tomita, *ibid.*, **17**, 1463 (1964).

22) The puckering found in the glycinato or the glycylglycinato chelate ring is somewhat smaller in size, and might be more flexible, than that of ethylenediamine chelate ring. CD data for the copper(II) complexes with some tetradentate ligands seem to reveal such a somewhat ambiguous nature of the conformations of the ligands; Ref. 5, and M. Parris and A. E. Hodges, *J. Am. Chem. Soc.*, **90**, 1909 (1968).

23) A. D. Liehr, *J. Phys. Chem.*, **68**, 3629 (1964).

24) H. Ito, J. Fujita and K. Saito, This Bulletin, **40**, 2584 (1967).

It is interesting to examine the relative order of the dissymmetric field strengths of the bidentate ligands in the complexes. The following orders are easily derived from the CD or the rotatory dispersion data:

L-alaaH$<$L-leuaH$<$L-valaH

for the B-type,

L-alaa$^-<$L-leua$^-<$L-vala$^-$

for the R-type, and

L-ala$^-<$L-leu$^-<$L-val$^-$

for the amino acidato copper(II) complexes.[3,4] From these orders, the relative dissymmetric field strengths seem to be determined by the mother amino acids. In addition the relative order, L-amino acidate$\sim$L-amino acid amide$<$L-amino acid amidate, is apparently observed for a series of the bis-type copper(II) complexes[3,4] with the ligands derived from a particular amino acid, and considered to originate from the different covalency in the coordination squares or from the different degree of the puckerings of the chelate rings.

4) CD Behavior of the Complexes with L-Proline-Amide, -Amidate and L-Prolinate. As shown in Fig. 1, the CD spectrum of Cu(L-proaH)$_2$SO$_4$ in the aqueous solution is markedly different from those of the corresponding species with the other four L-amino acid amides. It has been known[3] that Cu(L-pro)$_2$ and Cu(L-hypro)$_2$ reveal more distinct ligand field CD bands than those of the corresponding species with the other simple L-amino acidates. The CD spectrum of Cu(L-proaH)$_2$SO$_4$ is very similar to that of Cu(L-pro)$_2$ in aqueous solution. Cu(L-proa)$_2$ also reveals a very specific CD behavior, although its negative CD components are dominant as those of the other R-type complexes (Figs. 2 and 3). Similar behavior has been observed in Ni(L-proa)$_2$, too.[15] A common nature in the CD behavior among Cu(L-proa)$_2$, Cu(L-proaH)$_2^{2+}$ and Cu(L-pro)$_2$ could be derived from the fact that a positive component of the former complex in the dimethylformamide solution is so conspicuous as those of the latter two in the aqueous solutions (Fig. 3).

From these considerations, it may be possible to say that the dissymmetric fields produced near the Cu(N)$_4$ chromophores are specified by the coordinated L-proline-amide, -amidate and L-prolinate.[25] The specificity might potentially be derived from the following origins: i) asymmetry of the pyrrolidine nitrogen;[3] ii) direct interaction between the chromophore and one of the two hydrogen atoms attached to the fifth carbon atom of the pyrrolidine ring, which projects over the coordination square as shown in Fig. 6; and iii)

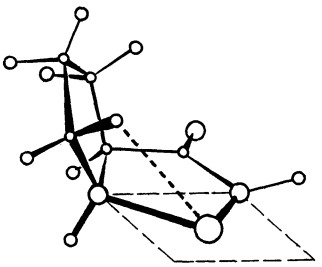

Fig. 6

fixed form of the chelate ring, which might be forced by the pyrrolidine ring together with the C–CO–O, C–CN–O or C–CO–N moiety. It may be said that the data for bis(*N*-methyl-L-prolinato)copper(II) show the effectiveness of i) or ii).[5] On the other hand, the CD behavior of Cu(L-proa)$_2$, which is considerably different from that of Cu(L-pro)$_2$ or Cu(L-proaH)$_2^{2+}$, may be considered to show the effectiveness of iii). As a consequence of iii), asymmetry of the electron distribution near the amidato nitrogen (or the coordinated carboxyl oxygen) should be noted. This effect cannot be simply ruled out, since the charge transfer band of Cu(L-proa)$_2$ (presumably, metal-amidate in nature), for example, occurs at rather lower wave number's (Fig. 3).

5) The Near-Ultraviolet Absorption Band of R-type Complex. All the R-type complexes

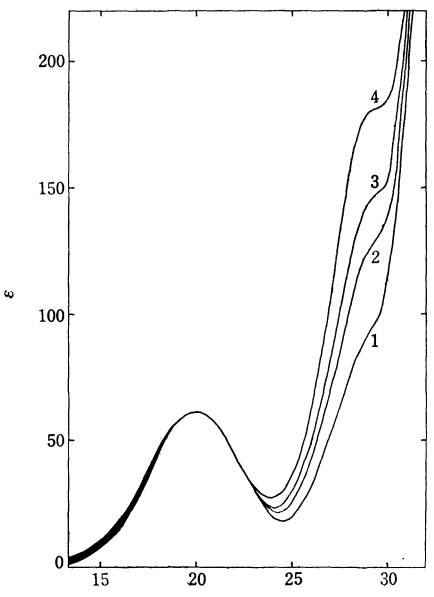

Fig. 7. Absorption spectrum of Cu(L-alaa)$_2$ in ethanol.
1: 8.4 mF 2: 2.8 mF 3: 1.4 mF 4: 0.7 mF

25) On the basis of this specification and the presumed trans structure of Cu(L-proa)$_2$, it seems to be rather unreasonable to assign cis structure to Cu(L-pro)$_2$ in water; R. D. Gillard, *Inorg. Chim. Acta Rev.*, **1967**, 69.

exhibit another kind of absorption bands (Band II) at about 29000 cm^{-1} in the alcoholic solutions (Table 2 and Figs. 2 and 7). (Band II seems to be almost embedded in the charge transfer band in the spectrum of the L-proline amidato complex.) These bands disappear in aqueous solution or in solid state, though the disappearance is not perfect in aqueous solution. As may be seen in Fig. 7, the Band II of Cu(L-alaa)$_2$ in the ethanolic solution is accompanied with the increase of intensity when the solution is diluted. Similar concentration dependence of Band II was observed for every R-type complex in the methanolic and aqueous solutions. The Band II cannot be, therefore, considered to originate in any association among the complexes. Cotton effects of the R-type complexes are negligible at about 29000 cm^{-1} as shown in Figs. 2 and 3. As a consequence, if Band II might be assigned to one of d–d transitions, it should be to $(z^2)\rightarrow(x^2-y^2)$ transition from a theoretical consideration.[6] Band II of Cu(L-alaa)$_2$ was, however, inclined to shift to lower wave number's when the solvent was changed from water to methanol, and to ethanol.[15] This behavior of the Band II cannot be consistently interpreted on the basis of the band assignment. It may be concluded, therefore, that Band II cannot be assigned to any d–d transition.

The authors wish to thank Mr. Masao Sekizaki of Nagoya University, Mr. Yasuo Nakao and Dr. Takaji Yasui of Osaka University for supplying their absorption data, which were very useful in the inspections of our data. The authors also wish to thank Mr. Norio Koine of Ehime University, whose suggestions were very helpful in preparing some of the ligands, and Dr. Seiko Komorita of Osaka University for valuable comments.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 177—180 (1969)

The Alkaline Hydrolysis of Halophenols*1

Shigeru OAE, Naomichi FURUKAWA and Takashi ASARI

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka

(Received April 12, 1968)

The mechanism of both the alkaline fusion and the alkaline hydrolysis of halophenols has been investigated. In case of alkaline fusion, the product identified is resorcinol, the formation of which has been found to proceed through the benzyne intermediate. While the alkaline hydrolysis of halophenols gives different ratio of dihydroxyphenol and phenol by changing the mole ratio of halophenol to alkali, by utilizing ^{14}C tracer experiment and substituted halophenol, the mechanism of the formation of both products has been revealed to proceed by way of the direct substitution of halide with hydroxide. Copper compounds are found to be effective in this reaction.

The aqueous alkaline hydrolysis of halobenzenes has been shown to proceed by way of benzyne mechanism, though it gives somewhat different results depending upon the reaction temperatures, halogen species and the concentration of alkali applied.[1] Whereas, the alkaline hydrolysis of halobenzenes activated with nitro or sulfone group, has been demonstrated to proceed through an S_N2 type substitution on carbon atom bearing halogen atom.[2] Although the alkaline hydrolysis of halophenols apparently gives several unusual products, for example, phenol which cannot possibly be obtained through either the benzyne process or the concerted S_N2 route alone, this process is patented as one of promising methods of preparing dihydroxyphenols, such as catechol.[3] However, the mechanism of this reaction has been completely unkown. Apparently the reaction carried out with molten alkali at high temperature proceeds through a different route from that performed in aqueous alkali at a moderately low temperature. Usually, the treatment of molten alkali on halophenols gives rearranged dihydroxy-benzene, for

example, resorcinol from *o*-chlorophenol, suggesting that the reaction proceeds through the route involving benzyne formation. While, the aqueous alkali gives unrearranged products, catechol from *o*-chlorophenol and the reaction can be interpreted as an aromatic S_N2 types subtitution, no clear cut mechanism has yet been suggested. The remarkable feature of this aqueous alkaline hydrolysis of the halophenol is that the reaction is catalyzed by heavy metals or metal ions such as copper. This paper will describe the preliminary results of our investigation and the implication on the mechanism of these reactions.

Results and Discussion

The Alkaline Fusion of Halophenols. The reactions of halophenols with molten alkali have been known to give phenol, dihydroxybenzene and unidentified products.[4] Usually, the yield of dihydroxybenzene by alkaline fusion is not as good as that of the aqueous alkaline hydrolysis of halophenols; usually yielding the product in less than 20%. Meoreover dihydroxybenzene obtained by this alkaline fusion is rearranged products; for example, the only isolable product in the alkaline fusion of both *o*- and *p*-chlorophenols is resorcinol.

One possibility is that resorcinol may be formed by way of the incipient formation of benzyne as an intermediate (Eq. (1)). Another conceivable mechanism may be the route involving the prior formation of phenol, followed by the oxidation of it to resorcinol (Eq. (2)), since it has been known that resorcinol can be prepared from the reaction of phenol with molten alkali.[5] The mechanisms may be illustrated as shown below.

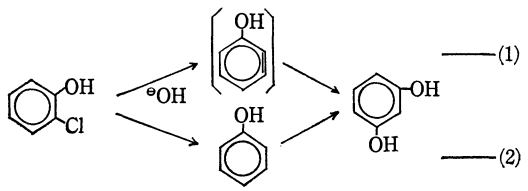

Fig. 1. Mechanism of the formation of resorcinol.

The choice between these two possible mechanisms can be readily made by means of ^{14}C tracer experiment using ^{14}C labeled phenol. Providing that the reaction would proceed through "benzyne route," resorcinol obtained would not have any ^{14}C activity, whereas if phenol would be the initial intermediate the original ^{14}C activity should be found in resorcinol. Accordingly *o*- or *p*-chlorophenol was mixed with the ^{14}C labeled phenol and the mixture was reacted with molten alkali for several hours and the resulting resorcinol was converted to its tribromide. From the activity measurement of the tribromoresorcinol obtained from the reaction was found to contain no ^{14}C activity. The ^{14}C tracer experiment reveals very clearly that "benzyne route" is considered to be the only plausible pathway for the alkaline fusion of halophenols.[2]

The Aqueous Alkaline Hydrolysis of Halophenols. The reaction is usually carried out in a copper tube which is placed in an autoclave kept at a temperature between 160—200°C for 4—6 hr. The reaction can also be carried out in a glass sealed tube containing a catalytic amount of a copper compound. After the reaction, the products were isolated as usual and identified by comparing their bp, mp, infrared spectra and gas-chromatographic behaviors with those of the authentic samples. The reaction has following few characteristic features. a) The main products are phenol and catechol but the product ratio changes by the change of the mole ratio of alkali to halophenol. The products and their yields are shown in Table 1. b) The relative ease of the halide - displacement in the halophenols appears to be in the following sequence $o \rangle p \gg m$. Although there is no detailed kinetic study available, *o*-chlorophenol appears to undergo the most facile reaction to afford the products under the reaction conditions. Under the same conditions, however, only a small amount of phenol can be detected through gas chromatography from the reaction of *p*-chlorophenol. *m*-Chlorophenol apparently do not react and can be recovered almost quantitatively. c) The reaction has been known to be facilitated by copper catalysts. Moreover, under the reaction condition of hydrolysis in which the formation of phenol is favorable, the reaction is catalyzed only by copper and no other metal exhibit any effective catalytic activity. Among the following metal compounds tested for catalyst only copper compounds showed noticeable activities;

Table 1. The yields of phenol and catechol

NaOH / Cl, OH — Mole ratio	Products		
	Phenol (%)	Catechol (%)	Residue (%)
1	56	trace	44
1.5	25	15	50
2	trace	58	42

Cu^0(Cu-tube), Cu^{1+}(Cu_2O), Cu^{2+}(CuO, $CuSO_4$); Ag^{+1}($AgNO_3$); Hg^{2+}($Hg(CN)_2$, $HgCl_2$); Fe^{2+} ($FeCl_2$), Fe^{3+}($FeCl_3$); Ni^{2+}($Ni(NO_3)_2$). Based on these observations one can construct the mechanisms of the hydrolysis reactions, especially of the formations of the two major products, *i.e.*,

4) H. E. Fierz-David and G. Stamm, *Helv. Chim. Acta*, **25**, 256 (1942).

5) J. F. Bunnett and R. E. Zahler, *Chem. Revs.*, **46**, 304 (1950).

phenol and catechol.

Mechanism of the Formation of Phenol. The yield of phenol was found to reach the maximum value when the reaction was carried out with 1:1 mole ratio of alkali to *o*-halophenol. The probable mechanism can be illustrated in Fig. 2.

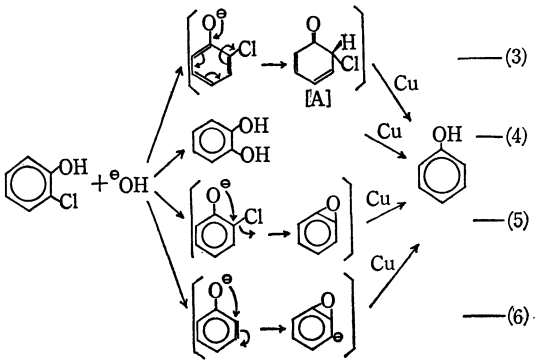

Fig. 2. Mechanism of the formation of phenol.

The Eq. (3), tentatively called as direct chlorine substitution, involves the initial formation of phenoxy anion followed by prototropy to form an intermediate (A) from which chlorine is abstracted by copper metal to produce phenol. Equation (4) demands that phenol is formed by way of the initial formation of catechol. This mechanism is also possible because catechol is always formed even when the concentration of alkali is relatively low. Equations (5) and (6) involve the incipient formation of the intermediate epoxy compound from which phenol is to be formed. The choice between the mechanisms, namely Eq. (3) and those (5) or (6) can be achieved by using a suitably substituted halophenol such as 2-bromo-4-methylphenol. Equation (3) will require cresol obtained from 2-bromo-4-methyl phenol to be *p*-cresol alone, whereas according to Eq. (5) or (6) both *m*- and *p*-cresols should be formed. When 2-bromo-4-methylphenol was actually subjected to the hydrolysis with an equal mole of alkali, phenolic products obtained in 35% yield contained phenol (5%) and *p*-cresol (30%), but no *m*-cresol. Since *m*- and *p*-cresols have characteristically different IR absorption spectra, their absence is readily confirmed. Consequently Eqs. (5) and (6), *i. e.*, the oxygen migration mechanism, can now be ruled out. Since no phenol formation was observed when catechol was treated under the same condition that applied to the hydrolysis, Eq. (4) can also be eliminated. Thus the phenol formation is considered to follow Eq. (3).

Now a question arises why *o*-halophenol is especially so reactive, since a similar mechainsm can be applied to *p*-halophenol which does not produce phenol so readily. The reason is probably illustrated by a complex formation between copper and *o*-halophenol at the transition state especially with *o*-hydroxyl group and halogen as shown below and the formation of such a complex may decrease the activation energy of the reaction. Moreover, the change of product ratio by changing the amount of alkali to *o*-halophenol can be explained by such a complex formation. Namely, when an excess amount of alkali to halophenol is used, hydroxide anion attacks preferentially the *o*-carbon atom bearing halogen atom, since carbon-halogen bond is probably loosen by such a complex formation, thus catechol is produced as a main product. While, in case of an equimolar amount of alkali, only halogen is abstracted by copper giving rise to phenol.

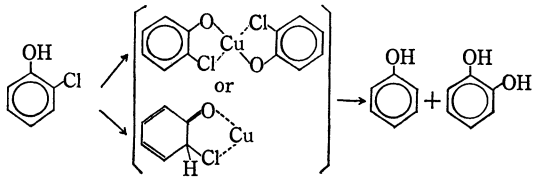

Fig. 3. Complex formation.

The Mechanism of the Formation of Catechol. The formation of catechol is also interesting in connection with the phenol formation, because copper catalyst is also necessary in this reaction.

Among several mechanisms conceivable, the one involving the initial benzyne formation followed by the epoxy intermediate formation can be ruled out from the afore-mentioned experiment using 2-bromo-4-methylphenol. While it is considered that the formation of catechol may be achieved by the direct nucleophilic substitution of chlorine by hydroxy group, there is another possibility, namely, the process involving the initial formation of phenol which is then oxidized to catechol in the presence of copper catalyst. The two mechanisms are depicted as shown below.

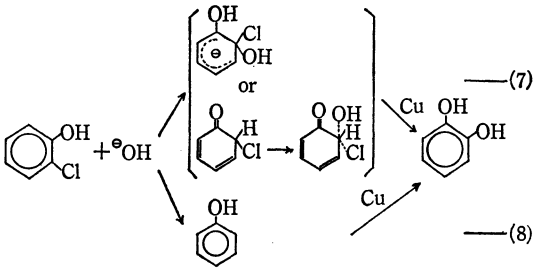

Fig. 4. The mechanism of the formation of catechol.

In order to make a choice between the two mechanisms, we have carried out a ^{14}C-tracer experiment using a small amount of ^{14}C-labeled phenol mixed with *o*-chlorophenol. If the reaction proceeds according to Eq. (8), the catechol obtained should have ^{14}C activity, whereas according to the

Eq. (7), catechol should have no ^{14}C activity. Our result revealed that less than 2% of the original ^{14}C activity was found in catechol. Moreover, from this experiment we have found that more than 95% of phenol was recovered unchanged. Therefore Eq. (8) can be eliminated. Thus the formation of resorcinol is considered to proceed through the direct nucleophilic substitution of chlorine by hydroxide, probably assisted by copper ion which acts as a Lewis acid.

Experimental

The Alkaline Fusion of *p*-Chlorophenol Mixed with ^{14}C Labeled Phenol. The experimental condition was same as that Fierz-David described. A mixture of sodium *p*-chlorophenolate (3 g) and sodium phenolate-^{14}C (0.5 g) was reacted in a nickel muffle heated in a silicone oil bath, the temperature of which was kept at 300°C for 5 hr. After the reaction, the vessel was cooled and the products were dissolved into a large amount of water To this aqueous solution was added bromine water. Solid precipitates were collected and dried. The yellow colored solid was extracted with *n*-hexane. The hexane solution was cooled with ice-bath. Crystalline precipitates were collected, recrystallized from *n*-hexane and then sublimed. Colorless needles were obtained, mp 104—106°C, and ^{14}C activities were measured by a liquid scintillation counter. The specific activities were: phenol, 9.2×10^4 dpm/mmol (as tribromide); resorcinol, 2.2×10^3 dpm/mmol (as tribromide).

The Aqueous Alkaline Hydrolysis of *o*-Halophenols. A typical example of the experiments are the following. *o*-Chlorophenol (commercially available, 1 g) was dissolved in 3 m*l* of water containing 0.4 g of sodium hydroxide and the whole mixture was placed in an ampoule. To this solution was added 1% of cuprous oxide. The ampoule was sealed and heated in an autoclave at a temperature between 180—200°C for 4 hr. After cooling the ampoule was broken and the mixture was filtered to remove polymeric substance and the catalyst. The filtrate was acidified with concentrated hydrochloric acid and extracted with ether. The ether extract was dried over magnesium sulfate. After ether was removed, the residue was distilled and product (0.4 g, bp 160—180°C) was obtained. Among the products identified were phenol and a small amount of recovered *o*-chlorophenol. The yield of phenol was 56%.

Similar experiments were carried out by changing catalyst, alkali concentration and halophenols. The results are summarized in Table 1.

2-Bromo-4-methylphenol. The titled phenol was prepared from *p*-cresol and bromine in carbon tetrachloride solution in 66% yield. The alkaline hydrolysis of 2-bromo-4-methylphenol (3 g) gave 1.1 g of liquid products (bp 160—200°C) among which were isolated *ca.* 1.5% of phenol and *p*-cresol (33%). The identification of these phenols was made by IR and gas chromatography.

The Reaction of Catechol with Alkali. A mixture of 1.0 g and 10 m*l* of 10% aqueous sodium hydroxide was sealed into a glass ampoule and was heated in an autoclave for 3 hr at 200°C. The isolation of products were performed similarly. Catechol was recovered in 50% yield but no phenol was isolated.

The Alkaline Hydrolysis of *o*-Chlorophenol and Phenol-1-^{14}C. *o*-Chlorophenol (2.62 g) and phenol-1-^{14}C (0.5 g) prepared from aniline-1-^{14}C was treated as similarly. After the reaction, catechol obtained was purified by sublimation, yield 58%, mp 104—106°C. ^{14}C activity was measured by a liquid scintillation counter. Sp. activity: Phenol-1-^{14}C (as tribromide), 1.12×10^5 dpm/mmol. Catechol, 1.36×10^3 dpm/mmol. Thus, 1.2% of the original ^{14}C activity was incorporated in catechol.

Recovery Test of Phenol-1-^{14}C. Phenol-1-^{14}C (0.41 g) was dissolved into 1 m*l* of 20% aqueous sodium hydroxide solution containing Cu_2O. The mixture was heated for 4 hr at 170—180°C. After the reaction was added 430 mg of the authentic phenol. The phenol recovered was converted to the tribromide and ^{14}C activities of the initial and the recovered tribromophenol were measured by a liquid scintillation counter. The ^{14}C activities are 4.19×10^4 dpm/mmol for the initial phenol and 2.02×10^4 dpm/mmol for the recovered phenol.

Thus, by means of the isotope dilution method, 95% of phenol was found to be recovered under the alkaline hydrolysis.

Studies of Acenaphthene Derivatives. XVI.[1] The Wittig Reaction with Acenaphthenequinone*1

Otohiko TSUGE, Masashi TASHIRO and Ichiro SHINKAI

Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka

(Received April 25, 1968)

The reactions of acenaphthenequinone (III) with several Wittig reagents have been studied. When III was reacted with equimolar amounts of benzylidenetriphenylphosphoranes (IV) at room temperature, the corresponding benzylideneacenaphthenones (V) were obtained in fairly good yields, but the reactions of benzil and phenanthrenequinone with IV did not take place under similar conditions. The reaction of III with two equivalents of IV under severe conditions afforded only V, and no dibenzylidene compounds were obtained. The reaction of III with resonance-stabilized phosphoranes, such as acetonylidene-, phenacylidene- and *p*-chlorophenacylidenephosphoranes, afforded the expected α,β-unsaturated ketones. In the reaction with ethoxycarbonylmethylenephosphorane, two stereo-isomeric ethoxycarbonylmethyleneacenaphthenones, which were also obtained from the reaction with diethyl ethoxycarbonylmethylphosphonate, were formed. The structures of the isomers were confirmed on the basis of NMR, UV, and mass spectral studies. Methylenephosphorane reacted with III to give methyleneacenaphthenone in a poor yield. On the contrary, the reaction with ethylidenephosphorane gave bis-2,2′-methyleneacenaphthenone, which was also formed by the reaction of acenaphthenone with glyoxal, in a good yield.

It has been shown that the 1,2-bismethylene derivative was obtained in an 85% yield by the Wittig reaction of benzocyclobutenedione with two equivalents of ethoxycarbonylmethylenetriphenylphosphorane at room temperature.[2] On the other hand, Parrick[3] has reported that some α-diketones, such as benzil (I) and phenanthrenequinone (II), will not react with two equivalents of a phosphorane. In both cases, the corresponding monobenzylidene compounds were obtained in low yields from the reaction with benzylidenetriphenylphosphorane at only one carbonyl group.

In earlier papers[4–7] in this series we have found that acenaphthenequinone (III) behaved differently from I and II in some reactions, and it was deduced that one carbonyl group in III is more reactive than that in I or II.

We have little information about the Wittig reaction with III. Accordingly, it will be interesting to investigate whether or not III will be able to react with two equivalents of a phosphorane, and to compare the reactivities of I, II, and III against the phosphorane.

When III was treated with benzylidenetriphenylphosphoranes (IV) in ethanol at room temperature, the corresponding benzylideneacenaphthenones (V) were obtained in fairly good yields. Under similar conditions, however, the reactions of I and II with IV did not take place. Even when two equivalents of IV were used under severe reaction conditions,

* CH: cyclohexane

IV reacted with only one carbonyl group in III to form V, and no 1,2-dibenzylideneacenaphthenes were obtained.

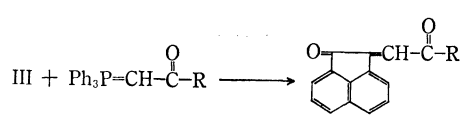
The yields in the reaction of III with equimolar amounts of IV at room temperature for 15 min (method i), and the physical properties and elemental analyses of V are summarized in Table 1.

The compounds V were proved, by admixed melting points and by a study of their infrared spectra as well as by elemental analyses, to be identical with the authentic samples prepared by the reaction of acenaphthenone with the respective benzaldehydes in the presence of sodium hydroxide (method ii). The yields in the method ii are also shown in Table 1.

In general, it is accepted that the reactivity of the phosphorane IV decreases with an increase in the electron-withdrawing power of the substituent. The data in Table 1 show that the phosphoranes with electron-withdrawing substituents, such as the *p*-chloro (IVd), *p*-nitro (IVe), and 3,4-dichloro compounds (IVf), are more reactive than *p*-methyl- (IVb) and *p*-methoxybenzylidene-phosphorane (IVc).

On the basis of the above observations and other data,[4-7] it may be expected that one carbonyl group in III will be able to react with a resonance-stabilized phosphorane.

The reaction of III with acetonylidene- (VIa), phenacylidene- (VIb), *p*-chlorophenacylidene- (VIc), and ethoxycarbonylmethylenetriphenyl-



VI VII

a: R = CH_3, b: R = C_6H_5, c: R = *p*-ClC_6H_4, d: R = OC_2H_5

phosphorane (VId) at room temperature in ethanol gave the corresponding α,β-unsaturated ketones (VII).

The yields, physical properties, and results of the elemental analyses of VII are listed in Table 2.

In the reaction of III with VId, two compounds, VIId and VIId′, were obtained. The reaction of III with diethyl ethoxycarbonylmethylphosphonate in dioxane in the presence of sodium hydride also gave VIId and VIId′ in 60 and 4% yields respectively.

On the basis of the NMR, mass spectra, and elemental analyses, it is deduced that compounds VIId and VIId′ are cis-trans isomers of ethoxycarbonylmethyleneacenaphthenone. The NMR spectra of VIId and VIId′ are illustrated in Fig. 1.

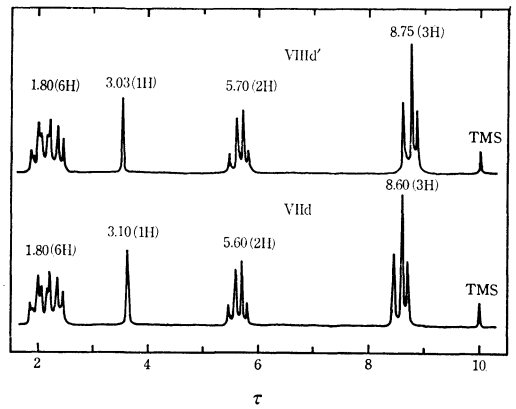


Fig. 1. NMR spectra of VIId and VIId′ in $CDCl_3$.

The vinyl-proton signal of VIId and the methylene-protons signal of VIId′ appeared at a field higher than those of VIId′ and VIId respectively. The differences can be understood in terms of the deshielding effect of the carbonyl group in the ethoxycarbonyl moiety and in terms of the shielding effect of the acenaphthene ring in the respective case.

The ultraviolet spectrum of VIId exhibited an absorption compatible with conjugation, but that of VIId′ indicated the presumable absence of conjugation. In addition, the fragmentation of VIId on electron impact was almost the same as that of VIId′. The mass spectrum of VIId is shown in Fig. 2.

The above observations can be explained by the structures for VIId and VIId′ which are shown in Fig. 3. The moiety, O=C–C=CHCOEt, in VIId is in a coplanar conformation, while that in VIId′ is not.

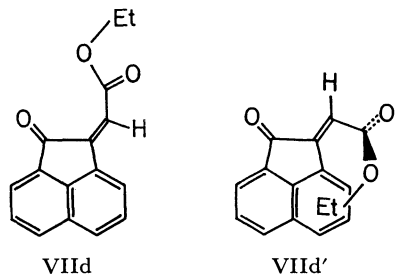

Fig. 3

The reaction of III with alkylidenetriphenylphosphoranes (VIII) was also investigated.

When III was allowed to react with methylenephosphorane (VIIIa) at room temperature, the expected methyleneacenaphthenone (IX) was obtained in a poor yield, accompanied by a larger amount of resinous material.

The reaction with ethylidenephosphorane (VIIIb) gave yellow needles (X), whose infrared spectrum was similar to that of 2,2′-diacenaphthylidene-

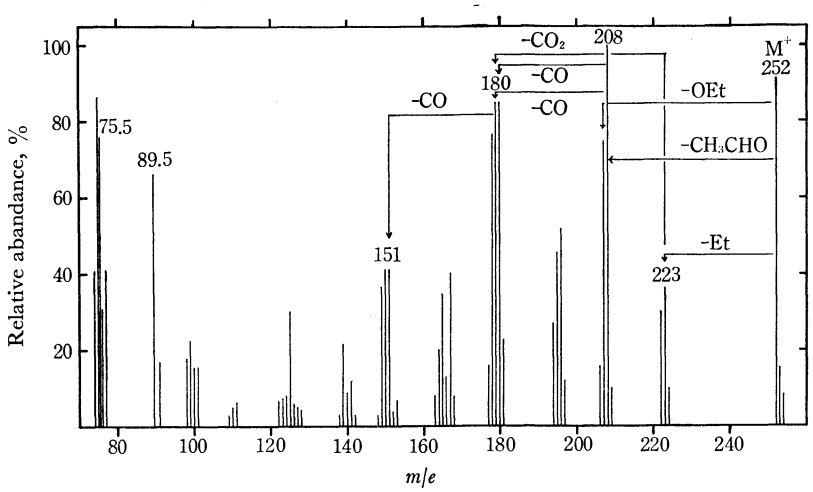

Fig. 2. Mass spectrum of VIId.

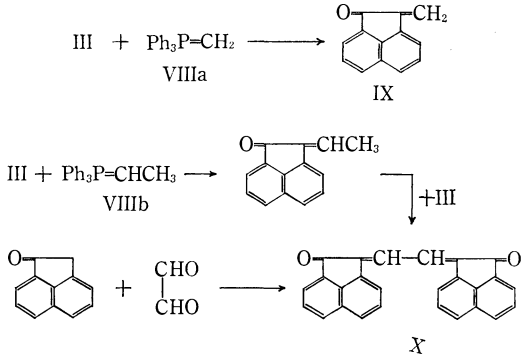
1,1′-dione,[8] in an 86% yield. The compound X was proved, by an admixed-melting-point determination and by a study of its infrared spectrum as well as by elemental analysis, to be identical with bis-2,2′-methyleneacenaphthenone prepared by the reaction of acenaphthenone with glyoxal in the presence of sodium hydroxide.

It may be considered that the compound X is formed by the condensation of the expected ethylideneacenaphthenone with a second quinone molecule.



On the other hand, the reaction with propylidenephosphorane (VIIIc) gave a resinous material exclusively under various conditions.

Experimental

All the melting points are uncorrected. The infrared spectra were measured in KBr disks, and the NMR spectra were determined at 60 Mc with a Japan Electron Optics JNM-3H-60 NMR spectrometer, using TMS as the internal reference. The mass spectra were obtained on a Hitachi RMU-6D instrument using a heated inlet, an ionization energy of 70 eV, an inlet temperature of 200—250°C, and a source temperature of 250°C. The elemental analyses were done by Mr. Eiji Shiozaki in our laboratory.

General Method for the Reaction of Acenaphthenequinone (III) with the Benzylidenetriphenylphosphorane (IV). A solution of 0.005 mol of the benzyltriphenylphosphonium bromide in 25 m*l* of absolute ethanol was treated with 5.5 m*l* of a 0.001 M solution of sodium ethoxide in ethanol with continuous stirring under an atmosphere of nitrogen; the orange color of the phosphorane (IV) appeared immediately.

After the solution had been stirred for 10 min, 0.9 g (0.005 mol) of III[9] was added, and then the mixture was stirred at room temperature for 15 min. During this time the mixture turned into a clear solution, except in the reactions with IVd and IVe. The reaction mixture was quenched with 20—30 m*l* of water and then heated on a steam-bath, affording yellow crystals. The crystals were collected by filtration; recrystallization gave the benzylideneacenaphthenone (V).

The yields, physical properties, and results of the elemental analyses of V are listed in Table 1.

General Method for the Reaction of Acenaphthenone with the Benzaldehyde. To a solution of 1.68 g (0.01 mol) of acenaphthenone[10] and 0.012 mol of the benzaldehyde, in 25 m*l* of ethanol, 3 m*l* of a 1 N aqueous solution of sodium hydroxide was added, drop by drop, at room temperature. The mixture was stirred at room temperature for 20 min and then refluxed for another 5 min.

After 5 m*l* of 1 N hydrochloric acid had been added to the reaction mixture, yellow crystals were collected, washed with water, and dried. Recrystallization gave V; the yields are shown in Table 1.

The Reaction with Ethoxycarbonylmethylenetriphenylphosphorane (VId). To a solution of the phosphorane (VId) in 30 m*l* of ethanol which had been prepared by the treatment of ethoxycarbonylmethyltriphenylphosphonium bromide (2.1 g) with sodium ethoxide, 0.9 g of III was added. After the mixture had been stirred at room temperature for 2 hr, filtration gave 0.6 g of a mixture of yellow and white crystals. Fractional recrystallizations from ethanol gave 0.48 g of yellow needles (VIId), mp 102°C, and 0.1 g of white prisms (VIId′), mp 97°C.

VIId: IR (KBr) 1720 (sh, C=O), 1700 cm^{-1} (vs, C=O); UV λ_{max}^{EtOH} mμ (logε) 225 (4.73), 232 (4.83), 274 (4.22), 312.8 (4.0).

VIId′: IR (KBr) 1720 (vs, C=O), 1700 cm^{-1} (sh, C=O); UV λ_{max}^{EtOH} mμ (logε) 220 (4.46), 260 (3.90).

Similar reactions with other phosphoranes (VIa–VIc) gave the expected α,β-unsaturated ketones (VIIa–VIIc). The yields, physical properties, and results of the elemental analyses of VII are summarized in Table 2.

The Reaction with the Ethoxycarbonylmethylphosphonate Anion. To a suspension of 0.9 g of III and 1.1 g of diethyl ethoxycarbonylmethylphosphonate in 15 m*l* of dioxane, 60 mg of sodium hydride in 50% mineral oil was added, drop by drop, with stirring at room temperature. The mixture was stirred at room temperature for 20 min and then heated at 60—70°C for 5 min. During this time the reaction mixture turned from violet to yellow.

After the reaction mixture had been quenched with 10 m*l* of water, the crystals were collected by filtration. The crystals were then extracted with petroleum benzine (bp 45—60°C), leaving 0.02 g of a solid. After the extract had been concentrated *in vacuo*, the fractional recrystallization of the residue from methanol gave 1.5 g of yellow needles, mp 102°C, and 0.1 g of white prisms, mp 97°C. These compounds were, respectively, identical with the two ethoxycarbonylmethyleneacenaphthenones, VIId and VIId′, which were obtained from the reaction of III with VId.

The Reaction with Methylenetriphenylphosphorane (VIIIa). Into a suspension of 0.9 g of methyltriphenylphosphonium bromide and 0.46 g of III in 20 m*l* of dioxane, 60 mg of sodium hydride in 50% mineral oil was added, drop by drop, with stirring. The reaction mixture was stirred at room temperature

for 10 hr and then heated at 55—60°C for 1 hr.

The reaction mixture was then quenched with 10 m*l* of water, and the resultant mixture was extracted with 30 m*l* of ether. The extract was washed with 10 m*l* of 50% aqueous ethanol and dried over sodium sulfate. The ether solution was chromatographed on alumina, affording a large amount of resinous materials and 23 mg (5%) of methyleneacenaphthenone (IX) as yellow needles, mp 148°C (decomp.).

Found: C, 86.43; H, 4.35%. Calcd for $C_{13}H_8O$: C, 86.65; H, 4.48%. IR (KBr): 1720 cm^{-1} (C=O).

The reaction with VIIIa, which had been prepared from the phosphonium bromide and sodium ethoxide in ethanol, at room temperature for 30 min gave IX in a 10% yield.

The Reaction with Ethylidenetriphenylphosphorane (VIIIb). To a solution of the phosphorane VIIIb in 30 m*l* of absolute ethanol, which had been prepared from 2.6 g of ethyltriphenylphosphonium bromide and sodium ethoxide, 1.8 g of III was added. After the reaction mixture had then been stirred at room temperature for 10 hr, filtration gave crystals; these crystals were then washed with ethanol and dried, giving 0.48 g (86%) of orange yellow crystals, mp 240—244°C. Recrystallization from dimethylformamide afforded bis-2,2′-methyleneacenaphthenone (X) as orange yellow needles, mp 245°C.

Found: C, 87.41; H, 3.92%. Calcd for $C_{26}H_{14}O_2$: C, 87.10; H, 3.91%. IR (KBr): 1700 cm^{-1} (C=O).

The Reaction of Acenaphthenone with Glyoxal. To a solution of 0.16 g of acenaphthenone and 0.06 g of glyoxal in 10 m*l* of ethanol, 0.5 m*l* of 1 N sodium hydroxide was added, drop by drop, at room temperature; crystals appeared immediately. Filtration gave 0.17 g (96%) of orange yellow crystals which, on recrystallization from dimethylformamide, gave X, mp 245°C. This compound was identical with the product obtained from the reaction of III with VIIIb.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 185—190 (1969)

Studies of Acenaphthene Derivatives. XVII.[1] The Reaction of Benzylideneacenaphthenone with Hydrazines*1

Otohiko TSUGE, Ichiro SHINKAI and Masashi TASHIRO

Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka

(Received May 6, 1968)

The reactions of benzylideneacenaphthenones with hydrazines are reported. The reaction of benzylideneacenaphthenone with hydrazine hydrate in methanol at 40°C gave 1-hydroxy-2-hydrazinobenzylacenaphthylene, which was then cyclized to the 1-acetylpyrazoline by treating it with acetic anhydride. The hydrazino compound reacted with phenyl isocyanate to give the 1:2-adduct, which, when then treated with hydrochloric acid, suffered ring closure to the pyrazoline compound. Under severe conditions with hydrazine hydrate, however, the reductive cleavage reaction took place, giving the hydrazones of both acenaphthenone and benzaldehyde. Similar phenomena were also observed in the reaction with *p*-substituted benzylideneacenaphthenones. On the other hand, the reaction with phenylhydrazines in ethanol containing sulfuric acid afforded directly the expected pyrazolines, from which pyrazoles were then prepared by treating them with lead tetraacetate. Furthermore, the corresponding pyridazine was formed in the reaction of phenacylideneacenaphthenone with hydrazine hydrate, while the reaction with 2,4-dinitrophenylhydrazine gave the pyrazoline compound.

Although it is well known that the most general synthetic method for pyrazolines, which are of interest as intermediates in the preparation of cyclopropanes, is the reaction of α,β-unsaturated carbonyl compounds with hydrazines,[2] little has been reported relating to the reaction of benzylideneacenaphthenones (I)[1] with hydrazines.

In the course of preparing the pyrazolines starting with I, we have found that the reaction of I with hydrazine hydrate (II) revealed unusal phenomena, while the reaction with phenylhydrazines (III) in ethanol containing a little sulfuric acid gave the expected pyrazolines in excellent yields; these results will be described in this paper.

This paper will also deal with the reaction of phenacylideneacenaphthenone (IV)[1] with hydrazines.

VI VI'

When benzylideneacenaphthenone (Ia) was treated with II in a 1 : 3 molar ratio in methanol at 40°C for 20 min, white needles (Va), $C_{19}H_{16}ON_2$, were obtained in a 96% yield, instead of the expected hydrazone, azine or pyrazoline compound. The infrared spectrum of Va exhibited characteristic bands due to the hydroxyl group at 3400 cm^{-1} and to the NH group at 3280 and 3220 cm^{-1}, but it did not reveal any bands for the carbonyl group. The NMR spectrum in DMSO-d_6 exhibited peaks at τ 7.5 (1H, methine-proton, singlet), 5.2–6.2 (4H, hydroxyl- and NH-protons, broad peak), and 2.2 (11H, aromatic protons, multiplet).

The above observations can be explained on the assumption that Va is 1-hydroxy-2-(hydrazinobenzyl)acenaphthylene. This structure was also confirmed by the following results.

The treatment of Va with *p*-nitrobenzaldehyde in ether at room temperature afforded Ia and *p*-nitrobenzaldazine; the latter was formed by the condensation of the hydrazone and aldehyde.

When Va was allowed to react with acetic anhydride at room temperature for 2 hr, the *N*-acetylpyrazoline compound (VI) was obtained in a 53% yield. Its structure was confirmed by the results of elemental analysis and by the infrared and NMR spectra. The infrared spectrum of VI showed absorptions at 1670 and 1620 cm^{-1}, while the NMR spectrum in pyridine exhibited peaks at τ 7.6 (3H, acetyl-protons, singlet), 5.3 (1H, methine-proton, doublet), and 4.8 (1H, methine-proton, doublet) (J=12 cps), as is shown in Fig. 1.

It has been reported by Hassner and Michelson[3] that *cis*-pyrazolines exhibit higher coupling constants (10—14 cps) than those (3–10 cps) of the corresponding *trans* isomers. On the other hand, in our study of the NMR spectra of acenaphtho[1,2-*d*]oxazolidines, in which 1- and 2-hydrogen are located in the *cis*-manner, the protons appeared as doublets at τ 4.0 and 4.3 (J=6 cps) respectively.[4]

Although two pyrazoline structures for VI are possible, the above observations support the structure of 4,5-*cis*-1-acetyl-5-phenylpyrazoline com-

3) A. Hassner and M. J. Michelson, *J. Org. Chem.*, **27**, 3974 (1962).

4) O. Tsuge, M. Tashiro and K. Oe, The 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967.

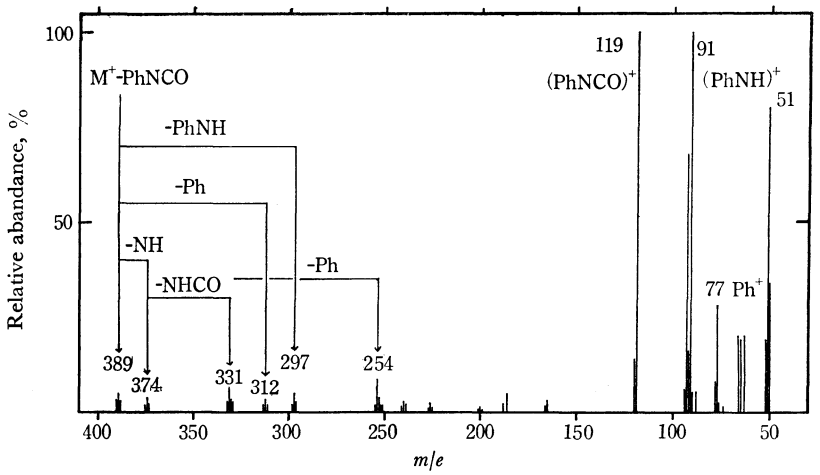

Fig. 2. The mass spectrum of VIII.

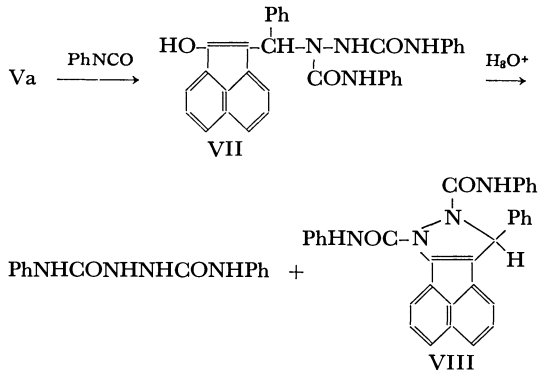
pound (VI) rather than the isomeric 4,5-*cis*-1-acetyl-3-phenylpyrazoline (VI').

Furthermore, the treatment of Va with two equivalents of phenyl isocyanate afforded the 1:2-adduct (VII) ($C_{33}H_{26}O_3N_3$) in a 96% yield. Its infrared spectrum showed bands to be ascribed to the NH group at 3300 cm^{-1} and to the carbonyl groups at 1700, 1690, and 1670 cm^{-1}. Also, VII hydrolyzed with 15% hydrochloric acid, giving *N*,*N*'-bisphenylcarbamoylhydrazine and orange yellow grains (VIII) in 34 and 44% yields respectively.



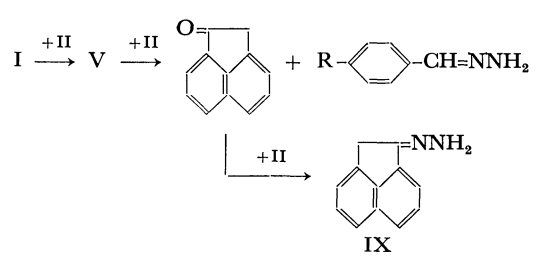
Compound VIII was assumed, on the basis of elemental analysis and a study of its infrared and mass spectra, to be 1,2-bisphenylcarbamoyl-3-phenylacenaphtho[1,2-*c*]pyrazoline. Its infrared spectrum exhibited characteristic bands due to carbonyl groups at 1720, 1680, and 1650 cm^{-1}, but it did not reveal any bands for the hydroxyl and NH groups.

The fragmentation on electron impact supported the proposed structure for VIII. As is shown in Fig. 2, the mass spectrum shows the *m/e* 389 peak, which is derived from the molecular ion upon the loss of a phenyl isocyanate moiety.

Similar reactions of *p*-methoxy- (Ic) and *p*-chlorobenzylideneacenaphthenone (Id) with II afforded the corresponding 1-hydroxy-2-hydrazinobenzyl compounds, Vc and Vd, in quantitative yields.

When an ethanol solution of Ia and II was refluxed for 10 min, the hydrazones of both acenaphthenone (IX) and benzaldehyde were obtained in excellent yields. In the reaction of Ib (R=Me), Id, and Ie ($R=NO_2$) under similar conditions, IX and the respective benzaldehyde hydrazone were obtained.

Similar phenomena were observed by Musante[5]: ω-nitrostyrene was cleft with II to give the azine and nitromethane.



It may be inferred that both the hydrazones are formed by the reductive cleavage of the carbon-carbon bond in V with II.

Raiford and Manley[6] have reported that phenyl hydrazones, which rearrange to isomeric pyrazolines on refluxing, can be isolated in the reaction of chalcones with phenylhydrazine (IIIa) in acetic acid at room temperature, and that pyrazolines forms directly when methanol containing a little acetic acid is used as the reaction medium.

When I was allowed to react with III in acetic

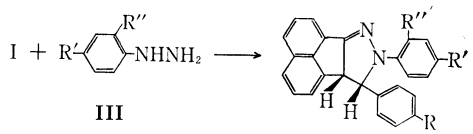
5) C. Musante, *Gazz. Chim. Ital.*, **67**, 579 (1937).
6) L. C. Raiford and R. H. Manley, *J. Org. Chem.*, **5**, 590 (1940).

acid at room temperature, the expected phenylhydrazones were not obtained; instead, a resinous material was exclusively formed.

In a methanol solution containing a little acetic acid, Id and Ie reacted with IIIa and IIIb (R′=NO_2, R″=H) to give the corresponding pyrazolines in moderate yields (60—75%). In the reactions of Ia, Ib, and Ic, however, a resinous material was formed exclusively. When Id and Ie were treated with IIIc (R′=R″=NO_2) under similar conditions, the expected pyrazoline was not obtained, but predominantly a resinous material was formed.

On the other hand, it has been found that I reacted smoothly with III in ethanol containing a little sulfuric acid, giving the corresponding pyrazolines (X) in quantitative yields.

The structures for X were confirmed on the basis



III

a : R′=R″=H
b : R′=NO_2, R″=H
c : R′=R″=NO_2

X

of elemental analyses, and on the basis of a study of the infrared and NMR spectra. The infrared spectra of all X structures exhibited the band ascribed to the C=N bond at about 1600 cm^{-1}, but there were no bands for the carbonyl, hydroxyl, and NH groups.

As is shown in Fig. 1, the NMR spectrum of Xe (R=Cl, R′=R″=H) in trifluoroacetic acid reveals peaks at τ 4.64, 4.04 (each 1H, methine-proton,

doublet, $J=13.5$ cps), and 2.4 (15H, aromatic protons, multiplet). For reasons pointed out in the discussion of VI, the above observations indicate that Xe is the 4,5-*cis*-1-phenyl-5-*p*-chlorophenyl-pyrazoline compound.

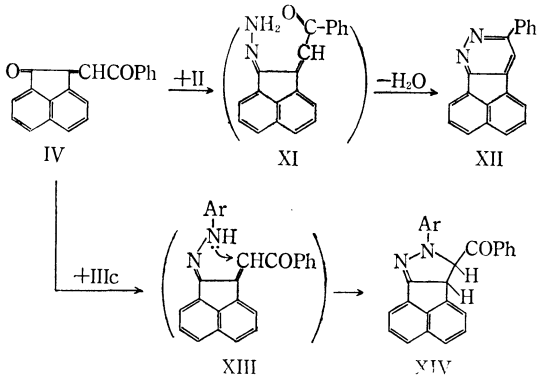
The physical properties and elemental analyses are summarized in Table 1.

It has been reported by Gladstone and Norman[7] that lead tetraacetate is an effective reagent for oxidizing pyrazolines to pyrazoles.

When X was oxidized with lead tetraacetate in dichloromethane, the corresponding pyrazole (XI), whose infrared spectrum was very similar to that of the pyrazoline, was obtained in a fairly good yield.

The yields, physical properties, and results of the elemental analyses of XI are listed in Table 2.

On the other hand, an ethanol solution of phenacylideneacenaphthenone (IV) and II was refluxed for 30 min, giving yellow needles (XII), mp 147°C, in a 33% yield. The molecular formula of XII agreed with $C_{20}H_{12}N_2$, and its infrared spectrum exhibited the band ascribed to the C=N bond at 1610 cm^{-1}, but it did not reveal any bands for the carbonyl group. On the basis of the above observations, the compound XII was assumed to be the pyridazine compound which was formed through the hydrazone intermediate (XI).



Ar=2,4-dinitrophenyl

While II exclusively attacked the carbon atom of benzylidene moiety in I, the reaction with IV proceeded through the formation of hydrazone.

When IV was treated with IIIc in ethanol containing a little sulfuric acid, reddish brown needles (XIV), mp 253°C, were obtained in a 75% yield. The compound XIV agreed with the formula, $C_{26}H_{16}O_5N_4$, and its infrared spectrum exhibited characteristic bands due to the carbonyl and C=N groups at 1650 and 1610 cm^{-1} respectively.

Considering the above observations, it may be deduced that the compound XIV is the pyrazoline compound formed through the hydrazone (XIII).

Experimental

All melting points are uncorrected. The infrared spectra were measured in KBr disks, and the NMR spectra were determined at 60 Mc with a Japan Electron Optics JNM-3H-60 NMR spectrometer, using TMS as the internal reference. The mass spectrum was obtained on a Hitachi RMU-6D instrument using a heated inlet, an ionization energy of 70 eV, an inlet temperature of 250°C, and a source temperature of 250°C. The elemental analyses were done by Mr. Eiji Shiozaki in our laboratory.

Benzylidene- (I) and phenacylideneacenaphthenone (IV) were prepared by a previously-reported method.[1]

General Method for the Reaction of the Benzylideneacenaphthenone (I) with Hydrazine Hydrate (II). i) After a solution of I (1.5 mmol) and II (4.5 mmol) in methanol (20 m*l*) had been heated at 40°C for 20 min, the reaction mixture was evaporated *in vacuo* to give white crystals. Recrystallization from methanol gave the corresponding 1-hydroxy-2-(hydrazinobenzyl)acenaphthylene (V).

Va (R=H), yield, 96%. Mp 74—75°C (decomp.), white needles. Found: C, 78.95; H, 5.59; N, 9.27%. Calcd for $C_{19}H_{16}ON_2$: C, 79.10; H, 5.56; N, 9.71%.

Vc (R=OCH_3), quantitative yield. Mp 96°C (decomp), white needles. Found: C, 75.13; H, 5.45; N, 9.25%. Calcd for $C_{20}H_{18}O_2N_2$: C, 75.45; H, 5.70; N, 8.80%.

Vd (R=Cl), quantitative yield. Mp 62°C (decomp.), white needles. Found: C, 70.04; H, 4.20; N, 8.55%. Calcd for $C_{19}H_{15}ON_2Cl$: C, 70.60; H, 4.64; N, 8.67%.

ii) After a solution of I (3 mmol) and II (9 mmol) in ethanol (20 m*l*) had been refluxed for 10 min, ethanol was distilled off *in vacuo* to leave an oily material. A solution of the oily material in petroleum benzine (bp 45—60°C) was then allowed to stand overnight, giving white crystals. Filtration afforded acenaphthenone hydrazone (IX), mp 107°C (decomp.), as white needles, in an excellent yield.

This compound was identical with the authentic sample prepared from acenaphthenone and II.

Found: C, 79.32; H, 5.27; N, 15.30%. Calcd for $C_{12}H_{10}N_2$: C, 79.12; H, 5.49; N, 15.39%.

A petroleum benzine solution was concentrated, leaving the benzaldehyde hydrazone as a colorless liquid. The corresponding benzaldazine was obtained by the treatment of the hydrazone with acetic acid.

The Reaction of Va with *p*-Nitrobenzaldehyde. A solution of Va (280 mg) and *p*-nitrobenzaldehyde (150 mg) in ether (10 m*l*) was stirred at room temperature for 2 hr: during this time yellow crystals appeared. Filtration gave *p*-nitrobenzaldazine (mp 293—295°C (decomp.)) in a quantitative yield. The ether filtrate was concentrated to give Ia.

The Reaction of Va with Acetic Anhydride. After acetic anhydride (430 mg) had been added to a solution of Va (1.2 g) in ether (30 m*l*), the reaction mixture was stirred at room temperature for 2 hr; during this time white crystals appeared. The crystals were collected by filtration, washed with ether, and dried. Yield, 645 mg (53%). Recrystallization from

7) W. A. F. Gladstone and R. O. C. Norman, *J. Chem. Soc.*, (*C*), **1966**, 1536.

benzene afforded white needles, *cis*-1-acetyl-5-phenylpyrazoline compound (VI), mp 168°C.

Found: C, 80.49; H, 4.69; N, 9.00%. Calcd for $C_{21}H_{16}ON_2$: C, 80.75; H, 5.16; N, 8.97%.

The Reaction of Va with Phenyl Isocyanate. To a solution of Va (500 mg) in ether (15 m*l*), a solution of phenyl isocyanate (410 mg) in ether (10 m*l*) was added, drop by drop, at room temperature. The reaction mixture was then stirred at room temperature for 30 min; during this time white crystals appeared. After the crystals had been collected by filtration, recrystallization from a dioxane - benzene mixture to give the 1 : 2 adduct (VII) as white grains, mp 225—226°C. Yield, 870 mg (96%).

Found: C, 74.98; H, 4.67; N, 10.53%. Calcd for $C_{33}H_{26}O_3N_4$: C, 75.20; H, 4.94; N, 10.64%.

The Hydrolysis of VII. After a suspension of VII (200 mg) in 15% hydrochloric acid (10 m*l*) had been heated at 100°C for 3 min, crystals were collected by filtration. These crude crystals were extracted with dioxane, leaving 35 mg (34%) of *N*,*N*′-bis(phenylcarbamoyl)hydrazine as white needles, mp 270°C; this compound was identical with the authentic sample prepared from the reaction of phenyl isocyanate with hydrazine.

The dioxane extract was concentrated *in vacuo* to afford the 1,2-bis(phenylcarbamoyl)-3-phenylpyrazoline compound (VIII) as orange yellow grains, mp 227—229°C. Yield, 85 mg (44%).

Found: C, 77.61; H, 4.63; N, 10.92%. Calcd for $C_{33}H_{24}O_2N_4$: C, 77.93; H, 4.76; N, 11.02%.

General Method for the Preparation of Pyrazoline Compounds (X). A solution of equimolar amounts of I and phenylhydrazines III (each 1.5 mmol) in 20 m*l* of ethanol containing a few drops of concentrated sulfuric acid was heated on a water-bath for 10 min. The crystals were then collected and purified by recrystallization. The yields of X were quantitative in all cases.

The physical properties and results of the elemental analyses of X are summarized in Table 1.

The Oxidation of the Pyrazoline (X) to the Pyrazole (XI). To a suspension of 240 mg of Xg (R=Cl, R′=R″=NO_2) in 6 m*l* of dichloromethane, a solution of 250 mg of lead tetraacetate in 3 m*l* of dichloromethane was added at room temperature. After the mixture had been stirred at room temperature for 24 hr, it was decomposed with acetic acid and hydrazine hydrate to give a tarry material. The benzene solution of the product was chromatographed on alumina, affording yellow crystals. Recrystallization from ethanol gave 140 mg (60%) of pyrazole (XIc), mp 270°C.

Similar oxidations of Xd and Xf gave the corresponding pyrazoles, XIa and XIb. The yields, physical properties, and elemental analyses of XI are listed in Table 2.

The Reaction of Phenacylideneacenaphthenone (IV) with II. A solution of 200 mg of IV and 1.5 equimolar amounts of II in 10 m*l* of ethanol was refluxed for 30 min. After the mixture had been concentrated *in vacuo*, it was allowed to stand overnight, thus giving crystals. Recrystallization from ethanol gave 65 mg (33%) of 3-phenylacenaphtho[1,2-*c*]pyridazine (XII) as yellow needles, mp 147°C.

Found: C, 85.85; H, 3.99; N, 10.03%. Calcd for $C_{20}H_{12}N_2$: C, 85.69; H, 4.32; N, 9.90%.

The Reaction of IV with 2,4-Dinitrophenylhydrazine (IIIc). A solution of 280 mg of IV and 200 mg of IIIc in 10 m*l* of ethanol containing two drops of concentrated sulfuric acid was refluxed for 15 min. After the reaction mixture had then been cooled, crystals were collected by filtration. Recrystallization from dioxane gave 350 mg (75%) of 1-(2,4-dinitrophenyl)-5-benzoylacenaphtho[1,2-*c*]pyrazoline (XIV) as reddish-brown needles, mp 235°C.

Found: C, 67.31; H, 3.52; N, 11.83%. Calcd for $C_{26}H_{16}O_5N_4$: C, 67.23; H, 3.47; N, 12.06%.

Synthesis of Albonoursin

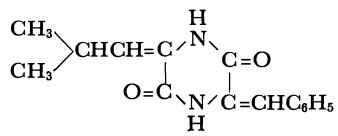
Chung-gi SHIN, Yasuhiro CHIGIRA, Mitsuo MASAKI and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received May 11, 1968)

Treatment of the ester of 2-(2-chloroacetamido)-2-alkenoic acid with ammonia led to the formation of 3-alkylidene-2,5-piperazinedione. By using this method, total synthesis of albonoursin was accomplished. 2-(2-Chloroacetamido)-4-methyl-2-pentenoic acid, derived from the condensation of 4-methyl-2-oxopentanoic acid with chloroacetonitrile or the pyrolysis of 2,2-bis(2-chloroacetamido)-4-methylpentanoic acid, was converted to the ethyl ester, which was treated with ammonia to give 3-isobutylidene-2,5-piperazinedione. The piperazinedione was also synthesized by the esterification of 2-(2-aminoacetamido)-4-methylpentenoic acid, followed by a cyclization of the ester. Condensation of the piperazinedione with benzaldehyde yielded 3-benzylidene-6-isobutylidene-2,5-piperazinedione, and its physical constants are virtually identical with those recorded for the natural albonoursin.

In 1963, Khoklov and Lokshin isolated a new product from the culture filtrates of two *Streptomyces* species, *i.e.*, *St. albus var. fungatus* and *St. noursei*, and designated it as albonoursin.[1] Before the year, Brown and Kelley had reported that *St. noursei* produced a substance, "component 2."[2] Also Rao and Cullen isolated a substance "B-73," from the culture filtrate of *St. albus*.[3] These two substances have been revealed to be identical with albonoursin.[1] The structural investigations were made independently by Khoklov and Lokshin,[1] Brown *et al.*,[4] and Vondracek and Vanek,[5] respectively, and all of them have assigned the 3-benzylidene-6-isobutylidene-2,5-piperazinedione structure (I) for albonoursin.



I

Although albonoursin has no special biological activity, it seems of much interest to investigate the synthetic method, since the structure may be regarded as the first cyclic dehydrodipeptide isolated from a natural origin.

In a previous paper,[6] we have described a method for the synthesis of 3-isopropylidene-6-aralkylidene-2,5-piperazinediones. The method consists in the treatment of methyl 2-amino-3-methylcrotonate with phthaloylglycyl chloride, giving methyl 3-methyl-2-phthaloylglycylaminocrotonate, which, after removal of the phthaloyl group, was cyclized to yield 3-isopropylidene-2,5-piperazinedione. The condensation of the piperazinedione with aromatic aldehydes gave 3-isopropylidene-6-aralkylidene-2,5-piperazinediones.

It was also shown, however, that methyl 2-amino-3-methylcrotonate could be obtained by the reduction of the corresponding 2-nitro compound with aluminum amalgam, while analogous reduction of other 2-nitro-2-alkenoic acid esters resulted in the formation of the 2-oximino-alkanoic acid esters as the isolated products.

In the present paper, we wish to report an alternative and more general route for the synthesis of 3-alkylidene-2,5-piperazinediones and the total synthesis of albonoursin.[7]

Treatment of ethyl 2-amino-3-methylcrotonate (II) with chloroacetyl chloride in an aqueous solution in the presence of sodium hydrogencarbonate afforded ethyl 2-(2-chloroacetamido)-3-methylcrotonate (III) in 47% yield. When the ester III was treated with ammonia in methanol at room temperature for 2 days, the amination and the subsequent or spontaneous cyclization reactions occurred to yield 3-isopropylidene-2,5-piperazinedione (IV).

In an extension of this method to the synthesis of albonoursin, the ester of 2-(2-chloroacetamido)-4-methyl-2-pentenoic acid is required. Meister and Greenstein have reported that the condensation reaction of α-ketoisocaproic acid with chloroacetonitrile in the presence of hydrogen chloride gave a mixture of 2-(2-chloroacetamido)-4-methyl-2-pentenoic acid (V) and chloroacetamide. The acid V has not been isolated but characterized by its conversion to 2-(2-aminoacetamido)-4-methyl-2-pentenoic acid (VI).[8] However, our modification of the method led to the isolation of V in a pure state (see Experimental). The acid V was also obtained by heating 2,2-bis(2-chloroacetamido)-4-methylpentanoic acid (VII) in acetic acid for 3 hr. The acid V was identified by a comparison with the sample obtained in the preceding paper[9] from 2-chloromethyl-4-isobutylidene-5-oxazolone.

The acid V was transformed into the corresponding ethyl ester (VIII) in 26% yield by heating in ethanol in the presence of sulfuric acid and *p*-toluenesulfonic acid.[10] Treatment of the ester with ammonia in methanol afforded 3-isobutylidene-2,5-piperazinedione (IX).

In an alternative route, 2-(2-aminoacetamido)-4-methyl-2-pentenoic acid (VI) derived from V was refluxed in methanol in the presence of hydrogen chloride to give the corresponding methyl ester (X). By heating in aqueous solution, the ester X gave also the piperazinedione IX in 28% yield.

When the piperazinedione IX was condensed with benzaldehyde in the presence of acetic anhydride and sodium acetate, 3-benzylidene-6-isobutylidene-2,5-piperazinedione (I) was obtained in 56% yield. The identity of the product was confirmed by elemental analysis as well as infrared and ultraviolet spectra. The spectral data and other properties indicate the identity of the natural albonoursin, as shown in Table 1.

Experimental[11]

Ethyl 2-(2-Chloroacetamido)-3-methylcrotonate

8) A. Meister and J.P. Greenstein, *J. Biol. Chem.*, **195**, 849 (1952).

9) H. Kurita, Y. Chigira, M. Masaki and M. Ohta, This Bulletin, **41**, 2758 (1968).

10) In general, the esterification of this type of compounds is difficult. *N*-Acetyl-dehydroalanine has been reported to be esterified by means of the use of diazomethane in 10% yield and of dimethyl sulfate or methyl iodide in 40—50% yield: T. Wieland, G. Ohnacker and W. Ziegler, *Chem. Ber.*, **90**, 194 (1957).

11) All melting points were determined in a liquid bath and are uncorrected.

(III). Chloroacetyl chloride (0.8 g) was added portionwise, with vigorous stirring at room temperature, to ethyl 2-amino-3-methylcrotonate (1 g) suspended in a solution of sodium hydrogencarbonate (0.6 g) in water (15 m*l*). After stirring for 30 min, crystalline precipitates were collected and washed with water. Recrystallization from 50% aqueous ethanol afforded colorless needles (0.7 g, 47%), mp 117—118°C. The product was identical in melting point and infrared spectrum with the sample obtained in the preceding paper.[9]

3-Isopropylidene-2,5-piperazinedione (IV). A solution of III (0.6 g) in methanol (15 m*l*) was saturated with dry gaseous ammonia under cooling. When the solution was allowed to stand at room temperature for 3 days, crystalline substance precipitated. The methanol was evaporated under reduced pressure and the residual crystalline product was washed with cold water. Recrystallization from water afforded colorless prisms (0.26 g, 61%), mp 260°C (decomp.). The infrared spectrum was superimposable on that of the authentic 3-isopropylidene-2,5-piperazinedione.[6]

2,2-Bis (2-chloroacetamido)-4-methylpentanoic Acid (VII). The same directions were followed as that used for 2,2-bis(2-chloroacetamido)propionic acid.[12]

By a reaction of 4-methyl-2-oxopentanoic acid (5 g) and chloroacetonitrile (6 g) in concentrated sulfuric acid (30 m*l*), followed by a recrystallization of the crude product from water, there were obtained colorless prisms (5.6 g, 50%), mp 183—184°C (lit.[13] mp 134°C).

Found: C, 40.41; H, 5.34; N, 9.20%. Calcd for $C_{10}H_{16}N_2O_4Cl_2$: C, 40.13; H, 5.35; N, 9.36%.

2-(2-Chloroacetamido)-4-methyl-2-pentenoic Acid (V). *A) From 4-Methyl-2-oxopentanoic Acid.* The procedure was modified from the method of Meister and Greenstein.[8] A mixture of 4-methyl-2-oxopentanoic acid (4 g) and chloroacetonitrile (2 g) was saturated with dry hydrogen chloride at 0°C, and then allowed to stand in a refrigerator for 3 days. The mixture was treated with dry ether and the crystalline substance, chloroacetamide, was filtered off. The filtrate was concentrated to give a yellow viscous residue (*residue A*), which was dissolved in water (20 m*l*). The pH of the solution was adjusted to 8 with a sodium bicarbonate solution and an insoluble oil formed was removed by extraction with ether. The aqueous layer was acidified to pH 3 with 3 N hydrochloric acid and well extracted four times with ether. The ethereal extract was dried over anhydrous sodium sulfate and then evaporated. Addition of di-*n*-butyl ether to the residual oil gave a crystalline product. Recrystallization from di-*n*-butyl ether afforded colorless needles (0.7 g, 14%), mp 128—129°C. The product was identical with the sample prepared in the preceding paper.[9]

B) From VII. A suspension of VII (3 g) in acetic acid (12 m*l*) was gently refluxed for 3 hr, and the resultant dark brown solution was concentrated under reduced pressure to give a yellow viscous residue, which was treated in the same manner as for the *residue A* in the method A, giving colorless needles (0.7 g, 36.8%), mp 128—129°C. The product was identical, in melting point and infrared spectrum, with the sample obtained by the method A.

Ethyl 2-(2-Chloroacetamido)-4-methyl-2-pentenoate (VIII). A suspension of V (4.8 g) in ethanol (20 m*l*) and benzene (20 m*l*) was refluxed in the presence of concentrated sulfuric acid (0.5 g) and *p*-toluenesulfonic acid (0.5 g) for 5 hr. The resultant solution was concentrated under reduced pressure to give an oily residue. Ether was added to the residue and then the insoluble *p*-toluenesulfonic acid was filtered off. The ethereal solution was washed successively with aqueous sodium bicarbonate and with water, and dried over anhydrous sodium sulfate. After evaporation of the ether, the residue was distilled to give a colorless viscous oil (1.4 g, 25.6%), bp 135—137°C/2 mmHg. Upon addition of petroleum ether, the oil gradually solidified. Recrystallization from petroleum ether afforded colorless prisms, mp 64—67°C.

Found: C, 51.36; H, 6.68; N, 6.10%. Calcd for $C_{10}H_{16}NO_3Cl$: C, 51.39; H, 6.85; N, 6.00%.

2-(2-Aminoacetamido)-4-methyl-2-pentenoic Acid (VI). The procedure was modified from the method of Meister and Greenstein.[8] A solution of V (2.0 g) in methanol (30 m*l*) was saturated with gaseous ammonia under ice cooling and then left to stand at room temperature overnight. The solution was concentrated under reduced pressure: the residual oily product solidified partially upon addition of methanol to give colorless needles (0.5 g), mp 266—267°C (decomp.).[14]

3-Isobutylidene-2,5-piperazinedione (IX). *A) From VIII.* A solution of VIII (0.6 g) in methanol (10 m*l*) was saturated with gaseous ammonia and the resultant mixture was treated in a manner analogous to the case of IV. Recrystallization from water gave colorless needles (0.25 g, 59%), mp 277—278°C (decomp.). ν_{max}^{KBr} 3170, 3050, 1700 and 1640 cm^{-1}. λ_{max}^{KBr} 220 mμ (ε =16600), 240 (14100).

Found: C, 56.81; H, 7.01; N, 16.85%. Calcd for $C_8H_{12}N_2O_2$: C, 57.13; H, 7.19; N, 16.66%.

B) From X. A suspension of VI (0.4 g) in methanol (15 m*l*) was refluxed, while dry hydrogen chloride was passed through the mixture for 2 hr. The solution was concentrated under reduced pressure to dryness giving the methyl ester hydrochloride (X·HCl) as a crystalline residue, which was used without further purification. A solution of the crude X and sodium bicarbonate (0.1 g) in water (10 m*l*) was heated on a steam bath for 3 hr. Crystals gradually precipitated from the solution. The precipitates were collected and recrystallized from 50% aqueous methanol to give colorless needles (0.1 g) mp 277—278°C. The product was identical, in melting point and infrared spectrum, with the sample obtained in method A.

3-Benzylidene-6-isobutylidene-2,5-piperazinedione (I). A mixture of IX (0.05 g) and benzaldehyde (0.2 g) in acetic anhydride (2 m*l*) was heated at 140°C for 5 hr. The mixture was treated with water (4 m*l*) and ether (2 m*l*), giving crystalline precipitates. The precipitates were collected, dissolved in acetic acid and then reprecipitated by addition of water. Recrystallization from acetone afforded colorless needles (0.03 g, 40%).

Found: C, 70.02; H, 6.39; N, 11.00%. Calcd for $C_{15}H_{16}N_2O_2$: C, 70.29; H, 6.29; N, 10.93%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 194—199 (1969)

The Synthesis of Cyclic α-Amino Acids. II

Mitsuhiro KINOSHITA, Hiroaki YANAGISAWA, Shuhei Doi, Eisuke KAJI and Sumio UMEZAWA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Koganei-shi, Tokyo

(Received May 23, 1968)

The reaction of substituted derivatives of α-nitrocinnamates bearing a nitro group or a chlorine atom at the *p*- or *m*-position with cyclopentadiene produced corresponding cyclic α-nitro esters (adducts) in a good yields. The reaction of ethyl α-nitrocrotonate with cyclohexadiene gave ethyl 3-methyl-2-nitrobicyclo[2.2.2]-5-octene-2-carboxylate. In the case of an adduct, ethyl 2-nitro-3-(*p*-nitrophenyl)bicyclo[2.2.1]-5-heptene-2-carboxylate, there could be isolated four diastereoisomers as crystalline forms by column chromatography and fractional recrystallization. The stereochemistry of the four isomeric adducts were established by NMR spectroscopy. The readily available three of those isomers were converted to corresponding pure isomers of amino acids by reduction followed by hydrolysis. From the other adducts the major amino acid isomers or the amino acid mixtures were obtained in an analogous route.

A recent publication[1] from this laboratory described the synthesis of cyclic α-amino acids from α,β-unsaturated α-nitro esters, which were used as dienophiles in the Diels-Alder reaction. The present paper is concerned with an extension of this work and presents the syntheses of 2-amino-3-(*p*- or *m*-substituted phenyl)bicyclo[2.2.1]heptane-2-carboxylic acids (IV, XI, XII) and 2-amino-3-methylbicyclo-[2.2.2]octane-2-carboxylic acid (XV) (Fig. 1).

The Diels-Alder reaction of ethyl α,*p*-dinitrocinnamate[2] (I) which was confirmed to be a single isomer by NMR, with excess cyclopentadiene in benzene at 120°C for 1.5 hr gave ethyl 2-nitro-3-(*p*-nitrophenyl) bicyclo[2.2.1]-5-heptene-2-carboxylate (II) in quantitative yield. The semicrystalline adduct II was shown to be a mixture of two fractions, II_1 (R_f, 0.5) and II_2 (R_f, 0.4), by thin layer chromatography. These fractions were effectively separated from each other by silica gel column chromatography. The ratios of II_1 to II_2 observed in several batches of II fell in a range of 1 : 9—1 : 10 by weight. The NMR spectra of II_1 and II_2 showed that both of them were mixtures of diastereoisomers. The fractional recrystallization of II_1 and II_2 resulted in the separation of the diastereoisomers. The components IIA and IID separated from II_1, and the other components IIB and IIC from II_2 were characterized as the pure diastereoisomers of the adduct II (Table 1). The ratios of IIA to IID and of IIB to IIC were estimated to be about 3.5 : 1 and 4 : 1 on the basis of NMR analysis, respectively.

Fig. 1.

The stereochemistry of the four diastereoisomers was established by NMR as shown in Fig. 2. Spectral features were assigned on the basis of chemical shifts, integrated area, magnitudess of plittings, and decoupled splitting patterns.[3] The assigned chemical shifts and coupling constants are listed in Tables 2 and 3, respectively.

IIA: $R_1=NO_2$, $R_2=CO_2C_2H_5$, $R_3=3n$, $R_4=C_6H_4NO_2(p)$
IIB: $R_1=NO_2$, $R_2=CO_2C_2H_5$, $R_3=C_6H_4NO_2(p)$, $R_4=3x$
IIC: $R_1=CO_2C_2H_5$, $R_2=NO_2$, $R_3=3n$, $R_4=C_6H_4NO_2(p)$
IID: $R_1=CO_2C_2H_5$, $R_2=NO_2$, $R_3=C_6H_4NO_2(p)$, $R_4=3x$
VIIA: $R_1=NO_2$, $R_2=CO_2C_2H_5$, $R_3=3n$, $R_4=C_6H_4NO_2(m)$
VIIB: $R_1=NO_2$, $R_2=CO_2C_2H_5$, $R_3=C_6H_4NO_2(m)$, $R_4=3x$

A letter *n* is added to the number of a hydrogen to denote an *endo* hydrogen and *x* is used to denote an *exo* hydrogen. For the 7-hydrogens the letter *s* specifies the hydrogen *syn* to the double bond and theletter *a* designates the *anti* hydrogen.

Fig. 2.

The bridgehead protons (1,4) are assigned by their broad patterns resulting from several coupling interactions. The bridgehead peak (6.80—6.76τ) at higher field in the isomer IIB and IID can be ascribed to the 4-proton by its coupling constant ($J_{3x,4}=3.3$ cps). It is ascertained that there is no coupling between the bridgehead protons (6.28—6.12τ) in lower field and the 3*x*-protons (doublet centered at 5.27—5.13τ). The olefinic protons (5, 6) in IIB and IID can be assigned by an existence of a remarkable coupling with the bridgehead protons (4, 1). Decoupling shows that the upfield-half of the eight-line pattern of the olefinic protons is coupled ($J_{4,5}=3.0$ cps) with the peak assigned as 4-proton.

In IIA and IIC, both of bridgehead protons show no detectable coupling with 3*n*-proton (doublet centered at 5.83τ). The zero coupling constant ($J_{3n,4}$) can be explained by the deformation of the vicinal dihedral angle[4,5] between 3*n*- and 4-proton. On the other hand, the bridgehead peak at lower field can be assinged to 1-proton as well as in the cases of IIB and IID on the basis of the electronegativity effect[5] of the nearby substituents R_1 and R_2. Decoupling shows that the upfield-half

TABLE 3. COUPLING CONSTANTS (cps) OF ADDUCT II

Compound	$J_{5,6}$	$J_{4,5}$	$J_{1,6}$	$J_{3n,4}$	$J_{3x,4}$	$J_{7s,3n}$	$J_{7s,7a}$
IIA	5.8	3.0	3.0	0	—	3.0	10.0
IIB	6.0	3.0	3.0	—	3.3	—	?
IIC	5.5	3.1	3.1	0	—	3.0	10.0
IID	6.0	3.0	3.4	—	3.3	—	?

of the eight-line pattern of the olefinic protons in IIA and IIC is coupled ($J_{1,6}=3.0$—3.1 cps) with the peak assigned as 1-proton.

It is interesting that the methylene bridge (7-protons) appear as the characteristic four-line pattern for the spin-spin coupling of two nonequivalent protons in the isomer IIA and IIC, and the geminal coupling constants are equal in both isomers ($J_{7s,7a}=10.0$ cps). However in both IIB and IID, the methylene bridge protons appear as a single peak (8.27—8.28τ) with barely detectable fine structure. In the adduct IIA and IIC, the upfield-doublet (7.92—8.00τ) of this pattern is further split into discernible features, while the downfield-doublet (7.20—7.23τ) is relatively unsplit. Decoupling shows that the upfield-pattern is coupled with the peak assigned as 3*n*-proton, and is attributed to 7*s*-proton. The long-range coupling constant ($J_{7s,3n}=3.0$ cps) falls in the range reported.[3,6,7] The downfield-doublet is then assigned to 7*a*-proton. A downfield shift for hydrogens *syn* to an *exo* substituent has been noted previously by Davis and Van Auken[3] in some *exo*-norbornene derivatives. The downfield shift for 7*a*-proton in IIA and IIC may be attributed to anisotropic effect of the *exo*-substituted *p*-nitrophenyl ring.

The above-mentioned NMR studies for the bridgehead protons, methylene bridge protons and 3-protons of the four isomeric adducts establish the following configurations of 3-*p*-nitrophenyl groups in the addcuts; *exo* in IIA and IIC, while *endo* in IIB and IID. The configurations of 2-carbethoxy groups in the addcuts are deduced on the basis of the chemical shifts of their methyl and methylene protons. Recently, Kleinfelter[8] reported that some phenylnorbornyl *p*-nitrobenzoates in which the *p*-nitrobenzoyl group is in a *cis* relationship with the phenyl group shows a great shielding of one proton pair of *p*-nitrobenzoyl group which is held close to the center of benzene ring. Kleinfelter also reported[9] that a 3-*exo*-phenyl group in 3-phenyl-2-nitrobornanols and their derivatives diamagnetically shields an eclipsed 2-*exo*-proton. A similar effect was observed in *trans*-1,2-diphenylcyclopentane in which the 1- and 2-hydrogens are shielded 0.40 ppm relative to the *cis* isomer.[10] As shown in Table 2, the carbethoxy proton absorptions of the adduct IIA and IID apparently occurred upfield from those of the adduct IIB and IIC. The "*cis*" relationship between the *p*-nitrophenyl and carbethoxy group may exist here in the addcut IIA and IID.

The catalytic hydrogenation of isomers IIA, IIB, IIC and the mixture adduct II with Raney Ni T-4[11] gave three isomers of ethyl 2-amino-3-(*p*-aminophenyl)bicyclo[2.2.1]heptane-2-carboxylate, *i. e.* IIIA, IIIB, IIIC and III, respectively. On hydrolysis with 6 N hydrochloric acid, IIIA, IIIB and IIIC afforded diastereoisomeric 2-amino-3-(*p*-aminophenyl)bicyclo[2.2.1]heptane-2-carboxylic acid, *i. e.* IVA, IVB and IVC, respectively (Table 5). It was interesting that the amino ester IIIA strongly resisted against hydrolysis and, especially, it suffered no hydrolysis in methanolic barium hydroxide solution at 37°C for eighty hours, while the other amino esters IIIB and IIIC were smoothly hydrolyzed. This fact supported the structure of the adduct IIA in which the 2-carbethoxy group undergoes more steric interference owing to the *cis*-3-*p*-nitrophenyl group. The dihydrochloride of major amino acid IVB was sparingly soluble in a cold 6 N hydrochloric acid as compared with its isomeric amino acid dihydrochlorides. On this basis, a convenient preparation of major amino acid IVB was accomplished with 40% overall yield by starting from the mixture adduct II.

In addition, two other amino acids 2-amino-3-(*m*-aminophenyl)bicyclo[2.2.1]heptane-2-carboxylic acid (XIB) and 2-amino-3-(*p*-chlorophenyl)bicyclo-[2.2.1]heptane-2-carboxylic acid (XII) of the above-mentioned type have been synthesized by a similar route. The reaction of cyclopentadiene with ethyl *a*,*m*-dinitrocinnamate (V) and ethyl *a*-nitro-*p*-chlorocinnamate[2] (VI) gave ethyl 2-nitro-3-(*m*-nitrophenyl)bicyclo[2.2.1]-5-heptene-2-carboxylate (VII) and ethyl 2-nitro-3-(*p*-chlorophenyl)bicyclo-[2.2.1]-5-heptene-2-carboxylate (VIII) in a good yield, respectively (Table 1).

The NMR analysis showed that the dienophile V is a single isomer. The NMR spectrum of the adduct VII which was very similar to the pattern of the adduct mixture II, showed the presence of two pairs of isomeric adducts, *i. e.*, VIIB—VIIC (major) and VIIA—VIID (minor) corresponding to the adduct pairs IIB—IIC and IIA—IID, respectively. The presence of about 70% of the main isomer VIIB in VII was also suggested on the basis of the relative intensity of the 3*x*-proton. The separation of the main isomer VIIB by chromatography and recrystallization was unsuccessful, however, sometimes, spontaneous partial separation of VIIA in pure crystalline state was observed. Its NMR spectrum was found to be closely similar to that of the adduct IIA with exception of pattern due to aromatic protons (Tables 1 and 2). The structures of VIIA and VIIB were assigned as shown in Fig. 2.

The hydrogenations of VII and VIII with Raney Ni T-4 gave ethyl 2-amino-3-(*m*-aminophenyl)-bicyclo[2.2.1]heptane-2-carboxylate (IX) and ethyl 2-amino-3-(*p*-chlorophenyl) bicyclo[2.2.1]heptane-2-carboxylate (X), from which crystalline amino esters, IXB and X′ were obtained respectively. The hydrolysis of IXB and X with 6 N hydrochloric acid or barium hydroxide afforded hydrochlorides of corresponding amino acids XIB and XII, respectively (Table 5).

The Diels-Alder reaction of ethyl α-nitrocrotonate[1,12] with 1,3-cyclohexadiene gave an adduct, ethyl 3-methyl-2-nitrobicyclo[2.2.2]-5-octene-2-carboxylate (XIII) in 25% yield. The gas chromatogram of XIII showed three peaks. Hydrogenation of XIII with Raney Ni T-4 gave ethyl 2-amino-3-methylbicyclo[2.2.2]octane-2-carboxylate (XIV), which, on hydrolysis with barium hydroxide, afforded 2-amino-3-methylbicyclo[2.2.2]octane-2-carboxylic acid(XV).

Experimental

Thin layer chromatography (TLC) was conducted by the use of silica gel (Daiichi Pure Chemicals Co., Inc.). The prepared plates were activated at 110°C. The spray reagent used was concentrated sulfuric acid and 0.25% pyridine solution of ninhydrin. Silica

12) S. Umezawa and S. Zen, This Bulletin, **36**, 1143 (1963).

gel column chromatography was carried out by the use of silica gel (Kanto Chemicals Co., Inc.) activated at 110°C before use. The pK_a values were determined by the method of Parks and Davis.[13] Gas-liquid chromatographic analysis was carried out with a Shimadzu-Kotaki Gas Chromatograph, Model GU-21. The NMR spectra were taken with a Japan Electron Optics JNM-H-60 spectrometer at a frequency of 60 Mc by using about 10—20% solution of the sample in deuteriochloroform with tetramethylsilane as an internal standard. Spin decoupling experiments were carried out by using Japan Electron Optics JNM-4H-100 spectrometer and JNM-SD-30 spin decoupler.

Ethyl 2-Nitro-3-(*p*-nitrophenyl)bicyclo[2.2.1]-5-heptene-2-carboxylate (II) (A typical example of the general procedure). A mixture of ethyl α,*p*-dinitrocinnamate (mp 108—109°C from ether) (1.0 g, 3.76 mmol), freshly distilled cyclopentadiene (2.0 g, 30.3 mmol) and dry benzene (2 m*l*) was heated for 1.5 hr at 120°C in a sealed tube. Unchanged cyclopentadiene and benzene were removed in a vacuum. The resulting red-brown oil was placed on a silica gel column (20 g, 2×15 cm) and eluted with 25% petroleum ether in benzene. The first effluent (*ca.* 90 m*l*) containing dicyclopentadiene was discarded. The second effluent (180 m*l*) gave the adduct II (1.26 g, 100%) as a pale-yellow crystalline solid. TLC (6 : 1 *n*-hexane/ethyl acetate) of II showed two spots having R_f-values of 0.5 and 0.4.

The other adducts VII, VIII and XIII were prepared by the general procedure (Table 1). The preparations of VIII and XIII, however, were carried out without solvent and purification was done by distillation. The gas chromatographic analysis of XIII on polyester-succinate column (1-m long) at 180°C with helium (40 m*l*/min) showed three peaks with elution times of 20.0, 22.0 and 26.4 min.

The Separation of Diastereoisomers of the Adduct II and VII. Separation of the Fraction II_1 and II_2. A sample of 1.04 g of II in a small amount of ethyl acetate was placed on a silica gel column (100 g, 3×38 cm) and eluted with 6 : 1 *n*-hexane/ethyl acetate in the flow rate of 12 m*l*/hr. Fractions (*ca.* 4 m*l*) were collected and examined by TLC with the same solvent system as the column chromatography. Fractions 80—118 (150 m*l*) gave II_1 (R_f 0.5; 70 mg, mp 74—114°C). Fractions 124—190 (270 m*l*) gave II_2 (R_f 0.4; 676 mg, mp 71—79°C) and fractions 119—123 (20 m*l*) gave a II_1-II_2 mixture (15 mg). Total yield was 73.2% based on the original adduct II.

Adduct IIA: Recrystallization of the fraction II_1 (230 mg) from methanol gave IIA (115 mg), colorless needles, mp 119—120°C.

Adduct IID: The separation of the adduct IID from its isomer IIA was a laborious work. The mother liquor separated from the first crop of IIA was evaporated to give a yellow crystalline mass melting at 64—70°C. A sample (30 mg) of the material was dissolved in hot methanol (0.6 m*l*). After inoculation of pure IID as a seed, the solution was allowed to stand overnight in a refrigerator to afford colorless large plates of IID (9 mg) which was partly contaminated by the needles of IIA. The plates (4 mg) of IID were picked out with a tweezer from the mixture; mp 79—80°C. The products from similar twelve batches were pooled (50 mg) and recrystallized from methanol to yield 33 mg of an analytical sample, mp 81—81.5°C.

Adduct IIB: A sample (656 mg) of the above-mentioned fraction II_2 was recrystallized from hot methanol (12 m*l*) by inoculation of pure crystals of IIB to give granular crystals (425 mg) of IIB melting at 104.5—106.2°C. Recrystallization afforded an analytical sample, mp 107—108°C. An additional crop (64 mg) of IIB was obtained from the mother liquor; total yield, 489 mg (74.5%).

Adduct IIC: The mother liquor separated from the second crop of IIB was evaporated to give a crystalline mass, which was recrystallized from methanol by inoculation of seed crystals of IIC to afford granular crystals (105 mg) melting at 78.5—80.0°C. An analytical sample of IIC was obtained by one recrystallization from methanol, mp 79—80°C.

Adduct VIIA: (A rare example of the separation of of VIIA). When a mixture adduct VII (1.20 g) prepared by above-mentioned general procedure was triturated with 3 m*l* of ethanol and the triturated mixture was allowed to stand for several hours in a cold place, there separated the crystals of VIIA; yield, 470 mg, mp 82—92°C. Two recrystallizations from ethanol afforded an analytical sample, mp 101—102°C.

Ethyl 2-Amino-3-(*p*-aminophenyl)bicyclo[2.2.1]-heptane-2-carboxylate (IIIB) (A typical example of the general procedure). A solution of ethyl 2-nitro-3-(*p*-nitrophenyl)bicyclo[2.2.1]-5-heptene-2-carboxylate (IIB) (1.5 g) in ether (25 m*l*) was shaken with Raney Ni T-4 (7 m*l*) at 20—25°C and 120 kg/cm² for 5 hr in an autoclave. The contents were then filtered to remove the catalyst and the solution was evaporated in a vacuum. A solution of the resulting oil (1.08 g) in ether (30 m*l*) was extracted with 1 N hydrochloric acid (9 m*l*), and the ethereal solution was washed with water (10 m*l*×4). The aqeuous layer and washings were combined, washed with ether (10 m*l*) and made alkaline by addition of a 50% potassium carbonate solution (2.5 m*l*). The liberated oil was extracted with ether (10 m*l*×4), and the ethereal extract was dried over potassium carbonate. After evaporation of the solvent, the amino ester IIIB was obtained as a pale-yellow viscous oil; yield, 967 mg (77.8%).

The other amino esters, III (isomeric mixture), IIIA, IIIC, IX, X and XIV were prepared by the general procedure. The hydrogenations of X and XIV were carried out in ethanol instead of in ether. The crystalline amino esters IXB and X′ were isolated from the corresponding mixed ester IX and X in a yield of 46.4% and 15%, respectively (Table 4).

The hydrochlorides of IIIA, IIIB, IIIC, IXB, X′, and XIV were obtained from their ethanolic hydrogen chloride solution by dilution with absolute ether (Table 4).

2-Amino-3-(*p*-aminophenyl)bicyclo[2.2.1]heptane-2-carboxylic Acid Dihydrochloride (IVB·2HCl) (A typical example of the general procedure). A solution of IIIB (220 mg) in 6 N hydrochloric acid (5.5 m*l*) was heated in a sealed tube at 110—120°C for 8 hr. After refrigeration of the reaction mixture, the precipitated dihydrochloride of IVB was collected and washed with acetone to afford colorless fine crytals; yield, 218 mg (85.2%). By concentration of the mother

13) T. V. Parke and W. W. Davis, *Anal. Chem.*, **26**, 642 (1954).

liquor the second crop of IVB·2HCl (42 mg) was obtained. Tow recrystallizations from methanol-diisopropyl ether gave an analytical sample, granular crystals; mp 270°C (decomp.).

The dihydrochlorides, IVC·2HCl and XIB·2HCl were prepared by the general procedure, but the isolation of IVC·2HCl was accomplished by evaporation of the reaction mixture, because of its high solubility in cold hydrochloric acid. An analytical sample of IVC·2HCl was obtained by recrystallization from absolute methanolic hydrogen chloride-diisopropyl ether.

2-Amino-3-(*p*-aminophenyl)bicyclo[2.2.1]heptane-2-carboxylic Acid Dihydrochloride (IVA·2HCl). A solution of IIIA (220 mg) in 6 N hydrochloric acid (5.0 ml) was heated in a sealed tube at 110—120°C for 16 hr. The resulting mixture was evaporated in a vacuum to give a solid mass, which was washed with ether and acetone. The yellow powdery product (180 mg) was placed on a silica gel column (1.5×30 cm) and developed with a solvent system of ethyl acetate-pyridine-methanol (3 : 1 : 1) until the yellow band of amino acid was separated completely from the orange band of unchanged amino ester on the column. The silica gel containing amino acid band in a upper portion of the column was scraped out and extracted out with methanol. The methanol extract was evaporated to give an oil which crystallized by trituration with absolute ether; yield, 130 mg (64%). Recrystallization from absolute ethanolic hydrogen chloride-diisopropyl ether afforded an analytical sample of IV·2HCl, mp 232°C(colored)—275°C(decomp.).

2-Amino-3-(*p*-chlorophenyl)bicyclo[2.2.1]heptane-2-carboxylic Acid (XII) and 2-Amino-3-methylbicyclo[2.2.2]octane-2-carboxylic Acid (XV). XII and XV were prepared from X and XIV, respectively by hydrolysis with 0.45 N barium hydroxide in aqueous methanol at 36—37°C for 20 hr, by the similar method as reported previously.[1] The hydrochlorides of XII and XV were obtained from their ethanolic hydrogen chloride solution by dilution with absolute ether.

Ethyl α,*p*-Dinitrocinnamate[2] (I). The NMR signals were observed at $\tau(CDCl_3)$: 2.04 (center of A_2B_2 pattern, aromatic protons); 2.35 (a singlet, β-proton); 5.53 (a quartet, ester methylene protons); and 8.62 (a triplet, ester methyl protons).

Ethyl α,*m*-Dinitrocinnamate (III). Prepared from *m*-nitrobenzylidene-*n*-butylamine[14] and ethyl nitroacetate by the same method as reported by Dornow and Menzel[2]; yield, 61%, mp 101—102°C (from ether). The NMR signals were observed at $\tau(CDCl_3)$: 2.28 (a singlet, β-proton); 5.54 (a quartet, ester methylene protons); and 8.59 (a triplet, ester methyl protons).

Found: C, 49.85; H, 3.95; N, 10.43%. Calcd for $C_{11}H_{10}O_6N_2$: C, 49.63; H, 3.79; N, 10.52%.

The authors are indebted to Professor Shoji Hara, Tokyo College of Pharmacy and Dr. Keishi Kotera, Tokyo Tanabe Seiyaku Co. for the measurement of NMR spectra, and Mr. Saburo Nakada for the microanalyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 199—202 (1969)

A New Synthesis of Tephrosic Acid*1

Kenji FUKUI, Mitsuru NAKAYAMA and Teruo HARANO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Sendamachi, Hiroshima

(Received May 27, 1968)

2′-Carboethoxymethoxy-4′,5′-dimethoxy-7-hydroxyisoflavone was prepared from 7-benzyloxy-4′,5′-dimethoxy-2′-hydroxyisoflavone *via* the corresponding 2′-carboethoxymethoxyisoflavone. The hydrolysis of the 7-hydroxyisoflavone with dilute alkali gave tephrosic acid (2,4-dihydroxyphenyl 2-carboxymethoxy-4,5-dimethoxybenzyl ketone) in a good yield.

Tephrosic acid (I) is an important intermediate in synthesizing rotenoids (*e. g.*, elliptone (II) and munduserone (III)). This acid, I, has been prepared from resorcinol and ethyl (2-cyanomethyl-4,5-dimethoxyphenoxy)acetate (IV) by the Hoesch reaction.[1] However, the preparation of the ester IV has been found to be disadvantageous because of either a poor over-all yield or the tediousness of separating an intermediate difficult to crystallize. The present paper will describe a convenient method of synthesizing I from 7-benzyloxy-4′,5′-dimethoxy-2′-hydroxyisoflavone (V)[2] according to a modification of a procedure reported earlier by the present

*1 The results of this investigation were presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967.

authors[3] and also be Chandrashekar *et al.*[4]

The reaction of the 2'-hydroxyisoflavone V with ethyl bromoacetate in the presence of anhydrous potassium carbonate afforded 7-benzyloxy-2'-carboethoxymethoxy-4',5'-dimethoxyisoflavone (VI) in a good yield. By catalytic hydrogenolysis over palladium-charcoal, the 7-benzyloxyisoflavone VI gave 2'-carboethoxymethoxy-4',5'-dimethoxy-7-hydroxyisoflavone (VII), which was then easily converted into its monoacetate by conventional methods. The treatment of VII with alcoholic potassium hydroxide gave the desired acid, I, in a good yield. This was identified with an authentic

specimen[5] by a mixed-melting-point determination and by infrared and ultraviolet spectral comparisons (Figs. 1 and 2).

The partial methylation of the acid I with diazomethane gave a methyl ester. A comparison of the NMR spectrum of the ester with that of the 2-hydroxy-4-methoxyphenyl 2,4,5-trimethoxybenzyl ketone (VIII)[6] (Table 1) indicated that the methylated specimen should be represented as 2-hydroxy-4-methoxyphenyl 2-carbomethoxymethoxy-4,5-dimethoxybenzyl ketone (IX). Finally, the hydrolysis of IX with dilute alkali gave tephrosic acid monomethyl ether (X), which had previously been obtained by an alternative route.[3]

Since the synthesis of (±)-II from I has already been carried out,[5] this paper completes the presentation of a new synthesis of (±)-II.

Experimental*2

7-Benzyloxy-2′-carboethoxymethoxy-4′,5′-dimethoxyisoflavone (VI). To a solution of isoflavone (V: mp 172—173°C)[2] (400 mg) and ethyl bromoacetate (200 mg) in anhydrous acetone (50 m*l*), anhydrous potassium carbonate (1.5 g) was added; the mixture was then refluxed for 24 hr. After the inorganic salts had been filtered off, the solution was concentrated to 5 m*l* and then diluted with water. The separated solid was collected and recrystallized from ethanol to give VI as colorless needles, mp 112—113°C; yield, 370 mg (77%). IR: 1736, 1640, 1620 cm^{-1} (C=O). UV: λ_{max} mμ (log ε); 248 (4.39), 296 (4.29).

Found: C, 68.38; H, 5.27%. Calcd for $C_{28}H_{26}O_8$: C, 68.57; H, 5.30%.

2′-Carboethoxymethoxy-4′,5′-dimethoxy-7-hydroxyisoflavone (VII). A solution of VI (320 mg) in ethyl acetate (100 m*l*) was submitted to catalytic hydrogenolysis at room temperature in the presence of Pd-C (10%: 90 mg). After the catalyst had been filtered off, the filtrate was evaporated under a vacuum; the residue was then recrystallized from ethanol to give VII as colorless microneedles, mp 217.5—218.5°C (lit.[7] mp 217—218°C); yield, 240 mg (92%). IR: 3250 (OH), 1735, 1633 cm^{-1} (C=O). UV: λ_{max} mμ (log ε); 255 (4.53), 296.5 (4.28), 336 (4.01).

Found: C, 63.08; H, 5.13%. Calcd for $C_{21}H_{20}O_8$: C, 62.99; H, 5.04%.

The acetate: acetic anhydride-anhydrous sodium acetate method; mp 137—138°C (colorless microneedles from ethanol). IR: 1768, 1733, 1655, 1625 cm^{-1} (C=O). UV: λ_{max} mμ (log ε); 294 (4.12).

Found: C, 62.19; H, 4.93%. Calcd for $C_{23}H_{22}O_9$: C, 62.44; H, 5.01%.

Tephrosic Acid (2,4-Dihydroxyphenyl 2-Carboxymethoxy-4,5-dimethoxybenzyl Ketone) (I). To a solution of VII (200 mg) in ethanol (50 m*l*), a 10% aqueous potassium hydroxide solution (20 m*l*) was added; the mixture was then refluxed for 2 hr. After the solvent had been removed as much as possible, the residue was acidified with 10% hydrochloric acid. The separated solid was collected and recrystallized from aqueous ethanol to give I as colorless microcrystals, mp 193—195°C (lit., mp 197°C,[1] mp 192.5—194°C,[5] mp 196°C[8]); yield, 100 mg (56%). It gave a reddish-brown color with an alcoholic ferric chloride solution. IR: 3530, 3430, 3230 (OH), 1715, 1638 cm^{-1} (C=O). UV: λ_{max} mμ (log ε); 231 (4.22), 282 (4.21), 314$_i$ (3.96).*3

Found: C, 58.07; H, 5.37%. Calcd for $C_{18}H_{18}O_8 \cdot \frac{1}{2}H_2O$: C, 58.22; H, 5.15%.

2-Hydroxy-4-methoxyphenyl 2-Carbomethoxymethoxy 4,5-dimethoxybenzyl Ketone (IX). I (25 mg) in ether (30 m*l*) was treated with an excess of diazomethane in ether. After standing at room temperature for 24 hr, the mixture was evaporated under a vacuum to dryness. The residue was recrystallized from ethanol to give IX as colorless needles, mp 125—126°C; yield, 25 mg (94%). It gave a reddish-brown color with an alcoholic ferric chloride solution. IR: 1740, 1635 cm^{-1} (C=O). UV: λ_{max} mμ (log ε): 229 (4.25), 278 (4.20), 316 (3.92).

Found: C, 61.62; H, 5.57%. Calcd for $C_{20}H_{22}O_8$: C, 61.53; H, 5.68%.

Tephrosic Acid Monomethyl Ether (2-Hydroxy-4-methoxyphenyl 2-Carboxymethoxy-4,5-dimeth-

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 202—205 (1969)

Studies of the Organic Reactions of Metal Carbonyls. XV.*1 The Reaction of Potassium Iron Carbonylates with Various Kinds of Olefin Oxides

Yoshinobu TAKEGAMI, Yoshihisa WATANABE, Takeaki MITSUDO and Hiromitsu MASADA

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received May 27, 1968)

The reaction between potassium iron carbonylates ($KHFe(CO)_4$, $K_2Fe(CO)_4$ and $K_2Fe_2(CO)_8$) and different olefin oxides has been studied. 1,2-Olefin oxides generally react with these carbonylates and carbon monoxide under an atmospheric pressure and at 30°C. This reduction gives the corresponding terminal olefins and the internal olefins which are formed from the 1-olefins by isomerization. Internal olefin oxides do not react with the carbonylates under the reaction conditions employed. The reduction reaction seems to compete with the carbonylation reaction. A mechanism for the reduction reaction is suggested.

Ethylene oxide and propylene oxide react with potassium iron carbonylates ($KHFe(CO)_4$, $K_2Fe(CO)_4$ and $K_2Fe_2(CO)_8$) and carbon monoxide;[1] carbon monoxide is readily absorbed, and carbonylated products, β-hydroxy esters, are obtained by the treatment of the reaction mixture with an alcoholic solution of iodine. The yield of the esters, however, is very low. Previously it has been shown that styrene oxide also reacts with these iron carbonylates and carbon monoxide to give styrene, α- and β-phenylethyl alcohol, and carbon dioxide, but no carbonylated compound.[2] These facts show that the structure of olefin oxides has a relatively large effect on this reaction. The present work will describe and interpret the reaction, mainly the reduction, o various olefin oxides with the iron carbonylates.

Experimental

The Preparation of Potassium Iron Carbonylates, $KHFe(CO)_4$, $K_2Fe(CO)_4$, and $K_2Fe_2(CO)_8$. The alcoholic solutions of these salts were prepared under a carbon monoxide atmosphere according to the method described in a previous paper:[1] a 50-m*l* portion of a 0.22 M $KHFe(CO)_4$, $K_2Fe(CO)_4$, or 0.11 M $K_2Fe_2(CO)_8$ solution was used in each run.

When $K_2Fe(CO)_4$ is prepared, two equivalent moles of water are formed:[3]

$$Fe(CO)_5 + 4KOH \xrightarrow{\text{in alcohol}} K_2Fe(CO)_4 + K_2CO_3 + 2H_2O \quad (a)$$

Therefore, when a dry solution of $K_2Fe(CO)_4$ was required, the solvent of the $K_2Fe(CO)_4$ solution was distilled off once under a vacuum and then 50 m*l* of a new dry solvent was added.

Materials. The ethylene oxide was obtained from ethylene chlorohydrin and alkali. The propylene oxide,

*1 Presented at the 21st Annual Meeting of the Chemical Society, Osaka, April, 1968. Part XIV: Y. Takegami, Y. Watanabe, I. Kanaya, T. Mitsudo, T. Okajima, N. Morishita and H. Masada, This Bulletin, **41**, 2990 (1968).

the butylene oxides, the iron pentacarbonyl, and the other compounds employed in this study were commercial products.

Reaction Procedures. To the solution of potassium iron carbonylate described above, 2.6 g of propylene oxide was added; the mixture was then agitated vigorously at 30°C under an atmospheric pressure of carbon monoxide or nitrogen. The amount of carbon monoxide absorbed was determined volumetrically. After a certain reaction time, the reaction flask was connected to a cold trap immersed in liquid nitrogen, which was joined with a vaccum pump. The gases were collected in the trap at 30 mmHg for five minutes. The trap was allowed to warm to room temperature and then heated to 80°C, and the gas evolved was analyzed. The reaction mixture was analyzed at the same time. The reactions of other olefin oxides with $K_2Fe(CO)_4$ were carried out similarly.

Analytical Procedure. The reaction products were analyzed by gas chromatography and by means of their infrared spectra, which had been taken on a Shimadzu model IR-27 infrared spectrometer.

Results

The Reaction of $K_2Fe(CO)_4$ and $KHFe(CO)_4$ with Ethylene Oxide. The results of the reaction are summarized in Table 1. The reactions were carried out at 5°C for 5 hr. Ethylene oxide readily reacts with $K_2Fe(CO)_4$ and carbon monoxide, while the reaction solution turns from light yellow to dark red brown. Ethylene is obtained as the reaction product in the amount of 0.5 mol*2 (Exp. 1). As a previous paper has shown,[1] 0.2 mol of a carbonylated product, β-hydroxypropionate, is obtained when the reaction mixture is treated with iodine and alcohol. The reaction also proceeds under nitrogen, but the yield of ethylene is low, 0.2 mol (Exp. 2). $KHFe(CO)_4$ is less reactive than $K_2Fe(CO)_4$ (Exp. 3).

Table 1. The reaction of ethylene oxide with potassium iron carbonylates*1

14	$K_2Fe(CO)_4$	dry EtOH	CO	4	1.8	0.25	0.26	0.08	0.59
15	$K_2Fe(CO)_4$	Acetone	CO	2	0	0	0	0	0

*1 1,2-Butylene Oxide/$Fe(CO)_4^{2-}$=3.2
*2 Carbonylated product (0.1 mol/mol-$Fe(CO)_4^{2-}$) and 0.13 mol/mol-Fe $(CO)_4^{2-}$ of *s*-butyl alcohol are obtained simultaneously.

*3 "Mol" means mole per gatom of Fe, which is present as iron carbonylate.

carbon monoxide. The carbon monoxide absorbed amounts to more than 2 mol, and 0.4 mol of a carbonylated product, β-hydroxybutyrate, is formed simultaneously. The reactions with $K_2Fe(CO)_4$ under nitrogen (Exp. 5) and with $KHFe(CO)_4$, (Exp. 6) have a tendency similar to those of the reactions of ethylene oxide (Exps. 2, 3).

The Reaction of $K_2Fe(CO)_4$, $KHFe(CO)_4$, and $K_2Fe_2(CO)_8$ with 1,2-Butylene Oxide. *In an Ethanol Solvent (Including 2 mol of H_2O).*[*3] The results are summarized in Table 3. 1,2-Butylene oxide is also reduced with $K_2Fe(CO)_4$ and carbon monoxide to give butenes. More than 2 mol of carbon monoxide is absorbed in several hours, but the formation of butenes ceases after 1 hr and its yield is 0.5 mol at the maximum. The major product is not 1-butene, the corresponding olefin, but 2-butenes, which may be derived from 1-butene by isomerization. In Exp. 9, a carbonylated product (0.10 mol) and *s*-butyl alcohol (0.13 mol) were also detected, and 2.0 mol of carbon dioxide was evolved when the reaction mixture was acidified with concentrated hydrochloric acid.

The reduction reaction also proceeds under nitrogen, but the yields of butenes are low (Exp. 10), and $KHFe(CO)_4$ is less reactive than $K_2Fe(CO)_4$ (Exp. 11). $K_2Fe_2(CO)_8$ also reacts with 1,2-butylene oxide, absorbing carbon monoxide rapidly, but hardly any butenes are detected (Exp. 12).

In a Dry Ethanol Solvent. When a dry ethanol solvent is used, the total yield of the olefins increases and the major product is 1-butene, showing that the isomerization to 2-butenes is fairly well retarded (*cf.* Exp. 9 and Exp. 13).

In an aprotic solvent such as acetone, 1,2-butylene oxide does not react with the iron carbonylates (Exp. 15).

TABLE 4. THE REACTION OF OTHER EPOXIDE COMPOUNDS WITH $K_2Fe(CO)_4$

Exp. No.	Epoxide	Reaction conditions: Atmosphere	Reaction conditions: hr	CO absorbed mol/mol-$Fe(CO)_4^{2-}$	Yield of propylene mol/mol-$Fe(CO)_4^{2-}$
16	Epichlorohydrin	CO	2	1.5	0.53
17	Epichlorohydrin	N_2	2	—	0.41
18	Allyl glycidyl ether	CO	3	2.4	0.54
19	Glycidol	CO	3	1.5	0.06

Solvent, EtOH at 30°C
Epichlorohydrin/$Fe(CO)_4^{2-}$=5.8
Allyl glycidyl ether/$Fe(CO)_4^{2-}$=3.2
Glycidol/$Fe(CO)_4^{2-}$=4.5

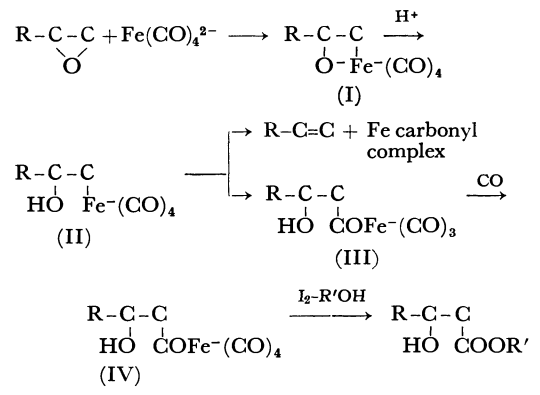
The Reaction of $K_2Fe(CO)_4$ with Epichlorohydrin, Allyl Glycidyl Ether, and Glycidol. The results are summarized in Table 4. These epoxide compounds also react with $K_2Fe(CO)_4$, absorbing a significant amount of carbon monoxide rapidly. Propylene, as the reaction product, is produced in any case, but allyl chloride, diallyl ether, and allyl alcohol, the corresponding reduction products, are not detected in the reaction mixture.

The Reaction of $K_2Fe(CO)_4$ with Internal Olefin Oxides. Internal olefin oxides, such as 2,3-butylene oxide and cyclohexene oxide, do not react with $K_2Fe(CO)_4$ under the conditions employed.

Discussion

The results obtained here show that 1,2-olefin oxides generally react with $K_2Fe(CO)_4$ and carbon monoxide to give not only the carbonylated products, but also the corresponding olefins. Further, the large amount of carbon monoxide absorbed suggests that some other reaction occurs. This complexity of the reaction was not observed in the reaction of $KCo(CO)_4$ with olefin oxides, which gives the carbonylated products selectively.[1]

The mechanism of the formation of olefin is not yet clear. One probable scheme is suggested below. The facts that $K_2Fe(CO)_4$ is the most active in the formation of olefins and that only the 1,2-olefin oxides react under the reaction conditions employed seem to support the following reaction scheme: in the first step, $Fe(CO)_4^{2-}$ makes a nucleophilic attack on the terminal carbon atom of 1,2-olefin oxide to give complex (I). In the reaction of internal olefin oxides, the nucleophilic attack of $Fe(CO)_4^{2-}$ may be retarded, mainly by a steric hindrance.



The complex (I) abstracts a proton from water or a solvent to give the complex (II). Olefin seems to be derived by the decomposition of the complex (II). This interpretation is supported by the fact that even under nitrogen the olefin is formed. Some iron carbonyl complex produced by the decomposition seems to regenerate iron carbonylate (Fe-

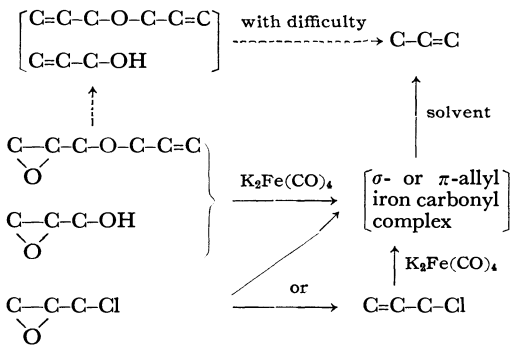
*3 *Cf.* Eq. (a).

$(CO)_4^{2-}$), with the absorption of CO, which then further reacts with olefin oxide. This scheme is supported by the fact that the yield of olefin under carbon monoxide is larger than that under nitrogen. From the complex (II), β-hydroxyacyliron carbonylate (III and IV) may also be derived to give a β-hydroxy ester when treated with an alcoholic solution of iodine.

In the reaction of 1,2-butylene oxide with $K_2Fe(CO)_4$, a dry ethanol solvent is favorable to the formation of butenes. This effect can also be observed in the reaction of styrene oxide with $K_2Fe(CO)_4$.[2] In a dry and moist ethanol solvents, the major products are 1-butene and 2-butene respectively. This fact can be explained by assuming that an equilibrium between $K_2Fe(CO)_4$ and $KHFe(CO)_4$ exists in the reaction solution; the reaction of $K_2Fe(CO)_4$ gives the corresponding olefin, and the reaction of $KHFe(CO)_4$ gives the isomerized olefin. Cramer and Lindsey showed that $KHFe(CO)_4$ is active in the isomerization of 1-butene to 2-butene.[4]

$$K_2Fe(CO)_4 + H_2O \rightleftarrows KHFe(CO)_4 + KOH$$

From allyl glycidyl ether, glycidol, and epichlorohydrin, the corresponding olefins, allyl ether, allyl alcohol, and allyl chloride, are not detected. However, propylene is formed in a relatively good yield. The fact that allyl ether and ally alcohol react with $K_2Fe(CO)_4$ with much difficulty indicates that these compounds are not the intermediates of the formation of propylene from allyl glycidyl ether and glycidol.



On the other hand, allyl chloride and its derivatives react with $K_2Fe(CO)_4$ very readily to give olefins such as propylene.[2,5] These reactions may be considered to proceed *via* σ- and π-allyl iron carbonylate. In the light of this fact, the reaction of allyl glycidyl ether and glycidol with $K_2Fe(CO)_4$ seems to proceed *via* a kind of allyl iron carbonyl complex. The reaction of epichlorohydrin involves two possible routes; one is *via* allyl chloride, while the other involves some other step to the formation of a π- or σ-allyl iron carbonyl complex, as in the reaction of allyl glycidyl ether and glycidol.

Studies of the Organic Reactions of Metal Carbonyls. XVI.*1 Solvent Effects on the Hydroformylation of Propylene and on the Reaction of Cobalt Hydrocarbonyl with 1-Pentene

Yoshinobu TAKEGAMI, Yoshihisa WATANABE, Hiromitsu MASADA and Takeaki MITSUDO

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received July 7, 1968)

In the reaction of cobalt hydrocarbonyl with 1-pentene at 10°C, solvents have a great effect on the distribution of the products, caproylcobalt carbonyl (I) and α-methylvalerylcobalt carbonyl (II). The I-to-II ratio is 72 : 28 in toluene, in toluene-dioxane (1 : 1 in volume), and in toluene-ethyl acetate. The percentage of II increases to 40—66% in toluene-diethyl ether, -tetrahydrofuran, -acetone, -ethyl alcohol, and -acetonitrile. In the hydroformylation of propylene, the distribution of the products, *n*- and isobutyraldehyde, is also affected by the solvents. In toluene, the *n*-to-iso ratio is about 75 : 25, while in dioxane and in butyl acetate the percentage of the *n*-aldehyde increases to 79—83%. In methyl alcohol, dimethyl acetals of the aldehydes and *n*- and isobutyrate are formed. The *n*-to-iso ratio is the highest in the esters (3.2—8.5), followed by the acetals (0.7—1.6) and the aldehydes (0.4).

Several workers have reported on the influence of the reaction variables on the hydroformylation reaction of olefins, mainly on the composition of the products.[1] In the course of hydroformylation, a cobalt catalyst is considered to react with olefins as cobalt hydrocarbonyl to give alkyl- and acylcobalt carbonyls as the reaction intermediates.[2]

Previous studies of the hydroformylation of ethyl acrylate in this laboratory have shown that the isomerization of alkyl- and acylcobalt carbonyls has a remarkable effect on the isomeric distribution of the products.[3] Some of the present authors have also shown that the isomerization of *n*- and isobutyrylcobalt carbonyl is highly affected by the solvents; in dioxane only the iso isomer is isomerized; in ethyl acetate both isomer are isomerized, in a 7 : 3 *n*-to-iso ratio, and in toluene the isomerization is very slow.[4] On the basis of these results, the solvents can reasonably be considered to have a marked effect on the hydroformylation of olefins, particularly on the isomeric distribution of the products.

In the present study, the effects of different solvents on the hydroformylation of propylene and on the reaction of 1-pentene with cobalt hydrocarbonyl have been examined in detail.

Experimental

Reaction Procedures. Hydroformylation. An autoclave of a 300 m*l* capacity, made of 18-8 nickel-chrome steel and equipped with a magnetic stirrer, was used. Eighty milliliters of the solvent and 8 m*l* of a dicobalt octacarbonyl solution (containing 1.9 mmol of $Co_2(CO)_8$) were put into the autoclave. After the air in the autoclave had been replaced with hydrogen, 20 m*l* of liquid propylene was put into it, and then hydrogen and carbon monoxide were introduced at certain pressures using a compressor. The autoclave was kept at a certain temperature by electrical heating, but the heating was turned off when the gauge pressure ceased to decline.

Reaction with $HCo(CO)_4$. The reaction of 1-pentene with cobalt hydrocarbonyl was carried out

in the way described in a previous paper.[3a)]

Analysis of the Products. The products were identified by a mixed gas chromatography with authentic samples. A column three meters long and 3 mm in diameter, and filled with dilauryl phthalate on cerite, was used. The column temperature was 70 to 80°C, and the flow rate of the carrier gas (hydrogen) was 60 ml/min. The infrared absorption spectrum was taken on a Shimadzu Model IR-27 spectrophotometer.

Materials. The propylene, toluene, dioxane, butyl acetate, and other organic compounds were commercial products which had been proved to be sufficiently pure by gas chromatography. As authentic samples, the following commercial compounds were used: *n*- and isobutyraldehyde, *n*- and isobutyl alcohol, methyl caproate, and methyl α-methylvalerate. The dicobalt octacarbonyl solution was prepared according to the method given in a previous paper.[5)]

Results and Discussion

The Reaction of 1-Pentene with Cobalt Hydrocarbonyl. The results are summarized in Table 1. The reaction was carried out at 10°C for 4 hr in a mixed solvent (toluene: other solvent = 1 : 1 in volume). The 1-pentene reacts with cobalt hydrocarbonyl to give caproyl- and α-methylvalerylcobalt carbonyl, which then give the corresponding esters upon treatment with an iodine and alcohol.[2)]

As Table 1 shows, the solvents have a great effect on the distribution of the two isomers. In toluene the isomer with a straight chain structure predominates (72%); this percentage is almost independent of the solvents in such mixtures as toluene-ethyl acetate and toluene-dioxane (Exps. 1—3). However, in toluene-acetonitrile, α-methylvalerate with a branched chain structure is

dominant. Tetrahydrofuran, acetone, diethyl ether, and ethyl alcohol are also a little more favorable to the formation of α-methylvalerate. In this reaction, the factors determining the distribution of the two isomers are the direction of the addition of cobalt hydrocarbonyl to the double bond of 1-pentene and the isomerization between the C_6-acylcobalt carbonyls. However, this iso-

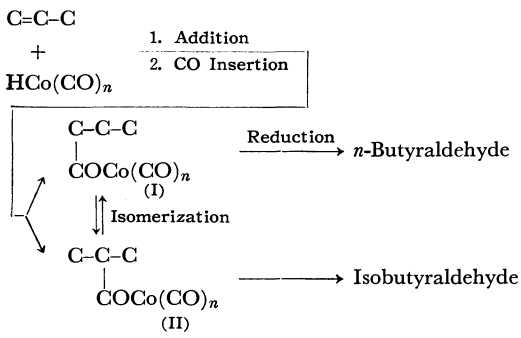
*** (iso-isomers/products) × 100.

merization occurs with much difficulty under the conditions employed.[4] Thus, the results obtained here show that the direction of the addition of cobalt hydrocarbonyl to the olefin is highly affected by the solvents.

Hydroformylation of Propylene. The effects of variables, especially solvents, on the distribution of the products were also examined. The results are summarized in Tables 2 and 3 and in Figs. 1 and 2. Under the conditions employed, butyraldehydes were obtained in 93—97% yields, while butyl alcohols were also produced as minor products in 3—7% yields. The reaction is considered to proceed as follows:



In Toluene. The percentage of *n*-butyraldehyde changes over the 73—77% range at 100°C. In the light of the fact that *n*- and isobutyrylcobalt carbonyl isomerize with much difficulty in toluene,[4a] the distribution of the two aldehydes may be determined mainly by the direction of the addition of cobalt hydrocarbonyl.

In Dioxane. Under any conditions, the percentage of *n*-butyraldehyde grows larger in dioxane (79—82% at 100°C) than in toluene (73—77% at 100°C). Dioxane has a great promoting effect on the isomerization of isobutyrylcobalt carbonyl to the *n*-isomer at room temperature.[4a] Under hydroformylation conditions in dioxane, such an isomerization can reasonably be considered to occur, thus affecting the distribution of the products. This consideration seems to be supported by the fact that dioxane has no effect on the addition of cobalt hydrocarbonyl to 1-pentene, as has been described above.

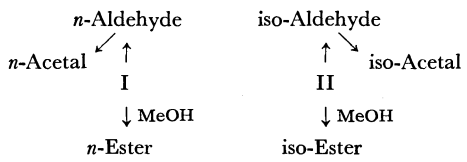
In Butyl Acetate. As Table 2b shows, butyl acetate is also a more favorable solvent for the formation of *n*-butyraldehyde than toluene. Acetate also promotes the isomerization of the isobutyrylcobalt carbonyl[4a] and has no effect on the addition of cobalt hydrocarbonyl to 1-pentene. Thus, it is possible to interpret the effect of butyl acetate by employing arguments similar to those presented for dioxane.

In Acetone and Diethyl Ether. The percentage of isobutyraldehyde increases to 35 and 40% in acetone and in diethyl ether respectively. This tendency is consistent with the fact that these are taken to be more favorable solvents for the formation of a compound with a branched chain structure in the reaction of cobalt hydrocarbonyl with 1-pentene. Under hydroformylation conditions in these solvents, isobutyrylcobalt carbonyl may be formed more readily by the addition of cobalt hydrocarbonyl to propylene.

Effects of Partial Pressures of Carbon Monoxide and Hydrogen. As Figs. 1 and 2 show, at 100°C in toluene the percentage of isobutyraldehyde decreases with an increase in the partial pressures of carbon monoxide, but increases with an increase in the partial pressures of hydrogen. In dioxane or butyl acetate, however, the percentage of the iso-aldehyde has a minimum at 80 atm of the initial partial pressures of both carbon monoxide and hydrogen. This phenomenon seems to be partly due to the tendency of butyrylcobalt carbonyls

to isomerize in these polar solvents. The distribution of the products is considered to depend in part on two competitive reactions, the reduction and the isomerization of butyrylcobalt carbonyls. Larger partial pressures of carbon monoxide have an inhibitory effect on these reactions,[2,4] but larger partial pressures of hydrogen seem to promote the reduction. The reason why the minimum is observed is, however, not completely clear.

In Methyl Alcohol. As Table 3 shows, in methyl alcohol *n*- and isobutyraldehyde (0—8%), *n*- and isobutyraldehyde-dimethyl acetal (30—80%), and methyl *n*- and isobutyrate (13—70%) are obtained. Under any conditions employed, the aldehydes are readily converted to the corresponding acetals. At low pressures of hydrogen the esters predominate, but at high pressures of hydrogen the acetals predominate. These compounds may be formed according to the following reaction scheme:



The *n*-to-iso ratio is the highest in the esters (3.3—8.5), followed by the acetals (0.7—1.6) and the aldehyde (0.4). In the light of this fact, the esterification of *n*-butyrylcobalt carbonyl (I) to *n*-butyrate may be said to occur more readily than that of the iso-isomer (II), but the reduction rate of the *n*-isomer is alsmost comparable with that of the iso-isomer. In the stage of the addition of cobalt hydrocarbonyl, equimolar amounts of the *n*- and iso-isomer seem to be formed in methyl alcohol.*2 Thus, under the conditions favorable for the formation of the esters, the fast esterification of I seems to promote the isomerization of II to I, and then the *n*-to-iso ratio of the products increases greatly (Exp. 48).

This work was supported in part by The Kawakami Foundation, to which our thanks are due. We are also grateful to Professor Y. Takezaki and Dr. N. Sugita for their permission to use the compressors.

*2 1-Pentene gives *n*- and iso-C_6-acylcobalt carbonyls in a 1-to-1 ratio in ethyl alcohol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 210—214 (1969)

Photolysis of Nitrosobenzene

Rikuhei TANIKAGA

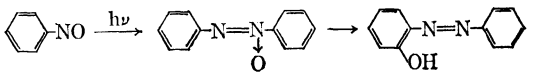
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto

(Received May 27, 1968)

The mechanism of the photochemical reaction of nitrosobenzene (I) has been investigated. The irradiation of I leads to the formation of a phenyl radical and nitric oxide. The reaction of the phenyl radical with I yields diphenylnitroxide, which is then easily reduced to diphenylamine. The reaction of diphenylamine with the nitric oxide gives *C*-nitrosodiphenylamines, which are then photochemically oxidized to *C*-nitrodiphenylamines. On the other hand, I is oxidized to nitrobenzene and is, at the same time, reduced to azoxybenzene and azobenzene. Azoxybenzene is photochemically rearranged to 2-hydroxyazobenzene.

Nitrosobenzene (I) is known to be photochemically unstable.

Bamberger reported that azoxybenzene (II), 2-hydroxyazobenzene (III), 4-hydroxyazobenzene, 2-hydroxyazoxybenzene, nitrobenzene, aniline, and other minor products were obtained by the photolysis of I in benzene with sunlight,[1] but it is not clear whether or not his products other than II and III were really formed by the photolysis, because his assignment was doubtful and his analytical methods involved such improper procedures as treatment with heat, an acid and a base.

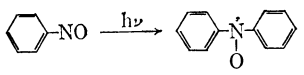


I II III

We found, by means of the ESR technique that the irradiation of I in tetrahydrofuran with a high-pressure mercury lamp led to the fission of the phenyl-nitroso bond and yielded diphenylnitroxide (IV).[2]

1) E. Bamberger, *Ber.*, **35**, 1606 (1902).

2) K. Maruyama, R. Tanikaga and R. Goto, This Bulletin, **37**, 1893 (1964).



I IV

Recently Shamma *et al.* irradiated I in ethanol at 253.7 mμ and obtained diphenylamine and *C*-nitrodiphenylamines by means of column chromatography; they then, without proof, assumed that the formation of diphenylamines could be followed by that of *N*-nitrosodiphenylamine.[3]

A principal objective of this work is to clarify the mechanism of the photochemical reaction of I by assigning the products.

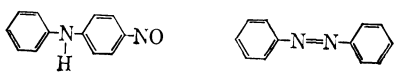
Results and Discussion

An ethanolic solution of nitrosobenzene (I) (10^{-1} M) in a Pyrex tube was irradiated with a high-pressure mercury lamp. The results are given in Table 1.

Table 1. Irradiation of nitrosobenzene (10^{-1}M) at 25.0±0.1°C

Irradn. time (hr)	Yields of products (%) 2	10
Nitrosobenzene (I)	85.4	63.9
Diphenylnitroxide (IV)	2.0	1.2
Diphenylamine (V)	2.9	6.4
4-Nitrosodiphenylamine (VI)	0.1	0.2
4-Nitrodiphenylamine (VII)	0.4	1.0
2-Nitrodiphenylamine (VIII)	0.6	1.5
Azoxybenzene (II)	3.9	5.4
2-Hydroxyazobenzene (III)	1.8	5.0
Azobenzene (IX)	0.9	3.1
Nitrobenzene (X)	—	*ca.* 1.0
Aniline (XI)	—	<0.5

No remarkable differences from the above results were found upon the irradiation of I in benzene under a nitrogen atmosphere. VI and IX had not previously been obtained.



VI IX

Thin layer chromatography (TLC) of the irradiated solution showed that the expected β-phenylhydroxylamine, *N*-nitrosodiphenylamine, and 3-nitrodiphenylamine were not formed; on the other hand, tarry materials and smaller amounts of by-products were present, especially after a long irradiation. Hence, irradiation for many hours is not desirable in the investigation of the photolysis of I.

Although the photolysis involves very complex reactions, it seems to be possible to divide these reactions into the following three classes:

i) Reaction Process A: The bimolecular reaction of nitrosobenzene (I), followed by a phenyl-nitroso bond-rupture, affords diphenylnitroxide (IV), diphenylamine (V), 4-nitrosodiphenylamine (VI), 4-nitrodiphenylamine (VII), and 2-nitrodiphenylamine (VIII).

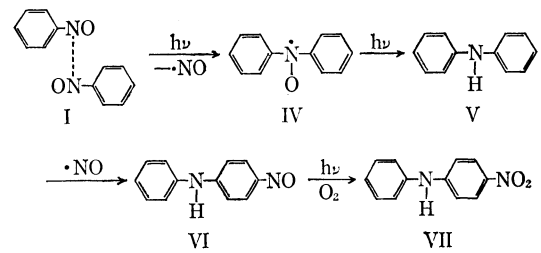
ii) Reaction Process B: The bimolecular reaction of I, followed by a N–O bond-rupture, affords azoxybenzene (II), 2-hydroxyazobenzene (III), and azobenzene (IX).

iii) Reaction Process C: The oxidation or the reduction of monomeric I affords nitrobenzene (X) or aniline (XI).

The mechanisms of these processes will be described below.

Reaction Process A:

Scheme A:



The photochemical reaction of I to IV was described in a previous paper.[2] Later, a similar reaction of nitrosoalkane was reported.[4,5] The finding that no benzene was obtained suggests that the dimeric or a similar form gave rise to the formation of IV.[6] This result is also consistent with the fact that no IV is formed from the photolysis of I with red light,[5] with which only the monomeric form could be excited.

IV is known to be unstable and has been supposed to give V in connection with aryl-*t*-butylnitroxides.[7] Indeed, the irradiation of IV in ethanol produces V easily.

In order to discuss the V-to-VI process, *N*-nitrosodiphenylamine (XII), which had been

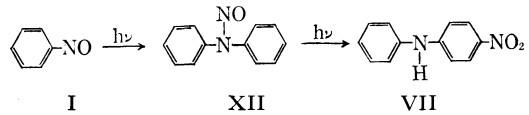
assumed to be an intermediate by Shamma *et al.*,[3] was chosen as a model compound for two reasons. One reason was that XII was expected to give both V and nitric oxide, as in the photolysis of *N*-nitrosamides.[8] The other was that no XII was obtained from the photolysis of I; therefore, it had to be decided whether XII was not an intermediate, or whether the photochemical reaction of XII was so fast that no XII could be detected.



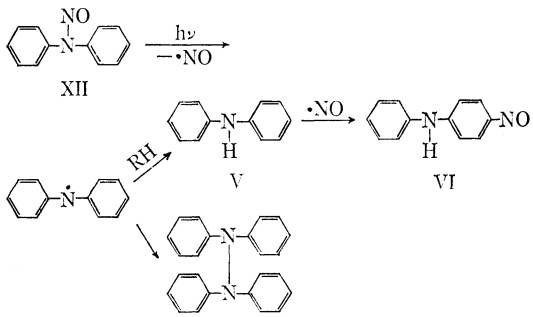
I XII VII

An ethanolic solution of XII (10^{-2} M) was irradiated with a Pyrex filter. The results are given in Table 2.

TABLE 2. IRRADIATION OF *N*-NITROSODIPHENYLAMINE (XII) (10^{-2}M) AT 25.0±0.1°C FOR 3 hr

Compd.	Yields of products (%)		
	Air	N_2	Degassed
XII	33.4	60.0	60.5
V	25.7	9.8	12.5
VI	0.5	1.7	0.0
VII	3.6	0.3	0.0
VIII	4.5	0.1	0.0
Carbazole	2.3	1.0	0.1

Table 2 shows that the N–N bond of XII was broken, and that then the nitric oxide intermolecularly attacked V to give VI. The homolytic fission of the N–N bond was also confirmed by the formation of tetraphenylhydrazine by the photolysis of a saturated ethanolic solution of XII.



XII V VI

Neither nitroso- nor nitro-diphenylamines were obtained in a degassed state. This finding can be explained by the removal of nitric oxide from the solution.

The well-known photochemical cyclization of V to carbazole[9] will not be discussed.

Under a nitrogen atmosphere, no nitro-compounds were obtained. This suggests that the nitrosodiphenylamine was photochemically oxidized to nitrodiphenylamine. In order to discuss this novel photochemical oxidation of a nitroso-compound to a nitro-compound, an ethanolic solution of VI (10^{-3} M) was irradiated with a Pyrex filter. The results are given in Table 3.

TABLE 3. IRRADIATION OF 4-NITROSODIPHENYLAMINE (10^{-3}M) AT 25.0±0.1°C

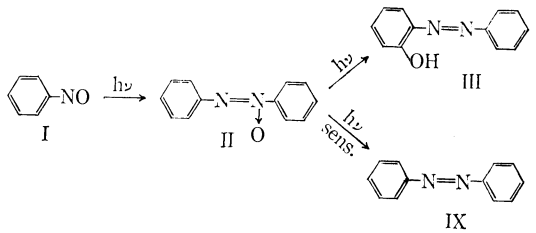
	Yields of products (%)		
Irradn. time	3 hr	3 hr	5 min
Sensitizer	—	V (10^{-2}M)	Ph_2CO (10^{-2}M)
VI	46.0	20.3	23.1
VII	13.8	17.3	24.4

Table 3 shows that VI underwent a photosensitized oxidation to VII, and that V could be a sensitizer, though not as efficient a one.

The results described above support Scheme A. XII cannot be an intermediate of I to nitrodiphenylamines, because the irradiation of I never afforded XII, whereas the photochemical reaction of XII was not fast enough.

Reaction Process B:

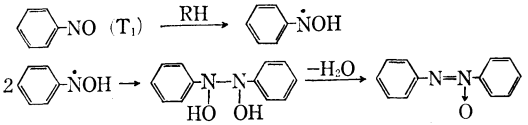
Scheme B:



I II III IX

III is formed from the excited singlet state of II,[10] and IX is formed from the excited triplet state of II,[11] as has been reported in previous papers. Although IX was never obtained upon the direct irradiation of II without a sensitizer, IX was obtained upon the irradiation of I. This finding can probably be explained in terms of sensitization of I through its excited triplet state.

Mauser *et al.*[12] postulated, without proof, the following mechanism for the photochemical reduction of I:



8) L. P. Kuhn, G. G. Kleinspehn and A. C. Duckworth, *J. Am. Chem. Soc.*, **89**, 3858 (1967).

9) D. C. Neckers, "Mechanistic Organic Photochemistry," Reinhold Publishing Corp., New York, N. Y. (1967), p. 239.

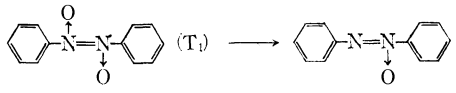
10) R. Tanikaga, This Bulletin, **41**, 2151 (1968).

11) R. Tanikaga, K. Maruyama, R. Goto and A. Kaji, *Tetrahedron Letters*, **1966**, 5925; R. Tanikaga, This Bulletin, **41**, 1664 (1968).

12) H. Mauser and H. Heitzer, *Z. Naturforsch.*, **20b**, 200 (1965).

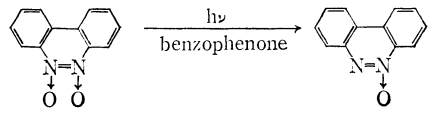
This mechanism may be probable in view of the mechanisms for the photochemical reduction of nitrobenzene[13,14] and the base-catalyzed reduction of I.[15,16]

Since nitrosobenzene in a solution exists in an equilibrium of a monomeric form (I) and a dimeric form (XIII),[17] the other possible mechanism is that II is formed from the excited triplet state of dimeric nitrosobenzene.



XIII II

This mechanism, similar to that for the photochemical reduction of II to IX *via* the excited triplet state,[11] may be supported by the findings that the irradiation of solid nitrosobenzene with a XIII structure also yielded II, and that an ethanolic solution of benzo[*c*]cinnoline 5,6-dioxide (XIV) with a structure similar to XIII underwent photochemical reduction of benzo[*c*]cinnoline 5-oxide (XV) in the presence of benzophenone.



XIV XV

However, it is impossible to decide which mechanism is more reasonable, because the reaction is very complex.

Reaction Process C:

Scheme C:

I X

I as well as VI was slightly oxidized, but the unimolecular reaction of I rarely occurred. This result is in contrast with that of the photolysis of I with hydrochloric acid, in which primary amines were obtained as the major products.[18]

At any rate, the dimeric or a similar form may be assumed to be important in the photolysis of nitrosobenzene.

Conclusion

The mechanism of the photolysis of nitrosobenzene (I) is as follows:

i) I undergoes the homolytic fission of a nitrosophenyl bond. The phenyl radical formed reacts with I to yield diphenylnitroxide, which is then reduced to diphenylamine. The nitric oxide reacts with diphenylamine to afford *C*-nitrosodiphenylamines, which are photochemically oxidized to *C*-nitrodiphenylamines.

ii) I is reduced to azoxybenzene, which is rearranged to 2-hydroxyazobenzene. Azoxybenzene undergoes a photosensitized reduction to azobenzene.

iii) I is slightly oxidized to nitrobenzene.

Experimental

Materials. Nitrosobenzene (I) was prepared by the reduction of nitrobenzene and was then recrystallized from ethanol (mp 68.0°C).[19] The authentic materials shown in Table 4 were also synthesized in order to determine the products.

color reactions with concentrated sulfuric acid upon the TLC (silica gel) of the solution showed the compounds, II—IX, in Table 1, but no β-phenylhydroxylamine, *m*-nitrodiphenylamine, *N*-nitrosodiphenylamine, and carbazole. The minor products other than II—IX could not be assigned. A small amount of nitrobenzene was detected by gas chromatography (Yanagimoto GCG-5DH, polyethylene glycol, He), but no aniline was. On the other hand, when the solution was diazotized and treated with 2-naphthol or NW-acid (1-naphthol-4-sulfonic acid), no coupling compound with aniline was detected on TLC. Since it was difficult to detect benzene in ethanol, I in cumene was irradiated in the same manner as has been described above for the detection of benzene, but the gas chromatography of the solution showed the absence of any benzene, while its TLC showed the presence of II—IX.

The yield of the product was determined as follows. After the irradiation, 2-hydroxy-4,4′-dichloroazobenzene ($\lambda_{max}^{CHCl_3}=339$ mμ, $\varepsilon_{max}^{CHCl_3}=19500$) was added to the solution as an internal standard. Each component was separated by TLC (Merck silica gel G, *n*-hexane - chloroform (3 : 1)) and then extracted with chloroform. The yield was determined from the intensity of the maximum absorption of the extract in an electronic spectrum, whose extinction coefficient had previously been determined by means of an authentic sample, as is shown in Table 4.

The amount of I unreacted was determined as follows. After the irradiation, ethanol (*ca.* 50 m*l*) was added to the solution; both ethanol and I were then distilled *in vacuo* at the room temperature and trapped in a receiver cooled by dry ice-acetone. The same procedure was repeated until no further I was distilled. The amount of I was determined from the intensity of the maximum absorption of the distillate (*ca.* 250 m*l*).

Photolysis of N-Nitrosodiphenylamine (XII). An ethanolic solution (2 m*l*) of XII (10^{-2} M) was irradiated in a Pyrex tube at 25.0±0.1°C for 3 hr. TLC (silica gel G, *n*-hexane - benzene (2 : 1)) showed the presence of V—VIII, carbazole, and some minor products not identified. Their yields were determined by the method described above. III was used as the internal standard.

When benzene was used as a solvent, the amounts of nitroso- and nitro-derivatives were larger.

Photolysis of 4-Nitrosodiphenylamine (VI). An ethanolic solution (2 m*l*) of VI (10^{-3} M) was irradiated in a Pyrex tube at 25.0±0.1°C. III or 1-benzeneazo-2-naphthol ($\lambda_{max}^{CHCl_3}=317$ mμ, $\varepsilon_{max}^{CHCl_3}=7470$) was added as an internal standard, and then VI and VII were separated by TLC (silica gel G, benzene - *n*-hexane (4 : 1)). Their yields were determined as above. The assignment of the other products was not attempted.

The author wishes to express his thanks to Professor Ryozo Goto for his helpful discussions and encouragement throughout the course of this work, and to Professor Aritsune Kaji for his valuable discussions. He is also indebted to Mr. Kiyomi Sakurai for assistance with part of the experimental work.

Some Observations on Photolysis of Fused Cyclopentyl Nitrites[1)]

Hiroshi SUGINOME, Norio SATO and Tadashi MASAMUNE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo

(Received May 31, 1968)

The results of photolysis of three fused cyclopentyl nitrites, Ib, VIIIb, XIV, all of which have 22,27-imino-17,23-oxidojervane framework, are described. In all three cases, competition among the reactions of 11-alkoxyl radical, which led to a variety of products, has been observed. However, the cleavage of α,β carbon-carbon bond to the nitrosoxyl group in these compounds is not the major course of the reaction. It has been found that whenever sterically possible (*e. g.*, Ib), 11-alkoxyl radical in these nitrites is capable of achieving the Barton reaction and the reaction leads to relatively few products. In two cases of these photolyses, the reaction is accompanied by epimerization of the relevant alkoxyl radicals. Some aspects of these transformations are considered in the light of other available data.

In connection with other investigations we were interested in the photolysis of 11-ol nitrites in C-nor-D-homosteroid framework which can be derived from readily-available veratrum alkaloid jervine.

In this paper, we shall describe the results of photolysis of three nitrites, all of which have 22,27-imino-17,23-oxidojervane framework, and will discuss some aspects of the observed transformations which are summarized in annexed charts.

We first examined photolysis of 3-*O*,*N*-diacetyl-22,27-imino-17,23-oxidojerv-5-ene-3β,11β-diol 11-nitrite (Ib). The reaction of 11β-ol (Ia)[2)] with nitrosyl chloride in pyridine[3)] readily afforded the corresponding stable nitrite (Ib), mp 208—210°C. This was photolyzed in toluene by a 150 W high pressure mercury arc lamp for 3 hr. The three major compounds produced (see Experimental) were isolated by preparative thin layer chromatography*[1] to afford a new compound (III), mp 234.5—235°C, (5%), 3-*O*,*N*-diacetyl-22,27-imino-17,23-oxidojerv-5-ene-3β,11α-diol (VI)[2)] (27%), and 3-*O*,*N*-diacetyl-22,27-imino-17,23-oxidojerv-5-en-3β-ol-11-one (VII)[4)] (24%). The new compound had a molecular formula $C_{31}H_{46}O_6N_2$ and could immediately be formulated as a 19-oximino derivative (III) of 3-*O*,*N*-diacetyl-22,27-imino-17,23-oxidojerv-5-ene-3β,11β-diol by the NMR spectrum which retained all signals between τ 9.13 and τ 7.5 except that of C-19 methyl protons in the 11β-ol (Ia) and showed a singlet absorption at τ 2.3 due to a methine proton at C-19.[5)]

The second nitrite photolyzed was *N*-acetyl-22,27-imino-17,23-oxidojerv-4-en-11β-ol-3-one 11-nitrite (VIIIb), in which A and B rings of Ib were modified. This nitrite was easily obtainable by partial acetylation of the 11β-alcohol (VIIIa)[2)] followed by nitrosation in usual way. Photolysis was carried out under comparable conditions with the photolysis of Ib. Contrary to the photolysis of Ib, the composition of the reaction product was complex (at least 8 spots on thin layer) and three major products, 11-ketone (IX), 11β-ol (X) and 11α-ol (XI) were isolated after extensive preparative thin layer chromatography in the yield of 3%, 23% and 2%,

Masamune, This Bulletin, **41**, 468 (1968). b) Regarding stereochemistry of jervine, see. J. W. Scott, L. J. Durham, H. A. P. deJongh, U. Burckhardt and W. S. Johnson, *Tetrahedron Letters*, **1967**, 2381. G. N. Reeke, Jr., R. L. Vincent and W. N. Lipscomb, *J. Am. Chem. Soc.*, **90**, 1663 (1968). S. M. Kupchan and M. I. Suffness, *ibid.*, **90**, 2730 (1968). c) The configurations at C-12 and C-13 of dihydrojervine (12αH, 13αH) and hence those of 11β-ol (Ia)were proposed by Wintersteiner and Moore (*Tetrahedron*, **20**, 1947 (1964)). However, our recent work shows that C-12 hydrogen of dihydrojervine is preferably β-configuration (T. Masamune, A. Murai, H. Ono, K. Orito and H. Suginome, *Tetrahedron Letters*, in press). Therefore, in this paper, a series of compounds derived from dihydrojervine will be formulated on the basis of this new evidence.

respectively.[6] The compounds IX and XI were new compounds and after the spectroscopic identification these were identified by direct comparison with those newly prepared. Thus, VIIIa[2] was oxidized with chromic anhydride-sulfuric acid in DMF to yield the corresponding 11-ketone (XII). The ketone was then acetylated to yield the corresponding *N*-acetyl derivative (IX) which was identical with the ketone obtained from photolysis.

The 11α-ol (XIa), on the other hand, was prepared by brief hydrolysis of the corresponding diacetyl derivative (XIb).[2]

Various pathways[7-11] have been found in

6) All other products were minor and ill-defined, but the absence of 19-oximino compound or substances having cyclopropane ring, was proved by the NMR spectra of the crude product.

photolysis of nitrites of cyclopentanol derivatives, and the competitive nature of β-scission and inter- or intramolecular hydrogen abstraction in simple alkoxyl radical reactions has been extensively investigated.[12]

It is interesting to note that in the two experiments above mentioned and the photolysis of the 11α-ol nitrite XIV (*vide infra*) none of the products which arise from the scission of α,β-carbon-carbon bond of alkoxyl radicals on five-membered ring[8,11] were found in noticeable amounts, and instead, products of the competition among epimerization, hydrogen abstraction and presumed scission of α,β-carbon-hydrogen bond of alkoxyl radicals were observed.

The formation of 11α-ols, VI, XIa, in these reactions would seem to necessitate inquiry into the possible mode of the transformation.

The most likely mechanism for this epimerization would be one involving reversible aldehyde formation such as IV and this pathway has recently been suggested by Wettstein and co-workers[13] and by Akhtar[7b] to interpret an epimerization[9] from α-caryophyllene alcohol nitrite to epi-α-alcohol, which is the only precedent for this type of transformation.[14]

On the other hand, if we assume that reacting cyclopentyl radicals are planer[15] or that they rapidly invert, other pathways such as *via* a rearrangement of the secondary alkoxyl radical, $RR'CH\text{-}O\cdot \rightarrow RR'\dot{C}\text{-}OH \rightarrow RR'CHOH$, or regeneration of the secondary alcohol followed by the loss of α-hydrogen,[16] $RR'CH'\text{-}O\cdot \rightarrow RR'CHOH \rightarrow RR'\dot{C}\text{-}OH \rightarrow RR'CHOH$, should also be considered, since these pathways can lead to the formation of both 11α and 11β-ols. In fact, two examples[9] of epimerization, including one of the present experiments, resulted in the isolation of both epimers although the ratio of isolated α- and β-epimers was quite different in each case.[17]

However, in regard to these alternatives, we may point out that if the latter mechanisms operate, alkoxyl radicals in six-membered rings must likewise suffer epimerization. Although a considerable number of results have been accumulated on the photolysis of nitrite esters in the field of normal steroids, epimerization of alkoxyl radical in six-membered ring has never been observed[7] and the epimerizations so far found have all been concerned with nitrite on five-membered rings in which a number of scission reactions has been observed.[8,9,11]

This seems to be in favor of the epimerization *via* reversible process as shown in the chart.

It has been found that no 18-oximino derivatives of 22,27-imino-17,23-oxidojervanes were formed in these photolyses. Exclusive attack by the O-radical on the C-19 methyl suggests that the C-18 methyl is not located in the range of attack of the 11-alkoxyl radical. Inspection of the Dreiding model of the 11β-ol (Ia)[1c] indicates that a plausible conformation of the D ring of this molecule, would be a chair form in which the C-18 methyl would occupy an equatorial position. This conformation leads the C-19 methyl to a nearer position than the C-18 methyl with respect to the 11β-alkoxyl radical,

In the NMR spectra of steroid, additivity of group effects for C-18 and C-19 proton signals was well established[18] and this principle has recently been shown to hold for those protons in jervine derivative.[2] It was expected that the present exclusive attack of the 11β-alkoxyl radical on the C-19 methyl might be correlated to these group effects. In 22,27-imino-17,23-oxidojervane derivatives, the deshielding effect of the 11β-hydroxyl for the C-18 proton signals is only 0.11 ppm and has virtually the same value as that of the 11α-hydroxyl group. However, the deshielding effect of the 11β-hydroxyl group for the C-19 methyl has been found to be 0.295 ppm which is close to the corresponding effects of the 11β-

16) M. S. Kharasch, J. L. Rowe and W. H. Urry, *J. Org. Chem.*, **16**, 905 (1951).

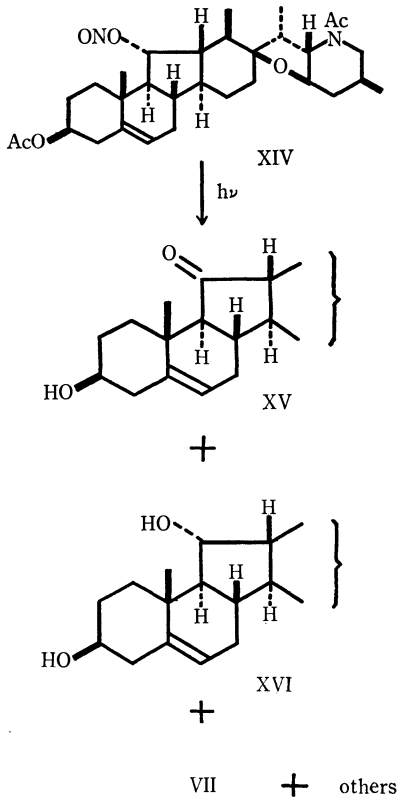
17) If these mechanisms operate, open-chain optically active secondary nitrites will produce racemic secondary alcohol on photolysis. The result of thermal decomposition of optically active 2-octyl nitrites in liquid phase (N. Kornblum and E. P. Oliveto, *J. Am. Chem. Soc.*, **71**, 266 (1949)) might be relevant at this point and we cited this in the preliminary communication.[1] However, since a recent investigation by Barton and co-workers demonstrated that the pyrolysis of nitrites in the molten state or solution may proceed *via* an ionic mechanism, this fact would not be relevant to the present argument. D. H. R. Barton, G. C. Ramsay and D. Wege, *J. Chem. Soc.*, (*C*), **1967**, 1915.

18) R. F. Zürcher, *Helv. Chim. Acta*, **46**, 2054 (1963). N. S. Bhacca and D. H. Williams, "Application of NMR Spectroscopy in Organic Chemistry," Holden-Day, San Francisco (1964), p. 13.

hydroxyl group in normal steroids. The difference in deshielding effects for the C-19 and C-18 methyls by the 11β-hydroxyl group is consistent with the results of the photolysis. The corresponding reaction in normal steroids, in which the 11β-hydroxyl group has almost the same deshielding effects (0.258 and 0.242 ppm) for the 19 and 18-methyl groups, leads to the formation of the oximino derivatives in both C-19 and C-18 methyls.[19] The correlation between the substituent effects and nitrite photolysis has recently been found in 3α,5α-cyclocholestan-6-ol nitrites.[20] It should be noted that in photolysis of VIIIb, the reaction which led to α-oximino-ketone (XIII) or 19-oximino derivative of 11β-ol (VIIIc) was not, at least, major. In the corresponding 11β-ol nitrite of the normal steroid having Δ^4-3-one, photolysis resulted in the formation of cyclopropane rings.[21]

In photolysis of 3-*O*,*N*-diacetyl-22,27-imino-17,23-oxidojerv-5-en-3β,11β-diol 11-nitrite (Ib) the formation of large amounts of 11-ketone (VII) together with 11α-ol (VI) would be rather distinctive. These can be produced before and (or) after epimerization *via* either disproportionation or α-hydrogen fission. Since a hydrogen on 11-carbon of this molecule is sterically very hindered, 11-ketone (VII) probably arises largely from α-hydrogen fission.[22]

Finally, photolysis of 3-*O*,*N*-diacetyl-22,27-imino-17,23-oxidojerv-5-ene-3β,11α-diol 11-nitrite (XIV), mp 146°C, which can be prepared quantitatively by nitrosation of the corresponding 11α-ol, is described. The irradiation of this compound in toluene for 3 hr led to a complex product mixture consisting of as many as 8 component as revealed by thin layer chromatography. 3-*O*,*N*-Diacetyl-22,27-imino-17,23-oxidojerv-5-en-3β-ol-11-one (VII) (7%), *N*-acetyl-22,27-imino-17,23-oxidojerv-5-en-3β-ol-11-one (XV) (8%), and a new compound melting at 279—281°C, (14%) could be separated by preparative thin layer chromatography. This compound was identified as *N*-acetyl-22,27-imino-17,23-oxidojerv-5-ene-3β,11α-diol (XVI) by direct comparison of its acetyl derivative with the corresponding 3-*O*,11-*O*,*N*-triacetyl derivative. Although it would appear that species generated from NO radical are playing a role in this facile deacetylation at 3 position, additional experimental work would be required before we could make any comments on this.



Experimental

Unless otherwise stated, infrared spectra were determined in Nujol using a Nihonbunko DS-402G type spectrophotometer or Jasco Model IR-E spectrophotometer. NMR spectra were determined on a Japan Electron Optics 3H-60 high resolution NMR spectrometer in deuteriochloroform solution using tetramethylsilane as an internal reference. The courses of reactions were followed by thin layer chromatography by using Wakogel B-5, unless stated otherwise.

3-*O*,*N*-Diacetyl-22,27-imino-17,23-oxidojerv-5-en-3β,11β-diol 11-Nitrite (Ib). This nitrite was prepared by nitrosation of 3-*O*,*N*-diacetyl-22,27-imino-17,23-oxidojerv-5-ene-3β,11β-diol in the usual way. The nitrite was recrystallized from chloroform-acetone mixture. Mp 209—210°C $[\alpha]_D$+33.7° *2 (*c* 1.9, chloroform). IR: ν_{max} 1734 (OAc), 1643 (N-Ac), 1725, 1621 (N-O), and 785 cm^{-1} (O-N). NMR: τ 8.95 C-19 methyl).

Found: C, 68.60; H, 8.50; N, 5.33%. Calcd for $C_{31}H_{46}O_6N_2$: C, 68.60; H, 8.54; N, 5.16%.

Photolysis of the Nitrite Ester Ib. The nitrite ester Ib (450 mg) in dry toluene (15 m*l*) under an atmosphere of dry nitrogen was irradiated with a 150-W high pressure mercury arc lamp for 3.5 hr. After evaporation of solvent, the residue was extracted with chloroform and the chloroform solution was washed with water. The residue (538 mg) gave 6 spots on thin

22) Although, in the preliminary communication,[1] we took the view that the formation of the 11-ketone (VII) might be attributed largely to disproportionation, this speculation might prove to be wrong on the basis of further experimental work.

*2 In the preliminary communication, this was reported as $[\alpha]_D$−30°.

layer chromatogram. Among these spots, second, third and sixth spots from the highest one were very minor (Merck aluminum oxide G, type E was used after adding a further 5% of gypsum. A mixture of methanol and ether (1 : 50 vol%) was used as solvent). Preparative thin layer chromatography afforded the following amounts of residues corresponding to each band. The highest band, 103 mg (A), second band, 17 mg (B), third band, 26 mg (C), fourth band, 117 mg (D), fifth band, 61 mg (E). The residue (A) showed mp 210—212°C and was identical with authentic 11-ketone, (VII).[8] R_f value of the residue (B) corresponded to that of Ia. However, this did not afford crystalline material and it has not yet been possible to identify it. The residue (C) was also minor and could not be identified. The residue (D) showed mp 236—238°C and was identical with authentic 11α-ol (VI). The residue (E) (61 mg) was separated into two substances by preparative thin layer chromatography. One (22 mg) melted at 234.5—235°C and was 19-oximino derivative III. IR: ν_{max} 1735 (OAc), 1668 (N-Ac), 3406, and 3205 cm^{-1} (OH). NMR: τ 2.35 (methine at C-19).

Found: C, 68.48; H, 8.47; N, 5.18%. Calcd for $C_{31}H_{46}O_6N_2$: C, 68.60; H, 8.54; N, 5.16%.

The other (5 mg) melted at 197—200°C and has not been identified.

N-Acetyl-22,27-imino-17,23-oxidojerv-4-en-11β-ol-3-one (VIIIC). 22,27-Imino-17,23-oxidojervan-4-en-11β-ol-3-one (500 mg) was dissolved in 22 m*l* of pyridine and 17 m*l* of acetic anhydride and set aside for 1.5 hr at room temperature. After work-up as usual chloroform-acetone solution of the residue yielded crystals of the *N*-acetyl derivative. 450 mg mp 240—242°C. IR: ν_{max} 1625 (N-Ac), 1652 (α,β-unsaturated ketone), and 3458 cm^{-1} (OH). NMR: τ 8.59 (C-19 methyl), τ 7.90 (*N*-acetyl) and τ 4.31 (C-4H).

Found: C, 73.86; H, 9.28; N, 2.84%. Calcd for $C_{29}H_{43}O_4N$: C, 74.16; H, 9.23; N, 2.98%.

N-Acetyl-22,27-imino-17,23-oxidojerv-4-en-11β-ol-3-one 11-Nitrite (VIIIb). *N*-Acetyl-22,27-imino-17,23-oxidojerv-3-en-11β-ol-3-one (300 mg) in pyridine (5m*l*) was cooled to −20——30°C. To this solution there was added dropwise nitrosyl chloride-pyridine mixture while stirring until the solution turned brown. The solution was further stirred for 20 min and was poured into water. Resultant precipitates were collected, dried and recrystallized from acetone-ether. Mp 175—180°C $[\alpha]_D$+186.2° (*c* 0.73, chloroform). IR: ν_{max} 1696 (α,β-unsaturated ketone), and 1662 cm^{-1} (N-Ac). NMR: τ 8.82 (C-19 methyl) and τ 7.95 (*N*-acetyl).

Found: C, 69.70; H, 8.68; N, 5.28%. Calcd for $C_{29}H_{42}O_5N_2$: C, 69.85; H, 8.49; N, 5.62%.

Photolysis of the Nitrite Ester VIIIb. The nitrite ester (828 mg) in dry toluene (13 m*l*) at room temperature and under an atmosphere of dry nitrogen was irradiated with 150-W high pressure mercury arc lamp for 2 hr. After removal of the solvent, the residue was extracted with chloroform. The chloroform solution was washed with water and dried over anhydrous sodium sulfate. The residue was a complex mixture and revealed at least 8 spots on thin layer chromatogram. The preparative thin layer chromatography (Wakogel B5) was carried out as follows: the reaction product was twice developed with a mixture of methanol and ether (1 : 15 vol%). The highest band (least polar compound) afforded the residue (82 mg). This was again purified by thin layer chromatography (solvent: ether), yielding crystals of IX, (16 mg), mp 223—225°C (acetone-ether). $[\alpha]_D$+94° (*c*, 1.5, chloroform). IR: ν_{max} 1652 (α,β-unsaturated ketone), 1729 (5-membered ketone), and 1642 cm^{-1} (N-Ac). NMR: τ 8.81 (C-19 methyl) and τ 7.88 (*N*-acetyl).

Found: C, 74.06; H, 9.00; N, 2.89%. Calcd for $C_{29}H_{41}O_4N$: C, 74.48; H, 8.84; N, 3.00%.

The second band which was major one was eluted to afford oil (120 mg) from which crystals (106 mg) were obtained. This was identical with 11β-ol (VIIIc). All but the above two bands were eluted and combined. The residue was developed twice with methanol and ether (1 : 10 vol%). The least polar compound (11 mg) melted at 249—252°C (acetone-ether). This was identified as 11α-ol (XIa) by comparison with the substance synthesized as below. $[\alpha]_D$ +93° (*c* 2.0, chloroform). IR: ν_{max} 1653 (α,β-unsaturated ketone), 3432 (OH), and 1642 cm^{-1} (N-Ac). NMR: τ 8.86 (C-19 methyl) and τ 7.89 (*N*-acetyl).

Found: C, 74.01; H, 9.20; N, 3.18%. $C_{29}H_{43}O_4N$: C, 74.16; H, 9.23; N, 2.98%.

The NMR spectrum of the crude substance obtained from the rest of the bands above revealed an absence of signals due to a methine proton on carbon bearing an oximino function.

N-Acetyl-22,27-imino-17,23-oxidojerv-4-en-11α-ol-3-one (XI). 11-*O*,*N*-Diacetyl-22,27-imino-17,23-oxidojerv-4-en-11α-ol-3-one (20 mg) in 5% aqueous ethanolic potassium hydroxide (10 m*l*) was refluxed for 40 min. After removal of the solvent, the residue was extracted with chloroforom and water. From the chloroform layer, 11α-ol (8 mg) was obtained. Mp 249—252°C (acetone-ether). This was identical with the product obtained from the photolysis above.

N-Acetyl-22,27-imino-17,23-oxidojerv-4-en-3,11-dione (IX). a) To 22,27-imino-17,23-oxidojerv-4-en-11β-ol-3-one (100 mg) and chromic anhydride (150 mg) in dimethylformamide (11 m*l*), there was added 3 drops of concentrated sulfuric acid and the mixture was stirred for 44 hr at room temperature. After decomposition of the excess chromic anhydride with aqueous saturated sodium bisulfite, tetrahydrofuran was added to the solution and the solution was filtered. Acetone was added to the residue obtained and the solution was again filtered. Removal of the solvent and the extraction of the residue with chloroform yielded crude diketone which was purified by preparative thin layer chromatography to yield amorphous 22,27-imino-17,23-oxidojerv-4-ene-3,11-dione (70mg). IR: ν_{max} 1730 (5-membered ketone), 1667 (α,β-unsaturated ketone), and 3441 cm^{-1} (NH). NMR: τ 8.80 (C-19 methyl).

Found: C, 73.83; H, 9.21; N, 3.04%. Calcd for $C_{29}H_{41}O_4N$: C, 74.48; H, 8.84; N, 3.00%.

This (30 mg) was acetylated in the usual way to yield *N*-acetyl-22, 27-imino-17, 23-oxidojerv-4-ene-3, 11-dione (18 mg), Mp 223—225°C. This was identical with the product obtained from the photolysis above. b) *N*-Acetyl-22,27-imino-17,23-oxidojerv-4-en-11α-ol-3-one (50 mg), chromic anhydride (50m g) and two drops of concentrated sulfuric acid in dimethylformamide (7 m*l*) were stirred for 44 hr at room temperature. After work-up as in the case of the procedure a) above, the residue was purified by preparative thin layer chromato-

graphy to yield diketone IX (20 mg). Mp 223—225°C. This was identical with the specimen obtained by a) above.

3-*O*, *N*-Diacetyl-22, 27-imino-17, 23-oxidojerv-5-en-3β,11α-diol 11-Nitrite (XIV). VI in pyridine was nitrosated at −30°C in usual way. The product was recrystallized from acetone-ether. Mp 146°C.

Found: C, 69.17; H, 8.86; N, 5.00%. Calcd for $C_{31}H_{46}O_6N_2$: C, 68.60; H, 8.54; N, 5.16%.

IR: ν_{max} 1731 (OAc), 1633 (N-Ac), 1644 (N-O), 764, and 777 cm^{-1} (O-N); NMR: τ 8.82 (C-19 methyl).

Photolysis of the Nitrite XIV. The nitrite above (450 mg) in dry toluene (15 m*l*) was irradiated under dry nitrogen at room temperature for 3 hr. After removal of the solvent under reduced pressure, the residue was extracted with chloroform. After usual work-up, the residue (556 mg) obtained was a complex mixture and at least 8 spots were observed on thin layer chromatogram. The three major compounds were isolated by preparative thin layer chromatography (Merck, aluminum oxide G, gypsum content 15%) as follows:

The reaction product was developed with ether. The highest band (least polar compound) afforded the residue (48 mg) from which pure 11-ketone, (VII), mp 210—212°C (from acetone), 30 mg, was obtained. Products from the second and third bands were minor and could not be identified. The residues from the fourth and fifth bands (172 mg) were combined and developed again. The fourth band afforded 42 mg of oily residue. Recrystallization from ether afforded 30 mg of crystals (mp 188°C) which was identified as *N*-acetyl-22,27-imino-17,23-oxidojerv-5-en-3β-ol-11-one, (XV). The residue (65 mg) from the fifth band afforded crystals of 54 mg, mp 279—281°C (from acetone), which was shown to be *N*-acetyl-22,27-imino-17,23-oxidojerv-5-ene-3β,11α-diol (XVI) by converting it into the diacetyl derivative. IR: ν_{max} 1647 (N-Ac) and 1677 cm^{-1} (trisubstituted double bond). NMR: τ 7.89 (N-Ac) and τ 8.98 (C-19 methyl).

Found: C, 73.43; H, 9.41; N, 2.77%. Calcd for $C_{29}H_{45}O_4N$: C, 73.84; H, 9.62; N, 2.97%.

Acetylation of *N*-Acetyl-22,27-imino-17,23-oxidojerv-5-en-3β,11α-diol. Photoproduct XVI was acetylated in usual way. The acetylated product was identical with 3-*O*,11-*O*,*N*-triacetyl-22,27-imino-17,23-oxidojerv-5-ene-3β,11α-diol in every respect.

The authors are indebted to Mr. S. Shimokawa for the measurements of NMR spectra and to the staff of the Laboratory for microanalyses, the Faculty of Pharmaceutical Science of Hokkaido University, for the elemental analyses.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 220—223 (1969)

The Cyclization of Benzoylacetonitrile and Ketones by Ammonium Acetate

Akio SAKURAI and Hiroshi MIDORIKAWA

The Institute of Physical and Chemical Research, Komagome, Bunkyo-ku, Tokyo

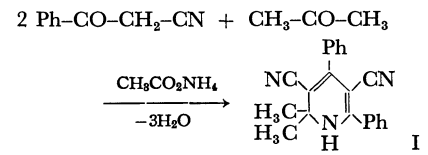
(Received June 6, 1968)

Several heterocyclic compounds, such as dihydropyridine, pyridine, tetrahydroquinoline and hexahydroquinoline derivatives, were prepared by the reaction of benzoylacetonitrile with such ketones as acetone, cyclopentanone, cyclohexanone, alkylcyclohexanone, alkylidenecyclohexanone, and aromatic α,β-unsaturated ketone in the presence of ammonium acetate.

In previous paper,[1-3] the syntheses of various nitrogen heterocyclic compounds by means of cyclization between active methylene compounds (ethyl cyanoacetate, ethyl acetoacetate, and malononitrile) and ketones in the presence of ammonium acetate have been reported.

The present paper will deal with the syntheses of similar heterocyclic compounds containing nitrogen by means of the reaction of benzoylacetonitrile with ketones in the presence of ammonium acetate.

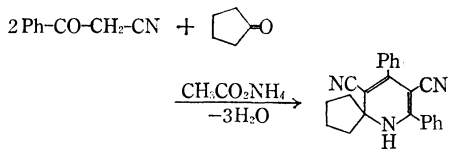
Benzoylacetonitrile and acetone in the presence of ammonium acetate reacted in a 2 : 1 molar ratio to give 3,5-dicyano-2,2-dimethyl-4,6-diphenyl-1,2-dihydropyridine (I), with the elimination of three moles of water, as is indicated in the following scheme:



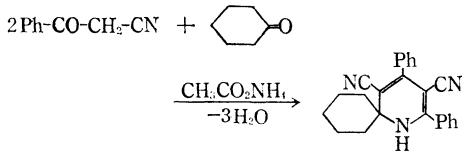
I

1) A. Sakurai and H. Midorikawa, This Bulletin, **40**, 1680 (1967).
2) A. Sakurai and H. Midorikawa, *ibid.*, **41**, 165 (1968).
3) A. Sakurai and H. Midorikawa, *ibid.*, **41**, 430 (1968)

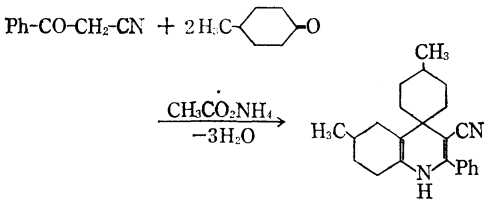
The condensations of benzoylacetonitrile with cyclic ketones are considered to proceed similarly to that of acetone. In these reactions, spiro compounds of such pyridine derivatives as 3,5-dicyano-4,6-diphenyl-1,2-dihydropyridine-2-spiro-1′-cyclopentane (II) and 3,5-dicyano-4,6-diphenyl-1,2-dihydropyridine-2-spiro-1′-cyclohexane (III) were prepared from cyclopentanone and cyclohexanone respectively. On the other hand, the reaction with such an alkylcyclohexanone as 4-methylcyclohexanone was abnormal, and afforded a spiro compound of hexahydroquinoline such as 3-cyano-6,4′-dimethyl-2-phenyl-1,4,5,6,7,8-hexahydroquinoline-4-spiro-1′-cyclohexane (IV), with the elimination of three moles of water from two moles of ketone, one mole each of benzoylacetonitrile and ammonia, as is illustrated below. In this



II



III



IV

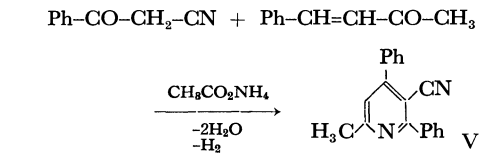
reaction, it was considered that two moles of 4-methylcyclohexanone first condensed, and then cyclized through a Michael reaction such as those of such alkylidenecyclohexanones as 2-benzylidenecyclohexanone and 5-methyl-2-isopropylidenecyclohexanone described below, while the reaction with 2-methylcyclohexanone did not give the dihydropyridine or hexahydroquinoline derivative under similar conditions.

Infrared spectra of compounds I, II and III revealed the absorption bands of imino groups (*ca.* 3200—3290 cm^{-1}) and conjugated cyano groups (*ca.* 2180—2200 cm^{-1}).

The structure of IV was supported by the IR and NMR spectra. Furthermore, the hydrolysis of the cyano group of IV by heating with 60% sulfuric acid gave 6,4′-dimethyl-2-phenyl-1,4,5,6,7,8-hexahydroquinoline-4-spiro-1′-cyclohexane sulfate, melting at 213—215°C with decomposition.

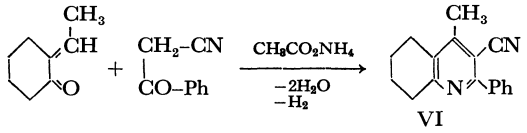
Attempts to prepare the corresponding dihydropyridine derivatives by condensations with such aliphatic higher ketones as methyl ethyl ketone, methyl *n*-propyl ketone, and diethyl ketone or such aromatic ketones as acetophenone and *o*-hydroxyacetophenone were unsuccessful under similar conditions. In these cases, the same compound as that prepared by the self-condensation of benzoylacetonitrile was obtained.

The reaction of benzoylacetonitrile with an α,β-unsaturated ketone such as benzalacetone in the presence of ammonium acetate in a 1 : 1 molar ratio took place, and the pyridine derivative was obtained through a Michael addition, with the elimination of two moles of water and one mole of hydrogen, as is illustrated below:

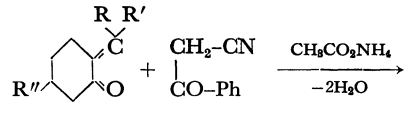


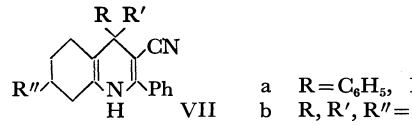
V

The condensations of benzoylacetonitrile with alkylidenecyclohexanones were considered to proceed similarly to that of the α,β-unsaturated ketone (molar ratio 1 : 1). From the reaction with 2-ethylidenecyclohexanone, 3-cyano-4-methyl-2-phenyl-5,6,7,8-tetrahydroquinoline (VI) was prepared through a Michael addition, with the elimination of two moles of water and one mole of hydrogen. On the other hand, the reactions with 2-benzylidenecyclohexanone or 5-methyl-2-isopropylidenecyclohexanone afforded hexahydroquinoline derivatives, such as 3-cyano-2,4-diphenyl-1,4,5,6,7,8-hexahydroquinoline (VIIa) and 3-cyano-4,4,7-trimethyl-2-phenyl-1,4,5,6,7,8-hexahydroquinoline (VIIb). The scheme of these reactions is indicated as follows:



VI





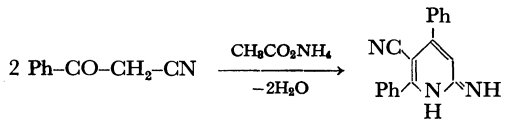
VII a $R=C_6H_5$, $R', R''=H$
b $R, R', R''=CH_3$

The infrared spectra of VIIa and VIIb exhibited the absorption bands of an imino group (3380—3260 cm^{-1}), but the compound VI gave no absorption band in this region. Also, the compounds VI, VIIa, and VIIb revealed the absorptions at 2200—2180 cm^{-1} due to the presence of a conjugated

cyano group. The NMR spectra supported these structures.

The hydrolysis of the cyano group of VI by heating with 60% sulfuric acid gave the corresponding amide melting at 217—219°C.

Benzoylacetonitrile afforded a pyridine derivative by self-condensation in the presence of ammonium acetate. When benzoylacetonitrile was heated with ammonium acetate in glacial acetic acid or alcohol, 6-amino-3-cyano-2,4-diphenylpyridine (VIII) was formed, with the elimination of two moles of water from two moles of benzoylacetonitrile and one mole of ammonia, as is indicated below:



VIII

This compound was also obtained when the reaction was carried out in another solvent, such as benzene or toluene, or without any solvent. The NMR spectrum of the compound VIII showed signals at 7.22 ppm (1H) and 7.85 ppm (1H) due to the presence of imino groups. This fact seems to indicate that the imino form is predominant over the amino form.

The reaction of mesityl oxide with benzoylacetonitrile did not give the expected pyridine derivative, but the same compound as that obtained by the reaction with acetone.

Experimental

All the melting points are uncorrected.

The infrared spectra were determined by means of pressed potassium bromide disks.

The NMR spectra were determined in trifluoroacetic acid or deuteriodimethylsulfoxide at a frequency of 60 Mc, using tetramethylsilane as an internal standard. The chemical shifts are given as ppm downfield from tetramethylsilane.

The Reaction of Benzoylacetonitrile with Ammonium Acetate. A mixture of benzoylacetonitrile (3 g, 0.02 mol) and ammonium acetate (1.6 g, 0.02 mol) was heated in 7 m*l* of alcohol for 4 hr. After it had then been cooled, a crystalline precipitate was obtained; the precipitate was collected and washed with water, dried, and treated with hot alcohol. It was divided into two parts: a hot alcohol-soluble part (A) and a hot alcohol-insoluble part (B). A small amount of water was added to the hot alcohol solution A. After standing overnight at room temperature, pale yellow crystals precipitated out. Recrystallization from dilute alcohol gave 6-amino-2,4-diphenylnicotinonitrile (VIII) melting at 217—218°C[4]; yield, 2 g (35%).

Found: C, 79.91; H, 4.82; N, 15.36%. Calcd for $C_{18}H_{13}N_3$: C, 79.68; H, 4.83; N, 15.49%.

IR: 3460, 3330 (ν NH), 2210 (ν C≡N), 1620, 1590, 1575, 1535, and 1500 cm^{-1} (hetero ring and C_6H_5).

NMR [$(CD_3)_2SO$]: 6.55 (–CH=, singlet, 1H), 7.22 (NH, singelt, 1H), 7.85 (NH, singelt, 1H), and 7.57 ppm (C_6H_5, singlet, 10H).

The hot alcohol-insoluble precipitate, B, was recrystallized from pyridine and a small amount of dilute methanol to give 0.7 g of yellow crystals, melting at 313—315°C. Its structure could not be confirmed.

3,5-Dicyano-2,2-dimethyl-4,6-diphenyl-1,2-dihydropyridine (I). To a mixture of benzoylacetonitrile (2.5 g, 0.017 mol) and acetone (1 g, 0.017 mol), ammonium acetate (1.2 g, 0.016 mol) was added. When the reaction mixture was then heated for 4 hr, a yellow crystalline matter precipitated. After it had been cooled at room temperature, the crystals were collected and washed with an ether-methanol solution and then with water. Recrystallization from glacial acetic acid afforded pale yellow needles, mp 282—284°C; yield, 1.5 g (56%).

Found: C, 81.17; H, 5.18; N, 13.46%. Calcd for $C_{21}H_{17}N_3$: C, 81.00; H, 5.50; N, 13.50%.

IR: 3250, 3200 (ν NH), 2195, 2205 (ν C≡N), 1640, 1580, and 1500 cm^{-1} (hetero ring and C_6H_5).

NMR (CF_3CO_2H): 1.7 (CH_3, singlet, 6H), 7.24 (NH, broad, 1H), and 7.6 ppm (C_6H_5, singlet, 10H).

3,5-Dicyano-4,6-diphenyl-1,2-dihydropyridine-2-spiro-1′-cyclopentane (II). To a mixture of benzoylacetonitrile (2.5 g, 0.017 mol) and cyclopentanone (1.5 g, 0.017 mol), ammonium acetate (1.2 g, 0.016 mol) was added, and the solution was refluxed for 3 hr. After the reaction mixture had been cooled, a crystalline precipitate was formed. It was collected and washed with acetone and then with water. Recrystallization from glacial acetic acid afforded 1 g (34%) of pale yellow needles, mp 281—283°C.

Found: C, 81.39; H, 5.23; N, 12.58%. Calcd for $C_{23}H_{19}N_3$: C, 81.87; H, 5.68; N, 12.45%.

IR: 3250, 3210 (ν NH), 2200 (ν C≡N), 1640, 1580, 1500, and 1480 cm^{-1} (hetero ring and C_6H_5).

NMR (CF_3CO_2H): 1.7—2.6 (ring CH_2, complex multiplet, 8H), 7.25 (NH, singlet, 1H), and 7.52 ppm (C_6H_5, singlet, 10H).

3,5-Dicyano-4,6-diphenyl-1,2-dihydropyridine-2-spiro-1′-cyclohexane (III). A mixture of benzoylacetonitrile (1.5 g, 0.01 mol), cyclohexanone (1 g, 0.01 mol), and ammonium acetate (0.6 g, 0.008 mol) was heated for 3 hr. The reaction mixture was then left to stand in a refrigerator overnight. The crystalline matter thus formed was separated on a filter, washed with an ether-methanol solution, and dried. It was recrystallized from alcohol-glacial acetic acid to give 1.5 g (27%) of pale yellow crystals metling at 224—227°C.

Found: C, 81.99; H, 5.96; N, 11.85%. Calcd for $C_{24}H_{21}N_3$: C, 82.02; H, 6.02; N, 11.96%.

IR: 3290, 3240 (ν NH), 2195, 2180 (ν C≡N), 1630, 1605, 1575, and 1490 cm^{-1} (hetero ring and C_6H_5).

3-Cyano-6,4′-dimethyl-2-phenyl-1,4,5,6,7,8-hexahydroquinoline-4-spiro-1′-cyclohexane (IV). A mixture of benzoylacetonitrile (2.9 g, 0.02 mol), 4-methylcyclohexanone (2.24 g, 0.02 mol), and ammonium acetate (2.3 g, 0.03 mol) was heated for 3 hr. After being left standing for several hours, a pale yellow precipitate began to separate from the solution. The precipitated crystals were collected and washed with ether-methanol and then with water. Recrystallization from alcohol gave 1.5 g (22.5%) of white needles, mp

196—199°C.

Found: C, 82.76; H, 8.20; N, 8.15%. Calcd for $C_{23}H_{28}N_2$: C, 83.08; H, 8.49; N, 8.43%.

IR: 3280 (νNH), 2180 (ν C≡N), 1670, 1590, 1570, and 1500 cm^{-1} (hetero ring and C_6H_5).

NMR [$(CD_3)_2SO$]: 1.00 (CH_3, doublet, 6H), 1.3—2.4 (ring CH_2 and –CH–, complex multiplet, 16H), 7.55 (C_6H_5, singlet, 5H), and 8.95 ppm (NH, broad, 1H).

Hydrolysis of 3-Cyano-6,4′-dimethyl-2-phenyl-1,4,5,6,7,8-hexahydroquinoline-4-spiro-1′-cyclohexane (IV). To a solution of 95% sulfuric acid (19.2 g) and water (10.8 g), IV (1.5 g) was added, and the mixture was heated for 1 hr. After it had then cooled, a pale yellow crystalline matter separated. It was collected and recrystallized from dilute alcohol to give 0.8 g of 6,4′-dimethyl-2-phenyl-1,4,5,6,7,8-hexahydroquinoline-4-spiro-1′-cyclohexane sulfate melting at 213—215°C with decomposition.

Found: C, 64.87; H, 7.61; N, 3.49; S, 7.71%. Calcd for $C_{22}H_{31}O_4NS$: C, 65.16; H, 7.71; N, 3.45; S, 7.89%.

6-Methyl-2,4-diphenylnicotinonitrile (V). A mixture of benzoylacetonitrile (2 g, 0.014 mol), benzalacetone (2 g, 0.014 mol), and ammonium acetate (1 g, 0.013 mol) was refluxed in 5 m*l* of glacial acetic acid for 5 hr. After cooling, a small amount of water was added to the reaction mixture and it was allowed to stand in a refrigerator overnight. The crystalline matter which was precipitated was collected on a filter and recrystallized from alcohol to afford 1.2 g (32%) of pale yellow needles, mp 150—151°C.

Found: C, 84.40; H, 5.17; N, 10.61%. Calcd for $C_{19}H_{14}N_2$: C, 84.42; H, 5.22; N, 10.36%.

IR: 2220 (ν C≡N), 1590, 1575, 1535, and 1500 cm^{-1} (hetero ring and C_6H_5).

NMR (CF_3CO_2H): 3.07 (CH_3, singlet, 3H), 8.05 (–CH=, singlet, 1H), and 7.8 ppm (C_6H_5, singlet, 10H).

3-Cyano-4-methyl-2-phenyl-5,6,7,8-tetrahydroquinoline (VI). A mixture of benzoylacetonitrile (2 g, 0.014 mol), ethylidenecyclohexanone (1.73 g, 0.014 mol), and ammonium acetate (1 g, 0.013 mol) was refluxed in 5 m*l* of glacial acetic acid for 6 hr. After cooling, the reaction mixture was neutralized with sodium carbonate and allowed to stand overnight at room temperature. A crystalline matter separated from the solution. It was collected and washed with water and then with dilute methanol. Recrystallization from alcohol gave 1.7 g (50%) of colorless needles, mp 127—129°C.

Found: C, 82.53; H, 6.50; N, 11.24%. Calcd for $C_{17}H_{16}N_2$: C, 82.22; H, 6.50; N, 11.28%.

IR: 2220 (ν C≡N), 1585, 1550, and 1500 cm^{-1} (hetero ring and C_6H_5).

NMR (CF_3CO_2H): 2.05 (ring CH_2, broad, 4H), 2.85 (CH_3, singlet, 3H), 2.97, 3.28 (ring CH_2, broad, 4H), and 7.75 ppm (C_6H_5, singlet, 5H).

Hydrolysis of 3-Cyano-4-methyl-2-phenyl-5,6,7,8-tetrahydroquinoline (VI). To a solution of 95% sulfuric acid (9.6 g) and water (5.4 g), VI (0.5 g) was added, and then the mixture was heated for 1 hr.

After being cooled, the solution was poured into ice water. The white precipitate which deposited was collected and dissolved in water, and a few drops of a 10% sodium hydroxide solution were added to it. The precipitated product was washed with water and recrystallized from dilute alcohol to give 0.2 g of 3-carbamoyl-4-methyl-2-phenyl-5,6,7,8-tetrahydroquinoline melting at 217—219°C.

Found: C, 76.48; H, 6.53; N, 10.41%. Calcd for $C_{17}H_{18}ON_2$: C, 76.66; H, 6.81; N, 10.52%.

3-Cyano-2,4-diphenyl-1,4,5,6,7,8-hexahydroquinoline (VIIa). A mixture of benzoylacetonitrile (2 g, 0.014 mol), 2-benzylidenecyclohexanone (2.6 g, 0.014 mol), and ammonium acetate (1.23 g, 0.016 mol) was heated for 5 hr. After the mixture had been left standing for several days, a crystalline mass separated. It was washed with ether, a small amount of a methanol mixture, and then with water. Recrystallization from dilute alcohol afforded 1.5 g (34%) of colorless crystals, mp 132—134°C.

Found: C, 84.42; H, 6.37; N, 8.98%. Calcd for $C_{22}H_{20}N_2$: C, 84.58; H, 6.45; N, 8.97%.

IR: 3380 (ν NH), 2180 (ν C≡N), 1695, 1610, 1600, 1575, 1550, 1505, and 1495 cm^{-1} (hetero ring and C_6H_5).

3-Cyano-4,4,7-trimethyl-2-phenyl-1,4,5,6,7,8-hexahydroquinoline (VIIb). A mixture of benzoylacetonitrile (2 g, 0.014 mol), 2-isopropylidene-5-methylcyclohexanone (2.1 g, 0.014 mol), and ammonium acetate (1.5 g, 0.02 mol) was refluxed in 5 m*l* of glacial acetic acid for 6 hr. After it had stood overnight, a crystalline matter separated; it was collected on a filter, washed with water, and recrystallized from glacial acetic acid to afford 0.9 g (24%) of colorless needles melting at 195—198°C.

Found: C, 81.81; H, 7.84; N, 10.04%. Calcd for $C_{19}H_{22}N_2$: C, 81.97; H, 7.97; N, 10.06%.

IR: 3260 (ν NH), 2180 (νC≡N), 1685, 1615, 1600, 1575, 1515, and 1495 cm^{-1} (hetero ring and C_6H_5).

NMR (CF_3CO_2H): 1.2 (7-CH_3, doublet, 3H), 1.45 (4-CH_3, doublet, 6H), 1.8—3.5 (ring CH_2 and –CH–, complex multiplet), and 7.55 ppm (C_6H_5, singlet, 5H).

The Reaction of Benzoylacetonitrile with Mesityl Oxide. To a mixture of benzoylacetonitrile (1.45 g, 0.01 mol) and mesityl oxide (0.98 g, 0.01 mol), ammonium acetate (0.77 g, 0.01 mol) was added, and the mixture was heated for 5 hr. After the reaction mixture had been left to stand at room temperature, a crystalline matter precipitated. It was collected on a filter, washed with water, and recrystallized from glacial acetic acid and water to afford 0.8 g (26%) of 3,5-dicyano-2, 2-dimethyl-4, 6-diphenyl-1, 2-dihydropyridine (I) as yellow needles, mp 278—281°C.

Found: C, 80.62; H, 4.98; N, 13.68%. Calcd for $C_{21}H_{17}N_3$: C, 81.00; H, 5.50; N, 13.50%.

This substance was identified with the compound obtained by the reaction between acetone and benzoylacetonitrile by a comparison of their infrared spectra.

The authors wish to express their thanks to Dr. Taro Hayashi and Dr. Tatsuo Takeshima for their kind advice. Thanks are also due to Dr. Haruo Homma and his staff for their microanalyses, to Mr. Jun Uzawa for his measurements of the NMR spectra, and to Mr. Hironori Ogawa for his measurements of the IR spectra.

Syntheses and Reactions of *N*-(Phenylpyruvoyl) Amino Acids

Yasuhiro CHIGIRA, Mitsuo MASAKI and Masaki OHTA

Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received September 11, 1968)

α-Ethoxy- and α-acetoxycinnamoyl chlorides were synthesized by treatments of α-ethoxy- and α-acetoxycinnamic acid with thionyl chloride and oxalyl chloride, respectively, and reactions of amino acid esters with the cinnamoyl chlorides were investigated in order to seek for a synthetic method of *N*-(phenylpyruvoyl) amino acids. *N*-Hydroxy- or *N*-benzyloxy-DL-alanine esters prepared from 2-bromopropionic esters and hydroxylamine or benzyloxyamine were treated with α-ethoxycinnamoyl chloride to give the corresponding *N*-(α-ethoxycinnamoyl) derivatives. Treatment of L-leucine ethyl ester with α-acetoxycinnamoyl chloride afforded *N*-(α-acetoxycinnamoyl)-L-leucine ethyl ester, the removal of the acetyl group from which was readily accomplished under mild, basic conditions, and *N*-(phenylpyruvoyl)-L-leucine ester was obtained. Treatment of the ester with ammonia yielded 3-benzylidene-6-isobutyl-2,5-piperazinedione.

There have been known several synthetic routes to *N*-pyruvoyl amino acids. Bergmann and his coworkers reported the formation of *N*-pyruvoylglycine or *N*-pyruvoylalanine on the acid hydrolysis of 3-methylene-2,5-piperazinediones prepared from *N*-glycyl- or *N*-alanylserine.[1] They have also described that some *N*-pyruvoyl or *N*-(phenylpyruvoyl) amino acids were prepared by the reaction of 4-acetamido-2,4-dimethyl- or 4-benzylidene-2-methyl-5-oxazolone with amino acids followed by acid hydrolysis of the resultant 2,2-diacetamidopropionyl[2] or α-acetamidocinnamoyl amino acids.[3] Direct condensations of pyruvic acid with amino acid esters by means of dicyclohexylcarbodiimide or phosphorus oxychloride have been reported by Stoll *et al.*[4] and Wieland *et al.*[5]

In our approach to the synthesis of *N*-(phenylpyruvoyl) α-hydroxyamino acids, the coupling methods of phenylpyruvic acid and α-hydroxyamino acids were studied. This paper deals with the preparation of α-ethoxy- and α-acetoxycinnamoyl chlorides and those reactions with α-amino and α-hydroxyamino acids.

α-Hydroxyamino acids have been reported to be prepared by the reaction of α-halo acids with hydroxylamine,[6] the hydrolysis of α-hydroxyamino nitriles,[7] or the hydrolysis of nitrones.[8] *N*-Hydroxy-DL-alanine *t*-butyl ester (Ia) was prepared in 98% yield by heating *t*-butyl 2-bromopropionate with hydroxylamine in methanol in the presence of triethylamine for 20 hr. Analogously, *N*-benzyloxy-DL-alanine *t*-butyl ester (Ib) and *N*-benzyloxy-DL-alanine ethyl ester (Ic) were readily prepared by condensations of the esters of 2-bromopropionic acid with benzyloxyamine in acetonitrile in 42% and 59% yield, respectively.

Some attempted reactions of 4-benzylidene-2-methyl-5-oxazolone with *N*-benzyloxy-DL-alanine ethyl ester (Ic) failed to give the *N*-(α-acetoamidocinnamoyl) derivative of the latter, but led only to recovery of the starting materials, possibly owing to the weakness of the nucleophilicity of the amine (Ic). The acid chloride method was then adopted for the coupling reaction. In order to protect the ketonic group of phenylpyruvic acid for such a reaction, the enol ether and the enol ester were employed.

α-Ethoxycinnamic acid was treated with thionyl chloride to give α-ethoxycinnamoyl chloride (II) in 92% yield, which was characterized by conversion to the corresponding anilide. Treatment of L-leucine ethyl ester (III) with the chloride (II) gave *N*-(α-ethoxycinnamoyl)-L-leucine ethyl ester (V), which was characterized by its conversion to the corresponding acid or amide. The hydrolysis of the enol ester moiety was attempted by treating with glacial acetic acid-hydrochloric acid, but the

starting material was recovered.

Acylation of *N*-hydroxy-DL-alanine *t*-butyl ester (Ia) with the chloride (II) yielded *N*-(*α*-ethoxycinnamoyl)-*N*-hydroxy-DL-alanine *t*-butyl ester (IVa) which gives a positive ferric chloride reaction characteristic of hydroxamic acid. The product IVa was confirmed by elemental analysis and the infrared spectrum. Analogously, treatment of *N*-benzyloxy-DL-alanine *t*-butyl ester (Ib) with the chloride (II) afforded *N*-benzyloxy-*N*-(*α*-ethoxycinnamoyl)-DL-alanine *t*-butyl ester (IVb) as an oily product in 69% yield, which was characterized by the infrared spectrum. When the ester IVb was treated with trifluoroacetic acid at room temperature for a day, both *t*-butyl and ethyl groups were removed and *N*-benzyloxy-*N*-(phenylpyruvoyl)-DL-alanine (VI) was obtained in 25% yield. Treatment of *N*-benzyloxy-DL-alanine ethyl ester (Ic) with the chloride (II) afforded *N*-benzyloxy-*N*-(*α*-ethoxycinnamoyl)-DL-alanine ethyl ester (IVc) as an oily product. Hydrolysis of the ester (IVc) with 20% aqueous sodium hydroxide failed to give the corresponding acid but furnished *α*-ethoxycinnamic amide (VII).[9] The catalytic hydrogenation of IVc gave *N*-(2-ethoxy-3-phenylpropionyl)-*N*-hydroxy-DL-alanine ethyl ester (VIII).

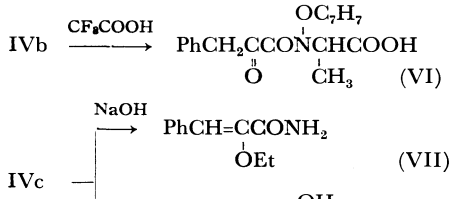
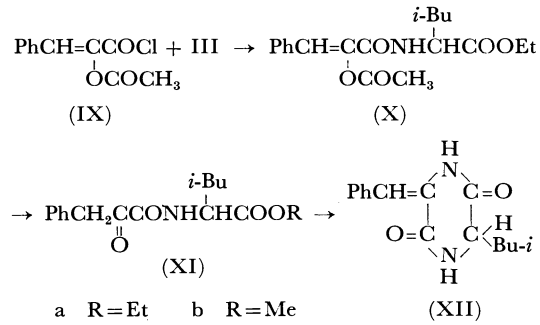
$R_1=i$-Bu, $R_2=H$, $R_3=Et$



α-Acetoxycinnamoyl chloride (IX) was synthesized in 79% yield by treating *α*-acetoxycinnamic acid with oxalyl chloride. The chloride was characterized by conversion into the corresponding anilide. Acylation of L-leucine ethyl ester (III) with the chloride (IX) afforded *N*-(*α*-acetoxycinnamoyl)-L-leucine ethyl ester (X) in 82% yield. The acetyl group was readily removed by treatment with aqueous sodium bicarbonate or with one equivalent of piperidine, and *N*-(phenylpyruvoyl)-L-leucine ethyl ester (XIa) was obtained in a good yield. The ester (XIa) was characterized by conversion to the 2,4-dinitrophenylhydrazone.

When the ester (XIa) was treated with ammonia in methanol, 3-benzylidene-6-isobutyl-2,5-piperazinedione (XII) was formed in 24% yield. The piperazinedione (XII) was directly obtained by treatment of X with ammonia in methanol. *N*-(Phenylpyruvoyl)-L-leucine prepared by the method of Bergmann *et al.*[3] was heated in methanol in the presence of hydrogen chloride to give the methyl ester (XIb), which, upon treatment with ammonia, also afforded the piperazinedione (XII).



a R=Et b R=Me

α-Acetoxycinnamoyl chloride appears to be the most convenient reagent for the synthesis of *N*-(phenylpyruvoyl) amino acids since the coupling reaction with amines and the removal of the protecting group are accomplished under milder conditions than those used in the aforementioned conventional method.

Experimental[10]

***N*-Hydroxy-DL-alanine *t*-Butyl Ester (Ia).** A solution of hydroxylamine prepared from the hydrochloride (7 g) and sodium (2.3 g) in methanol (90 m*l*) was added to a solution of *t*-butyl 2-bromopropionate (21.0 g) and triethylamine (10.1 g) in methanol (30 m*l*). The resultant solution was refluxed for 20 hr and then concentrated. Ether was added to the residue, and the insoluble substance, triethylamine hydrobromide (18 g), was filtered off. Evaporation of the ether afforded a crystalline residue which was treated with petroleum ether (bp 30—60°C) and collected. Yield was 16.0 g (98%). The product was recrystallized

9) The probable mechanisms for the reaction will be discussed in a subsequent paper.

10) All melting points were determined in a liquid bath and those and all boiling points are uncorrected. All concentrations and evaporations were carried out under reduced pressure. Infrared spectra were determined on a Hitachi EPI-S2 spectrophotometer as thin films of liquids, unless otherwise indicated. NMR spectra were recorded on JUM4H-100 spectrometer (Japan Electron Optics Laboratory Co.).

from petroleum ether (bp 50—90°C) to give colorless needles, mp 72.5—73.5°C.

Found: C, 52.05; H, 9.23; N, 8.34%. Calcd for $C_7H_{15}NO_3$: C, 52.15; H, 9.38; N, 8.69%.

IR (KBr): 3350 (OH), 3200 (NH), 1750 (COOBu-*t*) and 1170 cm^{-1}.

NMR ($CDCl_3$): τ 8.8 (d, 3H), 8.5 (s, 9H), 6.4 (q, 1H) and 3.5 (s, 2H).

***N*-Benzyloxy-DL-alanine *t*-Butyl Ester (Ib).** To a solution of *t*-butyl 2-bromopropionate[11] (10.0 g) in acetonitrile (100 m*l*) were added triethylamine (5.0 g) and benzyloxyamine[12] (6.0 g), and the solution was refluxed for 20 hr. After cooling, the resultant colorless needles (6.0 g) were filtered off. The filtrate was concentrated and the residue was dissolved in a mixture of ether and water. The ethereal layer was washed twice with water and dried over anhydrous sodium sulfate. After removal of the ether, the colorless oily residue was distilled to give a colorless oil (5.0 g, 42%), bp 126—127°C/2 mmHg.

Found: C, 67.15; H, 8.41; N, 5.53%. Calcd for $C_{14}H_{21}NO_3$: C, 66.90; H, 8.42; N, 5.57%.

IR: 3240 (NH), 1730 (COOBu-*t*), 1370, 1225, 1160 and 700 cm^{-1}.

***N*-Benzyloxy-DL-alanine Ethyl Ester (Ic).** The procedure is essentially the same as for Ib. The product was obtained in 59% yield, bp 123—125°C/3.5 mmHg.

Found: C, 64.84; H, 7.52; N, 6.42%. Calcd for $C_{12}H_{17}NO_3$: C, 64.55; H, 7.68; N, 6.27%.

IR: 3250 (NH), 1730 (COOEt), 1320, 1180, 1020 and 700 cm^{-1}.

NMR (CCl_4): τ 8.9 (d, 3H), 8.8 (t, 3H), 6.45 (q, 1H), 5.85 (q, 2H), 5.4 (s, 2H) and 2.7 (s, 5H).

α-Ethoxycinnamoyl Chloride (II). A mixture of α-ethoxycinnamic acid[13] (8.5 g) and thionyl chloride (18 m*l*) was refluxed for 30 min to afford a yellow clear solution. The excess thionyl chloride was evaporated and the residual oil was distilled to give a dark orange oil (8.6 g, 92%), bp 109°C/4 mmHg.

α-Ethoxycinnamic Anilide. A solution of II (1 g) in ether (10 m*l*) was added to a solution of aniline (0.4 g) and pyridine (0.35 g) in ether (10 m*l*). The mixture was treated with water and the insoluble crystalline product was collected. Recrystallization of the product from carbon tetrachloride gave colorless needles (1.1 g, 85%), mp 125°C.

Found: C, 76.03; H, 6.56; N, 5.24%. Calcd for $C_{17}H_{17}NO_2$: C, 76.38; H, 6.41; N, 5.24%.

α-Ethoxycinnamic Amide (VII). A solution of II (0.5 g) in ether was saturated with gaseous ammonia under ice cooling and allowed to stand for 2 hr at room temperature. The mixture was treated with water and the crystalline precipitates were collected and recrystallized from benzene to give colorless needles (0.3 g, 66%), mp 144°C.

Found: C, 69.30; H, 6.97; N, 7.62%. Calcd for $C_{11}H_{13}NO_2$: C, 69.09; H, 6.85; N, 7.33%.

IR (KBr): 3300, 3150 (NH_2), 1670 (C=C), 1620 (CONH), 1410, 1100, 1025 and 690 cm^{-1}.

N-(α-Ethoxycinnamoyl)-L-leucine Ethyl Ester (V). A solution of II (1.5 g) in absolute ether (10 m*l*) was added portionwise, with stirring at 0°C, to a solution of L-leucine ethyl ester (1 g) and pyridine (0.6 g) in absolute ether (10 m*l*). After stirred at room temperature for additional 2 hr, the mixture was treated with water. The ethereal layer was washed successively twice with water, aqueous sodium bicarbonate, water, 1 N hydrochloric acid and finally twice with water, and dried over anhydrous sodium carbonate. Evaporation of the ether afforded a pale yellow oil (1.5 g, 63%), which was used without further purification.

IR: 3300 (NH), 1735 (COOEt), 1670 (C=C), 1635 (CONH) and 1515 (CONH) cm^{-1}.

N-(α-Ethoxycinnamoyl)-L-leucine. A mixture of V (1 g) and 20% aqueous sodium hydroxide (10 m*l*) was stirred for 2 hr and water was added to the mixture until it became to a solution. Next day the aqueous solution was acidified with 3 N hydrochloric acid to afford a viscous oil. The oil was allowed to stand for 3 days in a refrigerator, when it had crystallized. Recrystallization from ligroin gave colorless needles (0.3 g, 33%), mp 101—102°C.

Found: C, 66.97; H, 7.51; N, 4.81%. Calcd for $C_{17}H_{23}NO_4$: C, 66.86; H, 7.59; N, 4.59%.

N-(α-Ethoxycinnamoyl)-L-leucine Amide. A solution of V (1 g) in methanol (40 m*l*) was saturated with gaseous ammonia. The solution was heated at 70°C in the presence of ammonium chloride (0.3 g) in a sealed tube for 2 days and concentrated to dryness. The residue was dissolved in a mixture of ether and water, and the ethereal layer was washed twice with water and dried over anhydrous sodium sulfate. Removal of the ether gave a yellow oil which gradually crystallized. Recrystallization from carbon tetrachloride afforded colorless needles (0.3 g, 32%), mp 114.5—115.5°C.

Found: N, 9.47%. Calcd for $C_{17}H_{24}N_2O_3$: N, 9.20%.

N-Benzyloxy-N-(α-ethoxycinnamoyl)-DL-alanine *t*-Butyl Ester (IVb). The procedure is essentially the same as for V. The product was obtained as a yellow oil in 69% yield, which was used without further purification.

IR: 2950, 1740 (COOBu-t), 1670 (C=C), 1660 (CON<), 1160 and 700 cm^{-1}.

N-Benzyloxy-N-(α-ethoxycinnamoyl)-DL-alanine Ethyl Ester (IVc). The procedure is essentially the same as for V. The product was obtained as a yellow oil in 63% yield, which was used without further purification.

IR: 2950, 1740 (COOEt), 1660 (broad, C=C and CON<), 1210 and 700 cm^{-1}.

NMR (CCl_4): τ 8.8 (t, 3H), 8.7 (d, 3H), 8.5 (t, 3H), 6.0 (q, 2H), 5.9 (q, 2H), 5.15 (m, 1H), 5.05 (s, 2H), 3.9 (S, 1H), 2.8 (s, 5H) and 2.6 (m, 5H).

N-(α-Ethoxycinnamoyl)-N-hydroxy-DL-alanine *t*-Butyl Ester (IVa). A solution of II (4.2 g) in absolute ether (30 m*l*) was added portionwise, with stirring, to a solution of Ia (3.2 g) and pyridine (1.6 g) in absolute ether (20 m*l*). After a day, the precipitated pyridine hydrochloride (1.9 g) was filtered off and the ethereal filtrate was washed twice with water and dried over anhydrous sodium sulfate. Evaporation of the ether afforded a pale yellow oil, which crystallized upon being allowed to stand in a refrigerator. Recrystallization from *n*-hexane gave pale yellow needles (3.4 g, 51%), mp 107—108°C. The product gave a wine red color with a methanolic ferric chloride solution.

Found: C, 64.54; H, 7.62; N, 4.18%. Calcd for $C_{18}H_{25}NO_5$: C, 64.46; H, 7.51; N, 4.18%.

IR (KBr): 3300 (OH), 1740 (COOBu-*t*), 1660 (C=C), 1620 (CON<), 1450, 1160 and 690 cm^{-1}.

N-Benzyloxy-N-(phenylpyruvoyl)-DL-alanine (VI). The crude IVb (1.0 g) was dissolved in trifluoroacetic acid (3 m*l*) and allowed to stand at room temperature for a day. Removal of the trifluoroacetic acid gave a pale black oil. The oil was dissolved in 1 N aqueous sodium hydroxide, and the solution was washed with ether, treated with activated charcoal and then acidified with 3 N hydrochloric acid. The precipitated oil was extracted with ether and the ethereal extract was dried over anhydrous sodium sulfate. Evaporation of the ether afforded the product as a yellow oil which was treated with petroleum ether (bp 30—60°C), thereby it crystallized gradually. The crystalline product (0.2 g, 25%) was collected and recrystallized from carbon tetrachloride into colorless powder, mp 107—108°C.

Found: C, 66.71; H, 5.54; N, 4.02%. Calcd for $C_{19}H_{19}NO_5$: C, 66.85; H, 5.61; N, 4.10%.

IR (KBr): 1750 (C=O), 1720 (COOH), 1630 (CON<), 1200 and 700 cm^{-1}.

NMR ($CDCl_3$): τ 8.5 (d, 3H), 6.0 (s, 2H), 5.15 (s, 2H) and 2.8 (s, 10H).

Reaction of IVc with Sodium Hydroxide. A mixture of IVc (1.0 g) and 20% aqueous sodium hydroxide (10 m*l*) was stirred at room temperature for 2 hr, and water was added to the mixture until it became to a solution. After a day, the aqueous solution was poured on water to afford α-ethoxycinnamic amide (VII) as crystalline precipitates (0.3 g, 62%). Recrystallization from carbon tetrachloride gave colorless needles which was identical, in melting point and infrared spectrum, with the sample obtained from the reaction of II with ammonia, mp 144°C.

N-(2-Ethoxy-3-phenylpropionyl)-N-hydroxy-DL-alanine Ethyl Ester (VIII). The crude IVc (1 g) was reduced with hydrogen-5% palladium on charcoal (0.5 g) at 50 kg/cm^2 initial pressure in methanol (50 m*l*). After hydrogen absorption had ceased, the catalyst was removed and the solution was concentrated. A solution of the residue in ethyl acetate was treated with activated charcoal and reprecipitated by the addition of petroleum ether (bp 30—60°C). The product (0.2 g, 26%) was recrystallized from carbon tetrachloride to give colorless needles, mp 121.5—122.0°C.

Found: C, 62.30; H, 7.69; N, 4.62%. Calcd for $C_{16}H_{23}NO_5$: C, 62.12; H, 7.49; N, 4.53%.

IR (KBr): 3400 (OH), 1740 (COOEt), 1630 (CON<), 1220, 1190 and 705 cm^{-1}.

α-Acetoxycinnamic Acid. The procedure was modified from the method of Hemmerlé.[14] A suspension of phenylpyruvic acid (2 g) in acetic anhydride (5 m*l*) was refluxed for 2 hr in the presence of *p*-toluenesulfonic acid (0.1 g). On cooling, the resultant clear solution afforded colorless needles (2.0 g, 79%) which was collected and recrystallized from ethyl acetate to give colorless needles, mp 170.5—171.5°C (lit. 168°C,[14] 171—173°C[15]).

α-Acetoxycinnamoyl Chloride (IX). A suspension of the acid (2.0 g) in oxalyl chloride (5 m*l*) was refluxed for 2 hr. The resultant clear solution was concentrated and distilled to give a yellow oil (2.0 g, 92%), bp 105°C/0.07 mmHg.

Found: C, 59.05; H, 4.27%. Calcd for $C_{11}H_9O_3Cl$: C, 58.81; H, 4.04%.

α-Acetoxycinnamic Anilide. The procedure was essentially the same as for α-ethoxycinnamic anilide. Colorless needles from ethyl acetate, mp 171—172°C.

Found: C, 72.35; H, 5.38; N, 5.09%. Calcd for $C_{17}H_{15}NO_3$: C, 72.58; H, 5.37; N, 4.98%.

N-(α-Acetoxycinnamoyl)-L-leucine Ethyl Ester (X). A solution of IX (3.7 g) in absolute ether (20 m*l*) was added portionwise with stirring to a solution of L-leucine ethyl ester (III) (2.6 g) and pyridine (1.14 g) in absolute ether (20 m*l*), and the mixture was stirred for 4 hr. The precipitated pyridine hydrochloride was filtered off and the ethereal filtrate was washed successively with water, aqueous sodium bicarbonate, water, 1 N hydrochloric acid and finally twice with water, and dried over anhydrous sodium sulfate. Evaporation of the ether afforded a crystalline residue which was recrystallized from *n*-hexane to give the product (4.7 g, 82%) as colorless scales, mp 94—96°C.

Found: C, 65.43; H, 7.21; N, 4.27%. Calcd for $C_{19}H_{25}NO_5$: C, 65.69; H, 7.25; N, 4.03%.

IR (KBr): 3320 (NH), 1755 (CH_3COO), 1730 (shoulder, COOEt), 1670 (C=C), 1640 (CONH), 1515, 1185, 1150 and 690 cm^{-1}.

N-(Phenylpyruvoyl)-L-leucine Ethyl Ester (XIa). To a solution of X (1 g) in tetrahydrofuran (10 m*l*) was added a solution of sodium bicarbonate (0.24 g) in water (10 m*l*) and methanol (2 m*l*). The resultant clear solution was stirred for 2 hr and concentrated. The residue was dissolved in ether and treated with 1 N hydrochloric acid. The ethereal layer was washed twice with water and dried over anhydrous sodium sulfate. Removal of the ether gave the product (0.8 g, 91%) as a pale yellow oil, which was used without further purification.

IR: 3300 (NH), 1740 (COOEt), 1700 (COCO), 1530, 1200 and 700 cm^{-1}.

2,4-Dinitrophenylhdrazone of XIa. Orange prisms from ethanol, mp 156—157°C.

Found: C, 56.73; H, 5.35; N, 14.53%. Calcd for $C_{23}H_{27}N_5O_7$: C, 56.90; H, 5.61; N, 14.43%.

N-(Phenylpyruvoyl)-L-leucine Methyl Ester (XIb). A solution of *N*-phenylpyruvoyl-L-leucine[1] (3.0 g) in methanol (30 m*l*) was refluxed in the presence of *p*-toluenesulfonic acid (0.5 g) for 4 hr and concentrated. Ether was added to the residue and then insoluble crystalline precipitates were filtered off. The ethereal filtrate was washed twice with water and dried over anhydrous sodium sulfate. Evaporation of the ether gave a pale yellow oily product (2.3 g, 73%), a portion of which was converted into the 2,4-dinitrophenylhydrazone.

IR: 3300 (NH), 1740 (COOMe), 1685 (COCO), 1530 (CONH), 1200, 1150 and 700 cm^{-1}.

2,4-Dinitrophenylhydrazone of XIb. Yellow prisms from methanol, mp 161°C.

3-Benzylidene-6-isobutyl-2,5-piperazinedione (XII). *From XIa.* A solution of the crude XIa (1 g) in methanol (20 m*l*) was saturated with gaseous ammonia under cooling and allowed to stand at room temperature for 24 hr. The crystalline precipitates were collected

and sublimed at 230°C under reduced pressure (2 mmHg). Recrystallization of the product from ethanol gave colorless needles (0.2 g, 24%), mp 237—238°C.

Found: C, 69.73; H, 6.70; N, 11.25%. Calcd for $C_{15}H_{18}N_2O_2$: C, 69.74; H, 7.02; N, 10.85%.

IR (KBr): 3200, 3050 (2NH), 1680 (C=C), 1630 (CONH), 1440, 1390 and 700 cm^{-1}.

From XIb. The crude XIb (1.5 g) in methanol (20 m*l*) was treated with gaseous ammonia in a manner analogous to the case of XIa to yield 0.4 g (30%) of the product. The product was identical, in melting point and infrared spectrum with the sample obtained from XIa.

From X. The piperazinedione (XII) was obtained in 15% yield from X by treating with ammonia in a manner analogous to the case of XIa.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 228—232 (1969)

Reaction of *N*-(α-Acetoxycinnamoyl)-*N*-hydroxy Derivatives of DL-Alanine Esters. Formation of Imidazolidinone and Its Transformations into Pyrrolidinedione and Oxazolidinone

Yasuhiro CHIGIRA, Mitsuo MASAKI and Masaki OHTA

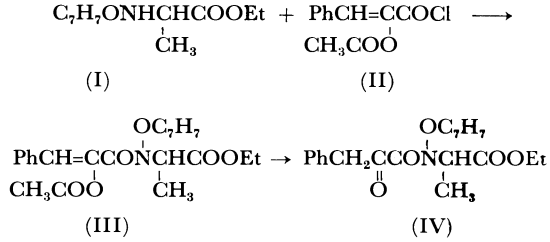
Laboratory of Organic Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 11, 1968)

Treatment of *N*-benzyloxy-DL-alanine ethyl ester (I) with α-acetoxycinnamoyl chloride (II) gave *N*-(α-acetoxycinnamoyl)-*N*-benzyloxy-DL-alanine ethyl ester (III), which was treated with aqueous sodium bicarbonate, piperidine or hydroxylamine to afford *N*-benzyloxy-*N*-(phenylpyruvoyl)-DL-alanine ethyl ester (IV). Reaction of III or IV with ammonia afforded 5-benzylidene-2-methyl-4-oxo-2-imidazolidinecarboxylic acid (V), which was transformed into 5-methyl-4-phenyl-2,3-pyrrolidinedione (VI) by treatment with aqueous sodium hydroxide and into methyl 5-benzylidene-2-methyl-4-oxo-2-oxazolidinecarboxylate (VII) by treatment with methanolic hydrogen chloride. VI was also derived from III or IV by treatment with sodium hydroxide. *N*-(α-Acetoxycinnamoyl)-*N*-hydroxy-DL-alanine *t*-butyl ester prepared from *N*-hydroxy-DL-alanine *t*-butyl ester and II, was treated with aqueous sodium hydroxide to give *t*-butyl 5-benzylidene-2-methyl-4-oxo-2-oxazolidinecarboxylate.

In the preceding paper we described the preparation of 3-benzylidene-6-isobutyl-2,5-piperazinedione by the reaction of esters of *N*-(α-acetoxycinnamoyl)-L-leucine with ammonia.[1] In an extention of the reaction to *N*-(α-acetoxycinnamoyl)-*N*-benzyloxy-DL-alanine ethyl ester, it might be expected that 1-benzyloxy-3-benzylidene-6-methyl-2,5-piperazinedione would be formed. This paper deals with an unexpected formation of imidazolidinone in such a reaction and its transformations into pyrrolidinedione and oxazolidinone.

Reaction of *N*-benzyloxy-DL-alanine ethyl ester (I) with α-acetoxycinnamoyl chloride (II) gave *N*-(α-acetoxycinnamoyl)-*N*-benzyloxy-DL-alanine ethyl ester (III), which was confirmed by infrared and NMR spectrum. The acetyl group of III could be easily removed by treatment with aqueous sodium bicarbonate, piperidine or hydroxylamine, and *N*-benzyloxy-*N*-(phenylpyruvoyl)-DL-alanine ethyl ester (IV) was obtained. The product was characterized by its conversion to the 2,4-dinitrophenylhydrazone.



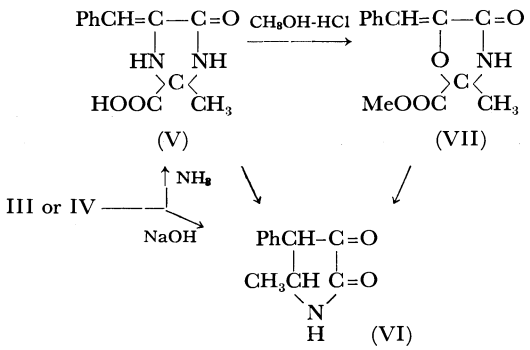
(I) (II)

(III) (IV)

Treatment of IV with ammonia failed to give the expected 2,5-piperazinedione but instead furnished a crystalline product with mp 228—229°C in 60% yield. This compound was also obtained directly from III by treatment with ammonia. Elemental analysis and determination of molecular weight indicated a molecular formula, $C_{12}H_{12}N_2O_3$ for the product, which gives a negative ferric chloride reaction and is insoluble in 1 N hydrochloric acid and in aqueous sodium bicarbonate. These properties as well as the infrared and NMR spectrum revealed the product to be 5-benzylidene-2-methyl-4-oxo-2-imidazolidinecarboxylic acid (V). The

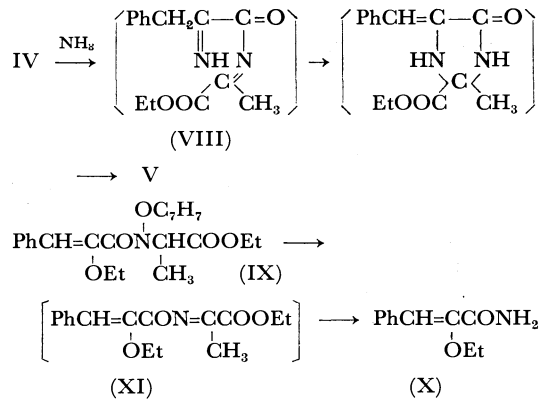
1) Y. Chigira, M. Masaki and M. Ohta, This Bulletin, **42**, 224 (1969).

infrared spectrum showed absorption bands at 3440, 3250 (NH), 3170 (NH), 1710 (COOH), 1690 (CONH), 1680 (C=C) and 1360 cm^{-1}, and the NMR spectrum exhibited signals at τ 8.3 (s, 3H), 7.95 (s, 1NH), 3.85 (s, 1H), 2.6, 2.25 (m, 5H), 2.3 (s, 1NH) and −0.1 (s, 1COOH).[2] 4-Imidazolidinones have been reported to show the infrared absorptions at 1690—1710 (C=O) and 1400—1420 cm^{-1}.[2d]

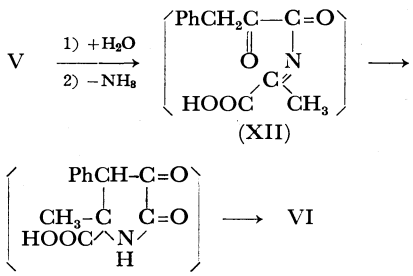


A probable pathway for this reaction would involve an initial elimination of benzyl alcohol from IV, followed or accompanied by the reaction of the ketonic group with ammonia to give ethyl 2 - (2 - imino - 3 - phenylpropionylimino)propionate (VIII) which then cyclized to the ethyl ester of V, and hydrolysis of the ester would yield V. The elimination of benzyl alcohol from IV appeared to be an unexpected reaction, since hydroxamic acids or *N*-acyl-*N*-(benzyloxy)amines are generally stable under the conditions used in the above reaction. However the ease with which benzylalcohol was eliminated from *N*-acyl-*N*-benzyloxy amino acid esters was supported by our previous observation: the alkaline treatment of ethyl *N*-(α-ethoxycinnamoyl)-*N*-benzyloxy-DL-alanine ethyl ester (IX) gave α-ethoxycinnamic amide (X).[1] This reaction was also explained by initial elimination of benzyl alcohol from IX followed by hydrolysis of the resultant ethyl 2-(α-ethoxycinnamoylimino)-propionate (XI) to give the amide (X).

When V was dissolved in aqueous sodium hydroxide and then neutralized with hydrochloric acid, the imidazolidinone (V) could not be recovered but instead pyrrolidinedione (VI) was obtained in 80% yield. The structure of VI was derived from elemental analysis, a positive ferric chloride reaction and spectral studies. The ultraviolet spectrum



showed absorption maxima at 221, 227 and 287 mμ and the infrared spectrum showed absorption bands at 3200 (NH), 1710 (C=O) and 1670 (CONH) cm^{-1}. This infrared absorption pattern is virtually identical with that described for pyrrolidinediones, *i. e.*, 1700—1730 (C=O) and 1670 (CONH) cm^{-1}.[3] The NMR spectrum exhibited a three-proton doublet at τ 8.8, a one-proton multiplet at 5.45 and a six-proton multiplet at 2.5. The transformation of V into VI would be reasonably explained by an initial hydrolytic fission of carbon-nitrogen bond of the enamine moiety in V accompanied by loss of ammonia to give 2-(phenylpyruvoylimino)-propionic acid (XII), a cyclization of which followed by the decarboxylation yielded VI. The involvement of the intermediate XII in this reaction was supported by the direct formation of VI from III or



IV. When III or IV was dissolved in 20% aqueous sodium hydroxide and then acidified with hydrochloric acid, pyrrolidinedione (VI) was obtained in 44% and 49% yield respectively.[4] In these reactions, the initial elimination of benzyl alcohol with base would give the ester of XII as intermediate.

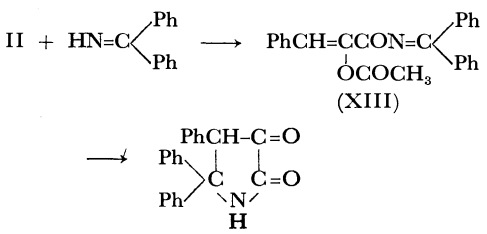
A pyrrolidinedione would be obtained if a α-

2) 4-Imidazolidinones have been prepared by desulfurization of thiohydantoins or by the condensations of α-amino nitriles or α-amino acid amides with carbonyl compounds: a) J. T. Eduards and E. F. Matlem, *Chem. Ind.*, **1954**, 193; b) K. Freter, J. Rabinowitz and B. Witkop, *Ann.*, **607**, 174 (1957); c) A. C. Davis and A. L. Levy, *J. Chem. Soc.*, **1951**, 3479; d) U. Zehavi and D. Ben-Ishai, *J. Org. Chem.*, **26**, 1097 (1961).

3) a) P. L. Southwick and E. F. Barnas, *ibid.*, **27**, 98 (1962); b) P. L. Southwick and J. A. Vida, *ibid.*, **27**, 3075 (1962).

4) 2,3-Pyrrolidinediones have been known to be synthesized by the condensations of α-keto acids or its esters with aldehydes and aromatic amines: a) H. Keskin, *Rev. faculté sci. univ. Istanbul*, **11A**, 1 (1946); *Chem. Abstr.*, **40**, 5427 (1946); b) J. R. Merchant, R. J. Shah and R. M. Bhandarkar, *Rec. Trav. Chim.*, **81**, 131 (1962).

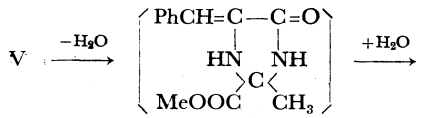
ketoacylimine was formed by an alternative route. Treatment of 1,1-diphenylmethylenimine with α-acetoxycinnamoyl chloride (II) afforded *N*-(α-acetoxycinnamoyl)-1,1-diphenylmethylenimine (XIII) which was unstable and decomposed gradually with atomospheric moisture at room temperature to yield α-acetoxycinnamic amide and benzophenone. When XIII was treated with sodium ethoxide, deacetylation followed by cyclization occurred and 4,5,5-triphenyl-2,3-pyrrolidinedione (XIV) was obtained as expected.



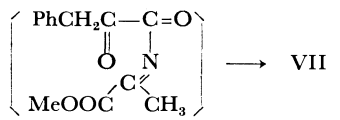
(XIII)

(XIV)

When V was treated with hydrogen chloride in methanol, methyl 5-benzylidene-2-methyl-4-oxo-2-oxazolidinecarboxylate (VII) was obtained in 38% yield. The structure was derived from elemental analysis and spectral studies. The infrared spectrum showed absorption bands at 3070 (NH), 1730 (COOMe), 1710 (CONH) and 1670 (C=C) cm^{-1}. The NMR spectrum exhibited signals at τ 8.15 (s, 3H), 6.2 (s, 3H), 3.65 (s, 1H), 2.6, 2.25 (m, 5H) and 1.05 (s, 1NH).[5] The transformation of V into VII would be rationalized as follows: an initial esterification of V would give the methyl ester (XV) and water, which reacted in the presence of proton to afford methyl 2-phenylpyruvoyliminopropionate (XVI). In contrast to the cyclization of XII into VI under a basic condition, XVI was cyclized to VII in the presence of acid. Treatment of VII with 1 N aqueous sodium hydroxide resulted in the transformation into the pyrrolidinedione (VI) quantitatively. The transformation of



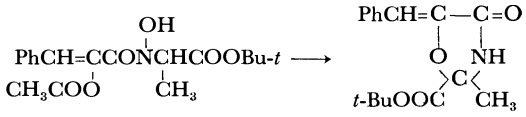
(XV)



(XVI)

VII into VI would involve again the intermediate XII.

In an analogous fashion, *N*-(α-acetoxycinnamoyl)-*N*-hydroxy-DL-alanine *t*-butyl ester (XVII) was prepared by treatment of *N*-hydroxy-DL-alanine *t*-butyl ester with α-acetoxycinnamoyl chloride (II) in the presence of pyridine. Reaction of XVII with 1 N aqueous sodium hydroxide afforded *t*-butyl 5-benzylidene-2-methyl-4-oxo-2-oxazolidinecarboxylate (XVIII). The structure of XVIII was confirmed by elemental analysis and spectral studies. The infrared spectrum showed absorption bands at 3250 (NH), 1735 (COOBu-*t*), 1710 (CONH) and 1680 (C=C) cm^{-1}. The NMR spectrum exhibited a nine-proton singlet at τ 8.5, a three-proton singelt at 8.2, a one-proton singlet at 3.7 and five-proton multiplets centered at 2.3 and 2.7. These absorption patterns were virtually identical with those of VII.



(XVII) (XVIII)

The formation of XVIII from XVII would be also rationalized by dehydration from the hydroxamic moiety of XVII and hydrolysis of the acetoxy moiety followed by a cyclization of the resultant *t*-butyl ester of XII. It is of contrast that the oxazolidinone (XVIII) was formed from *t*-butyl ester of XII under alkaline conditions, while XII was cyclized into the pyrrolidinedione (VI) under similar conditions. The difference should be attributed to the bulkiness of the *t*-butyl group: the formation of pyrrolidinedione from XVII would be impossible since the steric hindrance between phenyl and *t*-butyl groups is so strong that the imino carbon of *t*-butyl ester of XII can not be attacked by the methylene group flanked by phenyl and carbonyl groups, while the steric hindrance would not be so effective in the case of the formation of XVIII.

It is of interest that α-(*N*-acylimino) acid esters (VIII, XI and the esters of XII) were readily formed, but as intermediates, from *N*-acyl derivatives of *N*-benzyloxy- or *N*-hydroxy-DL-alanine esters (IV, IX and XVII) by elimination of benzyl alcohol or water under basic conditions.

Experimental[6]

N-(α-Acetoxycinnamoyl)-N-benzyloxy-DL-alanine Ethyl Ester (III). A solution of α-acetoxycinnamoyl

5) 4-Oxazolidinones have been prepared by the condensations of carbonyl compounds with α-hydroxy nitriles or α-hydroxy acid amides: a) K. Eichenberger, E. Ganz and J. Druey, *Helv. Chim. Acta*, **38**, 284 (1955); b) J. B. Bicking, S. F. Kwong, M. H. Fisher and W. H. Nicholson, *J. Med. Chem.*, **8**, 95 (1965); *Chem. Abstr.*, **62**, 5262 (1965).

6) All melting points were determined in a liquid bath. These and all boiling points are uncorrected. All concentrations and evaporations were carried out under reduced pressure. Infrared spectra were determined on a Hitachi EPI-S2 spectrophotometer as

chloride[1] (II) (3.5 g) in absolute ether (40 ml) was added in portions, with stirring under ice cooling, to a solution of *N*-benzyloxy-DL-alanine ethyl ester[1] (I) (3.5 g) and pyridine (1.2 g) in absolute ether (40 ml). After stirring for 1 hr, the precipitated pyridine hydrochloride (2.1 g) was filtered off. The filtrate was washed successively with water, aqueous sodium bicarbonate, twice with water, 1 N hydrochloric acid, and finally twice with water, and dried over anhydrous sodium sulfate. Evaporation of the ether yielded the product (5.2 g, 81%) as a sirup, which was homogeneous in thin-layer chromatography on silica gel [developed with benzene-alcohol (4:1) or ethyl acetate].

IR (liquid film): 2950, 1765 (CH_3COO), 1740 (COOEt), 1665 (C=C), 1645 (CON<), 1210 and 700 cm^{-1}.

NMR (CCl_4): τ 8.8 (t, 3H), 8.5 (d, 3H), 7.85 (s, 3H), 5.85 (q, 2H), 5.0 (s, 2H), 4.95 (q, 1H), 3.1 (s, 1H), 2.7 (s, 5H) and 2.6 (m, 5H).

***N*-Benzyloxy-*N*-(phenylpyruvoyl)-DL-alanine Ethyl Ester (IV).** *A)* To 1 N methanolic hydroxylamine solution (10 ml) was added III (2.0 g) and the resultant solution was allowed to stand at room temperature for 3 days and then heated at 50—60°C on a water bath for 2 hr. After removal of the methanol, the oily residue was dissolved in ether (20 ml). The ethereal solution was washed successively with water, aqueous sodium bicarbonate, water, 1 N hydrochloric acid and finally with water, and dried over sodium sulfate. The ether was evaporated to afford the product (1.35 g, 75%) as a sirup.

IR (liquid film): 2950, 1740 (COOEt), 1720 (C=O), 1675 (C=C), 1620 (CON<) and 700 cm^{-1}.

2,4-Dinitrophenylhydrazone of IV. To a solution of the product (0.3 g) in methanol (5 ml) was added a methanolic solution of 2,4-dinitrophenylhydrazine sulfate. After a day, the precipitated oily product was separated by decantation and washed twice with methanol. The oily product was dissolved in boiling methanol and the solution was allowed to stand for a week to afford crystalline precipitates. Recrystallization from ethanol afforded yellow needles (0.5 g), mp 135—136°C.

Found: C, 58.97; H, 5.25; N, 12.88%. Calcd for $C_{27}H_{27}N_5O_8$: C, 59.01; H, 4.95; N, 12.75%.

B) A solution of III (1.0 g) and piperidine (0.21 g) in tetrahydrofuran (25 ml) was allowed to stand at room temperature for a day. After removal of the tetrahydrofuran, the oily residue was treated in a manner analogous to the method A to give IV in 70% yield.

C) A solution of III (1.0 g) in tetrahydrofuran was added to a solution of sodium bicarbonate (0.2 g) in water (25 ml) and methanol (2 ml). After a day, the tetrahydrofuran was removed and the aqueous solution was extracted with ether and the ethereal extract was treated in a manner analogous to the method A to give IV in 68% yield.

5-Benzylidene-2-methyl-4-oxo-2-imidazolidinecarboxylic Acid (V). *A) From IV.* A solution of IV (0.8 g) in methanol (20 ml) was saturated with gaseous ammonia under cooling and allowed to stand at room temperature for a day. After removal of the methanol, the crystalline residue was treated with ether. Recrystallization from acetonitrile yielded colorless needles (0.3 g, 60%). A portion of the product was recrystallized from isopropyl alcohol into colorless needles and then from 80% aqueous methanol into colorless prisms, mp 228—229°C.

Found: C, 61.59; H, 5.05; N, 12.07%; mol wt 220. Calcd for $C_{12}H_{12}N_2O_3$: C, 62.06; H, 5.21; N, 12.06%; mol wt 232.

B) From III. A solution of III (0.6 g) in methanol (30 ml) was saturated with gaseous ammonia under cooling and allowed to stand for 2 days. After removal of the methanol, ethyl acetate was added to the residual mixture of an oil and crystals. The insoluble crystals were collected (0.15 g, 44%) and recrystallized from acetonitrile, mp 227—228°C. The product was identical, in melting point and infrared spectrum, with the sample obtained in method A.

5-Methyl-4-phenyl-2,3-pyrrolidinedione (VI). *A)* The imidazolidinone V (0.4 g) was dissolved in 1 N sodium hydroxide (10 ml) and allowed to stand at room temperature overnight. The solution was acidified with 1 N hydrochloric acid to afford gradually crystalline precipitates. The solid was collected and recrystallized from benzene into colorless needles (0.26 g, 80%), mp 228—229°C (with sublimation).

Found: C, 69.45; H, 5.82; N, 7.43%. Calcd for $C_{11}H_{11}NO_2$: C, 69.82; H, 5.86; N, 7.40%.

B) From III. A suspension of III (1.0 g) in 20% aqueous sodium hydroxide was stirred for 6 hr. The resultant clear solution was washed with ether, treated with activated charcoal and acidified with 3 N hydrochloric acid. The precipitated oily product was extracted twice with ether. The ethereal extract was dried over anhydrous sodium sulfate and then evaporated. Addition of carbon tetrachloride to the residual oil gave gradually crystalline product (0.2 g, 44%). Recrystallization from benzene afforded colorless needles, mp 228—229°C. The product was identical, in melting point and infrared spectrum, with the sample obtained by method A.

C) From IV. A suspention of IV (0.6 g) in 20% aqueous sodium hydroxide was treated in a manner analogous to method B to afford the product (0.15 g, 49%).

***N*-(α-Acetoxycinnamoyl)-1,1-diphenylmethylenimine (XIII).** A solution of α-acetoxycinnamoyl chloride (II) (1.5 g) in absolute ether (40 ml) was added in portions, with stirring under ice cooling, to a solution of 1,1-diphenylmethylenimine[7] (2.44 g) in absolute ether (20 ml). After stirring for 2 hr, the precipitated 1,1-diphenylmethylenimine hydrochloride (1.7 g) was filtered off, and the ethereal filtrate was concentrated to dryness. The crystalline residue was treated with dry petroleum ether (bp 30—60°C) to give colorless crystalline product (2.1 g, 84%). A portion of the product was recrystallized from di-*n*-butyl ether to give colorless prisms, mp 98.0—98.5°C.

Found: C, 77.23; H, 5.20; N, 4.35%. Calcd for $C_{24}H_{19}NO_3$: C, 78.03; H, 5.18; N, 3.79%.

KBr disks, unless otherwise indicated. NMR spectra were recorded on JUM4H-100 spectrometer (Japan Electron Optics Laboratory Co.) with tetramethylsilane as internal standard. Molecular weight was measured with a Hitachi-Perkin-Elmer 115 apparatus in dimethylformamide.

7) A. Lachman, "Organic Syntheses," Coll. Vol. II, p. 234 (1943).

IR: 1765 (CH_3COO), 1675 (C=C), 1635 (CON=), 1600, 1210 and 700 cm^{-1}.

This compound is very unstable and decomposed on recrystallization into benzophenone and α-acetoxycinnamic amide. The latter compound was recrystallized from benzene to give colorless needles, mp 143°C.

Found: C, 64.64; H, 5.38; N, 7.01%. Calcd for $C_{11}H_{11}NO_3$: C, 64.38; H, 5.40; N, 6.83%.

4,5,5-Triphenyl-2,3-pyrrolidinedione (XIV). A solution of XIII (0.7 g) in methanol (20 m*l*) was added to sodium methoxide solution [from sodium (0.05 g) and methanol (10 m*l*)] with stirring at room temperature. After a day, the crystalline solid was collected, washed with ether, and then suspended in 1 N hydrochloric acid (10 m*l*). The suspension was extracted with ether and the ethereal extract was dried over anhydrous sodium sulfate. Evaporation of the ether afforded the crystalline product, which was recrystallized from benzene to give colorless needles (0.45 g, 73%), mp 257—258°C.

Found: C, 80.01; H, 5.23; N, 4.55%. Calcd for $C_{22}H_{17}NO_2$: C, 80.71; H, 5.23; N, 4.28%.

IR: 3250 (NH), 1690 (C=O), 1430, 1300, 890, 760 and 700 cm^{-1}.

NMR ($CDCl_3$-DMSO-d_6): τ 6.6 (s, 1H), 2.7 (15H) and 1.65 (s, 1H).

Methyl 5-Benzylidene-2-methyl-4-oxo-2-oxazolidinecarboxylate (VII). A solution of V (0.1 g) in absolute methanol (10 m*l*) was refluxed for 1 hr, while dry hydrogen chloride was passed through the solution, and allowed to stand at room temperature overnight. After removal of the methanol, ether was added to the crystalline residue and the insoluble ammonium chloride (0.035 g) was filtered off. The ethereal filtrate was evaporated to give the crystalline product (0.04 g, 38%). Recrystallization from di-*n*-butyl ether afforded colorless needles, mp 124.5—125.0°C.

Found: C, 62.88; H, 5.36; N, 5.88%. Calcd for $C_{13}H_{13}NO_4$: C, 63.15; H, 5.30; N, 5.69%.

Reaction of VII with Sodium Hydroxide. A solution of VII (0.13 g) in 1 N aqueous sodium hydroxide (5 m*l*) was allowed to stand at room temperature overnight. Neutralization of the solution with 3 N hydrochloric acid afforded crystalline precipitates (0.1 g, 100%) which were collected and recrystallized from benzene, mp 228—229°C. The product was identical, in melting point and infrared spectrum, with the pyrrolidinedione (VI) obtained from V.

***N*-(α-Acetoxycinnamoyl)-*N*-hydroxy-DL-alanine *t*-Butyl Ester (XVII).** A solution of II (1.3 g) in absolute ether (20 m*l*) was added portionwise, with stirring, to a solution of *N*-hydroxy-DL-alanine *t*-butyl ester (0.93 g) and pyridine (0.4 g) in absolute ether (20 m*l*). After 1 hr, water was added to the mixture and the ethereal layer was washed successively with water, aqueous sodium bicarbonate, water, 1 N hydrochloric acid, and finally twice with water, and dried over anhydrous sodium sulfate. The ether was evaporated to afford the product as a pale yellow sirup (1.5 g, 74%), which gives a deep red color with a methanolic ferric chloride solution. The product was used in a succeeding reaction without further purification.

IR (liquid film): 1780 (CH_3COO), 1730 (COOBu-*t*), 1675, 1370, 1160 and 700 cm^{-1}.

***t*-Butyl 5-Benzylidene-2-methyl-4-oxo-2-oxazolidinecarboxylate (XVIII).** A solution of XVII (1 g) in 1 N aqueous sodium hydroxide was allowed to stand at room temperature overnight. The solution was washed twice with ether, treated with activated charcoal and then saturated with carbon dioxide to separate a mixture of crystals and a yellow oil, which was extracted four times with ether. The combined ethereal extracts were dried over anhydrous sodium sulfate and concentrated to give a crystalline residue (0.3 g, 36%). Rapid recrystallization from di-*n*-butyl ether (lower than 90°C) yielded colorless needles, mp 154.5—155.5°C.

Found: C, 66.20; H, 6.24; N, 4.87%. Calcd for $C_{16}H_{19}NO_4$: C, 66.42; H, 6.62; N, 4.84%.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 233—236 (1969)

The Synthesis of 3-Hydroxy-8,9-dimethoxypterocarpan*1

Kenji FUKUI, Mitsuru NAKAYAMA and Teruo HARANO

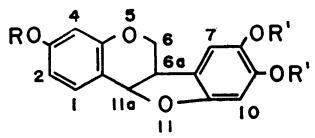
Department of Chemistry, Faculty of Science, Hiroshima University, Higashi Sendamachi, Hiroshima

(Received June 12, 1968)

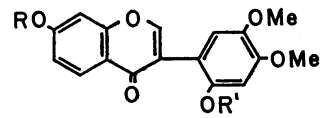
7,2′-Dihydroxy-4′,5′-dimethoxyisoflavone was obtained from 7-hydroxy-2′,4′,5′-trimethoxyisoflavone by selective demethylation with aluminum chloride in acetonitrile. By partial benzylation, the dihydroxyisoflavone then gave 7-benzyloxy-4′,5′-dimethoxy-2′-hydroxyisoflavone. The subsequent treatment of the latter with sodium borohydride afforded 3-hydroxy-8,9-dimethoxypterocarpan *via* its 3-benzyloxy-compound.

In connection with the investigation of the syntheses of natural pterocarpans (*e.g.*, (±)-maackiain (I)[1] and (±)-pterocarpin (II)[2]), the syntheses of the same oxygenated analogues and the spectral comparisons of these compounds were attempted. This paper will describe the syntheses of 3-hydroxy-8,9-dimethoxypterocarpan (III)*2 and related compounds from 7-hydroxy-2′,4′,5′-trimethoxyisoflavone (IV).[3]

The selective demethylation at the 2′-position[4] of the 7-hydroxyisoflavone (IV) or of its 7-benzyl derivative (V) in acetonitrile with aluminum chloride afforded 7,2′-dihydroxy-4′,5′-dimethoxyisoflavone (VI) in a good yield; the product then gave a diacetate with acetic anhydride. The partial benzylation of VI at room temperature yielded 7-benzyloxy-4′,5′-dimethoxy-2′-hydroxyisoflavone (VII), which was then easily converted to a monoacetate by a usual method. The treatment of VII with sodium borohydride in absolute alcohol-tetrahydrofuran furnished a product (VIII), $C_{24}H_{22}O_5$, mp 142—143°C, in a good yield. This product (VIII) shows no infrared absorption due to hydroxyl or carbonyl groups (Fig. 1). A comparison of the NMR spectrum (Fig. 2, Table 1)*3 of the product (VIII) with those of pterocarpan derivatives reported in the literature[5] indicates



I R = H R′-R′ = CH2
II R = Me R′-R′ = CH2
III R = H R′ = Me
VIII R = C6H5CH2 R′ = Me
X R = CH3CO R′ = Me
XI R = R′ = Me



IV R = H R′ = Me
V R = C6H5CH2 R′ = Me
VI R = R′ = H
VII R = C6H5CH2 R′ = H

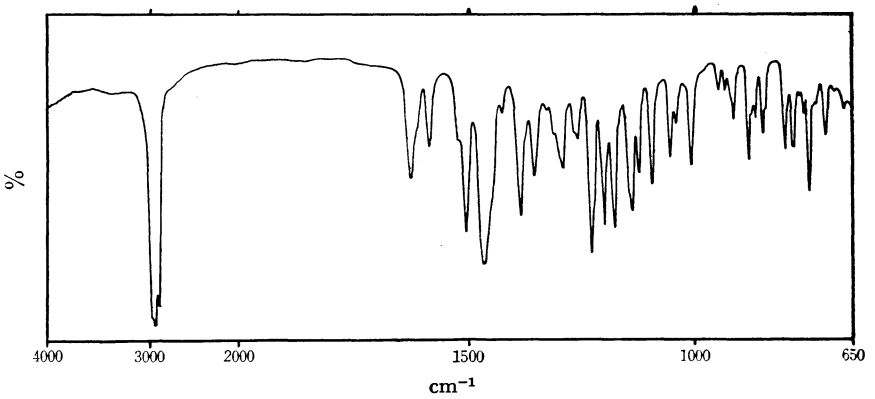

Fig. 1. IR spectrum of VIII (Nujol).

that the broad band at 5.35—5.55 (1H) is due to the C-11a proton, while the complex multiplet at from 3.5–4.5 (3H) surrounding the methoxy resonance is to be assigned to the C-6 protons and the C-6a proton. Accordingly, the structure of VIII is formulated as 3-benzyloxy-8,9-dimethoxypterocarpan. The reaction of the 2′-hydroxyisoflavone (VII) with sodium borohydride to the pterocarpan (VIII) can be postulated as proceeding through an intermediary, a 2′-hydroxyisoflavan-4-ol derivative, 7-benzyloxy-4′,5′-dimethoxy-2′-hydroxyisoflavan-4-ol (IX), followed by dehydration. Attempts to isolate the intermediate (IX) were, however, unsuccessful. The debenzylation of VIII with hydrogen afforded the desired pterocarpan, III, which was also obtained from the 7,2′-dihydroxyisoflavone (VI) by a similar method.

The structure of III is confirmed by the NMR spectra of III, its acetate (X), and methyl ether (XI), which were easily obtained by usual methods. These data are collected in Table 1. The representative NMR spectrum of the acetate (X) is shown in Fig. 3. The aromatic protons are assigned by comparing the data on them with the previously reported data on related compounds, the known values of substituent effects on chemical shifts in aromatic molecules,[6] and the characteristic magnitudes of the aromatic proton-proton splittings.[7]

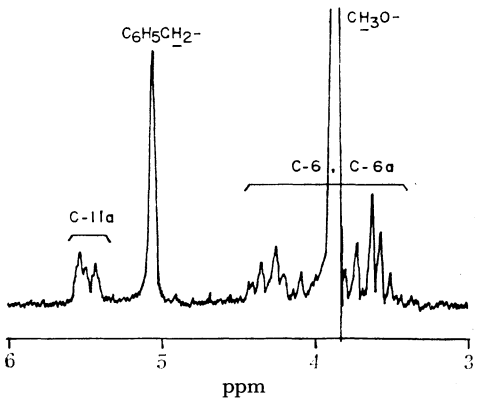

Fig. 2. NMR spectrum of VIII ($CDCl_3$).

Experimental*5

7-Benzyloxy-2′,4′,5′-trimethoxyisoflavone (V). A mixture of the isoflavone IV[3] (1.5 g), anhydrous potassium carbonate (5.0 g), and benzyl chloride (1.0 g) in anhydrous acetone (80 m*l*) was refluxed for 6 hr. The reaction mixture was then treated in a usual manner. The resulting solid was collected and recrystallized from ethanol to give colorless plates of V, mp 143—144°C (lit.[8] mp 144—145°C); yield, 1.5 g. IR: 1641 cm^{-1} (C=O). UV: λ_{max} mμ (log ε); 247.5 (4.40), 296.5 (4.32).

Found: C, 71.81; H, 5.43%. Calcd for $C_{25}H_{22}O_6$: C, 71.76; H, 5.30%.

7,2′-Dihydroxy-4′,5′-dimethoxyisoflavone (VI). *a) From IV.* A mixture of IV (1.2 g) and anhydrous aluminum chloride (4.0 g) in anhydrous acetonitrile (30 m*l*) was refluxed for 12 hr. After the solvent had been removed, the residue was treated with 10% hydrochloric acid. The resulting solid was collected, washed with water, and recrystallized from ethanol to give light yellow needles of VI, mp 236—237°C; yield, 1.0 g. IR: 3460 (OH), 1619 cm^{-1} (C=O). UV: λ_{max} mμ (log ε); 249_i (4.30),*6 265_i (4.22), 301 (4.28).

Found: C, 64.74; H, 4.58%. Calcd for $C_{17}H_{14}O_6$: C, 64.96; H, 4.49%.

The diacetate: hot acetic anhydride-anhydrous sodium acetate method; mp 152—153°C (colorless needles from ethanol). IR: 1755, 1640 cm^{-1} (C=O). UV: λ_{max} mμ (log ε): 245.5_i (4.38), 290 (4.06).

Found: C, 63.26; H, 4.60%. Calcd for $C_{21}H_{18}O_8$: C, 63.31; H, 4.55%.

b) From V. By a reaction similar to that described above, V (1.2 g), anhydrous aluminum chloride (4.0 g), and anhydrous acetonitrile (30 m*l*) gave VI, mp 236—237°C, which was identical with the sample derived by the above-described method a); yield, 0.85 g.

7-Benzyloxy-2′-hydroxy-4′,5′-dimethoxyisoflavone (VII). Dihydroxyisoflavone VI (0.4 g), benzyl chloride (0.15 g), and anhydrous acetone (100 m*l*) were kept at room temperature for 32 hr while being stirred. After the potassium salts and acetone had then been removed, the water was added to the residue. The resulting solid was collected and recrystallized from ethanol to give yellow needles of VII, mp 172—173°C; yield, 0.3 g. IR: 1622 cm^{-1} (C=O). UV: λ_{max} mμ (log ε); 245_i (4.35), 267 (4.27), 299 (4.32).

Found: C, 70.97; H, 4.98%. Calcd for $C_{24}H_{20}O_6$: C, 71.28; H, 4.99%.

The acetate: hot acetic anhydride-anhydrous sodium acetate method; mp 154—155°C (colorless needles from ethanol). IR: 1750, 1640, 1630 cm^{-1} (C=O). UV: λ_{max} mμ (log ε); 248 (4.40), 293.5 (4.19), 304_i (4.12).

Found: C, 70.13; H, 5.03%. Calcd for $C_{26}H_{22}O_7$: C, 69.94; H, 4.97%.

3-Benzyloxy-8,9-dimethoxypterocarpan (VIII). A solution of sodium borohydride (0.4 g) in absolute ethanol (10 m*l*) was added, drop by drop to a solution of the isoflavone VII (0.3 g) in anhydrous tetrahydrofuran (50 m*l*). The reaction mixture was then kept for 50 hr at room temperature while being stirred. After acetone (20 m*l*) had been added to decompose the excess reducing agent, the solvent was removed under reduced presusre, and 10% hydrochloric acid was added. The separated solid was collected, washed with water, and recrystallized from ethanol to give colorless plates of VIII, mp 142—143°C; yield, 0.22 g. IR: 1627, 1583, 1505 cm^{-1}

*5 All the melting points are uncorrected; the infrared spectra were measured in Nujol, while the ultraviolet spectra were measured in an ethanol solution.

8) K. Fukui and M. Nakayama, This Bulletin, **38**, 1803 (1965).

*6 i=inflection point.

(phenyl). UV: λ_{max} mμ (log ε); 287 (3.88), 298 (3.85).

Found: C, 73.99; H, 5.63%. Calcd for $C_{24}H_{22}O_5$: C, 73.83; H, 5.68%.

3-Hydroxy-8,9-dimethoxypterocarpan (III). *a) From VIII.* A solution of VIII (0.1 g) in acetic acid (40 ml) was submitted to catalytic hydrogenolysis at room temperature in the presence of Pd-C (10%: 0.04 g). After the catalyst had been filtered out, the filtrate was evaporated under reduced pressure; the residue was then recrystallized from dilute ethanol to give colorless crystals of III, mp 209—211°C; yield, 0.06 g. IR: 3460 (OH), 1625, 1595, 1515, 1495 cm^{-1} (phenyl). UV: λ_{max} mμ (log ε); 288 (3.85), 298 (3.85).

Found: C, 65.91; H, 5.68%. Calcd for $C_{17}H_{16}O_5 \cdot \frac{1}{2}H_2O$: C, 66.01; H, 5.54%.

b) From VI. By a reaction similar to that described above, VI (0.6 g) and sodium borohydride (0.7 g) were treated in ethanol - tetrahydrofuran for 60 hr, giving III, mp 209—211°C, which was identical with a sample derived by the above-described method a); yield, 0.5 g.

The acetate (X): hot acetic anhydride - anhydrous sodium acetate method; mp 146—147°C (colorless crystals from ethanol). IR: 1757 (C=O), 1620, 1592, 1501 cm^{-1} (phenyl). UV: λ_{max} mμ (log ε); 288_i (3.76), 300 (3.83).

Found: C, 66.63; H, 5.33%. Calcd for $C_{19}H_{18}O_6$: C, 66.66; H, 5.30%.

The methyl ether (XI): methyl iodide - anhydrous potassium carbonate-acetone method; mp 136—137°C (colorless needles from ethanol). IR: 1616, 1570, 1505, 1492 cm^{-1} (phenyl). UV: λ_{max} mμ (log ε); 288 (3.83), 300 (3.83).

Found: C, 68.49; H, 5.82%. Calcd for $C_{18}H_{18}O_5$: C, 68.78; H, 5.77%.

The authors wish to express their thanks to Professor Shô Itô, Tohoku University, for his NMR spectra measurements. This work was supported in part by a grant-in-aid from the Ministry of Education.

Spectrophotometric Determination of Iron(III) with Rhodamine B and Confirmation of the Composition of Its Complex*1

Hiromu IMAI and Tadahiko YAMADA

Faculty of Engineering, Kansai University, Senriyama, Suita-shi

(Received September 21, 1967)

Rhodamine B (RHCl) has been used in the spectrophotometric determination of gallium(III), gold(III), thallium(III), and antimony(V), forming a complex which can be extracted with organic solvents. Iron(III) also forms a complex with rhodamine B. Consequently, iron(III) in a sample solution interferes with the determination of the above metals.[1-3] It is reported that the iron complex could not be extracted from a 1 N hydrochloric acid solution with benzene by Snell and Snell,[4] or from a 6 N hydrochloric acid solution with isopropyl ether by Onishi and Sandell.[5] However, when a certain organic solvent was used, this complex could be extracted under satisfactory conditions. For these reasons, the spectrophotometric determination of iron(III) based on this color reaction was attempted in a previous work by extraction from a 6 N hydrochloric acid solution with benzene,[6] but this method was not satisfactory because of the lower sensitivity.

The purpose of the present work is to study the determination of a trace of iron(III) with high sensitivity by improving the procedure reported in the previous paper,[6] and to confirm the composition of this complex by employing the method of continuous variation, and that of Molland.

Experimental

Reagents. *Standard Iron(III) Solution.* The stock solution of iron(III) was prepared by dissolving about 3 g of a reagent-grade iron(III) chloride in 250 m*l* of 1 N hydrochloric acid. The concentration of iron in this solution was determined by the oxine method.[7]

Rhodamine B Solution. The solution was prepared by dissolving 0.3 g of RHCl (JIS special grade) dried at 110°C for about 3 hr in 100 m*l* of distilled water.

Extracting Agents. The organic solvents were used after they had been purified by the usual method.[8]

Butyl Cellosolve (BC) Solution. This solution was prepared by dissolving 100 m*l* of ethylene glycol monobutyl ether (butyl cellosolve of Wako Pure Chemicals) in 200 m*l* of distilled water.

Apparatus. A Hitachi photometric photometer, model FPW-4, and an Ito spectrophotometer, model QU-3, were empolyed for all the absorbance measurements, using a 1 cm glass cell.

Standard Procedure for the Determination. A given amount of RHCl, a small amount of BC, and a desired amount of hydrochloric acid were added to a 50 m*l* volumetric flask containing an iron(III) solution, and then mixture was diluted to the mark with water. A 25 m*l* portion of this solution pipetted in a 250 m*l* separating funnel was shaken vigorously with 10 m*l* of an adequate organic solvent for 2 min. The organic layer containing this complex was then completely separated from the aqueous layer by centrifugation. The absorbance of the colored organic layer was measured at 550 mμ or 562 mμ (absorption maximum) against a reference organic solvent treated by the same procedure.

Results and Discussion

The Effects of Extracting Agents. The rhodamine B-iron(III) complex can be extracted from a 6 N hydrochloric acid solution with benzene. The absorption maximum of the colored complex has been known to appear at 558 mμ.[6] If this

Bn: Benzene, MIBK: Methyl isobutyl ketone, DON: Dioxane, EA: Ethyl acetate, IAA: Isoamyl acetate, Ac: Acetone

complex was extracted with benzene only, the sensitivity of determination was relatively low compared the case with other methods. Then, the investigation of adding several mixed solvents to benzene was attempted, while varying the absorbance. The results are shown in Table 1.

The maximum degree of extraction of the complex formed in the aqueous solution was obtained by using the mixed solvent of benzene-MIBK. The reference solvent, when treated with the same procedure, gradually colored, while the MIBK concentration increased. As it is best for the color of the reference solvent to be colorless for the spectrophotometric determination, this complex was extracted with benzene containing 10 per cent MIBK by volume.

Effect of Hydrochloric Acid Concentration on the Extraction. The effect of acid concentration on the extraction was examined by using the above solvent.

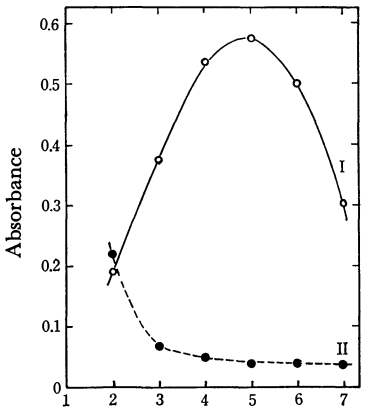

Fig. 1. Effect of acid concentration on absorbance.
Fe(III): 41.63 μg/50 ml, BC: 2 ml/50 ml, 0.3% RHCl: 5 ml/50 ml. Extracting solvent: Bn 9 ml+MIBK 1 ml/Sample soln. 25 ml. Wavelength: 550 mμ
I: Absorbance of this complex in the solvent
II: Absorbance of the reference solvent

From the curves shown in Fig. 1, it can be seen that the maximum absorbance is obtained when this complex was extracted from 5 N hydrochloric acid solution.

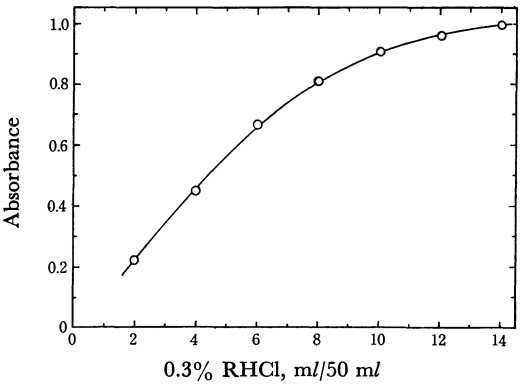

Fig. 2. Effect of RHCl concentration.
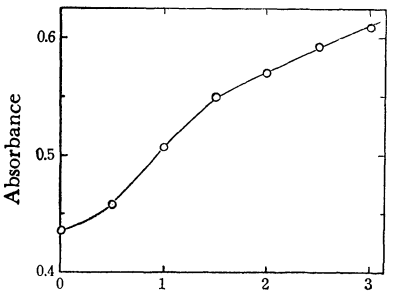
Fe(III): 41.63 μg/50 ml, HCl: 5 N, BC: 2 ml/50 ml. Extracting solvent: Bn 9 ml+MIBK 1 ml/Sample soln. 25 ml. Wavelength: 550 mμ

Effects of the Amounts of RHCl and BC. The effect of adding the RHCl concentration to the aqueous layer on the absorbance was also investigated.

As is shown in Fig. 2, the absorbance depends on the concentration of RHCl. The reference solvent was observed to color gradually with an increase in the RHCl concentration. In view of the color of the reference solvent, we used 10 ml of 0.3% RHCl in one further experiments.

The effect of the amount of BC on the absorbance was studied. The results are shown in Fig. 3.

The absorbance increased with an increase in the amount of BC. When more than 2.5 ml of BC was added, the reference solvent colored considerably, this color intensity was observed to change gradually, when the solvent was permitted to stand.



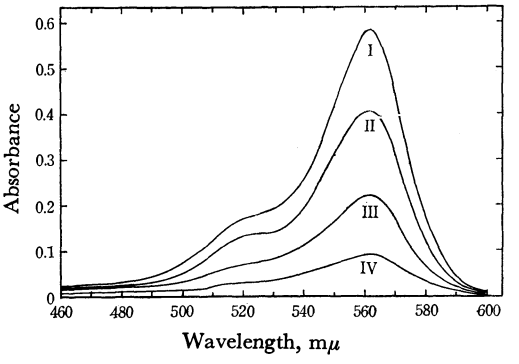
Amount of BC, m*l*/50 m*l*

Fig. 3. Effect of the amount of BC on absorbance. Fe(III): 23.75 μg/50 m*l*, HCl: 5 N, 0.3% RHCl: 10 m*l*/50 m*l*. Extracting solvent: Bn 9 m*l*+MIBK 1 m*l*/Sample soln. 25 m*l*. Wavelength: 550 mμ

Therefore, in further experiments, 2 m*l* of BC were used.

Effect of Time of Standing. The stability of the color intensity of the complex present in the mixed solvent was determined by measuring the absorbance of the organic layer after known periods of time. In such measurements, the absorbance remained almost constant for about 1.5 hr after extraction.

Absorption Spectra and Calibration Curve for Iron(III). Figure 4 shows the absorption spectra of the complex which was extracted from the solution prepared by the addition of varying amounts of 0.3% RHCl to a given amount of iron(III).



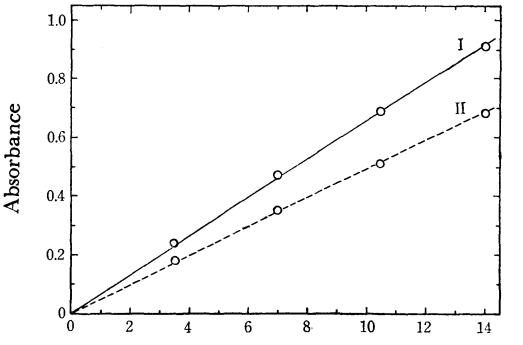
Wavelength, mμ

Fig. 4. Absorption spectra of complex. Fe(III): 23.75 μg/50 m*l*, HCl: 5 N, BC: 2 m*l*/50 m*l*. Extracting solvent: Bn 9 ml+MIBK 1 m*l*/Sample soln. 25 m*l*, 0.3% RHCl (m*l*/50 m*l*): I, 6.0; II, 4.0; III, 2.0; IV, 0.8

The maximum absorption wavelength in the range of RHCl concentration investigated was found at 562 mμ, this result indicated the presence of only one form of the complex.

The calibration curve for the iron(III) determination was prepared at the wavelengths of 550 mμ and 562 mμ in the manner described above.

In all the curves shown in Fig. 5, linear relationships between the absorbance and the concentration are found to be held up to 14 μg of iron(III) in 25 m*l* of the sample solution. The sensitivities of the determination at 562 mμ and 550 mμ were 0.0016 μg and 0.0021 μg iron(III) respectively per cm^2 for $\log(I_0/I)=0.001$. The determination at 562 mμ gives an approximately five-fold increase in the sensitivity compared with the previous investigation.[6]



Fe(III), μg/Sample soln. 25 m*l*

Fig. 5. Calibration curves. HCl: 5 N, BC: 2 m*l*/50 m*l*, 0.3% RHCl: 10 m*l*/50 m*l*. Extracting solvent: Bn 9 m*l*+MIBK 1 m*l*/Sample soln. 25 m*l*. Wavelength: I, 562 mμ; II, 550 mμ

The Effect of Diverse Ions. The interference of diverse metallic ions reacting with RHCl in the determination of iron(III) was studied under the conditions used in the proposed procedure. The results are summarized in Table 2.

It was found that gallium(III), gold(III), and thallium(III) interfered even in the smallest concentrations examined, while antimony(V) (in concentrations of more than about 7 μg/25 m*l*). Mercury(II), bismuth(III), and tin(IV) did not do so markedly.

The Composition of the Complex. The composition of the rhodamine B-iron(III) complex was determined by the two methods used in the determination of the compositions of rhodamine B-gold(III)[9] and -gallium(III) complex.[10]

The Method of Continuous Variation. The absorbance of the complex extracted from the aqueous layer, in which the total concentration of iron (III) and RHCl was 79.89×10^{-5} mol/*l* or 39.91×10^{-5} mol/*l* throughout, was plotted against [Fe]/([Fe]+[RHCl]).

Only one complex, 1 to 1, was recognized as being formed, because the average value of the intersecting points obtained from the curves shown in Fig. 6 was 0.51.

					Average value	1.19

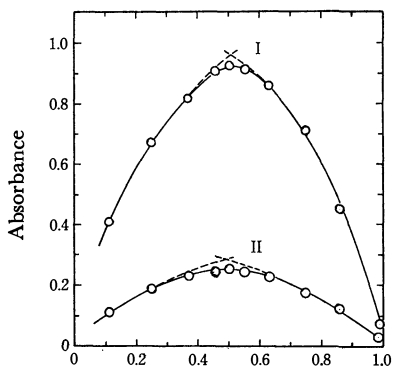

Fig. 6. Method of continuous variation.
Condition: measured at same condition as in Fig. 5. Wavelength: 550 mμ, [Fe]+[RHCl]: I, 79.89×10^{-5} mol/*l*, II, 39.91×10^{-5} mol/*l*

The Molland Method.[11] The formation of the rhodamine B-iron(III) complex can be represented by the following equation[12]:

$$n\mathrm{RH}^+ + m\mathrm{FeCl_4}^- \rightleftarrows (\mathrm{RH})_n\text{-}(\mathrm{FeCl_4})_m \quad (1)$$

Therefore, the absorbance (As_1) of the complex extracted from the solution prepared by the addition of an RHCl solution (b mol/*l*) to a solution containing iron(III) (a mol/*l*) can be written:

$$As_1 = \varepsilon l x_1 \simeq \varepsilon l a/m \quad (2)$$

where ε is the molar extinction coefficient of the complex, l, the thickness of the cell in cm, and x, the concentration of the complex formed.

On the contrary, the absorbance (As_2) obtained from the solution containing iron(III) (b mol/*l*) and RHCl (a mol/*l*) in the same manner as above can be given by:

$$As_2 = \varepsilon l x_2 \simeq \varepsilon l a/n \quad (3)$$

The ratio of n to m may be determined by taking the ratio of the absorbance obtained from both solution:

$$As_1/As_2 = n/m \quad (4)$$

The results obtained from this method are shown in Table 3.

Since the average value of the ratio of As_2 to As_1 obtained from Table 3 was 1.19, this complex was recognized as being 1 to 1.

Asymmetric Hydrogenation of C=O Double Bond with Modified Raney Nickel.*1 XI

Yoshiharu IZUMI, Masami IMAIDA, Tadao HARADA, Tadashi TANABE, Shinichi YAJIMA and Toshio NINOMIYA

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received March 1, 1968)

A series of studies of the asymmetric hydrogenation of methyl acetoacetate with the catalysts prepared from Raney nickel catalyst by modifications with aqueous solutions of various optically-active compounds has already been reported by the present authors.[1-11] The effect of the structure of the modifying reagent on the asymmetric activity of the catalyst has been extensively discussed. However, the relationship between the structure of the substrate and the asymmetric yield in the hydrogenation has not yet been reported. In order to clarify the mechanism of asymmetric hydrogenation with a modified Raney nickel catalyst, various substrates were examined with catalysts modified with D-tartaric acid, L-glutamic acid, and some other amino acids. In the present paper, a part of the accumulated results of this study will be given as a basis for future discussion.

e) The asymmetric yield was calculated from the conversion of methyl 3-hydroxybutyrate to the corresponding ester.
f) G. Senter, A. M. Ward, *J. Chem. Soc.*, **125**, 2142 (1924). The product was hydrolyzed and the asymmetric yield was measured in alcohol.
g) The product is 2,4-pentanediol and the optical resolution of it is in progress.
h) Pure methyl levulinate could not be obtained and the asymmetric yield was calculated by induction of the product to γ-valerolactone.

Experimental

The procedures for the preparation of modified Raney nickel catalyst and for the hydrogenation of the substrate were the same as have been reported in previous papers. The hydrogenation products were purified by distillation, and the optical rotations of the products were measured without dilution in a 1-dm tube. Esters of acetoacetic acid were prepared from diketene and the corresponding alcohols.[12]

Results and Discussion

The modifying conditions and the results are shown in Table 1. In general, it will be seen that better results are obtained in the asymmetric hydrogenation of β-ketoesters or β-diketone, such as esters of acetoacetic acid, ethyl benzoylacetate, and acetylacetone, the enol isomers of which are fairly stable. On the other hand, the asymmetric yields are very low in the hydrogenation of ketones without a β-carbonyl group and, hence, without the stable enol isomer, ketones such as mono-

ketone, ethyl pyruvate, diethyl α-ketoglutarate, methyl levulinate and diacetyl.

In the asymmetric hydrogenation of monoketone, the effect of the modifying pH on the asymmetric activity of the catalyst shows a tendency similar to that observed in the asymmetric hydrogenation of methyl acetoacetate. In the hydrogenation of the esters of acetoacetic acid, those esters with a bulkier alkoxyl moiety gave lower asymmetric yields of the products, the esters of 3-hydroxybutyric acid.

Recently, Petrov *et al.*[13] have reported the asymmetric hydrogenation of ethyl acetoacetate, following the methods of our studies with methyl acetoacetate and using a catalyst prepared by our method. Some of their results agree with those included in the present table, confirming that our results are reproducible.

More detailed results and a discussion of the mechanism of the asymmetric hydrogenation of the carbonyl group will be presented in this Bulletin in the near future.

Contact Potential in Vacuum for Titanium Dioxide Powder

Takeaki IIDA and Hiroshi NOZAKI

The Institute of Industrial Science, The University of Tokyo, 7-2-1, Roppongi, Tokyo

(Received March 15, 1968)

Titanium dioxide is well-known as a pigment. It is considered that the chalking phenomena of titanium dioxide paint have something to do with the behavior of adsorbates on the pigment surface. In the case of zinc oxide, both the photoelectric and the thermoelectric work function have already been determined by measurements of the external photoelectric effect[1] and contact potential[2] respectively, while the behavior of adsorbates has been considerably clarified by many experimental results.[3] However, in the case of titanium dioxide, the surface potential and the surface photovoltage have not been studied, and the behavior of adsorbates has not been clarified as yet. Hence we measured changes in the contact potential and the surface photovoltage of titanium dioxide powder by changing the atmosphere around the layer. These phenomena have significance especially in discussing the surface behavior of titanium dioxide powder.

Experimental

Titanium dioxide powder, which is of a special grade (the impurities are given as follows: Fe$<$0.001%, Pb$<$0.002%, As$<$0.0005%) and the crystal size of which is about 0.1—0.5μ, was dispersed in alcohol and spread uniformly on a 7×7 cm^2 aluminum plate. These specimens were dried at 100°C for 2 hr, and then left in a dark chamber for 48 hr or more. These layers were between 15 and 25 μ thick. The contact potential was measured by the Kelvin method using a nesa glass electrode. The sample was placed in a vacuum vessel, in which there was silicone grease and where a diffusion pump was used. The nesa glass electrode was vibrated by an oscillator at 1 kc/sec. The specimen was exposed to a tungsten lamp without any filters. All the measurements were made at room temperature by the following procedures. After the air in the vessel had been slightly evacuated, the pressure was kept at a given pressure for 2 hr. When the surface potential reached a stable value, we measured the surface potential. The pressure range studied was from normal air pressure to 10^{-5} mmHg. After evacuation to 10^{-5} mmHg, foreign gas was introduced into the system, and the photovoltage of the layer was measured by illuminating the sample surface with a white light of 480 lux.

Results

Figure 1 shows the curves of the surface potentials of rutile and anatase in the dark against the air pressure. The dotted line represents the potential of gold, which corresponds to the work function of 4.8 eV. It may be seen that the surface potential of rutile has a minimum at a pressure around 40 mmHg, and that the surface potential increases with the decrease in air pressure between 10 and

10^{-4} mmHg, gradually reaching 50—100 mV above the Au-potential at a pressure of 10^{-5} mmHg. The surface potential of anatase was about 400 mV higher than that of the rutile layer in atmospheric air, and monotonously increased with the decrease in air pressure.

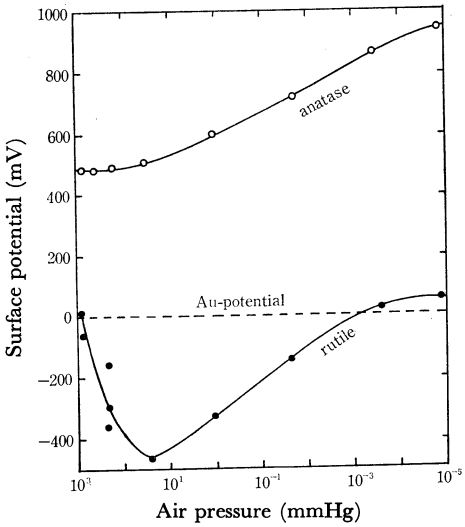

Fig. 1. Surface potential of the rutile and anatase layers in the dark against the air pressure.

In Fig. 2, the surface photovoltages of the rutile layer in various ambients are shown. On irradiation, a large photovoltage, 500 mV, was observed with a quick response in the vacuum of 3×10^{-4} mmHg. However, in dry air at normal pressure, the photovoltage amounted to 240 mV. Moreover, in wet air (relative humidity of 75%), the photovoltage has a very small value, 30 mV.

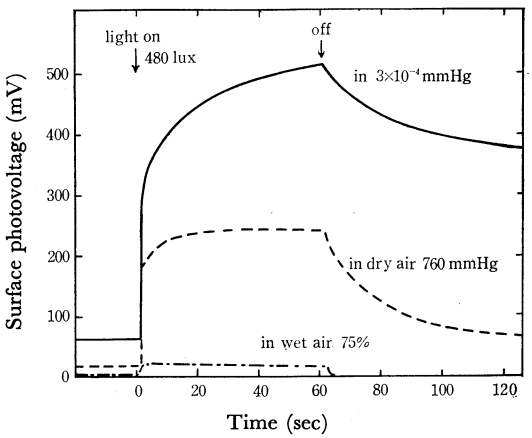

Fig. 2. Surface photovoltage of the rutile layer in various ambients.

Discussion

The adsorbates on the titanium dioxide surface at normal air pressure are considered to be oxygen and water. It has been recognized by ESR that oxygen chemisorbs on the titanium dioxide surface as a negative ion, O_2^-.[4] Therefore, if the air pressure around the layer is decreased, the adsorption equilibrium of oxygen slightly deviates from that at the normal air pressure. Then the surface potential increases with a decrease in air pressure. On the other hand, the behavior of water on the titanium dioxide surface has not yet been clarified. However, in the case of zinc oxide, the behavior of water on the surface has been studied to some extent, and it has been recognized that water chemisorbs on the zinc oxide surface donatively.[5] We assume that the same is the case with titanium dioxide. Therefore, the surface potential decreases if water desorbs from the surface. Figure 1 shows that the change in the surface potential of rutile resembles that of zinc oxide.[6] Therefore, the change in the surface potential of rutile in Fig. 1 means that the water on the surface desorbs first; after that, a part of the oxygen gradually desorbs from the surface. On the basis of these results only, we can not determine the absolute work function of titanium dioxide, because some other adsorbates remain on the suface even at the pressure of 10^{-5} mmHg. In the case of anatase, the minimum peak is not observed. This fact can not be explained easily on the basis of these results only.

The photovoltages observed under the illumination of a white light may be attributed to the desorption of oxygen. Therefore, these phenomena greatly depend on the ambient atmosphere around the layer. In the case of a vacuum of 3×10^{-4} mmHg, the photovoltage reaches a value as high as 500 mV. In wet air, however, the photovoltage greatly decreases. These phenomena indicate that the surface of titanium dioxide is greatly affected by the adsorption of water. Moreover, the rate of the dark decay of the surface photovoltage is slow in a vacuum, but quick, at normal air pressure. It may be said that the rate of the readsorption of oxygen, which is desorbed by light, is low in a vacuum and high at normal air pressure.

The authors wish to thank Mr. Isao Tashiro of the Rikoh Co., Ltd., for giving many useful suggestions about the measurement of the contact potential.

A Systematic Cation Exchange Separation with Oxalate

Toru NOZAKI, Osamu HIRAIWA, Chujiro HENMI and Kunji KOSHIBA

Department of Industrial Chemistry, Faculty of Engineering, Ehime University, Matsuyama-shi

(Received April 1, 1968)

A few years ago, one of the authors had an interest in oxalatocomplexes and reported spectrophotometric[1-3] and polarographic[4] investigations of several oxalato complexes. Recently, knowledge on stability constants of oxalato metal complexes has accumulated,[5] while only relatively few cation exchange separations with oxalate as an eluting agent have been reported.[6] The present paper contains a systematic, preliminary study of cation exchange separations of nineteen metallic elements with oxalate as an eluting agent. This investigation covered the range of pH 2 to 5 and concentration 0.01 to 0.5 M for the eluant.

It was found that these elements can be roughly classified into three groups according to their ion-exchange behavior. As examples, mutual separations of several metals were carried out.

Experimental

Standard Solutions of Metals. Perchlorates of Be, Al, Ga(III), In(III), Zr, Hf, Th, Fe(III), Co(II), U(VI), Cu(II), Zn, Cd, Mn(II) and Ni, chlorides of Sn(IV), Ti(IV) and Cr(III) and the nitrate of Pb(II) were dissolved in water containing minimum amounts of perchloric, hydrochloric and nitric acid, respectively, sufficient to suppress their hydrolysis and diluted to the concentration of 1×10^{-2} M with distilled water.

Eluting Agents. Oxalate solutions of 0.01, 0.02, 0.05, 0.1, 0.2, 0.4 and 0.5 M adjusted to pH 2.0, 3.0, 4.0 and 5.0, respectively, using a pH meter, were used. All reagents used were of guaranteed grade.

Resin and Column. The resin used was 60—100 mesh "Amberlite IR-120" in ammonium form. The resin bed of the column was 10 cm in height and 0.9 cm in diameter. Each column was preconditioned with 2 N hydrochloric acid, and 0.2 M ammonium chloride solution was passed through the resin bed for conversion to the ammonium form.

Decomposition of Oxalic Acid. For the chelatometric or colorimetric determination of the metals, except for Zn, Mn(II) and Cd, interfering oxalate in solution was eliminated. Various investigations indicated that the method of decomposition of oxalic acid by oxidation with ammonium peroxodisulfate was most suitable. Into a 100-ml flask, 10 ml of 0.1 M oxalate solution and 2.5 ml of 10% ammonium peroxodisulfate was taken, and about 40 ml of distilled water added. Being boiled for 5 to 10 min, the oxalate decomposed. Further, heating was continued for about an hour to decompose excess ammonium peroxodisulfate.

Methods for the Determination of the Metals. The concentrations of Be, Ti(IV) and Cr(III) were determined colorimetrically by the quinalizarine, hydrogen peroxide and chromate methods, respectively. For the other elements, chelatometric titration was used.

Distribution Coefficients. In order to find favorable conditions and a criterion for the separation of the metals adsorbed in the resin bed by elution with oxalate solution, the magnitude of the distribution coefficients

Table 1. Classification of metallic elements

	pH of eluant	Elution range (m*l*)	log K_d	Elements
Group I	2.0	0—120	<1	Cu(II), Al, Ga, In, Fe(III), Sn(IV) Ti(IV), Zr, Hf, U(VI), (Th)
Group II	3.0	10—180	<1	Be, Zn, Ni, Co(II)
Group III	3.0	220—	>1	Cd, Mn(II), Pb(II)

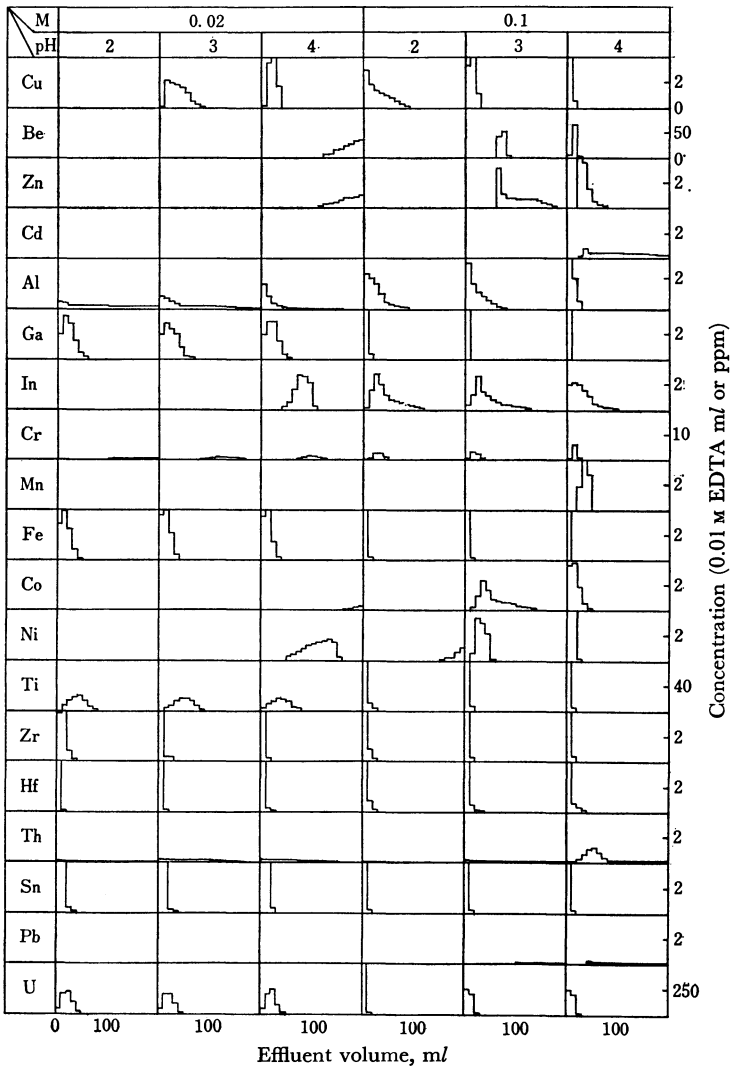

Fig. 2. Elution curves.

was measured by a batch method at varying concentrations and values of pH of oxalate solution. Into a 50-m*l* volumetric flask, 30 m*l* of the oxalate solution of varying concentration from 0.01 to 0.4 M and 10 m*l* of standard metal solution were taken, followed by adjustment of pH to a value between 2.0 and 4.0 with ammonia-water or perchloric acid, and 500 mg of air-dried resin was added and the solution diluted to the mark with distilled water. After standing for 24 hr at 25°C, the concentration of the metal in the aqueous phase was determined.

Elution Curves. Each solution containing about 10^{-4} mol of a metallic element was added to the top of the column. After washing the column with 2 m*l* of water twice, the eluant was passed through the column at a flow rate of 0.5 m*l*/min, and 10 m*l* of the effluent collected with a fraction collector. Each fraction being transferred to a 100-m*l* flask, the concentration of the metal in the fraction was determined after decomposition of the oxalato complex and excess oxalate with ammonium peroxodisulfate.

Results and Discussion

Some of the results on the distribution coefficients and elution curves are shown in Figs. 1 and 2, respectively. The elements investigated can be roughly classified into three groups in Table 1 according to their ion-exchange behavior which is reflected in the pH-distribution coefficient curves.

As shown in Fig. 2, there are many cases where mutual separation seems possible. As examples, the results of mutual separations of several metals are shown in Fig. 3.

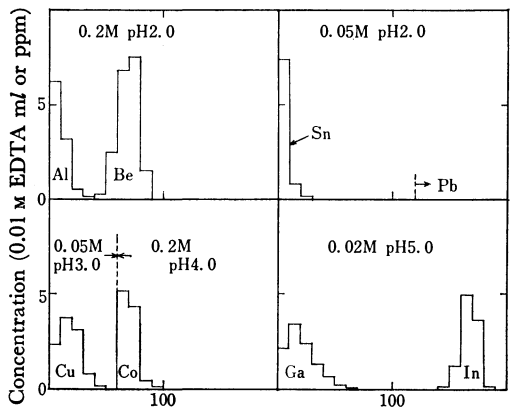

Fig. 3. Mutual separations.

Effect of pH. With 0.1 M eluant at pH 2.0, Be, Zn, Co(II), Mn(II) and Cd were not eluted until 200 m*l*, and Ni was not removed until 150 m*l* of effluent was reached. The rise in pH from 2.0 to 3.0 caused the beginning of elution of Be and Zn from 60 m*l*, and the elution of Ni and Co(II) from 20 m*l*, but Mn(II) and Cd did not elute until 200 m*l*.

Increasing the pH value to 4.0, Mn(II) and Cd began to elute from 30 m*l*.

Thus, the elutions of Be, Zn, Ni, Co(II) and Mn(II) were most sensitive to the pH value of the eluant, and next, those of Cu(II), Cd and Al were most sensitive. In addition, a shortening of the elution range with increase in pH of eluant to 3.0 or 4.0 was found especially with Cu, Zn, Al and Co(II).

Effect of Concentration. As shown in Fig. 2, the effect of concentration of eluant was not found to be great over the concentration range 0.2 to 0.05 M, but considerable delay in elution with 0.02 M eluant was found for In, Be, Zn, Co and Ni. In the case of Al, tailing was small with 0.2 M eluant at pH 2.0, whereas a decrease in concentration at the same pH caused greater tailing.

Table 2. Stability constants of metal-oxalato complexes

Metal	log K_1	log K_2	log K_3	Literature
Cd	2.78	1.60	0.98	4
Zn	5.15	2.21	1.15	5
Co(II)	4.7	2.0	3.0	5
Mn(II)	2.60	2.04	—	4
Ni	4.1	3.1	1.3	7
Al	7.25	5.75	3.3	5
Fe(III)	10.2	7.2	3.6	1
U(VI)	7.3	6.0	5.1	3

The elements in group 1, which are sharply eluted in 0—30 m*l* with 0.1 M eluant at pH 2.0, have large successive stability constants, whereas some elements in group 3 which show large tailing have smaller stability constants, as given in Table 2. Because of this for the latter elements, precipitates seem to form in the column and take much time to dissolve in the eluant at pH 3.0. Detailed mutual separations of the elements will be reported later.

The authors wish to thank Mr. M. Matsunaga and Mr. T. Kuribayashi for their assistance in the experimental work.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 248—250 (1969)

Interaction between Aldehyde and Tris(trimethylsiloxy)aluminum

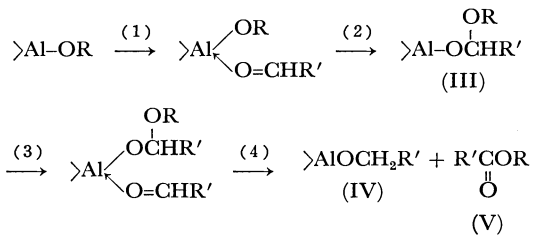
Takeo SAEGUSA, Takashi UESHIMA and Sadao KITAGAWA

Department of Synthetic Chemistry, Kyoto University, Sakyo-ku, Kyoto

(Received April 10, 1968)

The syntheses and properties of aluminum silanolates and organoaluminum silanolates have been reported by several workers.[1-3] We have now compared their catalytic properties with those of metal alkyls and metal alcoholates in the polymerizations of aldehydes and cyclic ethers.[4,5] Tris(trimethylsiloxy)aluminum (I), $Al(OSiMe_3)_3$, was compared with aluminum *t*-butoxide (II) as a catalyst for the Tishchenko reaction,[6] which is closely related to the aldehyde polymerization.[7-9]

The Tishchenko reaction proceeds through a cycle of four steps:[7-9]



(1) The coordination of aldehyde with an aluminum alcoholate. (2) The transfer of the alkoxyl group to the carbonyl of aldehyde to form an aluminum alcoholate of hemiacetal (III). (3) The coordination of the second aldehyde molecule to the hemiacetal alcoholate. (4) Hydride transfer from the hemiacetal alcoholate onto the second aldehyde to produce an aluminum alcoholate (IV) and ester (V). After the first cycle, the so-called Tishchenko ester, $R'CO_2CH_2R'$ (VI), is continuously produced. We[5] disclosed previously that the reaction on *n*-butyraldehyde with I did not produce the silyl ester of *n*-butyric acid, which was expected from the above scheme, but did give the *n*-butyrate of the aldol of *n*-butyraldehyde as a by-product.[6] In this reaction aldol was first formed; it was then reacted with I to give its aluminum alcoholate, which in turn acted as an initiator of the Tishchenko reaction of *n*-butyraldehyde, producing *n*-butyl *n*-butyrate.

The present study was designed to examine the interaction of I with aldehyde along the lines of the above scheme of the Tishchenko reaction.

The coordination of *n*-butyraldehyde with I was demonstrated by the shift of the IR carbonyl band of aldehyde, $\Delta\nu_{C=O}$, caused by I (145 cm^{-1}); this shift was even greater than that caused by II (140 cm^{-1}). The corresponding values of $\Delta\nu_{C=O}$ for CCl_3CHO were 125 cm^{-1} and 114 cm^{-1} respectively. The coordination was also indicated by NMR; *i. e.*, the chemical shift of aldehyde hydrogen in the NMR of a mixture of benzaldehyde and I was found to depend upon their ratio. This observation corresponds to that in the NMR spectrum of the acetone-aluminum isopropoxide system.[10]

The siloxyl transfer from I to aldehyde was examined by means of study by the NMR spectrum. We have demonstrated previously that the hydrogen of the aluminum alcoholate of hemiacetal III shows a chemical shift different from that of the formyl hydrogen of the starting aldehyde.[11] In the NMR spectrum of a mixture of I and benzaldehyde in *n*-heptane at 20°C, no new signal was detected after 3 days. This observation may be taken as obviating the transfer of the siloxyl group to benzaldehyde. In chloral, however, the transfer of the siloxyl group to chloral does take place, as is indicated by the formation of $CCl_3CO_2SiMe_3$. The difference in reactivity between benzaldehyde and chloral toward the siloxyl transfer may be explained by the electron-withdrawing effect of the trichloromethyl group; *i. e.*, chloral is more electrophillic, and hence it is more reactive.

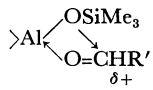
		VIII	0.2[d]		0.1[d]

a) Aldehyde 0.1 mol, aluminum compound 0.01 mol, *n*-heptane 10 m*l*, 20°C 3 days.
b) Aldehyde, aluminum compound, each 0.1 mol, *n*-heptane 40 m*l*, 30°C 13 days.
c) Aldehyde 0.1 mol, aluminum compound, 0.01 mol, benzene 50 m*l*, 80°C 10 hr.
d) Yield (%) based upon the initial aluminum.
e) The quantity was determined by the method described in the experimental section.



The hydride transfer from the alcoholate of silyl-hemiacetal to the coordinating aldehyde seems to occur quite easily. The formation of trimethylsilyl trichloroacetate from chloral and I implies the transfer of the hydrogen of the alcoholate of silyl-hemiacetal, $>AlOCHOSiMe_3$, to chloral in spite of the electron-withdrawing trichloromethyl group in the alcoholate. Therefore, the absence of the formation of n-$C_3H_7COOSiMe_3$ in the reaction of I with n-C_3H_7CHO may be ascribed to the lack of siloxyl transfer, but not to the lack of a hydride transfer reaction.

In the scheme from (1) to (4), the ester (V) consisting of the alkoxyl (or siloxyl) group which is originally attached to the catalyst was the key compound. The possibility of an ester exchange reaction between the catalyst alkoxyl group and the ester (VI) producing V has been eliminated by reference experiments; *i. e.*, a mixture of I or II and the VI ester under the same conditions did not give V. Furthermore, trimethylsilyl *n*-butyrate was found to be fairly stable; it does not decompose during the reaction.

In conclusion, the difference in catalyst behavior between I and II is due to the difference in transfer reactivity between siloxyl and alkoxyl groups. The lower reactivity of siloxyl transfer may be ascribed to a decreased nucleophilicity of the siloxyl group because of the electron-withdrawing effect of silicon through the $d\pi$-$p\pi$ bond. This assumption is supported by the lower basicity of trimethylsilanol compared with trimethylcarbinol.[12]

12) R. West and R. H. Baney, *J. Am. Chem. Soc.*, **81**, 6145 (1959).

Experimental

Materials. I and II were prepared and purified by procedures described before.[6] The benzaldehyde and chloral were commerical reagents which had been purified by repeated fractional distillations. Trimethylsilyl trichloroacetate, $CCl_3CO_2SiMe_3$, was prepared from sodium trichloroacetate and chlorotrimethylsilane by a procedure described before.[6]

$CCl_3CO_2SiMe_3$ is quite vulnerable to moisture and is readily hydrolyzed. The product was identified as follows. The NMR spectrum of $CCl_3CO_2SiMe_3$ shows a sharp singlet at 0.40 ppm (δ) assignable to protons of Si–CH_3. The product, 0.5375 g, was decomposed with water, and hexamethyldisiloxane was extracted with ethyl ether and analyzed by vpc. The CCl_3CO_2H in the water layer was titrated with 1/10 N NaOH. $Me_3SiOSiMe_3$.

Found: 0.1834 g. Calcd: 0.1852 g. Acidity, Found: 2.298×10^{-3} mol. Calcd: 2.282×10^{-3} mol.

The 2,2,2-trichloroethyl trichloroacetate was prepared by the method described in the literature.[13]

Products Analyses. The products were identified by vpc using two columns (PEG 20000 and Silicone DC 550). Silicone DC 550 and dioctyl phthalate were used for the identification of $CCl_3CO_2SiMe_3$.

Reactions of Chloral. A representative procedure was as follows. A mixture of 0.01 mol of chloral, 0.01 mol of I, and 40 m*l* of *n*-heptane was kept in a sealed tube at 30°C for 13 days. In order to avoid the hygroscopic decompsotion of the products, the reaction mixture was directly analyzed by vpc. The products were $CCl_3CO_2CH_2CCl_3$ (70.6%) and $CCl_3COOSiMe_3$ (0.21%). In the case of the reaction with aluminum *t*-butoxide, no reaction product was detected by vpc analysis. When the reaction system was treated with excess acetic anhydride and was subjected to vacuum distillation, 41% of $AcOCH(CCl_3)OCMe_3$ was obtained.

Found: C, 36.71; H, 5.18; Cl, 40.46%. Calcd for $C_8H_{13}O_3Cl_3$: C, 36.46; H, 4.97; Cl, 40.36%.

The NMR and IR spectra were compatible with this structure. The formation of this compound clearly

13) R. Dworzak, *Monatsh*, **47**, 11 (1927).

indicates the presence of $>Al-O-\underset{\underset{CCl_3}{|}}{\overset{\overset{H}{|}}{C}}-OCMe_3$.

Reaction of Benzaldehyde. A procedure similar to the above was adopted. After the reaction, the products were identified and determined quantitatively by vpc analysis without any after-treatment. In the case of I, no reaction product was found. In the NMR spectrum of the I-benzaldehyde system after the reaction, no signal except for those assignable to the starting reagents was recognized.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 250—252 (1969)

Reaction of Tetraethyl α-Phosphonodicarboxylates with Carbonyl Compounds

Kikumasa SATO, Masao HIRAYAMA and Takashi INOUE

Department of Applied Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama

and Shoji KIKUCHI

Konishiroku Photo Industry Co., Ltd., Hino, Hino-shi, Tokyo

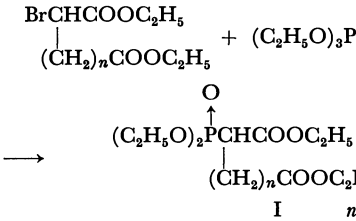
(Received April 20, 1968)

While the reaction of triethyl phosphonoacetate with carbonyl compounds has been well investigated,[1a-c] little attention has been paid to the reaction of tetraethyl α-phosphonodicarboxylates (I) with carbonyl compounds. Wadsworth[2] has reported the reaction of tetraethyl α-phosphonosuccinate with benzaldehyde to give diethyl α-benzylidenesuccinate. On the other hand, a survey of the literature has indicated that a general procedure for preparing diethyl α-alkylidenedicarboxylates (IV) has not yet been reported. Although α-alkylidenesuccinates[3] and glutarates[4] have been prepared by the Stobbe condensation reaction in a single-stage, the preparations of higher α-alkylidenedicarboxylates have dealt almost exclusively with the Reformatskii[5a,b] and Grignard[6] reactions. However, these methods have the disadvantage of low yields.

In connection with the total synthesis of phytol,[7] we have demonstrated that the triethyl phosphonocrotonate anion reacts with carbonyl compounds to give the corresponding α,β-,γ,δ-unsaturated esters. These studies suggest that tetraethyl α-phosphonodicarboxylate anions (II) may also condense with carbonyl compounds to give IV in a single-stage; if so, this reaction would be a more useful method for preparing IV. In the present paper, we have studied the reaction of I with carbonyl compounds in order to develop a new method of preparing IV.

The Michaelis-Arbuzov reactions of diethyl α-bromodicarboxylates with triethyl phosphite were all carried out at 155—160°C; they gave I (n=2, 3,7) in 59—75% yields. These compounds were identified by their elemental analyses and by a study of their infrared spectra. The results are summarized in Table 1.

Table 1. Reaction of diethyl α-bromodicarboxylates with triethyl phosphite



I n=2, 3, 7

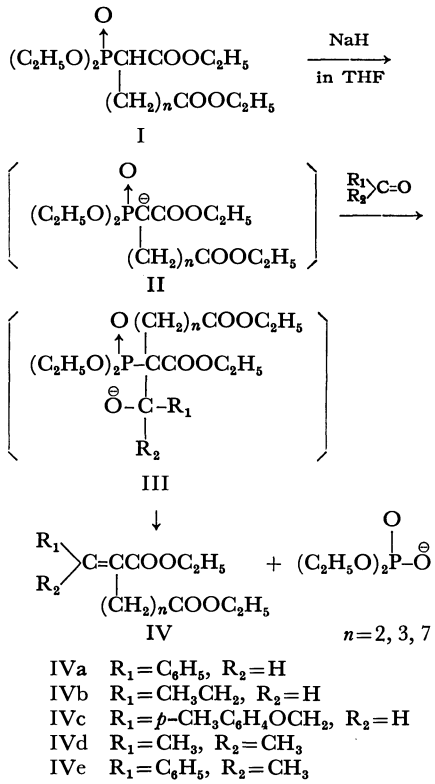
7) K. Sato, S. Mizuno and M. Hirayama, *J. Org. Chem.*, **32**, 177 (1967).

When phosphonate anions II (n=2,3,7), prepared by adding I to a slurry of sodium hydride in dry tetrahydrofuran (THF), were treated with carbonyl compounds, the corresponding α-alkylidenedicarboxylates, IV (n=2,3,7), were obtained in 10—86% yields. Phosphonate anions, II, reacted exothermically with benzaldehyde even at low temperatures to give the corresponding α-benzylidenedicarboxylates (IVa) (n=2,3,7) in good yields. Similarly, the reactions of II with aldehydes, such as propionaldehyde and p-toluoxyacetaldehyde, were carried out smoothly to give the corresponding α-propylidene- (IVb) and α-(p-toluoxyethylidene)-dicarboxylates (IVc) (n=2,3,7) in good yields. In contrast, the reaction with acetone resulted in a low yield of diethyl α-isopropylidenedicarboxylates (IVd) (n=2,3,7), and acetophenone failed to react with II at all. The results are summarized in Table 2.



IVa $R_1=C_6H_5$, $R_2=H$
IVb $R_1=CH_3CH_2$, $R_2=H$
IVc $R_1=p\text{-}CH_3C_6H_4OCH_2$, $R_2=H$
IVd $R_1=CH_3$, $R_2=CH_3$
IVe $R_1=C_6H_5$, $R_2=CH_3$

Recently Yanovskaya and her co-workers[1c] reported that triethyl phosphonoacetate did not react with diisopropyl ketone or di-t-butyl ketone, and that the reaction of triethyl phosphonoacetate with methyl t-butyl ketone gave ethyl 3,4,4-trimethyl-2-pentenoate in a poor yield. In explaining their data and also the results summarized in Table 2, the mechanism suggested by Wadsworth[2] can be applied to the behavior of carbonyl compounds toward II; such an application indicates that II is less reactive to ketones, which can find it difficult to take the intermediate III because of the steric hindrance, than to aldehydes, which can readily take III. The products IV (n=2,3,7) were confirmed by their elemental analyses and by a study of their infrared spectra, which showed two ester carbonyl absorptions of the α,β-unsaturated ester carbonyl group and the normal ester carbonyl group, in addition to the double-bond absorption.

In comparison with the Reformatskii reaction, the reaction using phosphonate anions, II, proceeds smoothly under mild conditions and, especially in the case of the reactions with aldehydes, gives the products in good yields. Therefore, the reaction is a useful method of preparing IV.

Table 2. Reaction of tetraethyl α-phosphonodicarboxylates (I) with carbonyl compounds

I, n	Aldehydes or ketones		Reaction condition		Product	Yield, %
	R_1	R_2	Temp., °C	Time, hr

	C_6H_5	CH_3	−10—room temp.	15	IVe	0

Experimental[8]

Materials. The triethyl phosphite was prepared by the procedure described by Ford-Moor and Perry.[9] The diethyl α-bromodicarboxylates were obtained by the method of Teichmann[10] in 30—40% yields.

Tetraethyl α-Phosphonoadipate (I, $n=3$). Typical Procedure for a Tetraethyl α-Phosphonodicarboxylates (I). A mixture of diethyl α-bromoadipate (26.4 g, 0.094 mol) and triethyl phosphite (20 g, 0.12 mol) was heated with stirring for 5 hr at 150—160°C. The distillation gave a 74.8% yield of (I, $n=3$), bp 150°C/0.5 mmHg, n_D^{20} 1.4403.

Found: C, 49.33; H, 8.73%. Calcd for $C_{14}H_{27}O_7P$: C, 49.70; H, 8.04%.

The Reaction of Tetraethyl α-Phosphonoadipate with Benzaldehyde. Typical Procedure for the Reaction of Tetraethyl α-Phosphonodicarboxylates with Carbonyl Compounds. Tetraethyl α-phosphonoadipate (15 g, 0.044 mol) was added, drop by drop at 0—5°C, to a slurry of 50% sodium hydride (2.4 g, 0.05 mol) in 100 m*l* of dry THF. After the addition, the mixture was stirred for 2 hr until the evolution of hydrogen gas had ceased. Benzaldehyde (4.7 g, 0.044 mol) was then added to the mixture at the same temperature, and the mixture was stirred for 3 more hr. The excess THF having been evaporated, the mixture was taken up in an excess of water, neutralized, and extracted with ether. The ether layer, after being dried over calcium chloride and evaporated, gave a liquid residue. The residue was then distilled, giving 11.1 g of a clear liquid, bp 150°C/0.22 mmHg (lit.[5a] 169°C/1.5 mmHg), 86% yield n_D^{20} 1.5170. The infrared spectrum of the product contained bands at 1620 cm^{-1} (C=C), 1730, and 1705 cm^{-1} (C=O).

Found: C, 70.39; H, 7.98%. Calcd for $C_{17}H_{22}O_4$: C, 70.32; H, 7.64%.

Electrolytic Separation with Glassy-Carbon Electrodes Prior to Emission Spectrography: Determination of Traces of Silver in High-Purity Zinc

Atsushi MIZUIKE, Nobuhiko MITSUYA and Kunio YAMAGAI

Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received April 22, 1968)

In ultratrace analysis by emission spectrography, various chemical or physical separation methods are often used to remove matrix elements prior to the excitation step. These preconcentrations[1] are effective in improving sensitivity, precision and accuracy beyond those which direct excitation of the sample would achieve, provided that the separation loss and contamination due to reagents, vessels and the atmosphere are negligible. This paper describes electrolysis with glassy-carbon cathodes for concentrating 0.01 to a few ppm of silver in zinc metal prior to emission spectrography. Glassy-carbon,[2] a new form of carbon, has been employed in the electrodes for electrolytic separation[3,4] and emission spectrography,[5,6] because of its desirable properties compared with other carbonaceous electrode materials. In the proposed technique, traces of silver are electrodeposited on the end of a glassy-carbon rod from 0.5 to 1.5 N nitric acid solutions in greater than 90% yields, leaving about 99.999% of zinc in the electrolyte. The cathode is then used as an electrode for spark emission spectrography. After completion of the work, the authors found a report[7] describing a similar technique using high-purity graphite or pyrolytic graphite by Alvarez (presented at the 1st Materials Research Symposium held at the NBS, Gaithersburg, Md., in October 1966), although detailed information was not available.

Experimental

Apparatus. A Shimadzu quartz Littrow spectrograph QL-170 (Slit width used: 15μ). A Shimadzu universal excitation source SA-1 (The Feussner circuit was used at 10 kV, 0.0066μF, 0.08 mH and 10Ω). A Rigaku Denki microphotometer CM-1A.

Electrodes, Reagents, *etc.* Glassy-carbon electrodes: Tokai Electrode Manufacturing Co. GC-30S; 4 mmϕ × 40 mm cathodes and 5 mmϕ × 50 mm anodes, unless otherwise stated. They were polished with a series of emery papers of increasing fineness, then with a chromium oxide suspension (0.5 μ) on a rotary table polisher, and washed with nitric acid (1 : 1), followed by water. The cathode was inserted in open-ended polyvinyl chloride tubing (30 mm long) to limit the working area of the surface to the end (0.13 cm^2).

Counter electrodes: Hitachi spectroscopic graphite electrodes (regular, 6.15 mmϕ) were machined into a 60° cone.

Photographic plates: Fuji process panchromatic 101 mm × 252 mm plates.

Standard silver solutions: Prepared from silver nitrate. ^{110m}Ag solution: The Radiochemical Centre Amersham. $AgNO_3$ in HNO_3.

Purified zinc nitrate solution: A 25-m*l* solution containing 11.5 g of $Zn(NO_3)_2 \cdot 6H_2O$ was electrolyzed with two glassy-carbon electrodes (5 mmϕ × 100 mm with no plastic sheath; working cathode area ~5 cm^2) at the total applied voltage of 2.0 V for 24 hr to remove traces of silver. This solution was used to prepare synthetic samples. The Ag/Zn ratio in this solution was found to be 6×10^{-9}, or less than was found by a procedure described later.

All reagents used were of reagent grade. Water purified by distillation and ion exchange was used throughout the work.

Procedure. Place 5.0 g of zinc metal in a 100-m*l* beaker, add 44 m*l* of 6.5 N nitric acid and heat to dissolve. Cool the solution and dilute to 50 m*l* with water. Transfer an aliquot (1 to 5 m*l*) of the solution to an electrolysis cell (23 mm in diameter and 55 mm in height), and add water and 6.5 N nitric acid to give 8 m*l* of 1 N nitric acid solution. Insert two glassy-carbon electrodes into the cell, immersing them 5 mm into the solution. Cover the cell with a sheet of filter paper, stir the solution with a magnetic stirrer and apply 2.0 V *d. c.* between the electrodes using crocodile clips for electrical connections. After 20 hr of electrolysis, remove the cathode without breaking the current. Rinse the lower part of the cathode with water, remove

the plastic sheath, rinse with water again and allow to air-dry. Prepare calibration standards by electrolyzing 1 N nitric acid containing known amounts (0.003, 0.01, 0.03, 0.1, 0.3, 1, 3μg) of silver by the same procedure as described above. Spark through a 3-mm gap between the silver-deposited and the counter (upper) electrode for 60 sec, and record the spectrum in the range of 2460 to 3480 Å on a photographic plate. Record the spectra of the calibration standards on the same plate. After photographic processing, measure the relative transmittance of the silver line 3280.683 Å against the background. Determine the amount of silver present by reference to a calibration curve (Seidel function *vs.* logarithm of quantity of silver) prepared from the calibration standards.

Results and Discussion

Electrolytic Separation of Silver. The conditions of electrolysis in the present work were developed from previous experiments.[3] In order to investigate the deposition rate and the recovery of silver, synthetic samples prepared from purified zinc nitrate, ^{110m}Ag and standard silver solutions were electrolyzed under conditions described previously. Aliquots (0.2 or 1 m*l*) were taken from the electrolyte during electrolysis, or from the 10-m*l* solution obtained by treating the cathode with 5 m*l* of hot nitric acid and water after electrolysis, and their gamma activities measured by means of a well-type scintillation counter. The results are shown in Fig. 1 and Table 1. Greater than 90% yields were achieved for 0.01 to a few μg of silver. About 2% of the total silver was adsorbed on the plastic sheath, and less than 1% deposited on the side of the cathode. Zinc accompanying silver was determined by square wave polarography, and found to be 4 μg when 500 mg of zinc was present before electrolysis.

Determination of Silver in Zinc. Synthetic samples prepared from purified zinc nitrate and standard silver solutions, and two samples of commercial high-purity zinc metal were analyzed, with the results given in Tables 2 and 3. The blank value through the entire procedure was less than 0.003 μg of silver. The calibration curves were linear over the range 0.003 to 3 μg of silver,

with a deviation of about ±10%. Although autoradiographs indicated that more silver electrodeposited near the circumference of the electrode, almost all the silver was evaporated from the electrode in the first 5-sec period of sparking. The lower limit of determination and the accuracy of the present method are about 0.01 ppm of silver in zinc, and about ±10% at the fractional to a few ppm level, respectively.

The authors are indebted to Dr. Kiyoshi Morita for help in part of the emission spectrography.

Reactive States of Acridine in Alcohols and the pK Value of T(n–π^*) State as judged from the pH Dependence of the Photoreduction Quantum Yield

Katsumi NAKAMARU, Shigeya NIIZUMA and Masao KOIZUMI

Department of Chemistry, Faculty of Science, Tohoku University, Katahiracho, Sendai

(Received April 23, 1968)

Previous work[1–5] on the photoreduction of acridine (A) in various alcohols has established that the reactive states are in general the singlet excited state S* and the triplet n–π^* state T_2 and that for each reactive state there are molecular (M) and radical (R) mechanisms; therefore generally speaking, four schemes, S*R, S*M, T_2R and T_2M participate in the reaction.

In this paper the similar problem is attacked from a different point of view for methanol, ethanol and isopropanol. As is well-known, pK_A of the ground state, S* and triplet π–π^*, T_1 are respectively 5.45,[6] 10.65[6] and 5.6[7] (for T_2, not known) and the acridinium ion (AH^+) is non-reactive;[8] hence, it is expected that the pH dependence of the photoreduction quantum yield, Φ reflects the pK_A's of the reactive state, provided the equilibrium state were realized in the excited state.

With such a view, the pH depencence of fluorescence and of Φ was investigated at first, using the water-alcohol mixture buffered with (CH_3COONa, HNO_3), (KH_2PO_4, Na_2HPO_4) and (Na_2CO_3, $NaHCO_3$). Taking into account the effect of alcohol on pH-values and Φ in the water-alcohol mixture, the volume ratio of water and alcohol was chosen as 2 : 1. The concentration of acridine was 1×10^{-4} M. Fluorescence was measured by an Aminco Bowman spectrofluorimeter. Since the fluorescence of AH^+ (peak at 470 nm) is very weak at the peak position of A (420 nm), the intensity at 420 nm was taken as the intensity of A. Reaction rate was investigated by illuminating the solution by 365 nm light and by measuring the intensity

of the transmitted 365 nm light.*1 In all cases $\ln(e^D-1)$ - t plot (D, optical density) was satisfactorily linear at least in the initial stage, showing that the reaction is simple with the rate only proportional to the light absorption.

The results, as shown in Fig. 1, clearly show the sharp change around pH ~5 for both the fluorescence intensity (I_F) and Φ. These results indicate that with the usage of the ordinary buffer solutions, the equilibrium in the ground state is still maintained in the excited state. A small change of I_F around pH 9.5 may be due to the quenching action of some inorganic ions. Twice as large Φ in the degassed solution as that in the aerated solution is interpreted to be due to the participation of S*R mechanism and perhaps also of T_2R in the reaction.

Since the acid-base equilibrium specific to the excited state was not realized in the ordinary buffer solution, it has been undertaken next, following Weller,[6] to use NH_4^+ as a proton donor for accelerating the proton transfer and to investigate the effect of $[NH_4^+]$ upon the fluorescence and upon Φ. Fixing $[NH_3]/[NH_4^+]=0.1$ (buffer consisting of NH_3 and NH_4NO_3, pH=8.2, $\log [AH^+]/[A]=-2.75$ in the ground state), the concentration of NH_4^+ was changed from 0.01 M to 2 M.

It was found that with the increase of $[NH_4^+]$, the fluorescence spectrum gradually changes from that of A to AH^+ with a clear isosbestic point, indicating the occurrence of Reaction $A^*+NH_4^+ \rightarrow AH^{+*}+NH_3$. The quenching constants of NH_4^+ for the fluorescence of A, in methanol, ethanol and isopropanol were respectively 2.7, 1.7 and 1.2.*2 Oxygen showed no quenching action. Φ was found also to decrease significantly by the increase of $[NH]_4^+$, as shown in Fig. 2. In this figure, I_F's (I_F at $[NH_4^+]=0.01$ M being normalized to the Φ-value at the same NH_4^+ concentration) are also plotted.

The very good agreement of the I_F- and Φ-plots for the aerated solutions for all alcohols, indicates that the reactive state in the aerated solution, is only S* (see below also). This is in complete agreement with the conclusion given in the previous paper.[4] In the aerated solution, radical mechanisms being eliminated, only S*M and T_2M mechanisms are possible, but the present results rule out the latter.

For the degassed solution, the S*R process contributes to the reaction, but this does not cause

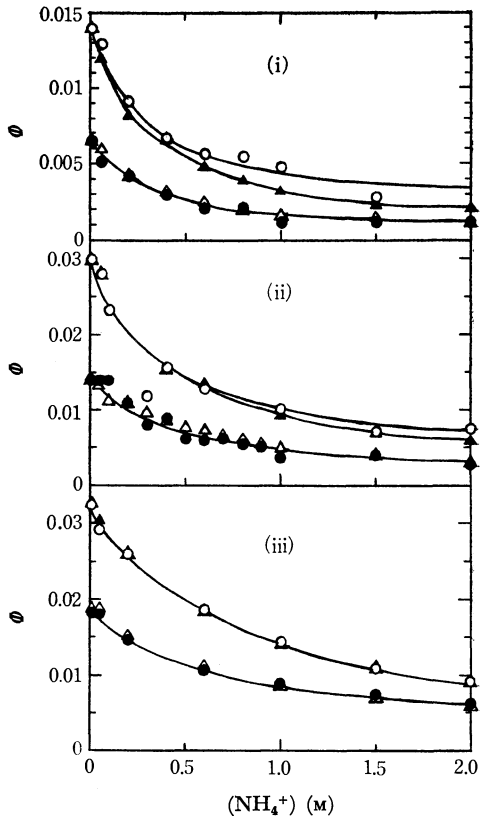

Fig. 2. Dependence of Φ and I_F on the concentration of buffer (NH_4NO_3-NH_3).
[A] = 1×10^{-4} M Temperature: 25°C
(i) water-methanol (2:1 in vol.)
(ii) water-ethanol (2:1 in vol.)

—▲— I_F, deaerated solution
—△— I_F, aerated solution

any difference between the I_F- and Φ-plots; hence it is only necessary to discuss the participation of T_2. When T_2 participates in the reaction in addition to S*, Φ at $[NH_4^+]=0.01$ M and at an arbitrary value of $[NH_4^+]$ may be put as follows,

$$\Phi_0 = (k_r + k_{ST}f^0)/k_e + k_d + k_r \quad \text{for 0.01 M of } [NH_4^+] \qquad (1)$$

$$\Phi = (k_r + k_{ST}f + k_Q[NH_4^+]\varphi'_{ST}f')/ k_e + k_d + k_r + k_Q[NH_4^+] \qquad (2)$$

where k_e, k_d, k_r and k_{ST} are respectively the rate constant for emission, deactivation (including intersystem crossing), photoreaction and for intersystem crossing and where k_Q is the rate constant for Process $A^*+NH_4^+ \rightarrow AH^{+*}+NH_3$*3 and φ'_{ST} is

*1 The reaction product was judged from UV spectra to be acridan or the like in the aerated solution while in the degassed solution, diacridan was also produced, as judged from the appearance of white precipitate.

*2 These values may be correlated with the viscosity of the solvents (Viscosities of the three alcohols at 30°C are 0.51, 1.00 and 1.76 in the above sequence).

*3 The contribution of the backward reaction, $AH^+ + NH_3 \rightarrow A + NH_4^+$ may be neglected, since the I_{F_0}/I_F-$[NH_4^+]$ plot does not deviate much from the Stern-Volmer plot even at high NH_4^+ concentrations.

the intersystem crossing probability for AH^+. f_0 is a probability (an eventual fraction) for one A_{T_2} molecule produced from S*, to undergo reaction at $[NH_4^+]=0.01$ M. $f(f')$ is the similar probability for A_{T_2} ($AH^+{}_T$) (as to the assignment of $AH^+{}_T$, see below) at $[NH_4^+]>0.01$ M and $f=f_0$ ($f'=0$) or $f<f_0$ ($f'>0$), depending upon whether A_{T_2} ($AH^+{}_T$) produced from S* has no probability or some probability of going to $AH^+{}_T$ (A_{T_2}). The situations can be described quantitatively as follows. The ratio of the quantities of A_{T_2} and $AH^+{}_T$ produced from S* (per unit time), may be approximated as $k_{ST}/k_Q[NH_4^+]\varphi'_{ST}$ and according to the relation,

$$k_{ST}/k_Q[NH_4^+]\varphi'_{ST} \lessgtr ([A_{T_2}]/[AH_T^+])_{eq} = K_{T_2}/[H^+] \quad (3)$$

the values of f and f' will be specified as follows,

$$\begin{cases} f=f_0 \\ f'>0 \end{cases} (\text{for} <) \quad \begin{cases} f=f_0 \\ f'=0 \end{cases} (\text{for} =) \quad \begin{cases} f<f_0 \\ f'=0 \end{cases} (\text{for} >) \quad (4)$$

From (1) and (2) the following relation can be derived straightforwardly.

$$(\Phi/\Phi)/(I_F/I_{F_0}) = \frac{k_r + k_{ST}f + k_Q[NH_4^+]\varphi'_{ST}f'}{k_r + k_{ST}f_0} \quad (5)$$

Three cases are discriminated from (5),

case a): $(\Phi/\Phi_0) > (I_F/I_{F_0})$

case b): $(\Phi/\Phi_0) = (I_F/I_{F_0})$

case c): $(\Phi/\Phi_0) < (I_F/I_{F_0})$

depending upon the following criterion,

$$k_{ST}f + k_Q[NH_4^+]\varphi'_{ST}f' \lessgtr k_{ST}f_0 \quad (6)$$

which in turn, depends upon (4) and accordingly upon (3).

The correlation between (3) and (4) is, however, purely mathematical, and from the practical viewpoint, one may safely say as follows from (6) in conjunction with (3) and (4).

i) Case a) occurs when pK_{T_2} is much smaller than ~ 8 and φ'_{TS} is not so small. ii) Case b) occurs when pK_{T_2} is similarly small and $\varphi'_{ST} \approx 0$, or when S* is an only reactive state.*4

Turning back to the experimental results, case a) fits for methanol and ethanol, and case b) for isopropanol. From the above criterion, it is concluded that for isopropanol S* is an only reactive state and for methanol and ethanol, T_2 also participates in the reaction. The larger difference between (Φ/Φ_0) and (I_F/I_{F_0}) for methanol than for ethanol, as seen in Fig. 2, implies the larger contribution of T_2 in the former case. All these conclusions are in complete agreement with the ones in the previous paper.[4]

Furthermore, the present investigation strongly suggests that pK_{T_2} is much less than ~ 8. This view is further supported from the holding of case a) or case b) throughout the whole range of $[NH_4^+]$, because if pK_{T_2} is near ~ 8, (6) requires the change from case c) to case b) and further to case a) with the increase in $[NH_4^+]$.

The values of $k_Q\varphi'_{ST}f'/(k_r+k_{ST}f_0)$, as estimated from the plot $(\Phi/\Phi_0)/(I_F/I_{F_0})$ *vs.* $[NH_4^+]$ is 0.2—0.3 for methanol. Although these values are not very reliable, yet, there is no doubt that both φ'_{ST} and f' are quite large. This is very important for characterizing $AH_T{}^+$. Firstly, a large value of f' implies the rapid occurrence of Reaction $AH^{+*} \rightarrow A_{T_2} + H^+$, and this is only possible *via* some higher $T(\pi\text{-}\pi^*)$ state or $T(\sigma\text{-}\pi^*)$ state of AH^+. The former, however, is very unlikely, because Process $AH^+{}_T(\pi\text{-}\pi^*) \rightarrow A_T(n\text{-}\pi^*) + H^+$ is the one between different electronic states and may not favorably compete with the transition to the lowest $AH^+{}_T(\pi\text{-}\pi^*)$. Then the quite large value of φ'_{ST} implies that the $T(\sigma\text{-}\pi^*)$ state which in general is highly located, is in the present case, at least lower than AH^{+*}. It is worth while to add that the present technique, at least in principle, enables us to determine the pK value pertaining to $AH^+{}_T(\sigma\text{-}\pi^*) \rightleftarrows A_T(n\text{-}\pi^*) + H^+$.

The authors are gratefull to Professor H. Kokubun for fruitful discussion.

*4 Case c) holds when pK_{T_2} is much larger than 8 and φ'_{ST} is not so large.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 258—260 (1969)

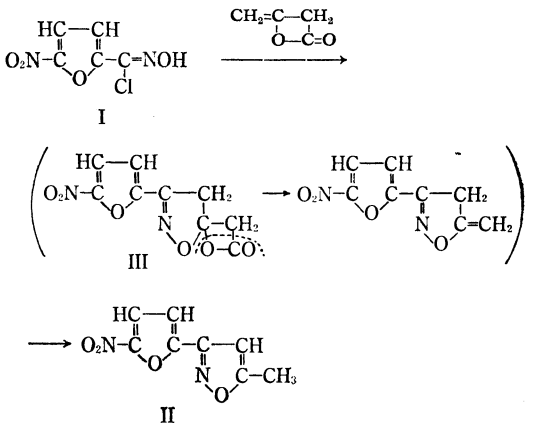
Studies of Heteroaromaticity. XX.[1] Novel Thermal 1,3-Dipolar Cycloaddition of 5-Nitrofuran-2-carbohydroxamoyl Chloride with Diketene and Dicyclohexylcarbodiimide

Tadashi SASAKI and Toshiyuki YOSHIOKA

Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received April 30, 1968)

Ketenes sometimes undergo 1,3-dipolar cycloaddition reactions, but with such typical 1,3-dipoles as nitrones[2] and *N*-oxides,[3] diphenylketene reacts in a different manner, affording an isoxazolone derivative.[4] However, there have been no reports concerning the similar reactions of nitrile oxides with diketene, presumably because of its inertness. Since ketene is generally generated by the pyrolysis of diketene,[5] we attempted the thermal 1,3-dipolar cycloaddition of 5-nitrofuran-2-carbohydroxamoyl chloride (I)[6] to diketene. I was heated in toluene with an equivalent amount of diketene until the evolution of hydrogen chloride gas had ceased; this afforded a crystalline product, II, in a 20% yield, in addition to the recovered I, after purification on a silica-gel (Mallinckrodt, 100 mesh) column. The yield of II was improved to 60% by adding excess amounts of diketene at intervals. The results of elemental analysis and the spectral data support the identification of II as 3-(5-nitro-2-furyl)-5-methylisoxazole, an isomer of 3-(5-nitro-2-furyl)-4-methylisoxazole,[7] mp 146—149°C; it could unambiguously be discriminated from II by an NMR spectral comparison.[8] It is noteworthy that the thermal procedure proceeded, presumably through an expectable intermediate adduct, III, followed by the elimination of carbon dioxide, thus affording an isoxazole derivative, II, instead of isoxazolone. 5-Nitrofuran-2-carbonitrile *N*-oxide did not react at all with diketene under the reaction conditions given by Minami and Matsumoto.[7] Similar treatments of *m*- and *p*-nitrobenzcarbohydroxamoyl chloride with diketene afforded only intractable tars, though the evolution of hydrogen chloride gas was observed in the course of the reactions.



Another interesting example was observed in the 1,3-dipolar cycloaddition reaction of I with carbodiimides. Carbodiimides as dipolarophilic heterocumulenes are known to react with dipolar compounds like hydrazoic acid, diazomethane, and nitrile imines,[9] and quite recently, the addition of aromatic nitrile oxides to diphenylcarbodiimide in the presence of boron trifluoride etherate as a catalyst has been reported to afford a spiro-1,2,4-oxadiazole, IV, *via* a 1 : 1 adduct, V.[10]

I was heated in toluene with an equivalent amount of dicyclohexylcarbodiimide (DCC) until the evolution of hydrogen chloride gas had ceased. The worked-up product (VI) consisted of yellow crystals; the results of the elemental analysis and the spectral data support the idea that VI is 1,4-dicyclohexyl-3-(5-nitro-2-furyl)-4,5-dihydro-5-oxo-1*H*-triazole. This was further confirmed by its chemical conversion to the known *N*,*N*′-dicyclo-

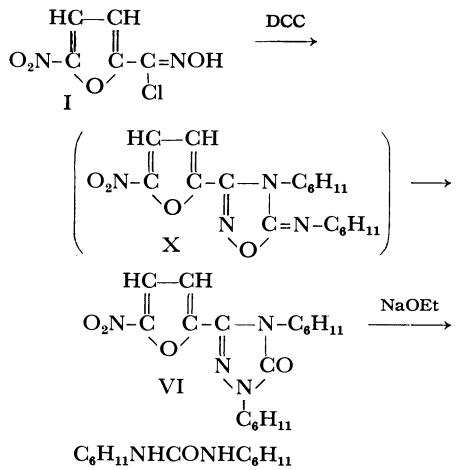
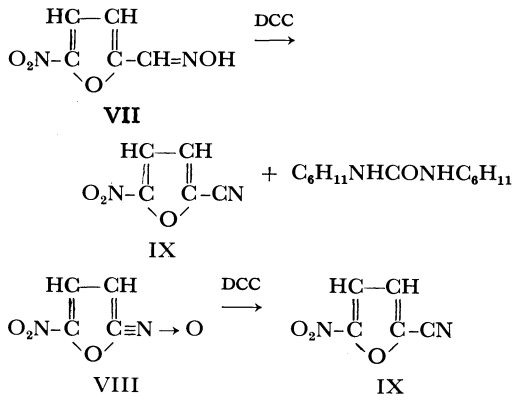
hexylurea[11] when its ethanolic solution was refluxed with sodium ethoxide. The similar thermal treatment of 5-nitrofuran-2-carboxaldehyde oxime (VII) with DCC and the normal treatment of 5-nitrofuran-2-carbonitrile oxide (VIII) with DCC in ether at room temperature both afforded 5-nitrofuran-2-carbonitrile (IX),[12] and no cyclization occurred. Considering the results given by





Grundman and Richter,[10] it seems reasonable to assume, in the reaction of I with DCC, that a 1 : 1 adduct like X might be produced as the first step and that this might then be thermally rearranged to VI. However, such a thermal rearrangement of oxadiazole to triazole has never been documented. Therefore, further investigation is necessary before the mechanism can be discussed in detail; this investigation is now being undertaken.

Experimental[13]

3-(5-Nitro-2-furyl)-5-methylisoxazole (II). I (0.88 g; 0.4 mmol) was treated with 1.0 g of diketene and 20 m*l* of toluene at reflux temperature for 18 hr, until the evolution of hydrogen chloride gas had ceased. After the removal of the solvent, the residue was dissolved in chloroform and chromatographed on a silica-gel column. 0.17 g (20%) of yellow crystals, mp 143—144°C, was obtained from the first fraction*1 after recrystallization from ethanol. UV λ_{max}^{EtOH} mμ (ε): 320 (14500). NMR ($CDCl_3$) τ: 2.56 (doublet, J=3.8 cps, 4-C–H of nitrofuran), 2.96 (doublet, J=3.8 cps, 3-C–H of nitrofuran), 3.53 (quartet, J=0.2 cps, 4-C–H), 7.46 (doublet, J=0.2 cps, 5-C–CH_3).

Found: C, 49.38; H, 3.17; N, 14.25%. Calcd for $C_8H_6O_4N_2$: C, 49.47; H, 3.12; N, 14.43%.

1,4-Dicyclohexyl-3-(5-nitro-2-furyl)-4,5-dihydro-5-oxo-1*H*-triazole (VI). I (0.95 g; 0.5 mmol) was refluxed with 1.0 g (0.5 mmol) of DCC in 20 m*l* of toluene for 7 hr, until the evolution of hydrogen chloride gas had ceased. After the removal of the solvent under reduced pressure, the residue was dissolved in chloroform and chromatographed on a silica-gel column. 0.7 g (40%) of VI, mp 146—148°C, was obtained from the first fraction after recrystallization from ethanol. UV λ_{max}^{EtOH} mμ (ε): 350 (3400, shoulder), 295 (9000). IR (KBr) cm^{-1}: 1700 (ν_{CO}). NMR ($CDCl_3$) τ: 2.58 (doublet, J=3.8 cps, 4-C–H of nitrofuran), 2.86 (doublet, J=3.8 cps, 3-C–H of nitrofuran), around 6.2 and 8.5 (multiplet, $-CH_2$).

Found: C, 60.10; H, 6.63; N, 15.71%. Calcd for $C_{18}H_{24}O_4N_4$: C, 59.68; H, 6.71; N, 15.55%.

Conversion of VI to *N,N'*-Dicyclohexylurea. A mixture of 0.23 g of VI, 0.1 g of sodium ethoxide, and 20 m*l* of ethanol was refluxed for 6 hr. After the ethanol had been removed under reduced pressure, the residue was made acidic by adding dilute hydrochloric acid, and then it was extracted with chloroform. After drying a chloroform layer over sodium sulfate, a chloroform solution was chromatographed on a silica

11) Mp 242°C. Found: C, 69.82; H, 11.04; N, 11.92%. Calcd for $C_{13}H_{24}ON_2$: C, 69.60; H, 10.78; N, 12.49%. IR (KBr) cm^{-1}: 3350 (νNH), 1630 (νCO). *Cf.* C. A. Dekker and H. G. Khorana, *J. Org. Chem.*, **76**, 3522 (1954).

12) Mp 62—64°C. T. Sasaki and T. Yoshioka, *Yuki Gosei Kagaku Kyokaishi* (*J. Synth. Org. Chem. Japan*), **25**, 665 (1967).

13) All melting points were determined on a Yanagimoto micromelting-point apparatus and have not been corrected. The ultraviolet spectra were run on a JASCO Model ORD/UV-5 optical rotary dispersion recoder, while the infrared spectra were measured on a JASCO Model IR-S spectrophotometer. The NMR spectra were taken on a Varian A-60 apparatus, with tetramethylsilane as an internal standard, and their chemical shifts are presented in terms of τ values.

*1 From the second fraction, I was recovered in a 56% yield.

column. 0.05 g (50%) of dicyclohexylurea[11] was obtained from the first fraction after recrystallization from benzene - petroleum ether.

N-Nitrofuran-2-carbonitrile (IX). *From 5-Nitrofuran-2-carboxaldehyde Oxime (VII).* A solution of 0.8 g of VII and 1.03 g of DCC in 25 m*l* of toluene was refluxed for 10 hr. After cooling, the resulting precipitates were filtered and washed with hot benzene to afford 1.0 g (87%) of dicyclohexylurea,[11] which was identified by infrared spectral comparison with an authentic specimen. The filtrate was condensed, redissolved in chloroform, and then chromatographed on a silica-gel column. 0.6 g (85%) of VIII[12] was obtained from the first fraction; it was identified by infrared spectral comparison with an authentic specimen.

From 5-Nitrofuran-2-carbonitrile Oxide (VIII). To a stirred solution of 0.8 g of I and 0.91 g of DCC in 30 m*l* of ether, there was added a solution 1 m*l* of triethylamine in 10 m*l* of ether at room temperature. Stirring was continued for 1 hr, after which the resultant triethylamine hydrochloride was filtered and washed with ether. The ether washings were combined with the filtrate and chromatographed on a silica-gel column, using chloroform as an eluent. From the first fraction a very small amount of IX was obtained, while from the third fraction, 0.5 g of dicyclohexylurea[11] was obtained; the other parts were intractable tars hard to characterize.

Halogenation Reaction of Bis(dithioacetylacetonato) Complexes of Cobalt(II) and Nickel(II)*1

Akiko FURUHASHI, Kunihiko WATANUKI*2 and Akira OUCHI*2

Department of Chemistry, College of Engineering and Science, Aoyama Gakuin University, Megurisawa, Setagaya, Tokyo

(Received May 7, 1968)

Reactions of halogenation reagents with acetylacetonato complexes have already been studied,[1,2] with the successful halogenation of the chelate ring. This reaction is one proof of the aromaticity of the acetylacetonato chelate ring. Thus, the halogenation of dithioacetylacetonato complexes is very interesting, and the chlorination or bromination of $M(L_{SS})_2$ type compounds (where M is Ni(II) or Co(II), HL_{SS} is dithioacetylacetone) prepared by a method given in a previous paper[3] was examined. However, in these cases the products obtained were another type of dithioacetylacetonato complex; *i. e.* $M(L_{SS})_2X_n$.[4,5] The chloro complexes thus obtained were green $M(L_{SS})_2Cl_4$, and the bromo complexes yellow $M(L_{SS})_2Br_6$. All are new compounds. Anlayses and the magnetic moments of these compounds are given in Table 1, IR spectral data between 1800 and 600 cm^{-1} in Table 2 and UV spectra of the methanolic solutions in Table 3. Assignments of the IR spectra are only tentative.[4,8]

The magnetic moments of these chloro compounds are a little higher than those calculated from the formula $\sqrt{n(n+2)}$. In the case of cobalt(II) complexes, these higher values are rather common for octahedral configurations. Although these higher values are not common in the case of nickel(II) octahedral complexes,[6,7] it is not probable that only the nickel complex has a structure different from the other $M(L_{SS})_2Cl_4$ type complexes.[8] As the general properties of complexes having the same general formula, including IR spectral data, are very similar, the structure of the Ni(II) and Co(II) complexes are as follows (shown in a previous paper[8]): four chlorine atoms are directly bonded to the central metal atom, and two dithiolium[9] ions to the metal as a mono-dentate. Their infrared spectra are very similar to those of usual $M(L_{SS})_2X_4$ type complexes. Although methanol decomposes these complexes into the metal, dithiolium and halogen ions, their methanol solution shows two characteristic peaks in the ultraviolet range due to dithiolium ion produced by solvolysis. The wave

numbers and absorption coefficients of the absorption maxima are very similar to those of dithiolium perchlorate reported in Schmidt's paper.[9] In the visible region only a broad band and a d-d band of the metal ion produced are observed in each case, as is usual for $M(L_{SS})_2X_4$ complexes.[8]

The bromo-complexes thus obtained contain six bromine atoms per metal atom, but from electrovalence consideration,[5] two of them should not be ionic. But it is not a mixture of two compounds,

as $M(L_{SS})_2Br_6$ (where M is Ni(II) or Co(II)) is yellow and the analyses and color do not change even after repeated washing with benzene or carbon tetrachloride; on the other hand, $Co(L_{SS})_2Br_4$ is green. All bromine is titrated by the Volhard method in an aqueous nitric acid solution. These compounds oxidize potassium iodide in aqueous acetic acid solution.

In the case of $Co(L_{SS})_2Br_6$, two atoms of bromine react very soon, but the reaction continues even after that and two more atoms of bromine react very slowly at room temperature. In the case of the nickel compound, the reaction is slow from the beginning but about four atoms of bromine per molecule react in a few hours at 20°C. The role of the dithiolium ion must be considered in the oxidation-reduction reaction too. Although dithiolium perchlorate does not liberate iodine from potassium iodide in aqueous acetic acid solution, the salt changes to orange yellow. Then the oxidation-reduction reaction of the complex is not simple, but at least the existence of labile bromine in it is recognized. $M(L_{SS})_2X_4$ complexes do not react with iodide under the same condition.[5]

These hexabromo complexes decompose rapidly at about 100°C, and slowly even at room temperature. At room temperature, $Co(L_{SS})_2Br_6$ evolves bromine and changes into $Co(L_{SS})_2Br_4$ in several months, but at higher temperatures it loses more, probably due to a second step reaction by evolved bromine. The nickel compound decomposes into bromine and a black product both at room temperature and 100°C. On the other hand, the usual $M(L_{SS})_2X_4$ complexes are far more stable.

The magnetic moments of these hexabromo-complexes are a little lower than those of the corresponding chloro-complexes, as shown in Table 1.

The infrared spectra of these hexabromo-complexes show a sharp peak at about 1600 cm^{-1} but other than that their general features are almost the same as those of usual $M(L_{SS})_2X_4$ type complexes; the ν(C=C) band near 1480 cm^{-1} also appears. (In the case of acetylacetonates, the ν(C=C) band near 1500 cm^{-1} disappears through halogenation though other parts of the spectra do not change seriously.[2]) The electronic spectra of their methanol solutions are almost the same as the usual tetrahalogeno complexes.

From these observations, although the two excess bromine atoms may bond to γ-carbon of the chelate or to β-carbon as proposed by Knauer in the case of $Fe(L_{SS})_2Cl_4$,[5] the bonds are very weak. Then it is reasonable to assume that these compounds are adducts of Br_2 to $M(L_{SS})_2Br_n$.

Milder halogenation reactions using *N*-chlorosuccinimide or *N*-bromosuccinimide were also tried with nickel(II) or cobalt(II) dithioacetylacetonate. Some adducts containing these reagents precipitated immediately, and from the filtrate, tetrachlorobis(dithioacetylacetonato)-cobalt(II) was obtained. But from the cobalt(II) complex and NBS or from the nickel complex and NCS or NBS, the products obtained by the same process were contaminated with the adduct of NXS, and the pure product was hardly obtained.

When solid mixture of sodium borohydride and halogeno complexes were treated with a little water, the starting $M(L_{SS})_2$ type complexes (where M = Co(II) or Ni(II)) were obtained. The yield was about 30%. These products were identified through their analyses, IR spectra and UV spectra of the methanolic solutions. This method is a new convenient synthesis of dithio-β-diketonato complexes.

Experimental

IR spectra were obtained through the nujol and hexachloro-1,3-butadiene mull procedure, using a DS 301 type infrared spectrophotometer of the Japan Spectroscopic Co., Ltd. Ultraviolet spectra were obtained with a Hitachi EPS-2 Spectrophotometer. Magnetic susceptibility measurements were carried out with a Gouy's balance at room temperature (15°C).

Synthesis of Tetrachlorobis (dithioacetylacetonato)nickel(II). Five hundred milligrams (1.56 mmol) of bis(dithioacetylacetonato) nickel(II) was suspended in 20 m*l* of carbon tetrachloride, and chlorine gas was bubbled in while stirring and cooling with ice. A green precipitate was obtained. The product was washed with carbon disulfide, chloroform, carbon tetrachloride and petroleum ether in that order. Recrystallization was not successful. The reaction was almost quantitative and the yield was 700 mg (1.52 mmol).

Other compounds were obtained by almost the same method.

The authors wish to thank the Analytical Division of the Department of Pharmacy for the elemental analyses and the Biochemistry Section of our college for the infrared spectra measurements. The useful discussions of Professor Yukichi Yoshino, Professor Yasumasa Hayakawa and colleagues of our laboratory are also gratefully acknowledged.

Space Effects of Tetra-*n*-alkyl Ammonium Ions on the Electrical Conduction of Tetracyanoquinodimethane Salts

Hideaki KUSAKAWA and Kazuko AKASHI*1

Mitsubishi Electric Corporation, Central Research Laboratory, Amagasaki, Hyogo

(Received May 24, 1968)

Several papers have been reported on the electrical properties of several kinds of TCNQ complexes,[1,2] but little attention has been paid to the effects of the molecular structure of paired ion on their electrical conduction.[3]

In this work we investigated how the electrical conductivities of TCNQ salts and complexes depend on the size of ammonium ions. Seven sorts of simple salts and six sorts of complex salts of TCNQ were prepared with various tetra-*n*-alkyl ammonium ions as the paired cation, and the space effects of these ammonium ions on the electrical conductivity were investigated. It was found that the electrical conductivities decrease with an increase in the number of carbon atoms in *n*-alkyl groups for the simple salts: on the other hand, for the complex salts the minimum resistivity appears when the tetra-*n*-butyl ammonium ion is used.

Experimental

Formation of Simple Salts. Tetra-*n*-alkyl ammonium halides and equimolar K^+ $TCNQ^-$ were dissolved and mixed in acetonitrile or ethyl acetate. After the potassium halide and solvent had been removed, the crude salt crystals were collected. These crystals were washed with water and dried, and were purified by means of recrystallization from the solvent used in the preparation.

Simple salts of tetra-*n*-amyl and tetra-*n*-hexyl ammonium were pasty and could not be dried completely even under reduced pressure for a long time.

The analytical results and preparation conditions of simple salts are summarized in Table 1.

Preparation of Complex Salts. TCNQ simple salt and equimolar neutral TCNQ were crushed into powder, mixed completely in an agate bowl, and dissolved in dried acetonitrile. After this had been kept at 70°C for one hour, blue-black plate crystals of complex salt were precipitated. Their elementary analytical data are listed in Table 2.

Measuring of Electrical Conductivity. The electrical conductivities of these specimens were measured by a method reported previously.[4]

Results and Discussion

TCNQ Simple Salts. Their electrical resis-

$(C_5H_{11})_4N\cdot(TCNQ)_2$	74.8	7.4	17.9	74.9	7.2	17.5
$(C_6H_{13})_4N\cdot(TCNQ)_2$	75.6	7.9	16.5	75.5	8.1	16.2

tivities at room temperature and the temperature dependence (activation energy) of the resistivity are summarized in Table 3. As Table 3 shows, tetra-*n*-alkyl ammonium-TCNQ simple salts can be classified into three groups; ammonium, tetramethyl- and tetraethylammonium salts belong to

TABLE 3. ELECTRICAL RESISTIVITY AND ACTIVATION ENERGY OF TCNQ SIMPLE SALTS

Simple salt	Resistivity at 20°C (Ωcm)	Activation energy E (eV)
$NH_4\cdot TCNQ$	4.3×10^4	0.22
$(CH_3)_4N\cdot TCNQ$	3.4×10^5	0.22
$(C_2H_5)_4N\cdot TCNQ$	$1.0+10^6$	0.28
$(C_3H_7)_4N\cdot TCNQ$	1.6×10^9	0.87
$(C_4H_9)_4N\cdot TCNQ$	4.8×10^{10}	0.88
$(C_5H_{11})_4N\cdot TCNQ$	non reproducible	
$(C_6H_{13})_4N\cdot TCNQ$	non reproducible	

the first, tetra-*n*-propyl- and tetra-*n*-butylammonium salts to the second, and tetra-*n*-amyl- and tetra-*n*-hexylammonium salts to the last group. The activation energies of salts in the first group are approximately 0.22 eV, and their resistivities become higher as the constructing-cation size increases. Of the second group of salts both the resistivity and the activation energy are much larger in magnitude in the first. The resistivities of the third group of salts could not be obtained with a good reproducibility. For tetra-*n*-alkylammonium-TCNQ simple salts a lower resistivity appears on the salt with a smaller ammonium ion size.

TCNQ Complex Salts. The resistivity and activation energies for the complex salts are listed in Table 4. In Fig. 1 the magnitudes of both the resistivity at 20°C and the activation energy of resistivity are plotted *vs.* the number of carbon atoms in the alkyl group.

For complex salts both the resistivity and the activation energy gradually decrease in magnitude with an increase in the ammonium ion size, the minimum values appearing at tetra-*n*-butylammonium complex salt. After this minimum points, each value rapidly increases again.

TABLE 4. ELECTRICAL RESISTIVITY AND ACTIVATION ENERGY OF COMPLEX SALTS

Complex salt	Resistivity at 20°C (Ωcm)	Activation energy E (eV)
$(CH_3)_4N\cdot(TCNQ)_2$	1.1×10^6	0.37
$(C_2H_5)_4N\cdot(TCNQ)_2$	3.3×10^4	0.34
$(C_3H_7)_4N\cdot(TCNQ)_2$	9.9×10^3	0.33
$(C_4H_9)_4N\cdot(TCNQ)_2$	9.7×10^1	0.21
$(C_5H_{11})_4N\cdot(TCNQ)_2$	1.0×10^7	0.75
$(C_6H_{13})_4N\cdot(TCNQ)_2$	4.6×10^8	0.93

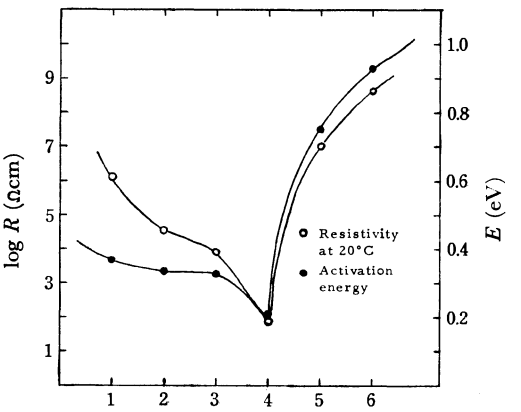

Fig. 1. Relation between resistivity and activation energy and carbon number of *n*-alkyl group in ammoniumion contained in TCNQ complex salts.

The crystal formation and electrical conductivity of complex salts are affected by the size of the paired ammonium ions. The crystal of ammonium complex salt could not be obtained, and the preparation of tetramethyl- and tetra-*n*-hexylammonium complex salts was difficult. It seems that the ammonium ion size influences the arrangement of TCNQ molecules in the complex crystal and that the overlapping of the molecular orbitals on TCNQ is varied. When the paired cation in the complex crystal is the tetra-*n*-butylammonium ion, the arrangemetn of the TCNQ molecule reaches the optimum for electrical conduction. As the

ion size of the paired cation is either smaller or larger than with tetra-*n*-butylammonium, the overlapping of moleculals on TCNQ decreases, thus leading to lower electrical conductivity.

On the Behavior of the Mixture of Trimethylstibine Sulfide and Tin(IV) Halides in Solution

Mizuo SHINDO, Yoshio MATSUMURA and Rokuro OKAWARA

Department of Applied Chemistry, Osaka University, Yamadakami, Suita, Osaka

(Received May 31, 1968)

In the previous papers[1,2] we have reported that the complexes, $R_2SnX_2 \cdot 2(CH_3)_3SbS$ ($R=CH_3$ or C_2H_5; $X=Cl$ or Br), change completely into three species with the exchange of the anionic ligands in $CHCl_3$ or CH_2Cl_2 as shown in (1).

$$R_2SnX_2 \cdot 2(CH_3)_3SbS \rightarrow (CH_3)_3SbS + (CH_3)_3SbX_2 + \tfrac{1}{3}(R_2SnS)_3 \quad (1)$$

This paper reports additional studies of these particular exchange reactions in $CHCl_3$ or CH_2Cl_2 with the mixtures of $(CH_3)_3SbS$ and R_3SnCl ($R=CH_3$ and C_6H_5) or $(C_6H_5)_2SnCl_2$, although we have not been able to isolate the complexes between the stibine sulfide and the tin chlorides.[2]

Experimental

The materials used in the present experiments and the experimental methods were described in the previous paper.[2]

Results and Discussion

The IR spectra of the mixtures of $(CH_3)_3SbS$ and $(CH_3)_3SnCl$ in various ratios were measured in solution and the relevant IR frequencies of a mixture of $(CH_3)_3SbS$ and $2(CH_3)_3SnCl$ in $CHCl_3$ are given in Table 1.

The spectrum can plausibly be interpreted as a superposition of the four compounds observed independently in $CHCl_3$; $(CH_3)_3SbS$,[2] $(CH_3)_3SnCl$, $(CH_3)_3SbCl_2$[2] and $[(CH_3)_3Sn]_2S$.

The NMR spectrum shown in Fig. 1 also supports this result.

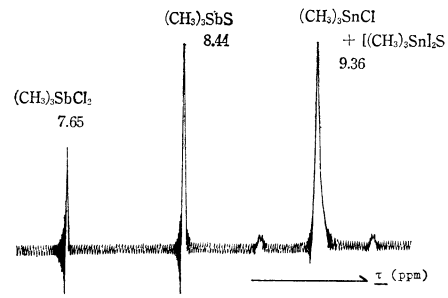

Fig. 1. The NMR spectrum of the mixture of $2(CH_3)_3SnCl$ and $(CH_3)_3SbS$ in $CHCl_3$ at 60 Mc/sec at 20°C.

For the antimony compounds the corresponding

1) M. Shindo and R. Okawara, *Inorg. Nucl. Chem. Letters*, **3**, 75 (1967).

2) M. Shindo, Y. Matsumura and R. Okawara, *J. Organometal Chem.*, **11**, 299 (1968).

two signals were observed. However, the tin compounds showed only one signal at 9.36 ppm. This signal is due to the rapid exchange of chlorine-sulfur atoms or methyl groups between $(CH_3)_3SnCl$ and $[(CH_3)_3Sn]_2S$, for the signal moves to higher field to approach that of $[(CH_3)_3Sn]_2S$ with decreasing ratio of $(CH_3)_3SnCl$ to $[(CH_3)_3Sn]_2S$. The same IR and NMR results were obtained in the case of a mixture of $(CH_3)_3SbCl_2$ and $[(CH_3)_3Sn]_2S$.

From these findings it is clear that the four species exist in equilibrium as shown in (2).

$$2(CH_3)_3SnCl + (CH_3)_3SbS \rightleftarrows (CH_3)_3SbCl_2 + [(CH_3)_3Sn]_2S \quad (2)$$

The molar concentrations of $(CH_3)_3SnCl$ and $[(CH_3)_3Sn]_2S$ can be determined from the intensity ratio of methyl protons of $(CH_3)_3SbS$ to those of $(CH_3)_3SbCl_2$ and Eq. (2). From these results the equilibrium constant, $K=[Me_3SbCl_2]\,[(Me_3Sn)_2S]/[Me_3SnCl]^2[Me_3SbS]$, of Eq. (2) was calculated to be 0.14 (l/mol) at 20°C. Similarly, in cases of $(C_6H_5)_3SnCl$ and $(C_6H_5)_2SnCl_2$, the equilibrium constants are 80(l/mol) and ∞(l/mol)$^{2/3}$, respectively. It can be understood that in the case of $(C_6H_5)_2SnCl_2$ the equilibrium goes, just in the cases of Eq. (1), too much toward the right side. From these it can be concluded that, in general, the equilibrium constant increases as the electron acceptor properties of the tin com- pounds increase.

$$(CH_3)_3SnCl < (C_6H_5)_3SnCl < (CH_3)_2SnCl_2 \sim (C_6H_5)_2SnCl_2$$

A Comparative Study of Electron Capture by Solutes in γ-Irradiated 2-Methyltetrahydrofuran Glass at 77°K

Terunobu WAKAYAMA, Toyoaki KIMURA, Tetsuo MIYAZAKI, Kenji FUEKI and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

(Received June 5, 1968)

It is generally believed that the behavior of electrons produced by the γ-irradiation of molecular compounds depends upon the states of aggregation; the electrons in the liquid phase are solvated and their reactions are mostly diffusion-controlled,[1-3] while they are, of course, free in the gas phase. A study[4] made of the reaction of electrons with a number of organic halides in 2-methyltetrahydrofuran (MTHF) glass at 77°K has led to the conclusion that electrons behave as quasi-free electrons*1 in the solid phase.

These studies of the behavior of electrons were, however, undertaken by different experimental techniques and the interrelation between electrons in the different phases is not clear at present.

It is widely accepted that nitrous oxide reacts with an electrons:

$$e^- + N_2O \longrightarrow N_2 + O^- \qquad (1)$$

Recently it has been shown by kinetic studies involving the analysis of final products that Reaction (1) alone is not sufficient to explain the yield of nitrogen.[5-8]

In the present work, we have studied, by the spectrophotometric method, the reactivities of N_2O, SF_6, and CO_2 with electrons in MTHF glass at 77°K and compared the results with those in the liquid and gas phases.[3,9] We have also studied the reaction of nitrous oxide with electrons by analyzing the final products in connection with the measurements of the reaction intermediates.

When MTHF glasses containing biphenyl are irradiated with γ-rays at 77°K, a fraction of the

electrons produced are captured by biphenyl to form biphenyl anions. The anion gives a sharp absorption band with $\lambda_{max}=410$ mμ and a broad band with $\lambda_{max}=660$ mμ. The absorption bands attributed to the biphenyl anion decrease in the presence of another electron scavenger (X) in the system. The relative electron attachment cross-section can be obtained from the following relation:[10]

$$\frac{1}{G(C_{12}H_{10}^-)} = \frac{1}{G(C_{12}H_{10}^-)_0} + \frac{\sigma_X[X]}{G(C_{12}H_{10}^-)_0\sigma_{C_{12}H_{10}}[C_{12}H_{10}]}$$

where $G(C_{12}H_{10}^-)_0$ is the yield of the biphenyl anion in the absence of the second solute (X) and where σ is the electron attachment cross-section. When the concentration of biphenyl is taken to be constant, $1/G(C_{12}H_{10}^-)$ is linearly related to the concentration of the second solute (Fig. 1). From the slopes and intercept of straight lines in Fig. 1 the relative electron-attachment cross-sections of SF_6, N_2O and CO_2 in MTHF glass are obtained; they are listed in Table 1. The electron attachment

△, SF_6; ⊙, N_2O; ⊡, CO_2

Table 1. Relative electron-attachment corss-sections of SF_6, N_2O, and CO_2

	Solid	Gas[9]	Liquid[3]
SF_6	2.3	10	1.0
N_2O	1.0	1.0	1.0
CO_2	0.3	0	1.0

cross-sections of SF_6, N_2O and CO_2 differ in the solid phase, while they are the same in the liquid phase. It has previously been proposed that the electron in the liquid phase is solvated and that its reactions with electron scavengers are diffusion-controlled.[1-3] The electron-attachment cross-sections of SF_6, N_2O and CO_2 in the solid phase are in the same order as those in the gas pahse. This implies that electrons are quasi-free electrons*1 in the solid phase, as has been suggested in previous studies.[4,8]

The reactions of nitrous oxide with biphenyl anions and with electrons in MTHF glass have been investigated by both the spectrophotometric measurement of biphenyl anions and the analysis of nitrogen. The absorption spectra of the biphenyl anion were measured after γ-irradiation to a dose of 8.49×10^3 rad, and nitrogen was measured at room temperature on the samples γ-irradiated at 7°K (dose: 3.91×10^5 rad) by a gas burette connected to a Toepler pump and a cupric oxide furnace kept at 240°C. The yield of biphenyl anions increases linearly with the dose, 8.49×10^3 to 3.91×10^5 rad. The effect of nitrous oxide on the yields of biphenyl anions and nitrogen is shown in Fig. 2. The yield of nitrogen increases rapidly

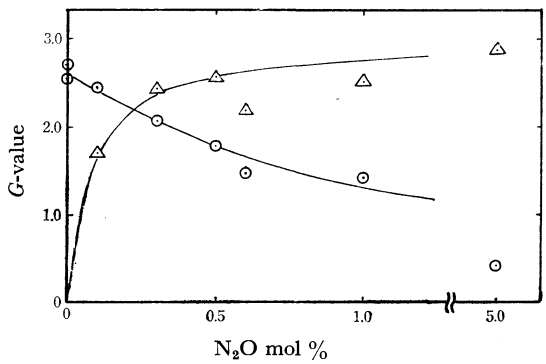

Fig. 2. Effect of nitrous oxide on the yields of biphenyl anion and nitrogen.
Concentration of biphenyl: 0.2 mol%
⊙—⊙, biphenyl anion
△—△, nitrogen

with an increase in the nitrous oxide and becomes constant at concentrations of nitrous oxide higher than 0.5 mol%, while the yield of biphenyl anions gradually decreases with an increase in the nitrous oxide. Though the decrease in biphenyl anions represents the amount of electrons captured by nitrous oxide, it does not correspond to the yield of nitrogen. The yield of nitrogen at high concentrations of nitrous oxide is about 2.6 (G unit), which is approximately equal to the yield of biphenyl anions in the absence of nitrous oxide. These results may be explained by the following scheme:

$$MTHF\text{-}\wedge\!\vee\!\wedge\!\rightarrow MTHF^+ + e^- \quad (2)$$

$$e^- + C_{12}H_{10} \longrightarrow C_{12}H_{10}^- \quad (3)$$

$$e^- + N_2O \longrightarrow N_2 + O^- \quad (1)$$

$$C_{12}H_{10}^- + N_2O \longrightarrow N_2 + O^- + C_{12}H_{10} \quad (4)$$

Reaction (4) probably occurs while the sample is

10) J. P. Guarino, M. R. Ronayne and W. H. Hamill, *Radiation Res.*, **17**, 379 (1962).

being warmed to room temperature. Reaction (4) requires that the electron affinity of nitrous oxide is greater than that of biphenyl, 0.41 eV. It may be concluded that nitrous oxide reacts with an electron to form one nitrogen molecule in MTHF glass

The Spectrophotometric Determination of Anions by Solvent Extraction with Metal Chelate Cations. V.*1 Thiocyanate with Tris(1,10-phenanthroline)iron(II) Chelate

Yuroku YAMAMOTO, Tsunehiko TARUMOTO and Yasuko HANAMOTO

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda, Hiroshima

(Received June 15, 1968)

A number of methods have been reported on the determination of thiocyanate. Aldridge[1] and Baker *et al.*[2] proposed colorimetric methods with a pyridine-benzidine mixture, both of which require quite tedious procedures. Kruse and Mellon[3] used copperpyridine as a color developer, the reaction mechanism of which is still obscure. Winkhaus and Uhrig[4] presented a spectrophotometric method by solvent extraction with di-π-cyclopentadienyltitanium(IV) which, though simple and sensitive, is effective only in a very narrow pH range in the acidic media. Koh and Iwasaki[5] recently reported another spectrophotometric method based on solvent extraction with methylene blue which attained very high sensitivity and was yet influenced to some extent by the reagent concentrations used in the experiment.

Here, we present a new and consistent method for the determination of a small amount of thiocyanate anions, in which thiocyanate as low as 2×10^{-6} in molar concentration was extracted from aqueous solution into nitrobenzene as tris(1,10-phenanthroline)iron(II) thiocyanate and determined spectrophotometrically.

Experimental

All the reagents used in this experiment were of analytical reagent grade and a Hitachi 139 spectrophotometer with 10 mm glass cells was used for measurement.

Recommended Procedure. Take 5 m*l* of thiocyanate solution of concentration ranging from 1×10^{-5} to 2×10^{-4} M in a 50 m*l* beaker. Add 5 m*l* of 0.02 M 1,10-phenanthroline solution, 5 m*l* of 5×10^{-3} M iron(II) solution prepared from Mohr's salt and 5 m*l* of phosphate buffer solution to adjust the pH of this mixture to 5—10. Transfer this into a separatory funnel and dilute to 25 m*l* with distilled water.

Add 10 m*l* of nitrobenzene previously equilibrated with water and shake the funnel for about 5 min. About 30 min after extraction, remove the organic layer and dehydrate with anhydrous sodium sulfate, allowing the mixture to stand another 10 min. Measure the absorbance of the organic phase at 516 mμ with the reagent blank as a reference.

Results and Discussion

The absorption spectrum of the extract is shown in Fig. 1. The absorption maximum was identical with that of tris(1,10-phenanthroline)iron(II) thiocyanate salt dissolved in nitrobenzene. The chemical formula of the extracted species was confirmed to be $[Fe(phen)_3](NCS)_2$ also by continuous variation method, where phen represents 1,10-phenanthroline. This species shows a constant absorbance when extracted from aqueous phase with a wide pH range of 5 to 10, indicating that the degree of extraction was maximum in this pH range. The percentage of the extraction was found to be 52% (*i. e.*, $D=2.7$) by referring the absorbance of the extract to that of a standard solution prepared by dissolving crystalline $[Fe(phen)_3](NCS)_2$ in nitrobenzene. The color was stable for about three hours before slight fading was observed.

Increasing the quantity of tris(1,10-phenanthroline)iron(II) against that of thiocyanate did not affect the degree of extraction, provided the former was 15 times more concentrated than the latter.

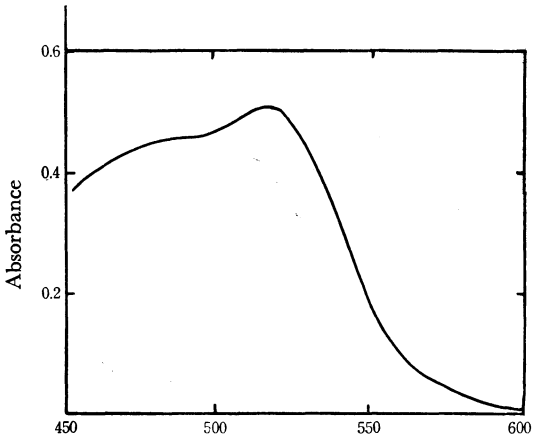

Fig. 1

Fig. 1. Absorption Spectrum of Tris(1,10-phenanthroline)iron(II) thiocyanate in Nitrobenzene Extract.
Tris(1,10-phenanthroline)iron(II) concentration $= 1.0 \times 10^{-3}$M
Thiocyanate concentration $= 4.0 \times 10^{-5}$M
Extraction was done according to the recommended procedure.
Reference : Reagent Blank.

Thus, the tris(1,10-phenanthroline)iron(II) concentration was kept at least 25 times in excess throughout the experiment.

A plot of absorbance in nitrobenzene phase *vs.* thiocyanate concentration in aqueous phase gave a linear relationship over the range of 2×10^{-6} to 4×10^{-5} M thiocyanate. As for the interference of diverse ions, metals highly reactive with thiocyanate, for example, cobalt, nickel, zinc or copper caused comparatively high negative errors when present in amounts equal to the thiocyanate concentration. Sodium, calcium, magnesium and manganese had negligible effects, even when 100 times the amount of thiocyanate was present. Perchlorate, as previously reported,[6] was the most extractable species and therefore its interference was serious. As to other anions, iodide and nitrate form ion pairs with tris(1,10-phenanthroline)iron(II) and therefore produce positive errors, while bromide, chloride, sulfate and phosphate had no appreciable effects even when present in considerable amounts, as may be seen in Table 1.

Table 1. Effect of diverse anions*2

Anion added as sodium salt	Concentration M	Relative error %
F^-	4×10^{-2}	0
Cl^-	2×10^{-3}	0
Br^-	2×10^{-4}	+10.8
I^-	2×10^{-5}	+69.5
NO_3^-	2×10^{-5}	+11.6
SO_4^{-2}	2×10^{-3}	+1.0
$H_2PO_4^-$	2×10^{-3}	0

*2 All the solutions are 2×10^{-5} M in thiocyanate concentration.

The interference of some cations may be easily masked with EDTA, but the interfering anions should be separated prior to the extraction of thiocyanate by proper methods like ion exchange.

Poisoning Effect of Carbon Disulfide on the Liquid-phase Hydrogenation of Acetone over a Raney-Nickel Catalyst

Sanae KISHIDA and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Machikaneyama-cho, Toyonaka, Osaka

(Received June 17, 1968)

Recently the present authors have reported[1] that the liquid-phase hydrogenation of open-chain ketones over a Raney-nickel catalyst could reasonably be interpreted by the rate equation derived from the Langmuir-Hinshelwood mechanism;

$$v = k \cdot a \cdot C_R/(1 + a \cdot C_R), \quad (1)$$

where k refers to the rate constant; C_R, the concentration of reactant to be hydrogenated, and a, the equilibrium constant concerning the adsorption strength of hydrogen and the reactant.*1

In a previous paper[2] the authors also studied the hydrogenation of mesityl oxide over a Raney-nickel catalyst poisoned by potassium iodide, and found that the equilibrium constant, a, and the rate constant decrease upon the poisoning. The authors, therefore, pointed out that not only the behavior of the rate, but also the change in the kinetics due to the poisoning, has to be taken into account in considering a mechanism of the poisoning in heterogeneous catalysis.

In the present study, the kinetics of acetone hydrogenation over a Raney-nickel catalyst progressively poisoned by carbon disulfide is investigated in detail. A poisoning curve and a mechanism of the poisoning are then discussed accordingly.

Experimental

Catalyst. 1.00 g of Raney-alloy (50.0% Ni) was leached with 50 m*l* of a 20% sodium hydroxide solution at 100°C for 60 min. The sample was then washed 5 times with 100 m*l* of water, 5 times with 25 m*l* of isopropyl alcohol, and 10 times with 25 m*l* of *n*-hexane under hydrogen. The sample was then poisoned by CS_2, and diluted with *n*-hexane. The concentrations were so low that the CS_2 in solution was completely adsorbed by the catalyst. The sample was then washed 5 more times with 25 m*l* of *n*-hexane.

Apparatus and Procedure. For the rate measurements they were as previously reported.[1]

Results

The concentration dependence of the initial rates at 30°C over the catalyst progressively poisoned are shown in Fig. 1. The peak shifts to higher concentrations with the progressive poisoning. The

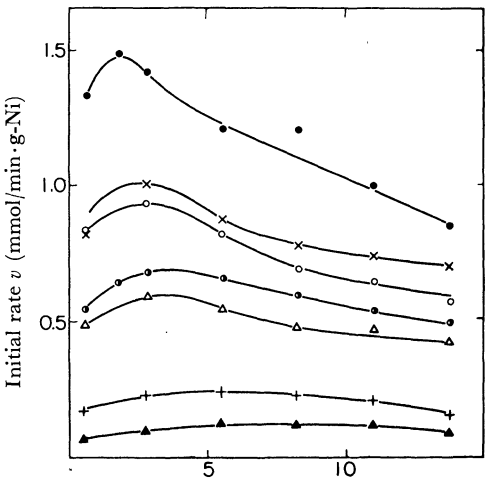

Fig. 1. Acetone hydrogenation over Raney-nickel catalyst progressively poisoned by CS_2.
The amount of CS_2 adsorbed are; ●, 0.0; ×, 0.0167; ○, 0.0474; ◑, 0.0660; △, 0.0835; +, 0.1885; ▲, 0.2505 mmol/g-Ni.

values of k and a for the poisoned catalyst were evaluated from the plots of $\sqrt{C_R/v}$ *vs.* C_R. It was found that k and a decrease in an exponential manner with the amount of carbon disulfide adsorbed, as is shown in Fig. 2; that is, k and a over the poisoned catalyst can be expressed as;

$$k = k_0 \exp(-\beta \cdot x),$$

$$a = a_0 \exp(-\alpha \cdot x),$$

where k_0 and a_0 refer to the rate constant and the equilibrium constant respectively over the un-

1) S. Kishida, S. Kajimoto and S. Teranishi, *Shokubai (Catalyst)*, **9**, 58 (1967); *J. Catalysis*, in printing.

*1 The accurate definition of a is: $a=(1/C_H) \cdot \exp(-\delta\Delta G/RT)$, where C_H refers to the liquid-phase concentration of hydrogen and where $\delta\Delta G$ is the difference in the free energies of the adsorption of hydrogen and a reactant. See Refs. 1 and 2.

2) S. Kishida and S. Teranishi, This Bulletin, **41**, (1968).

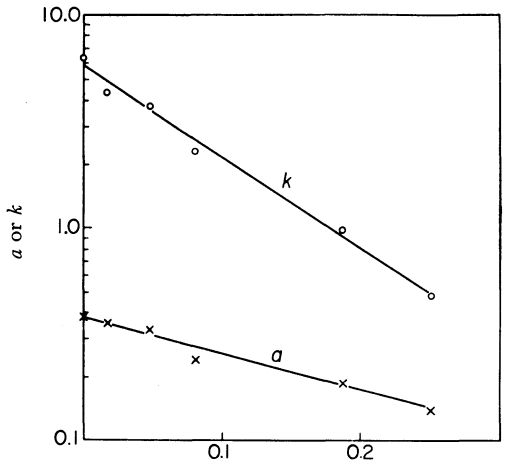

Fig. 2. Plotts of the logarithms of k and a *vs.* x.

poisoned catalyst, and x, the amount of carbon disulfide adsorbed. The β and α can be termed the poisoning coefficients for k and a respectively. From Fig. 2, the values of α and β are found to be 1.04 and 2.47 respectively. By substituting the above relations into Eq. (1), the rate equation available for the unpoisoned and poisoned catalyst can be obtained as:

$$v(x) = \frac{k_0 \cdot \exp(-\beta \cdot x) \cdot a_0 \cdot \exp(-\alpha \cdot x) \cdot C_R}{(1 + a_0 \cdot \exp(-\alpha \cdot x) \cdot C_R)^2}, \qquad (2)$$

where $v(x)$ is the reaction rate over the catalyst poisoned with x mmol of carbon disulfide per gram of Ni.

Discussion

The experimental finding that the peak of the rate *vs.* concentration plot shifts upon the poisoning seems to indicate that the adsorption coefficients of acetone or/and hydrogen are influenced in the presence of carbon disulfide.

Recently, Kishi, Ikeda and Hirota[3] have observed that the ultraviolet and visible absorption bands of acetylacetone adsorbed on evaporated iron shift in the presence of oxygen or water vapor. Eischens and Pliskin[4] reported many observations that the addition of a gas to a chemisorbed CO system shifts the frequency of the CO stretching bands. Blyholder[5] has lately proposed a qualitative interpretation of the phenomenon, applying the molecular orbital theory to a carbon-oxygen-metal system. He has shown that the shift of absorption could be explained as a result of the adsorption of a gas, by which an electron is added to or removed from the metal, with a consequent addition or removal of an electron from the chemisorbed CO. These results indicate an interaction among the adsorbed molecules.

It is necessary to mention that the hydrogenation of benzaldehyde over a Raney-nickel catalyst is markedly promoted in the presence of trimethylamine.[6] This indicates that the reaction rate of heterogeneous catalysis does not always decrease in the presence of a "poison." This so-called promoting effect must also be taken into account in discussing a poisoning mechanism.

As has been previously reported by the present authors[7] in connection with hydrogenation of isobutyl methyl ketone, the fractional surface coverage of adsorbed hydrogen during the reaction is increased by the poisoning. This phenomenon was interpreted as being due to the change in the adsorption strength of the ketone or/and hydrogen, a change caused by the potassium iodide adsorbed.

It seems that these and other phenomena can be reasonably explained and correlated by recognizing that adsorbed molecules interact directly or through the catalyst.[8] The poisoning can then be considered as a phenomenon caused by the interaction of "third material" with reacting molecules,*2 with a consequent change in the adsorption strength and hence, in the reactivity of the latter.

In view of this, a reaction rate over a catalyst progressively poisoned can generally be given by Eq. (2), which also gives a poisoning curve when $v(x)$ is plotted *vs.* x by fixing C_R. If $a_0 \cdot C_R \ll 1$, Eq. (2) becomes; $v(x) = k_0 \cdot a_0 \cdot C_R \cdot \exp(-(\beta+\alpha)x)$, and if $a_0 \cdot C_R \gg 1$, $v(x) = (k_0/a_0 \cdot C_R) \cdot \exp(-(\beta-\alpha)x)$. These are generally written as: $v(x) = (\text{constant}) \times \exp(-\gamma \cdot x)$, which can be expanded as:

$$v(x) = (\text{Constant}) \times (1 - \gamma \cdot x) \qquad (3)$$

in a small range of x, indicating that the rate first falls in a linear manner with poisoning if γ is positive. The poisoning curve of a flexed linear type[9] can now be reasonably interpreted by considering that Eq. (3) does not hold as x increases. Equation

8) M. Boudart, *J. Am. Chem. Soc.*, **74**, 3556 (1952).

*2 The fact that the kinetics of acetone hydrogenation are explained by the Langmuir-Hinshelwood mechanism can be interpreted as suggesting that the interactions of acetone-acetone, acetone-hydrogen, and hydrogen-hydrogen are not important enough to be taken into account in discussing the kinetics.

9) J. N. Pattison and E. F. Degering, *ibid.*, **73**, 611 (1951); E. F. G. Herington and E. K. Rideal, *Trans. Faraday Soc.*, **40**, 505 (1944).

(3) is substantially the same as that proposed by Maxted.[10]

The values of α and β are naturally different for different reactions, since they depend on the values of an interaction between a poisoning material and a reacting material. A given poison can, therefore, give different poisoning curves, especially in different types of reactions. In Fig. 3, three types of poisoning curves, predictable when α and β are positive, are shown. It can be seen that the reaction rate does not change or even increases, although the rate constant of a given reaction decreases, in the presence of a poison. It has been believed, according to the so-called "active patch" theory, that two different types of active sites can be experimentally distinguished when a given poison inhibits one reaction but does not influence another one.[11] Figure 3, however, suggests another possibility in interpreting the phenomenon. Since there is a possibility that α and β are negative, three more cases have to be taken into account in order to consider all of the poisoning curves predictable from Eq. (2), that is: (1) $\alpha<0$, $\beta<0$, (2) $\alpha<0$, $\beta>0$ and (3) $\alpha>0$, $\beta<0$. Nine other types of poisoning curves can, then, be deduced.

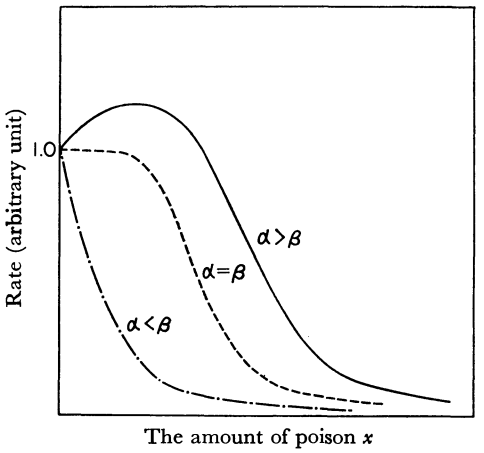

Fig. 3. Poisoning curves predictable from Eq. (2) in the case where α and β are positive

It can now be concluded that various types of observed poisoning curves can be interpreted by considering the poisoning as a phenomenon due to an interaction between a "third material" and the reacting molecules.

SHORT COMMUNICATIONS

π Complexes of Vinyl Alcohol and Propenyl Alcohol with Platinum(II)

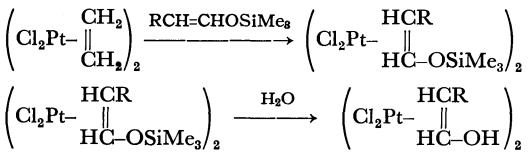
Yasuo WAKATSUKI, Shun'ichi NOZAKURA and Shunsuke MURAHASHI

Department of Polymer Science, Osaka University, Toyonaka, Osaka

(Received November 4, 1968)

The first description of the vinyl alcohol complex with a transition metal was made by Ariyaratne and Green; it was prepared by the protonation of an oxoalkyl-iron complex.[1]

In the present communication, we wish to report the preparation of vinyl alcohol and propenyl alcohol complexes with Pt(II) in a completely different manner. As is shown below, 1,3-bis-(alkenyl trimethylsilyl ether)-2,4-dichloro-μ-dichlorodiplatinum was synthesized by the replacement of ethylene by alkenyl trimethylsilyl ether, and then the Si–O bond was hydrolyzed to give alkenyl alcohol complexes.



R: H or CH_3

To a suspension of 100 mg of Zeise's dimer, $(Cl_2PtC_2H_4)_2$, in 5 m*l* of toluene, there was added about 0.1 m*l* of vinyl trimethylsilyl ether. The mixture turned orange and became homogeneous shortly after the addition. The toluene and the excess of vinyl trimethylsilyl ether were then evaporated at room temperature to give a yellow powder of $(Cl_2PtCH_2{=}CH{-}OSiMe_3)_2$, which decomposed under nitrogen at 120—122°C. Found: C, 15.77; H, 2.86; Cl, 19.13; Pt, 51.27%. Calcd for $C_5H_{12}Cl_2OSiPt$: C, 15.71; H, 3.16; Cl, 18.55; Pt, 51.04%. This powder was dissolved in 10 m*l* of benzene containing about 200 ppm of water. When the solution was allowed to stand overnight at room temperature, fine yellow crystals of the vinyl alcohol complex precipitated in a 68% yield; these crystals decomposed at 127—131°C. Found: C, 7.91; H, 1.33; Cl, 22.77; Pt, 62.77%. Calcd for $C_2H_4Cl_2OPt$: C, 7.75; H, 1.30; Cl, 22.87; Pt, 62.92%. IR(KBr disk): ν_{O-H} 3200(vs), $\nu_{=C-H}$ 3020(w) and $\nu_{C=C}$ 1548 cm^{-1}(vs).

Since the O–Si bond of the vinyl trimethylsilyl ether complex is extremely sensitive to moisture, the vinyl alcohol complex was also formed when the vinyl trimethylsilyl ether complex was exposed to air (70% humidity) at room temperature for about 10 min.

On the decomposition of the vinyl alcohol complex with pyridine, acetaldehyde was liberated; it was detected by gas chromatography.

A similar reaction of propenyl trimethylsilyl ether gave an orange-yellow powder of $(Cl_2Pt\ CH_3{-}CH{=}CHOSiMe_3)_2$ which decomposed at 118—121°C. Found: C, 18.02; H, 3.42; Cl, 18.68%. Calcd for $C_6H_{14}Cl_2OSiPt$: C, 18.19; H, 3.56; Cl, 17.90%. The hydrolysis was carried out similarly in moist benzene to give brown-yellow crystals of the propenyl alcohol complex after 10 days at room temperature. The yield was 61%. It decomposed at 118—121°C. Found: C, 11.28; H, 1.84; Cl, 22.37; Pt, 60.22%. Calcd for $C_3H_6Cl_2OPt$: C, 11.12; H, 1.87; Cl, 21.88; Pt, 60.20%. IR (Nujol mull): ν_{O-H} 3300(vs), $\nu_{=C-H}$ 3020(w) and $\nu_{C=C}$ 1545 cm^{-1}(s).

These specific absorptions and the absence of carbonyl absorption in the IR spectra are consistent with the proposed structure of the complexes. The NMR spectra were not studied because of the poor solubility of the complexes. The study of the *cis-trans* isomerism of the complexed olefin is now in progress.

The Syntheses of Bisdithiobenzoylacetonates and Its Halogeno Derivatives from Dithiolium Salt*1

Yoshiaki TAKAHASHI, Mitsuhisa NAKATANI and Akira OUCHI

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo

(Received November 6, 1968)

The dithio-derivatives of β-diketonates have very interesting properties and have previously been reported,[1-5] but all of them were then synthesized from metal β-diketonate. As the dithio-β-diketones are so easily dimerized that their monomers have not yet been isolated, these complexes are synthesized by trapping the newly-forming dithio-β-diketone by metal ions before the dimerization occurs.

The present authors previously obtained the dithiolium salts by the method of Schmidt and Schulz from β-diketones,[6] and using the 3-methyl-5-phenyl-1,2-dithiolium perchlorate, the syntheses of some dithio-β-diketonates and halogeno-dithio-β-diketonates have been successful. The bis(dithiobenzoylacetonato)cobalt(II) was synthesized from a mixture of anhydrous cobalt(II) chloride and dithiolium salt by a reduction reaction using sodium borohydride under ice cooling; the product was extracted with chloroform. The nickel(II) complex was obtained by a similar method. The trichlorodithiobenzoylacetonatozinc(II) was synthesized by the reaction of anhydrous zinc(II) chloride and the dithiolium salt in a concentrated hydrochloric acid medium under ice cooling. Other chloro- or bromo-derivatives of the ML_2X_4 and MLX_3 types were obtained by almost the same method. The chemical formulas of the products and their magnetic moments, measured by the Gouy balance method at room temperature, are shown in Table 1. The infrared spectroscopic results of typical compounds are shown in Table 2.

NiL_2 (where HL = dithiobenzoylacetone) obtained by this method was the same as that reported in a previous paper[4] and was isostructural to CoL_2. The CoL_2Cl_4 thus obtained was identical with that reported previously,[4] while the other three ML_2X_4-type complexes seem to be isostructural. The general properties of the MLX_3-type complexes resemble ML_2X_4-type ones.

The further application of this method is now going to be studied in our laboratory; the results will be published elsewhere.

New Five-coordinate Iridium Complexes

Hiroshi YAMAZAKI, Masahiko TAKESADA and Nobue HAGIHARA

The Institute of Physical and Chemical Research, Yamato-machi, Saitama
The Institute of Scientific and Industrial Research, Osaka University, Yamada-Kami, Suita, Osaka

(Received November 6, 1968)

Recently we have reported the preparation of methyl- and phenyl-(triphenylphosphine)-(1,5-cyclooctadiene)rhodium, and hydrido-tetrakis(triphenylphosphine)rhodium from the reactions of bis(1,5-cyclooctadienerhodium chloride) (I) with methyl, phenyl and isopropyl Grignard reagents in the presence of triphenylphosphine, respectively.[1] In the present communication, we wish to report the preparation of new five-coordinate methyl- and hydrido-iridium complexes resulting from an extended work to the iridium analogue of I.

Bis(1,5-cyclooctadieneiridium chloride) (II) and triphenylphosphine in benzene-ether mixture were treated with methylmagnesium iodide at an ice temperature. After hydrolysis, the organic layer was concentrated and subjected to chromatography on alumina with benzene as eluant. Concentration of the eluate, followed by the addition of hexane to the residue gave pale yellow crystals of methyl-bis(triphenylphosphine)-(1,5-cyclooctadiene)iridium (III) (Yield 17%, mp*1 146—147°C (with decomp). Found: C, 65.12; H, 5.45%. Calcd for $C_{45}H_{45}P_2Ir$: C, 64.34; H, 5.40%. NMR (in C_6D_6): 2.3—3.2τ (C_6H_5), 6.1 and 7.0τ (=CH), 8.1τ (CH_2), 9.44τ (CH_3).). Methyl proton resonance appeared as a singelt and suggested the existence of the phosphine interchange process which could be schematically pictured as:

$$C_8H_{12}Ir(CH_3)P^1 + P^2 \rightleftarrows C_8H_{12}Ir(CH_3)P^1P^2 \rightleftarrows C_8H_{12}Ir(CH_3)P^2 + P^1$$

Phosphine interchange would be rapid enough at room temperature to cause disappearance of P–H coupling. Evidence was obtained by the NMR spectrum at −60°C (in CH_2Cl_2) in which methyl protons showed triplet peaks of 1 : 2 : 1 ratio ($J_{PH}=10$ cps).

Vrieze and Volger[2] pointed out the presence of a five-coordinate short-lived intermediate (diolefin)-$MCl(L)_2$ (M = Rh, Ir and L = Group-V donor lignad) from the NMR studies of ligand exchange reaction of (diolefin)MCl(L), and they isolated $C_8H_{12}IrCl(PPh_3)_2$ when ethanol was used as solvent. It is interesting that the replacement of chlorine by methyl group made the five-coordinate iridium complex easy to isolate.

The reaction of II with isopropylmagnesium bromide in the presence of triphenylphosphine was carried out, in order to compare it with the case of rhodium in which cyclooctadiene was replaced by triphenylphosphine to give hydrido-tetrakis-(triphenylphosphine)rhodium. According to a similar procedure, white needles of hydrido-bis-(triphenylphosphine)-(1,5-cyclooctadiene)iridium (IV) were obtained in almost quantitative yield without loss of a cyclooctadiene ligand (mp*1 162—165°C (with decomp). Found: C, 64.22; H, 5.55; P, 7.33%. Calcd for $C_{44}H_{43}P_2Ir$: C, 63.98; H, 5.25; P, 7.50%). IV was relatively more stable than III. The NMR spectrum (in $CDCl_3$) showed peaks at 2.5—3.0τ (C_6H_5), 6.2 and 6.5τ (=CH, Former peak is broader than the latter), and 8.4τ (CH_2). Additional triplet of 1 : 2 : 1 ratio ($J_{PH}=22$ cps) was found at 23.7τ which was assigned to hydrogen directly bonded to the iridium. It is obvious that the phophine interchange proceed more slowly in this complex than in III.

More detailed studies of this type of complexes are now in progress.

Radiative and Radiationless Processes in Phthalazine*1

Hiroaki BABA, Iwao YAMAZAKI and Takeshi TAKEMURA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received November 11, 1968)

Although nitrogen heterocyclic compounds generally exhibit strong phosphorescence, *ortho*-diazines such as pyridazine, phthalazine, and 9,10-diazaphenanthrene are known to show either no phosphorescence or very weak phosphorescence. The problem of such puzzling emission properties of the *ortho*-diazines has attracted much attention,[1-4] but remains unsettled. With phthalazine, no emission has been reported, except for a phosphorescence emission in an acidic solution,[5] where the protonation may give rise to an essential change in its emission property. We have recently examined both the radiative and radiationless processes in phthalazine at 77°K. It was found that phthalazine gave no emission in hydrocarbon solvents, but in polar solvents like EPA it did exhibit phosphorescence. In all these cases we were unable to obtain fluorescence from phthalazine.

The phosphorescence spectrum in EPA is shown in Fig. 1, together with the excitation spectrum (corrected). The latter spectrum is seen to be in agreement with the absorption spectrum within experimental errors, indicating that the phosphorescence originates from phthalazine itself. A polarization measurement was made by the photoselection method, with the result that the transition moment of the phosphorescence is parallel to the moment of the 0–0 band of the $^1A \rightarrow {}^1L_b$ absorption; namely, the phosphorescence is polarized along the long axis of the molecule. The lifetime and quantum yield of the phosphorescence were determined to be 0.7 sec and 0.04, respectively.

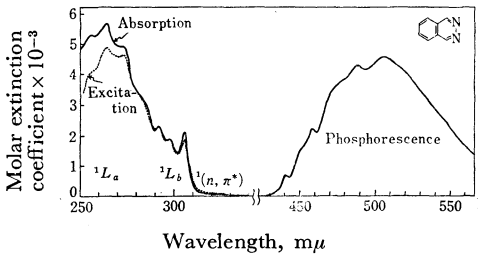

Fig. 1. Phosphorescence, excitation, and absorption spectra of phthalazine in EPA at 77°K.

The radiationless processes in phthalazine were investigated through the phenomenon of the intermolecular T–T energy transfer, with phthalazine as the donor and naphthalene as the acceptor. The solubility of phthalazine in the pure hydrocarbon was so low that a mixture of ether and isopentane (1 : 1) was used as the solvent. In this mixture phthalazine was found to give a phosphorescence emission with a quantum yield of 0.008. The donor(1×10^{-3} M)-acceptor(3.3×10^{-2} M) system was excited at 330 mμ in the region of the $n \rightarrow \pi^*$ absorption of the donor, where the absorption of the acceptor was negligible. An effective energy transfer occurred which led to the sensitized phosphorescence of naphthalene. The overall quantum yield of the acceptor phosphorescence (relative to the donor excitation) amounted to about 0.07. This figure implies that the donor molecule has a considerably high intersystem crossing yield (>0.7), since for naphthalene the ratio of the radiationless triplet-decay rate constant to the radiative constant is known to be large (>10).[1]

These observations lead to the following suggestions. (1) The lack of fluorescence in phthalazine is caused by an efficient intersystem crossing process. (2) The vanishing or low phosphorescence quantum yield of phthalazine results from an anomalously high radiationless rate constant as compared with the radiative rate constant for the $T_1 \rightarrow S_0$ transition. Details of the experiments and further discussions will be presented in a paper to be published later.

The Isolation of the Two Isomers of Bis(L-aspartato)cobaltate(III)[1]

Kinya HOSAKA, Hiroaki NISHIKAWA and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa

(Received November 12, 1968)

There have been only a few investigations of cobalt(III) complexes containing the aspartate anion as a tridentate ligand.[2,3] We have now isolated two isomers of bis(L-aspartato)cobaltate-(III) from a reaction mixture of tricarbonato-cobaltate(III) with L-aspartate.

Monopotassium L-aspartate (31.0 g, 0.2 mol) was added to a solution of tricarbonatocobaltate(III) ($CoCl_2 \cdot 6H_2O$ 23.8 g scale, 0.1 mol), and the mixture was stirred at 60°C for 5 hr.[4] This solution was then acidified with acetic acid and heated on a water bath for 2 hr in order to complete the evolution of carbon dioxide. The resulting solution was treated with methanol to precipitate a red-violet material. This was dissolved in water and used for ion-exchange chromatography. Each portion of the aqueous solution was added to a column (Dowex 1×8, 100—200 mesh, Cl-form, $\phi = 4$ cm, $h = 30$ cm). During elution with a 0.1 M $CaCl_2$ solution, a band at the top of the column separated into two: the first eluted band (red-violet) and the second one (blue-violet). These bands were collected in fractions. Evaporation and the addition of ethanol gave the calcium salts of the desired complex. These were characterized by means of a study of their UV and CD spectra (Fig. 1). The earlier-eluted isomer is designated here as E-1, and the later-eluted one, E-2. The total yields were 5 g (for E-1) and 4 g (for E-2).

Found: C, 23.99; H, 4.76; N, 7.15% for E-1. C, 24.03; H, 4.70; N, 7.17% for E-2. Calcd for $Ca_{0.5}CoC_8H_{17}N_2O_{11.5} = Ca_{1/2}[Co(L\text{-}asp)_2] \cdot 3.5H_2O$: C, 23.77; H, 4.24; N, 6.93%.

The same isomers were also obtained by means of direct synthesis from the components and lead dioxide.

For the bis(L-aspartato)cobaltate(III) ion, three isomers are possible: (a) *trans*(N)·*cis*(O)·*cis*(O_β), (b) *cis*(N)·*trans*(O)·*cis*(O_β), and (c) bis(N)·*cis*(O)·*trans*(O_β), (O_β represents the two β-oxygen atoms). It is considered, from the order of chromatographic elution, that E-2 is either one of the two *cis*(N) isomers, while E-1 is the *trans*(N) isomer or another one of the *cis*(N) isomers. The geometry of our complex ion resembles that of the bis(L-2,3-diamino-propionato)cobalt(III) ion[5] in that they both contain two optically-active tridentate ligands. The CD curve of E-1 is similar, in appearance and magnitude, to that of the L-3*1 isomer of the diaminopropionato complex, and the CD curve of E-2 is similar to that of L-1.*1 The geometry of L-1 has been determined as *trans*(O)·*cis*(N_α)·*cis*(N_β); hence, it seems that E-2 has the corresponding geometry *cis*(N_α)·*trans*(O)·*cis*(O_β). On the other hand, it is impossible to relate the geometry of E-1 to that of L-3, for the latter is not known definitely.

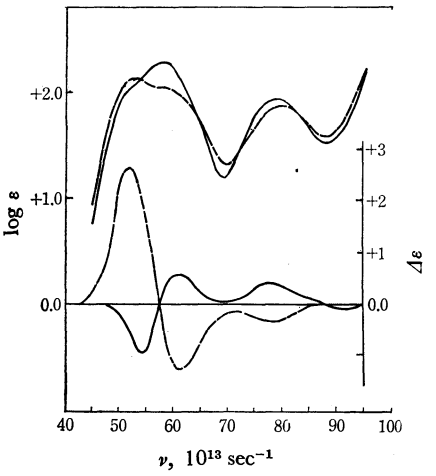

Fig. 1. UV and CD spectra of two isomers of $Ca_{1/2}[Co(L\text{-}asp)_2] \cdot 3.5H_2O$.
—— the ealier-eluted isomer (E-1)
--- the later eluted isomer (E-2)

The E-2 isomer is perhaps the first example of a complex differing in the splitting of the first band from the usual *cis*(N)-$[Co(O)_4(N)_2]$-type complexes.[6] For the *cis*(O)-$[Co(O)_2(N)_4]$-type complexes, such a splitting of the first band appears in the $[Co(L\text{-}asp)(NH_3)_3]^+$ [2] and bis(L-2,3-diamino-propionato)cobalt(III) complexes.[5]

A Novel Method for the Preparation of *p*-Methoxybenzyloxycarbonyl Amino Acids

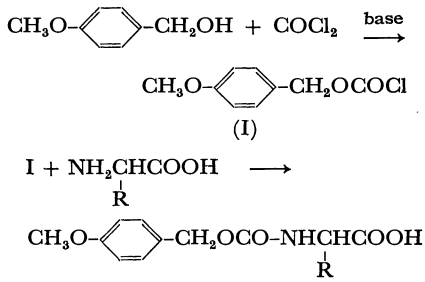
Shōsuke Sōfuku, Mitsuo Mizumura and Akira Hagitani

Department of Chemistry, Faculty of Science, Rikkyo (St. Paul's) University Toshima-ku, Tokyo

(Received November 20, 1968)

The *p*-methoxybenzyloxycarbonyl (*p*MZ-) group[1,2] has been widely used as a blocking substituent of the amino moiety of amino acids in peptide synthesis. In the present investigation, it was found that *p*MZ-amino acids were prepared directly from a number of amino acids and *p*-methoxybenzyl chloroformate[3,4] (I) under the conditions of the Schotten-Baumann reaction. The reagent (I) was prepared as follows: a solution of anisyl alcohol (12.4 m*l*, 0.1 mol) in dry ether (100 m*l*) was added to a solution of phosgene (21 m*l*, 0.3 mol) in dry ether (100 m*l*) over a period of 10 min. Then a solution of dimethylaniline (12.7 m*l*, 0.1 mol) in dry ether (100 m*l*) was added dropwise over a period of 1 hr, and the mixture was stirred for 2 hr at −5—−10°C. After filtration of the salt formed in the reaction, the filtrate was evaporated under reduced pressure to an oily residue at below 0°C. Twice more dry ether (100 m*l*) was added and evaporation was repeated to remove excess phosgene. This residue was immediately dissolved in tetrahydrofuran (70 m*l*) and the solution was ready for the next reaction.

The solution of the chloroformate was added little by little over a period of 10 min to a solution of



0.05 mol of the amino acid in 200 m*l* of *N* sodium hydroxide (L-glutamic acid: 1.5 N sodium hydroxide) containing tetrahydorfuran (40 m*l*) with vigorous stirring at 0—5°C. This stirring was continued for 2 hr; then the reaction mixture was washed with ether (100 m*l*) and acidified by the addition of solid citric acid. The product was extracted with ethyl acetate (500 m*l*). This layer was washed with water, dried over anhydrous sodium sulfate, and concentrated *in vacuo* to a residue, which was then crystallized from ethyl acetate-petroleum ether. If the product did not crystallize at this stage, the residue was neutralized with a calculated amount of dicyclohexylamine in ether, and the *p*MZ-amino acid was crystallized as the dicyclohexylammonium salt.

By the present method the following compounds were obtained:

*p*MZ-glycine (80.0%), mp 95—98°C*1 (lit.,[3] mp 95—98°C).

*p*MZ-L-alanine (65.4%), mp 78—81°C,*1 $[\alpha]_D^{22}$ −11.5 (*c* 2.0, acetic acid) [lit.,[2] mp 74—75°C, $[\alpha]_D^{22}$ −11.9 (*c* 3.11, acetic acid)]. (Found: C, 56.94; H, 5.83; N, 5.70%. Calcd for $C_{21}H_{15}NO_5$: C, 56.90; H, 5.98; N, 5.54%.)

*p*MZ-L-glutamic acid (46.1%), mp 109—112°C,*1 $[\alpha]_D^{22}$ −5.6 (*c* 2.0, acetic acid) [lit.,[2] mp 109—111°C, $[\alpha]_D^{22}$ −7.44 (*c* 2.02, acetic acid)]. (Found: C, 53.76; H, 5.22; N, 4.58%. Calcd for $C_{14}H_{17}NO_7$: C, 54.00; H, 5.50; N, 4.50%.)

*p*MZ-L-leucine dicyclohexylammonium salt (88.7%), mp 159—162°C,*1 $[\alpha]_D^{21}$ −6.0 (*c* 2.0, methanol) [lit.,[2] mp 162°C, $[\alpha]_D^{24}$ −6.67 (*c* 2.1, methanol)]. (Found: C, 68.04; H, 9.07; N, 6.01%. Calcd for $C_{27}H_{44}N_2O_5$: C, 68.03; H, 9.31; N, 5.88%.)

α-*N*-*p*MZ-δ-*N*-Cbz*2-L-ornithine dicyclohexylammonium salt (33.4%), mp 133—135°C,*1 $[\alpha]_D^{19}$ +6.3 (*c* 2.0, methanol). (Found: C, 66.91; H, 7.91; N, 6.94%. Calcd for $C_{34}H_{49}N_3O_7$: C, 66.75; H, 8.07; N, 6.87%.)

Concentration Polarization Phenomena in Ion-exchange Membrane Electrodialysis. I. Studies of the Diffusion Boundary Layer by Means of Six Different Measurements*1

Toshikatsu SATA, Reiichi YAMANE and Yukio MIZUTANI

Tokuyama Soda Co., Ltd., 1-1 Mikage-cho, Tokuyama, Yamaguchi

(Received December 25, 1967)

The behavior of the diffusion boundary layer in the electrodialysis using ion-exchange membranes, mainly a cation-exchange membrane, was studied by means of six different measurements: 1) the determination of the current-voltage curve or the current-(voltage/current) curve; 2) the relation of the pH change of the solution to the current density; 3) the relation of the charge retention, *i. e.*, the sum of the diffusion potential and the membrane potential generated from the concentration gradient across the membrane immediately after the current is shut off, to the current density; 4) the time required to reach a constant current value, namely, to obtain a stationary diffusion boundary layer, when a constant voltage is supplied to the system, *versus* the current density; 5) the change in the transport number of the counterion in the membrane with the current density, and 6) the relation of the permselectivity between sodium ions and potassium ions to the current density. The interrelation among these results was also examined. The quantity of hydrogen ions or hydroxide ions passing through the membrane increases abruptly at a current density lower than that at which the concentration at the membrane-solution interface in the desalting side attains its minimum. It was newly observed that the results of all the measurements, except for the pH change of the solution, show abnormal phenomena at a current density about twice the limiting current density.

In the electrodialysis using ion-exchange membranes, one of the most important phenomena is the concentration polarization at the membrane-solution interfaces. The concentration gradient is observed on both sides of the membrane-solution interfaces; ions are accumulated or depleted at the interfaces as a result of the difference in the transport numbers in the solution and in the membrane. This phenomenon, called the concentration polarization, is especially important at the membrane-solution interface on the desalting side.

Peers,[1] Rosenberg *et al.*,[2] Frilette,[3] and other investigators studied this phenomenon by observing the current-voltage curve of the membrane-solution system. Uchino *et al.*[4] and Gregor *et al.*[5] observed limiting current density through the relation of the current efficiency to the current density. Cooke[7-9] and Onoue[10] evaluated the interfacial concentration at the membrane-solution interface on the desalting side by determining the charge retention. Though the concentration polarization phenomenon has been studied in the various ways mentioned above, however, there still remain some uncertainties, and the interrelation among the results obtained by means of various measurements is not clear.

In this investigation this phenomenon was observed by means of the following six measurements, with an emphasis on the observation of the current-voltage curve of the membrane-solution system, and the results were compared with each other. The six measurements are: 1) the determina- the pH change of the solution in the electrodialysis system, while Kressman and Tye[6] observed the

Measurements. 1) *Current-voltage Curve.* The current-voltage curve was observed by using the apparatus shown in Fig. 1, which was also used in the other five measurements. In Fig. 1, 1 and 4 are silver chloride plate electrodes, and 2 and 3 are silver chloride wire probe electrodes which are put close to the membrane (about 2 mm apart). The current was increased automatically by means of a slow moving motor connected with a regulated direct current supply, Metronix Corp. Model 535. As the current-voltage curve varies with an increase in the speed of the current when it is too large, the increase in the speed was adjusted so as not to affect the current-voltage curve. The values

of the current and the voltage were recorded on an X-Y recorder, Watanabe Instruments Corp. Type WX-406.

2) *pH Change in the Solution.* A cell has a cation- or an anion-exchange membrane (4.0 cm² in area) to be examined and shielding cation- and anion-exchange membranes (36 cm² in area). An aqueous 0.500 N sodium chloride solution (3.0*l* in volume) was circulated in the desalting compartment (10 mm thick) at a laminar flow of 4.2 cm sec^{-1}, and an aqueous 2.500 N sodium chloride solution (50 m*l* in volume) was circulated in the concentrating compartment (3 mm thick) at a laminar flow of 1.3 cm sec^{-1}. The pH change in the solution in the concentrating compartment was observed continuously for an hour by using a glass electrode pH-meter, Denki Kagaku Keiki Co. Model MG-1, connected to an X-t recorder, Toa Electronics. EPR-2T, while the current was broken by the dripping of the solution. The difference in the pH of the solution between the starting time and after an hour was evaluated at various current densities at 30.0°C.

3) *Charge Retention.* In preparing Fig. 1 the X-t recorder was used instead of the X-Y recorder, and two turn-over switches were added between the 1 and 4 electrodes and the direct current supply, and between the 2 and 3 electrodes and the X-axis of the X-t recorder. After the membrane-solution system had been electrodialized at a constant current density until a stationary diffusion boundary layer had been obtained, the current was shut off and the charge retention was picked up with the 2 and 3 electrodes. The scanning speed of a pen on the recorder is more than 300 mm/sec, faster than that of turning switches. The decrement curve of the charge retention at various current densities was recorded on the X-t recorder. These measurements were carried out with a natural convection of an aqueous 0.104 N sodium chloride solution by using a membrane 2.0 cm² in area and at 25.0°C.

4) *Transport Number.* The cell was separated into two compartments by a membrane with an area of 2.0 cm². After the electrodialysis had been carried out at a constant current density for an hour using an aqueous 0.104 N sodium chloride solution, the transport number was calculated from the change in the concentration of chloride ions in each compartment and the amount of the electricity was measured with a copper coulometer. These measurements were carried

out with a natural convection and at various current densities at 25.0°C.

5) *Time Required to Obtain a Stationary Diffusion Boundary Layer.* When a constant voltage was supplied to the cell, the current passing through the membrane, as recorded on the X-t recorder, gradually decreased because of the growth of the diffusion boundary layer, the stationary current was then obtained. The time required to reach the constant current value was measured at various constant voltages. The measurements were made with a natural convection of an aqueous 0.104 N sodium chloride solution by using a membrane with an area of 2.0 cm^2 and at 25.0°C.

6) *Permselectivity.* The cell was separated into two compartments by a membrane with an area of 4.0 cm^2. After the system had been electrodialized at a constant current density for an hour using a mixed solution of 0.053 N sodium chloride and 0.053 N potassium chloride, the permselectivity of potassium ions to sodium ions was calculated from the change in the concentration in each compartment. The chloride ions were analysed by the Mohr method, while the potassium ions were analyzed by the gravimetric method using tetraphenylborate. The measurements were made with a natural convection and at various current densities at 25.0°C. The permselectivity is defined as $(t_K^M/t_{Na}^M)/(C_K/C_{Na})$. t_K^M and t_{Na}^M are respectively the transport numbers of the potassium ions and the sodium ions in the membrane, and C_K and C_{Na} are the concentrations of potassium ions and sodium ions respectively in the bulk solution.

Results and Discussion

Typical examples of the current-voltage curve and of the current-(voltage/current) curve obtained with a cation-exchange membrane, NEOSEPTA CL-2.5T, in an aqueous sodium chloride solution are shown in Fig. 2. A similar curve was obtained

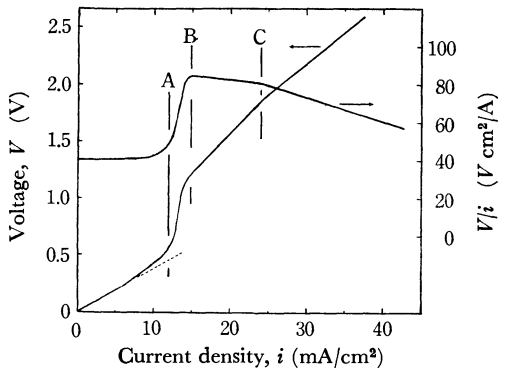

Fig. 2. An example of current-voltage curve and current-V/i curve.
Membrane: CL-2.5T (2.0 cm^2 in area)
Solution: 0.104 N NaCl aqueous solution in natural convection at 25.0°C

with an anion-exchange membrane, NEOSEPTA AVS-4T, in an aqueous sodium chloride solution. In this curve the voltage and the (voltage/current) of the system are anomalous at three different current densities, *i. e.*, A-, B-, and C-points. The current density at the A-point has been defined as the limiting current density.[11] The (voltage/current) ratio shows its maximum value at the B-point, a gradual decrease between the B- and C-points, and an abnormal decrease at the C-point.

The relationship between the pH change of the solution and the current density is shown in Fig. 3, in which the A- and B-points as determined

the sum of the diffusion potential and the membrane potential. For example, when the electrodialysis is carried out by using the cation-exchange membrane in an aqueous sodium chloride solution, the charge retention is shown by the following equation[7,10]:

$$E = \frac{RT}{F} 2(\bar{t}_+ - t_+) \ln \frac{(C_0+\Delta C)\gamma_1}{(C_0-\Delta C)\gamma_2} \qquad (1)$$

$\bar{t}_+$ and t_+ are transport numbers of the counterion in the cation-exchange membrane and in the solution, C_0 is the concentration in the bulk solution, ΔC is the difference in the concentration between the membrane-solution interfaces and the bulk solution, and γ_1 and γ_2 are activity coefficients of the counterion at the membrane-solution interfaces on the concentrating side and on the desalting side respectively. The charge retention increases abruptly at current densities lower than the A-point, and increases slowly between the A- and C-points. No change was observed at the B-point, and a constant value was obtained at current densities higher than the C-point. The same results were obtained with the anion-exchange membrane. The concentration at the membrane-solution interface on the desalting side could be calculated from Eq. (1) as long as the quantity of hydrogen ions is negligible in comparison with the quantity of sodium ions in the diffusion boundary layer and in the bulk solution. The calculated values are shown in Fig. 4.

The relation of the transport number to the current density is shown in Fig. 5. The transport

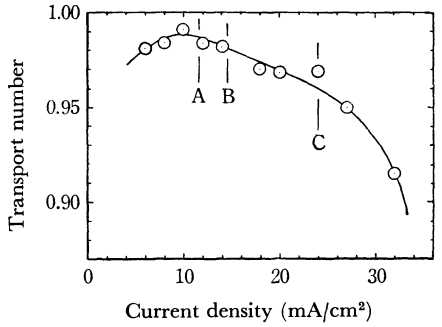

Fig. 5. Relation of transport number to current density.
Membrane: CL-2.5T
Solution: 0.104 N NaCl aqueous solution in natural convection

number shows its maximum value near the A-point; it gradually decreases between the B- and C-points and suddenly above the C-point.

The relation between the time required to obtain a stationary diffusion boundary layer and the current density is shown in Fig. 6. The change in the current with time is shown in Fig. 7 as an

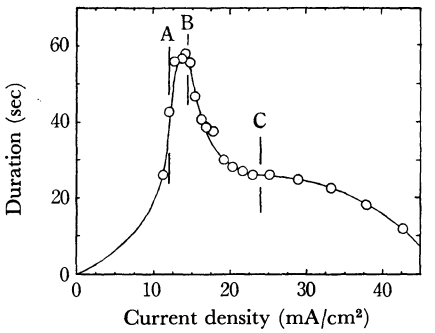

Fig. 6. Relation of duration required to obtain stationary diffusion boundary layer to current density.
Membrane: CL-2.5T
Solution: 0.104N NaCl aqueous solution in natural convection

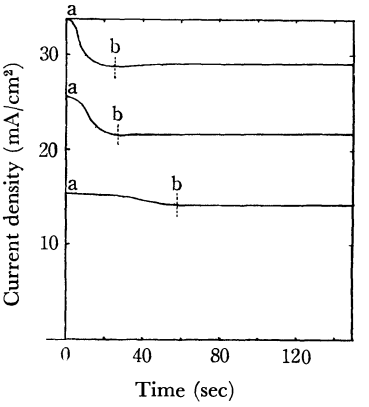

Fig. 7. Decrement curves of current when constant voltage is given to cation exchange membrane-solution system.
Time between a and b is the duration required to obtain the stationary diffusion boundary layer.

example. The time is defined as the time interval between a and b in Fig. 7. No change was observed at the A-point, the maximum was obtained near the B-point, and the duration decreased abruptly at current densities higher than the C-point. The stationary diffusion boundary layer was achieved on balancing the flux of ions passing through the membrane with that of ions transporting to the membrane-solution interface on the desalting side. When the current density increases, the concentration at the membrane-solution interface on the desalting side decreases and the time increases. When the interfacial concentration on the desalting side attained its minimum, the time reached its maximum. Thus, the maximum duration is obtained in the vicinity of the B-point. The duration decreases at current densities higher than the B-point. This behavior is analogous to the relation of the transition time to the current density in the chronopotentiometry. The transition time is

shown as follows:[12]

$$\tau^{1/2} = \frac{nF\pi^{1/2}D^{1/2}C}{2i} \quad (2)$$

C is the concentration of the solution; i is the current density; τ is the transition time; D is the diffusion coefficient, and n and F are the valency and the Faraday constant respectively. The $\tau \propto 1/i^2$ relation is inferred at the current densities between the B- and C-points in Fig. 6. However, the decrease in the duration at current densities higher than the C-point is anomalous.

Figure 8 shows the permselectivity of potassium

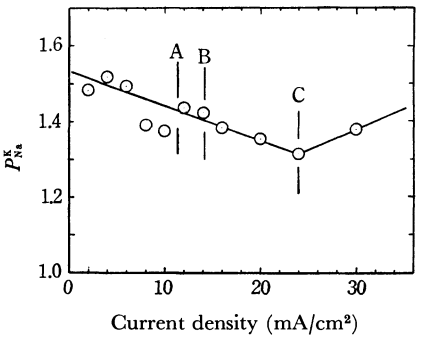

Fig. 8. Reltation of permselectivity between sodium ion and potassium to current density.

ions to sodium ions at several different current densities. As the permselectivity of potassium ions to sodium ions is larger than unity, the concentration of sodium ions becomes larger than that of potassium ions at the membrane-solution interface on the desalting side when the current increases, and so the permselectivity, p^{K}_{Na}, decreases. In Fig. 8 no change is observed at the A- and B-points, but some change is observed at current densities higher than the C-point.

The relation among the six experimental results mentioned above will now be discussed with emphasis on the interpretation of the A-, B-, and C-points. Near the A-point, the voltage of the membrane-solution system suddenly begins to increase, the increase in the charge retention becomes slower, the period required to obtain a stationary diffusion boundary layer increases continuously, and the transport number of the counterion in the membrane attains its maximum. The results on the current-voltage curve, the charge retention, and the duration show a further decrease in the concentration at the membrane-solution interface on the desalting side near the A-point. It was reported in a previous paper[6] that the transport number of sodium ions in the cation-exchange membrane decreases at higher current densities after showing its maximum value as a result of the increase in the transport number of hydrogen ions in the membrane. However, the pH change in the solution was detected between the A- and B-points. The pH change in the solution might arise from the following three causes. First, the pH change in the solution may be on account of the increase in the rate of the dissociation of water under a strong electric field; however, this has scarcely any effect on the pH change in the solution because the electric field of 10^4 V/cm increases the dissociation constant by only 1 percent.[13,14] Secondly, the ion-exchange membranes used in this experiment are reinforced with polyvinyl chloride and so would have conjugated double bonds through the decomposition of polyvinyl chloride during the introduction of sulfonic acid groups and other treatments.[15] If there were an electronic conduction based on conjugated double bonds, the ion-exchange membranes would function as electrodes. Therefore, the electrolysis of water could occur at the membrane-solution interfaces and cause the pH change in the solution. However, as the pH change in the solution was nearly constant in the ion-exchange membranes reinforced with other polymers, this effect would scarcely have any relation with the pH change in the solution. Thirdly, when the current density increases, the concentration of sodium or chloride ions on the desalting membrane-solution interface decreases and becomes nearly equal to the concentration of hydrogen or hydroxide ions (10^{-7} mol/l). Consequently, the quantity of hydrogen or hydroxide ions which pass through the membrane increases in comparison with that of sodium or chloride ions. Hydrogen or hydroxide ions pass through the membrane at current densities lower than the A-point, but the pH change in the solution could not be observed because it is too small to be detected by a usual pH-meter. It may be considered that the pH change in the solution in the electrodialysis is caused by the third reason. We attempted to observe the pH change in the solution visibly by adding a pH-indicator to the solution. However, the current-voltage curve observed in the solution with the pH-indicator differs from those in the solution without the pH-indicator and are not reproducible. The adsorption of the pH-indicator on the membrane would change the characteristics of the membrane.

The concentration of the desalting membrane-solution interface attains its minimum at the B-

point. This is unquestionably established by the observation of the current-(voltage/current) curve and the duration time. The pH change in the solution, the charge retention, and the permselectivity, P_{Na}^{K}, do not show any change at the B-point. Figure 2 shows that the current-(voltage/current) curve decreases at current densities higher than the B-point. In order to make clear the reason for this decrease, the current-voltage curve and the current-(voltage/current) curve were observed using the cation-exchange membrane, NEOSEPTA CL-2.5T, in an aqueous hydrochloric acid solution. The results are shown in Fig. 9.

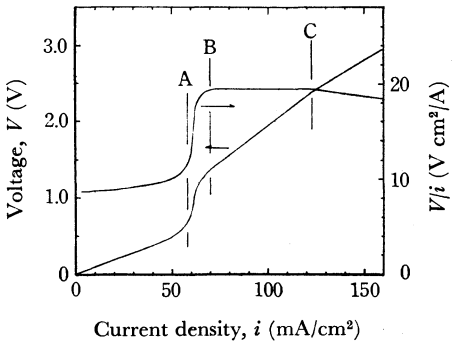

Fig. 9. Current-voltage and current-V/i curve measured in hydrochloric acid solution.
Membrane: CL-2.5T
Solution: 0.100 N HCl aqueous solution in natural convection at 25.0°C

The current-voltage curve does not decrease, but is parallel with the current-axis, between the B- and C-points, while it decreases above the C-point. Accordingly, the decrease in the current-(voltage/current) curve in a sodium chloride solution between the B- and C-points is due to the increase in the transport number of hydrogen ions in the membrane and their high conductivity. At and above the C-point, the current-(voltage/current) curve decreases still more, the duration time decreases abnormally, the decrease in the transport number is great, the permselectivity, P_{Na}^{K}, increases, and the charge retention attains a constant value. This behavior at and above the C-point can not yet be explained.

This paper has mainly described measurements of the cation-exchange membrane. The same results were obtained on the anion-exchange membrane, NEOSEPTA AVS-4T. It was reported in an earlier paper[7] that the extent of the pH change in the solution of the anion-exchange membrane system is larger than that in the cation-exchange membrane system. However, there is no difference between the cation-exchange membrane system and the anion-exchange membrane system in this experiment using NEOSEPTA. Figure 3 shows that the pH of the solution shifts to about 3 in the cation-exchange membrane system and to about 10 in the anion-exchange membrane system at a high current density.

The A-, B-, and C-points measured by means of the six measuring methods are relative values. These points vary with various factors, such as the concentration, the temperature, and the flow velocity of the solution, the structure of the cell, the ionic species, and so on. The effect of these factors on the limiting current density has been studied and will be reported on subsequent papers.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 285—289 (1969)

Shock Induced Reactions of Methane with Nitrous and Nitric Oxides

L. J. DRUMMOND

Australian Defence Scientific Service, Weapons Research Establishment, Salisbury, South Australia

(Received December 5, 1967)

Reflected shock waves, generated in a 5×3 inch shock tube, have been used to ignite mixtures of methane-nitrous oxide and methane-nitric oxide. Monochromators, a pressure transducer and an oscilloscope were used to determine the induction period to ignition (τ) after the reflected wave passed the window. A flash lamp and spectrograph were also used to obtain spectra before and after explosion. For CH_4-N_2O mixtures it was found that the plot of $\log(\tau[N_2O]p_5)$ against inverse temperature was linear and the activation energy was about 60 kcal/mol. This indicates that the rate controlling process was the reaction $N_2O(+M)\rightarrow N_2+O(+M)$. However, the reaction $CH_3+N_2O\rightarrow CH_2+N_2+OH$ may also be important. The results for CH_4-NO mixtures could be expressed by $\log(\tau[NO]p_5)=-10.2+49000/4.58T$ which suggests to the reaction $CH_2+NO\rightarrow CH+HNO$ may be rate controlling. Spectrographic plates showed that CN and OH were present during the induction period but only OH was detected after explosion. This indicates that the reactions $CH+NO\rightarrow CN+OH$ and $CN+NO\rightarrow N_2+CO$ may be a significant mechanism for achieving the reduction of nitric oxide.

The mechanism of methane oxidation with O_2 has been thoroughly examined by Miyama and Takeyama[1] who showed that different reactions governed the induction period to explosion of methane-rich and methane-lean mixtures. For the latter type, OH appeared before the rise in pressure due to exothermic reaction. The temperature dependence of these two induction periods indicated that they were associated with the oxidation of CH_3 and CH_2O respectively.

Our previous work showed that reaction of ammonia[2] and hydrogen[3] with N_2O was rapid and complete. However, with NO, reactions were incomplete even for temperatures of 2000°K and this was believed due to the formation of HNO and subsequent regeneration of NO.

The study is now extended to include methane, the simplest saturated hydrocarbon, as fuel with the hope of identifying the rate-controlling reaction during the induction period and of assessing the influence of the fuel-oxidant ratio on the mechanisms.

Experimental

The shock tube and ancillary equipment have been described.[2] The optical path was 14 mm from the end plate in all experiments. The 1 mm wide beam was split so that the upper half entered a Hilger monochromator set to detect absorption at one wavelength, and the lower half passed to a Bausch and Lomb monochromator set to monitor absorption by OH at 3070 Å. The outputs of the photomultiplier tubes were fed to a Tektronix 555 dual beam oscilloscope. A pressure transducer (Kistler 603 A) was installed in the floor of the shock tube with its centre 2.5 mm from the end plate. Its amplified output was placed on one trace of the oscilloscope set in chopped mode. Alternatively, spectrographic plates were obtained with the use of a Hilger medium quartz spectrograph and a small flash lamp (7.5 μsec duration, 100J). The signal from the detector station due to arrival of the incident shock, instead of triggering the oscilloscope, was fed to a delay unit and then to the flash lamp. With a series of shocks of comparable strength, progressive increase of the delay allowed absorption spectra to be obtained before, at, and after explosion of reactant mixtures which had been processed at comparable temperatures.

The speed of the incident shock (U_s) was measured over 267 mm just before arrival at the end plate. The speed of the reflected shock (U_r) was measured over 135 mm after it had travelled 27 mm from the end plate. An IBM 7090 computer program was used to calculate, for a given value of U_s, the speed of the reflected shock and the pressure (p_5), density and temperature (T_5) of the reactant mixture before reaction occurred. For mixtures containing 80% or more of argon it was possible also to calculate these parameters when reactants had passed instantly to equilibrium products behind this shock.

Helium or hydrogen was used as driver gas, and the initial reactant pressure was 44 Torr in all experiments.

Methane (Phillips, 99.98% pure), nitrous oxide (C.I.G., 99.6% pure) and argon (C.I.G., 99.9% pure) were used directly from cylinders. Nitric oxide, prepared from KNO_2-KI-H_2SO_4, was distilled at low pressure until it was a white solid, melting to a pale

green liquid.

Mixtures were made up manometrically to 700 Torr pressure and stirred magnetically for two hours before use.

Results

Methane Lean-Nitrous Oxide-Argon Mixtures. Three mixtures (2/8/90, 4/16/80 and 6/24/70) were used. Induction periods (τ_1) were read as the time intervals between the reflected shock passing the window and attainment of maximum [OH] after reaction occurred. Ignition delays, measured to the commencement of N_2O disappearance, were in agreement with τ_1 values. The delay (τ_2) to the pressure rise at the end plate due to the onset of exothermic reaction behind the reflected shock, was somewhat bigger than the corresponding τ_1 value measured 14 mm from the end plate. Results were obtained for $1495 < T_5 < 1935$°K and $2.5 < p_5 < 4.5$ atm. As p_5 was not constant the values of τ_1 and τ_2 were linearly normalised by multiplying by the appropriate p_5 value and Fig. 1 shows logarithmic values of $\tau_1 p_5[N_2O]$ and $\tau_2 p_5[N_2O]$ plotted against $1/T$. Least squares treatment yield the equations

$$\log(\tau_1 p_5[N_2O]) = -(13.82 \pm 0.12) + (60540 \pm 900)/4.58T$$
$$\log(\tau_2 p_5[N_2O]) = -(13.34 \pm 0.25) + (57700 \pm 1900)/4.58T$$

If τ values were not pressure normalised the equations are

$$\log(\tau_1[N_2O]) = -(14.16 \pm 0.16) + (59200 \pm 1200)/4.58T$$
$$\log(\tau_2[N_2O]) = -(13.70 \pm 0.15) + (56500 \pm 1100)/4.58T$$

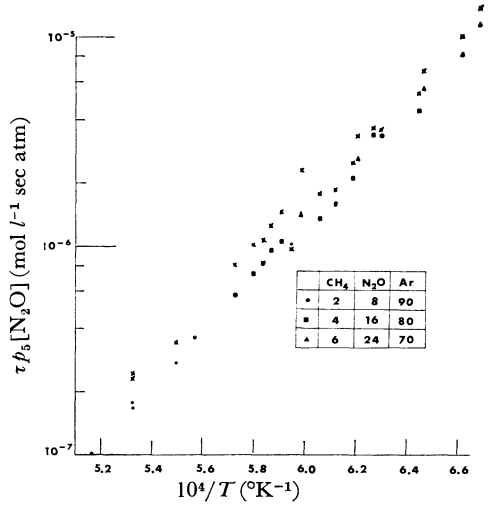

Fig. 1. Plot of $\log(\tau p_5[N_2O])$ against $1/T$ for CH_4 -N_2O-Ar mixtures. Values denoted by X are from pressure records; all others from OH absorption records.

Methane Rich-Nitrous Oxide-Argon Mixtures. Three mixtures (3.3/6.7/90, 6.6/13.4/80 and 10/20/70) were studied for the conditions $1500 < T_5 < 1985$°K and $2.8 < p_5 < 4.6$ atm. Results are summarised as

$$\log(\tau_1 p_5[N_2O]) = -(13.91 \pm 0.21) + (62400 \pm 1600)/4.58T$$
$$\log(\tau_2 p_5[N_2O]) = -(13.53 \pm 0.25) + (60200 \pm 1900)/4.58T$$

If τ values were not pressure normalised the equations are

$$\log(\tau_1[N_2O]) = -(14.22 \pm 0.23) + (60500 \pm 1800)/4.58T$$
$$\log(\tau_2[N_2O]) = -(13.85 \pm 0.18) + (58300 \pm 1400)/4.58T$$

General Obsevations. For each mixture there was a certain driver pressure (and hence T_5 value) below which reaction was not initiated. The pressure records showed that a drop in pressure occurred about the time that reaction should have taken place. The reactant mixture had been chilled by a rarefaction wave reflected back from the zone of collision between reflected shock and contact surface. Thus the shock tube was too short to obtain measurements of long induction periods (about 600 μsec) at temperatures around 1550°K.

The 4/16/80 mixture was studied at a temperature of about 1730°K using the flash lamp and spectrograph. No absorption bands were found during the induction period. At, and after explosion, strong bands due to OH at 2811 and 3064 Å were present.

Measurement of reflected shock speeds were obtained for all mixtures and those for the 3.3/

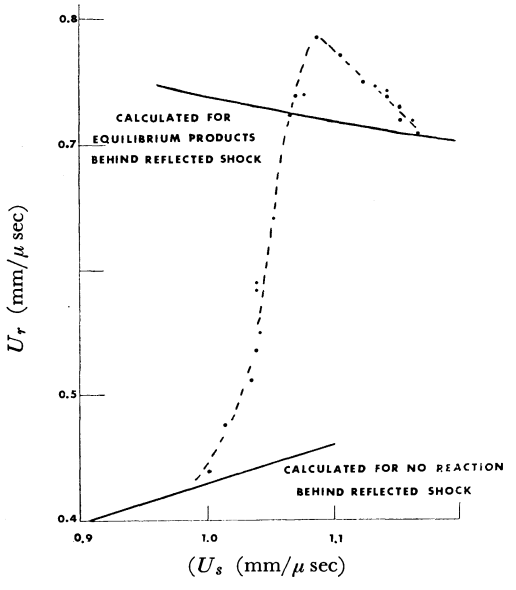

Fig. 2. Shock speed measurements in mixtures of CH_4-N_2O-Ar (3.3/6.7/90).

6.7/90 mixture are shown in Fig. 2.

The phenomenon of "overshoot" (less marked in other mixtures such as 4/16/80) has been seen in other systems,[2,3] and indicates a region in which an overdriven explosion front travels faster than the anticipated combustion-driven wave.

Chemical Reactions. Attempts to identify the rate controlling reaction during the induction period involve choosing a set of reactions such that: the rate determining reaction has an enthalpy change in agreement with the measured activation energy; the number of molecules of fuel (m) and oxidant (n) involved in this reaction agree with the values required for $\log(\tau[\text{fuel}]^m[\text{oxidant}]^n)$ to have a linear relationship with $1/T$; and the remaining reactions in the set should lead to a number of differential equations satisfying the condition that some of the molecules involved in these reactions are in a stationary state condition. A criticism of this method for discerning the rate determining step concerns the assumption that calculations made for non-stationary state conditions are applicable to the steady state. This matter has been discussed recently by Bradley.[4]

However, if we follow the method of Miyama and Takeyama for CH_4-O_2 mixtures, there appear to be two feasible mechanisms for CH_4-N_2O mixtures:

(a) If the reactions

$$N_2O(+M) \longrightarrow N_2 + O(+M) \quad (\Delta H = 40 \text{ kcal}) \qquad (1)$$

$$CH_4 + O \longrightarrow CH_3 + OH \quad (\Delta H = 0 \text{ kcal}) \qquad (2)$$

$$CH_4 + OH \longrightarrow CH_3 + H_2O \quad (\Delta H = -17 \text{ kcal}) \qquad (3)$$

$$CH_3 + N_2O \longrightarrow CH_2 + N_2 + OH \quad (\Delta H = 53 \text{ kcal}) \qquad (4)$$

are of importance during the induction period, then, assuming that O and OH are steady state intermediates and that CH_3 is the principal chain carrier, it is necessary for $k_1[N_2O][M]\tau$ to be constant. Putting $k_1[M] = k'_1 = A\exp(-E/\boldsymbol{R}T)$, the plot of $\log(\tau[N_2O])$ *vs.* $1/T$ should be a straight line, whose slope is the activation energy of reaction (1). We obtained a value of about 60 kcal/mol and previously[2] had measured 57 kcal/mol in a study of the decomposition of nitrous oxide.

(b) If the reactions (3), (4) and

$$CH_4 + N_2O \longrightarrow CH_3 + N_2 + OH \quad (\Delta H = 40 \text{ kcal}) \qquad (5)$$

$$CH_3 + OH \longrightarrow CH_2 + H_2O \quad (\Delta H = -4 \text{ kcal}) \qquad (6)$$

are the important ones, then, assuming that OH is the steady state intermediate and CH_3 is the principal chain carrier, it is necessary for $k_4[N_2O]\tau$ to be constant. Thus $\log(\tau[N_2O])$ *vs.* $1/T$ should be a straight line, whose slope is the activation energy of reaction (4).

Methane - Nitric Oxide - Argon Mixtures. Three mixtures (2/8/90, 4/16/80 and 5/10/85) were used under the conditions $2085 < T_5 < 2810$°K and $3.8 < p_5 < 5.1$ atm. The third mixture (methane-rich) could only be studied over a narrow temperature range due to the low intensity of the OH absorption signal. At these high temperatures there was not a large increase in pressure when reaction occurred and, for this reason, induction periods were only available from OH absorption records. Maximum values of [OH] did not occur rapidly as in a real explosion, but were achieved

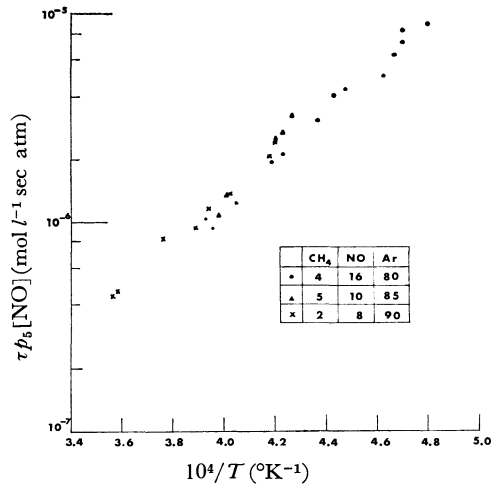

Fig. 3. Plot of $\log(\tau p_5([NO])$ against $1/T$ for CH_4-NO-Ar mixtures.

over tens of micro-seconds after passing through a point of inflexion. A plot of $\log(\tau p_5[NO])$ *vs.* $1/T$ is shown in Fig. 3. Least squares treatment of all data gave the equations

$$\log(\tau\, p_5[NO]) = -(11.20 \pm 0.13) + (49300 \pm 1400)/4.58T$$

$$\log(\tau\, [NO] = -(11.18 \pm 0.16) + (53100 \pm 1800)/4.58T$$

If the methane-rich mixture was ignored

$$\log(\tau\, p_5[NO]) = -(10.17 \pm 0.11) + (49000 \pm 1200)/4.58T$$

$$\log(\tau\, [NO] = -(11.14 \pm 0.17) + (52600 \pm 1800)/4.58T$$

In addition to monitoring OH, monochromator settings of 4320, 3875 and 3360 Å were used. The records indicated that CH and NH were absent but that CN was present during the induction period, disappearing by the time that [OH] had reached about 50% of its maximum value (see Fig. 4). These results were confirmed when the 4/16/80 mixture was studied at a temperature of about 2140°K using the flash lamp and MQ spectrograph. During the induction period the (0,0) and (1,1) bands of the $B^2\Sigma$-$X^2\Sigma$ transition of CN were seen at 3871 and 3883 Å and also,

4) J. N. Bradley, *Trans. Faraday Soc.*, **63**, 2945 (1967).

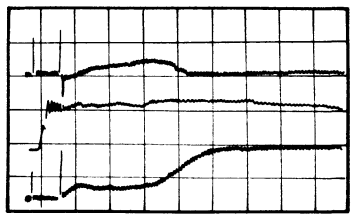

Fig. 4. Oscilloscope record obtained with a mixture of CH_4-NO-Ar (4/16/80). Top trace is absorption at 3875Å, centre trace is pressure, bottom trace is absorption at 3070Å (T_5 is c. 2260°K, 50 μsec/division).

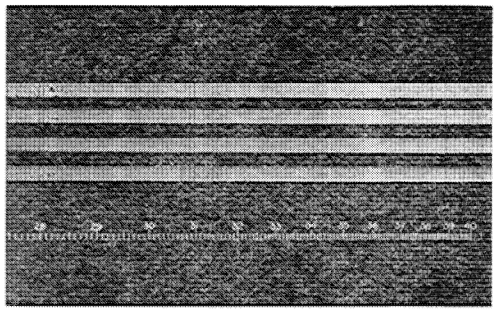

Fig. 5. Spectropgraph obtained with a mixture of CH_4-NO-Ar (4/16/80). First exposure, lamp alone; second, lamp fired 250 μsec after shock passed window; third, delay was 350 μsec; fourth, delay was 450 μsec.

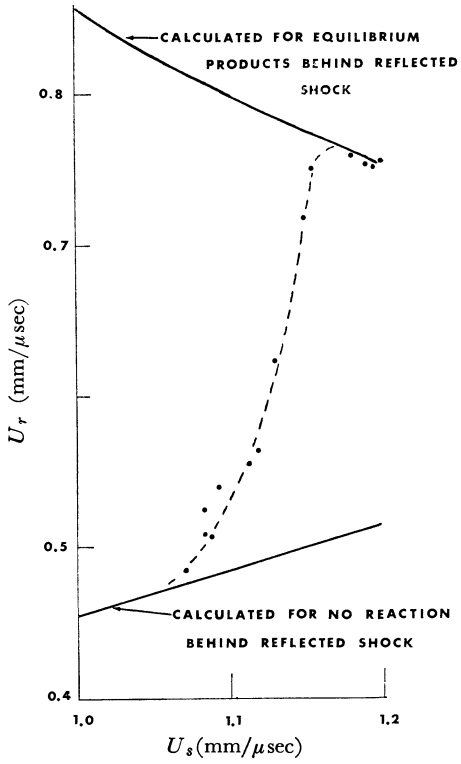

Fig. 6. Shock speed measurements in mixtures of CH_4-NO-Ar (4/16/80).

but faintly, the (0,0) band of OH at 3064 Å. After reaction, only intense bands of OH at 2811 and 3064 Å were seen (Fig. 5).

Figure 6 shows that the measured speed of the fully established combustion-driven shock agrees with that computed for conversion to equilibrium products behind the reaction wave. The initiating reaction for this system could be

$$CH_4 + NO \longrightarrow CH_3 + HNO \quad (\Delta H = 52\,\text{kcal}) \quad (7)$$

At these high temperatures HNO would rapidly decompose and thus further oxidations involving NO and producing HNO could be

$$CH_3 + NO \longrightarrow CH_2 + HNO \quad (\Delta H = 65\,\text{kcal}) \quad (8)$$

$$CH_2 + NO \longrightarrow CH + HNO \quad (\Delta H = 49\,\text{kcal}) \quad (9)$$

The presence of CN and OH during the induction period may be explained by the reaction

$$CH + NO \longrightarrow CN + OH \quad (\Delta H = -45\,\text{kcal}) \quad (10)$$

Assuming that CH_3 is a steady state intermediate and CH_2 is the principal chain carrier it is possible to show that $\log(\tau[NO])$ *vs.* $1/T$ should be a straight line, the slope of which is the activation energy of reaction (9).

Towards the end of the induction period the cyano radical is probably removed by the reaction

$$CN + NO \longrightarrow CO + N_2 \quad (\Delta H = -157\,\text{kcal}) \quad (11)$$

and the heat release of this strongly exothermic reaction causes [OH] to increase, either due to acceleration of reactions (7) through (10) or to reactions such as

$$CH + NO \longrightarrow CO + NH \quad (\Delta H = -101\,\text{kcal}) \quad (12)$$

$$NH + NO \longrightarrow N_2 + OH \quad (\Delta H = -91\,\text{kcal}) \quad (13)$$

Conclusion

Reactions in CH_4 - N_2O mixtures have been initiated by reflected shocks at temperatures above 1500°K. The induction period to explosion, determined from the increase in pressure or achievement of maximum [OH], was inversely proportional to $[N_2O]$. The temperature dependence of the ignition lag indicates that the rate controlling reaction was $N_2O(+M) \rightarrow N_2 + O(+M)$. However the possibility exists that the reaction $CH_3 + N_2O \rightarrow CH_2 + N_2 + OH$ is of importance also. A series of comparable shocks and the use of a spectrograph and flash lamp which was fired at progressively increasing delays after the shock had passed the windows, confirmed that OH was present at, and after, explosion. Measurements of the speed of the combustion-driven shock agreed with those computed for equilibrium conditions behind the shock.

Temperatures above 2080°K were used to induce reactions behind reflected shocks in CH_4 - NO mixtures. Absorption spectroscopy using spectro-

graphic plates showed that CN and OH were present before complete reaction but only OH was detectable afterwards. Absorption records using a monochromator showed that [OH] rose slowly to its maximum value. The induction period tc maximum [OH] was inversely proportional to [NO] and the temperature dependence of the ignition delay indicates that the rate controlling reaction prior to complete combustion is $CH_2+NO\rightarrow CH+HNO$. The detection of CN suggests that the reaction $CN+NO\rightarrow CO+N_2$ may be of importance in accounting for the reduction of nitric oxide.

Dr. I. M. Napier is thanked for assistance in obtaining spectrographic exposures using a lamp of his design. Mr. D. Graham assisted with all shock tube experiments.

Effect of Ultrasonic Waves on Eriochrome Black T

Sheo PRAKASH and S. K. JAIN

Chemical Laboratories, University of Allahabad, Allahabad, India

(Received March 30, 1968)

Ultrasonic waves of high frequency (1 Mc/sec) have been employed to study the effects on the dilute aqueous solution of Eriochrome Black T. The deaeration of the solution by nitrogen does not greatly affect the rate of decolourization. The process is irreversible and the kinetic study shows it to be unimolecular. Oxidation and subsequent destruction of the dye molecule has been found to be the cause of the fading of the dye solution.

The decolourization of dyes by ultrasonic waves has been reported by Olson and Garden,[1] Azami and Hinohara[2] and Prakash and Prakash.[3-6] The aqueous solutions of various dyes have been found to be decolourized when subjected to the action of light, X-rays and γ-rays. The present paper describes the effect of ultrasonic waves on an aqueous solution of Eriohcrome Black T (abbreviated as EBT).

Experimental

Mullard's high frequency generator type E-7562 having a barium titanate ceramic crystal acting as the transducer was used as the source of ultrasonic power. The work reported here was done at a frequency of 1 Mc/sec. The circuit diagram of generator and ultrasonic bath has been reported earlier.[7]

A stock solution of EBT was prepared by dissolving 0.2306 g of the EBT (BDH) in one litre double distilled water. This was diluted to the desired concentration. The solution was found to be quite stable towards the atmosphere during the period of study.

Twenty-five milliliters of dye solution were irradiated in a round bottom ground stoppered jena bottle which was placed vertically above the transducer so that the sound waves entered the vessel vertically upwards. The solution irradiated for different periods and the change in colorimetric readings noted from Klett Summerson Photoelectric colorimeter, employing the filter No. 55 (transmission 520—600 mμ) which was found to be most suitable for the purpose. The absorption maximum of EBT was 560 mμ and this falls well within the range of this filter. For measuring hydrogen ion concentration a Leeds Northrup A.C. pH meter with glass electrodes was used. In order to see the effect of presence of nitrogen gas on the ultrasonic decolourization of EBT solution nitrogen gas, after passing through suitable traps to remove traces of oxygen, was bubbled for 20 min each time before exposure and then the solutions were irradiated for different intervals of time as usual and change in colour noted.

Results and Dicsussion

Figure 1 is a plot of exposure time *vs.* $-\log(a-x)$ where a is the initial dye concentration and $(a-x)$ its concentration after lapse of exposure time t.

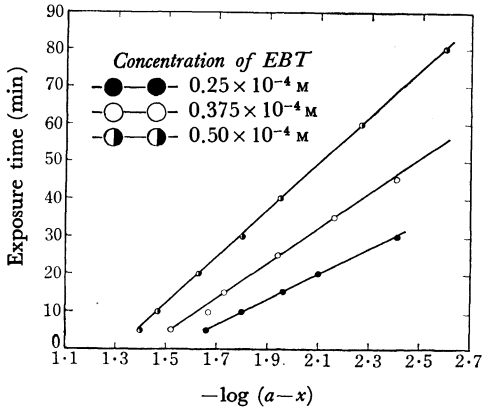

Fig. 1

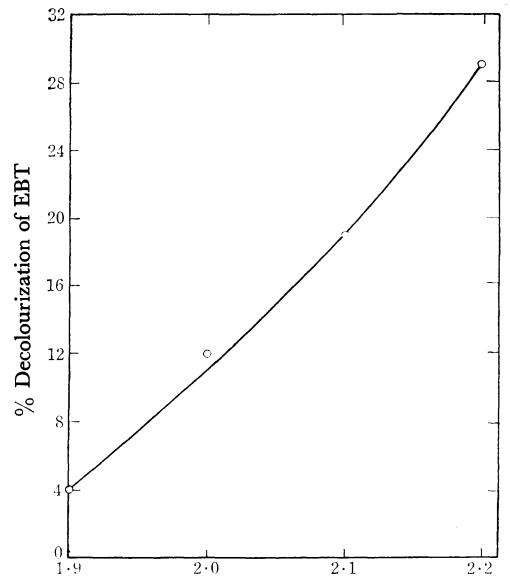

Fig. 2

The decolourisation process has been found to be unimolecular as is evident from the straight line curves obtained. It belongs to the category where the number of molecules of EBT undergoing change per second is proportional to the unreacted molecules present at that instant. This fading varies with change in intensity of the ultrasonic waves (Fig. 2).

The Spectrophotometric studies show that the absorption maximum of the EBT does not change with time of exposure (Fig. 3). Since the molecule breaks up into colourless products which do not exhibit any absorption maximum, the same value is obtained after different intervals of time because of the presence of unbroken EBT molecules.

8) O. Lindstrom and O. Lamm, *J. Phys. Colloid. Chem.*, **55**, 1439 (1951).

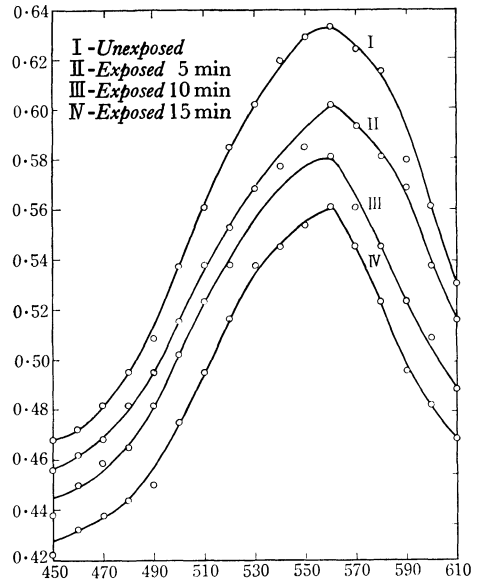

Fig. 3

When an aqueous solution is exposed to ultrasound, hydrogen peroxide is produced along with the formation[8] of H, OH, H_2 and HO_2.

$$H_2O \longrightarrow H, OH, HO_2, H_2O_2$$

A blank experiment was carried out to see whether hydrogen peroxide was responsible for the fading by adding hydrogen peroxide of different concentrations (1.62, 3.25, and 6.5×10^{-2}) to the EBT solution (0.5×10^{-4} M) and keeping it for some time. Even after 24 hr the change was about 6% only. This means that hydrogen peroxide may to some extent be helpful in fading,

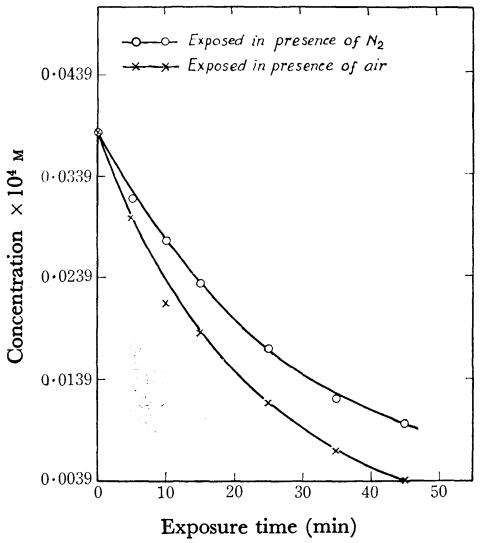

Fig. 4

but is not wholly responsible for it. It is very likely that the fading takes place with a more active reagent prior to the formation of hydrogen peroxide.

When air of the solution was replaced by nitrogen by bubbling the gas before exposure, even then the decolourization occurred, though the rate was reduced considerably (Fig. 4). This is in confirmity with the observations that the ultrasound is able to bring about chemical change even in absence of air or oxygen.

Organic compounds like acetone, dioxane, methyl alcohol, allylthiourea, ether and acrylamide act as inhibitors when they are present in minute quantity (4% by volume). The inhibiting action can be interpreted as due to high vapour pressure, surface tension and internal pressure changes. Most of the sonochemical reactions have been explained on the basis of cavitation, *i. e.*, formation and collapse of the cavity in the solution. The bursting of these cavities generates what is known as cavitational energy and this energy ruptures the bonds of the molecules undergoing change. In presence of substances having high vapour pressure, low surface tension and internal pressure this cavitation is suppressed to a great extent and hence the required energy is not available either to break the molecules of water to produce reactive species H, OH and HO_2 or the reacting molecules themselves.

Unlike photofading of dyes where the primary action is the activation of the molecules, the sonofading is the result of secondary reaction due to the free radicals produced from water by the ultrasonic waves. Also, once the molecule has been decolourized the colour is not restored back, suggesting that the permanent rupture of the molecule takes place. It is oxidation, sometimes reduction or dealkylation which causes the decolourization. However, it is a complex phenomenon and it is difficult to say what is the exact course of the reaction.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 291—298 (1969)

Effect of Cationic Detergents on the Lecithin Stabilized O/W Emulsion

T. G. SASTRY and S. N. SRIVASTAVA

Chemistry Department, Agra College, Agra, India

(Received March 29, 1968)

An oil-in-water system (Nujol being the oil phase) stabilized by the phospholipid, lecithin, has been chosen in this study. The system being negatively charged initially, cationic detergents like lauryl pyridinium chloride (LPC), Cetyl pyridinium bromide (CPB), Phenyl trimethyl ammonium chloride (Ammonyx-200) and Cetyl dimethyl benzyl ammonium chloride (CDBAC) have been employed in order to study their influence on the flocculation and coalescence rates and the degree of aggregation haemocytometrically. Zeta potentials (ξ) have been determined at the corresponding concentrations of the detergents by microcataphoresis and with these values the potential energies and then ultimately the operating van der Waals constant of the system has been determined. From the log C-ξ values it is evident that except Ammonyx-200 which is not an effective cationic detergent, all the others have reversed the charge of the system and their efficiencies are in the order CDBAC>CPB>LPC. The different binding parameters, number of binding sites available for adsorption and free energy of the surface have also been calculated.

The practical utility of detergents in technological field as well as in experimental studies is well known because of their surface activity. Of late much attention is being paid to probe into the more and more complicated structural aspects of these detergents and their molecular orientation on the surfaces and allied aspects. The relative efficiencies of these detergents depend on their carbon chain length and the corresponding adsorbabilities of these complex ions on the surfaces. Cationic surface-active agents are characterised by the fact that the hydrophobic grouping is found in the cation.

In the present studies some of the cationic detergents have been tried in the studies of oil-in-water emulsions stabilised by lecithin, an important phospholipid, which acts as an emulsifying agent in aqueous medium alone and promotes O/W

emulsions in the same way as do proteins. Although many earlier workers[1-7] have tried to use different types of detergents in various O/W-W/O systems, the non-availability of adequate quantitative data with particular reference to the modern theory of colloid stability developed independently by Derjaguin, Verwey and Overbeek (DVO theory),[8-11] prompted us to take up these investigations with the phospholipid as an emulsifying agent in O/W system where Nujol has been chosen as the oil phase. In a previous communication,[12] the effect of inorganic cations has been tried with the same system and this is an extension with complex cationic detergents.

Zeta potentials have been determined at the corresponding concentrations of the detergents where degree of aggregation has been studied haemocytometrically, by microcataphoresis. With these values, the potential energies and then the operating van der Waals constant have been obtained. The binding parameters, number of binding sites available and the free energy of adsorption were also calculated with the electrokinetic data.

Experimental

Materials. The emulsifying agent, lecithin was of BDH quality and the oil phase which consisted of a mixture of Nujol and chlorobenzene were of Ward, Blenkinsop and Co. Ltd., and Polshic Odezymiki Chemiezue, Gliwico (Poland) respectively. Nujol was purified with NaOH.[13]

The detergents lauryl pyridinium chloride (LPC) and cetyl dimethyl benzyl ammonium chloride (CDBAC) were obtained from Industrial Chemical Products, Bombay and further purified with acetone and alcohol respectively. Cetyl pyridinium bromide (CPB) given by I.C.I. (India) was also purified with acetone. Ammonyx-200 (Phenyl trimethyl ammonium chloride) was from Onyx Corporation (U.S.A.) and not further purified. Pyrex galssware and double distilled water were used throughout the studies.

Experimental Methods. The emulsion was prepared by taking 1% of oil (a mixture of 5 parts of Nujol and 6.25 parts of chlorobenzene) containing 1% of emulsifying agent *i.e.*, lecithin with aqueous KCl (0.01 M). The mixture was shaken for a few minutes and homogenised with the hand operated stainless steel homogenizer. (Fisher Scientific Co., U.S.A.). In all the estimations emulsion was prepared under identical conditions.

Flocculation studies were carried out by taking a sample of the emulsion on a double Neubauer model haemocytometer and the counts were taken in 32 squares of the graticule fitted in the eye-picee (each square corresponds to a volume of 7.74×10^{-7} m*l*) with the help of a tally counter under an Olympus microscope (15×62 times magnification). A duplicate counting was always done and the average was taken, the reproducibility being about 5%. The size of the emulsion drops was determined to be 0.70μ dia. from the size frequency analysis of a microphotograph. The electrokinetic potentials were determined by microcataphoresis at a constant temperature of 30°C.

Calculations

The following theoretical aspects were considered before explaining the results of these investigations. In order to apply the D.V.O. theory to the present system, the interaction energy of a colloidal system is given by $V=V_R+V_A$ where V_R is the repulsive energy, V_A is the attraction energy and V is the sum of the two. These two types of energies were calculated with the following Eq.[14]

$$V_R = \frac{\epsilon a \psi_0^2}{2} \ln(1+e^{-\chi H}) \quad (1)$$

$$V_A = \frac{-Aa}{12H} \quad (2)$$

where ψ_0 is the surface potential (assumed equal to the electrokinetic potential for the present system having $\chi a \gg 1$), ϵ the dielectric constant in the double layer (assumed equal to the bulk value 80 of that of water), a the particle radius, H the interparticle distance, χ the Debye-Hückel parameter, and A the van der Waals constant which is taken to be equal to 2.0×10^{-13} erg.

The theoretical degree of aggregation is evaluated as a function of A from the formula.[15]

$$D = 4\pi a^3 n_0 \int S^2 \exp\left(-\frac{V}{kT}\right) ds \quad (3)$$

Ammonyx-200	$C_6H_5N(CH_3)_3Cl$	No reversal of charge even after the addition of 1.0×10^{-1}% (5.83×10^{-3} M)
LPC	$C_{12}H_{25}$–C_6H_5NCl	7.95×10^{-5} M
CPB	$C_{16}H_{33}$–C_6H_5NBr	6.31×10^{-5} M
CDBAC	$C_{16}H_{33}$–$N(CH_3)_2$–CH_2–C_6H_5Cl	1.0×10^{-6} M

where n_0 is the equilibrium number of unassociated particles and $S=2+H/a$. The integration of the above expression is evaluated graphically. The degrees of aggregation thus obtained are plotted against A values and from the graphs correct values of A are determined by interpolation of observed degree of aggregation determined haemocytometrically.

The extent of reversible flocculation can be calculated from the formula.

$$D=\frac{\text{Number of doublets}}{\text{Number of doublets}+\text{Number of singlets}} \quad (4)$$

where D is the number of particles associated with a specific particle *i. e.* the degree of aggregation. Here the singlet means one oil globule which is unassociated and doublet means the combination of two singlets *i. e.*, just flocculated but no coalesced.

From the mobility data, the potentials were calculated by using the Overbeek equation[16] for symmetrical electrolytes, where the relaxation correction has been applied as the particle was small.

$$U=-\frac{\varepsilon\zeta E}{6\pi\eta}\left[f_1(\chi a)-\mathcal{Z}^2\left(\frac{e\zeta}{kT}\right)^2 f_3(\chi a)-\frac{\rho_+-\rho_-}{6\pi\eta e}\left(\frac{e\zeta}{kT}\right)^2 f_4(\chi a)\right] \quad (5)$$

where U, velocity of the particle (average of 10 readings was taken), ρ_+ and ρ_- the friction constants, η the viscosity of the dispersion medium, k the Boltzmann constant, e the electronic charge, $f_1(\chi a)\cdots f_4(\chi a)$ the functions taken from Table 2 (Overbeek *loc. cit.*).

The charge density of an emulsion droplet by adding small quantities of cationic detergents which are likely to adsorb is given by Stern equation.[17]

$$\sigma_s=\frac{\mathcal{N}_1 e z}{1+\frac{55.6}{c}\exp\left(\frac{\Delta G}{kT}\right)} \quad (6)$$

where c is the molar concentration of the added detergent, $\mathcal{N}_1$ the binding sites per cm^2 and ΔG is the free energy of adsorption per molecule. The same equation can be written in the form (*cf.* Wilkins *et al.*[18] and Ottewill *et al.*[6])

$$\sigma_s=\frac{K_1 c}{1+K_2 c} \quad (7)$$

where $K_2=\dfrac{e^{-\Delta G/kT}}{55.6}$ and $K_1=\mathcal{N}_1 K_2 ez$.

K_1 and K_2 are the adsorption constants which have been calculated from the treatment given by Srivastava[19] at zero point of charge which finally yields the following equations.

$$\frac{1}{c}=\frac{4\pi z e\mathcal{N}_1 k_2}{\chi\varepsilon\psi_0\delta}-k_2 \quad (8)$$

$$\left(\frac{d\psi\delta}{d\ln C}\right)_{\psi_0\delta=0}=\left(\frac{\chi\varepsilon\psi\delta}{4\pi ez\mathcal{N}_1}-1\right)_{\psi_0\delta} \quad (9)$$

where z is the valency and $\left(\dfrac{d\psi\delta}{d\ln C}\right)_{\psi_0\delta=0}$ is the slope of the loc C-zeta potential curve (assuming $\psi_0\delta=\zeta$), C the concentration of the detergents at the zero point of charge.

Results and Discussion

(a) Effect of Detergents on Flocculation. The flocculation of the emulsion droplets has been studied by adding different concentrations of the four detergents and counting the number of singlets

and doublets present at various intervals of time. The initial particle concentration of the emulsion was found to be 8.05×10^8 globules/m*l*. Graphs have been plotted between the number of particles (n_1: 10^8 unit) and time. Here only one of the typical graphs (graph 1) obtained from CPB has been given. From the graph it is evident that with increase in concentration of detergent the number of particles decrease gradually and almost attains constancy after some time which shows that reversible flocculation occurs in the system. At comparatively higher concentration the charge reversal takes place and the number of particles suddenly decreases implying thereby that coalescence is appreciable.

(b) Effect on Zeta Potential. Changes in zeta potentials by the addition of these above mentioned cationic detergents have been studied. In our present investigations the pH of the emulsion after the addition of detergents being almost neutral, lecithin is not exhibiting any positive charge as was found by Hanai *et al.*[20] in the acidic range. On the other hand, the slight positive charge of tetramethyl amino group appears to be internally neutralised when it is taken in Nujol and its predominant negative bearing phosphotydal group seems to be contributing to the overall negative charge of the emulsion. So these cationic detergents have been used in flocculation as well as in electrokinetic potential determinations. The corrected zeta values were plotted against the

logarithmic concentrations of the detergents (graph 2). From the graph it is clear that except Ammonyx-200, all the other detergents (LPC, CPB and CDBAC) have reversed the charge of the emulsion globules. The relative efficiencies of these detergents are clearly indicated by the charge reversal concentrations as given in Table 1.

The reversal of charge is due to the adsorption

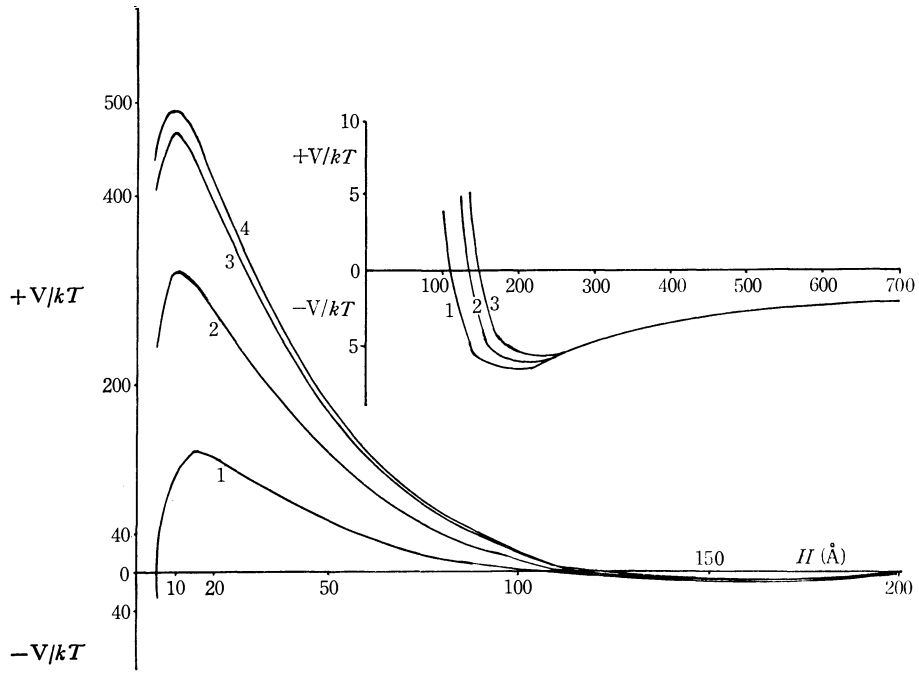

Fig. 6. Plots of distance and potential energy of interaction for CDBAC at different concentrations showing the heights of maxima and enlarged secondary minima separately (1) 1.92×10^{-5} M (2) 2.83×10^{-5} M (3) 1.92×10^{-4} M (4) 3.83×10^{-4} M.

of the cation onto the surface of the lecithin micelles. The flocculation results were also in conformity with the values of zeta potential variations. The efficacy of each detergent could easily be explained by the length of the carbon chain and critical micelle concentration (CMC). The CMC of LPC is determined as 1.66×10^{-2} whereas that of CPB is lower than this. The carbon chain lengths and so flocculating powers are in the increasing order of Ammonyx-200, LPC, CPB and CDBAC.

(c) Interaction Energy Curves and the Stability of Emulsion. In order to test the DVO theory in the present case and also to study the nature of flocculation, the interaction energies V/kT where V comprises of V_R+V_A have been calculated and are plotted as a function of the interparticle distance H (Å) and are presented in graphs 3—6. The high energies exhibited in different systems would naturally indicate the stability of the emulsion and the possibility of only reversible flocculation. When the surface of the emulsion droplet strongly adsorbs the ions of the opposite charge, the coated droplets act as a lyophobic colloid. So the flocculation can be either irreversible in the primary minima or reversible in the secondary minima. In the present investigations under question, the latter aspect seems to be more predominant as evidenced by the high energy above 25 kT and shallow minima of not more than 7 to 8 kT deep at an interparticle distance of 100—150 Å. The enlarged secondary minima portion have also been presented in the same graphs 3—6.

The details of the detergent concentrations and their corresponding zeta potentials, the energy maximum, depth of the secondary minima *etc.* are presented in Table 2.

These results are in conformity with our previous findings with inorganic cations.[12] The only difference which is obvious is that the overall energy barriers have been reduced as compared to the previous ones, presumably, owing to the combined effect of 0.01 KCl+the highly effective cations of the detergents.

By counting the number of singlets and doublets by haemocytometry while doing flocculation studies, the degree of aggregation has been calculated. The theoretical value of the same has also been obtained.[21] These two values did not agree because of the difference in van der Waals constant taken (2.0×10^{-13} erg). So a graph was plotted between different van der Waals constants and the theoretical values of D% (graph 7). From this graph the value of A corresponding to the observed value of D has been noted and found to be 2.6×10^{-13} erg which is almost same as obtained before with electrolytes. This further confirms the range of A obtained by earlier workers.[19-22]

Constants. With the help of the treatment given[17] regarding the calculation of the different binding parameters, number of binding sites available for adsorption and free energy of the surface have been calculated and presented in the Table 3.

From these obtained values it is evident that all these detergents have less number of available sites for adsorption than Ammonyx-200 reported earlier[23] which gives some indication for their capacity to charge reversal. Out of these three presented in the table LPC seems to be weaker than the other as confirmed from the electrokinetic and flocculation measurements. The free energy values are not significantly different from one another.

Finally it may be concluded from the above findings that Ammonyx-200 is not an effective cationic detergent whereas the others are capable of strong adsorption on the lecithin coated oil drops in aqueous KCl so as to cause the charge reversal and their relative efficiencies are in the

Kinetics and Mechanism of the Oxidation of Citric and Glyoxylic Acids by Cerium(IV) Ion

Kalyan K. SENGUPTA

Department of Physical Chemistry, Jadavpur University, Jadavpur, Calcutta-32, India

(Received April 26, 1968)

The mechanism proposed by Waters (*J. Chem. Soc.*, **1955**, 217) for the oxidation of α-hydroxy acids by manganic pyrophosphate accounts for the kinetics of oxidation of citric acid by cerium(IV) ion. The oxidation appears to proceed through the initial formation of complex and subsequently through free radicals.

According to Benrath and Ruland,[1] the reaction between citric acid and cerium(IV) is a complicated one and does not follow the simple kinetic order. Willard and Young[2] oxidized citric acid by ceric sulphate with an idea to find a new method for the quantitative estimation of the hydroxy acid. They oxidized the hydroxy acid up to formic acid. The method described by them was tedious and hence Duke and Smith[3] developed a simpler method using cerium(IV) perchlorate as oxidant. In a more recent communication, Ghosh and Mehrotra[4] showed that the above reaction is a bimolecular one when reactants were of equimolar quantities. According to them both formic acid and formaldehyde are the products of oxidation. It has already been shown that formaldehyde[5] is very sensitive to cerium(IV) ion and two equivalents of cerium(IV) ion were needed per mole of formaldehyde, and so we were suspicious about its existence in the solution specially when it was stored in excess cerium(IV) for several days. Moreover, the stoichiometry of the oxidation reaction reported by different workers was different and the mechanism up to formic acid is not yet known. It was, therefore, intended to reinvestigate the reaction in details. Since glyoxylic acid is one of the possible intermediates of citric acid oxidation, the kinetics of the oxidation of glyoxylic acid has also been studied, the data for which are not available in the literature. A possible mechanism up to formic acid has been suggested.

Experimental

Ceric ammonium sulphate was of E. Merck's (G.R.) grade and the solution of the salt in sulphuric acid was directly made. Ceric ammonium nitrate which was used for the preparation of cerium(IV) perchlorate was of 'AnalaR' grade. Cerium(IV) perchlorate was prepared by the electrolytic oxidation of Ce(III) perchlorate by the method suggested by Smith[3] and finally stored in an ice box until ready for use. Cerium(IV) ion was standardized by the iodometric method.[6] Citric acid was of 'AnalaR' grade whereas glyoxylic acid (Fluka) was purified by recrystallisation. The organic acids were standardized against standard caustic soda. The details of other reagents and experimental set up have been describede lsewhere.[7-9] The reactions have been followed volumetrically and an aliquot part of the reaction mixture was withdrawn at suitable intervals and analysed for residual cerium(IV) by the iodometric method.

The stoichiometry was determined by allowing reaction mixtures containing a large excess of Ce(IV) ion to stand for several days at 30°C. The excess Ce(IV) ion was then estimated as described previously. It has been found that 14.0 and 2.0 equivalents of cerium(IV) reacted per mole of citric and glyoxylic acids respectively.

The oxidations have been studied mainly in the presence of excess cerium(IV) ions (up to 10 fold excess in the case of citric and 2 fold excess in the case of glyoxylic acids) and the rate was found to be first order in both cases.

Dependence of Rate on Ho in H_2SO_4. The reactions were studied at different sulphuric acid concentrations which retarded the rate of reaction. The plot $\log K$ against $-H_0$ (H_0=Hammett acidity) was linear which was confirmed from two sets of experiments at two different temperatures. (Fig. 1), where the rate constant of first order was denoted by K in sec.$^{-1}$ The values of H_0 at different sulphuric acid concentrations have been taken from the tables of Paul and Long.[10]

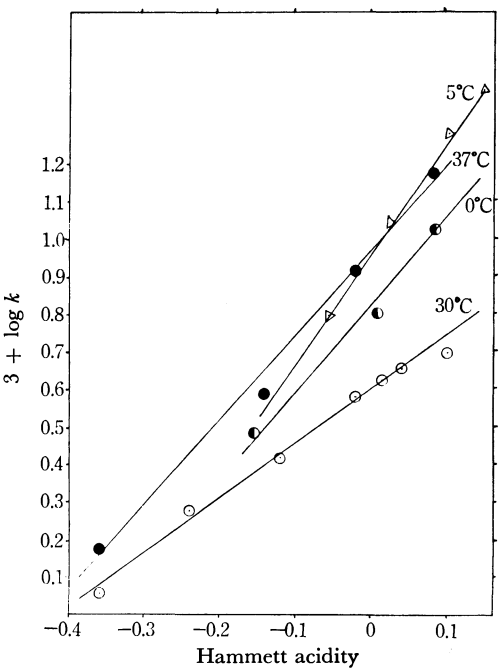

Fig. 1. Variation of $\log k$ against Hammett acidity.
⊙ ● Citric acid
◐ △ Glyoxylic acid

Influence of Salts on the Rate Constants. The reactions have been investigated in the presence of different salts, *e. g.*, potassium chloride, sodium perchlorate, sodium sulphate and magnesium sulphate. Sodium perchlorate had no influence on the rate constant. But there was a slight decrease of rate constant in the case of potassium chloride possibly because of the fact that chloride ion complexes[11] with cerium(IV) thereby decrease the concentration of active species of cerium(IV). Thus no effect of ionic strength has been found on the overall kinetics of the reaction. As usual both sulphate and bisulphate ions retarded the rate of reaction (Tables 1 and 2) and the plots $[SO_4]^{2-}$ against $1/K$ have been shown in Fig. 5. The inhibiting effect of addition of sulphates or sulphuric acid can be explained in the light of the complex nature of ceric sulphate in the solution. This has been discussed in previous communications.[7-9]

experiment was carried out at identical concentrations of sulphuric acid and the reactants. The results have been plotted (Figs. 3, 4 and 6). From the plot of log K *vs.* $1/T$, the activation energy has been calculated. The values of the activation energy and entropy of activation for the different cases of oxidation have been recorded in Tables 3 and 4.

Discussion

On oxidation of citric acid by cerium(IV) ion, CO_2 is evolved and formic acid remains in solution. When large excess of cerium(IV) ion was present (about 20 times excess) a total of about 14 equivalents of cerium(IV) was destroyed per mole of citric acid and this confirms the observation of Smith,[3] and 1.95 mol of formic acid were produced per mole of the citric acid. When Ce(IV) perchlorate was used as oxidant, the reaction was completed within an hour at 30°C up to formic acid which remained unaffected even in excess of cerium(IV) ion. Therefore,

$$C_6H_8O_7 + 14Ce(IV) + 5H_2O \longrightarrow 4CO_2 + 2HCOOH + 14H + 14Ce\ (III)$$

would represent the stoichiometry of the equation. The presence of formic acid was confirmed by

chromotropic acid reaction which was estimated by the usual procedure.[12] Finally, an attempt was made to distinguish between mechanisms (a) and (b).

$$\text{(a)}\quad \mathrm{Ce(IV)} + \mathrm{HCl} \overset{K_1}{\rightleftharpoons} \mathrm{Ce(IV)\cdot HCi}.$$

$$\mathrm{Ce(IV)\cdot HCi} \xrightarrow{K'} \mathrm{Ce\ (III)} + \text{product}$$

(subsequent steps fast)

$$\text{(b)}\quad \mathrm{Ce(IV)} + \mathrm{HCi} \xrightarrow{K_2} \mathrm{Ce\ (III)} + \text{product}$$

(subsequent steps fast)

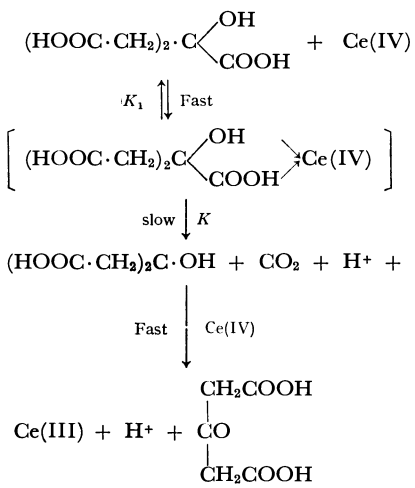
The immediate change in colour from orange to red (the colour was more prominent when ceric perchlorate was used as oxidant) which again changes to its original colour clearly shows the occurrence of an unstable chelate at the initial stage. A few attempts were made to investigate the complex by Job's method of continuous variation but failed owing to its highly unstable character. The kinetic evidence only indicates that citric acid is oxidized *via* complex formation and the plot $1/K$ against 1/[substrate] labels[13] the corresponding $1/K$ axis indicating information of a complex. This shows that the rate dependence is according to (a)

$$\frac{-\mathrm{d[Ce(IV)]}}{\mathrm{d}t} = \frac{K'K[\mathrm{Ce(IV)}][\mathrm{HCi}]}{1+K[\mathrm{HCi}]}$$

and not the simple dependence (b)

$$-\frac{\mathrm{d[Ce(IV)]}}{\mathrm{d}t} = K[\mathrm{Ce(IV)}][\mathrm{HCi}]$$

The complex finally decomposes to give a free radical[14] the formation of which was tested by induced reduction of mercuric chloride. During the oxidation of citric acid by Ce(IV) ion, mercuric chloride was found to be reduced indicating the formation of a reducing intermediate,[15] *e. g.*, free radical. The reduction was more prominent in concentrated solutions of citric acid and Ce(IV) ion. The free radical further picks up Ce(IV) ion and is oxidised in the following manner.



The subsequent steps up to formic acid are also considered to be very fast and an attempt was made to investigate the initial rates of the expected intermediates under comparable conditions. The concentration of the oxidant was three times that of the substrate and the experiments were carried out at 30°C and at sulphuric acid concentration of 0.5 M. The values of K_{Citric} and K_{Malonic} were found to be 4.99×10^{-3} ($\mathrm{sec^{-1}}$) and 10.07×10^{-3} ($\mathrm{sec^{-1}}$) respectively. Again under the same experimental condition glyoxylic acid was instantaneously oxidized and with two fold excess of the oxidant at 5°C, $K_{\mathrm{glyoxylic}}$ was found to be 1.84×10^{-2} ($\mathrm{sec^{-1}}$). The comparison of the values of activation energy of Table 3 also shows the following order:

$$K_{\mathrm{citric}} < K_{\mathrm{malonic}} < K_{\mathrm{glyoxylic}}$$

The oxidation of expected acetone dicarboxylic acid may now take place either through acetone which is formed by the successive decarboxylations of two carboxyl groups as in the case of the oxidation of citric acid[16] by potassium permanganate or by the cleavage of C–C bond of citric acid molecule. It is interesting to examine which of the paths explains the following experimental results. In the oxidation of acetone by Ce(IV) sulphate, Hinshelwood and Shorter[12] found that 8.6 equivalents of Ce(IV) ion are required per mole of acetone even at 70°C. So if acetone dicarboxylic acid is to give acetone and then subsequently oxidized it would need only 8.6 equivalents with the overall consumption of 10.6 equivalents of the oxidant. This rules out the possibility that CH_3-$COCH_3$ is an intermediate. Therefore acetone dicarboxylic acid is oxidized to give one mole of malonic acid and one mole of glyoxylic acid with the overall consumption of four equivalents of Ce(IV) ions in the following way (Scheme 1.)

The formation of glyoxylic acid *via* glycollic acid is not possible as the oxidation of glycollic acid is too slow.[9] The oxidation[17] of malonic acid by cerium(IV) ion may be represented stoichiometrically by the equation:

$$\mathrm{CH_2(COOH)_2} + 6\mathrm{Ce(IV)} + 2\mathrm{H_2O} \longrightarrow 2\mathrm{CO_2} + \mathrm{HCOOH} + 6\mathrm{Ce(III)} + 6\mathrm{H^+}$$

The possible mechanism of the above reaction has already been discussed in the previous communi-

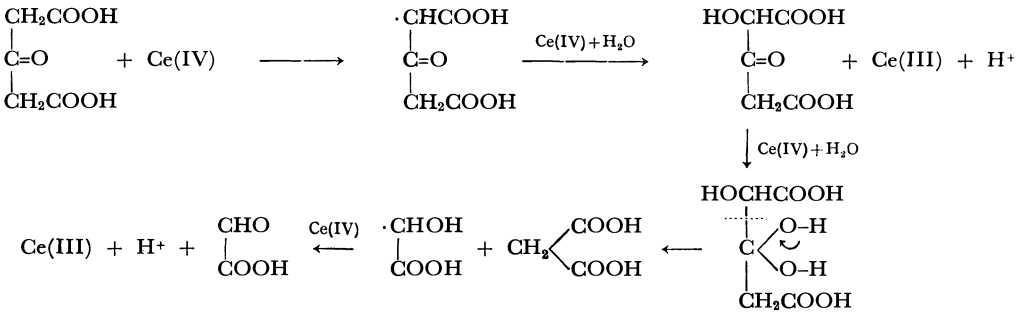
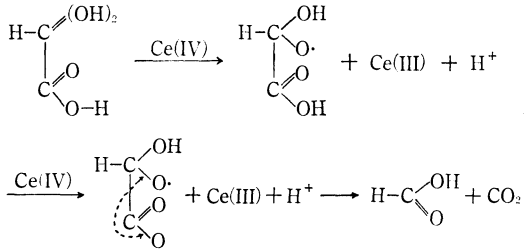


Scheme 1

cation.[17] Malonic acid is oxidized initially to give tartronic acid which by fast steps is further oxidized to produce glyoxylic acid. Glyoxylic acid is then hydrated and oxidized instantaneously at 30°C to give formic acid with the consumption of two equivalents of Ce(IV) ion.



The other mole of glyoxylic acid which has been obtained from acetone dicarboxylic acid has also been oxidized in the above manner to give other mole of formic acid.

While discussing the mechanism through which the reaction proceeds, it has been suggested that the first step is the formation of a complex between ceric ion and the substrate. The question that would occur is why one prefers to assume an initial complex formation and then an electron abstraction by ceric ion to give cerous ion. The possible alternative would be to assume the initiation step as in the case of the oxidation by hydrogen peroxide or a more plausible analogue than by Co^{3+} salt. In cases of both these oxidation processes, formic acid is found to be oxidized, whereas in the oxidation by Ce(IV) salt, formic acid is never oxidized but constitutes one of the products of oxidation reaction. The choice, therefore, falls on the mechanism in which the initiation of the reaction through the formation of a complex and abstraction of electron by ceric ion, is a general first step. The radical would next be involved in reactions be lost, before it can be stabilized. That the reaction is not ionic is supported by the fact that ionic strength had no effect on the rate of oxidation in systems contain- ing perchlorates.

It has been observed that when the oxidant is in excess, the reaction (the consumption of ceric) follows a first order rate. This has been explained on the basis that a steady state concentration[18] of free radical is attained and this finally reacts with ceric ion.

When the organic acid is equivalent or in excess the radical will react with the complex (if it is stable) and then the reaction is apparently a second order one. This is possibly what has been observed by Ghosh and Mehrotra.[4] On the other hand, if the complex is weak the radical will react with ceric ion and the reaction will continue to be the first order. Thus if the organic acid forms a stable complex with the ceric ion, the reaction will pass to one of second order when it goes from excess oxidant to excess of the substrate. Thus stability of the complex plays a role in determining the order of the reaction.

Concerning the thermodynamic constants in the presence of different oxidants, it has been observed that the activation energy in the case of the oxidation by Ce(IV) perchlorate is less than that of the Ce(IV) sulphate. This is possibly due to the fact that sulphate ion forms strong complexes with Ce(IV) ion while perchlorate ion is a weak complex forming anion. Therefore Ce(IV) sulphate will react more slowly with the substrate than Ce(IV) perchlorate. This may also be explained in the light of oxidation potential of Ce(IV)—Ce(III) system which depends on acidity as well as on the kinds of anion present. The oxidation potential of Ce(IV) perchlorate (1 M—2 M acid) is 1.87 V whereas that of Ce(IV) sulphate in sulphuric acid (1M—2 M acid) is 1.44 V which shows that the oxidizing capacity of Ce(IV) sulphate should be less than that of Ce(IV) perchlorate. On the other hand the reaction should be retarded in Ce(IV) sulphate solution requiring a greater energy in the medium.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 303—308 (1969)

The Structure Theory of Water. I. Two State Theory

Kiyoshi ARAKAWA and Katsutaka SASAKI

Research Institute of Applied Electricity, Hokkaido University, Sapporo

(Received March 29, 1968)

A statistical thermodynamic theory was successfully applied to liquid water, based on the two state model which consists of an ice-like structure (class I) and unbonded monomers (class II). The resulting partition function was formulated and calculated using the two quantities, the energy difference between class I and class II, ε, and the free volume per molecule, v_f, as the adjustable parameters which were varied within the physically-reasonable range. The magnitudes of ε and v_f were estimated to be 3 kcal/mol and 4.0×10^{-25} cm^3 respectively to give the best fit of calculated values to the experimental data. From the partition function obtained, the Helmholtz energy, the internal energy, the entropy, and the specific heat were calculated. The agreement between the calculated values and the experimental data was found to be satisfactory. From the obtained result it may be concluded that the simple two state model is adequate to explain the thermodynamical data for liquid water.

A number of studies have been made on the structure of liquid water since Bernal and Fowler[1] proposed a pseude crystal model based on the tetragonal structure in water. However, many problems are left unsolved at present. Morgan and Warren[2] gave the radial distribution curve for water from their X-ray diffraction data, and estimated the average number of first nearest neighbors to be 4.4—4.9 at temperatures from 1.5 to 83°C.

The approach to the structure theory of water based on the ice-like structure, as made by Bernal and Fowler, that is, the approach from the viewpoint that the main structure of liquid water is solid-like, has been taken by many workers. The bent-hydrogen-bonding chain theory given by Pople[3] and the structure theory of Davis and Litovitz[4] are typical of the solid-like theory. However, these theories were found to be able to explain the properties of water only partly. On the other hand, Eucken[5] proposed an association theory, in which water was supposed to be an equilibrium mixture of monomer, dimer, tetramer and octamer.

In 1948, Hall[6] presented a two state theory of water, which was based on the assumption that liquid water was composed of an ice-like structure ("open structure") and unbonded water molecules ("close-packed structure"), in order to explain the ultrasonic absorption data. Hall's theory succeeded in the interpretation of ultrasonic absorption data, but was pointed out by Litovitz and Carnevale[7] to be unsatisfactory for the explanation of the pressure dependence of ultrasonic absorption. Since then, the two state theory of liquid water has been developed in various ways by a number of authors. Some of them, the theories of Samoilov,[8] Frank and Quist,[9] *etc.* were found to emphasize the solid-like structure. On the other hand Frank and Wen[10] proposed a flickering cluster model based on the cooperative nature of hydrogen bonding formation, and pointed out the life time of the cluster to be as short as 10^{-10} or 10^{-11} sec from the relaxation data. According to the suggestion of Frank and Wen, Némethy and Scheraga[11] have presented a refined statistical theory, in which water is assumed to be an equilibrium mixture of flickering clusters and unbonded molecules. The clusters are supposed to be composed of tetra-, tri-, di-, and singly-hydrogen-bonded water molecules, and therefore, Némethy and Scheraga's theory is also regarded as a five state theory.

11) G. Némethy and H. A. Scheraga, *J. Chem. Phys.*, **36**, 3382 (1962).

After the proposition of Némethy and Scheraga's theory, several studies have been made along this line. Vand and Senior have recently presented a nine-state theory,[12] and, proposed further an energy band theory. Vand and Senior introduced an additional assumption of the energy band into the structure theory of water without any theoretical explanation. This assumption means a continuous distribution of energy for water molecules and also means the introduction of a very large number of states since the energy changes continuously. It is questionable that, when the life time of the hydrogen-bonded region is known to be as short as 10^{-11}—10^{-10} sec, a number of different states within the hydrogen-bonded region could be distinguished each other, for a "state" has to be regarded as corresponding to a "structure." The assumption of the presence of a number of distinguishable states with as short a life time as 10^{-11}—10^{-10} sec may be doubtful, when the energy difference between the states is as small as the energy of thermal motion. It may be generally said that, on constituting the theory, the number of states assumed is desirable to be as small as possible, so long as the increase in the number of states means the increase in the number of parameters.

Therefore, the authors have made a theoretical investigation on the structure of water based on the two state model, and investigated the effectiveness and the limitation of the two state theory.

Theory

Two State Model. It is assumed that liquid water is an equilibrium mixture of two classes of molecules. Class I is constituted by hydrogen-bonded molecules (open structure or ice-like structure) and class II is constituted by unbonded monomers (close-packed structure). The molecules in each class are assumed to be in a uniform state on the average, and the energy level of the molecules in class II is ε ($\varepsilon>0$), taking the level of those in class I as the ground level. A molecule changes its state fluctuationally with lapse of time, and the life time during which a molecule stays in the state of class I is of the order of 10^{-11}—10^{-10} sec, as pointed out by Frank and Wen[10] based on relaxational data concerning the life time of flickering clusters. It is assumed that a molecule acts as in a solid phase while it stays in the state of class I, and that it acts as in a gaseous phase while in class II.

Statistical Treatment. The formulation of the partition function, $\mathcal{Z}$, for the mixture of Nx molecules in class I and $N(I-x)$ molecules in class II is made as follows,

$$\mathcal{Z}=\frac{N!}{(Nx)!\{N(1-x)\}!}(f_{\mathrm{I}})^{Nx}(f_{\mathrm{II}}\mathrm{e}^{-\varepsilon/RT})^{N(1-x)}, \quad (1)$$

where f_{I} and f_{II} are partition functions for each species. The partition function $\mathcal{Z}$ for the equilibrium mixture is equated to the maximum term as usual regarding x as a parameter. The mole fraction x for class I in the equilibrium mixture is determined by the maximization of $\mathcal{Z}$ concerning x as a variable, using Stirling's approximation,

$$\frac{\partial \ln \mathcal{Z}}{\partial x}=0. \quad (2)$$

Introducing Eq. (1) to Eq. (2), we obtain Eq. (3) for the equilibrium value of x,

$$x=\frac{f_{\mathrm{I}}}{f_{\mathrm{I}}+f_{\mathrm{II}}\mathrm{e}^{-\varepsilon/RT}}, \quad (3)$$

and, introducing Eq. (3) into Eq. (1), the partition function, $\mathcal{Z}$ for the equilibrium mixture, is represented as follows,

$$\mathcal{Z}=(f_{\mathrm{I}}+f_{\mathrm{II}}\mathrm{e}^{-\varepsilon/RT})^{N}. \quad (4)$$

The Helmholtz energy, A is obtained from the following equation (5),

$$A=-kT\ln\mathcal{Z}=-NkT\ln(f_{\mathrm{I}}+f_{\mathrm{II}}\mathrm{e}^{-\varepsilon/RT}) \quad (5)$$

and the energy and entropy can be calculated by Eqs. (6) and (7).

$$E=kT^2\frac{\partial\ln\mathcal{Z}}{\partial T}$$
$$=NkT^2\left(\frac{\partial f_{\mathrm{I}}}{\partial T}+\frac{\partial f_{\mathrm{II}}}{\partial T}\mathrm{e}^{-\varepsilon/RT}+\frac{\varepsilon}{RT^2}\mathrm{e}^{-\varepsilon/RT}f_{\mathrm{II}}\right)\Big/ (f_{\mathrm{I}}+f_{\mathrm{II}}\mathrm{e}^{-\varepsilon/RT}) \quad (6)$$

$$S=(E-A)/T \quad (7)$$

The specific heat, C_V, is derived from the energy, E.

$$C_V=\left(\frac{\partial E}{\partial T}\right)_V \quad (8)$$

The partition functions of each species, f_{I} and f_{II}, are given in the following equations, Eq. (9) and Eq. (10),

$$f_{\mathrm{I}}=\prod_{i=1}^{6}\left(\frac{1}{1-\mathrm{e}^{-h\nu_i/kT}}\right) \quad (9)$$

$$f_{\mathrm{II}}=\left\{\left(\frac{2\pi mkT}{h^2}\right)^{3/2}v_f\right\}\left\{\frac{(8\pi^2kT)^{3/2}(\pi ABC)^{1/2}}{2h^3}\right\}, \quad (10)$$

where ν_i is the frequency of translational vibrations and librations in the state of class I, v_f is the free volume[13] available to a molecule in the state of class II, and A, B and C are the principal moments of inertia of water molecule. The factor in the first bracket of f_{II} corresponds to the translational degrees of freedom and that in the second bracket to the rotational ones. The contribution from intramolecular vibrations into f_{I} and f_{II} is ignored, because it may be safely regarded as 1 at temperatures from 0 to 100°C.

Results

Determination of Parameters. The energy difference between two states, ε, and the free volume, v_f, which is available to a molecule in the state of class II, are two main parameters used in this theory. It is impossible to determine the magnitude of ε and v_f precisely from theory at present, and therefore, they have been treated as the adjustable parameters to give the best fit of calculated values to experimental data. The variation of parameters was, of course, limited within the physically reasonable range. In the earlier treatment based on the two state model the magnitude of ε has been estimated to be within the range of 2.5—3.0 kcal/mol. Smith and Lawson estimated the magnitude of ε to be 2.6 kcal/mol from their sound velocity data,[14] and Lawson *et al.* estimated it to be 3 kcal/mol from their thermal conductivity data.[15] Wada used the value of 2.51 kcal/mol in his treatment.[16]

Taking account of the heat of fusion of ice in addition to the estimation described above, we have taken the range of ε to be 2.75—3.15 kcal/mol.

The magnitude of v_f has been found to be of order of 1% of the volume per molecule (molecular volume) for many liquids.[13,17] Némethy and Scheraga used the value of 4.4×10^{-25} cm^3 which was about 1.5% of the molecular volume of water.[11] The magnitude of v_f calculated from the heat of vaporization of water[13] was 1.1×10^{-25} cm^3 (about 0.35%), and the magnitude of "fluctuation volume" calculated from the distance at the second peak in the Morgan and Warren's radial distribution curve[11,13] was 2.6×10^{-25}—4.6×10^{-25} cm^3, when that distance was taken to be 3.1—3.2 Å. Therefore, calculations have been made within the range of v_f from 1.1 to 4.6×10^{-25} cm^3 as the adjustable parameter. It has been found that the best fit of the calculated to the experimental data has been obtained when the magnitudes of ε and v_f have been taken to be 3 kcal/mol and 4.0×10^{-25} cm^3 (about 1.3% of the molecular volume) respectively.

As for the frequencies which have been attributed to intermolecular vibrations a tentative assignment has been made referring to the data from the infrared and Raman spectroscopy: 210 cm^{-1} for three modes of translational vibrations[11,18,19] and 500 cm^{-1} for three modes of librations on the average.[18,20],*1 The principal moments of inertia have been given to be the same as in the vapor state:[21] $A=1.024\times10^{-40}$, $B=1.921\times10^{-40}$, and $C=2.947\times10^{-40}$.

Calculations of Thermodynamic Variables. Using the values of parameters described above calculations of thermodynamic functions have been made over the temperature range from 0—100°C at 10°C intervals. The calculated values of the Helmholz energy, A, the internal energy, E, the entropy, S, and the specific heat at constant volume, C_V, are given in Table 1, and are plotted against temperature in Fig. (1)—(4). The results calculated are compared with the experimental data for water, which are taken from Dorsey.[11,22] The agreement between the observed and the calculated results is very good for the free energy, and is fairly good for the internal energy and the entropy. The values of E and S calculated are a little larger than the observed. The maximum deviation in the energy is 300 cal/mol, which amounts to 10% of the observed, and that in the entropy is 0.8 e.u., which is 4.7% of the observed. The agreement is found to be better at higher temperatures than at lower temperatures for A, E, and S. The circumstances are a little different for the specific heat, C_V. The curve calculated is found to cross at about 40°C with the experimental curve. The maximum percent deviation in C_V is 17%, which is observed at the boiling point. The agreement between the calculated and the observed specific heat is, however, better than for the curve given by Némethy and Scheraga's theory,[11] as it is seen in Fig. 4.

The magnitude of the mole fraction x has been calculated from Eq. (3), and given in Table 2, together with those given by Némethy and Scheraga,[11] and Buijs and Choppin.[23]

Molar Volume of Water. Concerning the molar volume of water, we assume that it is represented by the linear summation of the volume

Discussions

As seen in Figs. (1)—(5), the results of calculations are found to be satisfactory on the whole, taking into account the simplicity of the model used. This fact supports the idea that the two state model used is an adequate representation of the structure of liquid water in order to describe the thermodynamical behavior. And it is also concluded that thermodynamic data are not sensitive to the detailed structure of each class and are governed by the average character on the whole.

Recently, Eyring and coworkers have proposed the significant structure theory for water.[21,24,26] The earlier theory proposed by Marchi and Eyring[21] used a two state model, but the monomer concentration at the melting point calculated was only 2.5 mol %. This is unreasonably small. The later theory presented by Jhon, Grosh, Ree, and Eyring[24] was a three state theory which assumed that water consists of Ice-I-like structure, Ice-III-like structure, and monomers. The agreement to experimental data was certainly improved in the latter theory,[24] compared with that in the former theory.[21] However, additional assumptions were introduced into the latter theory.

The theory of Némethy and Scheraga may be said to be successful in the approximate description of thermodynamical behaviors of water. However, in the results calculated it is seen that several problems are found left unsolved in addition to the deviation of the magnitude of specific heat from the observed data. The one is the abnormally small magnitude of the mole fraction of di-hydrogen-bonded species, which is unreasonable.[12] Further studies are required.

In the present theory the ice-like structure (class I) is regarded as a uniform state on the average without any further assumption to its structure. Though the present theory has turned out to be successful for the description of thermodynamical behaviors of water, it is, of course, necessary to introduce a further structural assumption concerning the structure of the ice-like region in order to describe the various kinds of relaxational behaviors. From the view-point of relaxational process, it has been proposed, as pointed out by Frank and Wen,[10] that the ice-like structure is composed of flickering clusters.[10,11] It is impossible to determine the size of clusters, exactly speaking, the distribution of the cluster size in the ice-like portion, using the theory based on the two state model which consists of each uniform-structure region, as in the present theory. For the purpose of determining the cluster size the introduction of third state, "the surface state on the cluster" is required, and the investigations by authors along this line are proceeding.

As for the calculation of the partition function concerning f_I (Eq. (9)), the frequency assignment used is, of course, an oversimplification, though the exact assignment has not been determined at

*2 The magnitude of V_{II} corresponds to the molar volume of spherical molecules with the diameter of 3.2 Å, arrayed in b.c.c. lattice, where the void fraction is assumed to be about 10%.

present. This deficiency will be supplemented in the further investigations.

Conclusion

A statistical thermodynamic theory based on the two state model has been successfully applied to liquid water. The two state model firstly proposed by Hall turned out to be an adequate description to the thermodynamical behaviors of water, in spite of its simplicity.

We wish to thank to Miss Yuko Endo for her cooperation in performing this study.

Anomalous Viscosity of Bitumen Solutions and the Agglomeration of "Molecules"

Katsuya INOUYE,* Junichi TATSUTA*1 and Tsutomu SAKABE**

* *Department of Chemistry, Faculty of Science, Chiba University, Chiba*

** *Resources Research Institute, Kawaguchi*

(Received April 30, 1968)

The flow property of catechol and phenol solutions of 14 bitumen fractions was examined by means of a horizontal viscometer to compare with the molecular weight values of the fractions determined in each solvent. The catechol solutions showed Newtonian flow which corresponds to the homogeneous solutions containing molecules of a limited value of molecular weight. The molecular weight from phenol solutions varies with the fractions, and all fractions showed non-Newtonian (structural) viscosity. The experimental results indicated that bitumens in phenol agglomerate to different extent particular to each fraction. It was presumed that the stress destroys the agglomerated state to a monodisperse state, which is gradually recovered to the original state on standing. It was noted however that the unit particle (or molecule) composing each fraction is not identical in the apparent size in phenol, but varies with fractions.

It has been well recognized that the apparent molecular weight of bitumen fractions extracted from coals or hydrogenated coals showed values within the limited range of 200 to 350, when determined cryoscopically in catechol.[1,2] The fact has consequently led to the concept that the coal or bitumen as coal component is composed of "molecules" of molecular weight of approximately 300. The apparent molecular weight determined by use of other solvents, however, gives different values with fractions. For example, the molecular weight obtained by Weiler *et al.*,[1] determined from the boiling-point elevation of benzene solutions and the freezing-point depression of diphenyl solutions vary considerably with the fractions.

The problem has not been solved if the coal "molecules" of an identical size exist, which may form, in particular situations, their aggregated clusters, or if the varying molecular weights indicate continuously differing dimensions of coal constituting substances.

The present work intends to ascertain the existence of the aggregated state of bitumen "molecules" in the specific solvent by determining the viscosity behavior of the solution. The Newtonian viscosity would be observed, if the "molecules" of the same size or covalently bonded particles of different sizes are dissolved in a solvent, while an anomalous (non-Newtonian) viscosity would appear due to the breaking-down of apparent aggregates with the shear stress in the course of the viscosity measurement.

Experimental

a) Materials. The preparation of fractions has been described in a preceding paper.[3] A Japanese bituminous coal (Yubari) of 83% carbon was ground under 60 Tyler meshes and extracted with benzene

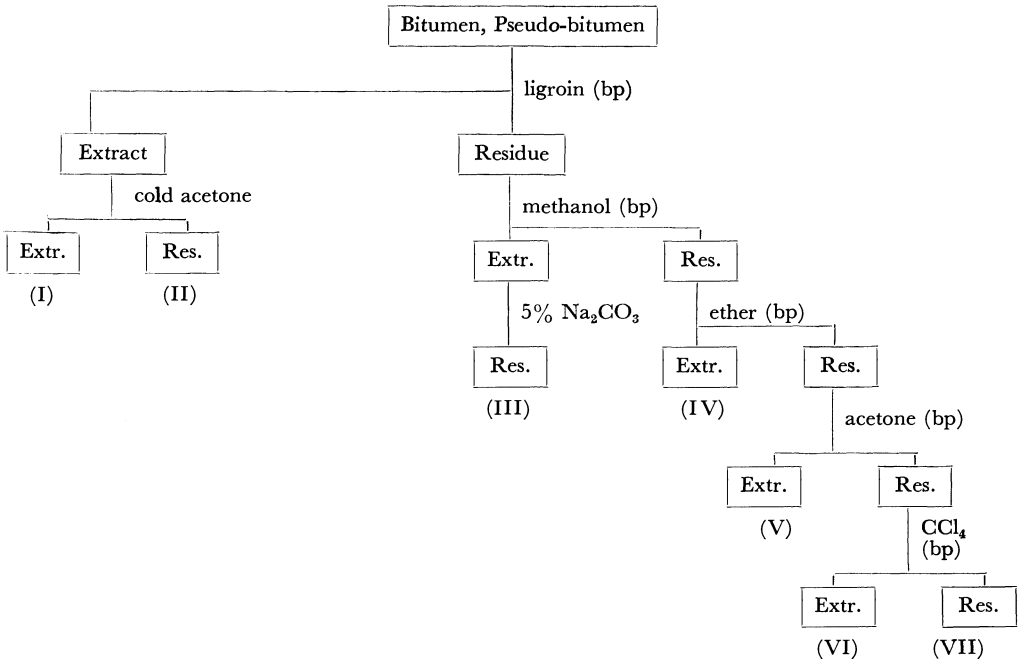

Fig. 1. Fractionation of bitumen and pseudo-bitumen.

at 220—260°C for 15 hr in total in a rotating autoclave. The solid bitumen from the extract, washed repeatedly with petroleum ether, was 7.0% of the original coal (dry-ash-free basis).

The residue of the above extraction was then subjected to catalytic hydrogenation in the autoclave with decalin in the presence of Adkins Ba-Cu-Cr oxide catalyst at 350°C for 6 hr and the initial hydrogen pressure of 100 atm. The product was extracted with benzene at 260°C for 9 hr in total, followed by the separation from the solvent. The pseudo-bitumen obtained was 50.7% of the original coal.

The bitumen and pseudo-bitumen thus obtained were fractionated successively by use of ligroin, methanol, ether, acetone and carbon tetrachloride to give the fractions shown in Fig. 1. Each of the seven fractions from bitumen and pseudo-bitumen is denoted respectively as B-I, -II, -III, -IV, -V, -VI and -VII and PB-I, -II, -III, -IV, -V, -VI and -VII.

Various properties (melting point, ultimate analysis, iodine value, true density, ultraviolet absorption, X-ray diffraction and diamagnetic susceptibility) of the similar fractions have been reported elsewhere.[3]

b) Molecular Weight. The cryoscopic molecular weight in phenol solvent was determined for 4 to 5 solutions of different bitumen concentrations in the range of 0.5 to 2.0%, with much care of avoiding moisture. The melting-point depression value at the zero concentration was obtained by the least-square method. In the case of catechol solvent, the method by Smith and Howard[4] was employed. The molecular depression of 59 was used for the molecular weight calculation.

c) Viscosity Measurement. The viscometer used in this work is a slightly modified Tsuda horizontal viscometer,[5] shown in Fig. 2, with a capillary of 0.5 mm

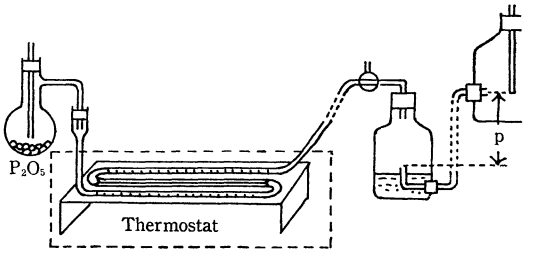

Fig. 2. Horizontal viscosimeter.

inner diameter and 20 cm length. Apart from the original Tsuda viscometer, the moisture absorption into sample solutions was carefully avoided by connecting it with a drying vessel containing P_2O_5.

The absolute viscosity determined by the present viscometer of phenol and catechol was 4.949×10^{-2} poise at 41.0 ± 0.5°C and 3.11×10^{-2} poise at 105 ± 0.5°C, respectively. In case of the determination using catechol solvent, the viscometer was submerged in a liquid-paraffin thermostat.

The time (t) required for 1 cc sample solution to flow through the capillary was measured at various pressure differences (p) supplied from two large water containers, as also schematically illustrated in Fig. 2.

For Newtonian liquids the following relationship is applied:

$$tp = \text{constant.} \quad (1)$$

The product tp is, therefore, independent of p. According

5) S. Tsuda, *Kolloid-Z.*, **45**, 325 (1928).

to Ostwald,[6] the non-Newtonian "structural" viscosity is well expressed by

$$tp^n = \text{constant } (k), \qquad (2)$$

where the tp value decreases with the increase of p in characteristic manner to the state of secondary "structure" of colloidal particles in the solution. The relationship between log t and log p, which is to be linear, gives the values of n and the constant k in Eq. (2).

Results and Discussion

a) Viscosity of Bitumen Solutions in Catechol. The *pt-p* relationships of catechol solutions in each case gave an identical result that the product *pt* is independent of *p* and consequently that bitumen solutions in catechol show the Newtonian flow.

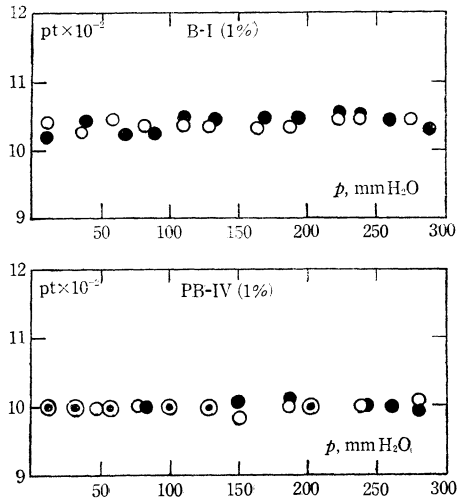

Fig. 3. The *pt-p* relationships of catechol solutions.

Figure 3 shows those of 1.0% solutions of B-I and PB-IV fractions determined at 105±0.5°C. The measurement was performed, at first, in increasing pressure (○), followed then by decreasing pressure (●); no departures were observed between values in the elevating and reversed pressure changes. The results also would indicate the absence of any agglomerates in the solutions.

TABLE 1. ABSOLUTE VISCOSITY AND MOLECULAR WEIGHT OF CATECHOL SOLUTION (1%)

Sample	Absolute viscosity (η), poise	Molecular weight
B-I	3.29×10^{-2}	330
B-VII	3.38×10^{-2}	280
PB-I	3.23×10^{-2}	320
PB-IV	3.23×10^{-2}	360
PB-VII	3.38×10^{-2}	300

6) Wo. Ostwald, *Kolloid-Z.*, **36**, 99 (1925).

Table 1 gives the absolute viscosity calculated from *pt* values at $p=0$ for the solutions of some fractions with respect to the molecular weight determined cryoscopically in catechol solvent. The molecular weight in catechol solvent appears to represent, as discussed by Dryden[2] and Sakabe *et al.*,[3] a more or less degradated state, although the elucidation has not fully been given on the reason why a value of around 300 is usually found.

b) Viscosity of Bitumen Solutions in Phenol. The *pt-p* curves given by the phenol solutions determined at 41±0.5°C, were those of typically non-Newtonian structural viscosity for each solution. There are, however, three types of curves (A, B and C) as illustrated in Fig. 4 as examples. In Type A, the change of *pt* with increasing pressure (○) is almost exactly similar to that with decreasing pressure (●). For the samples of Types B and C, curves of reversed directions do not coincide, but the *pt* values in pressure change of decreasing direction are more or less lower than those in increasing direction. Particularly in Type C, the above mentioned discrepancy is quite apparent so as to indicate that the "structure" in the solution is completely destroyed by the foregoing application of the shearing stress.

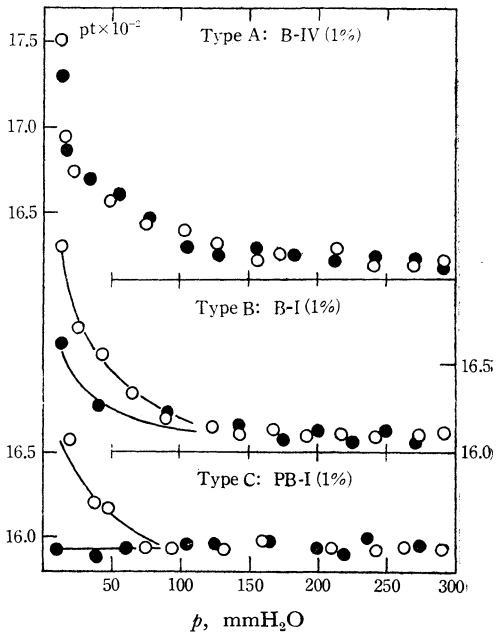

Fig. 4. The *pt-p* relationships of phenol solutions.

If the solutions of Types B and C are subjected to stand at the same temperature after the end of measurement, in other words, after supposed breaking of the secondary structure, the *pt* value increases gradually with the standing time up to the original high value in 24 hr, suggesting that

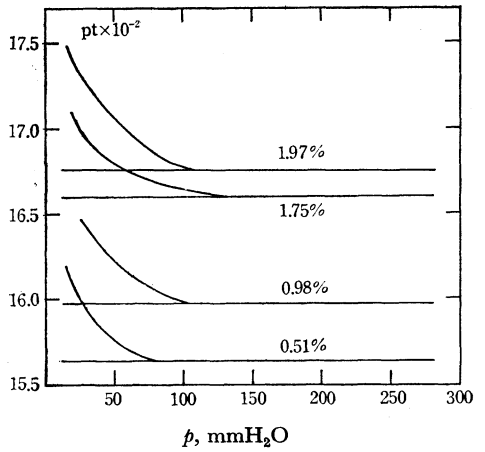

Fig. 5. The variations of *pt-p* relations with concentrations of phenol solutions; sample: PB-I.

Table 2. Absolute viscosity, n, k and molecular weight of phenol solutions (1%)

Sample	Absolute viscosity (η), poise	n	k	Molecular weight
B-I	5.19×10^{-2}	1.01	3.23	347
B-II	5.28×10^{-2}	—	—	350
B-III	5.23×10^{-2}	1.04	3.25	406
B-IV	5.22×10^{-2}	1.05	3.28	522
B-V	5.22×10^{-2}	1.04	3.26	638
B-VI	5.31×10^{-2}	1.08	3.31	1085
B-VII	5.34×10^{-2}	1.08	3.33	1359
PB-I	5.12×10^{-2}	1.03	3.24	396
PB-II	5.21×10^{-2}	1.03	3.25	590
PB-III	5.20×10^{-2}	—	—	392
PB-IV	5.25×10^{-2}	1.04	3.26	539
PB-V	5.34×10^{-2}	1.03	3.26	623
PB-VI	5.32×10^{-2}	1.06	3.30	1085
PB-VII	5.32×10^{-2}	1.09	3.35	1139

the once destroyed structure is ultimately recovered, but in a rather slow process.

Figure 5 gives the influence of concentration on the viscosity behavior (*pt-p* relation) in the case of PB-I fraction. It is suggested that the shape of *pt-p* curve is identical and that the viscosity calculated from *pt* at the non-structural state increases with the concentration.

The values of absolute viscosity (η), n and k in Eq. (2) are tabulated in Table 2 with respect to the molecular weight. Values given were obtained from measurements for the 1% solutions. Values of n are nearly equal to unity, but both the values n and k tend to increase with the molecular weight. It appears that the molecular weight approaches to a value around 300, when n approaches to unity. This result would be plausible, if one assumes that the molecular weight is measured at a state in which agglomerates are incompletely destroyed by the stirring during the course of cryoscopic measurement.

The absolute viscosity, increasing with the molecular weight, is also characterized by the following results. Table 3 gives the η values at different concentrations for some selected fractions as well as the intrinsic viscosity $[\eta]$. Once again, the increase of $[\eta]$ with molecular weight is observed. The linear relationship between $[\eta]$ and the molecular weight, accepted generally for chain polymers, can not however be applied in the present case.

The results shown in Table 3 are also expressed in a different manner. From concentration and pycnometric true density measured at 25.0°C in methanol, the volume fraction (ϕ) occupied by the bitumen was calculated and inserted in the following Einstein equation[7]:

$$\eta = \eta_0(1+\alpha\phi). \quad (3)$$

The value of α obtained from the inclination of linear relationships between η and ϕ, is also

Table 3. Variation of absolute viscosity with concentration of phenol solutions, intrinsic viscosity ($[\eta]$) and Einstein constant (α)

Sample	Molecular weight	Concentration, %	Absolute viscosity (η), poise	Intrinsic viscosity ($[\eta]$), poise	Einstein constant (α)
PB-I	396	0.51	5.02×10^{-2}	3.0×10^{-2}	2.5×10^{-3}
		0.98	5.12×10^{-2}		
		1.75	5.32×10^{-2}		
		1.99	5.37×10^{-2}		
PB-IV	539	0.50	5.07×10^{-2}	5.2×10^{-2}	4.1×10^{-3}
		1.02	5.25×10^{-2}		
		1.52	5.39×10^{-2}		
		2.01	5.54×10^{-2}		
PB-VII	1139	0.50	5.18×10^{-2}	6.8×10^{-2}	5.2×10^{-3}
		1.00	5.32×10^{-2}		
		1.51	5.50×10^{-2}		
		1.99	5.71×10^{-2}		

7) *Cf.* M. Reiner, "Deformation and Flow," H. K. Lewis and Co., London (1949), Chapt. 4.

given in Table 3. The η_0 observed graphically from the similar linear relations at $\phi=0$ was 4.90×10^{-2} poise, which is coincident with the viscosity of pure phenol (4.949×10^{-2} poise).

All these results described above strongly suggest that bitumens in phenol, contrary to the cases of catechol solutions, agglomerate to different extent particular to each fraction. It is generally recognized that the application of shearing stress by the flow dissociates the agglomerated state easily into a monodisperse state, which may be recovered to the original state on standing.

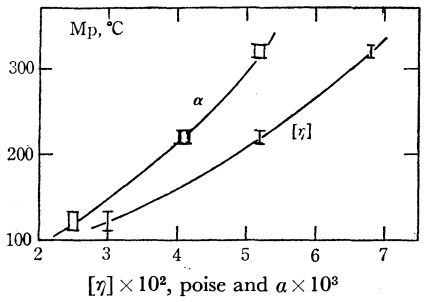

Fig. 6. The increase of melting temperature with intrinsic viscosity and Einstein constant.

However, it is noteworthy that there is no constancy in the values of n and k in Table 2 as well as more apparently of α in Table 3 for different fractions. The fact that these constants show in each case the same tendency to increase with the increase of molecular weight seems to indicate that the unit particle composing each fraction is not identical in the apparent size, but varies from a fraction to another. The increasing tendency described above would mean that the apparent particle size is larger for the fraction which gives larger molecular weight. Also referring to the previously published data,[3] the softening (melting) temperature is almost linearly related with $[\eta]$ and α, as shown in Fig. 6.

It is concluded therefore that the variation of molecular weight obtained by use of phenol solvent is caused partly by the agglomeration of unit particles and partly by the variation of dimension of unit particle. It seems apparent that the dimension of unit particle is larger for the fractions showing larger molecular weights in phenol, and therefore that the molecular weight by phenol is more relevant to the ultimate state of bitumens.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 312—318 (1969)

The Catalytic Activity of Onium Compounds in the Homogeneous Liquid Phase Oxidation of Cumene and α-Pinene

Kenichi FUKUI, Katsutoshi OHKUBO and Tokio YAMABE

Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto

(Received May 29, 1968)

The catalytic activity of onium compounds was studied in the homogeneous liquid phase oxidation of cumene and α-pinene. The onium salts, particularly sulfonium, phosphonium, selenonium, arsonium and telluronium were found effective. This result is connected to the fact that the central atom in these onium has vacant d orbitals. Among the anions of the onium salts tested, phosphate and sulfate were most effective. The aryl substituents in the central sulfur in sulfonium lessened the activity, while alkyl substituents made it greater. These facts were attributed to charge migration from the substituents and the anionic part to the central atom.

In earlier papers,[1,2] it was reported that phosphonium and sulfonium halides were effective catalysts in the liquid phase oxidation of hydrocarbons such as tetralin, cumene and *p*-xylene, and that the activity of these catalysts was dependent upon the kind of halogen anions involved. Phosphonium and sulfonium tetrafluoroborates were not as effective as halides. Bredereck[3] also reported a similar effect of halogen anions in tetralin oxidation by several alkyl ammonium salts.

It was found later, however, that phosphate and sulfate anions of sulfonium salt were in some cases more active than halogen anions. In addition, the previous papers[1,2] had not discussed the effect of

1) K. Fukui, K. Kanai, T. Takezono and H. Kitano, *Kogyo Kagaku Zasshi* (*J. Chem. Soc. Japan, Ind. Chem. Sect.*), **67**, 1131 (1964).

2) K. Kanai, K. Ohkubo, H. Kitano and K. Fukui, *Bull. Japan Petr. Inst.*, **7**, 52 (1965).

3) H. Bredereck, A. Wagner, R. Blascke, C. Demetriades and K. G. Kottenhahn, *Chem. Ber.*, **92**, 2628 (1959).

the structure of əɥ cation part of onium salts From this point, it was hoped to reinvestigate the catalytic activity of these onium salts in more detail.

It was attempted in the present paper to clarify mainly the role of the cation part of various onium salts in their catalytic action, in connection with the mechanism of interaction of onium catalysts with the oxygen molecule.

In order to investigate the effect of the cation part, the homogeneous liquid phase oxidation of cumene and α-pinene in the presence of tetrafluoroborates of the following oniums was carried out; carbonium, ammonium, oxonium, silyl, phosphonium, sulfonium, arsonium, selenonium and telluronium. The silyl compound was added to the group of onium compounds for comparison's sake. The central atoms of these oniums and their lowest vacant atomic orbitals which might play an important role in interaction with the oxygen molecule (discussed later) are listed in Table 1.

Table 1. The lowest vacant atomic orbitals of central atoms of onium ions

C (2p)	N (3s)	O (3s)
Si (3p)	P (4s, 3d)	S (4s, 3d)
	As (5s, 4d)	Se (5s, 4d)
		Te (6s, 5d, 4f)

It was found that, in these onium salts, phosphonium, sulfonium, selenonium, arsonium, and telluronium were effective; in particular, the first three were outstanding. These compounds are characterized in that the central atoms possess low-lying vacant d orbitals. The order of activity of these onium salts as compared with those with central atoms of elements in the same row of the periodic table was the following:

$$\text{carbonium} < \text{ammonium} < \text{oxonium}$$

$$\text{silyl} < \text{phosphonium} \simeq \text{sulfonium}$$

$$\text{arsonium} (\simeq \text{telluronium}) < \text{selenonium}$$

In order to investigate the effect of the anion part of onium salts, the oxidation of cumene was carried out with various triphenylsulfonium salts as catalysts, such as phosphate, sulfate, nitrate, chromate, perchromate, *etc.* It was found that triphenylsulfonium phosphate and sulfate were more effective than triphenylsulfonium halides in the initial step of oxidation. Furthermore, the effect of substituents of the cation part was investigated using a series of sulfonium tetrafluoroborates. Finally, the mechanism of this homogeneous oxidation with particular reference to the interaction between molecular oxygen nda catalysts was discussed.

Experimental

Material and Method of Oxidation. Cumene was washed with conc. sulfuric acid and dried with anhydrous magnesium sulfate, then distilled to collect the fraction (bp 152.0—152.5°C) which was used for oxidation. α-Pinene was distilled to obtain the 155—156°C fraction. The distillate (10 m*l*) was warmed in the presence of onium salts (0.03 mmol) to 85°C in a nitrogen atmosphere before charging with oxygen. The almost homogeneous solution obtained was subjected to oxidation with the same apparatus and in the same way as reported in a previous paper.[1]

Catalysts. *Triphenylcarbonium Tetrafluoroborate.* Equimolar amounts of triphenylmethyl chloride and silver tetrafluoroborate were mixed in ethyl alcohol and stirred for about 5 hr to form a precipitate of silver chloride. After filtering the precipitate, the filtrate was evacuated to separate reddish yellow crystals of triphenylcarbonium tetrafluoroborate (yield 62%) melting at 207—210°C (dec.).

Found: C, 32.1; H, 6.29%. Calcd for $C_{18}H_{15}CBF_4$: C, 32.4; H, 6.10%.

Tetraethylammonium Tetrafluoroborate. After an equimolar mixture of triethyl amine and ethyl bromide was left standing for about a day in ethyl acetate, a precipitate of tetraethylammonium bromide was obtained, which was filtered and dried *in vacuo*, then, an equimolar mixture of tetraethylammonium bromide and silver tetrafluoroborate was similarly treated to obtain hygroscopic colorless crystals of tetraethylammonium tetrafluoroborate.

Found: C, 44.3; H, 9.22; N, 6.92%. Calcd for $C_8H_{20}NBF_4$: C, 44.2; H, 9.43; N, 6.79%.

Triphenyloxonium Tetrafluoroborate. Phenyldiazonium tetrafluoroborate (10. 5 g) and diphenyl ether (150 g) were refluxed in acetone (300 m*l*) at 80—90°C for half an hour and the solution quenched. The resulting precipitate was dried *in vacuo* to obtain colorless crystals (recrystallized from acetone and ether), melting range between 226 and 227°C (dec.).

Found: C, 28.3; H, 6.17%. Calcd for $C_{18}H_{15}OBF_4$: C, 28.5; H, 6.19%.

Triphenylsilyl Tetrafluoroborate. Tetrachlorosilane (5.7 g) was added to an ether solution of phenylmagnesium bromide (18.1 g) and the mixture refluxed to obtain colorless crystals of triphenylchlorosilane (90% yield), melting at 110—111°C, and equimolar quantities of triphenylchlorosilane and silver tetrafluoroborate were treated in the same way as mentioned above to obtain colorless crystals which were recrystallized from ether and ethyl acetate, mp 314—315°C.

Found: C, 62.4; H, 4.33%. Calcd for $C_{18}H_{15}SiBF_4$: C, 62.1; H, 4.35%.

Triphenylsulfonium-, Tetraphenylphosphonium-, Triphenylselenonium-, and Triphenyltelluronium Tetrafluoroborates. These onium salts were prepared by methods similar to those reported in a previous paper.[4]

4) T. Hashimoto, M. Sugita, H. Kitano and K. Fukui, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **88**, 991 (1967).

Compound	Appearance	Mp (°C)	Found		Calcd	
			C (%)	H (%)	C (%)	H (%)
$(C_6H_5)_3S$-$\frac{1}{3}PO_4$	Colorless needles	201—201.5	72.2	5.09	72.0	5.11
$(C_6H_5)_3Se$-$\frac{1}{3}PO_4$	Colorless crystals	178—178.5	63.2	4.39	62.9	4.42
$(C_6H_5)_3Te$-$\frac{1}{3}PO_4$	Colorless crystals	240—240.5	60.5	4.20	60.1	4.41

Triphenylsulfonium-, Triphenylselenonium- and Triphenyltelluronium Phosphate. Twenty milliliters of an aqueous solution of potassium phosphate (0.4 mmol) were added to ethyl alcohol (200 m*l*) solutions of triphenylsulfonium, triphenylselenonium and triphenyltelluronium tetrafluoroborates (1 mmol), and the solutions kept standing for about 24 hr. The precipitates of potassium tetrafluoroborate were filtered off, and the filtrates evacuated in a nitrogen atmosphere. The raw crystals were recrystallized from chloroform and ether. Their appearances and analytical data are listed above.

Tetraphenylphosphonium and Triphenylsulfonium Chlorides. These chlorides were prepared as in previous papers.[1,5] Their appearances and analytical data are listed in the following.

Compound	Appearance	Mp (°C)	Found Cl (%)	Calcd Cl(%)
$(C_6H_5)_4PCl$	Colorless needles	271—272	9.6	9.5
$(C_6H_5)_3SCl$	Colorless needles	297—298	11.6	11.9

Tetraphenylarsonium Tetrafluoroborate. 41.9 g of tetraphenylarsonium chloride (colorless crystals melting at 256—257°C) and 19.47 g of silver tetrafluoroborate were treated similar to the sulfonium fluoroborates. Colorless crystals were obtained, melting at 318—319°C. Found: BF_4, 23.0%. Calcd for $C_{24}H_{20}AsBF_4$: BF_4, 23.4%.

Triphenylsulfonium Nitrate and Tetraphenylphosphonium Nitrate. These salts were prepared by a method similar to that given in a previous paper.[4] The former consisted of colorless needles melting at 225.5—226°C. (Found: C, 66.7; H, 4.71; N, 4.0%. Calcd for $C_{18}H_{15}SNO_3$: C, 66.4; H, 4.65; N, 4.3%), and the latter of colorless crystals melting at 283—284°C. (Found: C, 71.9; H, 5.1; N, 3.7%. Calcd for $C_{24}H_{20}PNO_3$: C, 71.8; H, 5.0; N, 3.5%.)

Triphenylsulfonium Salts. Triphenylsulfonium tetrafluoroborate and potassium salts were treated similar to triphenylsulfonium phosphate. The raw crystals were recrystallized from chloroform and ether. Triphenylsulfonium salts ($(C_6H_5)_3SX$) obtained are described below.

Alkyldiphenylsulfonium Tetrafluoroborate. Equimolar amounts of diphenyl sulfide and silver tetrafluoroborate were kept standing at room temperature to precipitate dark brown crystals which were dried *in vacuo*. Hygroscopic dark brown crystals of diphenyl sulfide-silver fluoroborate complex (90% yield) were obtained which melted at 54—55°C (dec.). (Found: C, 38.5; H, 2.5%. Calcd for $C_{12}H_{10}SBF_4Ag$: C, 37.9; H, 2.6%.) Alkyl iodide (0.08 mol) was added to an ethylene chloride solution of the complex (0.056 mol). The solution was stirred for *ca.* 2 hr at room temperature and left standing overnight to precipitate silver iodide which was removed. After the solvent was removed from the nitrogen atmosphere, crystals were obtained which were recrystallized from chloroform and ether. The products are listed below.

$(C_6H_5)_2RSBF_4$ R	Yield (%)	Mp (°C)	BF_4 Found (%)	BF_4 Calcd (%)
CH_3	44	61—62	30.5	30.9

5) K. Fukui, K. Kanai and H. Kitano, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **82**, 178 (1961).

to an ethylene chloride solution of equimolar (0.056 mol) amounts of silver tetrafluoroborate and benzylphenylsulfide or dibenzylsulfide. The mixture was treated similar to alkyldiphenylsulfonium tetrafluoroborate, and the following sulfonium tetrafluoroborates obtained: $C_6H_5CH_2(CH_3)(C_6H_5)SBF_4$ melting at 126.5—127.5°C (Found: BF_4, 28.6%. Calcd for $C_{14}H_{15}SBF_4$: BF_4, 29.1%) and $(C_6H_5CH_2)_2CH_3SBF_4$ melting at 214—215°C. Found: BF_4, 29.1%. Calcd for $C_{13}H_{17}SBF_4$: BF_4, 29.7%.

Phenyl-bis-(p-fluorophenyl) sulfonium Tetrafluoroborate. Equimolar quantities of phenylmagnesium bromide and di-*p*-fluorophenylsulfoxide were refluxed in benzene for *ca.* 2 days to precipitate phenyl-bis-(*p*-fluorophenyl) sulfoxymagnesium bromide. The precipitates were triturated with 20% hydrogen tetrafluoroborate and after extraction of the benzene phase by chloroform, followed by the removal of chloroform and recrystallization from chloroform and ether, colorless crystals of phenyl-bis-(*p*-fluorophenyl) sulfonium tetrafluoroborate were ob tained, melting at 185—186°C. Found: BF_4, 22.1%. Calcd for $C_{18}H_{13}SBF_6$: BF_4, 22.5%.

Tribenzylsulfonium Tetrafluoroborate. An equimolar mixture of benzylmagnesium bromide and dibenzylsulfoxide was refluxed in benzene and treated similar to phenyl-bis-(*p*-fluorophenyl)sulfonium tetrafluoroborate. Colorless crystals of tribenzylsulfonium tetrafluoroborate were obtained. Mp 177.5—178.5°C. Found: BF_4, 21.8%. Calcd for $C_{21}H_{21}SBF_4$: BF_4, 22.1%.

Results

The Effect of the Central Atom of the Onium Cation. In order to investigate the effect of a difference in nature of the central atom of the onium cation, the liquid phase oxidation of cumene and α-pinene (10 m*l*) was carried out at 85°C in the presence of 0.03 mmol of triphenyl- or tetraphenyl-onium tetrafluoroborate (except for ammonium, where the tetraethyl derivative was taken), and the amounts of the following main products were determined; cumene hydroperoxide (CHP), dicumyl peroxide (DCP), acetophenone (AP) and α-cumyl alcohol (α-CA) in cumene oxidation products, and hydroperoxides (HPO) containing myrtenyl-, verbenyl- and pinocarveyl hydroperoxides and verbenone (VN) in α-pinene oxidation products. Catalysts used and oxidation products are listed in Tables 2 and 3.

Table 2. The effect of the difference in the onium central atom on cumene oxidation
(Reaction temp.: 85°C, Reaction time: 4.0 hr)

$(C_6H_5)_4PBF_4$	2.0	4.58	0.89	100
$(C_6H_5)_3SBF_4$	2.0	5.82	0.97	99.9
none	3.0	3.21	0.34	31.2

In these and subsequent tables, the percentage of a product (for instance, CHP (%) in Table 2) is defined by

$$\frac{\text{moles of the product cocerned}}{\text{total moles } O_2 \text{ absorbed}} \times 100$$

But in the case of DCP (%), the percentage is defined by

$$\frac{2 \times \text{moles of the product concerned}}{\text{total moles } O_2 \text{ absorbed}} \times 100$$

All products were analyzed according to a procedure similar to that described in the preceding paper. Since all products except DCP mentioned here are formed in the equimolar consumption of oxygen molecules, the total sum of such percentages must be nearly one hundred, as seen in each table.

The approximate order of catalytic activity of these onium tetrafluoroborates was determined as the combined results of cumene and α-pinene oxidations as follows: carbonium<ammonium<oxonium, silyl<phosphonium<sulfonium, arsonium≃telluronium<selenonium. This order was defined by the total sum of oxygen absorbed which almost paralleled the maximum reaction rate at the propagation step, as seen in Tables 2 and 3.

In order to investigate further the effect of the cation central atom, the oxidation of cumene (10 m*l*) was carried out in the presence of tetraphenylphosphonium nitrate and triphenylsulfonium nitrate (0.03 mmol), and α-pinene (10 m*l*) oxidation by triphenylsilyl, tetraphenylphosphonium, triphenylsulfonium and tetraphenylarsonium chlorides (0.03 mmol). The results are listed in Tables 4 and 5.

The oxidation of cumene (10 m*l*) was also carried out with triphenylsulfonium triphenylselenonium and triphenyltelluronium phosphates (0.03 mmol). The results are presented in Table 6.

In these phosphates, the order of activity was found to be the following: sulfonium>selenonium>telluronium. As seen in Table 6, phosphates exhibited remarkable activity in oxygen absorption.

The Effect of Substituents of the Onium Cation. It is of interest to examine the effect of substituents of the onium cation in connection with knowledge on the nature of the reaction mechanism. The oxidation of α-pinene (10 m*l*) was carried out with sulfonium tetrafluoroborates (0.03 mmol) with

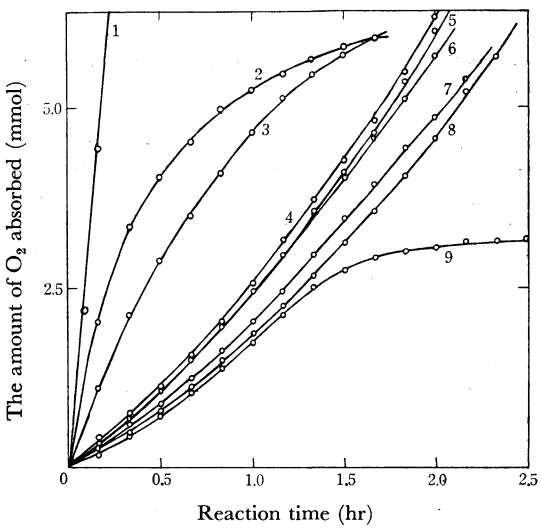

Fig. 1. The oxygen absorption curve of α-pinene the presence of sulfonium tetrafluoroborate $(R_1\text{-}(R_2)(R_3)SBF_4)$.

different alkyl or aryl substituents on the sulfur atom. The results are shown in Fig. 1. As shown in Fig. 1, the more aryl substituents attached to the sulfur atom, the lower the activity became.

The oxidation of α-pinene (10 m*l*) was also carried out with alkyldiphenylsulfonium tetrafluoroborates (0.03 mmol) in which the alkyl was methyl, ethyl, *n*-propyl or *n*-butyl at 85°C for 2.5 hr. The results given in Table 9 show that the larger the alkyl group, the higher the catalytic activity became.

The present reaction is a liquid phase (essentially homogeneous) oxidation in which the catalyst structure can be systematically varied, if desired. An investigation of the relation between the structure and the activity of catalysts is expected to supply a clue to the reaction mechanism on a molecular level. It is stressed in this connection that these onium catalysts are, in general, thermally stable and are little oxidized by oxygen molecules, so that we might conclude that they would not act as radical sources in these homogeneous liquid phase oxidations.*1

Discussion

Tables 2 and 3 indicate that the onium salts in which the central atoms are S, Se, Te, P and As are effective catalysts in the liquid phase oxidation of cumene and α-pinene. These atoms are characterized by the fact that they possess vacant d orbitals not far above their valence shells. In view of the widely known participation of d-orbital expansion in the chemistry of sulfur or related atom compounds,[6] it may be worth-while to examine the possibility of relating the outstanding activity of the onium salts to the interaction of their d orbitals.

The electronic state of the onium ion may be thought to be such that the electrons in surrounding alkyl or aryl groups are partially transfered to the spacially far-reaching vacant d orbitals, the energy of which is considerably lowered by the positive charge of the central atom. It is also probable that the anion might take part in this interaction since the "bond" between the anion and the cation part might reasonably be considered to have a more or less covalent nature.

The positive charge on the central atom may thus be partially neutralized by an inflowing electronic charge, and consequently the vacant d orbitals become partially occupied. The resulting electronic state of the onium central atom will, in part, resemble that of the transition metal atoms bearing d electrons properly and exhibiting a variety of catalytic activities in many heterogeneous catalyses.

In this connection, it is of interest to inspect the possibility of interaction between the "partially occupied" d orbital at the onium center considered above and the half-occupied, doubly-degenerate $1\pi_g$ molecular orbitals of the ground-state $^3\sum_g^-$ oxygen molecule. A mode of interaction will become probable when the orbital symmetry relationship becomes favorable.[7]

The circumstances are illustrated in Fig. 2, where the mode of interaction of the oxygen molecule is assumed parallel to the ligand plane. The d orbitals which can be utilized for interaction with O_2 are d_{xy} and d_{xz}. The latter, being of lower energy, would be able to partake in dp–σ type bonding through favorable orbital overlapping. The former d orbital will concern a more labile bond of a dp–π type, also contributing to the bonding interaction between onium and oxygen.

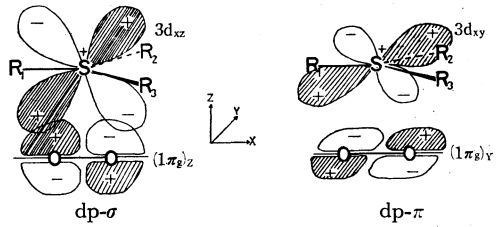

Fig. 2. The interaction between 3d orbital of sulfonium and $1\pi_g$ molecular oxygen.

First comes the depression of catalyst activity by the coexistence of a certain group of compounds which might be thought to possess a stronger affinity to sulfonium salts than molecular oxygen. It is well known[8] that sulfonium halides form stable trihalides in the presence of halogen molecules. Triphenylsulfonium iodide (mp 214—215°C (dec.)) or tetraphenylphosphonium bromide (mp 288—289°C (dec.)) does not initiate cumene oxidation at all at 85°C when used with an equimolar amount of iodine. Also, oxidation proceeding with these sulfonium halides stops completely upon the addition of equimolar iodine. Triphenylsulfonium

*1 In fact, more than 70% of catalysts were recovered from the reaction mixtures, and no appreciable amount of decomposed or oxidized products of catalysts was detected by gas chromatography. Triphenylsulfonium tetrafluoroborate decomposed gradually at 300—350°C to produce fluorobenzene, diphenylsulfide and boron trifluoride. But under the reaction conditions in the present paper, neither sulfide, sulfoxide nor fluorobenzene was detected by gas chromatography. The deactivation of catalysts by the addition of oxidation products was observed, which will be discussed in detail in a subsequent paper.

triiodide (brown crystals, mp 137—138°C) and tetraphenylphosphonium diiodobromide (brown crystals, mp 249—250.5°C) exhibited no activity as catalysts for cumene oxidation.

Such a remarkable deactivation is also seen in the employment of solvents bearing lone-pair electrons. Chloroform, dioxane or acetic acid used as solvent causes the activity of triphenylsulfonium salts to completely disappear. These results might come from the blocking effect of these additives against the interaction of the sulfur d orbital with molecular oxygen.

TABLE 9. α-PINENE OXIDATION BY THE USE OF ALKYL DIPHENYLSULFONIUM TETRAFLUOROBORATE
(Reaction temp.: 85°C, Reaction time: 2.5 hr)

none*	3.12	1.00	31.2	0.69	21.5

* Reaction time was 3.0 hr.

As understood from Fig. 1 and Table 9, the catalytic activity is affected by substituents on the sulfur atom. The mode of partial occupation of d orbital mentioned above may be influenced by substituents. The charge of a d orbital will be increased by electron-donor groups like methyl, ethyl, or larger alkyls attached to the central atom, whereas it will be decreased by such groups as phenyl or *p*-fluorophenyl, so that the interaction of a d orbital with an oxygen molecule may be weakened.

Second, the effect of the anion part should be mentioned. The tetrafluoroborates of such oniums as carbonium, ammonium and oxonium are less active than other onium salts mentioned above. This is probably because their ionic character is too large to transfer electrons from anion to onium, so that interaction between their vacant orbitals and molecular oxygen orbitals is only slight.

In this connection, it is interest to see the relation between the pK_1 value of the acid corresponding to the anion and catalytic activity. An apparent correlation is found in Fig. 3. A suitable range of acidity seems to exist, corresponding to a suitable range of covalent nature of the "bond" between the onium and anion parts.

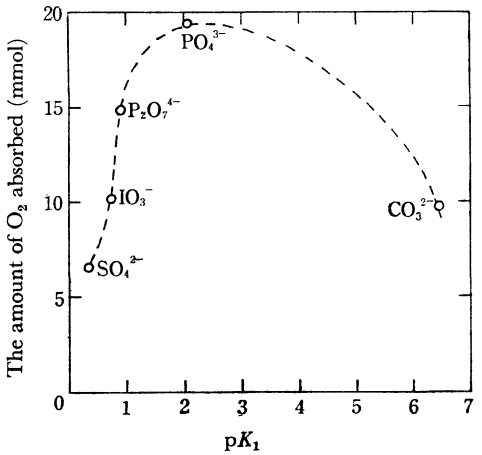

Fig. 3. The effect of pK_1 of the acid corresponding to the anion upon the catalytic activity of triphenylsulfonium salts.

Third, it should be noted that kinetic investigation also seems to favor the molecular oxygen association mechanism, the details of which will be reported in a subsequent paper. The reaction scheme required to satisfy the experimental results involves the interaction of molecular oxygen with the catalyst molecule.

Part of the cost of this investigation was defrayed by a Scientific Research Grant from the Ministry of Education, to which the authors' thanks are due.

The pNa Study of Sodium Alkyl Sulfates in Aqueous Solutions

Iwao SATAKE, Takashi TAHARA and Ryohei MATUURA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Fukuoka

(Received May 30, 1968)

The counter-ion activity coefficient of sodium alkyl sulfate with chain length from C_8 to C_{14} was determined in aqueous solutions and in the presence of added magnesium ion. The degree of association of sodium ion to the micelle (β) can be deduced from the concentration dependence of the counter-ion activity. The value of β so determined in the presence of magnesium ion was confirmed to decrease rapidly as the relative concentration of magnesium ion increases. The observed change of counter-ion activity with concentration was found to be interpreted in terms of a lameller micelle model.

The counter-ion activity coefficient in detergent solutions has recently been estimated by applying the membrane electrodes inclusive of the cation sensitive glass electrode. Botré *et al.*[1] used the membrane electrodes of both negative and positive types, and evaluated the degree of dissociation of micelles in aqueous solutions of sodium lauryl sulfate, sodium laurate and laurylamine hydrochloride. Shedlovsky *et al.*[2] used the sodium sensitive glass electrode for estimating the counter-ion activity in mixed solution of sodium alkyl sulfate with chain length from C_{10} to C_{14}. Feinstein and Rosano,[3] using the cationic glass electrode, determined the degree of dissociation of potassium and sodium carboxylate micelles at a constant cation concentration. Further, Stenius and Ekwall[4] obtained the sodium ion activity in a sodium caprylate solution by using the sodium responsive glass electrode.

Although the single-ion activity coefficient is a conventionally defined quantity in nature, the interpretation of which is subject to the same limitations as that of pH, it is of interest to estimate the counter-ion activity coefficient in detergent solutions in order to elucidate the degree of dissociation of the micelle and other related properties.

The present paper is concerned with the determination of counter-ion activities of sodium alkyl sulfates in aqueous solutions with and without added magnesium ion which is almost insensitive to the sodium glass electrode.

Experimental

In the present experiment, we used a Horiba pNa meter model N-5 with the following cell:

Na glass electrode | Detergent solution | N NH_4NO_3 | 3.33 N KCl agar bridge | Caromel electrode.

The detergents used were sodium alkyl sulfate with chain length from C_8 to C_{14}, prepared by the esterification of purified long chain alcohols.

It was rather difficult to obtain the reliable e.m.f. when the reference caromel electrode was directly immersed into the detergent solution, on account of the formation of potassium alkyl sulfate which is sparingly soluble in water at the temperature of experiment. The use of N NH_4NO_3 liquid junction, however, permits the precise determination of e.m.f. with an accuracy of ± 0.005 pNa unit. The whole system was maintained at constant temperature of 25°C for C_8 to C_{12} and 35°C for C_{14} and C_{12} with added magnesium ion.

The measurement on the system of sodium dodecyl sulfate (SDS) in salt solutions was performed at a constant mole ratio (R) of $MgSO_4$ to SDS throughout a series of experiment.

The sodium sensitive glass electrode was calibrated with a sodium chloride solution of known activity.[5,6]

Results and Discussion

In Figs. 1—4, the observed values of log a_+ are plotted against the logarithm of total analytical concentration (C) in mol/l of the detergent solutions. In all cases, plots of log a_+ *vs.* log C are nearly linear over the concentration range below the critical micelle concentration (CMC). In this concentration range, the apparent counter-ion activity coefficient (γ_+) defined by a_+/C might be expected to be comparable with that of simple

electrolyte, *e.g.* NaCl. The experimental fact is, however, not the case. The typical plot of log γ_+ *vs.* $C^{1/2}$ for sodium octyl sulfate (SOS) is given in Fig. 5 together with the value of $\gamma_\pm$ obtained for NaCl by Brown and MacInnes.[5] It will be noted that the value of γ_+ for SOS is considerably small relative to the mean activity coefficient of NaCl in an equivalent solution.

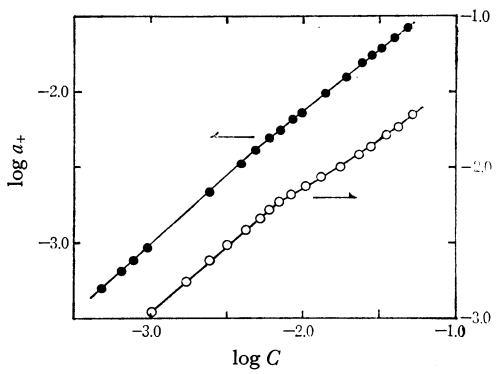

Fig. 4. The plots of log a_+ *vs.* log C for SDS at 35°C.
○: $R = 0.0957$, ●: $R = 0.299$

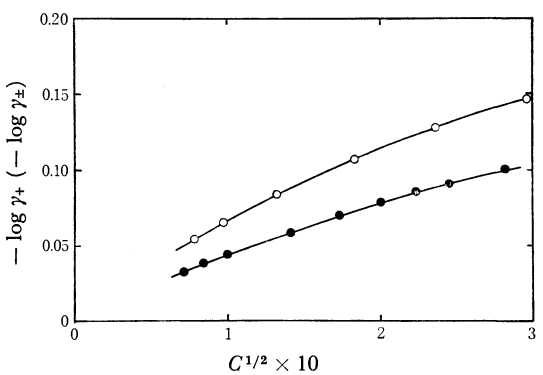

Fig. 5. The plots of $-\log \gamma_+$ *vs.* $C^{1/2}$ for SOS at 25°C.
○: SOS, ●: NaCl ($\gamma_\pm$)[5]

If the Debye-Hückel theory may also be applicable to detergent solutions, the observed deviation must be ascribed either to the increased ional concentration due to the formation of polyvalent aggregates or to the existence of undissociated detergent molecules, *i. e.*, neutral ion pairs. The critical interionic distance for ion pair formation of 1–1 electrolyte is 3.57 Å in water at 25°C. It is, therefore, rather doubtful to assume the formation of neutral ion pairs with such bulky ions as octyl sulfate.

Mukerjee *et al.*[7] suggested the existence of detergent dimer on the basis of conductivity measurement for SDS. In the present case, it is difficult to account for the observed reduction of γ_+ without assuming even higher order association of detergent anions than dimer, *e. g.*, the existence of detergent pentamer. It will be, however, reasonable to assume the existence of small aggregates in the dilute concentration range below CMC, though no conclusive evidence has yet been obtained for such

7) P. Mukerjee, K. J. Mysels and C. I. Dulin, *J. Phys. Chem.*, **62**, 1390 (1958); P. Mukerjee, *ibid.*, **62**, 1397 (1958).

a higher aggregate as pentamer.

The deviation from linearity appearing above the CMC suggests the low degree of dissociation of the micelle. In the presence of the added magnesium ion, a break at the CMC became more obscure as the value of R, the mole ratio of $MgSO_4$ to SDS, increased and no break could be detectable above $R=0.5$. This result indicates that the fraction of sodium ion bound at the micellar surface decreases rapidly as the relative concentration of magnesium ion increases.

In general, the equilibrium distribution of counter-ion is determined by the equality of the electrochemical potential of sodium ion in bulk phase and in the micellar surface region, so that

$$\bar{\mu}_b = \bar{\mu}_s \tag{1}$$

where

$$\bar{\mu}_b = \mu_b^0 + kT \ln a_+ + \varepsilon\psi_b \tag{2}$$

for sodium ion in bulk phase and

$$\bar{\mu}_s = \mu^0{}_s + kT \ln C_s + \mu_s^e \tag{3}$$

for sodium ion bound at the micellar surface. Here, ψ_b is the electrical potential of the bulk phase and ε is the electronic charge. μ_s^e is the electrical part of free energy and C_s is the concentration of bound sodium ion, both at the micellar surface region. We put $\psi_b=0$ according to the common practice. It follows from Eqs. (1), (2) and (3) that

$$\ln a_+ = (\mu_s^0-\mu_b^0)/kT + \ln C_s + \mu_s^e/kT. \tag{4}$$

Suppose that the micelle is lamellar and consists of m alkyl sulfate ions and $m\beta$ sodium ions bound at the micellar surface region V, giving the net charge $-m(1-\beta)\varepsilon$. Then we have

$$C_s = 1000\, m\beta/NV \tag{5}$$

and

$$\psi_s = -(kT/\varepsilon) \ln (2000\pi\sigma^2/DNkTC_b) \tag{6}$$

for the electrical potential at the outer part of Stern layer, where N is the Avogadro number, D the dielectric constant of the medium, σ the surface charge density of the micelle, and C_b the concentration of free sodium ion in the bulk solution, *i. e.*,

$$C_b = C_0 + (1-\beta)(C-C_0). \tag{7}$$

Here, C_0 is the CMC and C is the total analytical concentration of the detergent in mol/l. The expression for the electrical free energy term, μ_s^e, may be obtained by the charging process with respect to the sodium ion charge, q, at the micellar surface.

$$\mu_s^e = \int_0^\varepsilon \psi_s \, dq \tag{8}$$

It follows from Eqs. (6) and (8), with substitution

$$\sigma = -(\varepsilon-\beta q)/A, \tag{9}$$

that

$$\mu^e{}_s = kT[-\ln \{2000\pi\varepsilon^2(1-\beta)^2/DNkTA^2C_b\} + 2\{1+(1/\beta) \ln (1-\beta)\}]. \tag{10}$$

Here, A denotes the area occupied by an alkyl sulfate ion at the micellar surface. Substitution of Eqs. (5) and (10) into Eq. (4) gives

$$\ln a_+ = (\mu_s^0-\mu_b^0)/kT + \ln \{DkTA^2m\beta/2\pi V\varepsilon^2(1-\beta)^2\} + 2\{1+(1/\beta) \ln (1-\beta)\} + \ln\{C_0 + (1-\beta)(C-C_0)\}. \tag{11}$$

If it is assumed that the micellar parameters A, m, V and β are constant throughout the whole concentration range studied, we have

$$a_+ = \text{Const.}\{C_0+(1-\beta)(C-C_0)\}. \tag{12}$$

From the boundary condition that $a_+ \to a_+^0$ $(=\gamma_+C_0)$ when $C\to C_0$, we obtain

$$\gamma_+ = a_+/C = \gamma_+^0\{(1-\beta)+\beta C_0/C\} \tag{13}$$

and

$$\ln \gamma_+^0 = (\mu_s^0-\mu_b^0)/kT + \ln \{DkTA^2m\beta/2\pi V\varepsilon^2(1-\beta)^2\} + 2\{1+(1/\beta) \ln (1-\beta)\}, \tag{14}$$

where, γ_+^0 is the apparent activity coefficient of sodium ion at $C=C_0$. Using Eq. (13), we can estimate the value of β from the slope of γ_+ *vs.* C_0/C plot. It is to be noted that the equation assumed by Botré *et al.*[1] for estimating the degree of dissociation of the micelle can be derived from the lamellar micelle model.

In the presence of added magnesium ion, we assumed that Eq. (13) may also be applicable if the relative concentration of $MgSO_4$ to SDS is small, which is the case for the present experimental condition. Under this condition, the potential determining ion of the diffuse double layer will be assumed to be the sodium ion, since the majority of the added magnesium ion will be bound at the micellar surface on account of the strong coulombic interaction with the micelle. In Fig. 6, the typical plot of γ_+ *vs.* C_0/C is given for sodium tetradecyl sulfate in water at 35°C. The linearity

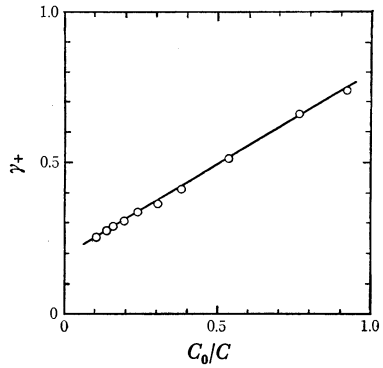

Fig. 6. The polts of γ_+ *vs.* C_0/C for STS at 35°C.

of the line is satisfactory over the whole concentration range studied. In the presence of added magnesium ion, however, the deviation from

linearity is found to appear in higher concentration range above CMC. In these cases, therefore, we used the limiting slope at the CMC in the plot, γ_+ *vs.* C_0/C. The values of β are summarized in Table 1, together with those evaluated by several authors.

TABLE 1. THE VALUES OF β DETERMINED FROM pNa DATA

Detergent*	Temp. (°C)	R	CMC** (mol/l)	β	β(lit.)
SOS	25		1.27×10^{-1}	0.56	
SDeS	25		3.16×10^{-2}	0.62	0.70[2]
SDS	25		7.95×10^{-3}	0.75	0.84,[1] 0.78[2] 0.71,[8] 0.82[9]
STS	35		2.07×10^{-3}	0.76	0.87(25°C)[2]
SDS	35		8.22×10^{-3}	0.72	
SDS+$MgSO_4$	35	0.0467	7.33×10^{-3}	0.52	
SDS+$MgSO_4$	35	0.0957	6.38×10^{-3}	0.42	
SDS+$MgSO_4$	35	0.299	4.83×10^{-3}	0.18	
SDS+$MgSO_4$	35	0.510	3.2×10^{-3}	0.14	

* SOS: Sodium octyl sulfate, SDeS: Sodium decyl sulafte, SDS: Sodium dodecyl sulfate, STS: Sodium tetradecyl sulfate.

** Determined from a break point of log a_+ *vs.* log C plot.

As is clearly shown in Table 1, the value of β increases with increasing chain length and for the same chain length it decreases with increasing temperature. Further, it is confirmed that the addition of magnesium ion to SDS gives rise to the rapid reduction of β.

Once the value of β is determined, we can estimate the specific adsorption energy $\Delta\mu^0$ ($=\mu_s^0-\mu_b^0$) with the additional assumptions for V and A. If it is assumed here that the thickness of the Stern layer is in the order of the diameter (l) of hydrated sodium ion, the available volume for Na^+ ion in the Stern layer may be written as

$$V = mAl. \tag{15}$$

From Eqs. (14) and (15) we have

$$\Delta\mu^0/kT = \ln\{2\pi l\varepsilon^2(1-\beta)^2\gamma_+^{0}/DkTA\beta\} - 2\{1+(1/\beta)\ln(1-\beta)\}. \tag{16}$$

Introducing $A=33$ Å^2 which was determined from the surface adsorption study of tritiated SDS in water,[10] $l=4.6$ Å and $\gamma_+{}^0=0.815$ into Eq. (16), we obtain $\Delta\mu^0=0.85\,kT$ for SDS at 25°C. By using the spherical micelle model, Stigter[11] obtained $\Delta\mu^0=0.5kT$ for the same detergent. The value of $\Delta\mu^0$ estimated above, however, depends on the selected values of A and l, and in fact it tends to zero as the value of A increases. Hence it will be reasonable to assume that the area obtainable by substituting $\Delta\mu^0=0$ into Eq. (16) gives the upper limit of the area per polar head of a detergent anion at the micellar surface. The values of A so determined are 77 Å^2 for SDS, 112 Å^2 for SDeS and 126 Å^2 for SOS at 25°C, respectively. These figures reflect the expanding nature of the micelle with increasing degree of dissociation of the micelle. The true areas will be smaller than these values owing to the definite positive values of $\Delta\mu^0$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 323—329 (1969)

Formulas for One- and Two-center Moment Integrals between Slater Type s, p-Orbitals with Integer Effective Principal Quantum Numbers of 1 to 5

Masaru SUZUKI, Yoshimasa NIHEI and Hitoshi KAMADA

Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received June 6, 1968)

Expansion formulas are presented for one- and two-center moment integrals between Slater type s,p-orbitals with integer effective principal quantum numbers of 1 to 5, together with the procedure. These formulas are useful in the calculation of a dipole moment and a transition moment from a charge distribution calculated by LCAO-MO method. A FORTRAN subprogram containing most of these formulas, which are important in practice, occupies about $7.7K$ of the core memory of a computer, HITAC 5020.

In application of LCAO-MO calculation to the interpretation of the electronic absorption spectra of various molecules, it is useful to compare the calculated values of the intensity as well as the transition energy with the observed values. For this purpose it is necessary to evaluate one-electron moment integrals between all the possible pairs of the atomic orbitals (AO's) taken as bases. Then, these integrals can also be used to calculate the dipole moment of the molecule and to test the accuracy of the calculated charge distribution. Hence it is convenient to write a computer program for the continuous calculation of the dipole moment and the transition moments between any molecular orbitals (MO's) after solving the secular equations for molecules containing any kinds of atoms.

Two-center moment integrals between Slater-type AO's (STO's) with integer effective principal quantum number (n^*) are expressed by formulas similar to those for overlap integrals with auxiliary functions, A_m and B_m with integer m.*1 Some of these formulas for s,p-AO's with small values of n^* (1 and 2) are found,[1,2] but, as far as we know, no adequate table has been published containing STO's with larger values of n^*. This paper will present many of these formulas, together with the procedure.*2

Procedure

MO's, φ's, are taken as linear combination of AO's, χ's, which are centered on the various atoms in the molecule:

$$\varphi_i = \sum_p C_{pi}\chi_p \tag{1}$$

Then the one-electron moment integrals between these MO's are decomposed into integrals with AO's:

$$R_{ij} = \int \varphi_i \, r \, \varphi_j \, d\tau = \sum_{p,q} C_{pi}C_{qj}T_{pq}$$

$$T_{pq} = \int \chi_p \, r \, \chi_q \, d\tau \tag{2}$$

χ_p and χ_q are the AO's centered on atom P and Q respectively, and $\boldsymbol{r}$ is the position vector of an electron relative to an origin fixed in the molecule. When $\boldsymbol{r}_0$ is the position vector of the middle point of P and Q, and $\boldsymbol{r}'$ is of an electron relative to this point, $\boldsymbol{r} = \boldsymbol{r}_0 + \boldsymbol{r}'$, hence:

$$\begin{aligned} T_{pq} &= \int \chi_p \, (\boldsymbol{r}_0 + \boldsymbol{r}') \chi_q \, d\tau \\ &= \int \chi_p \, \boldsymbol{r}_0 \chi_q \, d\tau + \int \chi_p \, \boldsymbol{r}' \chi_q \, d\tau \\ &= \boldsymbol{r}_0 S_{pq} + M_{pq} \end{aligned} \tag{3}$$

where S is an overlap integral, and M is a moment integral relative to the middle point of P and Q. In the following section, three components of $\boldsymbol{r}$, *i. e.*, z, x and y are treated.

Two-center Integrals. Any coordinate systems, (z,x,y), with an origin on PQ, and parallel to the coordinates fixed in the molecule, are transformed by the following transformation matrix to a local coordinate system, (Z,X,Y), with the positive direction of the Z axis from P toward Q as is shown in Fig. 1:

*1 In this paper, a principal quantum number, n, and an effective principal quantum number, n^* $(=n-\delta)$, are distinguished.

*2 For the purpose of convenience some partial overlapping with the books of Miller *et al.*,[1] and Kotani *et al.*,[2] is not avoided.

$$\begin{pmatrix} z \\ x \\ y \end{pmatrix} = \begin{pmatrix} \gamma_z & -\gamma_z\gamma_x/\delta & -\gamma_y/\delta \\ \gamma_x & \delta & 0 \\ \gamma_y & -\gamma_x\gamma_y/\delta & \gamma_z/\delta \end{pmatrix} \begin{pmatrix} \mathcal{Z} \\ X \\ Y \end{pmatrix}$$
$$\delta = (1-\gamma_x^2)^{1/2} \qquad (4)$$

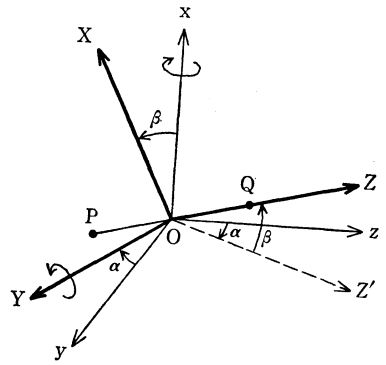

Fig. 1. Transformation to local coordinates.

where γ_z is the direction cosine of $\mathcal{Z}$ axis relative to z axis fixed in a molecule, and so on.

We take STO's as bases, which consist of appropriate combinations of z,x,y and a function of r, where z, x and y are transformed as mentioned above, but r is not. As for the two-center moment integrals relative to the local coordinate system, $(\mathcal{Z},X,Y)$, only those integrals containing none or even numbers of X and/or Y respectively have non-zero values in symmetric property. When only s- and p-AO's are treated, the following nine types are all of the necessary basic two-center integrals:

$(S|\mathcal{Z}|S)$, $(S|\mathcal{Z}|P_Z)$, $(S|X|P_X)$. $(P_Z|\mathcal{Z}|S)$, $(P_X|X|S)$, $(P_Z|\mathcal{Z}|P_Z)$, $(P_Z|X|P_X)$, $(P_X|\mathcal{Z}|P_X)$, $(P_X|X|P_Z)$*3

Any two-center moment integrals between s,p-AO's relative to the original coordinate system are linear combinations of some of the above basic integrals (Table 1).

TABLE 1. DECOMPOSITION OF TWO-CENTER MOMENT INTEGRALS*

$(s\,|\,i\,|\,s) = \gamma_i(S|\mathcal{Z}|S)$
$(s\,|\,i\,|\,p_i) = \gamma_i^2(S|\mathcal{Z}|P_Z) + (1-\gamma_i^2)(S|X|P_X)$
$(p_i\,|\,i\,|\,s) = \gamma_i^2(P_Z|\mathcal{Z}|S) + (1-\gamma_i^2)(P_X|X|S)$
$(s\,|\,i\,|\,p_j) = \gamma_i\gamma_j\{(S|\mathcal{Z}|P_Z) - (S|X|P_X)\}$
$(p_j|\,i\,|\,s) = \gamma_i\gamma_j\{(P_Z|\mathcal{Z}|S) - (P_X|X|S)\}$
$(p_i\,|\,i\,|\,p_i) = \gamma_i[\gamma_i^2(P_Z|\mathcal{Z}|P_Z) + (1-\gamma_i^2)\{(P_Z|X|P_X) + (P_X|\mathcal{Z}|P_X) + (P_X|X|P_Z)\}]$
$(p_i\,|\,j\,|\,p_j) = \gamma_i[(1-\gamma_i^2)(P_Z|X|P_X) + \gamma_i^2\{(P_Z|\mathcal{Z}|P_Z) - (P_X|\mathcal{Z}|P_X) - (P_X|X|P_Z)\}]$
$(p_i\,|\,j\,|\,p_i) = \gamma_j[(1-\gamma_i^2)(P_X|\mathcal{Z}|P_X) + \gamma_i^2\{(P_Z|\mathcal{Z}|P_Z) - (P_Z|X|P_X) - (P_X|X|P_Z)\}]$
$(p_i\,|\,i\,|\,p_j) = \gamma_j[(1-\gamma_i^2)(P_X|X|P_Z) + \gamma_i^2\{(P_Z|\mathcal{Z}|P_Z) - (P_Z|X|P_X) - (P_X|\mathcal{Z}|P_X)\}]$
$(p_i\,|\,j\,|\,p_k) = \gamma_i\gamma_j\gamma_k\{(P_Z|\mathcal{Z}|P_Z) - (P_Z|X|P_X) - (P_X|\mathcal{Z}|P_X) - (P_X|X|P_Z)\}$

* Each of i, j and k denotes either z, x or y.

*3 Integrals with Y are equivalent to those with X.

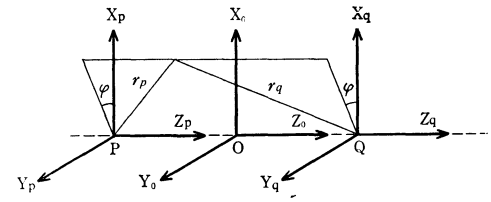

Fig. 2. Local coordinate system.*

* It should be noted that $\mathcal{Z}_p$, $\mathcal{Z}_0$ and $\mathcal{Z}_q$ axes have the same direction.

The actual calculations are performed after the transformation of the local coordinates to the spheroidal coordinate system, (ξ,η,φ). By the use of the latter, each of the basic integrals is expanded into a formula with A_m and B_m as overlap integrals in Ref. 3. Our choice of coordinates (Fig. 2) will result in the folloinwg equations:

$$r_p = R(\xi+\eta)/2, \quad r_q = R(\xi-\eta)/2,$$
$$\mathcal{Z}_p = R(\xi\eta+1)/2, \quad \mathcal{Z}_q = R(\xi\eta-1)/2, \quad \mathcal{Z}_0 = R\xi\eta/2,$$
$$X_p = X_q = X_0 = R\{(\xi^2-1)(1-\eta^2)\}^{1/2}\cos\varphi/2,$$
$$Y_p = Y_q = Y_0 = R\{(\xi^2-1)(1-\eta^2)\}^{1/2}\sin\varphi/2 \qquad (5)$$

where R is the interatomic distance, and:

$$A_m(a) = \int_1^\infty \xi^m e^{-a\xi}\,d\xi$$
$$B_m(b) = \int_{-1}^1 \eta^m e^{-b\eta}\,d\eta$$
$$a = R(\mu_p+\mu_q)/2R_H = (a_p+a_q)/2$$
$$b = R(\mu_p-\mu_q)/2R_H = (a_p-a_q)/2$$
$$a = R\mu/R_H \qquad (6)$$

where R_H is the Bohr radius and μ denotes the exponent of STO. The parameter a and b correspond to p and pt respectively in Ref. 3. When both AO's have integer n^*, m is also an integer, and these expansion formulas are easily obtained with a computer, given the number of each variable as input data. In this work the program was tested by obtaining the corresponding formulas of overlap integrals, in agreement with those in Ref. 3, except the difference in the direction of $\mathcal{Z}_q$ axis.*4

One-center Integrals. One-center moment integrals may be calculated directly in a spherical coordinate system, and only those of the type, $(s|i|p_i)$ or $(p_i|i|s)$ have non-zero values for s,p-AO's, where i denotes either of z,x or y.

Results and Discussion

In Table 2, all expansion formulas of basic two-center moment integrals between s,p-AO's with integer n^*, $1 \leqq n_1^* \leqq n_2^* \leqq 5$, for $b \neq 0$, are presented. Formulas for $b=0$ are derived from the corresponding formulas for $b \neq 0$, by noting that $B_m(0) = 2/(m+1)$ for m even, and $B_m(0)=0$ for m odd. In practice only those for $n_1^* = n_2^*$ are important,

4	4	$4608(h_1^9\,h_2^9/3)^{1/2}/(h_1+h_2)^{10}$
4	5	$30720(h_1^9\,h_2^{11}/30)^{1/2}/(h_1+h_2)^{11}$
5	5	$22528(h_1^{11}\,h_2^{11}/3)^{1/2}/(h_1+h_2)^{12}$

which are presented in Table 3. In Tables 2 and 3, each formula is to be multiplied by a parameter c which is common to formulas for a same pair of n_1^* and n_2^*. In Table 4, one-center moment integrals are also collected, where $h=\mu/R_H$.

For $n_1^*>n_2^*$. According to our choice of coordinates (Fig. 2), the following two rules are derived as for basic two-center integrals.

i) Those which contain none or even number of $\mathcal{Z}$ (type 1) do not change the sign through the exchange of two AO's with each other, and the other (type 2) change the sign.

ii) $B_m(b)=B_m(-b)$ for m even, and $=-B_m(-b)$ for m odd.

From the above two rules, the formulas for $n_1^*>n_2^*$ are derived in the following way. When $b\neq 0$, the sign of a term with B_m is changed if m is odd for type 1, and even for type 2, in the formula with two exchanged AO's. When $b=0$, signs of all terms are changed for type 2, and none for type 1. For example:

$$\text{type 2: } (2S|\mathcal{Z}|1S) = (a_1^5\,a_2^3/3)^{1/2}(R/16)(A_4B_1+A_3B_2-A_2B_3-A_1B_4)$$

$$\text{type 1: } (2P_z|\mathcal{Z}|1S) = (a_1^5\,a_2^3)^{1/2}(R/16)(A_4B_2+A_3B_1-A_2B_4-A_1B_3)$$

Other Values of n^*. Basic two-center integrals

for larger values of n^* are derived from formulas of the same type for n^*-1 with the rule presented by Lofthus for overlap integrals.[4] Integrals for non-integer n^* may be evaluated by interpolation from the values for appropriate integer n^*'s, when not so high accuracy is needed.

Programming. Basic moment integrals may be calculated together with corresponding overlap integrals, since values of all parameters are common in both cases. A FORTRAN subprogram including all formulas of one- and two-center moment integrals for s,p-AO's with n^* of 1 to 4 (for $b=0$, only those for $n_1^*=n_2^*$ are included), and an interpolation technique with a parabola, written for a HITAC 5020 computer at the computation center of the University of Tokyo, occupies about $7.7K$ of the core memory, $65K$, while a subprogram for overlap integrals in the same region of n^* occupies about $5K$.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 329—333 (1969)

The Efficiencies of Hydrocarbons and Hydrogen in Quenching Triplet Cadmium Atoms

Shigeru TSUNASHIMA, Shin SATOH and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 11, 1968)

The relative efficiencies of sixteen hydrocarbons and of hydrogen in quenching triplet cadmium atoms have been measured at 270±1°C by the competitive quenching method, using the cadmium-photosensitized *cis-trans* isomerization of *cis*-2-butene as a detector reaction. The quenching efficiencies of all the olefins studied and of acetylene were almost the same. The efficiencies of saturated hydrocarbons were, however, very low compared with those of unsaturated ones. Hydrogen was as efficient as unsaturated hydrocarbons.

Electronic energy-transfer reactions in the gas phase are of fundamental interest in chemical kinetics. In spite of many investigations, however, little is understood about the mechanism and the rate-controlling parameters.

Recently, Rebbert and Ausloos measured the efficiencies of various unsaturated hydrocarbons in quenching triplet acetone, and found that the efficiency of olefin depends strongly on its structure.[1] For quenching triplet benzene, Hanninger and Lee found that the efficiencies of ethylene derivatives depend greatly on the number of substitution; *i. e.*, the efficiency of tetramethylethylene is more than ten times as great as that of ethylene.[2] Similar results have been obtained by Morikawa and Cvetanović.[3] In the mercury-photosensitization, however, no such strong dependence has been observed.[4]

In this respect, the measurement of the efficiencies for quenching triplet cadmium atoms should be of interest because a triplet cadmium atom (Cd $5(^3P_1)$; 87.7 kcal) is similar to a triplet mercury atom (Hg $6(^3P_1)$; 112.7 kcal) in its electronic property and is close to triplet benzene (C_6H_6 $(^3B_{1u})$; 84.4 kcal[5]) in its excitation energy.

In cadmium-photosensitization, as was shown in a previous short communication,[6] the quenching efficiencies of ethylene derivatives are almost all the same and the trend of the efficiencies is similar to that obtained by quenching triplet mercury, but is different from those obtained by quenching triplet benzene and acetone. In the present paper, we will present the details of the measurement and of the date obtained after the previous communication was reported.

Experimental

Research-grade acetylene, ethylene, propylene, isobutene, 1-butene, *trans*- and *cis*-2-butenes, trimethylethylene, tetramethylethylene, cyclohexene, methyl-

acetylene, vinylacetylene, 1,3-butadiene, propane, and cyclopropane supplied by the Takachiho Shoji Co. were used after bulb-to-bulb distillations. The gas-chromatographic analyses showed that the impurities were less than 0.5%. *Trans*- and *cis*-2-pentenes supplied by the Takachiho Shoji Co. were used after separating them from each other by gas chromatography. Hydrogen supplied by the Suzuki Shokan Co. was used after passing it through a trap at the temperature of liquid nitrogen. The mass-spectrometric analyses of acetylene-d_2 synthesized from calcium carbide and deuterium oxide, and ethylene-d_4 synthesized from deuterium and acetylene-d_2[7] showed that the isotopical impurities were less than 2%.

The light source and the apparatus were similar to those reported on in a previous paper.[8]

For each experiment, the pressure of *cis*-2-butene was kept almost constant (22—32 mmHg), while the pressure of the quencher was varied. After irradiation with a cadmium lamp at 270±1°C, the products were analyzed by gas chromatography using a column packed with dimethylsulforane on celite (30 m long) supplied by Shimadzu Co. Immediately after each run, the light intensity of the 3261 Å resonance line was measured using the cadmium-photosensitized *cis-trans* isomerization of *cis*-2-butene on the assumption of the quantum yield being 0.5.[8]

Treatment of the Data

The competitive quenching method used is based on the following reactions[8]:

$$\mathrm{Cd} + h\nu \longrightarrow \mathrm{Cd}^* \qquad (1)$$
$$\mathrm{Cd}^* + \mathrm{C} \longrightarrow \mathrm{Cd} + \mathrm{B}^* \qquad k_b \qquad (2)$$
$$\mathrm{Cd}^* + \mathrm{T} \longrightarrow \mathrm{Cd} + \mathrm{B}^* \qquad k_b \qquad (3)$$
$$\mathrm{Cd}^* + \mathrm{X} \longrightarrow \mathrm{Cd} + \mathrm{X}' \qquad k_x \qquad (4)$$
$$\mathrm{B}^* + \mathrm{M} \longrightarrow \tfrac{1}{2}\mathrm{C} + \tfrac{1}{2}\mathrm{T} + \mathrm{M} \qquad (5)$$

where Cd* and B* represent, respectively, a triplet cadmium atom and an excited 2-butene molecule which isomerizes to *cis*- or *trans*-2-butene after collisional deactivation. T and C are *trans*- and *cis*-2-butenes respectively. X is a quencher molecule. As has been suggested in a previous paper,[8] the spontaneous emission process of a triplet cadmium is negligible compared with the process of the isomerization at the higher-than-1 mmHg 2-butene.

The steady-state treatment of the above mechanism gives the following relation;

$$R_0/R = 1 + (k_x/k_b)([\mathrm{X}]/[\mathrm{B}]) \qquad (\mathrm{I})$$

where R_0 and R represent the rates of the isomerization of 2-butene in the absence and in the presence of quencher molecules respectively. k_x and k_b are the efficiencies of a quencher and 2-butene for quenching triplet cadmium atoms respectively.

Equation (I) suggests that the plots of R_0/R as a function of the concentration ratio, [X]/[B], should give a straight line and that the slope of the straight line is relative quenching efficiency of the quencher competitive with 2-butene, k_b/k_x. In the present study, *cis*-2-butene is used as the detector compound.

In order to achieve good analytical accuracy as regards the values of initial rate of the isomerization, it was necessary to make higher conversions. The initial rate of the isomerization was estimated from the raw data using Eq. (II). Equation (II) was derived under the assumptions that the quantum yield of the isomerization of 2-butene is 0.5 and that the efficiency of *trans*-2-butene in quenching triplet cadmium is equal to that of *cis*-2-butene.[8]

$$R = (([\mathrm{C}] + [\mathrm{T}])/2t) \ln (([\mathrm{C}] + [\mathrm{T}])/([\mathrm{C}] - [\mathrm{T}])) \qquad (\mathrm{II})$$

Here, t represents the reaction time. [C] and [T] are the amounts of *cis*- and *trans*-2-butenes respectively obtained after the irradiation.

Results and Discussion

Quenching Data. The presence of quencher molecules retarded the isomerization of 2-butene. The R_0/R ratio was plotted against the concentration ratio, [X]/[B]. Figure 1 shows typical

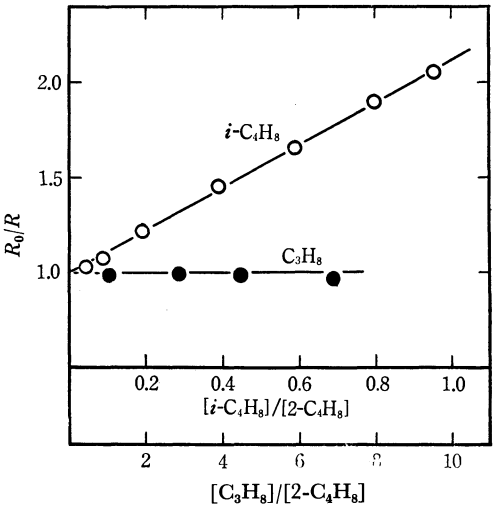

Fig. 1. The ratio of R_0/R as a function of the ratio of the pressure of competing quencher to that of *cis*-2-butene.

results obtained for propane and isobutene as competitive quenchers. Similar plots were obtained with all quenchers examined except for hydrogen. The case of hydrogen will be discussed later. The relative quenching efficiencies calculated from the slopes of the straight lines by the method of least squares are listed in Table 1. Table 1 also shows the relative quenching efficiencies for triplet cadmium,[9] mercury,[4] and

a′ Ref. 9, b′ Ref. 4, c Ref. 2, d Ref. 3, e′ Ref. 1

acetone,[1] efficiencies which were determined by the physical method, and also for triplet benzene,[2,3] which were determined by the competitive quenching method. The relative efficiencies for quenching triplet cadmium measured by the present method agree with those obtained by the physical method within the range of experimental error.

Unsaturated Hydrocarbons. In the case of unsaturated hydrocarbons, the experimental accuracy can be expected to be very high, because unsaturated hydrocarbons strongly quench triplet cadmium and small amounts of impurities and/or small amounts of side-reaction products do not affect the main reactions. No measurable amounts of side-reaction products were observed in any case examined except in the cases of methylacetylene and *cis*-2-pentene. In the case of methylacetylene, allene was obtained even in a dark reaction at 270±1°C. In the case of *cis*-2-pentene, *trans*-2-pentene was formed with a high quantum efficiency. The quantum yield of *trans*-2-pentene increased with an increase in the concentration of *cis*-2-pentene (Fig. 2).

More serious systematic errors may arise from the neglect of the following reaction, if they occur:

$$X' + C(\text{or } T) \longrightarrow X + B^* \quad (6)$$
$$X' + M \longrightarrow X + M \quad (7)$$

where X′ represents an energized quencher molecule which is formed by the reaction (4). If the reaction (6) is involved in the mechanism, *i. e.*, if X′ can transfer its energy to 2-butene and cause the *cis-trans* isomerization, the slope of the straight line of the plots of R_0/R *vs.* [X]/[B] does not show the relative quenching efficiency. However, the reaction (6) may be neglected in the case of the quencher examined here, because: (a) the plots of R_0/R as a function of the concentration ratio showed a straight line in every case; (b) in the case of 2-pentene, the total quantum yield of the isomer formations of 2-butene and 2-pentene was 0.5 at various concentration ratios of 2-pentene to 2-butene (Fig. 2); (c) the value of the relative quenching efficiency of 2-pentene as estimated

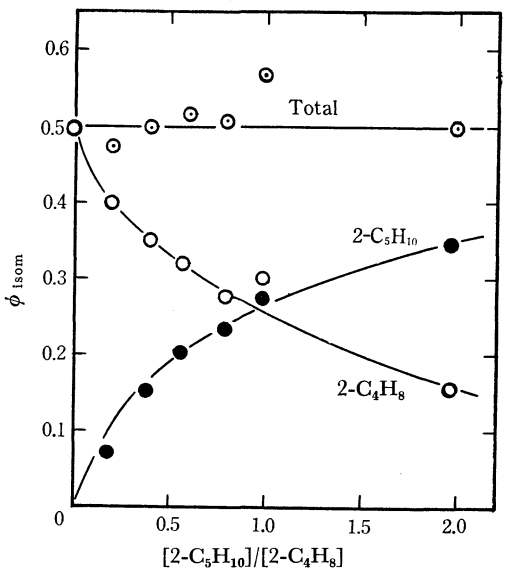

Fig. 2. Quantum yields of isomers formed in the reaction of the mixture of *cis*-2-butene and *cis*-2-pentene photosensitized by triplet cadmium at 270 ±1°C.

from the decrease in the rate of the isomerization of 2-butene is equal to that estimated from the increase in the rate of the isomerization of 2-pentene (Fig. 2); and (d) the quenching efficiencies determined by the present method agree well with those determined by the physical method* (Table 1).

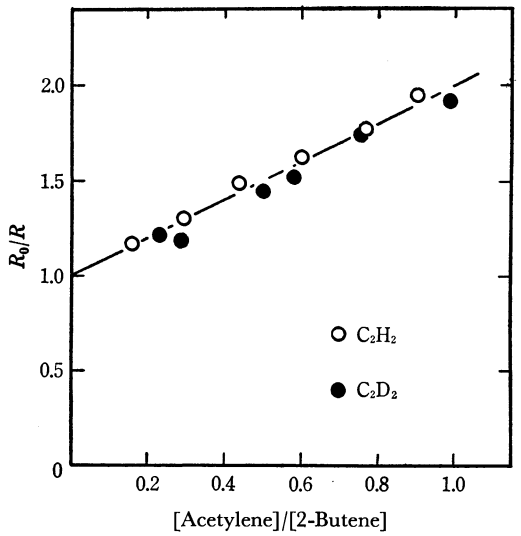

Fig. 3. Isotope effect in the quenching efficiency of acetylene for triplet cadmium atoms at 270±1°C.

Isotope Effects. As is shown in Fig. 3 and in Table 1 the isotope effect in quenching triplet cadmium atoms by acetylene or ethylene is negligibly small.

Comparison with Other Sensitizers. As is also shown in Table 1, the trend of quenching efficiencies obtained in the cadmium-photosensitization is similar to that obtained in the mercury-photosensitization and is different from those obtained in the benzene- and acetone-photosensitizations, in spite of the fact that the energy transferred in the cadmium-photosensitization is close to that transferred in the benzene-photosensitization.

The trend obtained in the acetone-photosensitization was explained by Rebbert and Ausloos as follows[1]: when the energy-transfer process is endothermic,*2 the quenching efficiency increases with a diminishment in the enthalpy change of the reaction. A similar consideration can explain the trend observed in the benzene-photosensitization, but not the trend in the cadmium-photosensitization, even though the quenching measurement of the cadmium-photosensitization were carried out at high temperatures (270±1°C). Morikawa and Cvetanović[3] found that the relative rates of the energy-transfer from the benzene triplet are affected by the temperature and that the apparent activation energy of the quenching efficiency of butadiene is about one kcal smaller than that of *cis*-2-butene. When the relative quenching efficiency of butadiene against *cis*-2-butene is extrapolated to 270°C using their data, it reduces to about 5. However, the relative quenching efficiency of butadiene in comparison with *cis*-2-butene in the cadmium-photosensitization is about unity. Although further experiments are needed, the difference in trend between benzene- and cadmium-photosensitizations is probably not due to the temperature.

Another possible explanation for the difference in the trend is the difference in the electronic property of the photosensitizer, as has been mentioned in a previous short communication.[6]

Saturated Hydrocarbons. The rate of the isomerization of *cis*-2-butene in the cadmium-photosensitization was scarcely affected at all by the addition of propane or cyclopropane. Non-condensible gases at the temperature of liquid nitrogen were not detected in the competitive quenching study. In the cadmium-photosensitized decomposition of pure propane, however, the formation of hydrogen was observed.[10] These results suggest that the quenching efficiency of saturated hydrocarbons is very low compared with that of olefins (Table 1). Therefore, in the reactions of pure saturated hydrocarbons, negligibly small amounts of impurities and side-reaction products may bring about a larger experimental error.

Table 2. Products from the reaction of the mixture of hydrogen and *cis*-2-butene photosensitized by triplet cadmium at 270±1°C[a]

Pressure of hydrogen mmHg	Products μmol				
	C_3H_6	C_4H_{10}	1-C_4H_8	*t*-C_4H_8[b]	*c*-C_4H_8[c]

16.6	0.90	0.77	0.22	4.20	27.9
21.2	1.10	0.82	0.19	3.95	26.7
26.8	1.21	0.97	0.22	3.91	27.6
31.7	1.32	1.13	0.26	3.95	25.5

a) Pressure of *cis*-2-butene: 25.1 mmHg
light intensity: 0.364 μE/min
irradiation time: 30 min
b) *trans*-2-butene
c) *cis*-2-butene

*1 The physical method is based on the measurement of the intensity of phosphorescence.[4]

*2 They compared the vertical triplet energies of olefins with the triplet energy of acetone. In the present authors' opinion, however, the lowest triplet energies of the olefins (which are twisted) should be used for the comparison. In this treatment, therefore, the energy transfer process will always be exothermic. However, their discussion of the trend is still relevant.

10) P. Agius and B. DeB Darwent, *J. Chem. Phys.*, **20**, 1679 (1952).

Hydrogen. As is shown in Table 2, propylene, *n*-butane, and 1-butene were formed together with *trans*-2-butene when a mixture of hydrogen and *cis*-2-butene was photosensitized by triplet cadmium. The quantum yields of the product formations increased with an increase in the pressure of hydrogen. The relative quenching efficiency of hydrogen could not be determined from Eq. (I) because of the large amounts of side-reaction products.

A possible reaction mechanism to account for the formations of propylene and *n*-butane is as follows:

$$Cd^* + C(\text{or } T) \longrightarrow Cd + B^* \qquad k_b \quad (2,3)$$
$$Cd^* + H_2 \rightarrow CdH + H \rightarrow Cd + 2H \qquad k_h \quad (8)$$
$$H + C_4H_8 \longrightarrow CH_3 + C_3H_6 \quad (9)$$
$$\longrightarrow C_4H_9 \quad (10)$$
$$2C_4H_9 \longrightarrow C_4H_8 + C_4H_{10} \quad (11)$$
$$\longrightarrow C_8H_{18} \quad (12)$$

where CdH formation is assumed following Bender and Olsen.[11] This compound, however, may decompose to cadmium and hydrogen atoms through collisions with other molecules, because the heat of the formation of CdH is estimated to be only 15.5 kcal.[10] Usually, the reaction (10) requires a collisional deactivation. Rabinovitch *et al.* found that the efficiency of 2-butene in deactivating the chemically-activated *s*-butyl radicals was much higher than that of hydrogen.[12] Therefore, the reaction (10) may be treated as pressure-independent under the present experimental conditions, *i. e.*, when the pressure of 2-butene is kept constant (25 mmHg) and when the pressure of hydrogen is varied (9—32 mmHg). The C_4H_8 formed by the reaction (11) involves 1-butene, *cis*-, and *trans*-2-butenes. This is the reason that the quenching efficiency of hydrogen can not be calculated with Eq. (I). In this experiment, the amounts of C_8-products formed by the reaction (12) have not been measured. This probably explains the material balance in Table 2.

The steady-state treatment of the above mechanism gives the following equations;

$$1/\phi(C_3H_6) = \tfrac{1}{2}(1+k_{10}/k_9)(1+(k_b/k_h)([B]/[H_2])) \quad (III)$$
$$1/\phi(C_4H_{10}) = (1+k_{12}/k_{11})(1+k_9/k_{10})(1+(k_b/k_h)([B]/[H_2])) \quad (IV)$$

where $\phi(C_3H_6)$ and $\phi(C_4H_{10})$ are the quantum yields of the propylene and *n*-butane formations respectively. k_h is the quenching efficiency of hydrogen, *i. e.*, the rate constant of the reaction (8). The relations of Eqs. (III) and (IV) are plotted in Fig. 4. The intercepts and the slopes of the straight lines in Fig. 4, as calculated by the method of least squares, are listed in Table 3. The

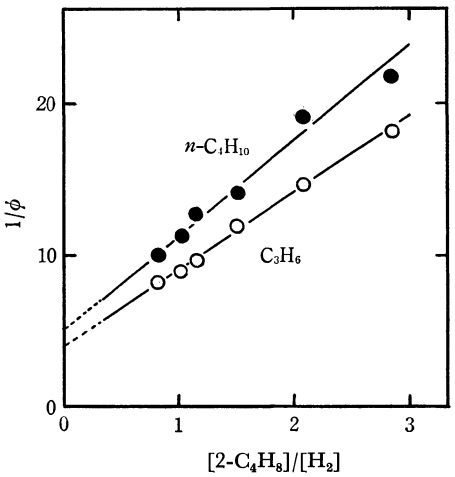

Fig. 4. Plots of the reciprocal of the quantum yields of propylene and *n*-butane formed in the reaction of hydrogen and *cis*-2-butene photosensitized by cadmium as a function of the concentration ratio of *cis*-2-butene to hydrogen.

TABLE 3. THE VALUES OF THE SLOPES AND THE INTERCEPTS OF THE STRAIGHT LINES IN Fig. 5

	Slope	Intercept	Slope/Intercept
$\phi(C_3H_6)$	5.1±0.2	4.0±0.3	1.3±0.1
$\phi(C_4H_{10})$	6.2±0.4	5.2±0.8	1.2±0.3

k_{12}/k_{11} value (the ratio of the disproportionation/recombination of *s*-butyl radicals) is estimated to be ~0.3. This value is appreciably lower than the value estimated by Kraus and Calvert (2.3),[13] but is close to that obtained by Rabinovitch *et al.* (~0.6).[12] The difference may be due to the difference in the source of the radical and/or to the neglect of other possible reactions of *s*-butyl radicals.

From the values of the intercepts and the slopes in Table 3, the relative quenching efficiency of hydrogen against *cis*-2-butene was calculated to be 0.83±0.18 (by using Eq. (IV)) and 0.79±0.08 (by using Eq. (III)). The agreement of these two values is satisfactory. Therefore, it can be said that the quenching efficiency of hydrogen is comparable to those of olefins.

An X-Ray Determination of the Structure of Chamaecynenol

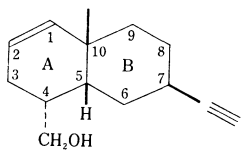
Hirotaka SHIMANOUCHI and Yoshio SASADA

Laboratory of Chemistry for Natural Products, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 12, 1968)

Crystals of chamaecynenol 4-bromo-3-nitrobenzoate, $C_{21}H_{22}O_4NBr$, are monoclinic, with two molecules in a unit cell of the dimensions, $a=10.47$, $b=14.08$, $c=6.75$ Å, and $\beta=101.8°$, and with the space group of $P2_1$. The intensities were recorded on multiple-film equi-inclination Weissenberg photographs and measured visually with a standard scale. The structure was determined by the heavy atom method. The positional and thermal parameters were refined by the least-squares method. The final R factor for the observed reflections is 0.090. The absolute configuration was also determined using anomalous dispersion effect of the bromine atom. It was thus established that chamaecynenol is 7β-ethynyl-4β-hydroxymethyl-10β-methyl-Δ^1-*cis*-octaline in the steroid conformation.

Recently, chamaecynenol $C_{14}H_{20}O$, a novel norsesquiterpenoid, was isolated from the Benihi tree (*Chamaecyparis formosensis* Matsum., Cupressaceae) as a minor constituent.[1] This is an interesting substance as an example of a natural acetylenic compound of terpenoid origin. From chemical and spectroscopic properties, the structure was suspected to be I of the non-steroid *cis*-decalin conformation. However, further chemical investigation was impossible due to too small a quantity of the sample. An X-ray analysis was undertaken in order to reveal such stereochemical details. A heavy atom derivative, chamaecynenol 4-bromo-3-nitrobenzoate, was prepared and supplied by Professor Takase and Dr. Asao.



(I)

Experimental

The compound crystallizes from a benzene solution in the form of colorless plates elongated along the c axis. The unit cell dimensions were determined from zero-layer Weissenberg photographs about the b and the c axes, calibrated with superimposed Al powder photographs.

Equi-inclination Weissenberg photographs were taken at room temperature for the layer lines from 0 to 10 about the b axis and from 0 to 4 about c, using Cu$K\alpha$ radiation. The crystals used had the following maximum and minimum dimensions at right angles to the axis of rotation:

0.01 × 0.02 cm for the b axis rotation,
0.01 × 0.03 cm for the c axis rotation.

Intensities were estimated by visual comparison with a standard scale prepared with the same crystals. The multiple-film technique was used to correlate strong and weak reflections, ranging in relative intensities from 8000 to 1. Out of 1982 reflections recorded, about 190 were too weak to be measured. The corrections for the Lorentz and polarization factors were made as usual and those for variation in spot-size in higher layer photographs by the Phillips method.[2] The correction for absorption was neglected.

Crystal Data

The crystallographic and physical data obtained are: Chamaecynenol 4-bromo-3-nitrobenzoate $C_{21}H_{22}O_4NBr$, mp 179—180°C. Monoclinic, $a=10.47$Å, $b=14.08$ Å $c=6.75$ Å, $\beta=101.8°$. Absent spectra, ($0k0$) when k is odd. Space group, $P2_1$. Two molecules per unit cell. Volume of the unit cell, 974.0 Å^3. Density (by flotation), 1.49_4 g·cm^{-3}. Density (calculated), 1.47_4 g·cm^{-3}. Linear absorption coefficient for Cu$K\alpha$ radiation, $\mu=34.5$ cm^{-1}. Total number of electrons per unit cell, $F(000)=444$.

Structure Determination

The x and z coordinates of the bromine atom were obtained from the Harker section and the y coordinate was set arbitrarily as zero. The four images of the benzene ring were easily picked up by inspecting the sharpened Patterson function around the origin, but it was impossible to select the correct one from the two possible positions of the benzene ring which were related to each other by non-crystallographic two-fold axis in the crystal

1) K. Takase, S. Ibe, T. Asao and T. Nozoe, Private Communication.

2) D. C. Phillips, *ActaC ryst.*, **7**, 746 (1954).

through the bromine atom. The minimum function was formed based on Br–Br vector and it gave the peaks for seven carbon atoms (six ring carbons and a carbonyl carbon) and a nitrogen atom. A three-dimensional Fourier synthesis was made with the phases derived from these nine atoms. An approximate mirror plane was found at $y=0$, due to the predominant contribution from the bromine atom to the phases, and each correct light atom peak in the map was accompanied by a peak of considerable height at the position of mirror image. However, it was possible to assemble a plausible molecular model by selecting them. In order to examine more quantitatively the validity of the model, all possible intra- and intermolecular distances less than 4.0 Å were evaluated. Since no unusual surrounding was found for any of the atoms, the second electron-density distribution was evaluated by taking into account the contribution from all atoms. The resulting map clearly showed the peaks of reasonable height for these atoms, very few background noise peaks being observed.

The positional parameters thus obtained, together with isotropic temperature factors, initially set to 4 Å^2, were refined by block-diagonal matrix least-squares method. After three cycles of refinements,

Table 1. Final atomic coordinates and temperature factors

The anisotropic temperature factors are expressed in the form of $\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$.

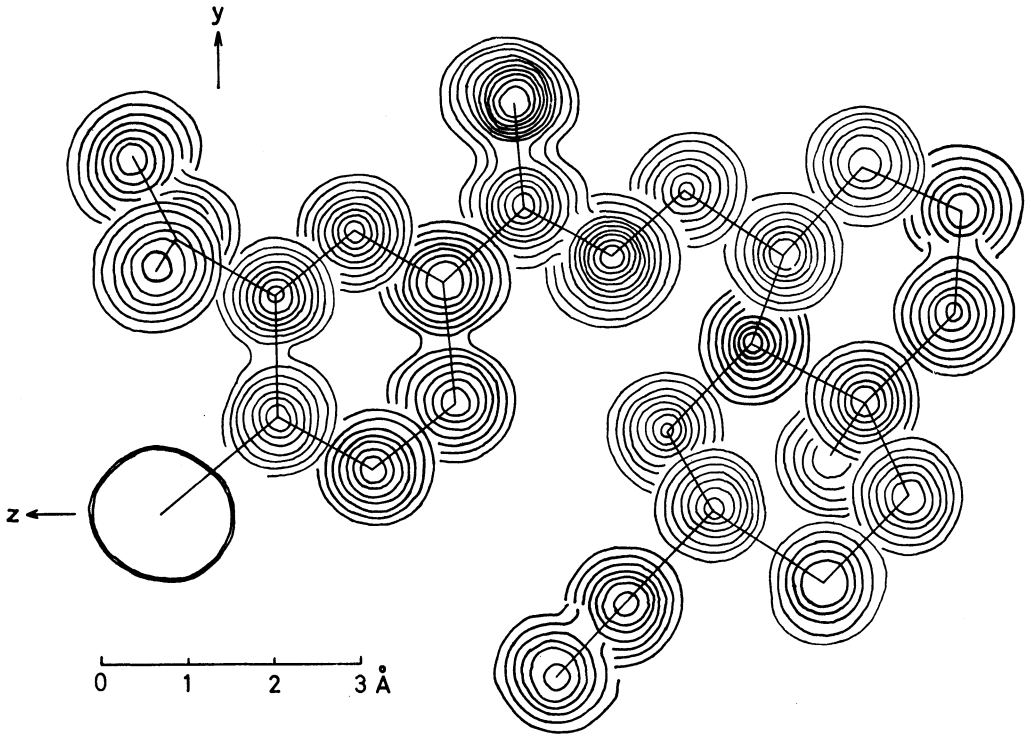

Fig. 1. Composite electron density diagram of sections parallel to (100). The contours are at intervals of 1.0 e. Å^{-3} starting with 1.0 e. Å^{-3}. The contours of the bromine atom are omitted.

the discrepancy factor, $R=\sum \| F_o| - |F_c| / \sum |F_o|$ was about 0.16. At this stage anisotropic temperature factors of the form, $\exp\{-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)\}$, were applied for the bromine atom. Four cycles of refinement reduced the R factor to 0.090 for the observed reflections. The atomic scattering factors used in the calculations were taken from the International Tables for X-ray Crystallography (1962).[3] The final atomic coordinates and the temperature factors are given in Table 1, and their standard deviations in Table 2. The observed and calculated structure factors are listed in Table 3. The final three-dimensional electron-density distribution calculated with phases based on these parameters is shown in Fig. 1.

The computations were done on a HITAC 5020 computer in the University of Tokyo with programs written by Dr. T. Ashida.

Determination of Absolute Configuration

After errors caused by neglect of the absorption correction were taken into account, seven sets of Bijvoet pairs were observed to have significantly different intensities in the upper layer photographs around the c axis. For the Bijvoet pairs, $|F(hkl)|$ and $|F(h\bar{k}\bar{l})|$ were calculated using $\Delta f'$ and $\Delta f''$

3) "International Tables for X-ray Crystallography," Vol. 3, Kynoch Press, Birmingham, England (1962), p. 202.

TABLE 4. THE DETERMINATION OF THE ABSOLUTE CONFIGURATION

$h\ k\ l$	Calculated			Observed	
	$\|F(hkl)\|$		$\|F(\bar{h}\bar{k}\bar{l})\|$	$I(hkl)$	$I(\bar{h}\bar{k}\bar{l})$
4 1 0	26.2	>	25.2		<
1 2 0	4.4	<	7.0		>
4 1 1	8.3	>	6.8		<

for the bromine atom on the basis of the model in a right-handed coordinate system. As shown in Table 4, inequality relations in each pair are the reverse of observed and calculated values, so that model used in the calculations is the mirror image of the actual molecule. Therefore, chamaecynenol has the absolute configuration indicated in Fig. 2. The hydroxymethyl group on C(4) and the ethynyl group on C(7) are in the β orientation.

Results and Discussion

Molecular Structure. From the X-ray analysis described in the preceding paragraphs, the steric structure of the molecule has been determined without any ambiguity. The intramolecular bond lengths and angles are shown in Figs. 3 and 4, respectively. The mean estimated standard deviation in a bond length is about 0.020 Å and in a

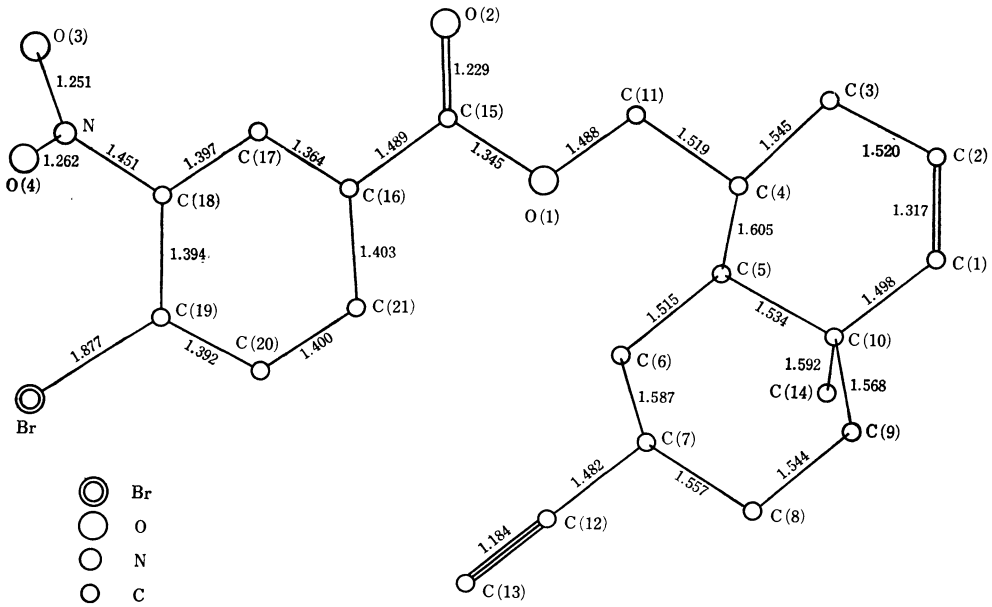

Fig. 3. Bond lengths (Å).

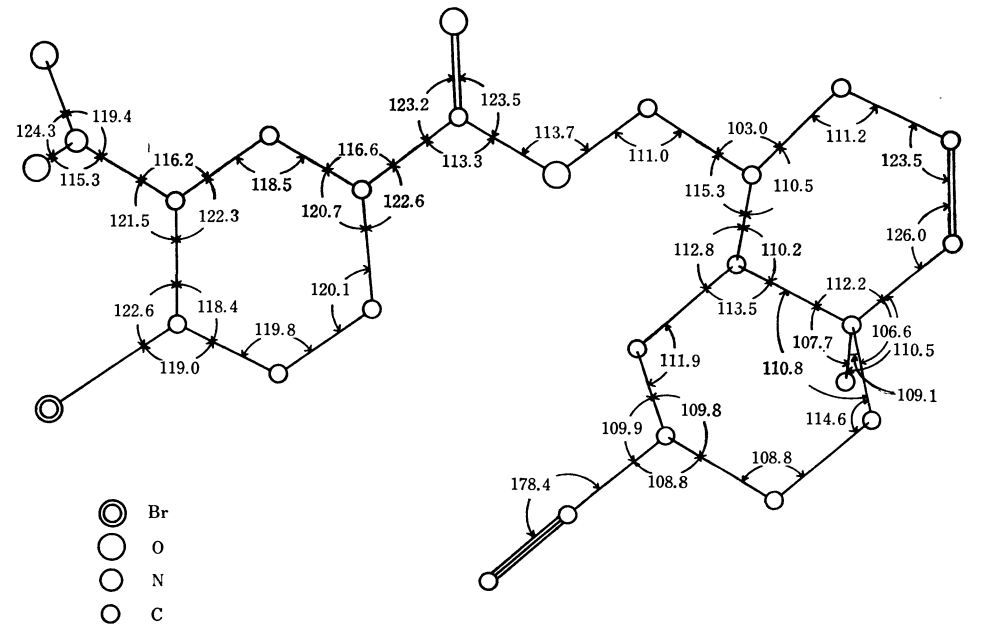

Fig. 4. Bond angles (degrees).

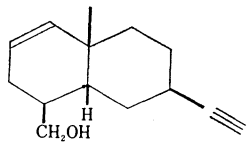

(II)

bond angle about 1.1°. All bond lengths and angles are reasonable within the errors. The locations of the double and the triple bonds are assigned unambiguously, and are the same as those in chamaecynone and isochamaecynone.[4] Thus the chemical structural formula of chamaecynenol has been established as II.

ring assumes the chair form. It is indicated that no strain occurs in the ring system.

That the steroid conformation of the present compound is more favorable can be reasonably explained from the stereochemical point of view. If the molecule were forced to take the non-steroid form keeping the chair and the half-chair conformation of the two rings, strong 1,3-diaxial interaction between 4β-hydroxymethyl group and 10β-methyl group would occur as shown in Fig. 8(a). Alternatively, if 4β-hydroxymethyl group were in the equatorial position in order to avoid such 1,3-diaxial interaction, the ring A should be in the less stable half-boat conformation as shown in Fig. 8(b). Consequently, the steroid conformation of this compound is more stable than the non-steroid one. If 4-hydroxymethyl group is in the α orientation, the non-steroid conformation can occur favorably.

Crystal Structure. The packing diagrams of the crystal viewed along the a, b and c axes are shown in Figs. 9, 10 and 11, respectively, together with the short intermolecular distances. The strong dipolar nature of the C=O group may fix the orientation of the nitro group to give the shortest intermolecular carbon-oxygen distance (3.13 Å). The shortest carbon-carbon, oxygen-oxygen, bromine-carbon and bromine-oxygen distances are 3.42 Å, 3.20 Å, 4.00 Å and 3.52 Å, respectively. No unusual short approaches are observed.

The authors are indebted to Professor Kahei Takase and Dr. Toyonobu Asao of Tohoku University for kindly giving us the sample.

Decomposition of Ammonia and Reactivity of Nitrogen Absorbed on Molybdenum

Susumu TSUCHIYA and Atsumu OZAKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 16, 1968)

Adsorption measurements during the course of ammonia decomposition over molybdenum catalyst have been carried out in a closed circulating system. It was found that most of the nitrogen produced was taken up by molybdenum, and the initial rate of the reaction was independent of the ammonia pressure in a certain region. During the decomposition the nitrogen uptake was several times as much as the amount required to saturate the catalyst surface, which indicates the formation of nitride layers. The catalytic activity of molybdenum trioxide for ammonia decomposition was also observed, and the formation of nitride layers was again suggested. The nitrogen sorbed on molybdenum was removed as ammonia by admitting hydrogen and was displaced by oxygen added afterwards.

Extensive studies[1-4] have been carried out on the ammonia synthesis or decomposition reaction over molybdenum, and the decomposition was found to be zero-order. It is generally admitted that the reaction follows zero-order kinetics when the catalyst surface is fully covered by the reactant or the reaction inermediate. In the case of ammonia decomposition over molybdenum, the zeroth order kinetics might be due to the saturated adsorption of nitrogen on the catalyst surface. The formation of nitride layers was suggested during the decomposition reaction of ammonia on tungsten, which is of zero-order kinetics.[5] Further information on the surface species would be obtained by measuring the adsorption during the ammonia decomposition reaction over molybdenum.

Nitrogen is an inactive element as is well known, and the formation of reactive nitrogen is a subject of interest. The reactant adsorbed must be more reactive than it is in the gas phase, and thus the nitrogen adsorbed on the molybdenum would be reactive.

In this study, the authors also investigated the reactivity of nitrogen sorbed on molybdenum with hydrogen and oxygen, and obtained some information on this system.

Experimental

The apparatus employed is a closed circulating system and the experimental procedures are similar to those described in a previous paper.[6] The amounts of gases sorbed on the catalyst surface were estimated from the amounts of reactants introduced, and the pressure and composition of the circulating gas. The composition of the circulating gas mixture comprised of ammonia, nitrogen and hydrogen was determined by gas chromatography after removing ammonia by means of a trap. The amount of ammonia in the gas phase was estimated from a knowledge of the volume of the system and the decrease in the total pressure by trapping.

Before hydrogen was introduced, the gases were removed by a few minutes' evacuation of the system, assuming that the nitrogen uptake on the surface can hardly be lost by pumping.

The reaction between hydrogen and sorbed nitrogen was carried out in the circulating system with trap cooled in liquid nitrogen. The amount of ammonia thus formed and collected in the trap was estimated from the increase in the total pressure on removal of the liquid nitrogen and a knowledge of the volume of the system.

The ammonia was obtained by distillation from ammonium hydroxide at room temperature and was purified by repeated fractional distillation from dry-ice to liquid nitrogen traps.

The molybdenum-A catalyst was prepared by treating and stabilizing reagent grade commercial molybdenum, with ammonia several times, the decomposition of ammonia taking place. The commercial molybdenum was reduced at 600°C with hydrogen for 50 hr to prepare the molybdenum-B catalyst. No water formed when

both molybdenum-A and -B were reduced at 500°C with hydrogen. The molybdenum trioxide catalyst was prepared by decomposing ammonium molybdate at 400°C. Before each run, the catalysts were evacuated to 10^{-4} mmHg for four hours at 580°C, and the molybdenum-B catalyst was beforehand treated with hydrogen at 580°C to remove the sorbed nitrogen, the amount of ammonia formed by the treatment being checked. In this way the experimental results were satisfactorily reproducible.

Results

Typical results of ammonia decomposition reaction over molybdenum are shown in Figs. 1 and 2, where the catalysts used were different. (Fig. 1: cat. A 160 g, Fig. 2: cat. B 39.6 g) As the decomposition proceeded, the partial pressure of ammonia decreased with time, and the pressure of hydrogen and nitrogen increased, while the uptake of nitrogen increased, and the amount of hydrogen taken up was very small as shown in Fig. 1. In the case shown in Fig. 2, no uptake of hydrogen was observed. At higher temperatures above 500°C, no uptake of hydrogen took place, even when molybdenum-A was used as the catalyst, and at 560°C the atomic ratio of molybdenum to sorbed nitrogen increased to approximately 0.5. The sample was identified as Mo_2N by X-ray diffraction.

The results for decomposition of various amounts of ammonia are shown in Fig. 3, where the initial rate of increase of the hydrogen pressure due to

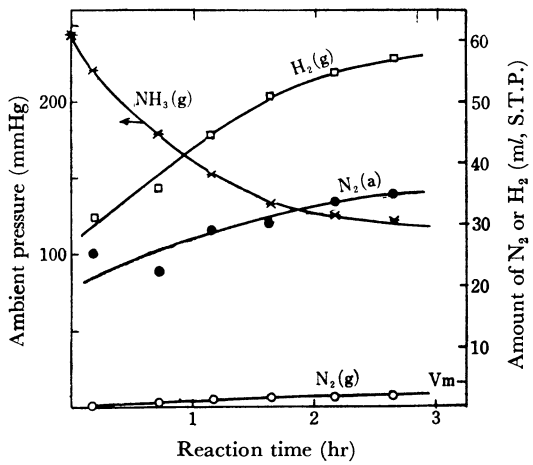

Fig. 2. Decomposition of ammonia over molybdenum-B at 404°C. The symbols used are the same as Fig. 1.

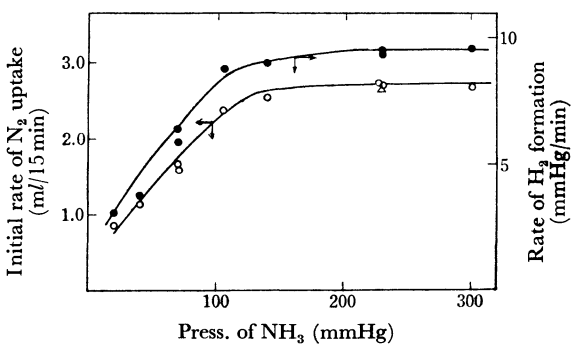

Fig. 3. The plots of the rate of ammonia decomposition (○) and the amounts of nitrogen uptake (●) against the initial partial pressure of ammonia at 454°C (Mo-A).

the ammonia decomposition and the amounts of nitrogen uptake over first fifteen minutes are plotted against the ambient pressure of ammonia. Both the initial rate of the formation of hydrogen and the rate of nitrogen uptake at the initial stage of the reaction were almost independent of the pressure of ammonia above 140 mmHg; rate dependence upon the pressure of ammonia, however, occurs below 140 mmHg.

The apparent activation energies of the ammonia decomposition over the different catalysts, together with those of other workers relevant to the discussion, are given in Table 1, being estimated from the Arrhenius plots (shown in Fig. 4) of the amounts of gas initially evolved. These values are in good agreement with one another.

Table 1. Activation energies for the decomposition of ammonia over molybdenum catalyst

Catalyst	Temperature (°C) range	Activation energy (kcal/mol)
Mo-A	390 — 610	42.6
Mo-B	400 — 440	40.0
MoO_3	400 — 460	43.4
Mo powder[2]	447 — 550	42.5
Mo wire[1]	725 — 850	42.7

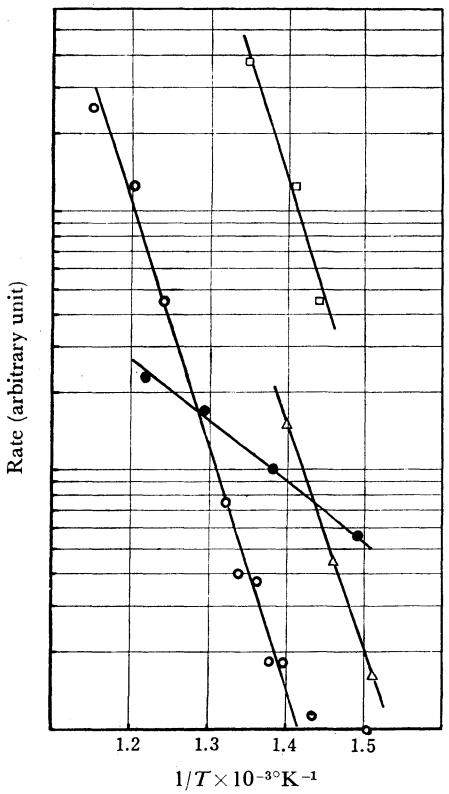

Fig. 4. Arrhenius plots for the ammonia decomposition over different catalyst (○ Mo-A, △ Mo-B, □ Mo oxide) and the reaction between nitrogen sorbed and hydrogen (●).

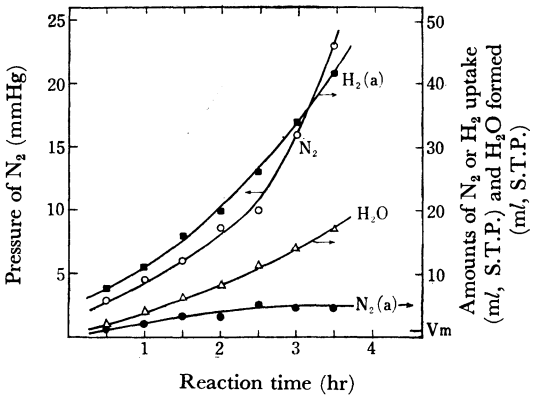

Fig. 5. Decomposition of ammonia over molybdenum trioxide (3.45 g) at 420°C.
△: water vapor formed, the other symbols used are the same as Fig. 1.

When molybdenum trioxide was used as the catalyst, the ammonia was also decomposed, considerable amount of hydrogen and nitrogen was taken up and the formation of water vapor and nitrogen gas was observed, while no hydrogen was detected in the gas phase, as shown in Fig. 5. The hydrogen taken up may exist in the form of H_2O.

The reaction between the hydrogen and nitrogen held on molybdenum was also carried out with the nitrogen-sorbed surface being prepared by decomposition of ammonia and the product observed was identified as only ammonia from its vapor pressure measurement.

The hydrogen pressure dependence of the rate of the hydrogenation of sorbed nitrogen, represented by the cumulative amount of ammonia formed over the first one-hour period, was proportional to $P_{H_2}^{1.5}$ as shown in Fig. 6, where P_{H_2} is the pressure of hydrogen, ammonia being formed linearly with time. The ambient pressure of the hydrogen was represented by the average value over the one-hour period.

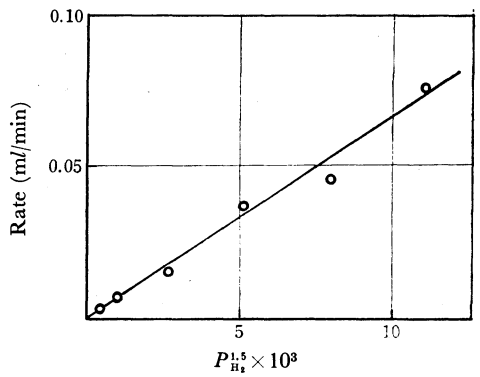

Fig. 6. Dependence of the reaction rate on hydrogen pressure (510°C), the amount of nitrogen uptake being 40 ml (Mo-B).

The rate of the reaction depends on the amount of the nitrogen presorbed on molybdenum as shown in Fig. 7. The rate is proportional to the amount of nitrogen presorbed until the amount reaches eleven times the monolayer value of 4.5 m*l* for the surface.

The apparent activation energy for the hydrogenation was estimated from the Arrhenius plot of the amounts of ammonia formed at fixed conditions of hydrogen pressure (400 mmHg) and nitrogen sorbed (40 m*l*), to be 12 kcal/mol as shown in Fig. 4.

The influence of the oxygen addition to the nitrogen uptake is shown in Fig. 8, and the nitrogen taken up was displaced by successive additions of oxygen where the time intervals between each run were about one-hour. In this case the total displacing ratio of nitrogen to oxygen was approximately ten.

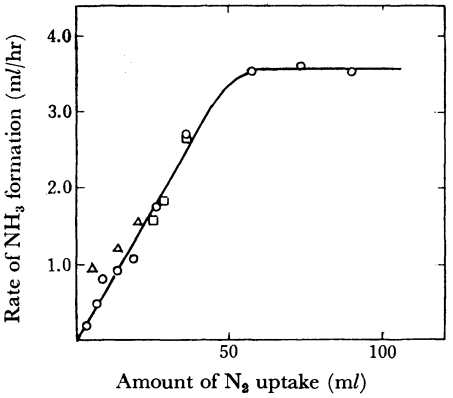

Fig. 7. The dependence of the rate of the reaction upon the amounts of nitrogen uptake at 510°C, the ambient pressure of hydrogen being 400 mmHg (Mo-B).

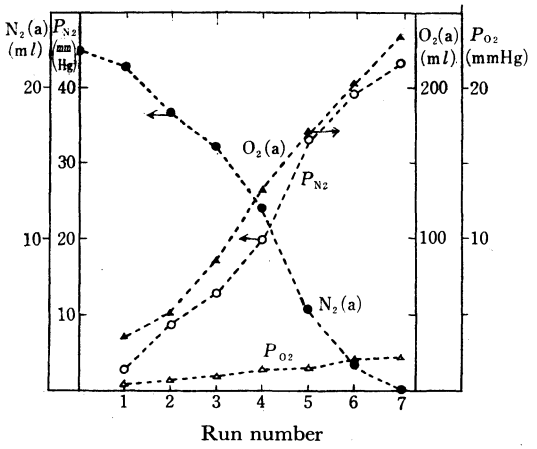

Fig. 8. The effect of oxygen addition to the nitrogen uptake on molybdenum at 400°C. ○: ambient pressure of nitrogen, ●: amounts of nitrogen uptake N_2(a), △: ambient pressure of oxygen, and ▲: amounts of oxygen uptake O_2(a) (Mo-B).

The BET method with nitrogen adsorption revealed the surface area of molybdenum-A to be 0.8 m^2/g, that of molybdenum-B 0.5 m^2/g, and that of molybdenum trioxide, 1.2 m^2/g.

Discussion

1. Decomposition

As shown in Figs. 1 and 2, during the reaction the amounts of nitrogen uptake are greater than V_m in the BET equation, 31.4 m*l*/160 g and 4.56 m*l*/39.6 g, respectively. The results suggest that "surface nitride layers" ate formed of several layers thickness during the ammonia decomposition reaction; the ratio of molybdenum to nitrogen uptake and the result of X-ray diffraction of the sample over which the ammonia was decomposed at higher temperature also support this suggestion.

The decomposition of ammonia over molybdenum may accordingly be shown as

$$NH_3 + 2Mo \rightarrow Mo_2N + 3/2H_2$$

As shown in Fig. 3, the rate of reaction of ammonia with molybdenum is almost independent of the ambient pressure of ammonia above 140 mmHg and seems to be controlled by the rate of diffusion of adsorbed nitrogen into the bulk molybdenum.

The reaction of ammonia with molybdenum trioxide resulted in the decomposition of ammonia to form nitrogen and water vapour, considerable amount of nitrogen being taken up, and the rate of evolution of nitrogen increased with time as shown in Fig. 5. The results may be explained in the following way: molybdenum trioxide is first reduced by ammonia being accompanied by the formation of the nitride; the nitride surface thus formed is active for the decomposition of ammonia and the number of active sites increases with time, while the hydrogen formed may be oxidized immediately to water by molybdenum trioxide.

The agreement in the value of activation energies of the decomposition carried out on the different kinds of catalyst suggests that the active sites on the surfaces are of the same kind and that they exist on a molybdenum nitride surface.

2. The Hydrogenation

The rate of hydrogenation of sorbed nitrogen can be expressed by Eq. (1), as evidenced by the results shown in Figs. 6 and 7.

$$r = k P_{H_2}^{1.5} X_{N_2}$$

where X_{N_2} is the amount of nitrogen taken up, provided that the volume of X_{N_2} is less than 50 m*l*/39.6 g. This dependence of the rate on the amount of nitrogen sorbed is to be noted. Since the monolayer of nitrogen on the surface of the catalyst is 4.6 m*l*, the amount of nitrogen up to 50 m*l* substantially exceeds the V_m value. The fact means that the nitrogen sorbed into the bulk does promote

the rate of hydrogenation of surface nitrogen.

The heat of adsorption of nitrogen on a metal would reasonably be expected to be higher than on a metal nitride, and the stability of the adsorbed nitrogen would be decreased due to the nitride layers. The saturation of the promotion shown in Fig. 7 suggests that the bulk nitride phase is established by sorbed nitrogen.

The interpretation of the reaction order in hydrogen must await further investigation.

The high displacing ratio (such as ten) of nitrogen desorbed to oxygen sorbed must be due to oxygen having a higher affinity than nitrogen for molybdenum, and the formation of bulk oxide is suggested.

The interconversions between metal, nitride and oxide are schematically expressed as follows:

An MO-Theoretical Study of Several Bimolecular Reactions of Nucleophilic Reagents

Kenichi FUKUI,* Hideyuki HAO** and Hiroshi FUJIMOTO*

* *Department of Hydrocarbon Chemistry, Kyoto University, Kyoto*
** *Ōe Works, Sumitomo Chemical Co., Ltd., Niihama, Ehime*

(Received June 14, 1968)

The relative ease of the occurrence of S_N2 and E2 reactions and the mechanism of related bimolecular processes, such as the base-catalyzed hydrolysis of carboxylic esters and the acid-catalyzed halogenation of aliphatic ketones, are discussed in connection with the MO-theoretical reactivity indices. The results indicate that the valence-inactive populations in the lowest unoccupied (LU) MO are useful reactivity indices for these nucleophilic reactions.

The molecular orbital (MO) theory has been applied by the present authors to the discussion of the mechanism of S_N2 and E2 reactions.[1,2] These two processes are known to take place more or less concurrently, in the reaction of molecules bearing a nucleophilic group with a nucleophilic reagent. In the present paper the relative ease of the occurrence of these two processes is discussed in connection with the MO-theoretical reactivity indices, while a simultaneous discussion of related bimolecular processes, such as the base-catalyzed hydrolysis of carboxylic esters[3a] and the acid-catalyzed halogenation of aliphatic ketones,[3b] is given.

The method of calculation is based on the extended Hückel approach,[4] which has already proved to be useful in the elucidation of the mechanism of many other kinds of reactions.[5–10] As MO-theoretical reactivity indices, the populations of the frontier orbitals[11] are employed, which have been defined in the frame of the extended Hückel approach. For the nucleophilic reactions as treated in the present paper, the valence-inactive population[12] of each position (atom or atomic orbital (AO)) in the lowest unoccupied (LU) MO serves as the frontier electron density. It has been ascertained that this quantity becomes a useful

reactivity index in various types of reactions.[13]

Calculations

For the sake of simplicity, chlorine is adopted as a representative of the nucleophilic group throughout the calculations.

The numerical values used in the extended Hückel calculation are given in Table 1. The overlap integrals are evaluated by the use of Mulliken's formula[14] with Slater-type AO's.

Table 1. The effective nuclear charge ($\mathcal{Z}$) of the Slater-type orbitals and the Coulomb integrals (h_{rr})

	H	C	O	Cl	Ref.
$\mathcal{Z}$	1.0	3.25	4.55	6.10	
$h_{rr}(ns)$, eV	−13.60	−21.43	−35.30	−25.23	15
$h_{rr}(np)$, eV	——	−11.42	−13.61	−13.34	15

In order to interpret the experimental data, the following MO-theoretical quantities[16] are calculated and employed:

The partial valence-inactive[12] AO population of AO r in the jth MO:

$$p_r^j = 2(C_r^j)^2$$

The partial valence-inactive atom population of the atom A in the jth MO:

$$p_A^j = \sum_r^A p_r^j$$

The partial atom bond population between the atoms A and B in the jth MO:

$$M_{AB}^j = 2\sum_r^A \sum_s^B C_r^j C_s^j S_{rs}$$

where C_r^j stands for the coefficient of AO r in the jth MO and where $\sum^A$ signifies the summation over all the AO's belonging to the atom A.

The geometry of molecules is determined by the following interatomic distances:

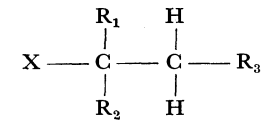
C—H 1.09 Å C—Cl 1.76 Å ^{acyl}C—O 1.36 Å
C—C 1.54 Å C=O 1.22 Å ^{alkyl}C—O 1.46 Å

with the valence angles of carbon and oxygen atoms given by Wheland's monograph,[17] except in chlorine-containing molecules, for which a uniform value, 109°28′, is adopted for carbon for the sake of simplicity.

Results and Discussion

As has been mentioned earlier, it should be noted that the comparison is made between the experimental results, in which the nucleophilic group X is not always a chlorine atom, and the theoretical values calculated with respect to the case where X is equal to chlorine.

1. S_N2 and E2 Reactions. A molecule bearing a nucleophilic group X:



is considered, in which R_1 and R_2 represent a hydrocarbon rest or a hydrogen atom, and in which R_3 is an arbitrary group. The reaction designated as E2[3d] is a double-linkage-forming process by way of the elimination of XH, in which the abstraction takes place dominantly at that hydrogen atom *trans* coplanar with respect to X. This process, which is known as the "*trans*" elimination, has already been treated by the present authors in the frame of the frontier electron method.[2] The experimental results have been interpreted satisfactorily by means of the population of LU MO at each hydrogen atom, p_H^{LU}; the population has completely paralleled the reactivity of many halogenated hydrocarbons, being largest at the β-hydrogen *trans* with respect to the halogen atom.

On the other hand, the S_N2 process is considered to occur by way of the attack of a nucleophile from the backside of the carbon to which the nucleophilic group is attached, leading in general to Walden's inversion. The present authors have already treated[1] this problem MO-theoretically with regard to methyl chloride. The LU MO has been found to localize strongly at the carbon 2p AO lying on the C–Cl axis, extending from the carbon mostly in the direction reverse to the C–Cl bond. This finding reflects the experimental result mentioned above.

It is well known that these two bimolecular processes can frequently take place in a competitive fashion in the same reactant molecule by way of the attack of the same nucleophilic reagent. In order to elucidate the factor determining the readiness of the two processes, the following reactivity indices are employed in interpreting the experimental results.

First, the partial valence-inactive population of the β-hydrogen 1s AO in LU MO, $p_{\beta\text{-}H}^{LU}$, is used for the reactivity index of the β-hydrogen atom in the E2 reaction. As has been mentioned before, this value is expected to parallel the reactivity.

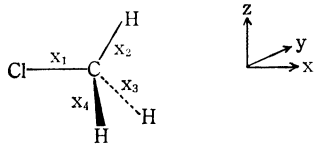
(2) $RBr + Cl^- \xrightarrow{k_2} RCl + Br^-$ (S_N2)[18a]

(3) $RCH_2CR'R''Br + C_2H_5O^- \xrightarrow{k_3} RCH{=}CR'R'' + C_2H_5OH + Br^-$ (E2)[18b]

RCl	ε^{LU} (eV)	$\frac{1}{2}p^{LU}_{x(C-Cl)}$	S_N2 reactivity $k_1\times10^5$ at 55°C ($l\,mol^{-1}\,sec^{-1}$)	S_N2 reactivity k_2 relative value	$\frac{1}{2}p^{LU}_{\beta-H}$	E2 reactivity $k_3\times10^5$ at 55°C ($l\,mol^{-1}\,sec^{-1}$)	M^{LU}_{CCl}
CH_3Cl	1.8702	1.0914	——	100	——	——	−1.1392
C_2H_5Cl	1.6242	0.9289	118.2	1.97	0.0793	1.2	−0.9321
$(CH_3)_2CHCl$	1.4873	0.9137	2.1	0.040	0.0862	7.6	−0.9028
$(CH_3)_3CCl$	1.2370	0.8466	small	0.009	0.0911	50	−0.8359

Secondly, the S_N2 process is treated in the following way. The four hybrids belonging to the tetravalent carbon atom attached to the chlorine atom are designated as x_1, x_2, x_3, and x_4; of those, x_1 is taken to be associated with the C–Cl bond. The LU MO obtained by the extended Hückel calculation is transformed into the linear combination of x_1, x_2, x_3, and x_4. The partial valence-inactive AO population of $x_1(=x(C-Cl))$ in LU MO, $p^{LU}_{x(C-Cl)}$, is calculated as responsible for the data being comparable with those of the experimental data. This theoretical index corresponds to the frontier electron density for S_N2 reactivity in the frame of the extended Hückel scheme.



An illustration of the calculations is the case of methyl chloride. The coordinates are taken as indicated. The hybrids are represented by:

$$x_1 = 0.5(2s) - 0.866025(2px)$$
$$x_2 = 0.5(2s) + 0.288675(2px) + 0.816497(2pz)$$
$$x_3 = 0.5(2s) + 0.288675(2px) + 0.707107(2py) - 0.408249(2pz)$$
$$x_4 = 0.5(2s) + 0.288675(2px) - 0.707107(2py) - 0.408249(2pz)$$

The extended Hückel MO of LU level is given by:

$$\psi^{LU} = -0.193928x_{2s} + 1.094344x_{2px} + \cdots$$

which can easily be transformed into:

$$\psi'^{LU} = -1.044694x_1 + 0.218946(x_2+x_3+x_4) + \cdots$$

Hence, the index $\frac{1}{2}p^{LU}_{x(C-Cl)}$ is calculated to be 1.091386.

Such a computation was made with various alkyl chlorides; the results are indicated in Table 2, together with the experimental data. The partial atom bond population between α-carbon and chlorine in LU MO, M^{LU}_{CCl}, is also given in Table 2 in order to explain the reaction mechanism.

The experimental results are taken from the case of alkyl bromides, which can provide abundant data for a comparison with the theory. This substitution is possible as long as one is concerned only with the change in the relative rate resulting from the structural difference of alkyl groups.

From Table 2 it can be seen that, as the alkyl group varies from CH_3 to C_2H_5, i-C_3H_9, and t-C_4H_9, the index $p^{LU}_{x(C-Cl)}$ clearly decreases, while $p^{LU}_{\beta-H}$ increases. This implies that the nucleophilic reactivity of α-carbon diminishes in this order and that the β-proton becomes more and more reactive toward abstraction by nucleophiles; this agrees with our experience that the S_N2 reactivity is $CH_3 > C_2H_5 > i\text{-}C_3H_7 > t\text{-}C_4H_9$, while the E2 reactivity is $C_2H_5 < i\text{-}C_3H_7 < t\text{-}C_4H_9$.

The value of M^{LU}_{CCl} is calculated to be always negative. This means that the C–Cl bond is weakened by the approach of an electron-donor reagent. In addition, the absolute value of M^{LU}_{CCl} decreases in the order of alkyl groups mentioned above; this is consistent with, or, more strictly, not contradictory to, the experimental results in which the S_N2 reactivity decreases in this order.

Table 2 also indicates the energy of LU MO, ε^{LU}. This energy decreases in the order of alkyls stated above. It appears that this implies that the nucleophilic reactivity increases in this order. However, if one assumes the ionization potential of an

18) C. K. Ingold, "Structure and Mechanism in Organic Chemistry," Cornell University Press, Ithaca, New York (1953), a) p. 306; b) p. 419; c) M. L. Dhar, E. D. Hughes, C. K. Ingold and S. Masterman, *J. Chem. Soc.*, **1948**, 2055.

alkoxyl anion to be *ca.* 6—8 eV,[19] the ratio of $\Delta\varepsilon^{LU}$ to $(\varepsilon^{LU}-\varepsilon'^{HO})$, where ε'^{HO} is the energy of the highest occupied (HO) MO of the reagent, is small compared to $\Delta p_r^{LU}/p_r^{LU}$. According to the perturbation theory[20] for the interaction between reactant and reagent, the stabilization energy in an nucleophilic attack is approximately proportional to:

$$\frac{p_r^{LU}}{\varepsilon^{LU}-\varepsilon'^{HO}} \quad (r\text{: } x\text{(C-Cl) or } \beta\text{-H})$$

Therefore, the result reported above implies that in the present case the reactivity can be discussed most conveniently in terms of p_r^{LU}.

The reason for the positive ε^{LU} value should be mentioned here. The basis functions usually adopted in extended Hückel MO's, and in the present case as well, are those AO's in the occupied valence shell only, so the unoccupied MO's are generally calculated to possess an unreasonably high energy. This point is improved by a suitable basis-set extension.[21]

Furthermore, $p_{\beta\text{-H}}^{LU}$ is calculated with respect to various alkyl chlorides and compared with their E2 reactivities in Table 3. Moreover, in this case, the E2 reactivity data are taken from the corresponding bromide reactions. The calculation is carried out with regard to the all-staggered conformation for each compound which is considered to possess the largest existence probability.

The parallel between the calculated results and the experimental results is satisfactory. However, primary alkyl halides like *n*-propyl chloride have no *trans*-hydrogen in the staggered conformation and its β-hydrogen has only a very small $p_{\beta\text{-H}}^{LU}$ value, as may be seen in Fig. 1. On the other hand, the *trans* β-hydrogen appearing in the gauche conformation has a very large $p_{\beta\text{-H}}^{LU}$ value. Although the staggered form is 2.0 kcal more stable than the gauche one, as is indicated in Fig. 1, it is of interest that the gauche form is *ca.* 2.4 kcal more stable than the staggered in the species in which CH_3O^- is placed near the β-hydrogen. This leads one to presume that, in the transition state, the gauche form is more stable instead. For primary alkyl halides, consequently, the values p_r^{LU} of the *trans* β-hydrogen in the gauche conformation have been calculated; they are listed in Table 3.

The Saytzeff rule has already been given a theoretical foundation by the aid of the index $p_{\beta\text{-H}}^{LU}$ with regard to only one case 2-chlorobutane.[2] Here the rule is similarly explained also in the

Table 4. Relation between M_{CCl}^{LU} and total rate of bimolecular nucleophilic reactions[18c]

Reaction: $RBr + C_2H_5O^- \xrightarrow{k}$ Olefin and ROC_2H_5

RCl	M_{CCl}^{LU}	$k \times 10^5$ at 55°C ($l\,mol^{-1}\,sec^{-1}$)
C_2H_5Cl	−0.9321	174
$CH_3CH_2CH_2Cl$	−0.9149	60.0
$CH_3CH_2CH_2CH_2Cl$	−0.6028	43.9
$CH_3CH_2CH_2CH_2CH_2Cl$	−0.3164	39.2

cases of 2-amyl chloride and *t*-amyl chloride, so as to demonstrate a more general applicability of the theory. The results are indicated in Fig. 2, exhibiting the predominance of secondary β-hydrogens over primary ones.

The partial atom bond population of α-carbon and the chlorine atom in LU MO, M_{CCl}^{LU}, is compared to the total rate of S_N2 and E2 reactions in Table 4. As has been pointed out earlier, the LU MO localizes in the C–Cl bond and is antibonding with respect to C–Cl, contributing to the weakening of the bond in the interaction with an electron donor. It should be noted that a parallel can be seen in the table between the absolute value of M_{CCl}^{LU} and the total rate.

2. Base-catalyzed Hydrolysis of Carboxylic Esters. The base-catalyzed bimolecular hydrolysis of carboxylic esters with acyl-oxygen fission ($B_{AC}2$), the mechanism of which was established by the early experiment of Polanyi and Szabo[22] using $H_2{}^{18}O$, is considered to take place through the attack of a nucleophile on the acyl carbon.

The partial valence-inactive atom populations in LU MO, p_A^{LU}, calculated for methyl acetate, ethyl acetate, methyl monochloroacetate, and methyl dichloroacetate are indicated in Fig. 3. The results indicate a distinct population localization at the acyl carbon; this is in accordance with our expectation of the selective attack of a nucleophile at that position.

The values of the partial atom bond population in LU MO, M_{AB}^{LU}, are also shown in the same figure; they indicate the strong antibonding character of this MO at the bond between acyl carbon

22) M. Polanyi and A. L. Szabo, *Trans. Faraday Soc.*, **30**, 508 (1934).

and ester oxygen, whereas this MO is bonding at the alkyl-oxygen bond, in agreement with the experimental results.

3. Acid-catalyzed Halogenation of Ketones. The accelerating effect of acids in the halogenation (and also in the deuteration and racemization) of enolizable ketones is thought to take place by way of an enol intermediate.[3c] Cardwell and Kilner[23] have reported that the Saytzeff rule applies in this process. Recently, Rappe[24] attributed the predominance of the position 3 over the position 1 in the acid-catalyzed halogenation or deuteration of 2-butanone to the difference in stability between the corresponding enol intermediates.

1. Methyl Ethyl Ketone

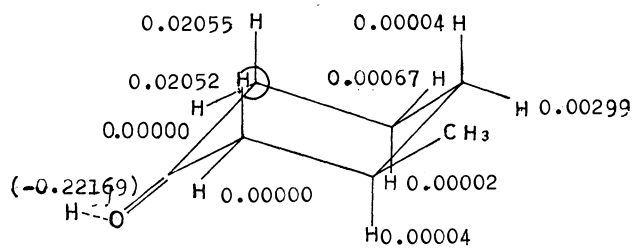
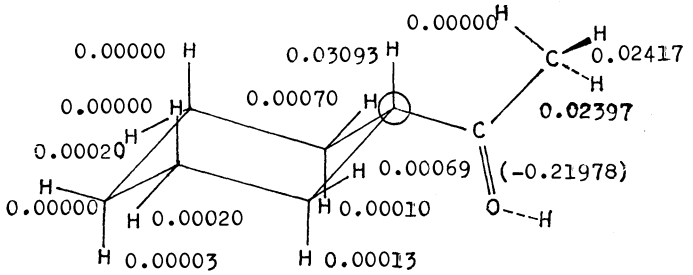
4. 3-Methyl Cyclohexanone



5. Methyl Cyclohexylketone



6. 2,5-Dimethyl Clohexanone

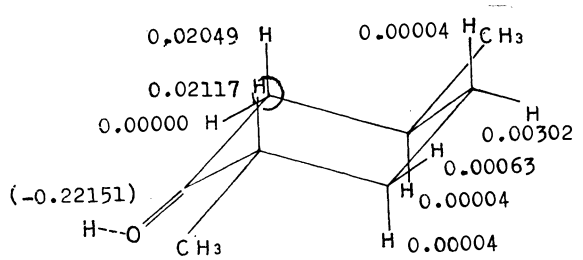


Fig. 4. The $\frac{1}{2}p_H^{LU}$ values of protonated ketones. (The position of proton is 1.1 Å from oxygen in the carbonyl plane, the angle H–O–C being 105°. The figurues in parentheses are M_{AB}^{LU}.)

In connection with this information, the p_H^{LU} values are calculated with respect to the various aliphatic or alicyclic ketones in which a proton is attached to their carbonyl oxygen. Since the location of the proton does not seriously affect the result, it is tentatively taken to be as is indicated in Fig. 4. The methylene hydrogen has a larger p_H^{LU} than the methyl hydrogen in aliphatic ketones, while in alicyclic ketones the p_H^{LU} of the methyne hydrogen is larger than that of the methylene hydrogen.

The site of attack known from experimentation is shown by a circle;[23] this site is easily verified to be consistent with the theoretical result, except in the case of 2,5-dimethylcyclohexanone. As the reagent nucleophile (the acid anion or the base part of a solvent molecule) approaches a hydrogen atom, the carbonyl C–O double bond is weakened and shifts toward a single bond, since LU MO is strongly antibonding in this region. (The M_{AB}^{LU} values are indicated in parentheses in Fig. 4). These circumstances display the orienting effect of the carbonyl group, resembling that of the nucleophilic group in E2 reactions.

It is also of interest to note the reactivity of α-hydrogens in cyclohexanones. As the diagrams for 2-methylcyclohexanone and 3-methylcyclohexanone indicate, axial hydrogens are expected to be more reactive than equatorial ones; this is in accord with Corey's observation of the enolization of 3-β-acetoxycholestan-7-one in hydrobromic acid.[25]

The calculations were carried out on the HITAC 5020 computer at the computation center of the University of Tokyo.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 356—362 (1969)

Mechanism of Intramolecular Energy Transfer in Rare Earth Chelates as Revealed by Infrared Absorption Measurements

Yoshihisa MATSUDA,*1 Shoji MAKISHIMA and Shigeo SHIONOYA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo

(Received June 24, 1968)

The purpose of this paper is to clarify the mechanism of intramolecular energy transfer from the triplet state of the ligand to the excited levels of the central ion in rare earth chelates. As to seven kinds of samarium β-diketonates, the frequency of infrared absorption due to the stretching vibration of the chelate bond, $\tilde{\nu}_{MO}$, and the manner of energy transfer are investigated. The probability of energy transfer is estimated from the ratio of the intensity of the samarium emission to that of the ligand phosphorescence, I_{Sm}/I_{ph}. The overlap integral, S, between the ligand phosphorescence spectrum and the samarium absorption spectrum is obtained. It was found that a linear relation roughly holds between $\log\{(I_{Sm}/I_{ph})/S\}$ and $\tilde{\nu}_{MO}$. On the basis of this fact, one is led, by making some arguments, to the conclusion that intramolecular energy transfer is dominated by the resonance mechanism due to the exchange interaction of the π electron system of the ligand triplet state with the f electron system of the central rare earth ion.

In chelates of rare earths such as europium, intramolecular energy transfer takes place from the ligand to the central rare earth ion, and consequently luminescence of line spectrum due to the f–f transition of the rare earth ion is emitted. The manner and mechanism of this intramolecular energy transfer process has been recently studied by a number of investigators. This has attracted interest also from the viewpoint that these chelates are important as laser materials.

In our previous paper,[1] we have elucidated that after absorption from the ground state to the excited singlet state of the ligand relaxation takes place to the triplet state of the ligand, and then energy is transferred to the central rare earth ion. The purpose of this paper is to clarify the mechanism of this energy transfer process. It is considered that the nature of the chelate bond is closely connected with the efficiency of the energy transfer process. The strength and electron density of the chelate bond will be widely changed with the change of the ligand. This would be strongly reflected to the manner of infrared absorption due to the vibration of the chelate bond. Therefore, it would be useful, for clarifying the mechanism of energy transfer, to investigate the correlation of the efficiency of intramolecular energy transfer with the frequency of the infrared absorption of the chelate bond.

The infrared absorption of metal chelates has been studied by several investigators. Nakamoto and Martell[2] calculated the frequency of the stretching vibration of chelate bond for transition metal acetylacetonates by the normal-coordinate analysis, and made the assignment of observed infrared absorption bands. Misumi and Iwasaki[3] also carried out the normal-coordinate analysis for acetylacetonates of various rare earths, and stated that the force constants for the stretching of rare earth-oxygen (M–O) bond are nearly proportional to the reciprocal values of M–O bond length.

Previously, we have investigated[4] the correlation between the manner of the temperature quenching of the emission of chelated europium ion and the frequency of the M–O bond stretching vibration for seven kinds of europium β-diketonates. It was found in general that the higher the frequency of the M–O bond vibration is, the less quenched the europium emission is with increasing temperature. It was reported by Bhaumik[5] that both the intensity and the lifetime of the emission of chelated europium ion decrease with increasing temperature from 77°K, but that the intensity starts to decrease at lower temperatures than the lifetime does. For instance, in the case of europium

dibenzoylmethide, the intensity starts to decrease at 120°K while the lifetime at 220°K. Similar tendencies were observed for the other europium chelates. From these facts it is suggested that the manner of the temperature quenching is mainly dominated by the temperature dependence of the non-radiative process taking place in the ligand part before intramolecular energy transfer occurs. Then, our results as mentioned above are regarded as indicating that for those europium chelates in which the temperature quenching hardly occurs, the efficiency of intramolecular energy transfer is high and also the frequency of absorption bands due to the M–O bond stretching vibration is high. This was thought to imply that the shorter the M–O bond length is, the higher the efficiency of energy transfer becomes. It was, however, difficult for europium chelates to estimate quantitatively the efficiency of intramolecular energy transfer. If it could be done, it would present more useful information for clarifing the mechanism of intramolecular energy transfer.

It is known that samarium β-diketonates show both the samarium emission and ligand emission, although europium β-diketonates show only the europium emission. Therefore, in case of samarium chelates, it would be possible to estimate the efficiency of energy transfer from the relation between the intensity of the ligand emission and that of the samarium emission. In this paper, as to seven kinds of samarium β-diketonates, infrared absorption due to the vibration of the chelate bond and the manner of intramolecular energy transfer are investigated.

In rare earth chelates, the absorption spectra of the ligand parts show no significant difference in comparison with those of the free ligand molecules,[1] and also the emission spectra of the chelated rare earth ions are very similar to those of the free ions in solutions. Furthermore, energy transfer from the ligand to the rare earth ion is suggested to occur only in a short range, on the basis of the fact, reported by us,[1] that energy transfer does not take place if β-diketone is not coordinated to the rare earth ion in solution. From these facts, the ligand π electron system, *i. e.* energy donor, is considered to interact very weakly with the f electron system of the rare earth ion, *i. e.* energy acceptor. Therefore, it would be inferred that the theory of intermolecular energy transfer due to the resonance mechanism in condensed systems, as developed by Förster[6] and further by Dexter,[7] is also applicable to the intramolecular energy transfer in the present case. It is, therefore, necessary, for discussing the problem along this inference, to take the energy overlap of the ligand triplet level with the excited levels of the chelated rare earth ion into consideration. This energy overlap is estimated from spectral measurements. As will be described below, it has been revealed that the intramolecular energy transfer is governed by the resonance mechanism due to the exchange interaction between the ligand and the central rare earth ion.

Experimental

1) Samples. Hexa-coordinated β-diketonates of samarium were used in this investigation, although octa-coordinated ones were used by many other investigators. The reason is that octa-coordinated chelates are dissociated in solutions so that errors might be caused. The chelates used are listed with their abbreviations in Table 1. These samples were prepared by the following methods.

Table 1. List of samarium β-diketonates, $R_1 \cdot CO \cdot CH_2 \cdot CO \cdot R_2$, used in this investigation

Chelates	Abbreviation	R_1	R_2
Samarium acetylacetonate	SmAA	CH_3	CH_3
Samarium trifluoroacetylacetonate	SmTAA	CF_3	CH_3
Samarium benzoylacetonate	SmB	CH_3	C_6H_5
Samarium trifluorobenzoylacetonate	SmBFA	CF_3	C_6H_5
Samarium dibenzoylmethide	SmD	C_6H_5	C_6H_5
Samarium thenoyltrifluoroacetonate	SmTTA	CF_3	C_4H_3S
Samarium furoyltrifluoroacetonate	SmFTA	CF_3	C_4H_3O

a) SmAA, SmTAA, SmB, SmBFA: About 100 m*l* of xylene solution containing 5 g of β-diketone was refluxed with the stoichiometric quantity of metallic sodium untill all the quantity of sodium had reacted. The precipitate was filtered and was washed with *p*-xylene, benzene and ether in this order. The product, *i. e.* sodium β-diketonate, was dried by air. Aqueous solution of samarium chloride was mixed with aqueous solution of sodium β-diketonate. The precipitate, *i. e.* octa-coordinated chelate, was filtered and washed several times with water. The product was recrystallized in acetone-water, and then was dried under vacuum for 20 hr at 80—100°C in order that it is converted to hexa-coordinated chelate.

b) SmD: The octa-coordinated chelate was prepared by the ordinary piperidine method at first. This was kept under vacuum for 24—30hr at 150°C to obtain hexa-coordinated chelate.[8]

c) SmTTA, SmFTA: Aqueous solution of samarium nitrate was added to toluene solution containing about 30% excess ligand in a separatory funnel. About 50% excess piperidine was added to the solution. This was then shaken and was separated into aqueous and toluene solutions. Normal pentane was added to the toluene solution. The precipitate was collected, and

8) R. E. Whan and G. A. Crosby, *J. Mol. Spectry.*, **8**, 315 (1962).

recrystallized in toluene-pentane. The product, *i. e.* octa-coordinated chelate, was kept under vacuum at 120—150°C for 20 hr to obtain hexa-coordinated one.

2) Optical Measurements. *a) Infrared Absorption Spectra.* The measurement was made with a Hitachi EPI-2 infrared spectrophotometer with an NaCl or KBr prism for NaCl or KBr region, respectively, by means of the KBr disk method.

b) Emission Spectra. The measurement was made at liquid nitrogen temperature for methanol-ethanol (1 : 3) solutions of the chelates with the concentration of 5×10^{-3} M. A Kipp & Zonen prism double monochromator and an EMI 9558QB photomultiplier were used. As the exciting light, the 365 mμ line obtained from a 1 kW high pressure mercury lamp combined with a Bausch & Lomb grating monochromator was used.

c) Emission Lifetime. An Edgerton FX-3 type xenon flash lamp (energy: 1 joule/pulse, duration: 2μsec) with an ultraviolet-pass filter was used as the exciting light source. The response of an RCA 931A photomultiplier was fed to an oscilloscope, and decay curve was photographed. All the measuremens were made for methanol-ethanol (1 : 3) solutions of the concentration of 1×10^{-3} M at liquid nitrogen temperature.

Results and Discussions

Infrared absorption spectra were measured for seven kinds of samarium β-diketonates listed in Table 1. As examples, the spectra of SmAA and SmD are shown in Fig. 1.

The assignment of infrared absorption bands for metal acetylacetonate was made, as mentioned already, by several investigators. The theoretical assignment was given first by Nakamoto and Martell[2] for transition metal acetylacetonates. Misumi and Iwasaki[3] carried out a similar calculation for rare earth acetylacetonates. Liang *et al.*[9] also carried out a similar analysis for EuAA. It was pointed out by both of these authors that in rare earth chelates an absorption band in a region of 400 to 450 cm^{-1} is mainly due to the M–O bond stretching, and that another absorption band located at the second place counted from the short wavelength side in a region of 1500 to 1700 cm^{-1} is mainly due to the C–O bond stretching. The assignment for other rare earth β-diketonates was made empirically on the basis of the calculation for acetylacetonate.

Misumi and Iwasaki[3] showed for acetylacetonates of various rare earth ions that the larger the atomic number of the central ion is, the higher the frequency of the absorption band due to the M–O bond stretching is. We measured the frequency of this band in six kinds of β-diketonates, other than acetylacetonates, of lanthanum, samarium, europium and gadolinium, and found that this kind of tendency also holds.

The observed frequency of the absorption bands due to the M–O and C–O bond stretching, $\tilde{\nu}_{MO}$

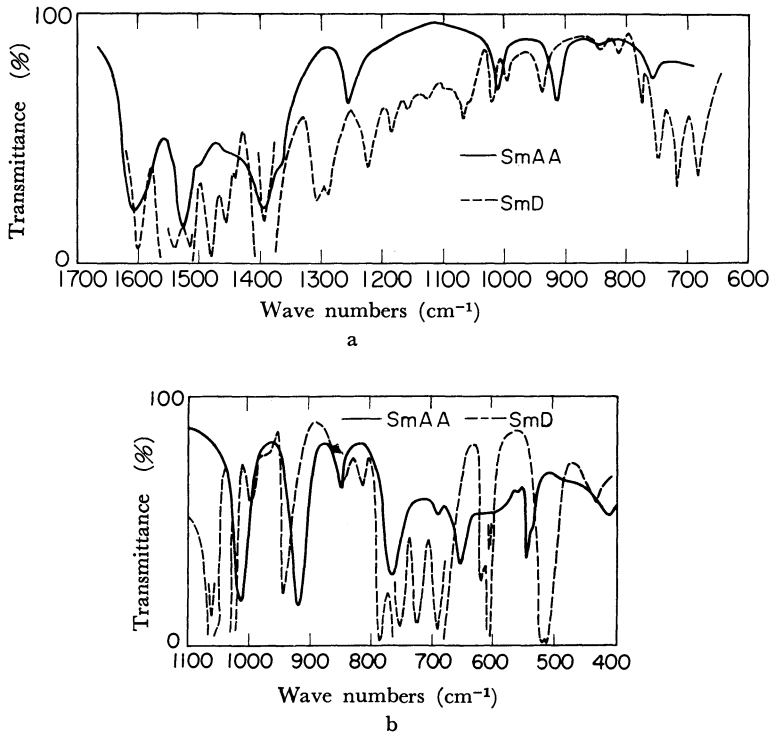

Fig. 1. Infrared absorption spectra of SmAA and SmD, a) obtained by NaCl prims, and b) by KBr prism.

and $\tilde{\nu}_{CO}$, for seven kinds of samarium β-diketonates are given in Table 2. The frequency for the M–O bond stretching changes with the change of R_1 and R_2 in β-diketonates. Namely, the value of $\tilde{\nu}_{MO}$ becomes smaller in the order of $C_6H_6 \rightarrow CF_3 \rightarrow CH_3$. On the other hand, the value of ν_{CO} does not show such a systematic change.

TABLE 2. INFRARED ABSORPTION FREQUENCY DUE TO M–O AND C–O BOND STRETCHING, $\tilde{\nu}_{MO}$ AND $\tilde{\nu}_{CO}$, RATIO OF THE INTENSITY OF SAMARIUM EMISSION TO THAT OF LIGAND PHOSPHORESCENCE, I_{Sm}/I_{ph}, OVERLAP INTEGRAL BETWEEN LIGAND PHOSPHORESCENCE SPECTRUM AND SAMARIUM ABSORPTION SPECTRUM, S, AND $(I_{Sm}/I_{ph})/S$, FOR SEVEN KINDS OF SAMARIUM β-DIKETONATES

Samarium β-diketonates show, under the excitation by ultraviolet light, the emission due to the f–f transitions in the chelated samarium ion, the fluorescence from the excited singlet state of the ligand and the phosphorescence from the triplet state of the ligand. As an example, the emission spectrum of SmAA at liquid nitrogen temperature is given in Fig. 2.

We observed[1] that there is no significant difference between the phosphorescence spectra of lanthanum and gadolinium chelates which do not show the emission of the central ions. This fact indicates that the ligand triplet state is hardly affected by changing the central ion. In Fig. 2, the spectrum of the total ligand emission is separated into the phosphorescence and the fluorescence by referring to their spectra in lanthanum and gadolinium chelates.

The decay times for the samarium emission in seven kinds of samarium β-diketonates were measured by picking a part arround 600 mμ in the spectra up with color filters. It was found that the decay times are in a range of 25 to 35 μsec. The decay times for the phosphorescence were measured for a part arround 490 mμ in the spectra. Those of SmB, SmD and SmBFA were 5, 5 and 7μsec, respectively. For other samarium chelates the measurement could not be made because of low intensities of their phosphorescence.

We reported, as mentioned above, that in rare earth chelates the transfer of excitation energy takes place from the triplet state of the ligand to the excited levels of the chelated rare earth ion. For the samarium chelates studied the probabilities of non-radiative transition within the samarium excited levels would be nearly equal among each other at liquid nitorgen temperature, since there is no significant difference among the lifetimes of the samarium emission. If the transition probability from the triplet state to the ground state of the ligand does not change among these chelates, the probability of intramolecular energy transfer should be proportional to the intensity ratio of the samarium emission to the ligand phosphorescence, I_{Sm}/I_{ph}. However, the transition probability from the triplet to ground state of the ligand cannot be measured for samarium chelates, because of the reason that the lifetime of the triplet state of

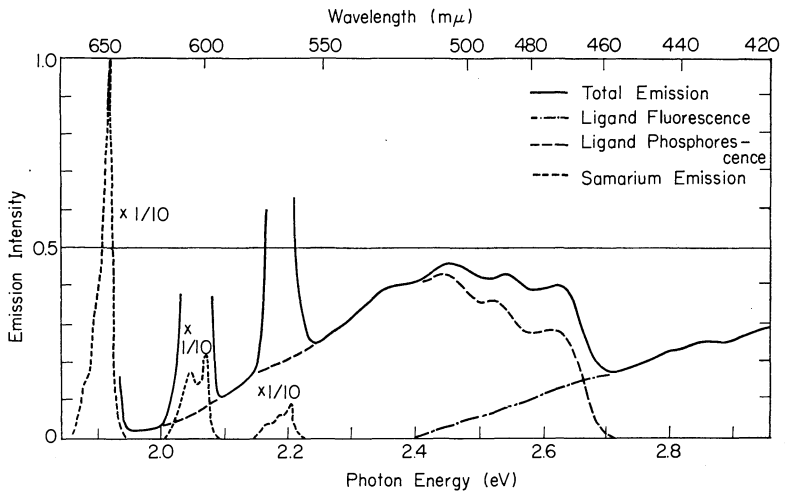

Fig. 2. Emission spectrum of SmAA at liquid nitrogen temperature. The total emission is separated into ligand fluorescence, ligand phosphorescence and samarium emission. "$\times 1/10$" indicates that emission intensity is reduced to one tenth.

samarium chelate is made shorter by the occurrence of intramolecular energy transfer, so that one can not estimate the transition probability from the observed lifetime of the phosphorescence. In the gadolinium β-diketonates, however, intramolecular energy transfer does not occur. Therefore, for seven kinds of gadolinium chelates, the ligands of which are the same as those of samarium chelates under study, the lifetime of the phosphorescence was observed, and was found to be in a range of 35 to 45μsec.

From this it may be considered that these samarium β-diketonates have nearly equal transition probabilities from the triplet to ground state of the ligand. Therefore, the probability of intramolecular energy transfer is regarded to be proportional to I_{Sm}/I_{ph}. The observed values are given in Table 2. Here, I_{Sm} and I_{ph} were obtained, respectively, from the areas of the spectra for the samarium emission and the ligand phosphorescence.

It is clearly observed from the table that the transfer efficiency is enhanced by the fluorination of the ligand or by the enlargement of the conjugate system. Further from the observation of the table, it is very roughly said that in these seven kinds of samarium chelates the larger the value of I_{Sm}/I_{ph} is the higher the frequency of $\tilde{\nu}_{MO}$ is, although there are some exceptions. As for the frequency of $\tilde{\nu}_{CO}$ such a tendency is more obscure.

Since it is inferred, as mentioned already, that the resonance between the π electron system in the ligand and the f electron system in the rare earth ion might be responsible for energy transfer, one has to take the overlap between the spectrum of the phosphorescence from the triplet state of the ligand and that of the absorption of the rare earth ion into consideration for discussing the mechanism of the intramolecular energy transfer. Therefore, the overlap integral, S, as expressed by the following equation was estimated,

$$S = \int I_{ph}(E)\, a(E)\, dE, \qquad (1)$$

where $I_{ph}(E)$ is the phosphorescence spectrum and $a(E)$ is the absorption spectrum of the chelated samarium ion, both being normalized as

$$\int I_{ph}(E)dE = 1 \text{ and } \int a(E)\,dE = 1.$$

Since the absorption spectra of the chelated samarium ions in the chelates used could not be measured because of their very small absorption coefficient, the absorption spectrum of $SmCl_3$ solution was used as a substitute. The absorption and emission spectra of $SmCl_3$ in ethanol solution with the concentration of 1 M are shown in Fig. 3. The absorption measurement was made with a Cary model 14 spectrophotometer at room temperature. This shows an emission spectrum similar to that of the chelated samarium ion; that is, the positions of the emission peaks differ only by 0.006—0.009 eV from those of the chelated samarium ion. The band-width of the phosphorescence spectrum of samarium β-diketonates is about 0.4 eV as seen from Fig. 2. The peak position of the phosphorescence spectrum depends markedly on the kind of the ligand in samarium β-diketonates. It differs at least by 0.25 eV among the seven chelates studied. Therefore, the slight difference of the samarium emission spectra between the chelates and chloride is negligible in comparison with the difference of the phosphorescence spectra. From these facts, it is reasonable to use the absorption spectrum of samarium chloride as a substitute for that of the chelates. The results for S thus estimated are given in Table 2. The values are expressed by normalizing the largest value to be unity.

As is well known Förster[6] investigated the theory of intermolecular energy transfer by resonance mechanism. Dexter[7] developed the theory further to the case where the resonance due to various types of interactions take place. In the case of energy transfer due to exchange interaction, which occurs when energy donor and acceptor are located in close ranges, the probability of transfer, P_t, is approximately given by[7]

$$P_t = \text{const. } S\exp(-2R/L), \qquad (2)$$

where R is the donor-acceptor distance, L is the

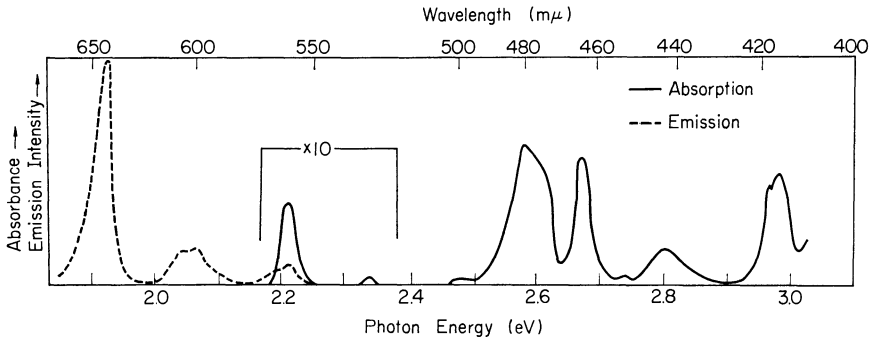

Fig. 3. Absorption spectrum at room temperature and emission spectrum at liquid nitrogen temperature of $SmCl_3$ in ethanol solution. "$\times 10$" indicates that absorbance is ten times magnified.

effective average Bohr radius for the excited and unexcited states of donor and acceptor and S is the overlap integral as defined by Eq. (1). The exponential term of this equation represents the magnitude of the spacial overlap of the wave functions of donor and acceptor.

I_{Sm}/I_{ph} is, as described above, proportional to the probability of intramolecular energy transfer. It was found, after some graphical trial, that a linear relation roughly holds between the values of log $\{(I_{Sm}/I_{ph})/S\}$ and $\tilde{\nu}_{MO}$ as shown in Fig. 4. Namely,

$$I_{Sm}/I_{ph} \propto P_t = a\,S\exp(b\,\tilde{\nu}_{MO}), \tag{3}$$

where a and b are constants.

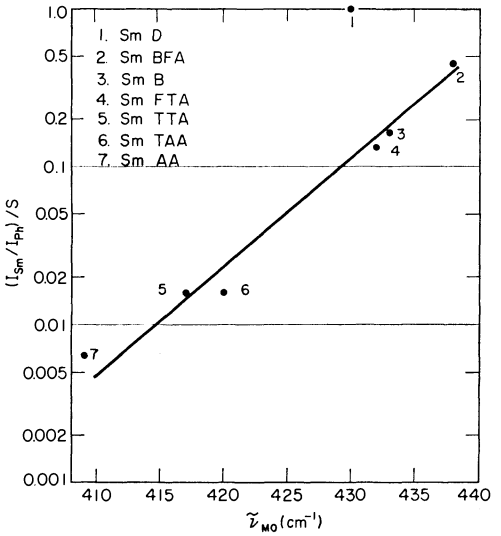

Fig. 4. Plotting of $\tilde{\nu}_{MO}$ *vs.* $(I_{Sm}/I_{ph})/S$ (in logarithmic scale) for seven kinds of samarium β-diketonates.

Let us examine how this experimentally obtained equation is correlated with Eq. (2), the theoretical one for the case of energy transfer due to the exchange interaction. The reduced mass relating with $\tilde{\nu}_{MO}$ in Eq. (3) has the same value for all chelates studied, since M is always samarium. Therefore, $\tilde{\nu}_{MO}$ is proportional to the square root of the force constant of the M–O bond stretching, $\sqrt{k_{MO}}$. Since all the observed values of $\tilde{\nu}_{MO}$ are located in a small range of frequency, *i. e.* in 409 to 438 cm^{-1}, $\tilde{\nu}_{MO}$ can be approximately replaced by k_{MO}. Then, Eq. (3) can be rewritten as,

$$P_t = a'S\exp(b'\,k_{MO}), \tag{4}$$

where a' and b' are constants. It was confirmed that if the plot of $\tilde{\nu}_{MO}{}^2$*vs.* log $\{(I_{Sm}/I_{ph})/S\}$ is made, a rough straight line as in Fig. 4 is obtained.

Several authors studied the correlation of the force constant of chelating bond with the bond length and also with the electron density at the bond. Misumi and Iwasaki[3] reported, as mentioned already, that k_{MO} is nearly proportional to the reciprocal value of the M–O bond length for various rare earth acetylacetonates, if the sum of the ionic radii of oxygen and rare earth ion is taken as the bond length. For the acetylacetonates they studied, the bond length is in the range of 1.43 to 1.56 Å, and $\tilde{\nu}_{MO}$ in the range of 420 to 432 cm^{-1}. The observed values of $\tilde{\nu}_{MO}$ shown in Table 2 change from 409 to 438 cm^{-1}. The M–O bond length in this case, therefore, would be regarded to change a little more widely than the case reported by Misumi and Iwasaki. It would be likely that in various samarium chelates the real length of the M–O bond changes by the change of ligand. Since k_{MO} would be affected by the M–O bond length, r_{MO}, one may assume that the correlation between k_{MO} and r_{MO}, as reported by Misumi and Iwasaki, also holds in this case in which the ligand, but not the central ion, is changed. Since the change of r_{MO} in various samarium chelates is limited only in a narrow range, the inverse proportion of k_{MO} to r_{MO} can be replaced by a simpler dependence, in other words, k_{MO} may be regarded to decrease linearly with the increase of r_{MO}.

Nakamoto *et al.*[10] showed that k_{MO} of transition metal β-diketonates is increased, if the electron density at oxygen in chelate bond is increased by the substitution of R_1 and R_2. Taking it into consideration that k_{MO} is increased with the increase of the electron density at oxygen and also with the increase of electronegativity of the central ion, one can assume that k_{MO} is increased with the increase of electron donation from oxygen to the central ion in chelate bond. The increase of the electron donation would cause the reduction of the bond length.

From the above-mentioned discussion, one may say that k_{MO} is decreased approximately in proportion to the increase of r_{MO}. Therefore Eq. (4) can be rewritten as,

$$P_t = a''S\exp(-b''\,r_{MO}), \tag{5}$$

where a'' and b'' are constants. This equation is equivalent to Eq. (2).

This indicates that the theory of intermolecular energy transfer due to the exchange interaction can be applied also to intramolecular energy transfer in the chelate system. In other words, this indicates that the intramolecular energy transfer under discussion is dominated by the resonance mechanism due to the exchange interaction of the π electron system of the ligand triplet state with the f electron system of the central rare earth ion.

Summary and Conclusion

In order to clarify the mechanism of intramolecular energy transfer in rare earth chelates, the correlation of the efficiency of energy transfer with the frequency of the infrared absorption of the chelate bond was investigated. It is known that this energy transfer takes place *via* the triplet state of the ligand. Seven kinds of samarium β-diketonates as shown in Table 1 were used, since samarium chelates show both the samarium emission and ligand emission so that they are more suitable for the present investigation than the chelates of other rare earths. The probability of intramolecular energy transfer was estimated from the ratio of the intensity of the samarium emission to that of the ligand phosphorescence. It is inferred that the theory of intermolecular energy transfer due to the resonance mechanism would be also applicable to the intramolecular energy transfer in the present case. To make discussion along this inference, the overlap integral between the ligand phosphorescence spectrum and the samarium absorption spectrum was estimated.

It was found that an experimental relation as expressed by Eq. (3) roughly holds among the probability of intramolecular energy transfer, the frequency of infrared absorption due to the stretching vibartion of the chelate bond and the overlap integral. By some arguments it was shown that this equation is equivalent to the theoretical equation, Eq. (2), expressing the probability of energy transfer by the resonance mechanism due to the exchange interaction. In conclusion, one can say that intramolecular energy transfer in rare earth chelates is dominated by the resonance mechanism due to the exchange interaction of the π electron system of the ligand triplet state with the f electron system of the central rare earth ion.

The authors wish to thank Mr. M. Morita in this laboratory for his discussion.

Some Remarks on the Fragmentation of Excited Ions in the Radiolysis of Hydrocarbons

Tetsuo MIYAZAKI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya

and Kuniyasu TANNO and Shoji SHIDA

Laboratory of Physical Chemistry, Tokyo Institute of Technology, Meguro-ku, Tokyo

(Received June 26, 1968)

The fragmentation of excited ions in the liquid-phase radiolysis of hydrocarbons is explained by a new mechanism, which involves the fragmentation of a highly excited ion (M^{+**}). The M^{+**} ion is considered here to be the electronic excited states and to decompose by the following mechanism. The electronic excitation energy can spread over all C–C bonds in a molecule before its fragmentation and, when the mean excitation energy per C–C bond exceeds its bond energy, the excited ion decomposes instantaneously in one vibration. Further, the mass spectra of isobutane and isooctane are calculated by a simplified quasi-equilibrium theory by introducing the highly excited ion and are compared with experimental mass spectra and with the calculated values without introducing the highly excited ion.

The mechanism of fragmentation of excited ions in gases at low pressure has usually been studied by an analysis of mass spectra. Quasi-equilibrium theory originally proposed by Rosenstock *et al.*[1] has been developed by several investigators[2] and successfully applied to an interpretation of mass spectra of polyatomic molecules. The theory is based on the fundamental assumption that the

randomization of excitation energy among oscillators occurs before dissociation of the excited ion.

Molecular orbital theory developed by Hirota *et al.*[3] has been successfully applied to the mass spectra of organic compounds.

Recently, the present authors studied the radiolysis of hydrocarbons such as neopentane,[4] isooctane,[4] isobutane,[5] isopentane[5] and 2,3-dimethylbutane[5] in the liquid phase, and found that the fragmentation of excited ions is important. Since collisions between neighboring molecules in a liquid take place roughly in 10^{-13} sec, some of the excited ions must decompose in the period of one vibration ($\lesssim 10^{-13}$ sec) before collisional deactivation. Therefore, the mechanism of such a fast decomposition should be explained by some new theory other than the quasi-equilibrium theory which assumes the randomization of vibrational excitation energy among oscillators.

In the present work, we attempt to explain the fragmentation of excited ions in the liquid phase by a new simple mechanism.

Mechanism of Fragmentation of Excited Ions

It was found by a previous study[6] on the effect of density in the radiolysis of butanes that excited ions are divided into two types. Thus, the ionic fragmentation of a hydrocarbon molecule can be depicted as

$$M \longrightarrow M^{+*} + e \quad (1)$$
$$\longrightarrow M^{+**} + e \quad (2)$$
$$M^{+*} \longrightarrow F^+ + R \quad (3)$$
$$M^{+*} + M \longrightarrow M^+ + M \quad (4)$$
$$M^{+**} \longrightarrow F^+ + R \quad (5)$$

where M is the hydrocarbon molecule, for example, C_4H_{10}, M^{+*} is the excited ion which decomposes slowly and consequently is more efficiently deactivated with increasing density. M^{+**} is another type of ion which is highly excited and decomposes in the period of one vibration, not being susceptible to collisional deactivation even at high densities above 0.1 g cc^{-1}. F^+ is a fragment ion, for example $C_3H_7^+$, and R is a fragment radical, for example CH_3. In order to obtain further information on the fragmentation of highly excited ions, the ionic fragmentation of several hydrocarbons in the liquid phase was studied using ion scavengers. Results reported previously[4,5] are summarized in Table 1. $G(M^{+**})$ represents the yields of ionic fragmentation in the liquid phase, obtained from the yields of carbonium ion (F^+). $G(M^{+*}) + G(M^{+**})$ represents the yields of ionic C–C bond rupture from the total excited ions and can be obtained from radiolysis in the gas phase or from the mass spectrum assuming $W = 25$ eV. The yields of ionic C–C bond rupture from the M^{+**} ion relative to those from total excited ions are represented by $f = G(^{+**})/\{(G(M^{+*}) + G(M^{+**})\}$. Though the bond energy of isobutane is approximately the same as that of isooctane, the f-value of isobutane is much greater than that of isooctane. This indicates that the fragmentation of M^{+**} ion depends upon the number of carbon atoms in the ion. On the other hand, though the number of carbon atoms in neopentane is the same as that of isopentane, the f-value of neopentane is much greater than that of isopentane. This shows that the fragmentation of M^{+**} ion also depends upon the bond energy of ions. The selective C–C bond rupture of M^{+**} ion suggests intramolecular energy transfer within the period of one vibration. It is difficult to attribute the energy transfer in a short time ($\lesssim 10^{-13}$ sec) to the transfer of vibrational energy. Therefore, it is attributed to the transfer of electronic excitation energy. The rate of intramolecular

transfer of electronic excitation energy is given by the following equation,[8]

$$\Delta n = 2.22 \times 10^{15} |\beta| t \qquad (I)$$

where β is the resonance integral between neighboring carbon atoms in a molecule and Δn the numbers of carbon atoms over which the excitation energy can migrate in t sec. Since β of saturated hydrocarbons amounts to 1—2 eV, we get $\Delta n = 100-200$ at 5×10^{-14} sec. That is, the excitation energy can spread in a time of 5×10^{-14} sec over a large number of atoms, C_{100}–C_{200}. If the highly excited ion (M^{+**}) decomposes from the electronically excited states, it may be reasonable to assume the following mechanism: First, the electronic excitation energy can spread over all C–C bonds in a molecule prior to its fragmentation, even in a highly exicted ion. Second, the excited ion decomposes instantaneously in one vibration, when the mean excitation energy per C–C bond exceeds its bond energy. If the potential energy surfaces for the excited states are repulsive, the second assumption may be valid. In the present study, the distribution function of excitation energy for saturated hydrocarbons is taken from that for *n*-butane, which was obtained experimentally by Chupka and Kaminsky.[9] Since the number of C–C bonds in the isobutane ion is three and the bond energies are 0.61 eV, ions with an excitation energy exceeding 1.83 eV behave as a $C_4H_{10}^{+**}$ ion and ions with an exictation energy of 0.61 eV to 1.83 eV behave as an $C_4H_{10}^{+*}$ ion. The amounts of $C_4H_{10}^{+**}$ and $C_4H_{10}^{+*}$ ions present are obtained from the distribution function of excitation energy. The calculated f is compared with the observed one in Fig. 1. Allowing for

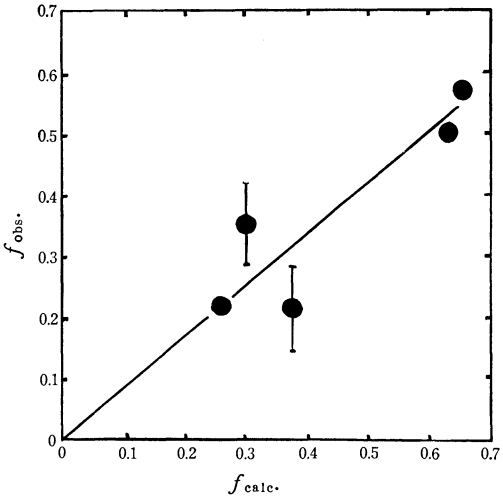

Fig. 1. Comparison of calculated f-values with obseved f-values.

the simplicity of the present treatment and some errors in the experimental values, we may say that the fragmentation of excited ions in the liquid phase is explained by this mechanism. The calculated values of f are slightly higher than the experimental ones. This result suggests that part of excitation energy spreads over C–H bonds, and that about 15% of the total excitation energy may spread over C–H bonds in the short time of rapid decomposition. The distribution of excitation energy in an ion may be related to the initial energy absorption of atoms in the ion. If the initial energy absorption is assumed proportional to the electron density of atoms in the ion, about 70% of the total energy will be absorbed in the carbon atoms in a saturated hydrocarbon ion. It is nescessary in the future to investigate the competing fragmentation reaction with the intramolecular energy transfer from a theoretical as well as an experimental aspect.

Interpretation of Mass Spectra by the Introduction of a Highly Excited Ion (M^{+**})

The mass spectra of saturated hydrocarbons have hitherto been explained by quasi-equilibrium theory.[1] According to a simplified treatment[10] of this theory, the rate constant for dissociation

8) J. L. Magee, "Comparative Effects of Radiation," John Wiley and Sons, Inc., New York (1960), p. 130. The system consists of a chain of N molecules. When the system suffers particle impact, at the initial instant of time $t=0$, the excitation is located on a particular member of the chain, say the p_{th}. The excitation will migrate after a lapse of time. The probability that the excitation will be located on the q_{th} member of the chain at time t is expressed as

$$P(p, q, t) = \left[J_{p-q}\left(\frac{4\pi|\beta|t}{h}\right)\right]^2$$

where $J_{p-q}(4\pi|\beta|t/h)$ is the Bessel function of integral order $p-q$ of the argument $4\pi|\beta|t/h$. β is the resonance integral between neighboring molecules of the chain. If the excitation spreads over Δn units of the chain at time t,

$$(\Delta n)^2 = \overline{(q-p)^2} = \sum_{c=1}^{N}(q-p)^2 P(p, q, t)$$

If we limit our consideration to long chains, it follows that

$$(\Delta n)^2 = \overline{(q-p)^2} = 2\sum_{n=0}^{\infty} n^2 J_n{}^2\left(\frac{4\pi|\beta|t}{h}\right)$$

and it has been found by the use of tabulated Bessel functions that

$$\Delta n = 0.707 \times \frac{4\pi|\beta|t}{h} = 2.22\times10^{15}|\beta|t$$

It is necessary to refer to the original paper by J. L. Magee for more detailed arguments.

of a molecule ion with an excitation energy of ε is given by $k(\varepsilon)$:

$$k(\varepsilon) = A\left(1-\frac{\varepsilon_0}{\varepsilon}\right)^{S-1} \qquad \text{(II)}$$

where S is the number of degrees of vibrational freedom of the ion and ε_0 the bond dissociation energy. A is the frequency factor and is taken as 10^{14} sec^{-1} for a simple bond dissociation process. It has been reported that if k is calculated from Eq. (II) using the experimental values of ε_0 and ε and the full number of degrees of vibrational freedom (S), the mass spectrum can not be understood. Several modifications[2] have been undertaken in order to improve the rate constant for fragmentation. For example, it was assumed that the higher transition probability of the excited ion compared with the experimental value was taken in the region of high excitation energy and that the effective number of internal degrees of freedom was considerably less than the full number expected from the molecular structure of the ions.

As proposed in the previous section, the excited ions are divided into two species, M^{+*} and M^{+**}. Since the existence of M^{+**} ion has been hitherto ignored in the calculation of mass spectra by quasi-equilibrium theory, we therefore attempt here to calculate mass spectra introducing the highly excited ion (M^{+**}) in addition to the M^{+*} ion which decomposes according to quasi-equilibrium theory (Calculation A). We also calculate mass spectra by the quasi-equilibrium theory without introducing the M^{+**} ion (Calculation B). Calculations are carried out under the following assumptions.

Calculation A: The excited ion consists of two species M^{+*} and M^{+**}, and the formation of either M^{+*} or M^{+**} is determined by the following two conditions. First, when the mean excitation energy per C–C bond exceeds the bond energy, the excited ion belongs to the M^{+**} ion and decomposes in the period of one vibration.

$$k(\varepsilon) \geqq 10^{13}\,\text{sec}^{-1}, \quad \varepsilon_{max} \geqq \varepsilon > n\varepsilon_0$$

where n is the number of C–C bonds in an ion. Second, when the mean excitation energy per C–C bond does not exceed the bond energy, the excited ion belongs to the M^{+*} ion and decomposes after the accumulation of excitation energy in a particular bond.

$$k(\varepsilon) = \text{Eq. (II)}, \quad n\varepsilon_0 \geqq \varepsilon > \varepsilon_0$$

Calculation B: Only the fragmentation of M^{+*} ion is considered and quasi-equilibrium theory is applied over the whole range of excitation energy.

$$k(\varepsilon) = \text{Eq. (II)}, \quad \varepsilon_{max} \geqq \varepsilon > \varepsilon_0$$

The distribution function of excitation energy for isobutane and isooctane was taken as that of n-butane.[9] For analytical convenience, $k(\varepsilon)$ was calculated from Eq. (II) summing over integrals for all internal energies of 0.5 eV. ε_0 used is given in Tables 2 and 3. The effective number of internal degrees of freedom (S) was determined using the condition $k(\varepsilon_{max}) \leqq 5\times10^{12}$ sec^{-1}. Under this condition, the quasi-equilibrium of vibrational excitation energy among the oscillators may be satisfied. In the present calculation, only the primary decomposition was considered. Actually, the secondary decomposition of fragment ions (reaction (7) and (8)) follows after the primary decomposition (reaction (6)) in a msas spectrometer.

$$i\text{-}C_4H_{10}^+ \longrightarrow C_3H_7^+ + CH_3 \qquad (6)$$
$$C_3H_7^+ \longrightarrow C_3H_5^+ + H_2 \qquad (7)$$
$$C_3H_5^+ \longrightarrow C_3H_3^+ + H_2 \qquad (8)$$

The amount of $C_3H_7^+$ produced in the primary decomposition of isobutane ion can be considered as the sum of $C_3H_7^+$, $C_3H_5^+$ and $C_3H_3^+$. In Tables 2 and 3, the calculated yields of major fragment ions from isobutane ion and isooctane ion are compared with experimental mass spectra. The mass spectra of isobutane are correctly interpreted qualitatively by assuming both M^{+*} and M^{+**} (Calculation A), while the treatment assuming only M^{+*} (Calculation B) fails in a proper interpretation. The mass spectra of isooctane can be understood through both methods of calculation. This is because the ratio of M^{+**} to the total excited ions of isooctane is at best about 25% and the introduction of M^{+**} does not appreciably affect the results, while the corresponding ratio of isobutane amounts to 60%.

Table 2. Fragmentation of i-$C_4H_{10}^+$

	ε_0	Mass spectra	Calculation A[a]	Calculation B[b]
$C_3H_7^+$	0.61 eV	1	1	1
$C_3H_6^+$	0.25 eV	0.23	0.50	1.49

a) Calculated by assuming M^{+**} and M^{+*}
b) Calculated by assuming only M^{+*}

Table 3. Fragmentation of i-$C_8H_{18}^+$

	ε_0	Mass spectra	Calculation A[a]	Calculation B[b]
$C_4H_9^+$	0.56 eV	1	1	1
$C_4H_8^+$	0.40 eV	0.31	0.22	0.25

a) Calculated by assuming M^{+**} and M^{+*}
b) Calculated by assuming only M^{+*}

It has been shown above that the highly excited ion (M^{+**}) is probably important in the radiolysis of hydrocarbons. However, the mechanism of its fragmentation proposed here is too simple and requires revision in the future from a theoretical as well as experimental aspect.

The authors wish to express their appreciation to Professor Zen-ichiro Kuri and Dr. Kenji Fueki for many helpful discussions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 366—369 (1969)

Electrical Conduction of TCNQ Ion Radical Salts under High Pressure

Ichimin SHIROTANI, Takashi KAJIWARA, Hiroo INOKUCHI and Syun-iti AKIMOTO

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Tokyo

(Received June 28, 1968)

With an increase in the pressure, the electrical resistance of several TCNQ anion radical salts dropped rapidly in the low-pressure region and levelled off at high pressures. The temperature dependence of the resistance of compressed salt was studied over the region from 77°K to 200°K. The values of the activation energy decreased with an increase in the pressure. However, the metallic behaviour was not observed under very high pressures. The conduction mechanism of TCNQ salts was discussed from the point of view of a band scheme.

During the past decade, there has been a great expansion in the amount of high-pressure work, even in the field of molecular crystals.[1,2] Generally speaking, the electrical conductivity of aromatic crystals, typical organic semiconductors, increases with an increase in the pressure. Since the mobility of the charge carriers in the crystal is not very sensitive to applied pressure,[3] the large increase in the conductivity under high pressure is mostly due to the great increment in the concentration of the charge carrier.[4,5] Similar phenomena have also been observed with charge-transfer complexes;[6] the resistance of the less conductive compound has dropped sharply with an increase in the pressure, although that of the high conductive complex had not shown any pronounced effect of the pressure.[7]

Several TCNQ ion radical salts with aromatic cations have a very high conductivity, in one case the highest yet reported for organic semiconductors, and a very small activation energy.[8] The conductivity of these solids arises from the motion of the odd π-electron among the TCNQ sites and they show semiconductive behaviour.[9] As the pressure increases, the resistance of some TCNQ salts falls rapidly in the low-pressure region until it levels off under high pressure.[10] However, the pressure effects on their thermal activation energy are still not known.

In this paper we will report our results on the temperature-dependence measurements of the resistance of several TCNQ salts at high pressure and will discuss their conduction mechanism.

Experimental

The samples used in the experiment were quinolinium-$(TCNQ)_2$ ($Q(TCNQ)_2$), bipyridinium$(TCNQ)_2$ ($BiP(TCNQ)_2$), 4-amino-2, 3, 5, 6-tetramethylanilnium-$(TCNQ)_2$ ($DAD(TCNQ)_2$), cobaltinium$(TCNQ)_2$ ($CoC(TCNQ)_2$), and lithium(TCNQ) (Li(TCNQ)). These compounds were provided by Kondow, who has reported their preparations in detail previously.[9] The samples were studied in the form of powder pressure-fused into flat platelets. The high-pressure cell for resistance measurements was similar as those used previously.[5]

The temperature dependences of the electrical resistance were measured under a constant pressure in the temperature range of 77°K—200°K. The calibration of the pressure with the cell was made using bismuth and lead phase changes at known pressures.

Results

Figures 1 and 2 show the effect of the pressure on the resistance of three TCNQ salts at room temperature. As has been observed in the case of other organic semiconductors, TCNQ complexes showed a decrease in resistance with an increase in the pressure. The decrement was much slower in the high-pressure region. The resistance of less conductive salts such as Li(TCNQ) showed a marked pressure dependence. However, those of

the high-conductive salts, such as $Q(TCNQ)_2$ and $DAD(TCNQ)_2$, were insensitive to pressure at room temperature.

Figures 3,4 and 5 show the pressure-resistance curve in the low-temperature region for $DAD(TCNQ)_2$, $Q(TCNQ)_2$ and $BiP(TCNQ)_2$ respectively. Above 100 kbar, the resistance of $Q(TCNQ)_2$ at room temperature rose with an increase in the pressure and drifted upward with time.[10] In the low-temperature region, at 78°K, these phenomena were not found; this means that no chemical reaction occurred.

The activation energies decreased with an increase in the pressure, but did not converge to zero up to 200 kbar. Table 1 shows the values of the activation energies under high pressures.

Discussion

A pressure-induced phase transition to the conducting state has been found for inorganic semiconductors, such as silicon and germanium;[11] their crystal structures change from the diamond type to the white-tin type.[12] However, molecular crystals have not become metallic except for I_2, Se, SnI_4 and pentacene*1 under high pressures. Though the behaviour of the pressure-resistance relation of these exceptional crystals is similar to that of organic semiconductors, the energy gaps become zero without crystal transformation at high pressures.[2]

Kepler *et al.* proposed that $Q(TCNQ)_2$ shows a metallic behaviour at atmospheric pressure: temperature-independent conductivity as high as 10^2 $ohm^{-1}\,cm^{-1}$ and temperature-independent paramagnetic susceptibility.[8] Recently, on the other hand, we have found that $Q(TCNQ)_2$ behaves as a typical semiconductor:[9] it shows a temperature-dependent conductivity of the single crystal, a slightly - temperature - dependent magnetic susceptibility, and also an absorption edge in the far infrared-wavelength region (about 40 cm^{-1}).

In accordance with Mott's criterion for the metal-semiconductor transition,[13] LeBlanc proposed that:

$$2E = C - \Delta \qquad (1)$$

where E is the activation energy, C is the electrostatic energy, and Δ is the band width.[14] When the $C > \Delta$ relation is satisfied, the system is semiconductor, and when $C < \Delta$, the system is metal. The same author estimated the values for TCNQ salts as:

$$\Delta \simeq 0.1\,eV \quad \text{and} \quad C < 0.5\,eV \qquad (2)$$

Since Δ seems to be more sensitive to the pressure than C does in the first approximation, these compounds may be expected to become metals under high pressure. On the contrary, as Table 1 shows, their energy gaps did not reach zero, at least not up to 200 kbar.

Generally, an increase in the pressure results in an increase in the band width. An energy band of a molecular crystal such as anthracene widened 5—6 times at 161 kbar as compared with the value at atmospheric pressure.[4] However, the band width of high-conductive TCNQ salts seems to be less affected by the pressure.*2

In several TCNQ salts with aromatic cations, the line shape of the absorption curve at the edges can be expressed by Eq. (3) at room temperature;[9]

$$k \propto (\nu - \nu_G)^n$$
$$(\nu_G = 36.5\,cm^{-1};\ n = 0.46 \pm 0.05 \text{ for } Q(TCNQ)_2) \qquad (3)$$

where k is the absorption coefficient; ν, the wave number of the incident light, and ν_G and n, the constants. The shape of this absorption edge is due to the direct allowed transition from the valence band to the conduction band. Further, the slightly-tempeature-dependent paramagnetic susceptibility of $Q(TCNQ)_2$ can be explained tentatively in terms of the band theory.[9]

On the other hand, the mobility of the carrier is less than 0.1 $cm^2/V{\cdot}sec$,[8] though the energy gap

12) J. C. Jammison, *Science*, **139**, 762 (1963).

*1 The confirmation of the transition from semiconductor to metal is very difficult, because the chemical change is superposed on the transition.

13) N. F. Mott, *Phil. Mag.*, **6**, 287 (1961).

14) O. H. LeBlanc, *J. Chem. Phys.*, **42**, 4307 (1965).

*2 Their compressibility has not been measured. Probably, they are less compressible than ordinary hydrocarbon solids.

of high conductive TCNQ salts is very small; moreover they have partly-filled bands when considered simply, but they do not show a metallic behaviour even at high pressures. Considering these points, the conduction mechanism can not be explained by the usual band theory. Therefore, on the basis of the experimental results we suggest that even if a conduction band exists, the band width is probably very narrow.

Generally, a presssure coefficient for the optical energy gap of inorganic semiconductors agrees with the value determined by measuring the intrinsic resistivity as a function of the pressure. A similar behaviour has been observed in such molecular crystals as quaterrylene ($C_{40}H_{20}$).[15] If the pressure effect of the far-infrared absorption spectra of TCNQ salts could be studied, these electronic states could be discussed in detail.

The authors wish to thank Dr. T. Kondow for his helpful discussion.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 369—372 (1969)

The Formation of Transient Aromatic Ions in Solutions by the Flash Illumination

Kiyoshi KAWAI, Naoto YAMAMOTO and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka

(Received July 1, 1968)

Flash illumination of an oxygen-free acetonitrile solution containing *p*-dimethoxybenzene (DMB) and *s*-trinitrobenzene or chloranil gave a transient absorption spectrum of DMB cation. The decay of the transient absorption spectra follows the second-order reaction kinetics proving that the decay is brought about by the recombination of the anion and the cation after the flash illumination. The formation of the ion-pair may be explained as follows:

$$A + h\nu \longrightarrow A^*$$
$$A^* + D \longrightarrow A^- - D^+$$
$$\downarrow$$
$$A^-_{solv.} + D^+_{solv.} \longrightarrow A + D$$

It was found by Leonhardt and Weller that the fluorescence of perylene in non-polar solvents was quenched by addition of anilines or amines and new fluorescence bands appeared, which were ascribed to the charge transfer fluorescence (CT-fluorescence) emitted from the excited CT-complex formed by an excited perylene and an amine in the ground state.[1,2]

In polar solvents, such CT-fluorescence was not observed and by the flash illumination a transient absorption spectrum attributed to perylene anion was observed. This anion was assumed to be formed *via* the CT-complex of the excited perylene with the ground state amine or *via* a solvent-shared ion pair ($A^-_{solv.}\cdots D^+_{solv.}$).[3]

Though this is a very interesting result, there had been a few reports[1-4] concerning this problem. It is our opinion that further work is needed in order to prove the formation of an ion pair, $A^-_{solv.}$ and $D^+_{solv.}$, by the mechanism proposed by Weller.

Recently, we have found that *N*,*N*,*N'N'*-tetramethyl-*p*-phenylenediamine (TMPD) and α-methylnaphthalene, or other naphthalene derivatives, show similar fluorescence spectrum attributable to the CT-fluorescence in non-polar solvents.[5] In polar

solvents, the same system showed transient absorption spectra assigned to the TMPD cation and naphthalene in the triplet state.[6] This result indicates that excited TMPD and ground state naphthalene derivatives partly form TMPD cation (and probably α-methylnaphthalene anion, though its spectrum was not observed), and partly form the triplet state of α-methylnaphthalene by energy transfer. We have confirmed that the yield of the cation in solution is independent of the light intensity but dependent on the total light input. This finding provides evidence for the generation of the cation by a single-photon process and therefore supports Weller's mechanism.

It was thought to be interesting to find more examples of the ion-pair formation from the donor-acceptor pairs by the flash technique. In the present paper some of the results are reported.

Experimental

The instrument used for the flash illumination has been described elsewhere.[7] The electric energy of a flash was about 250 J and the flash light had the duration time of about 3μsec. A cylindrical quartz sample cell 20 cm long and 1.5cm in diameter was used. Two photolysis flash lamps were made of quartz tube, 20 cm long and 1.0 cm in diameter, with tungsten-electrodes at both ends. These tubes were filled with argon to a pressure of about 100 mmHg. Oxygen in the sample solution was removed by bubbling highly purified nitrogen gas. *p*-Dimethoxybenzene (DMB) used was recrystallized from ethanol and was sublimed. Chloranil was sublimed in vacuum. Acetonitrile was refluxed with phosphorus pentoxide and distilled. Ethanol was dried with calcium oxide and barium oxide and then distilled.

The spectra shown in Fig. 4 were recorded with Cary Spectrophotometer Model 15. All other spectra were obtained by the photographic method followed by recording with a Nalumi microphotometer NLM V11.

Results

***p*-Dimethoxybenzene-*s*-Trinitrobenzene System.** Flash illumination of *s*-trinitrobenzene (2×10^{-3} M) in an oxygen-free acetonitrile solution containing 10^{-3} M *p*-dimethoxybenzene (DMB) gave a transient absorption spectrum showing maxima at 456 mμ and 431 mμ and a shoulder at 414 mμ (Fig. 1a). The transient absorption spectrum was detectable by the photographic measurement until about 50 μsec after the flash illumination. The flash light was filtered by a highly concentrated DMB solution so that only the acceptor molecule, trinitrobenzene, was excited. The sample solution showed no absorption band ascribable to the CT-complex between DMB and trinitrobenzene. In the absence of DMB, no transient absorption spectrum was observed by the flash irradiation of trinitrobenzene in acetonitrile. No transient absorption spectrum attributable to DMB cation was observed by the flash illumination of DMB and trinitrobenzene in non-polar solvents such as benzene or methylcyclohexane.

free acetonitrile solution containing about 10^{-3} M DMB and 10^{-4} M chloranil, a transient absorption spectrum was observed with maxima at 446 mμ and a shoulder near 420 mμ as shown in Fig. 2a. A glass filter was used so that only chloranil was excited. The sample solution showed no characteristic band of the CT-complex of DMB and chloranil. The flash illumination of a solution containing only chloranil gave a transient absorption spectrum different from that shown in Fig. 2(a), which may probably be attributable to the semiquinone radical  formed by the hydrogen abstraction from solvent on account of the resemblance of the spectrum with that of *p*-benzosemiquinone.

The change of the absorbance of the transient spectrum of Fig. 2(a) was followed by the photographic method until about 300 μsec after the flash illumination. If the transient species formed by the flash illumination is assumed to decay by the second-order reaction kinetics, the absorbance (a) may be represented as follows:

$$\frac{1}{a} = kt + c \quad (k, c\text{: constant}, t\text{: time})$$

Figure 3 shows that the above relation holds well for the absorbance at 446 mμ.

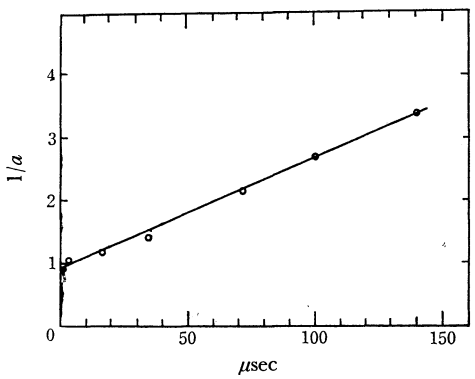

Fig. 3. Relation between the reciprocal of the absorbance (a) of the transient absorption spectrum shown in Fig. 2(a) and the time after the flash. The absorption was measured at 446 mμ.

In the case of an ethanol solution of chloranil and DMB, a flash illumination gave an absorption spectrum with maxima at 428 mμ and 452 mμ and a shoulder at 408 mμ (Fig. 2b).

Spectra of DMB$^+$ and Chloranil$^-$. In order to obtain the spectrum of DMB cation (DMB$^+$), DMB was added to an acetonitrile solution containing a small amount of antimony pentachloride at room temperature. The yellow solution thus obtainde showed a spectrum with maxima at 433 mμ and 458 mμ and a shoulder near 410 mμ as shown in Fig. 4a. The ESR spectrum obtained coincides

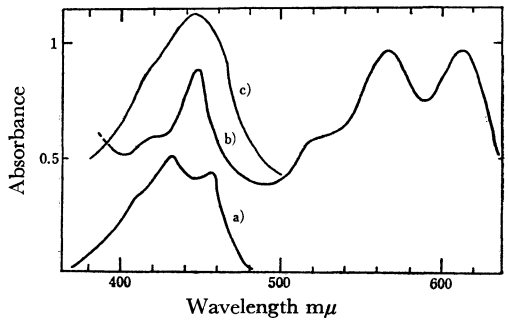

Fig. 4.
(a) Absorption spectrum of *p*-dimethoxybenzene cation formed in the acetonitrile solution containing a small amount of antimony pentachloride.
(b) Absorption spectrum of an acetonitrile solution of *N*,*N*,*N*′,*N*′-tetramethyl-*p*-phenylenediamine and chloranil.
(c) Reproduction of curve (a) of Fig. 2.

well with that of DMB$^+$ measured by Sullivan and Forbes in a sulfuric acid solution of DMB.[8] The visible absorption spectrum (Fig. 4a) also agrees with that of DMB$^+$ formed by the photolysis of DMB in the 1 : 1 mixture of concentrated sulfuric and acetic acid at 77°K.[9]

Figure 4 (b), in the 400—500 mμ region shows the spectrum of chloranil anion prepared by the chemical reduction of chloranil with tetramethyl-*p*-phenylenediamine (TMPD) in the acetonitrile solution at room temperature. The two maxima at 448 mμ and 422 mμ agree with the absorption spectrum of chloranil anion obtained by reducing chloranil with sodium in tetrahydrofuran solution.[10] The spectrum beyond 500 mμ is obviously that for the cation of TMPD.[7]

Discussion

The spectra shown in Fig. 1(a) and Fig. 4(a) agree well in the positions of their maxima and shoulders. If we take into acount of the fact that Fig. 1(a) was obtained by the photographic method followed by recording with a microphotometer and Fig. 4(a) was obtained by the Cary spectrophotometer, we may conclude that the identity of the spectra shown in Fig. 1(a) and Fig. 4(a) are fairly good. These results indicate that DMB

8) W. H. Forbes and P. D. Sullivan, *Canad. J. Chem.*, **44**, 1501 (1966).
9) H. Tsubomura, K. Kimura, H. Yamada and M. Kato, *Tetrahedron Letters*, **47**, 4217 (1965).
10) H. Kainer and A. Ůberle, *Chem. Ber.*, **88**, 1147 (1955).

cation was formed by the flash illumination of *s*-trinitrobenzene in the acetonitrile solution containing DMB and *s*-trinitrobenzene. The formation of DMB cation radical (DMB^+) may be explained by the same mechanism as that proposed by Weller *et al.*[2]:

$$A + DMB \xrightarrow{h\nu} A^* + DMB \longrightarrow (A^* \cdots DMB) \text{ or } (A^{\delta-} \cdots DMB^{\delta+}) \longrightarrow A^-_{solv.} + DMB^+_{solv.}$$

A: *s*-trinitrobenzene (or chloranil)

No spectrum attributable to trinitrobenzene anion was observed. This result shows that trinitrobenzene anion is either very unstable at room temperature or has no absorption band in the visible region.

In the case of DMB-chloranil system, the absorption spectrum obtained (Fig. 2a) is considerably different from that of DMB^+. It seems obvious that this spectrum represent the sum of the absorption spectra of DMB^+ and chloranil anion from the comparison of curves (a), (b) and (c) of Fig. 4.

As stated before, the decay of the transient absorption spectra follows the second order reaction kinetics (Fig. 3). The fact proves that the decay is brought about by the recombination of the anion and the cation after the flash illumination.

In the case of the flash illumination of chloranil in the ethanol solution containing DMB and chloranil, only the transient DMB^+ spectrum appeared, indicating that the chloranil anion is very short-lived in the ethanol solution. To confirm it, the acetonitrile solution containing 10^{-4} M chloranil, 5×10^{-1} M ethanol, and 10^{-3} M DMB was flash illuminated. After the flash illumination the transient spectrum was identical with that shown in Fig. 2 (a) for a time shorter than about 20μsec, then the shape of the transient spectrum gradually changed until about 50μsec after the flash, and finally became identical with that shown in Fig. 2 (b). This experiment shows that chloranil anion formed by the flash illumination reacts very quickly with ethanol.

From the experimental results stated above, it has been unambiguously settled that the cation of *p*-dimethoxybenzene is formed by the flash illumination of it with some acceptors (*s*-trinitrobenzene or chloranil), in polar solvents such as acetonitrile or ethanol. It is well known that these molecules form the charge transfer complexes. But in our experiment the concentrations are so low that essentially all molecules are free from complex formation. In non-polar solvents, no transient ions were observed by similar flash experiments. Leonhardt and Weller showed that the excitation of a donor resulted in the formation of a transient ion of the donor. Our results have shown that the excitation of acceptors also leads to the formation of the transient donor cation.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 372—378 (1969)

Optical and Acoustic Branches and Frequency Distribution of Polyethylene Glycol Chain

Hiroatsu MATSUURA and Tatsuo MIYAZAWA

Institute for Protein Research, Osaka University, Kita-ku, Osaka

(Received July 15, 1968)

Optical and acoustic branches of chain vibrations of polyethylene glycol were treated. The nature of these branches was elucidated on the basis of potential-energy distributions and phase relations. From dispersion curves (frequency *versus* phase difference), the frequency distribution of chain vibrations was calculated, in order to analyze thermal-neutron scattering spectra. Vibrational assignments of scattering peaks in the region 600—200 cm^{-1} were made with reference to the frequency distribution peaks and potential-energy distributions calculated for the single chain.

Infrared absorption, Raman scattering, and neutron inelastic scattering measurements are three important methods for studying chain vibrations of helical polymer molecules. The selection rules for infrared absorption and Raman effect are related with the angle (θ) of rotation, per unit, about the helix axis. Infrared absorption bands arise from vibrations with the phase difference of

$\delta=0$ or θ, while Raman lines arise from vibrations with $\delta=0$, θ, or 2θ.[1,2] For neutron scattering, however, there is no selection rule and chain vibrations for any phase difference contribute to inelastic scattering. Accordingly, frequency distribution peaks give rise to inelastic scattering peaks. For polyethylene glycol, neutron inelastic scattering was observed by Trevino and Boutin[3] and observed scattering peaks were analyzed with reference to the frequency distribution peaks calculated for an isolated chain of polyethylene glycol.[4]

In our previous study,[5] the force field of polyethylene-glycol chain was refined and the nature of observed infrared bands and Raman lines was discussed on the basis of potential-energy distributions. With the refined force field, in the present study, optical and acoustic branches of polyethylene-glycol chain were treated and the nature of these branches was elucidated. Dispersion curves (frequency *versus* phase difference) are useful for analyses of vibrational spectra of model oligomers in the crystalline state.[6] Also, the frequency distribution of chain vibrations was calculated and the nature of neutron scattering peaks was elucidated.

Normal Coordinate Treatment

Polyethylene-glycol chain is in the 7_2 helical conformation (seven units of CH_2CH_2O and two helical turns per fiber period),[7,8] having two twofold axes per unit. One axis bisects the C–O–C bond angle while the other axis intersects the C–C bond at right angle. Accordingly, this polymer chain belongs to dihedral group. A general method for treating helical chain vibrations was described previously.[2,9,10]

Normal vibrations of polyethylene-glycol chain were treated previously for the phase differences of $\delta=0$ (A_1 and A_2) and for $\delta=\theta$ (E_1).[5] In the present study, normal vibrations were treated for the phase differences of $\delta=0°$, 15°,···, 165° and 180°, with the interval of 15°.*1 Bond-stretching, angle-bending, and internal-rotation coordinates were transformed into local-symmetry coordinates; namely σ_{ss} (CH_2 symmetric stretching), σ_{as} (CH_2

*1 Only the phase-difference region of $0\leq\delta\leq\pi$ need be treated, since frequenices for $\delta=2\pi+\alpha$ are the same as for $\delta=\alpha$, and frequencies for $\delta=\pi+\beta$ are the same as for $\delta=\pi-\beta$.

antisymmetric stretching), σ_{sc} (CH_2 scissoring), σ_{wa} (CH_2 wagging), σ_{tw} (CH_2 twisting), σ_{ro} (CH_2 rocking), $\sigma_{CC\ st}$ (C–C stretching), $\sigma_{CO\ st}$ (C–O stretching), σ_{CCO} (C–C–O bending), σ_{COC} (C–O–C bending), $\sigma_{CC\ to}$ (C–C internal-rotation), and $\sigma_{CO\ to}$ (C–O internal-rotation).[5] Inverse-kinetic energy matrices $\boldsymbol{G}(\delta)$ were constructed with the molecular parameters listed previously.[5]

Local-symmetry force constants[11] of polyethylene-glycol chain were refined previously[5] so that frequencies calculated for A_1, A_2 and E_1 vibrations reproduce observed infrared and Raman frequencies with a root-mean-squared deviation as small as 0.9%. The same set of force constants was used in the present study for constructing potential-energy matrices $\boldsymbol{F}(\delta)$.

Vibrational frequencies calculated for $\delta=0°$, 60°, 120°, and 180° are listed*2 in Tables 1 and 2, together with potential-energy distributions (PED) and phase-angle differences[5,9] (phase relations in normal modes of degenerate vibrations). Vibrational modes with $\Delta\varepsilon(OCH_2\text{–}CH_2O) \sim 0°$ and $\sim \pm 180°$ are quasi-symmetric and quasi-antisymmetric, respectively, with respect to the twofold axis that intersects the CH_2–CH_2 bond. Similarly, vibrational modes with $\Delta\varepsilon$(C–O–C) $\sim 0°$ and $\sim \pm 180°$

11) T. Shimanouchi, *Nippon Kagaku Zasshi* (*J. Chem. Soc. Japan, Pure Chem. Sect.*), **86**, 261, 768 (1965); Symposium on Molecular Structure, Tokyo, 1964; Toyonaka, 1966.

*2 A more detailed list is given in Ref. 13, p. 69, including $\delta=30°$, 90° and 150°.

are quasi-symmetric and quasi-antisymmetric, respectively, with respect to the twofold axis that intersects the C–O–C angle. For the phase difference of $\delta=0°$, chain vibrations are classified into A_1 vibrations [$\Delta\varepsilon=0°$] and A_2 vibrations [$\Delta\varepsilon=180°$] while for the phase difference of $\delta=180°$, chain vibrations are classified into B_1 vibrations [$\Delta\varepsilon(OCH_2\text{–}CH_2O)=0°$ and $\Delta\varepsilon(C\text{–}O\text{–}C)=180°$] and B_2 vibrations [$\Delta\varepsilon(OCH_2\text{–}CH_2O)=180°$ and $\Delta\varepsilon(C\text{–}O\text{–}C)=0°$].

Dispersion curves (frequency *versus* phase difference) of twenty-one vibrational branches of polyethylene-glycol chain are shown in Figs. 1 and 2, together with observed infrared and Raman frequencies (excepting ν_{16}, only the infrared frequencies are shown for $\delta=\theta$). Main terms of potential-energy distributions for the branches ν_{11}—ν_{21} are shown in Figs. 3 and 4.

High Frequency Branches

For a helical polymer chain, two branches in the lowest-frequency region are acoustic branches, and other higher-frequency branches are optical branches. For polyethylene glycol, there are seven atoms per repeat unit of CH_2CH_2O, and accordingly chain vibrations consist of twenty-one branches, namely nineteen optical and two acoustic branches (Figs. 1 and 2).

In the highest-frequency region of 3000—2800 cm^{-1}, there are four branches, ν_1—ν_4. The ν_1 and ν_2 branches are associated with CH_2 antisymmetric stretching modes, while ν_3 and ν_4 branches are associated with CH_2 symmetric stretching modes (Table 1). With respect to the local twofold symmetry axis, the ν_1 and ν_3 branches are quasi-antisymmetric ($160°<\Delta\varepsilon\leq180°$) whereas the ν_2 and ν_4 branches are quasi-symmetric ($0°\leq\Delta\varepsilon<20°$). Atomic displacements of these vibrations are highly localized in the CH_2–CH_2 groups so that frequencies of these four branches do not vary with phase difference.

In the polarized infrared spectra of polyethylene glycol, the parallel band at 2890 cm^{-1} is assigned to the $\nu_3(0)$ vibration (A_2), the perpendicular band at 2950 cm^{-1} to the $\nu_1(\theta)$ and $\nu_2(\theta)$ vibrations (E_1), and the perpendicular band at 2885 cm^{-1} to the $\nu_3(\theta)$ vibration (E_1). The medium-intensity Raman line at 2939 cm^{-1} is assigned to the $\nu_2(0)$ vibration while the strong line at 2890 cm^{-1} is assigned to the CH_2 symmetric stretching modes (ν_3 and ν_4).

The ν_5 and ν_6 branches are associated with quasi-symmetric and quasi-antisymmetric scissoring modes, respectively, of CH_2–CH_2 groups (Table 1). Frequencies of these two branches vary little with phase difference. The doublet parallel bands at 1463 and 1457 cm^{-1} are assigned to $\nu_6(0)$ (A_2) and the perpendicular bands at 1470 and 1453 cm^{-1} are assigned to $\nu_5(\theta)$ and $\nu_6(\theta)$ (E_1), respectively. The strong Raman line at 1484 cm^{-1} is assigned to $\nu_5(0)$ (A_1) and weak line at 1449 cm^{-1} to $\nu_6(\theta)$.

The ν_7 and ν_8 branches are due to quasi-symmetric ($0°\leq\Delta\varepsilon<80°$) and quasi-antisymmetric ($100°<\Delta\varepsilon\leq180°$) CH_2 wagging modes, respectively, for $\delta=0$—120°. For the ν_7 branch, the C–C stretching mode contributes to PED by 15—20%. The $\nu_7(0)$ vibration was observed as the Raman line at 1398 cm^{-1} while the $\nu_7(\theta)$ vibration was observed as the perpendicular infrared band at 1415 cm^{-1}. Infrared bands due to $\nu_8(0)$ and $\nu_8(\theta)$ were observed at 1345 cm^{-1} (parallel) and 1364 cm^{-1} (perpendicular), respectively.

The ν_9 and ν_{10} branches are due to CH_2 twisting modes. For $\delta=0°$, the $\nu_9(0)$ and $\nu_{10}(0)$ vibrations are antisymmetric and symmetric, respectively, with respect to the local twofold axis. The parallel infrared band at 1244 cm^{-1} is assigned to $\nu_9(0)$. As δ is increased from 0°, however, phase relations of these vibrations are gradually changed and finally are interchanged for $\delta>45°$. Thus the perpendicular bands at 1283 and 1236 cm^{-1} are assigned to $\nu_9(\theta)$ and $\nu_{10}(\theta)$ which are quasi-symmetric and quasi-antisymmetric, respectively.

The ν_{11}—ν_{15} branches in the region 1200—

a) Phase-angle differences $\Delta\varepsilon(OCH_2\text{–}CH_2O)$ are shown for CH_2 ro and CCO, while $\Delta\varepsilon$(C–O–C) are shown for CO st and CO to.

800 cm^{-1} are associated with C–O and C–C stretching modes and CH_2 rocking modes (Table 2, Fig. 1). Vibrational coupling among these modes is also shown in Fig. 3.

The ν_{11} and ν_{15} branches arise from vibrational coupling of CH_2 rocking modes and quasi-symmetric C–O stretching modes, although relative contributions of these modes vary with phase difference (Fig. 3). Also phase relations ($\Delta\varepsilon$) of rocking modes of CH_2–CH_2 groups vary with phase difference (δ), from $\Delta\varepsilon=0°$ for $\delta=0°$ to $\Delta\varepsilon=180°$ for $\delta=180°$. The Raman lines at 1126 and 861 cm^{-1} are assigned to $\nu_{11}(0)$ and $\nu_{15}(0)$ and the perpendicular infrared bands at 1149 and 844 cm^{-1} are assigned to $\nu_{11}(\theta)$ and $\nu_{15}(\theta)$, respectively.

The ν_{12} branch around 1100 cm^{-1} is primarily associated with the C–O–C antisymmetric stretching mode ($125°\leq\Delta\varepsilon\leq180°$), in accord with empirical assignments of strong bands around 1100 cm^{-1}. The very strong parallel band at 1102 cm^{-1} and strong perpendicular band at 1119 cm^{-1} are assigned to $\nu_{12}(0)$ and $\nu_{12}(\theta)$, respectively. C–C stretching modes contribute about 20% of PED for $\delta>60°$ (Fig. 3).

The ν_{13} and ν_{14} branches are associated with C–O and C–C stretching modes and CH_2 rocking modes. Frequencies of the ν_{13} branch do not vary much with phase difference (δ), but the nature of ν_{13} vibrations changes markedly with δ. For $\delta=0°$, the $\nu_{13}(0)$ vibration is due to the C–O–C symmetric stretching mode ($\Delta\varepsilon=0°$) and C–C stretching mode. As δ is increased, however, PED contributions of these modes decrease and instead PED of CH_2 rocking modes increases up to 60% for $\delta=180°$ (Fig. 3). The perpendicular infrared band at 1062 cm^{-1} is assigned to $\nu_{13}(\theta)$.

The $\nu_{14}(0)$ vibration is primarily associated with the CH_2 rocking mode ($\Delta\varepsilon=180°$), giving rise to the parallel infrared band at 963 cm^{-1}. As phase difference is increased, PED contribution of C–C stretching modes increases, and for $\delta=\theta$ the $\nu_{14}(\theta)$ vibration is due to the coupling of the quasi-symmetric CH_2 rocking mode and C–C stretching mode, giving rise to the perpendicular band at 947 cm^{-1}.

Low Frequency Branches

In the region below 600 cm^{-1}, there are six vibrational branches, ν_{16}—ν_{21}, as shown in Fig. 2. These branches are associated with C–C–O and C–O–C bending modes and C–O and C–C internal-rotation modes (Table 2 and Fig. 4).

The $\nu_{16}(0)$ vibration is primarily associated with the antisymmetric C–C–O bending mode, giving rise to the parallel band at 529 cm^{-1} with a weak component at 508 cm^{-1}. The doublet splitting is due to Fermi resonance.[5] Because of appreciable contribution of the CH_2 rocking mode (33% of PED), this infrared band is shifted to 444 cm^{-1} (doublet) for perdeuterated species $(-CD_2CD_2O-)_p$. As phase difference is increased, PED contributions of quasi-antisymmetric C–C–O bending mode and quasi-antisymmetric CH_2 rocking mode are gradually replaced with PED of the C–O–C bending mode (Fig. 4). For $\delta=\theta$, the $\nu_{16}(\theta)$ vibration gives rise to the Raman line at 537 cm^{-1}.

The Raman line at 279 cm^{-1} is due to the $\nu_{17}(0)$ vibration of the A_1 species, a coupled vibration of the C–C–O and C–O–C bending modes and C–O and C–C internal-rotation modes (Fig. 4). As δ is increased, PED changes remarkably until finally, for $\delta=180°$, PED is essentially associated with the symmetric C–C–O bending mode. For $\delta=\theta$, $\nu_{17}(\theta)$ is a coupled vibration of the quasi-symmetric C–C–O bending mode and C–O–C bending mode, giving rise to the infrared band and Raman line at 363 cm^{-1}.

The Raman line at 216 cm^{-1} is due to the $\nu_{18}(0)$ vibration, a heavily coupled vibration of bending and internal-rotation modes (Fig. 4). Again PED contributions of the four modes vary markedly with phase difference. The $\nu_{18}(\theta)$ vibration gives rise to the perpendicular infrared band at 216 cm^{-1}.

The parallel far-infrared band at 107 cm^{-1} is due to the $\nu_{19}(0)$ vibration, associated with the antisymmetric internal-rotation mode of C–O bonds. However, as δ is increased, PED contribution of the C–O internal-rotation mode is gradually replaced with PED of the C–C internal-rotation mode (Fig. 4). The $\nu_{19}(\theta)$ vibration gives rise to the perpendicular infrared band at 165 cm^{-1}.

Acoustic Branches

The lowest-frequency branches, ν_{20} and ν_{21}, are the acoustic branches of polyethylene-glycol chain. The non-genuine vibrations $\nu_{20}(0)$ and $\nu_{21}(0)$ correspond to the translation (along the axis) and rotation (about the axis). For $\delta\sim0°$, the longitudinal stretching mode and twisting mode of the chain are coupled to yield the ν_{20} (coupling ratio of 3 : −2) and ν_{21} (ratio of 2 : 3) vibrations.*3 Potential energies of these vibrations are associated largely with quasi-symmetric C–C–O bending mode and with internal-rotation modes of C–C and C–O bonds (quasi-symmetric), respectively.

For $\delta=\theta$, the ν_{21} vibration is reduced to a non-genuine vibration corresponding to the translational mode perpendicular to the chain axis. For $\delta\sim\theta$, the ν_{21} vibration is the bending vibration of the molecular chain. The potential energy of this bending vibration is largely associated with internal-rotation modes of C–O bonds.

Frequency Distribution

For analyses of neutron-scattering peaks, in the present study, the frequency distribution of chain vibrations was calculated from dispersion curves of the twenty-one branches of polyethylene glycol (Figs. 1 and 2). The phase-difference region of $0°\leq\delta\leq180°$ was equally divided into 1800 subsections, and representative phase differences were taken as 0.05°, 0.15°,⋯, 179.85° and 179.95°, for which vibrational frequencies of each branch were calculated.

For the phase-difference region of $0°\leq\delta\leq15°$, vibrational frequencies of the optical branches (ν_1—ν_{19}) were calculated with even functions,

$$\nu(\delta)=\nu(0°)+a_2\delta^2+a_4\delta^4 \quad (1)$$

which satisfy frequencies previously calculated for $\delta=0°$, 15° and 30°, whereas frequencies of the acoustic branches (ν_{20} and ν_{21}) were calculated with odd functions,

$$\nu(\delta)=a_1\delta+a_3\delta^3 \quad (2)$$

which satisfy frequencies for $\delta=0°$, 15° and 30°.

An intermediate phase-difference region was divided into sub-regions of 15—30°, 30—45°,⋯, 135—150°, and 150—165°. For each sub-region of $\delta_0\leq\delta\leq\delta_0+15°$, vibrational frequencies were calculated with the following equation,

$$\nu(\delta)=\nu(\delta_0)+b_1(\delta-\delta_0)+b_2(\delta-\delta_0)^2+b_3(\delta-\delta_0)^3 \quad (3)$$

which satisfies frequencies for $\delta=\delta_0-15°$, δ_0, $\delta_0+15°$ and $\delta_0+30°$.

Finally, for the phase-difference region of $165°\leq\delta\leq180°$, vibrational frequencies were calculated with even functions,

$$\nu(\delta)=\nu(180°)+c_2(180°-\delta)^2+c_4(180°-\delta)^4 \quad (4)$$

which satisfy frequencies for $\delta=150°$, 165° and 180°.

*3 For the polyethylene-glycol chain in the right-handed 7_2 helix, the stretching mode of the chain is accompanied with rotation of the twisting mode in the left-handed and right-handed sense, respectively, for the ν_{20} and ν_{21} vibrations for $\delta\sim0°$.

After vibrational frequencies were calculated for all the branches, the number of vibrations was counted in the frequency sections of 10 cm^{-1} for high-frequency branches ($>700\ cm^{-1}$) and of 5 cm^{-1} for low-frequency branches ($<700\ cm^{-1}$). The frequency-distribution histograms thus obtained are shown in Figs. 1 and 2, together with dispersion curves.

Neutron Scattering Peaks

Thermal-neutron scattering of polyethylene glycol was measured by Trevino and Boutin[3] and inelastic-scattering peaks were observed at 535, 380—310 and 228 cm^{-1} in the frequency region of 600—200 cm^{-1}.*4 Vibrational assignments of these peaks will be made with reference to frequency distribution peaks (and PED) calculated in the present study.

The observed scattering peak at 535 cm^{-1} corresponds to the distribution peaks at 530 and 515 cm^{-1}. These distribution peaks arise from the ν_{16} vibrations for $0° \lesssim \delta \lesssim 110°$ and are largely associated with quasi-antisymmetric C–C–O bending mode. Another distribution peak at 585 cm^{-1} (C–O–C bending) was not resolved in the neutron-scattering measurement.

The broad scattering peak around 380—280 cm^{-1} corresponds to the distribution peaks at 370, 315 and 280 cm^{-1}. The peak at 370 cm^{-1} arises from the maximum portion of the ν_{17} branch for $\delta = 90$—$120°$. As shown in Fig. 4, these ν_{17} vibrations are associated with C–O–C bending and quasi-symmetric C–C–O bending modes. On the other hand, the peak at 315 cm^{-1} arises from the ν_{17} vibrations for $\delta \sim 180°$, and accordingly is due to quasi-symmetric C–C–O bending mode. The distribution peak at 280 cm^{-1} arises from ν_{17} vibrations for $\delta \sim 0°$ and ν_{18} vibrations for $\delta \sim 180°$.

The high distribution peak at 220 cm^{-1} arises from the flat portion of the ν_{18} branch, where vibrational frequencies hardly vary for phase differences of $0° \lesssim \delta \lesssim 120°$ (Fig. 2). In fact, a strong scattering peak was observed at 228 cm^{-1}. These ν_{18} vibrations are coupled vibrations of C–O–C and C–C–O bending modes and C–C and C–O internal-rotation modes.

Thus, neutron-inelastic scattering peaks in the region 600—200 cm^{-1} were assigned, with reference to the frequency distribution calculated for an isolated single chain of polyethylene glycol. However, in the region below 200 cm^{-1}, interchain interactions become significant, so that observed scattering peaks may not be compared with the distribution peaks of an isolated chain. For more realistic analyses of neutron scattering in the low-frequency region, treatments of crystal vibrations are required. Nevertheless, inelastic scattering peaks were observed at 120 and 80 cm^{-1}, apparently corresponding to the Raman lines at 126 and 75 cm^{-1}.[12]

Conclusion

The infrared absorption, Raman scattering, and neutron inelastic scattering spectra of polyethylene glycol were analyzed, on the basis of dispersion curves, frequency distribution and potential-energy distributions calculated for an isolated chain. The dispersion curves are also useful for vibrational analyses of infrared and Raman spectra of model oligomers and for treating heat capacities due to optical branches. The present study was reported, in more detail, in a thesis by Matsuura.[13]

Numerical calculations of the present study were carried out with a HITAC 5020E computer at the University of Tokyo and a NEAC 2200-500 computer at Osaka University.

*4 In the region above 600 cm^{-1}, a scattering peak was observed at 868 cm^{-1}.[3] This scattering peak corresponds to the distribution peak at 870 cm^{-1} (Fig. 1), which is associated with C–O stretching and CH_2 rocking modes.

Structure of Vinylacetylene Determined by Electron Diffraction and Spectroscopy

Tsutomu FUKUYAMA, Kozo KUCHITSU and Yonezo MORINO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo

(Received July 30, 1968)

The average structure of vinylacetylene has been determined by making combined use of the electron-diffraction intensities obtained in the present study and the rotational constants supplied by microwave spectroscopy. The two sorts of data have been found consistent to the uncertainties given below. With the molecular symmetry assumed to be C_s, the following parameters have been obtained in regard to the zero-point average structure: $r(\text{C–C}) = 1.431_0 \pm 0.003_4$, $r(\text{C=C}) = 1.341_6 \pm 0.004_2$, $r(\text{C}\equiv\text{C}) = 1.208_6 \pm 0.002_8$, $r(\text{C–H})_{\text{vinyl}} = 1.087 \pm 0.010$, $r(\text{C–H})_{\text{ethynyl}} = 1.062 \pm 0.018$ Å, $\angle(\text{C=C–C}) = 123.1 \pm 0.5°$, $\angle(\text{C–C}\equiv\text{C}) = 177.9 \pm 1.2°$, $\angle(\text{H–C=C}) = 120.6 \pm 1.5°$, $\angle(\text{C}\equiv\text{C–H}) = 182.3 \pm 3.8°$. There seems to be a significant difference between the C–C length of vinylacetylene and that of propynal. The result has been discussed in terms of the bond-order bond-length correlation.

How does the length of a carbon-carbon bond vary with its environment? This is one of the problems which attract the interest of physical and organic chemists. On the basis of the extensive research by means of rotational spectroscopy, Stoicheff and Costain[1,2] deduced a comprehensive rule, which states that the length of a CC bond is primarily determined by a linear relation depending on the number of atoms adjacent to the carbon atoms at both ends. This rule was shown to hold for a wide range of molecules. For a critical examination of the validity and the limit of applicability of the rule, it is necessary to obtain precise structural parameters of molecules for which neither spectroscopy nor electron diffraction alone can give unique geometry. This requirement was shown to be met in our studies[3-5] by a complementary combination of the two sorts of data. The results of those studies have shown significant deviations from the Stoicheff rule when heteroatoms are present in the system, whereas the rule is valid for pure hydrocarbons.

For butadiene, acrolein, and glyoxal, the central C–C bond increases its length according as it is adjacent to the C=O bond.[3] A similar systematic lengthening has been observed for cyanogen[4] as compared with diacetylene.[6] The first three are conventionally classified as molecules with an sp^2-sp^2 C–C bond, while the latter two are those with an sp-sp C–C bond. It is natural, then, to expect an analogous heteroatom effect in a system containing an sp^2-sp C–C bond. In fact, a deviation from the Stoicheff rule was first observed for an sp^2-sp C–C system by Costain, Stoicheff, and Morton.[1,7] They pointed out that the r_s(C–C) distance of propynal was longer by 0.0025 Å than the value predicted by the linear rule, to which the r_s(C–C) distance of vinylcyanide fitted nicely.

There remains, however, another simple molecule which has a C–C bond of this type: vinylacetylene. No precise structure has been reported for this molecule, although an unpublished work of Bastiansen[8] was cited by Serre,[9] and an r_0 structure was calculated by Whiffen[10] from the rotational constants reported by Morgan and Goldstein.[11] A favorable situation for filling this gap has been brought about by a recent investigation of the microwave spectrum of this molecule by Hirose[12] and by the study of its intramolecular force field by Abe.[13] Taking advantage of these circum-

stances, an electron diffraction measurement has been carried out, and the average structure of vinylacetylene has been determined following the procedure applied to butadiene, acrolein, and glyoxal.

Experimental

The vinylacetylene sample supplied by the Tokyo Kagaku Seiki Co., Ltd. as a standard substance for gas chromatography was used without further purification. No impurity line was observed in the infrared spectrum of a freshly supplied sample.[13] Experimental conditions were similar to those described elsewhere.[3] The observed molecular intensity is shown in Fig. 1. Figure 2 illustrates the radial distribution curve.

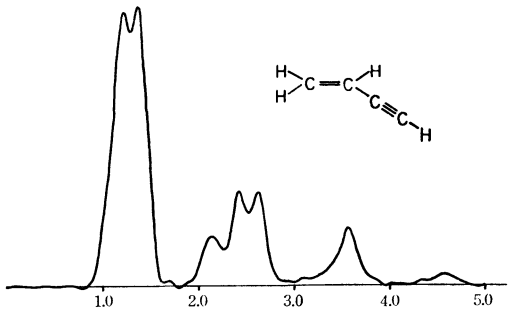

Fig. 2. Radial distribution curve for vinylacetylene.

Analysis

Since the details of the analytical procedure are the same as those described in Ref. 3, only an outline is given here. The calculations have been carried out by a HITAC 5020E Computer at the Computer Center, the University of Tokyo.

It was assumed that the molecule has C_S symmetry, namely that it is planar. With this assumption the number of independent parameters is thirteen for defining the molecular geometry, but in the analysis of the molecular scattering intensity the number of parameters was reduced by the following additional assumptions: Three C–H bond lengths and C=C–H angles in the vinyl group were assumed to be equal. The difference between the C–H bond length in the ethynyl group and those in the vinyl group was fixed at 0.027 Å according to the difference between the r_z(C–H) of acetylene[14] and that of ethylene.[15] Furthermore, the C≡C–H angle was assumed to be 180°. All the above assumptions were applied to the r_α^0 structure, from which the effect of thermal vibrations was removed.

The correction terms for the conversion of r_α into r_α^0 distances were calculated by the procedure given in Refs. 16 and 3. The force constants necessary for the calculation were offered for our use by Abe.

The most probable values of the parameters, r_α^0, obtained by the least-squares analysis are shown in Table 1 with their uncertainties. Table 2 lists the most probable values and the uncertainties of the mean square amplitudes in comparison with the values calculated with the force constants determined by Abe. The agreement is satisfactory. The mean amplitudes for the other atom pairs were fixed at the calculated values throughout the analysis. The parameters of asymmetry κ were estimated as described in Ref. 3, and were fixed at 1.89×10^{-5} and 1.59×10^{-5} Å^{-3} for C–H_{vinyl} and C–$H_{ethynyl}$, respectively.

a) All the vinyl C-H amplitudes were assumed to be equal. Mean amplitudes for C-H_e were varied with fixed difference from those for C-H_v (l(C-H)$_v$ − l(C-H)$_e$=0.0033 Å).

b) Numbering of carbon atoms: C_1=C_2-C_3≡C_4.

The rotational constants B_0 and C_0 for the normal and the deuterated species (deuterated on the ethynyl hydrogen) determined by microwave spectroscopy were communicated by Hirose. After being converted into B_z and C_z, namely into the rotational constants corresponding to the average structure r_z, they were used in the least-squares calculations, in which the rotational constants were combined with the molecular scattering intensity as joint observables. The method is based on the assumption that the r_α^0 structure obtained from electron diffraction and the r_z structure from spectroscopy have essentially the same physical significance so that it is possible to use the two sorts of data to complement one another upon the conversion into those structures. The result is shown in Table 1 as r_{av}. Most of the assumptions with regard to the structure of the vinyl and the ethynyl groups were removed by this procedure. Namely, it became possible to treat the three C=C-H angles, r(C-H)$_{ethynyl}$ and the angle C≡C-H as independent parameters. Although it was not possible to set the C-H distances of the vinyl group free from the restraint that they were equal, this assumption turned out to have no significant effect upon the values of the other parameters: even if any two of the three C-H lengths were assumed to be different by ±0.005 Å, the rest of the parameters changed by not more than 0.001 Å. The isotopic difference r_{av}(C-H) − r_{av}(C-D) was assumed to be 0.0012±0.0020 Å, the value calculated by Eq. (5) of Ref. 5. The observed rotational constants B_0 and C_0, B_z and C_z derived from B_0 and C_0, and the best-fit B_z and C_z are shown in Table 3. The consistency

TABLE 3. OBSERVED AND CALCULATED ROTATIONAL CONSTANTS (in MHz)

calculated difference $r_g - r_a^0$. It is shown in Table 4. This structure is considered to be appropriate for comparison of the bond lengths for different molecules.[5] On the other hand, the angles are given in the r_{av} structure, which is suitable for the description of the shape of a molecule.[5]

Discussion

The structure of vinylacetylene shown in Table 1 is close to that given by Bastiansen, although it is not clear whether they are of comparable physical significance.

Table 4 lists the structures of vinylacetylene, vinylcyanide, and propynal. It must be emphasized that the latter molecules are described in the r_s structure whereas the parameters for vinylacetylene are given in the r_g or r_{av} structure. Although no quantitative relation connecting the r_g with the r_s distances has been set forth, there is little doubt in that the former is longer than the latter. The difference is expected to be in the range of several thousandths of an angstrom. In this consideration, it is probable that the r_g(C–C) of propynal is longer than that of vinylacetylene by more than 0.01 Å. Thus the present system provides another example of the lengthening of a C–C bond adjacent to a heteroatom. On the other hand, it is premature to draw any conclusion about whether or not a similar heteroatom effect also exists between vinylacetylene and vinylcyanide, since the r_g(C–C) of vinylcyanide may be close to 1.430 Å. In order to elucidate this point, and to grasp the heteroatom effect more quantitatively, an electron-diffraction investigation of vinylcyanide and propynal is now under way in our laboratory.

It is interesting in this connection to note that molecular-orbital calculations of bond orders have been reported by Moffat,[17] who has shown that the bond order for the C–C bond in vinylacetylene is smaller than that for the corresponding bond in vinylcyanide. According to his calculations, the C–C bond of vinylacetylene should be longer than that of vinylcyanide. He has asserted the agreement of his prediction with the experimental results by comparing directly the electron-diffraction structure of vinylacetylene with the r_s structure of vinylcyanide. This comparison may not be justified in view of the difference between r_g and r_s stated above. Our preliminary calculation by the Pariser-Parr-Pople method shows that the relative magnitude of the C–C bond orders for these molecules depends on the integral parameters, and especially, on the core resonance integral β used in the calculation. It is likely, however, that for any choice of parameters the difference in the observed sp^2-sp C–C bond lengths is larger than that predicted by the bond order-bond length correlation curve proposed by Julg and Pellégatti.[18] The same tendency has been pointed out for butadiene, acrolein, and glyoxal.[3]

The lengths of C=C and C≡C are slightly larger than those of ethylene and acetylene, respectively. A similar lengthening of the C=C double bond has been observed for butadiene (r_g(C=C) = 1.345± 0.002 Å[3]), and that of the triple bond for diacetylene (r_g(C≡C) = 1.218±0.001 Å[6]). These results are suspected as indications of the conjugation effect. On the other hand, the C–H lengths and C=C–H angles are close to those in ethylene or acetylene. The angles C=C–C in butadiene and acrolein are different beyond the limit of uncertainty, as pointed out in Ref. 3. (123.3° and 121.0°, respectively). The corresponding angle in vinylacetylene is found to be close to the former. A slight bend is observed in the C–C≡C chain of vinylacetylene, while C≡C–H is linear within the limit of error. The ethynyl group of propynal has been shown to have a similar r_s structure.[7]

The authors are indebted to Dr. Chiaki Hirose for providing them with the rotational constants for vinylacetylene before publication. Their thanks are also due to Mr. Koichi Abe who offered the vinylacetylene sample and who supplied the force constants for the molecule before publication.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 383—386 (1969)

Gravimetric Determination of Palladium, Silver, Mercury and Copper with 2-Mercaptomethylbenzimidazole

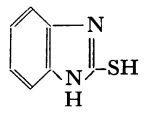
Bimal C. BERA*1 and M. M. CHAKRABARTTY

Research and Control Laboratory, Durgapur Steel Plant, Durgapur-3, West Bengal, India

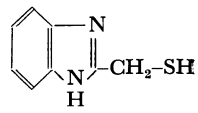
(Received May 17, 1968)

New selective methods are described for the gravimetric determination of palladium, silver, copper and mercury with 2-mercaptomethylbenzimidazole. In the presence of EDTA or tartrate, palladium, silver and mercruy are determined at pH of 4—5. Copper is determined as the copper-(I) complex in the same pH range using cyanide as a reducing and complexing agent. Thermogravimetric studies reveal adequate thermal stability of the complexes. X-Ray studies confirm the identity of the end products in the thermolysis of the copper(I) and copper(II) complexes.

2-Mercaptobenzimidazole (A) is a widely used organic precipitant for cations,[1] and has been employed in the gravimetric,[2] spectrophotometirc,[3,4] amperometric[5] determination of palladium and spectrophotometric determination of osmium.[6] Though extensively used as an analytical reagent it is highly non-specific.[7] As part of an investigation on the analytical applications of some analogous heterocyclic thiols, 2-mercaptomethylbenzimidazole (B) was selected. As in this compound the thiol group is linked to the ring system through an additional carbon atom, it may form five-membered chelates with metal ions and may exhibit a greater degree of selectivity compared to (A). The compound forms chelates[8] with nickel and copper and has been used in the spectrophotometric determination[9] of palladium and in the amperometric titration[10] of palladium, silver and copper.



(A)



(B)

The present study shows that the reagent can be successfully utilised for the gravimetric determination of palladium, silver and mercury in the pH range of 4—5 by weighing their 1:2, 1:1 and 1:2 complexes respectively. Copper can be determined in the same pH range as the copper(I) complex, because the precipitate of the copper(II) complex is finely divided and is difficult to work with.

In the presence of tartrate or EDTA most of the common ions do not interfere in the determination of palladium, silver and mercury. Interferences of Pt^{4+}, Cu^{2+}, Ag^{+} or Hg^{2+} in the determiantion of palladium are obviated by masking palladium with cyanide. Copper, silver and mercury interfere mutually. The selectivity for copper is achieved by using cyanide as a masking and reducing agent.

Thermogravimetric studies indicate that the complexes have adequate thermal stabilities. The complexes of palladium and silver are decomposed into metals. The mercury complex is converted into metallic mercury which finally escapes. The complexes of copper leave a residue which is a mixture of Cu(I) and Cu(II) oxides as confirmed by X-ray analysis.

Experimental

Apparatus. Measurements of pH were made with a Beckman model G pH meter. A Chevenard thermobalance of type 3 of ADAMEL[11] (Paris) was used for thermal analysis. X-Ray studies were performed in

Siemens Krystalloflex-4 using copper target at 35 kV and 16 mA. The exposure time was 3 hr with a 114.6 mm dia. camera.

Reagent Solution. 2-Mercaptomethylbenzimidazole was prepared as described[8] and a 0.5% (W/V) solution in 50% (V/V) aqueous ethanol was employed.

Standard Solutions. Stock solutions of palladium, silver and mercury were prepared and standardised as described earlier.[12] For the standard solution of copper an accurately weighed amount of electrolytic copper (99.99% pure) was dissolved in nitric acid and the excess acid was expelled from the solution.

Preparation of the Complexes. Moderate excess of the reagent was added to the solution of metal ions, buffered with sodium acetate and acetic acid in the pH range of 4—5. The precipitates were allowed to settle, filtered, washed with water and dried in air. The palladium complex was yellow and the copper(II) complex was blue in colour. The other complexes were light yellow.

For preparation of the copper(I) complex, sufficient quantity of saturated sodium sulphite solution or 5% solution of an alkali cyanide was added to copper(II) solution and the pH of the solution was adjusted to 4—5. The solution was heated on the water bath and copper was precipitated as the yellow copper(I) complex. The precipitate was filtered, washed with hot water and dried in air.

Composition of the Complexes. The air dried complexes were dried at 110°C for at least 1 hr and were preserved in a desiccator. The sulphur contents of all the complexes and the metal contents of the palladium, silver and mercury complexes were determined in the same way as reported earlier.[12]

The copper(I and II) complexes were decomposed with concentrated nitric acid. Excess nitric acid and the oxides of nitrogen were expelled by carefully evaporating the solutions with concentrated sulphuric acid and copper was determined iodometrically.

The compositions were as follows:

Found: Pd, 24.56; S, 14.66%. Calcd for $Pd(C_8H_7N_2S)_2$:Pd, 24.58; S, 14.85%. Found: Ag, 39.72; S, 11.70%. Calcd for $Ag(C_8H_7N_2S)$: Ag, 39.80; S, 11.82%. Found: Hg, 37.80; S, 11.93%. Calcd for $Hg(C_8H_7N_2S)_2$: Hg, 38.06; S, 12.17%. Found: Cu, 16.18; S, 16.26%. Calcd for $Cu(C_8H_7N_2S)_2$: Cu, 16.30; S, 16.44%. Found; Cu, 28.10; S, 14.10%. Calcd for $Cu(C_8H_7N_2S)$: Cu, 28.02; S, 14.14%.

Thermal Studies of the Reagent and the Complexes. Aliquots (50—100 mg) of the reagent and the complexes were separately taken in a micro crucible and heated in the thermobalance at the rate of 5°C per minute. The thermogravimetric analysis cruves are shown in Fig. 1.

The reagent started decomposing around 170°C and the destruction of the organic matter continued till 620°C, when the crucible was empty.

The palladium complex remained stable up to 200°C, thereafter underwent slow decomposition till 410°C. Above this point the decomposition was rapid and the level of metallic palladium appeared near 500°C.

The silver complex was stable up to 165°C, then

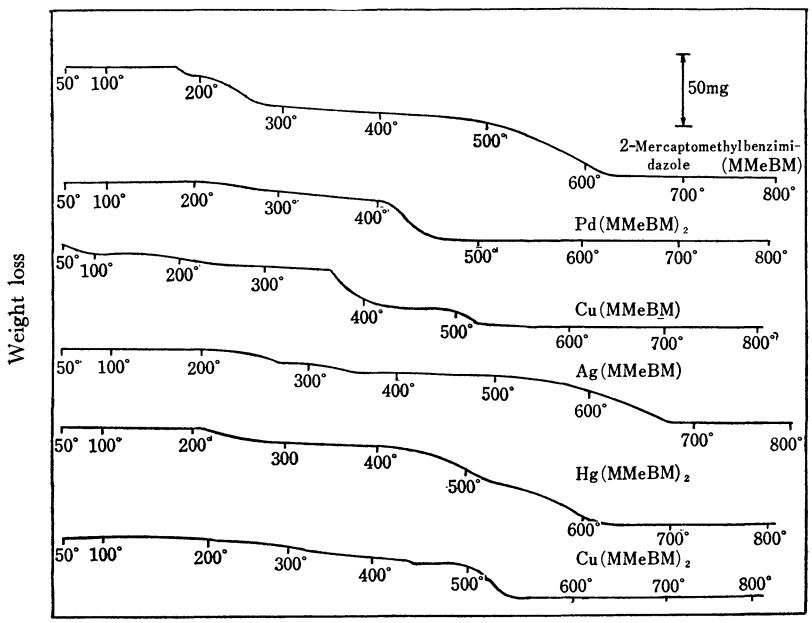

Fig. 1. Thermogravimetric analysis curves.

decomposed slowly till 500°C and rapidly thereafter till 658°C where the horizontal due to metallic silver appeared.

The mercury complex began to lose weight slowly above 180°C till about 400°C when the rate became rapid and the crucible was empty at 640°C. Probably around 400°C mercury was set free from the complex and the rapid loss in weight was due to the escape of mercury and destruction of organic matter.

The initial slope in the T.G.A. profile of the copper-(II) complex was due to the loss of adsorbed moisture. The short horizontal of 105—130°C was due to the diligand complex. The decomposition over the range fo 130—577°C appeared stepwise but there was no strict horizontal. The residue was a mixture of copper(I and II) oxides as confirmed by X-ray studies.

The copper(I) complex was stable up to 170°C, then slowly decomposed till 500°C. Above this point, the rate of decomposition was rapid and a horizontal appeared at 560°C. The residue was again a mixture of the two oxides of copper.

The limiting temperatures of the initial horizontals in the respective thermograms exhibit a decreasing order, such as, Pd(200°C)>Hg(180°C)>Cu^{I}(170°C)>Ag(165°C). This may be taken to be a rough order of the relative thermal stabilities of the complexes. Properties, such as, ionic radii[13] or atomic weights of the metals do not conform to such an order. However, the "ionic potentials" (the ratio of charge to ionic radius) decrease in the order $Pd^{2+}>Hg^{2+}>Cu^{+}>Ag^{+}$ which is in agreement with the above sequence of thermal stability. But the exclusion of the copper(II) complex is not clear. Though the "ionic potential" of Cu^{2+} is higher than that of Hg^{2+}, the complex exhibits the least thermal stability.

Procedure for Palladium, Silver and Mercury. Sufficient amount of 10% (W/V) EDTA. (disodium salt) or tartaric acid solution was added to the solution of a metal ion. The solution was made just alkaline, diluted to about 150 m*l* and the pH was adjusted to 4—5 by adding dilute sodium hydroxide or acetic acid. Moderate excess of the reagent was added with stirring. The precipitates was allowed to settle, filtered through a weighed gooch crucible (G_3 or G_4), washed with hot water (the mercury precipitate was washed with cold water), dried at 110°C and weighed. The results are recorded in Table 1.

Procedure for Copper. To an aliquot of the copper (II) solution 5 m*l* of 5% sodium or potassium cyanide solution was added and the pH was adjusted as usual. The solution was heated to around 70°C on a water bath, copper was precipitated and the mixture was left on the water bath for 10—15 min. The precipitate was filtered, washed with hot water, dried at 110°C and weighed. The results are shown in Table 1.

The metal ions were quantitatively precipitated in the pH range of 4—10, but the precipitates conformed to the above formulas at a pH 4—5. The high results beyond this range were due to the insolubility of the reagent while the values at lower pH were due to the solubility of the complexes.

The reagent not being very soluble a large excess of it was avoided. Generally, 10 m*l* of the reagent solution was sufficient for complete precipitation of 10 mg of palladium or copper and 20 mg of silver or mercury.

Effect of Diverse Ions. Excess EDTA or tartrate solution was added to the palladium, silver or mercury solution containing the diverse ions. The volume of the solution was made to 150 m*l* and the pH was adjusted to 4—5. The metal ions were precipitated with the requisite amount of the reagent. The precipitates were filtered, dried and weighed as usual. Interferences of Pt^{4+}, Cu^{2+} Ag^{+} and Hg^{2+} in the determination of palladium were obviated by complexing palladium with cyanide and precipitating the above ions with the reagent. The filtrate was then evaporated carefully to decompose the cyanide. After complete removal of the cyanide as detected by the copper acetate-benzidine

The Yields of Photonuclear Reactions in Titanium and Vanadium with Bremsstrahlung up to 60 MeV

Yoshinaga OKA, Toyoaki KATO and Nobuyoshi SATO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received June 6, 1968)

The yields of a number of radioactive nuclei produced by (γ,xnyp) reactions on titanium and vanadium targets have been determined at four different bremsstrahlung maximum energies, 30, 45, 55 and 60 MeV, with the aid of radiochemical methods and gamma-ray spectrometric measurements. The linear electron accelerator of Tohoku University was the bremsstrahlung source. Yields have been expressed as production rates of given radioactive end-products relative to that of the $^{12}C(\gamma,n)^{11}C$ process. Over the range of energies investigated, the yield of each nuclide increases with increasing maximum energy. The yield of a reaction with the emission of more than one nucleon appeared to be strongly energy dependent. Reaction paths leading to the formation of each nuclide were investigated. The photoproduction of ^{47}Ca from titanium has been observed.

In previous work,[1-6] a number of problems involving reaction yields and applicabilities of induced activities to the activation analysis of many elements have been investigated in the energy region of 20 MeV bremsstrahlung. This energy corresponds to giant resonance for photon absorption and, in this energy region, the main nuclear events are the emission of one neutron, one proton, or occasionally one alpha-particle. The excitation of a nucleus by gamma-rays with higher energies gives rise to more complex events. Apart from reactions with the emission of a single particle, those involving the emission of just two or more nucleons become important. Studies of production rates or yields of such photonuclear reactions are helpful in understanding the processes by which particle emissions take place, as well as in considering the applicability of the resultant activities to activation analysis.

Titanium and vanadium, on the other hand, when irradiated with high-energy photons, undergo photodisintegrations leading to the production of ^{45}Ti, ^{48}V, $^{46-48}Sc$ and other nuclides, which are convenient for the gamma-ray spectrometric determinations of these elements. Abe[7] reported methods for the determination of titanium in iron and vanadium, utilizing the 20 MeV linear electron accelerator. Since yield is a strong function of photon energy, it should be noted that higher sensitivities are expected with an accelerator capable of producing bremsstrahlung radiation of higher energies.

Although a number of studies have been performed on photonuclear reactions in the region of medium weight nuclei,[8-12] relatively little has been determined with regard to photonuclear properties of titanium and vanadium at energies beyond giant resonance.

Sherwood *et al.*[13] determined the cross-sections, integrated to 31 MeV, of photonuclear reactions involving titanium nuclides, and Pai *et al.*[14] measured the yields of protons ejected from titanium nuclides irradiated by 22 and 30 MeV bremsstrahlung.

The present report describes some experimental details on the relative yields of various nuclides

resulting from the irradiation of titanium and vanadium targets by bremsstrahlung with energies up to 60 MeV. The linear electron accelerator of Tohoku University was used as the bremsstrahlung source, and yields were measured for each nuclide at just four different maximum energies, 30, 45, 55 and 60 MeV, with the aid of radiochemical methods.

Experimental

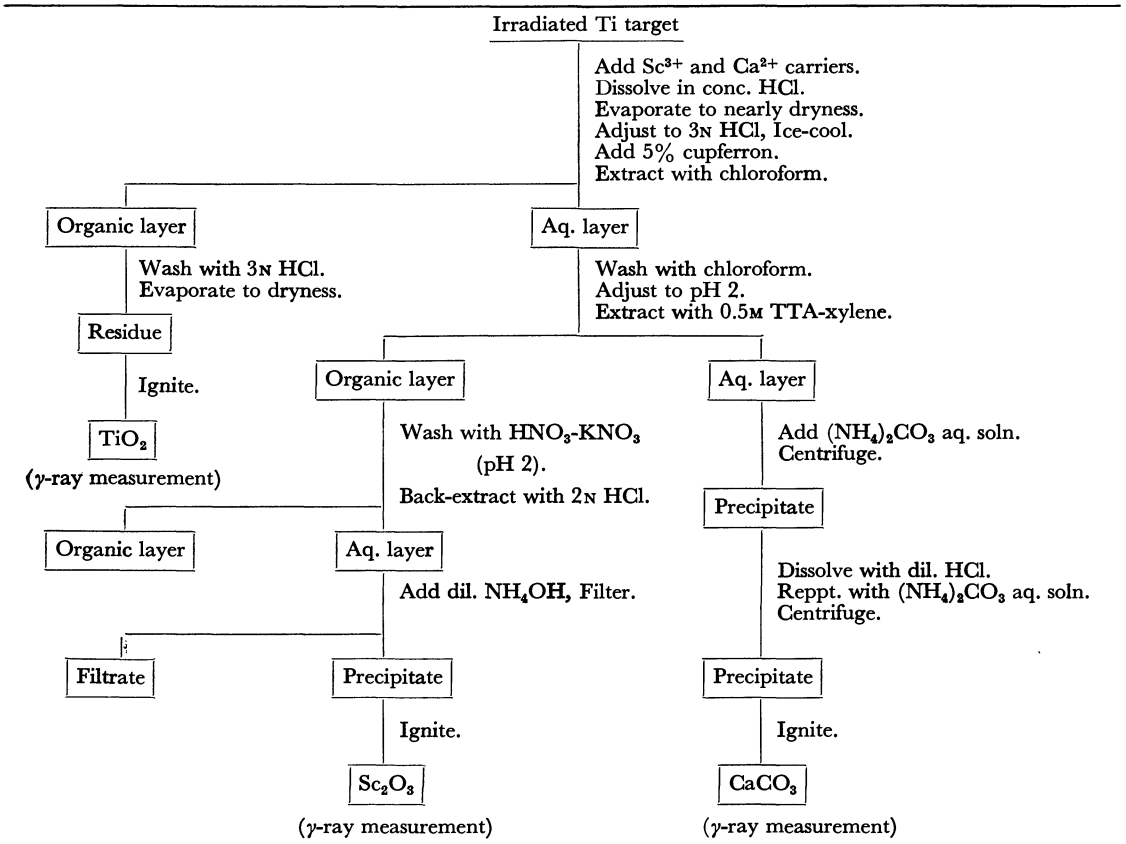
Target Materials. The target materials used were titanium of 99.9% purity, in the form of the elemental powder, and "specpure" grade vanadium pentoxide. A definite amount of each sample (approximately 100 mg) was wrapped in thin aluminum foil and made into a small disk with a diameter of 7 mm and a thickness of 3 mm.

Linac and Irradiation. The 300 MeV linear electron accelerator of Tohoku University was the bremsstrahlung source. The machine was operated with the "High Current" accelerating section which provided a high intensity electron current, the peak current being at least 100 mA with energies up to 100 MeV.[15] The beam was deflected 90° from the original beam path of the accelerating section, and again deflected 45° onto the beam exit window. The spread of electron energies in this operating condition is 3% from the selected value. The electron beam produced bremsstrahlung in a platinum converter with a thickness of 3 mm located 3 cm from the beam exit window. In the energy range from 30 to 60 MeV, used in these experiments, the average beam current was at least 30μA, measured at the position of the converter using a current monitor. Targets were set in a water-cooled target holder on the bremsstrahlung beam axis immediately behind the converter. A typical irradiation was terminated in 1 to 2 hr. The bremsstrahlung flux was monitored using a thin sheet of gold (10μ thick, 7 mmφ) adjacent to the samples.

Radiochemical Separations. After irradiation, the target materials were dissolved along with the addition of scandium and calcium carriers, and subjected to separation procedures diagrammed in Tables 1 and 2. The final precipitates were packed in a small glass tube having an internal diameter of 4 mm for the determination of chemical yield and for gmama-ray counting.

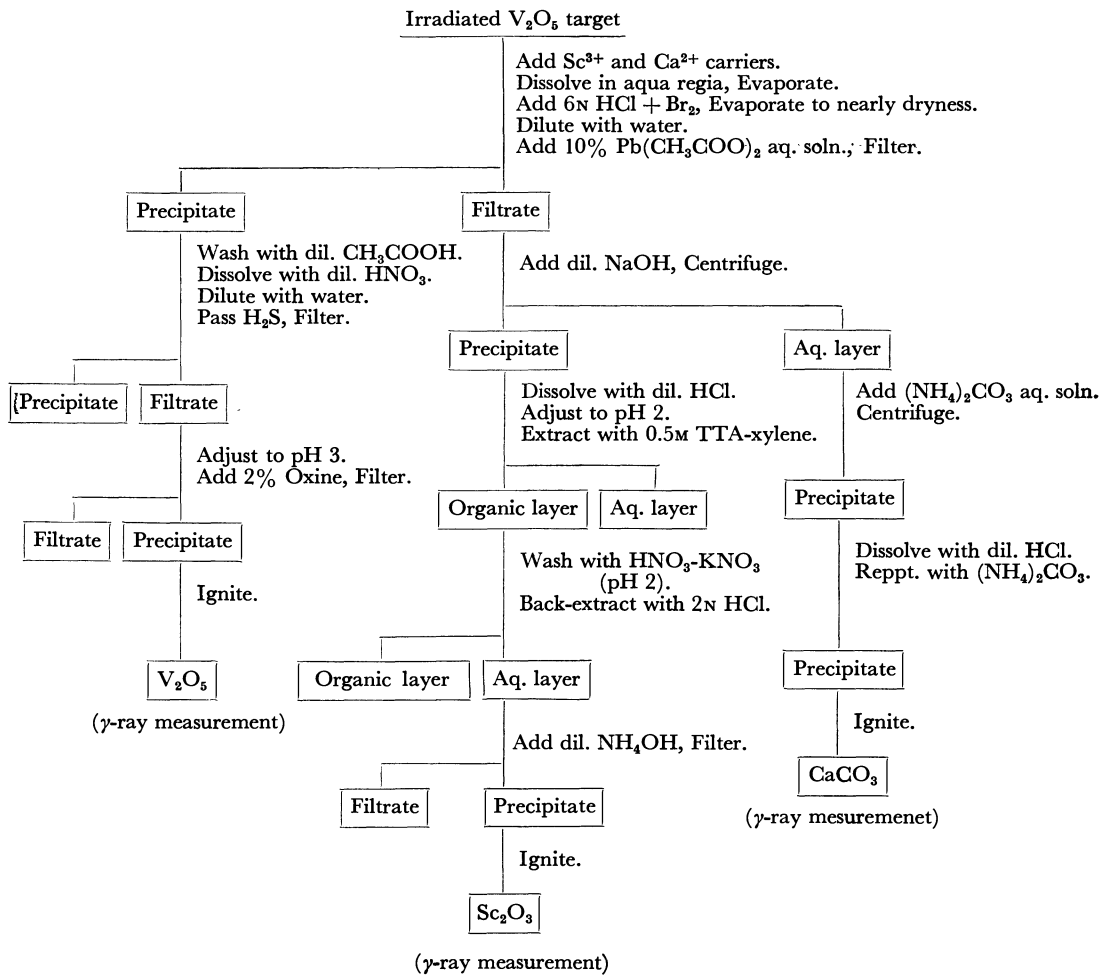
Radioactivity Measurement. For measurements of gamma-ray spectra, a 3″ dia. × 3″ NaI(Tl) detector coupled to a 800-channel pulse-height analyzer made

TABLE 1. SEPARATION SCHEME FOR TITANIUM, SCANDIUM AND CALCIUM ACTIVITIES FROM IRRADIATED TITANIUM TARGET



15) In many cases, the pulse repetition rate was 200 pps with a pulse width of 3μ sec.

TABLE 2. SEPARATION SCHEME FOR VANADIUM, SCANDIUM AND CALCIUM ACTIVITIES FROM IRRADIATED VANADIUM TARGET



by Tokyo Shibaura Electric Co. Ltd., was employed. Counting efficiencies had been previously determined as a function of source distance and gamma-ray energy. The sample to be measured was centered in a Lucite cylinder with walls thick enough to absorb positions from the decay of any positron emitters. Decay curve analyses were performed to distinguish and to separate the undesired activities. The gamma-ray energies used in the yield determination are given in Table 3.

Yield Determination. Yield is defined as the production rate of a given radioactive end-product per atomic weight of the target element when a standard amount of bremsstrahlung radiation with a given maximum energy is passed through the target during the irradiation period. The initial rates of the various activities present were determined from a decay curve analysis of the counting rate of the relevant photopeak area. Corresponding saturation rates were computed and normalized for bremsstrahlung intensity, which was measured by the amount of ^{196}Au activity in a gold foil irradiated together with the target. After correcting for chemical yields, counting efficiencies, branching

TABLE 3. SOME NUCLEAR DATA FOR NUCLIDES USED FOR YIELD DETERMINATION

Nuclide	Half-life	Gamma-ray used	
		Energy (MeV)	Branching ratio (%)
^{45}Ti	3.09 hr	0.511[a)]	168
^{44}Sc	3.92 hr	0.511[a)]	188
^{46}Sc	83.9 d	1.12	100
^{47}Sc	3.43 d	0.160	73
^{48}Sc	1.83 d	1.31	100

^{48}V	16.0 d	1.31	97

a) Annihilation radiation.

ratio[16] and the internal conversion electrons,[17] data were expressed as yields.

These yields were expressed relative to that of the $^{12}C(\gamma,n)^{11}C$ process, which was measured by the amount of 0.511 MeV gamma-rays arising from the annihilation of positrons in a standard carbon disk[18] irradiated together with the target.

Results and Discussion

Gamma-Ray Spectra. Figures 1—3 show gamma-ray spectra obtained for separated activities obtained from a titanium target irradiated with 60 MeV bremsstrahlung. A typical gamma-ray spectrum of a titanium fraction is shown in Fig. 1. The decay curve of the area under the 0.511 MeV photopeak showed a half-life of 3.09 hr, which agrees with the literature value of ^{45}Ti. The gamma-ray spectra of the scandium fraction separated from an irradiated titanium target show ones composed of ^{44}Sc, ^{46}Sc, ^{47}Sc and ^{48}Sc. The production of ^{47}Ca from a titanium target is revealed by the characteristic gamma-ray photopeaks at 0.49, 0.81 and 1.30 MeV, as shown for a typical gamma-ray spectrum in Fig. 3.[19]

II : 5.2 d after irradiation
III: 38 d after irradiation

The gamma-ray spectra of the vanadium and scandium fractions from a vanadium target irradiated with 60 MeV bremsstrahlung are shown in Figs. 4 and 5. Photoproductions of vanadium activities other than 16.0-day ^{48}V could not be observed, and no ^{44}Sc activities occurred to any appreciable amount in an irradiated vanadium target under the present experimental conditions. In addition, no gamma-activity could be detected in the calcium fraction.

Reaction Path. The most abundant naturally

16) The decay schemes used were those listed in C. M. Lederer, J. M. Hollander and I. Perlman, "Table of Isotopes," sixth Ed., John Wiley & Sons, Inc., New York (1967).

17) The tables in M. E. Rose, "Internal Conversion Coefficients," North-Holland Publ. Co., Amsterdam (1958), were used.

18) From the carbon rod used as an electrode in emission spectroscopy, small pieces 7 mm ϕ × 3 mm were cut out and used.

19) The gamma-ray at 0.160 MeV is due to the growth decay of ^{47}Sc, the daughter nuclide of ^{47}Ca.

occurring isotope of vanadium is ^{51}V (99.76%). This fact makes the assignments of parent isotopes for observed radionuclides convenient. Titanium, on the other hand, has five naturally occurring isotopes: ^{46}Ti (7.93%), ^{47}Ti (7.28%), ^{48}Ti (73.94%), ^{49}Ti (5.51%) and ^{50}Ti (5.34%). Competitive nuclear reactions should occur in the energy region covered in this experiment. In Tables 4 and 5 are listed the possible nuclear reactions together with their calculated mass thresholds[20] for the production of each radioactive end-product from both elements with natural compositions. In many cases, radionuclides can be formed through several different reaction paths. Photoproduction of ^{45}Ti from vanadium was excluded by considering the natural abundances and threshold energies. Almost all reactions leading to the photoproduction of ^{44}Sc from the parent ^{51}V have threshold energies greater than 50 MeV. This fact makes unlikely a detectable contribution from photonuclear reactions in vanadium to scandium gamma-ray spectra. Finally, the production of ^{47}Ca from vanadium is also unlikely. The reactions producing ^{47}Ca are: ^{50}V $(\gamma,3p)^{47}$Ca, $-Q=28.71$ MeV; ^{51}V$(\gamma,3pn)^{47}$Ca, $-Q=39.75$ MeV; ^{51}V$(\gamma,2pd)^{47}$Ca, $-Q=37.52$ MeV; and ^{51}V$(\gamma,^3Hep)^{47}$Ca, $-Q=32.03$ MeV. Restric-

20) Nuclidic mass values used were those listed in G. Friedlander, J. W. Kennedy and J. M. Miller, "Nuclear and Radiochemistry," 2nd Ed., John Wiley & Sons Inc., New York (1964), p. 533.

tions posed by the high potential barriers are inherent in these reactions.

Reaction Yield. The yields relative to ^{12}C (γ,n)^{11}C obtained in this experiment are given as a function of the bremsstrahlung maximum energy in Fig. 6. The cross-sectional curve for the reaction ^{12}C(γ,n)^{11}C, reported by Cook *et al.*,[21] has a sharply-peaked resonance centered at 23 MeV, and shows a high energy tail extending at least to 60 MeV. The energy range used herein is well beyond the giant resonance of the ^{12}C(γ,n)^{11}C reaction, and the yield curve for this reaction exhibits a slight increase with increasing energy. Over the range of energies investigated, the relative yield of reactions involving the emission of a single particle do not vary significantly. The yield of a reaction with the emission of more than one nucleon seems likely to be strongly energy dependent.

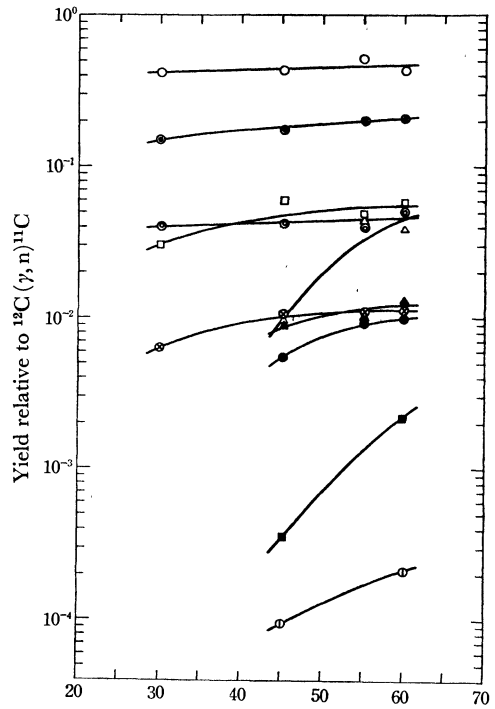

Fig. 6. The yield relative to ^{12}C(γ,n)^{11}C as a function of bremsstrahlung maximum energy.

^{45}Ti from Titanium. The main reaction which can be attributed to the production of ^{45}Ti is the (γ,n) reaction on ^{46}Ti. With high energies, however, contributions from both the ^{47}Ti(γ,2n)^{45}Ti and ^{48}Ti(γ,3n) ^{46}Ti reactions to the total production rate should be taken into account.

$^{44,46-48}$Sc from Titanium. Since ^{44}Sc activity could

Table 6. The relative yields for (γ, p) reactions on titanium nuclei expressed as those per mole

Reaction	Yield per mole relative to $^{12}C(\gamma, n)^{11}C$			
	30 MeV	45 MeV	55 MeV	60 MeV
$^{47}Ti(\gamma, p)^{46}Sc$	5.4×10^{-1}	5.8×10^{-1}	5.4×10^{-1}	6.3×10^{-1}
$^{48}Ti(\gamma, p)^{47}Sc$	2.0×10^{-1}	2.4×10^{-1}	2.8×10^{-1}	2.8×10^{-1}
$^{49}Ti(\gamma, p)^{48}Sc$	1.2×10^{-1}	2.1×10^{-1}	2.2×10^{-1}	2.1×10^{-1}

not be detected from irradiated titanium in the energy region of 30 MeV bremsstrahlung, its production rate due to the reactions $^{46}Ti(\gamma,d)^{44}Sc$, $^{46}Ti(\gamma,pn)$ ^{44}Sc and $^{47}Ti(\gamma,t)$ ^{44}Sc would be very small. The upward trend of the yield curve for ^{44}Sc with increasing energy is likely attributable to the reactions (γ,tn), (γ,d2n) and (γ,p3n) in ^{48}Ti.

In this experiment, the gamma-activity attributed to ^{44m}Sc is too weak to be clearly distinguished from those due to the decay of ^{44}Sc and other products. The reason responsible for this behavior is the spin difference between the two isomeric states. In many cases in which an excited state of the residual nucleus can decay to either isomer through intermediate states in gamma-cascades, gamma-transitions of low multipolarity are accorded preference over those of high multipolarity.[4] The spins and parities in ^{44}Sc and ^{44m}Sc are 2^+ and 6^+, respectively, and those of the target nuclides are $0^+(^{46}Ti)$, $5/2^-(^{47}Ti)$ and $0^+(^{48}Ti)$. Since the spin in ^{44}Sc is closer to that of the target nuclides than in ^{44m}Sc, the relative probability of forming these two states is expected to be favorable of ^{44}Sc. The main reaction producing ^{46}Sc from titanium may by the (γ,p) reaction on ^{47}Ti. The $^{48}Ti(\gamma,pn)^{46}Sc$ and $^{48}Ti(\gamma,d)^{46}Sc$ reactions would occur by a considerable amount at higher energies. By taking the abundance of ^{48}Ti into account, almost all ^{47}Sc comes from the parent ^{48}Ti through the (γ,p) process, though a considerable amount may be due to the $^{50}Ti(\gamma,pn)^{48}Sc$ reaction.[22]

Assuming that all of the observed ^{46}Sc, ^{47}Sc and ^{48}Sc indeed arise from the parent nuclides through (γ,p) processes it is possible to convert each yield to that per mole of target nuclide, instead of the yield per atomic weight of target element. In Table 6 are given the results thus obtained. The yield values for the production rates of ^{46}Sc, ^{47}Sc and ^{48}Sc decrease in that order.[23] These results are consistent with the fact that the cross-section for photoproton emission from a neutron excess nuclide is expected to be small.

^{47}Ca from Titanium. The formation of ^{47}Ca could not be attributed to a unique reaction, but to the competitive reactions listed in Table 4. The yields amount to about 1—2 per cent of those for the reaction producing ^{48}Sc, which can be taken as equivalent to the emission of one excess proton from a parent nuclide.

^{48}V from Vanadium. An irradiated vanadium target did not show any ^{48}V activity at 30 MeV, but its production rate increases markedly with increasing maximum energy. It seems likely that almost all of the ^{48}V comes from ^{51}V through the (γ,3n) process.

$^{46-48}Sc$ from Vanadium. For the production of ^{47}Sc and ^{46}Sc from ^{51}V, the only paths which have mass thresholds below 30 MeV are the (γ,α) and (γ,αn) reactions. Of the reaction pathways leading to the production of both nuclides, these two seem to be most important in the energy range investigated. The yield ratios for the production of ^{46}Sc and ^{47}Sc from vanadium have been found to be about 0.2. The reaction which gives rise to ^{48}Sc is about 3—17 per cent as possible as that yielding ^{46}Sc, and is about 0.6—4 per cent as possible as that yielding ^{47}Sc in the energy region from 45 to 60 MeV. The reaction leading to the production of ^{48}Sc from vanadium corresponds to that of ^{47}Ca from titanium. The yields of these reactions can be considered to be low. It appeared unlikely, just as in the case of the titanium target, that any ^{44m}Sc was produced in the irradiation of vanadium.

For analytical purposes, the lower limits of detection under the present experimental conditions were estimated. One mg of titanium gives an activity under the 0.511 MeV photopeak of 4.4×10^4 cpm,[24] so the lower limit of the titanium determination can be set at 1 μg. For vanadium, the limits of detection of 2 mg from the 1.31 MeV peak of ^{48}V and 60μg from the 0.160 MeV peak of ^{47}Sc are obtained.

22) The relative yields reported by Pai *et al.*[14] for the $^{49}Ti(\gamma,p)$ ^{48}Sc, $^{50}Ti(\nu,pn)^{48}Sc$ and $^{50}Ti(\gamma,pn)^{48}Sc$ reactions are 1.5, 0.17 and 0.37, respectively, at 30 MeV.

23) The same order in yield values was obtained in the irradiation of titanium with 20 MeV bremsstrahlung.[2]

24) The corrected value at the end of one-hour irradiation with 60 MeV bremsstrahlung (average beam current, 45μA): The geometry is 10% with a 3″ dia. × 3″ NaI(Tl) crystal.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 394—399 (1969)

Polarographic Study of Copper(II)-*N*-(2-Hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetate and -2,2′-Ethylenedioxybis-[ethyliminodi(acetate)] Chelates

Mutsuo KODAMA and Yayoe TOMINAGA

Department of Chemistry, Ibaraki University, Mito, Ibaraki

(Received June 8, 1968)

D.c. polarographic behavior of copper(II) ion in *N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetate (EDTA-OH) and 2,2′-ehtylenedioxybis[ethyliminodi(acetate)] (GEDTA) solutions was studied systematically. In an EDTA-OH solution, copper(II) ion gave invariably a single well-defined wave corresponding to the following two-electron reduction.

$$CuX^- + nH^+ + Hg + 2e^- \rightleftarrows Cu(Hg) + H_nX^{n-3}$$

On the other hand, in a GEDTA solution, two waves were obtained. The height of the first wave, which is reversible in nature, increases with increasing pH of the solution at the expense of the height of the irreversible second wave. From the relation between the half-wave potential and the concentrations of hydrogen ion, GEDTA and acetate ion, determined experimentally, the compositions and the stability constants of copper(II)-GEDTA chelates in solution were determined and the electrode reaction mechanism established:

$$\begin{array}{c} CuZ(Ac)^{3-} \\ \uparrow\downarrow \\ CuZ_2^{6-} \rightleftarrows CuZ^{2-} + nH^+ + Hg + 2e^- \rightleftarrows Cu(Hg) + Ac^- + H_nZ^{n-4} \\ \uparrow\downarrow \\ CuHZ^- \end{array}$$

Copper(II) ion has been reported to form stable chelates with several polyaminocarboxylic acids.[1] Generally, copper(II) ion and its chelates behave reversibly in polarographic electrolysis. Therefore, the polarographic method is well suited to the study of copper(II) chelates.

In this paper, results of a polarographic study of copper(II) chelates of *N*-(2-hydroxyethyl)ethylenediamine-*N*,*N*′,*N*′-triacetic acid (EDTA-OH) and 2,2′-ethylenedioxybis [ethyliminodi (acetic acid)] (GEDTA) are presented.

Experimental

Reagents. Purification of EDTA-OH and GEDTA and the preparation of their solutions were as described previously.[2] Preparation and standardization of copper(II) perchlorate solution are also given is a previous paper.[3] All other chemicals were analytical reagent grade, and were used without further purification. The ionic strength of the sample solutions was adjusted to 0.30 by adding $NaClO_4$ solution.

Apparatus and Experimental Procedure. All apparatus (manual and pen-recording polarographs, and the dropping mercury electrode (DME)) and experimental procedures were as employed previously.[4]

Results and Discussion

D. C. Polarographic Behavior of Copper(II)-*N*-(2-Hydroxyethyl) ethylenediamine-*N*, *N*′, *N*′-triacetate Chelate. The d. c. polarographic behavior of copper(II) ion in an EDTA-OH solution was studied systematically in the pH range 3.80 to 5.90. To maintain the pH of the solution constant, acetate buffer (total concentration of acetate = 0.10 M) was used. As illustrated by the curve in Fig. 1, copper(II) ion in an EDTA-OH solution gave invariably a single well-defined wave over the entire pH range studied. The plot of $\log(i/(i_d-i))$ *versus* potential E gave a straight line with a slope of -32 mV (Fig. 2). Here, i_d and i denote the limiting current and current at potential E, respectively.

The limiting current i_d was exactly proportional to the bulk concentration of copper(II) ion and to the square-root of the effective pressure on the dropping mercury electrode (Tables 1 and 2). These facts clearly imply that the electrode reaction of copper(II) ion in an EDTA-OH solution proceeds reversibly in the usual polarographic sense, corre-

Concentration of EDTA-OH=20.0 mM
Concentration of copper(II)=0.682 mM

sponding to a two-electron reduction.

When the bulk concentration of uncomplexed EDTA-OH is constant, the half-wave potential $(E_{1/2})_{CuX}$ shifts linearly to negative potentials with decreasing $\log(a_H)_x$ value of EDTA-OH, obeying the following relation (Fig. 3).

$$\frac{\Delta(E_{1/2})_{CuX}}{\Delta \log (a_H)_x} = 31 \text{ mV} \quad (1)$$

Here, $(a_H)_x$ is given by

$$(a_H)_x = 1 + \frac{[H^+]}{k_3} + \frac{[H^+]^2}{k_3 \cdot k_2} + \frac{[H^+]^3}{k_3 \cdot k_2 \cdot k_1} \quad (2)$$

where k's are dissociation constants of EDTA-OH.

When the hydrogen ion concentration of solution was kept constant, $(E_{1/2})_{CuX}$ also shifted to negative potentials with increasing concentration of uncomplexed EDTA-OH, obeying the following relation (Table 3),

$$\frac{\Delta(E)_{1/2})_{CuX}}{\Delta \log [X]_f} = -31 \text{ mV}, \quad (3)$$

but was independent of acetate ion concentration (Table 4).

Table 1. Dependence of the wave-height on the concentration of copper (II)

2.72_8	11.78_0	4.33

Table 2. Dependence of the wave-height on the effective height of mercury column
pH = 5.86, μ = 0.30
Concentration of EDTA-OH = 20.0 mM
Concentration of copper(II) = 1.36_4 mM

Effective height of mercury column h_c, cm	Limiting current id, μA	$i_d/h_c^{1/2}$
49.2	5.33_8	0.761
59.2	5.88_0	0.765
79.2	6.84_1	0.768

Table 3. Dependence of the half-wave poteetial on the ccncentration of EDTA-OH
pH = 5.62, μ = 0.30
Concentration of copper(II) = 0.682 mM
Concentration of acetate ion = 0.10 M

Concentration of EDTA-OH mM	Half-wave potential V vs. SCE	$\Delta E_{1/2}$, mV Calcd	Obsd
10.0	−0.290	0	0
20.0	−0.300	9.0	10
40.0	−0.310	18.0	20

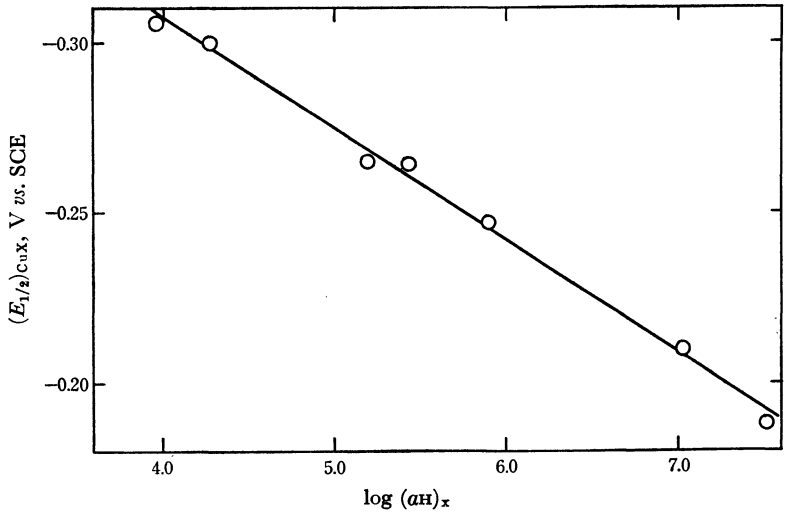

Fig. 3. The relation between the half-wave potential and the pH. μ=0.30
Concentration of EDTA-OH=20.0 mM
Concentration of copper(II)=0.682 mM

TABLE 4. DEPENDENCE OF THE HALF-WAVE POTENTIAL ON THE CONCENTRATIONS OF ACETATE ION OR COPPER(II) ION

pH = 4.85, μ = 0.30
Concentration of EDTA-OH = 20.0 mM

Concentration of acetation M	Concentration of copper(II) mM	Half-wave potential V *vs.* SCE
0.05	0.682	−0.265
0.10	0.682	−0.263
0.10	1.36$_4$	−0.264
0.20	0.682	−0.264

From the above facts, it can be safely concluded that copper(II) ion forms only a normal chelate of 1 to 1 composition with EDTA-OH under the present experimental conditions, and not a protonated chelate or mixed ligand chelate involving acetate ion. The above conclusion was also confirmed by the fact that $(E_{1/2})_{CuX}$ was independent of the concentration of copper(II) ion, provided that the concentration of EDTA-OH and the pH of the solution were kept constant (Table 4).

From the above experimental results and discussion, it is evident that the electrode reaction of copper(II) ion in EDTA-OH solution can be expressed as

$$CuX^- + nH^+ + Hg + 2e \rightleftarrows Cu(Hg) + H_nX^{n-3}, \quad (4)$$

with the half-wave potential $(E_{1/2})_{CuX}$, corresponding to:

$$(E_{1/2})_{CuX} = E^0_{Cu} + 0.0296[\log f_{Cu^{2+}} + \log \frac{k_{Cu(Hg)}}{k_{CuX}} + \log(a_H)_x - \log K_{CuX} - \log[X]_f], \quad (5)$$

where E^0_{Cu} denotes the standard potential, K_{CuX} the stability constant of copper(II)-EDTA-OH chelate, k's the diffusion current constants, $f_{Cu^{2+}}$ the activity coefficient of copper(II) ion at μ=0.30 and $[X]_f$ the bulk concentration of uncomplexed EDTA-OH.

As stated already, the relations between the half-wave potential and the concentrations of acetate ion, EDTA-OH and hydrogen ion, predicted from Eq. (5), were verified satisfactorily by the experimental results.

For the reversible two-electron reduction of copper(II) ion at the mercury electrode, the half-wave potential can be derived as

$$(E_{1/2})_{Cu^{2+}} = E^0_{Cu} + 0.0296\left[\log \frac{k_{Cu(Hg)}}{k_{Cu^{2+}}} + \log f_{Cu^{2+}}\right] \quad (6)$$

Therefore, the shift of the half-wave potential of copper(II) due to the chelate formation with EDTA-OH becomes

$$\Delta(E_{1/2}) = (E_{1/2})_{Cu^{2+}} - (E_{1/2})_{CuX} = 0.0296\left[\log K_{CuX} + \log \frac{k_{CuX}}{k_{Cu^{2+}}} + \log[X]_f - \log(a_H)_x\right] \quad (7)$$

Using the $\Delta(E_{1/2})$ value at $(a_H)x=1$, log K_{CuX} was calculated to be 16.96*1 with the aid of Eq. (7). This agrees well with the value reported by Moeller and Ferrus,[5] and confirms the above explanation.

D. C. Polarographic Behavior of Copper(II)-

*1 This value corresponds to 17.41 at ionic strength 0.10.

5) T. Moeller and R. Ferrus, *J. Inorg. Nuclear Chem.*, **11**, 261 (1961).

2,2'-Ethylenedioxybis[ethyliminodi(acetate)] Chelate. The polarographic behavior of copper(II) ions in a GEDTA solution was studied under experimental conditions similar to those employed in the EDTA-OH system. Copper(II) ion in EDTA-OH solutions gave invariably a well-defined single wave over the entire pH range studied. However, copper(II) ion in a GEDTA solution gave two waves, the heights of which were exactly proportional to the bulk concentration of copper(II) ion and to the square-root of the effective mercury pressure on DME at a given pH (Fig. 4).

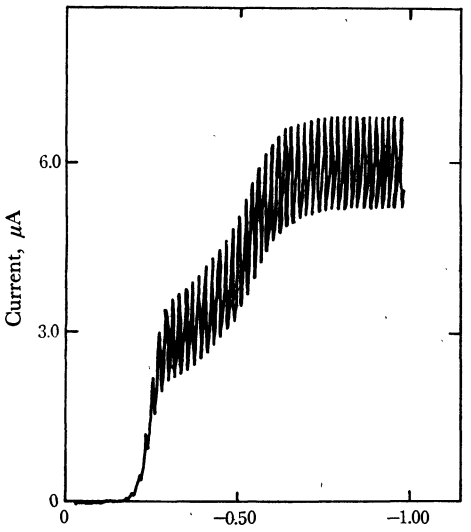

Fig. 4. D. c. polarogram of copper(II)-GEDTA chelate.
pH=5.54 (acetate bufier, 0.10M), μ=0.30
Concentration of GEDTA=18.6 mM
Concentration of copper(II)=1.36$_4$ mM

The height of the first wave, which is reversible in nature, increases with increasing concentration of hydrogen ion at the expense of the height of the irreversible second wave. The sum of two wave heights is almost constant under the experimental conditions employed (3.30<pH<6.00, acetate buffer). When the pH value of the solution is kept constant, with increasing concentration of acetate ion or of GEDTA, the first wave height also increases and the half-wave potential shifts to more negative potentials.

As shown in Fig. 5, a plot of $\log[i/(i_l-i)]$ *vs.* E for the first wave gave a straight line with a slope of −31 mV, corresponding to the two-electron reversible reduction. Here i_l means the limiting current.

These facts may suggest that the first wave corresponds to a two-electron reduction involving copper(II)-GEDTA chelates and the electrode reaction can be expressed as

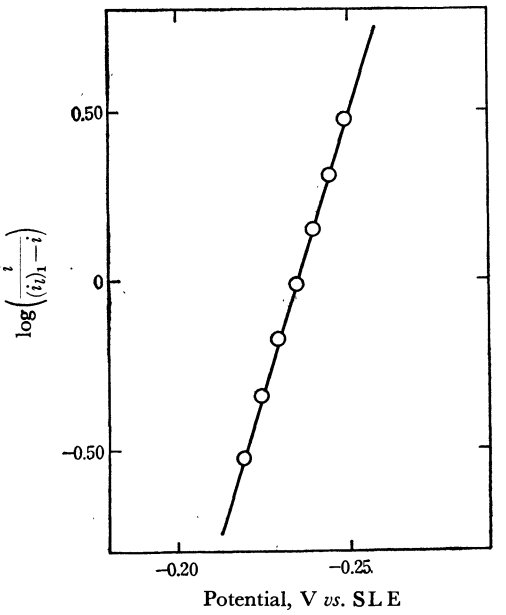

Fig. 5. The d. c. log-plot analysis of the first wave.
pH=5.54 (acetate buffer, 0.10M), μ=0.30
Concentration of GEDTA =18.6 mM
Concentration of copper(II)=1.36$_4$ mM

$$\begin{array}{c} \mathrm{CuZ(Ac)^{3-}} \\ \uparrow\downarrow \\ \mathrm{CuZ_2^{6-}} \rightleftarrows \mathrm{CuZ^{2-}} + n\mathrm{H^+} + \mathrm{Hg} + 2\mathrm{e^-} \rightleftarrows \\ \downarrow\uparrow \\ \mathrm{CuHZ^-} \end{array}$$

$$\mathrm{Cu(Hg)} + \mathrm{Ac^-} + \mathrm{H}_n\mathrm{Z}^{n-4} \qquad (8)$$

where $CuHZ^-$ denotes the protonated chelate, $CuZ(Ac)^{3-}$ the mixed chelate involving acetate ion, CuZ^{2-} and CuZ_2^{6-}, normal chelates of 1 to 1 and 1 to 2 compositions and Z^{4-} completely de-protonated GEDTA anion.

For the above electrode reaction, one can derive the following relation thermodynamically by assuming that all diffusion current constants of copper(II) GEDTA chelates are the same.

$$(E_{1/2})_{CuZ} = E^0_{Cu} - 0.0296\Big[\log K_{CuZ}\Big(1 + K^{H}_{CuZ}[H^+] + K^{Ac}_{CuZ}[Ac^-] + K^{Z}_{CuZ}\frac{[Z]_f}{(\alpha_H)_z}\Big) - \log(\alpha_H)_z + \log[Z]_f + \log\frac{k_{CuZ}}{k_{Cu(Hg)}} + \log f_{Cu^{2+}}\Big], \qquad (9)$$

where $(\alpha_H)_z$ is the (α_H) value of GEDTA and other notations used are defined as follows.

$$K^{AC}_{CuZ} = \frac{[CuZ(Ac)^{3-}]}{[CuZ^{2-}]\cdot[Ac^-]}, \quad K^{H}_{CuZ} = \frac{[CuHZ^-]}{[CuZ^{2-}]\cdot[H^+]}$$

$$K^{Z}_{CuZ} = \frac{[CuZ_2^{6-}]}{[CuZ^{2-}]\cdot[Z^{4-}]}$$

Equation (9) indicates that if the above electrode reaction mechanism proposed is correct, it would be possible to calculate K^{H}_{CuZ}, K^{Ac}_{CuZ} and K^{Z}_{CuZ} values, at least from six $(E_{1/2})_{CuZ}$ values observed at various

concentrations of three species, namely, hydrogen ion, acetate ion and GEDTA. The three K values thus estimated should explain satisfactorily the change in height of the first wave with change in concentrations of the above three species.

K^{H}_{CuZ}, K^{Ac}_{CuZ} and K^{Z}_{CuZ} values were calculated using the half-wave potentials given in Tables 5, 6 and 7, and are listed in Table 8.

Table 5. Dependence of the half-wave potential and the wave-height on pH

Table 7. Dependence of the half-wave potential and the wave-height on the concentration of GEDTA

pH = 5.54, μ = 0.30
Total concentration of acetate = 0.10 M
Concentration of copper(II) = 1.36_4 mM

Concn. of GEDTA mM	$E_{1/2}$ of the first wave V *vs.* SCE	Wave-height, μA		$(i_l)_1/(i_l)_2$ ratio	
		$(i_l)_1$	$(i_l)_2$	Calcd	Obsd
13.6	-0.228	2.41_1	3.41_0	1.00	1.00
18.6	-0.235	2.75_2	3.17_1	1.12	1.22
38.6	-0.249	3.11_5	2.85_7	1.53	1.54

Since the half-wave potential of the second wave also shifts to more negative potentials with increasing concentration of GEDTA and pH, this step also corresponds to the reduction of copper(II)-GEDTA chelate. If two species of copper(II)-GEDTA chelates, which show different polarographic behavior, co-exist in equilibrium in solution, the following relation would be expected on the assumption of equal diffusion current constants.

$$\frac{(i_l)_1}{(i_l)_2} = \frac{[CuZ^{2-}]+[CuHZ^{-}]+[CuZ(Ac)^{3-}]+[CuZ_2^{6-}]}{[Cu(II)\text{-}GEDTA^*]} = \frac{1+K^{H}_{CuZ}[H^+]+K^{Ac}_{CuZ}[Ac^-]+K^{Z}_{CuZ}[Z]_f/(a_H)_z}{K}, \quad (10)$$

where $(i_l)_1$ and $(i_l)_2$ denotes the limiting currents of the first and second steps, respectively, and K the equilibrium constant defined as $K=[Cu(II)\text{-}GEDTA^*]/[CuZ^{2-}]$. Here, Cu(II)-GEDTA* means the species which corresponds to the second step.

The ratios $(i_l)_1/(i_l)_2$'s, calculated using K^{H}_{CuZ}, K^{Ac}_{CuZ} and K^{Z}_{CuZ} are listed in Tables 5, 6 and 7 together with observed values. The calculated values agree well with those observed. Although there may be some small doubt about the presence of normal copper(II)-GEDTA chelate of a 1 to 2 composition, this agreement supports the above explanation.

With the aid of Eqs. (6) and (9), log K_{CuZ} was also calculated to be 17.44 (μ=0.10) using the K^{H}_{CuZ}, K^{Ac}_{CuZ} and K^{Z}_{CuZ} values. This also agrees well with the reported value,[6] giving further confirmation to the above explanation.

Table 8. Numerical values

Since there is little reason to believe that the two ether oxygens in GEDTA can not partake in the chelate formation of GEDTA, it can not rule out the possibility that there exist two species of copper(II)-GEDTA chelates. Because of its irreversibility, further systematic studies on the nature of the second step were not conducted in this investigation, but to get an insight into the precise nature of the chelate corresponding to the second wave, further systematic investigations by the methods other than polarography should be carried out.

The 1:1 Complexes of Pyridine-2-carboxamide with Bivalent Metals

Masao SEKIZAKI, Masakazu TANASE and Kazuo YAMASAKI

Inorganic Chemistry Laboratory, Faculty of Science, Nagoya University, Nagoya

(Received June 7, 1968)

The 1 : 1 complexes of pyridine-2-carboxamide (piaH) with the bivalent metals, nickel, copper, cobalt, zinc and cadmium, were prepared and their structures determined through measurements of diffuse reflectance spectra, magnetic moments and infrared spectra. In these complexes, MX_2-(piaH) (X=halogen), pyridine-2-carboxamide is likely to be coordinated to the metal through N(pyridine) and O(amide) atoms with two halogen atoms in the cis-position.

In preceding reports,[1-5] the 1 : 2 complexes of pyridine-2-carboxamide (picolinic acid amide, piaH) with nickel, copper, cobalt, iron and palladium having the general formulae, $[M(pia)_2]$ and $[M(H_2O)_2(piaH)_2]Cl_2$ were studied by various methods. The former complex had N(pyridine) and N(amide) coordination, while the latter N(pyridine) and O(amide) coordination. The 1 : 1 complexes, however, have scarcely been studied except for a copper complex.[6] In the present paper, the syntheses, properties and structures of the 1 : 1 complexes of nickel, copper, cobalt, cadmium and zinc with pyridine-2-carboxamide will be reported.

Experimental

Materials. Pyridine-2-carboxamide is the product of Tokyo Kasei Co. and was used without further purification.

Preparation of Complexes. 1) $CuCl_2(piaH)$*1: This complex was prepared by mixing together an ethanolic solution of 2.4 g (0.02 M) of the ligand and that of 3.4 g (0.02 M) of copper(II) chloride dihydrate.[6] A blue-green powder precipitated. Yield 4 g.

Found: Cu, 24.87; N, 11.35%. Calcd for $C_6H_6N_2OCuCl_2$: Cu, 24.76; N, 10.92%.

2) $CuBr_2(piaH)$: To an ethanolic solution of 2.2 g (0.01 M) of copper(II) bromide, 1.2 g (0.01 M) of the ligand dissolved in ethanol was added. The reddish-brown powder which precipitated was washed with ethanol. Yield 3 g.

Found: Cu, 18.45; N, 8.04%. Calcd for $C_6H_6N_2OCuBr_2$: Cu, 18.39; N, 8.11%.

3) $NiCl_2(piaH)\cdot 2.5H_2O$: Four grams (0.017 M) of nickel chloride hexahydrate, which had been partially dehydrated at 40°C for an hour, was dissolved in ethanol and an ethanolic solution of the ligand (1.2 g, 0.01 M) was added. The mixed solution was concentrated on a water bath until yellowish-green crystals precipitated. Yield 1.4 g.

Found: Ni, 19.88; N, 9.38; Weight loss *in vacuo* at 150°C: 15.33%. Calcd for $C_6H_6N_2ONiCl_2 2.5H_2O$: Ni, 19.78; N, 9.43; H_2O, 15.18%.

4) $CoCl_2(piaH)\cdot 2H_2O$: To an ethanolic solution of 10 g (0.04 M) of cobalt chloride hexahydrate, 1.2 g (0.01 M) of the ligand dissolved in ethanol was added. The purple powder which precipitated on concentrating the solution on a water bath was washed with ethanol. Yield 2 g.

Found: Co, 20.40; N, 9.44; Weight loss *in vacuo* at 150°C: 12.94%. Calcd for $C_6H_6N_2OCoCl_2 2H_2O$: Co,

*1 Dichloro(pyridine-2-carboxamide) copper(II). Other complexes are named in a similar way.

20.46; N, 9.73; H_2O, 12.51%.

5) $ZnCl_2$(piaH): Ethanolic solutions of 3 g (0.02 M) of zinc chloride and of 1.2 g (0.01 M) of the ligand were mixed together. The white powder which precipitated after one day was washed with ethanol. Yield 0.9 g.

Found: Zn, 25.03; N, 10.57%. Calcd for $C_6H_6N_2OZnCl_2$: Zn, 25.30; N, 10.84%.

6) $CdCl_2$(piaH): To an aqueous solution of 1.2 g (0.01 M) of the ligand, an aqueous solution of 2.5 g (0.01 M) of cadmium chloride was added. White crystals which precipitated were recrystallized from water. Yield 2.3 g.

Found: Cd, 36.58; N, 9.11%. Calcd for $C_6H_6N_2OCdCl_2$: Cd, 36.80; N, 8.77%.

The deuterated complex, $CdCl_2$(piaD) was prepared by recrystallizing $CdCl_2$(piaH) from 99.75% D_2O.

7) $CdBr_2$(piaH): This complex was prepared in a similar way to the corresponding chloro complex.

Found: Cd, 28.48; N, 7.16%. Calcd for $C_6H_6N_2OCdBr_2$: Cd, 28.50; N, 7.10%.

8) CdI_2(piaH): This complex was prepared in a similar way to the corresponding chloro complex.

Found: Cd, 22.85; N, 5.87%. Calcd for $C_6H_6N_2OCdI_2$: Cd, 23.02; N, 5.74%.

9) $Cd(NCS)_2$(piaH): To a mixture of 2.6 g (0.01 M) of cadmium sulfate 8/3 hydrate and 1.2 g (0.01 M) of the ligand dissolved in warm water, a warm aqueous solution of 2 g (0.02 M) of potassium thiocyanate was added. White crystals which precipitated were recrystallized from water. Yield 1.9 g.

Found: Cd, 32.26; N, 15.90%. Calcd for $C_6H_6N_2OCd(NCS)_2$: Cd, 32.05; N, 15.98%.

Magnetic and Spectroscopic Measurements. Magnetic moments were determined by the Gouy method at room temperature (17.5—20°C). Diffuse reflectance spectra were obtained using a Hitachi EPU-2A spectrophotometer equipped with attachments. Infrared spectra were measured with a JASCO DS-402G spectrophotometer (4000—700 cm^{-1}) and a Hitachi EPI-L spectrophotometer (700—200 cm^{-1}) using Nujol or hexachlorobutadiene mulls.

Results and Discussions

1. General Properties of the Complexes. Among the 1 : 1 complexes studied, only the cadmium complexes (Nos. 6—9) are soluble in water, while the others (Nos. 1—5) are all insoluble and readily decompose in water. All complexes are difficult to dissolve in ethanol and stable in air up to 150°C.

2. Magnetic Moments. The magnetic moments measured are listed in Table 1. The values for nickel and cobalt complexes correspond to two and three unpaired electrons, respectively, and suggest octahedral structures.[7] The values for the copper complexes are normal, indicating square planar or distorted octahedral structures without interaction between copper atoms. Zinc and cadmium complexes are all diamagnetic.

Table 1. Magnetic moments of the 1 : 1 complexes (17.5—20°C)

	Complex	Moment observed	Moment calcd. by the spin-only formula
1	$CuCl_2$(piaH)	1.88 B.M.	1.73 B.M.
2	$CuBr_2$(piaH)	1.82	1.73
3	$NiCl_2$(piaH)·$2.5H_2O$	3.21	2.82
4	$CoCl_2$(piaH)·$2H_2O$	4.97	3.88
5	$ZnCl_2$(piaH)	diamagnetic	
6	$CdCl_2$(piaH)	diamagnetic	
7	$CdBr_2$(piaH)	diamagnetic	
8	CdI_2(piaH)	diamagnetic	
9	$Cd(NCS)_2$(piaH)	diamagnetic	

3. Diffuse Reflectance Spectra. The diffuse reflectance spectra of the nickel complexes are shown in Fig. 1. The bands at 1300, 700 and 415 mμ for the 1 : 1 complex are assigned to the transitions $^3A_{2g} \rightarrow {}^3T_{2g}$ $^3A_{2g} \rightarrow {}^3T_{1g}(F)$ and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$, respectively.[8] The corresponding bands for the 1 : 2 complex, $[Ni(H_2O)_2(piaH)_2]Cl_2$ appear at 875, 625 and 350 mμ.

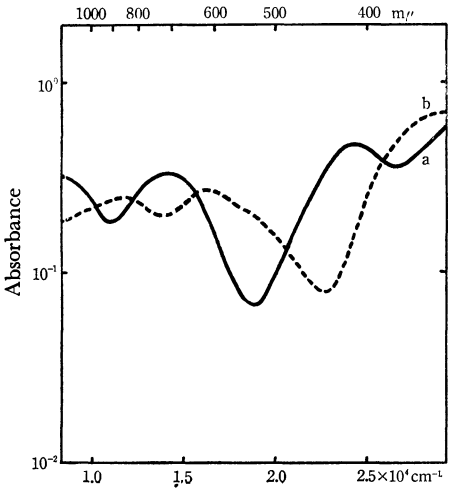

Fig. 1. Diffuse reflectance spectra of the nickel complexes.
a: $NiCl_2$(piaH)·$2.5H_2O$
b: $[Ni(H_2O)_2(piaH)_2]Cl_2$

The diffuse reflectance spectra of the cobalt complexes are shown in Fig. 2. Spectroscopic and magnetic data for the 1 : 1 complexes strongly suggest the octahedral coordination of cobalt compared with the 1 : 2 complex, $[Co(H_2O)_2(piaH)_2]Cl_2$. Absorption bands beyond 1100 mμ and at 550 mμ are assigned to the transitions

All the 1 : 1 complexes of nickel and copper show d–d transition bands at longer wavelengths than the corresponding 1 : 2 complexes. This may be due to the coordination of two halogen atoms in the 1 : 1 complexes instead of a pyridine-2-carboxamide molecule.

As shown in Fig. 3, the 1 : 1 complexes of copper, $CuX_2(piaH)$, give two bands in the visible region. The band at 370 mμ for the chloro complex shifts to 470 mμ for the bromo complex and this band is not found for the 1 : 2 complex, $[Cu(H_2O)_2(piaH)_2]Cl_2$. Therefore this band may be assigned to a charge transfer band related to the coordination of halogen atoms. The band due to the d–d transition is observed at 830 mμ for the chloro complex, at 750 mμ for the bromo complex and at 660 mμ for the 1 : 2 complex. These 1 : 1 copper complexes are all thought to be of distorted octahedral or square planar structures, but it is difficult to decide from spectroscopic and magnetic data alone.

Zinc and cadmium complexes show no absorption bands in the visible region.

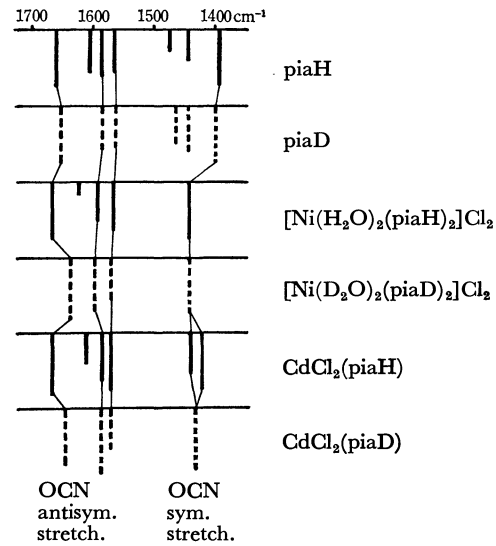

Fig. 4. Infrared spectra of ligands, nickel (1 : 2) and cadmium (1 : 1) complexes.

4. Infrared Spectra. Infrared spectra of the 1 : 1 complexes shown in Figs. 4, 5 and 6 are similar to each other, indicating similar structures; namely octahedral structures for nickel, cobalt, zinc and cadmium complexes, and probably for copper complexes as well.

In the region 4000—700 cm^{-1} some characteristic bands due to the amide group of the ligand are observed. The spectra of the free ligand, the 1 : 1 complexes $MX_2(piaH)$ and 1 : 2 complexes $[M(H_2O)_2(piaH)_2]X_2$,[3] and their deuterated compounds are shown in Fig. 4 and Table 2. In comparing the amide bands of the 1 : 1 complexes with those of the 1 : 2 complexes which had been found to be N and O coordination, a close similarity is observed in the following points: (1) Upon

deuteration, the band of OCN antisymmetric stretching vibration mode of both the 1 : 1 and 1 : 2 complexes at 1670—1640 cm^{-1} shifts to lower frequency by 20—30 cm^{-1}, while the shift for the free ligand is small; (2) The band of OCN symmetric stretching vibration mode at 1440-1410 cm^{-1} is observed in a region higher than that of the free ligand by about 40 cm^{-1}, and the shift upon deuteration is small; (3) The band at about 1600 cm^{-1}, which is due to NH_2 scissoring is observed almost at the same position for various complexes. The close similarity of spectra between the 1 : 1 and 1 : 2 complexes suggests similar structures, *i. e.* N(pyridine) and O(amide) coordination for the 1 : 1 complexes, $MX_2(piaH)$, as well as for the 1 : 2 cationic complexes, $[M(H_2O)_2$-$(piaH)_2]X_2$. Entirely different spectra for the 1 : 2 non-ionic complexes, $M(pia)_2$, reported earlier,[3] rule out the possibility of N(pyridine) and N(amide) coordination for the 1 : 1 complexes.

Far infrared spectra (700—200 cm^{-1}) are shown in Figs. 5 and 6 and Table 3, with tentative assignments. The spectra of the 1 : 2 complexes of nickel and the free ligand[3] are also shown for comparison. In this region two characteristic bands due to the amide group are found at about 600 and 500 cm^{-1}. The former band is assigned to the CO in-plane bending mode and the latter to the CO out-of-plane bending mode. The frequency of

*4 $Cd(NCS)_2(piaH)$ shows a band at 461 cm^{-1} due to the NCS bending

the CO in-plane bending mode for the 1 : 1 chloro complexes decreases in the following order: Ni~Zn>Co≥Cu>Cd. If the corresponding band is compared for different halogen-substituted complexes of the same metal, the frequency decreases in the following order for copper and cadmium: Cl>NCS>Br>I. On the other hand, frequencies of the CO out-of-plane bending mode show only small differences from each other, and there is no regularity in the shift. Therefore, some correlation between the coordination of halogen atoms and the CO in-plane bending mode seems to exist. Based on the above results, the structure shown in Fig. 7 is proposed for the 1 : 1 complexes, in which the metal, halogen atoms and the am ide group of the ligand are all situated in the same plane.

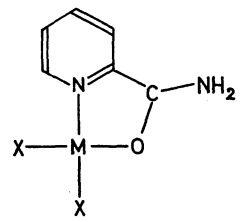

Fig. 7. The proposed structure for the 1 : 1 complex.

Several strong bands observed in the region 320—200 cm^{-1} are assigned to the skeletal vibration correlated with the chelate ring vibration. Of these bands, the one observed for the free ligand at 252 cm^{-1} and the band observed for 1 : 1 complexes at 235—303 cm^{-1} are assigned to the pyridine-amide torsional mode. Several bands are observed at 300 and 250—200 cm^{-1} for the 1 : 1 complexes, but not for the free ligand. These bands are mainly due to the metal - N (pyridine) or metal - O(amide) stretching vibration modes coupled with metal - halogen stretching. For the nickel and cobalt complexes, strong and broad absorptions due to the libration of lattice waters are present in the region 800—200 cm^{-1}.

Far infrared spectra were measured in the laboratory of Professor Shimanouchi, the University of Tokyo, and in the Naka Works, the Hitachi Ltd. The present authors wish to thank for their kindness shown during the measurements, and the Ministry of Education for a research grant.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 404—406 (1969)

The Effect of Acetate Ion on the Rate of the Reaction between Cobalt(II) and Manganese(II)-Ethylenediaminetetraacetate Complexes

Masaru KIMURA

Department of Applied Chemistry, Yamagata University, Yonezawa, Yamagata

(Received June 14, 1968)

The kinetics of the substitution reactions of cobalt(II) ions and manganese(II)-ethylenediaminetetraacetate complexes have been studied in acetate buffer solutions at 25°C and at ionic strength of 0.2. The reaction was treated as to proceed through both hydrated metal ions and monoacetato complexes. The rate constants for six elementary reaction paths, three of which involve hydrated cobalt(II) ions and the others, monoacetatocobalt(II) complexes, were determined. The values obtained indicate that all the reactions proceeding through monoacetatocobalt(II) complexes are about three times faster than the corresponding reactions proceeding through hydrated cobalt(II) ions.

In the previous papers on substitution reactions involving copper(II)-nitrilotriacetate (NTA) complexes[1] and lead(II)-ethylenediaminetetraacetate (EDTA) complexes,[2] it has been shown that monoacetatocopper(II) ions and monoacetatolead(II) ions react more slowly with NTA anions and EDTA anions respectively, than the corresponding hydrated metal ions do. However, recently, Tanaka and Kimura[3] have shown that monoacetatonickel(II) ions react with NTA anions faster than hydrated nickel(II) ions do. Tanaka and Sakuma,[4] and Bydalek,[5] who studied the effect of acetate ions on reactions involving nickel(II) ion, obtained results similar to those reported by Tanaka and Kimura.[3] It seemed to be important and interesting that the effect of acetate ions on the reactions involving nickel(II) ions is the reverse of that on the reactions involving copper(II) and lead(II) ions. This fact was considered to be due to the characteristics of acetatometal complexes, but not of NTA or EDTA; confirmation was sought in the present study. The behavior of the acetatocobalt(II) ions used in the present study was considered to be similar to that of acetatonickel(II) ions.

The substitution reactions between cobalt(II) ions and manganese(II)-ethylenediaminetetraacetate complexes have been investigated in acetate buffer solutions at an ionic strength of 0.2 at 25°C, and the rate constants of the paths by which the reactions proceed through hydrated cobalt(II) ions and monoacetatocobalt(II) complexes have been determined and compared with those of the corresponding reactions of other metal ions.

was standardized by using a standard copper(II) solution by amperometric titration using a dropping-mercury electrode as the indicator electrode. A standard solution of manganese(II) nitrate was prepared from the guaranteed reagents and was standardized amperometrically by the standard solution of EDTA. The preparation and standardization of all the other chemicals and solutions used were the same as have been described in a previous paper.[3]

The rate of the reaction between cobalt(II) ions and manganese(II)-EDTA complexes was determined by measuring the polarographic limiting-diffusion current of cobalt(II) ions in acetate buffer solutions at 25°C and at an ionic strength of 0.2. The ionic strength was adjusted with potassium nitrate. Polyoxyethylene lauryl ether (LEO) (2×10^{-6} M) was added as a maximum suppressor. The pH of the solution was measured after polarographic measurements with a Hitachi-Horiba Model F-5 pH meter.

Results and Discussion

In a solution containing acetate ions up to a concentration of 0.2 M, the overall substitution reaction of cobalt(II) ions and manganese(II)-EDTA complexes can be expressed as follows:

$$\left\{\begin{array}{c}Co^{2+}\\ \downarrow\uparrow\\ CoOAc^{+}\end{array}\right\} + MnY^{2-} \overset{V^{+}_{0,app}}{\rightleftharpoons} CoY^{2-} + \left\{\begin{array}{c}Mn^{2+}\\ \downarrow\uparrow\\ MnOAc^{+}\end{array}\right\} \quad (1)$$

where Y^{4-} denotes a tetravalent EDTA anion.

The apparent concentrations of cobalt(II) ions that can be determined polarographically, $[Co^{2+}]_{app}$ are give by

$$[Co^{2+}]_{app} = [Co^{2+}] + [CoOAc^{+}] \quad (2)$$

Under the present experimental conditions, the rate of the substitution reaction between Co(II) and Mn(II)-EDTA complexes was so slow that the apparent initial rates of the reactions, $-\Delta[Co^{2+}]_{0,app}/\Delta t$, could be measured accurately; the subscript 0 indicates the initial state.

The apparent initial rates of the forward reaction (1), $V^{+}_{0,app}$ were obtained at various pH's with two different concentrations of Mn(II) and acetate ions. The plots of $V^{+}_{0,app}/([Co^{2+}]_{0,app}[MnY^{2-}]_0)$ *versus* $[H^+]$ gave straight lines as is shown in Fig. 1.

On the basis of these facts, the following mechanisms can be suggested for reaction (1).

(i) $$Co^{2+} + MnY^{2-} \overset{k^{+}_{1h}}{\rightleftharpoons} CoY^{2-} + Mn^{2+} \quad (3)$$

$$CoOAc^{+} + MnY^{2-} \overset{k^{+}_{1s}}{\rightleftharpoons} CoY^{2-} + MnOAc^{+} \quad (3')$$

(ii) $$MnY^{2-} + H^{+} \rightleftharpoons MnHY^{-} \quad (4)$$

$$Co^{2+} + MnHY^{-} \overset{k^{+}_{11h}}{\rightleftharpoons} CoHY^{-} + Mn^{2+} \quad (5)$$

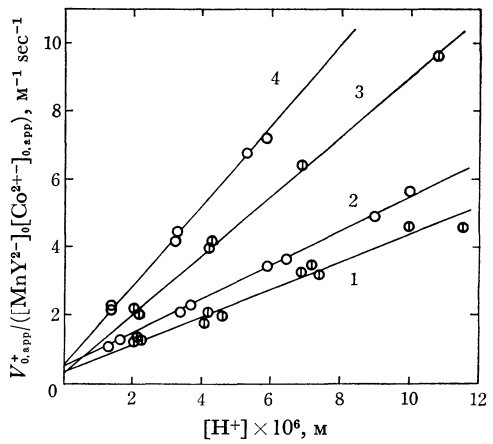

Fig. 1. $V^{+}_{0,app}/([MnY^{2-}]_0[Co^{2+}]_{0,app})$ as a function of hydrogen ion concentration in acetate buffer-potassium nitrate solutions of ionic strength 0.2 at 25°C.
Initial concentrations are $[MnY^{2-}]_0 = 0.378$ mM; $[Co^{2+}]_{0,app} = 0.193$ mM; $[Mn^{2+}]_{0,app} = 4.875$ mM (cruves 3 and 4) and 12.04 mM (curves 1 and 2). Concentrations of acetate ions are 0.039 M for ①, and 0.168 M for ○.

$$CoOAc^{+} + MnHY^{-} \overset{k^{+}_{11s}}{\rightleftharpoons} CoHY^{-} + MnAOc^{+} \quad (5')$$

$$CoHY^{-} \rightleftharpoons CoY^{2-} + H^{+} \quad (6)$$

(iii) $$MnY^{2-} + H^{+} \rightleftharpoons HY^{3-} + \{Mn^{2+} \rightleftharpoons MnOAc^{+}\} \quad (7)$$

$$Co^{2+} + HY^{3-} \overset{k^{+}_{111h}}{\rightleftharpoons} CoY^{2-} + H^{+} \quad (8)$$

$$CoOAc^{+} + HY^{3-} \overset{k^{+}_{111s}}{\rightleftharpoons} CoY^{2-} + H^{+} + OAc^{-} \quad (8')$$

In the experimental treatment, it was assumed that the equilibria between hydrated ions and acetato complexes were maintained while the substitution reactions took place. From the same treatment in principle as in the previous papers,[1-3] Eq. (9) was obtained as the rate equation of reaction (1).

$$V^{+}_{0,app} = \frac{[Co^{2+}]_{0,app}[MnY^{2-}]_0}{1+\beta_{CoOAc}[OAc^-]}\left\{k^{+}_{1h} + k^{+}_{1s}[OAc^-] + (k^{+}_{2h} + k^{+}_{2s}[OAc^-])[H^+] + (k^{+}_{3h} + k^{+}_{3s}[OAc^-])\frac{1+\beta_{MnOAc}[OAc^-]}{[Mn^{2+}]_{0,app}}[H^+]\right\} \quad (9)$$

where: $k^{+}_{1s} = k^{+}_{1s}\beta_{CoOAc}$, $k^{+}_{2h} = k^{+}_{11h}K^{H}_{MnHY}$,
$k^{+}_{2s} = k^{+}_{11s}\beta_{CoOAc}K^{H}_{MnHY}$, $k^{+}_{3h} = k^{+}_{111h}/(K_{MnY}K_{HY})$,
$k^{+}_{3s} = k^{+}_{111s}\beta_{CoOAc}/(K_{MnY}K_{HY})$ (9')

β_{CoOAc} and β_{MnOAc} represent the overall formation constants of the acetatocobalt(II) and acetatomanganese(II) complexes respectively. K^{H}_{MnHY} represents the equiliblium constant of reaction (4), K_{MnY} the formation constant of MnY^{2-}, and K_{HY} the fourth dissociation constant of EDTA. In these equations, the changes in the initial concentrations during the measurements of the initial reaction rates were considered to be negligibly small under these experimental conditions.

The rate constants in Eq. (9) were obtained from an analysis of the plots in Fig. 1; they are given in Table 1.

TABLE 1. RATE CONSTANTS IN EQ. (9) OBTAINED AT IONIC STRENGTH 0.2 AT 25°C

	Rate constant	
k^{+}_{1A}	0.3	$l\,mol^{-1}sec^{-1}$
k^{+}_{1a}	1.3	$l^{2}\,mol^{-2}sec^{-1}$
k^{+}_{2A}	$\sim 6\times10^{4}$	$l^{2}\,mol^{-2}sec^{-1}$
k^{+}_{2a}	$\sim 7\times10^{4}$	$l^{3}\,mol^{-3}sec^{-1}$
k^{+}_{3A}	3.3×10^{3}	$l\,mol^{-1}sec^{-1}$
k^{+}_{3a}	1.1×10^{4}	$l^{2}\,mol^{-2}sec^{-1}$

The rate constants for reactions (3), (3′), (5), (5′), (8), and (8′) were calculated from the relations given in Eqs. (9′) and are given in Table 2. The values of β_{CoOAc},[6] β_{MnOAc},[6] K_{MnY},[7] K_{HY}[7] and K^{H}_{MnHY}[7] which have been used in the calculation

TABLE 2. RATE CONSTANTS FOR REACTIONS, (3), (3′), (5), (5′), (8) AND (8′) AT IONIC STRENGTH 0.2 AT 25°C

Rate constant, $l\,mol^{-1}sec^{-1}$

k^{+}_{IA}	k^{+}_{Ia}	k^{+}_{IIA}	k^{+}_{IIa}	k^{+}_{IIIA}	k^{+}_{IIIa}
0.3	1.1	—6—0	~60	1×10^{7}	3×10^{7}

are 1.2, 1.6, $10^{13.79}$, $10^{-10.22}$, and $10^{3.1}$ respectively.

The rate constants in Table 2 indicate that all the reactions proceeding through Co^{2+} (hydrated ions) are slower than the corresponding reactions proceeding through $CoOAc^{+}$ ions. Similar phenomena have been found in the complex-forming reactions of Ni(II)-NTA complexes[3] and Ni(II)-EDTA complexes,[4] and in substitution reactions between nickel(II) and copper(II)-EDTA complexes.[5] It is noteworthy that these phenomena are unlike those obtained in reactions involving copper(II) ions[1] and lead(II) ions.[2]

The author wishes to thank the Ministry of Education for the financial support granted for this research.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 407—411 (1969)

The Effect of Phthalate Ion and Acetate Ion on the Rate of the Reaction between Nickel(II) and Cobalt(II)-Nitrilotriacetate Complexes

Masaru KIMURA

Department of Applied Chemistry, Yamagata University, Yonezawa, Yamagata

(Received June 14, 1968)

A kinetic study of the substitution reactions of nickel(II) ions and cobalt(II)-nitrilotriacetate complexes in phthalate and in acetate buffer has been carried out using a procedure previously reported. The reaction was made to proceed through both hydrated nickel(II) ions and monophthalatonickel(II) complexes or monoacetatonickel(II) complexes. The rate constants for eight elementary reaction paths, four of which involve the hydrated nickel(II) ions, while the others involve the monophthalatonickel(II) complexes (the monoacetatonickel(II) complexes in the case of the measurements in acetate media), were determined at an ionic strength of 0.2 at 25°C. The values obtained indicate that all the reactions proceeding through the monophthalatonickel(II) complexes are slower than the corresponding reactions proceeding through hydrated nickel(II) ions; however, all the reactions proceeding through monoacetatonickel(II) complexes are faster than the corresponding reactions proceeding through hydrated nickel(II) ions. Thus, the kinetic reactivity is in the order of: $NiOAc^+ > Ni^{2+} > NiPh$, where Ph^{2-} indicates a bivalent phthalate anion.

A previous study[1] showed that monoacetatocobalt(II) ions react with ethylenediaminetetraacetate (EDTA) anions and Mn(II)-EDTA complexes faster than with hydrated cobalt(II) ion. This trend has been considered to be due to the characteristics of $CoOAc^+$, the value of the stability constant of which is rather small, and not to those of EDTA and cobalt(II); confirmation was sought in the present study. Since it seems to be important and necessary to extend the study to the investigation of the effect of various anions on the rates of the reactions, and to compare the corresponding reactions, the effect of the phthalate ion and of the acetate ion on the rate of the reaction between nickel(II) and cobalt(II)-nitrilotriacetate (NTA) complexes was examined in the present study.

Experimental

For potassium biphthalate, guaranteed reagents were used without further purification. All the other chemicals and solutions were prepared and standardized in ways described in a previous paper.[2] The method and the procedure employed in the present study were, in principle, the same as those described in previous papers.[1,2]

Results

Under the conditions of the present experiments, the formation of complexes with a metal-to-ligand ratio of 1 : 2 was considered to be negligible. Therefore, the overall substitution reactions between nickel(II) and cobalt(II)-NTA complexes are expressed by:

$$\left\{\begin{matrix} Ni^{2+} \\ \uparrow\downarrow \\ NiZ^{(2-z)+} \end{matrix}\right\} + CoX^- \overset{V^+_{0,app}}{\rightleftharpoons} NiX^- + \left\{\begin{matrix} Co^{2+} \\ \uparrow\downarrow \\ CoZ^{(2-z)+} \end{matrix}\right\} \quad (1)$$

where Z^{z-} indicates a bivalent phthalate anion (Ph^{2-}) or an acetate ion (OAc^-) and X^{3-}, a tervalent NTA anion.

The apparent concentrations of nickel(II) ions, $[Ni^{2+}]_{app}$ that can be determined polarographically are given by:

$$[Ni^{2+}]_{app} = [Ni^{2+}] + [NiZ^{(2-z)+}] \quad (2)$$

In a previous paper,[2] kinetic studies of the reactions between nickel(II) ions and Co(II)-, and Cu(II)-NTA complexes in acetate media were reported. On the basis of the same treatment as in previous studies,[1,2] the reactions of Eq. (1) may be considered to proceed through the following reaction paths:

$$\text{(i)} \quad Ni^{2+} + CoX^- \overset{k^+_{1h}}{\rightleftharpoons} NiX^- + Co^{2+} \quad (3)$$

$$NiZ^{(2-z)+} + CoX^- \overset{k^+_{1s}}{\rightleftharpoons} NiX^- + CoZ^{(2-z)+} \quad (3')$$

$$\text{(ii)} \quad CoX^- + H^+ \rightleftharpoons CoHX \quad (4)$$

1) M. Kimura, This Bulletin, **42**, 404 (1969).
2) N. Tanaka and M. Kimura, *ibid.*, **40**, 2100 (1967).

$$Ni^{2+} + CoHX \overset{k^{+}_{IIh}}{\rightleftharpoons} NiHX + Co^{2+} \quad (5)$$

$$NiZ^{(2-z)+} + CoHX \overset{k^{+}_{IIz}}{\rightleftharpoons} NiHX + CoZ^{(2-z)+} \quad (5')$$

$$NiHX \rightleftharpoons NiX^{-} + H^{+} \quad (6)$$

(iii) $$CoX^{-} \rightleftharpoons X^{3-} + \left\{ \begin{matrix} Co^{2+} \\ \uparrow\downarrow \\ CoZ^{(2-z)+} \end{matrix} \right\} \quad (7)$$

$$Ni^{2+} + X^{3-} \overset{k^{+}_{IIIh}}{\rightleftharpoons} NiX^{-} \quad (8)$$

$$NiZ^{(2-z)+} + X^{3-} \overset{k^{+}_{IIIz}}{\rightleftharpoons} NiX^{-} + Z^{z-} \quad (8')$$

(iv) $$CoX^{-} + H^{+} \rightleftharpoons HX^{2-} + \left\{ \begin{matrix} Co^{2+} \\ \uparrow\downarrow \\ CoZ^{(2-z)+} \end{matrix} \right\} \quad (9)$$

$$Ni^{2+} + HX^{2-} \overset{k^{+}_{IVh}}{\rightleftharpoons} NiHX \quad (10)$$

$$NiZ^{(2-z)+} + HX^{2-} \overset{k^{+}_{IVz}}{\rightleftharpoons} NiHX + Z^{z-} \quad (10')$$

On the basis of this reaction mechanisms, Eq. (11) is obtained from reaction (1):

$$V^{+}_{0,app} = \frac{[CoX^{-}]_0 [Ni^{2+}]_{0,app}}{1+\beta_{NiZ}[Z^{-z}]} \Big\{ k^{+}_{1h} + k^{+}_{1z}[Z^{z-}] + k^{+}_{2h}[H^{+}] + k^{+}_{2z}[Z^{z-}][H^{+}] + (k^{+}_{3h} + k^{+}_{3z}[Z^{z-}] + k^{+}_{4h}[H^{+}] + k^{+}_{4z}[Z^{z-}][H^{+}]) \frac{1+\beta_{CoZ}[Z^{z-}]}{[Co^{2+}]_{0,app}} \Big\} \quad (11)$$

where: $k^{+}_{1z} = k^{+}_{1z}\beta_{NiZ}$, $k^{+}_{2h} = k^{+}_{IIh}K^{H}_{CoHZ}$, $k^{+}_{2z} = k^{+}_{IIz}\beta_{NiZ}K^{H}_{CoHZ}$
$k^{+}_{3h} = k^{+}_{IIIh}/K_{CoX}$, $k^{+}_{3z} = k^{+}_{IIIz}\beta_{NiZ}/K_{CoX}$,
$k^{+}_{4h} = k^{+}_{IVh}/(K_{CoX}K_{HX})$, $k^{+}_{4z} = k^{+}_{IVz}\beta_{NiZ}/(K_{CoX}K_{HX})$ (11')

0.04	5.83	1.73	0.77*				

The apparent initial rates were measured under varied conditions. The results are given in Tables 1 and 2.

Equation (11) indicates that, if the values of $V^{+}_{0,app}/([CoX^{-}]_0[Ni^{2+}]_{0,app})$ are plotted against $1/[Co^{2+}]_{0,app}$ under conditions at which all quantities but $[Co^{2+}]_{0,app}$ are kept constant, a straight line should be obtained with a slope given by:

$$\frac{1+\beta_{CoZ}[Z^{z-}]}{1+\beta_{NiZ}[Z^{z-}]}\left\{k^{+}_{3h}+k^{+}_{3z}[Z^{z-}]+(k^{+}_{4h}+k^{+}_{4z}[Z^{z-}])[H^{+}]\right\} \quad (12)$$

The slopes obtained from the plots of $V^{+}_{0,app}/([CoX^{-}]_0[Ni_0{}^{2+}]_{0,app})$ *versus* $1/[Co^{2+}]_{0,app}$ were plotted against the hydrated ion concentration according to Eq. (12). These plots gave straight lines, as is shown in Fig. 1.

The rate constants in Eq. (11) were obtained by analyzing the plots of Fig. 1 and the data given in Table 1 and Table 2; they are given in Table 3.

The rate constants for reactions (3), (3′), (8), (8′), (10), and (10′) calculated from the relations given in Eq. (11′), are given in Table 4. The formation constants, K_{CoX}, β_{CoOAc}, β_{NiOAc}, β_{CoPh}, and β_{NiPh}, and the dissociation constant, K_{HX}, which were used in these calculations are given in Table 5.

The values of β_{NiOAc}[3] and β_{CoOAc}[4] were

4) H. Ogino, *ibid.*, (1965).

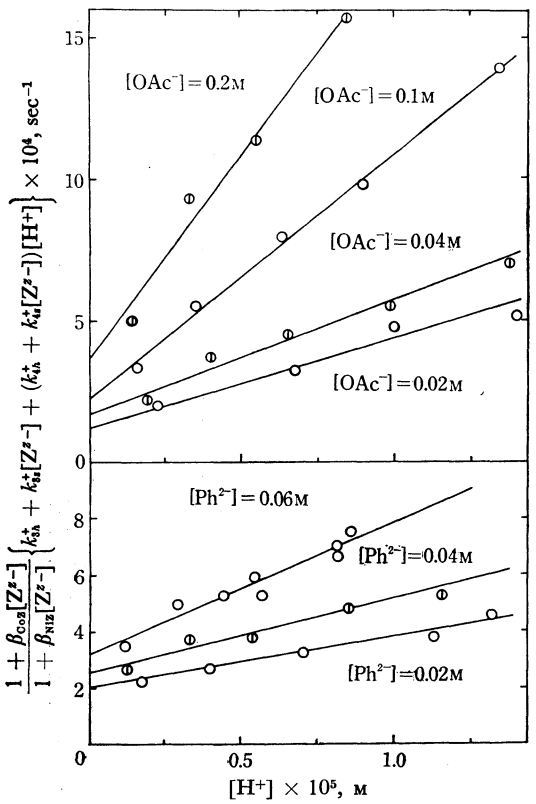

Fig. 1. Eq. (12) as a function of the hydrogen ion concentration.
The conditions are the same as in Tables 1 and 2.

determined by the polarographic method at an ionic strength of 0.2 at 25°C. The value of β_{NiPh} determined at an ionic strength of 0.1 at 25°C by Yasuda *et al.*[5] was used after correction for the ionic strength. The value of β_{CoPh} determined at an ionic strength of 0.4 at 18—25°C by Bobtelsky and Bar-Godda[6] was used without any correction. The thermodynamic constant of K_{HX} determined by Hughes and Martell[7] at 0, 10, 20, and 30°C was used after correction for the temperature and the ionic strength. The value of K_{CoX} determined at an ionic strength of 0.1 at 20°C by Schwarzenbach and Gut[8] was used after correction for the ionic strength.

Discussion

The values in Table 4 indicate that the kinetic reactivity of nickel is in the order of: $NiOAc^+ > Ni^{2+} > NiPh$. This may be compared with the results obtained in the case of the substitution reactions involving cobalt(II) ions,[1] copper(II) ions,[9] and lead (II) ions.[10] The ratios of the rate constant for the two reactions:

$$M^{2+} + L^{3-} \xrightarrow{k^L_M} ML^-$$

$$MZ^{(2-z)+} + L^{3-} \xrightarrow{k^L_{MZ}} ML^- + Z^{z-}$$

can now be discussed. Previous studies dy the present author showed that the comparison of

the rate constant is $k^{HY}_{Co} < k^{HY}_{CoOAc}$,[1] but that, on the contrary, $k^{X}_{Cu} > k^{X}_{CuOAc}$.[9] Recently, however, Tanaka and Ogino[10] reported on the kinetics of the substitution reaction between lead(II) and zinc(II)-EDTA complexes. Their results showed that the comparison of the rate constant is $k^{HY}_{Pb} > k^{HY}_{PbOAc}$.

Since it seems important and interesting to investigate the relations between the stability constant of $MZ^{(2-z)+}$ and the ratios of the rate constants, k^{L}_{M}/k^{L}_{MZ}, the plots of k^{L}_{M}/k^{L}_{MZ} against β_{MZ} are given in Fig. 2 together with the results obtained by other researchers.

Figure 2 indicates that the kinetic reactivity of the weak complexe, *i. e.*, $MZ^{(2-z)+}$, may be mainly due to the stability of the weak complex. Inner-sphere complexes, such as $MZ(H_2O)_{n-z}$, which may correspond with $CuOAc^+$, NiPh, and $PbOAc^+$ in Fig 2, seem to have less kinetic reactivity than the corresponding hydrated metal ions. However, outer-spher complexes, that is outer-spher ion-association complexes, such as $M(H_2O)_n^{2+}$–Z^{z-}, or outer-sphere hydrogen-bonding complexes, such as $M(H_2O)^{z+}_n O\langle^{H}_{H}\rangle Z^{z-}$, seem to have larger kinetic reactivities than the corresponding hydrated metal ions. Monoacetatonickel(II) and monoacetatocobalt(II) complexes may be considered to be outer-sphere complexes on the basis of their stability constants.

Stability Constants of Some Uranyl Complexes. II

S. RAMAMOORTHY and M. SANTAPPA

Department of Physical Chemistry, University of Madras, Madras-25, India

(Received April 10, 1968)

Stability constants of complexes of uranyl ion with various carboxylic acids were determined by the pH titration method at 31°C and $\mu=0.1$ ($NaClO_4$) in the pH range 2.5—3.5. The 1 : 1 and 1 : 2 complexes were formed with crotonic, pyruvic, malonic, and diglycolic acids and only the 1 : 1 complex with formic, propionic, succinic, adipic, maleic, fumaric acids. The effect of ring size and presence of oxygen atom as keto or ether oxygen or that of double bonds in the ligand acids on the stabilities of the corresponding complexes are discussed.

Recently Rajan and Martell[1] in a potentiometric study of chelates of uranyl perchlorate with carboxylic acids reported the stability constants of uranyl ion-maleate complexes (1 : 1 and 1 : 2), uranyl ion-succinate complex (1 : 1) and uranyl ion-maleate complex (1 : 1) in the pH range 2—4 at 25°C and $\mu=1$ M(KNO_3). As a part of our studies on the complexes of uranyl ion with various organic acids, systems of uranyl ion with formic, propionic, crotonic, pyruvic, malonic, succinic, adipic, maleic, fumaric and diglycolic acids were studied by the pH titration method at 31°C ±0.1°C and $\mu=0.1$ ($NaClO_4$) with a view to determine the

compositions and stability constants of the complexes in the pH range 1.5—3.5 in which hydrolysis of uranyl ion may completely be neglected[2] and the effect of ring size on stabilities of the complexes and coordinating tendencies of ligands containing oxygen atoms as keto or ether oxygen. The effects of various oxygen donor compounds on the stabilities of the metal chelates are compared with the chelating behaviour of compounds containing no additional coordinating group other than carboxylate group.

Experimental

Materials. Preparation of uranyl perchlorate as well as other reagents and their estimations have been given earlier.[3] Formic (M and B; AnalaR), propionic (B.D.H.; AnalaR), crotonic (Chem. pure; AnalaR), pyruvic (Ingelheim, Germany; pure), malonic (Fluka; purum), succinic (Riedel; pure), adipic (Fluka; purum), maleic (Riedel; pure), fumaric (Fluka; purum) and diglycolic (Fluka; purum) acids were used as such for ligands. These acids were standardized with sodium hydroxide solution (0.1 M).

Procedure. The details of apparatus and of experimental technique used to obtain the Bjerrum-Calvin titration curves and methods of calculation of dissociation constants of ligand acids, and stability constants of complexes by Irving and Rossotti's difference method[4] were outlined in our earlier paper.[3] Acid dissociation constants, pK, of monobasic acids were evaluated from the value of $-\log[H^+]$ at $\bar{n}_H=0.5$, utilising a value of 0.83 for the activity coefficient[5] of 0.1 N [H^+] (Table 1 and Fig. 1A) and K_1 and K_2 of dibasic acids were determined more conveniently by the method of slope and intercept due to Irving and Rossotti[6] (Table 2 and Fig. 2). Stability constants of the complexes, log K_{ML_1} and log K_{ML_2} evaluated from the values of pL ($-\log$ [Ligand]) at $\bar{n}$ (formation function)=0.5 and 1.5 respectively from the formation curves of the systems (Table 1 and Fig. 1B) were only approximate when they did not differ greatly in magnitude (<2.5 log units)[6]; exact values were determined by Eq. (1) according to Irving and Rossotti[6] (Table 3).

where K_{ML_1}, K_{ML_2},..., K_{ML_n} are successive stability constants, [L]=free ligand anion concentration, $\bar{n}=$

$$\frac{\bar{n}}{(\bar{n}-1)[L]} = K_{ML_1} + K_{ML_1}\cdot K_{ML_2}\cdot\frac{(2-\bar{n})[L]}{(1-\bar{n})} + \sum_{n=3}^{N} K_{ML_1}, K_{ML_2}\ldots\ldots K_{ML_n}\cdot\frac{(n-\bar{n})[L]^{n-1}}{(1-\bar{n})} \quad (1)$$

formation function of the system. The formation of only 1 : 1 complex was obvious from the plots of $\bar{n}/(1-\bar{n})[L]$) *versus* $((2-\bar{n}))[L]/(1-\bar{n})$ which was parallel to abscissa (Fig. 2) and in the plots of pL *versus* $\bar{n}$ (Fig. 1B) magnitude of the latter was less than unity, even when $[T_L]/[T_M]$ was 1 to 10, T_L and T_M being total

concentrations of the ligand and the uranyl ion respectively. In such cases, the log K_{ML_1}, calculated graphically from the $\bar{n}$ *versus* pL curves agreed very well with those calculated from Eq. (1). The formation of higher complexes was indicated by the value of $\bar{n}$ going beyond unity in some of the systems studied

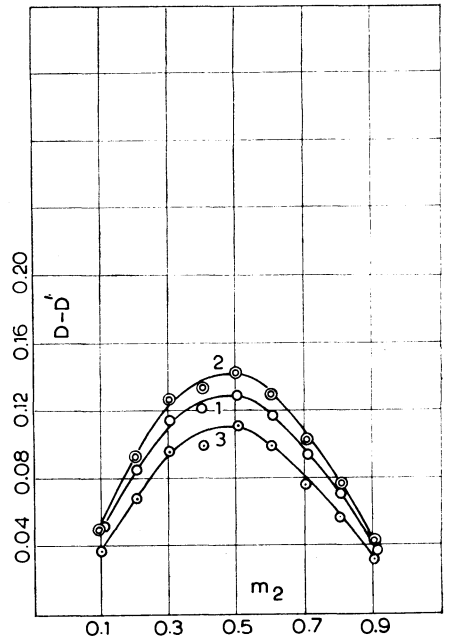

Fig. 3.

(uranyl ion-malonic, uranyl ion-pyruvic, uranyl ion-crotonic and uranyl ion-diglycolic acids) (Fig. 1B). In such cases, K_{ML_1} and K_{ML_2} were evaluated from Eq. (1) by the least squares treatment (Table 3). It may be mentioned that since the pH measurements and consequently log K_{ML} values are accurate to ±0.02 units, the log K_{ML_1} and log K_{ML_2} values from half integral values of pL will also be accurate[7] to −log 0.02 units even if log (K_1/K_2) is <2.5. The K_{ML} values reported (Table 2) are concentration (stoichiometric) stability constants as concentrations were used in place of activities. The data at values of pH> 3.5 were not used in the calculation of stability constants. Formation curves which were constructed from the values of pL and $\bar{n}_{calculated}$ using values of log K_{ML_1} and log K_{ML_2} obtained from Irving and Rossotti's equation (1) showed very slight deviations from the formation curves of pL *versus* $\bar{n}_{exp.}$ within the limits of experimental errors. For values of pH>3.5, $\bar{n}_{exp.}$ deviated greatly from $\bar{n}_{calc.}$ probably due to considerable hydrolysis of uranyl ion (Fig. 1B).

Results

The titration curves for (i) perchloric acid-

7) K. E. Jabalpurwala, K. A. Venkatachalam and M. B. Kabadi, *J. Inorg. Nucl. Chem.*, **26**, 1011, 1027 (1964).

sodium perchlorate, (ii) perchloric acid-ligand acid-sodium perchlorate and (iii) uranyl perchlorate - ligand acid - perchloric acid - sodium perchlorate systems against sodium hydroxide are presented for the uranyl ion - formic acid system in Fig. 1A. The $\bar{n}_H$, $\bar{n}$ and pL values are given in Table 1.

Discussion

Most of the data reported in the present paper were obtained for the first time, though reported data on the stability constants in the case of malonic, succinic and maleic acids were obtained under somewhat different experimental conditions of ionic strength (1 M KNO_3) and temperature (25°C). Results for systems of uranyl ion with itaconic, thiomalic, benzoic, phenylacetic and phenoxyacetic acids are taken from the previous paper[3] for comparison and discussion.

(a) Uranyl Ion-Simple Monocarboxylic Acids (Formic, Propionic, Benzoic and Phenylacetic Acids). Dissociation constants of ligand acids are listed in Table 2. The pK of the ligand acid increases in the order formic<benzoic< phenylacetic<propionic acids and K_{ML_1} increases in the order, formic=benzoic<phenylacetic>propionic acids (Table 2). It may be mentioned that $\bar{n}$ did not exceed unity even when $[T_L]/[T_M]$ was 1 to 10 in all the four systems. The formation of only 1 : 1 complex was also obvious from the plots of $\bar{n}/((1-\bar{n})\ [L])$ *versus* $((2-\bar{n})([L])/(1-\bar{n})$ which was parallel to the abscissae (Fig. 2). The stability constants calculated from $\bar{n}$ *versus* pL curve agreed very well with those calculated from Eq.(1). The substitution of H atom in formic acid by a phenyl group caused no change in the stability of the corresponding uranyl complex, while substitution by a benzyl group as well as an ethyl group increases the stability of the respective complexes. This kind of increase was not observed in the case of copper(II) complexes (formic, acetic and propionic acids)[8] and there the alkyl substitution caused no detectable effect on the values of stability constants of the complexes.

b) Uranyl Ion-Monocarboxylic Acid Containing -O- and -CO- linkages (Phenoxyacetic and Pyruvic Acids). From acid dissociation constants (Table 2), it is obvious that pK's of phenoxyacetic and pyruvic acids are very much lower than the corresponding acids, phenylacetic acid and acetic acid[9] (pK=4.64 at μ=0.2 (KCl) and T=20°C) (without -O- and -CO- groups). The stability constants were obtained from the plots of $\bar{n}$ *versus* pL as well as from $\bar{n}/(1=\bar{n})\ [L])$ versus $((2-\bar{n})\ [L])/(1-\bar{n})$ since the difference between log K_{ML_1} and log K_{ML_2} determined from half integral values was less than 2.5 log units. However the half integral values would be in error by -0.02 log units, when the difference in $\log(K_1/K_2)$ is 1.78. The system of uranyl ion-phenoxyacetic acid differed very much from the uranyl ion-pyruvic acid system in number of complexes formed as well as the stability range of the latter; for the former, the value of $\bar{n}$ did not exceed unity even with excess of ligand, [ligand]/[uranyl ion]=1 to 10, indicating the absence of formation of higher complexes, while for the latter, the value of $\bar{n}$ was as high as 0.7 at pH 1.80 and reached 2.0 at pH 3.00. The log K_{ML_1} value of the uranyl ion pyruvic acid system in consistent with the fact that pK of pyruvic acid is lower than that of phenoxyacetic acid. From the orders of stability constants (log K_{ML_1}) of the systems uranyl ion-pyruvic acid, uranyl ion-phenoxyacetic acid, uranyl ion-benzoic, uranyl ion-formic acid complexes etc., it is obvious that neither the phenoxy oxygen in phenoxy-acetic acid nor keto oxygen in pyruvic acid was involved in complexation. However, from the observation that precipitation in the system uranyl ion-pyruvic acid did not occur till pH 10.5, coupled with the fact that complexation was considerable even at low pH, it might be inferred that the keto oxygen stabilized the complex probably through coordination to the uranyl ion. The ether oxygen atom of phenoxyacetic acid has very little tendency for coordination with uranyl ion compared with carbonyl oxygen atom of keto group of pyruvic acid.

c) Uranyl Ion-Simple Dicarboxylic Acids (Malonic, Succinic and Adipic Acids). It may be seen that the difference between pK_1 and pK_2 of the ligand acids (Table 2) decreases as the number of carbon atoms separating the two COOH groups increases *i. e.* malonic→succinic→adipic acids. In other words, the basicity of the first COOH group increases in the same order. It is evident from the log K_{ML_1} values (Table 2) that, of the three ligands malonic acid forms the most stable chelate with uranyl ion with a six membered ring and the stability of the chelate ring decreases with the increase in ring size *i. e.*, from six→seven→ nine memered ring, from malonic→succinic→adipic acids. Though the basicity of the first carboxyl group increases from malonic acid to adipic acid as evident from the pK_1 values, the increasing ring size from malonic acid to adipic acid decreases the stabilities of the chelates in the same order (*i. e.* malonic acid→adipic acid). The formation of the 1 : 2 complex was favoured only in the uranyl ion-malonic acid system (six membered rings), but not in the uranyl ion-succinic acid or uranyl ion-adipic acid system. The difference between the authors' values and those of Rajan

8) S. Ramamoorthy and M. Santappa, *J. Inorg. Nucl. Chem.*, **30**, 2393 (1968).

9) R. K. Cannan and A. Kibrick, *J. Am. Chem. Soc.*, **60**, 2314 (1938).

and Martell (Table 2) may be due to the somewhat different experimental conditions; the latter were measured in 1 M KNO_3 and at 25°C, while authors' values were at 0.1 M $NaClO_4$ and at 31°C. The stability decrease in the series, uranyl ion-malonic acid→uranyl ion-succinic acid→uranyl ion-adipic acid, is consistent with the earlier observations with other metal ions.[10]

d) Uranyl Ion-Substituted Dicarboxylic Acids (Thiomalic and Itaconic Acids). From the results with succinic acid, it was obvious that the formation of the 1 : 2 complex was not indicated with thiomalic (mercapto succinic) and itaconic (methylene succinic) acids. Moreover, from comparison of stability order of thiomalic acid and malic acid complexes, and then itaconic acid and succinic acid complexes, it is believed that the chelate ring is stabilized by the presence of a double bond or by an SH group, and more so by the former.

e) Uranyl Ion-*cis* and *trans* Dicarboxylic Acids (Maleic and Fumaric Acids). The pK_1 and pK_2 values for maleic and fumaric acids (Table 2) calculated by the least squares treatment of Irving and Rossotti's equation indicate the obvious fact that the two COOH groups are well separated in maleic acid, while they are overlapping in fumaric acid. Both the ligands form only 1 : 1 complexes with uranyl ion. From the results (Table 2) of stability of the uranyl ion-maleic acid and uranyl ion-fumaric acid complexes, it was evident that maleic acid formed a seven membered chelate ring with uranyl ion through the two carboxyl groups, while fumaric acid being a trans isomer of maleic acid with two COOH groups separated farther away, formed only a complex (not a chelate) with uranyl ion through one COOH group only. The stability range of the uranyl ion-fumaric acid complex (log K_{ML_1}= 3.05) (*cf.* log K_{ML_1} of the uranyl ion-formic acid complex, 2.61) also supported this argument. If there were no chelate ring in the uranyl ion-maleic acid complex, the stability of the uranyl ion-maleate complex would have been lower than the uranyl ion-fumarate complex from considerations of different pK_1 values of these two ligand acids. On the other hand, the stability of the uranyl ion-maleate system is comparable to any seven-membered chelate ring structure such as the uranyl ion-succinic acid system.

f) Uranyl Ion-Diglycolic Acid System (Dicarboxylic Acid Containing–O–Linkage). The pK_1 and pK_2 values obtained from the slope and intercept method are given in Table 2. Successive formation of the 1 : 1 and 1 : 2 complexes of the uranyl ion-diglycolic acid system was evident from the fact that $\bar{n}$ value reached 1.5 at pH 3.50. It is very interesting that log K_{ML_1} (4.90) is very high for the chelate structure with the eight-membered ring involving two COO^- groups for coordination to metal (*cf.* log K_{ML_1} of the uranyl ion-adipic acid system=4.08 or the uranyl ion-glutaric acid system) and it is comparable to the stabilities of the chelates with five or six-membered rings (*cf.* log K_{ML_1} of the uranyl ion-malonic acid system=5.28). The most probable structure for the uranyl ion-diglycolic acid chelate, therefore, might involve two COO^- groups with additional stabilisation through the –O– group. In fact, Suzuki and Yamasaki[11] showed that diglycolic acid chelates were much more stable than the glutaric acid chelates (absence of –O– groups). The Job's method of continuous variations (Fig. 3) for the uranyl ion-diglycolic acid system gave a peak at m_2 (mole fraction of uranyl ion)=0.5, indicating the 1 : 1 complex. The formation of a higher complex (1 : 2) was shown by a slight shoulder at m_2=0.33. This observation indicated the absence of free carboxylate ion in the uranyl ion-diglycolic acid chelate. It is to be noted that in the copper(II)-malic acid system a 2 : 1 complex was formed as the second carboxylate group was free.[12] **g) Uranyl Ion-Unsaturated Carboxylic Acids; Crotonic Acid.** The values of pK and log K_{ML_1} and K_{ML_2} are listed in Tables 2 and 3. The higher stability of the uranyl ion-crotonic acid complex is due to the hig her basicity of the ligand (*cf.* log K_{ML_1}=2.61 for the uranyl ion-formic acid complex) due to the inductive effect of the methyl group as well as the presence of the double bond in the structure.

From the results, it may be concluded that basicities of the monodentate ligands have very little influence on the stabilities of the corresponding uranyl ion complexes. Steric factors and ring size presumably determine the metal chelate stabilities with bidentate ligands. In general, the uranyl-carboxylate chelates are more stable than the corresponding copper chelates conforming to the extended Irving-Williams order in which uranyl ion occupies a higher place over copper(II).[13]

(Received June 17, 1968)

In order to test the substituent effect or the effect of variations in chemical structures on the demagnetization and d–d band shift in dimeric copper(II) halide complexes with pyridine *N*-oxides and some related ligands, a variety of electron-donating or electron-withdrawing substituents attached in 2-, 3- and 4-positions in the pyridine ring of the ligand were extensively studied. In these dimeric complexes, no correlation was observed between the Hammett's σ constants and the observed d–d band positions or magnetic moments. However, irrespective of the nature of the substituents, a linear relation was observed to exist between the d–d band positions and the magnetic moments, indicative of a magnetochemical support for the interpretation of the spectrochemical series through the idea of symmetry-restricted covalency. For the monomeric complexes with the same ligands, a linear relation exists between Hammett's constants and the d–d band positions for each series of the electron-donating and electron-withdrawing substituents. Experimental results indicate that the most important factor determining the non-applicability of Hammett's Rule in these dimeric complexes is the steric condition of the metal ions which shields them from the influence of other molecules or ions. The larger demagnetization effect of the bromide ion compared to the chloride ion has been interpreted as due to its larger nephelauxetic effect. On the basis of the established structure of the parent compound, two pathways for superexchange interaction have been proposed. The importance of a σ type orbital overlap compared to the π type is discussed.

Recently a large number of copper(II) complexes have been reported which have subnormal magnetic moments at room temperature. Quagliano and his coworkers[1] noticed a low magnetic moment, 0.85 B.M., for the 1 : 1 complex of copper(II) chloride with pyridine *N*-oxide. Many studies have been undertaken on this compound and its homologues in order to elucidate the relations between the chemical structures or substituent effects on the demagnetization mechanism. The structure of the parent compound which has recently been determined by X-ray analysis,[2-5] is an excellent model to examine these correlations for the following reasons:

1) Since pyridine *N*-oxide is a monodentate ligand, its coordinate bond to the metal ion is not involved in any other metal ligand bond. This

eliminates the possible complexity in the demagnetization mechanism which may occur if a similar coordinate bond were part of a chelate ring.

2) The electronic effect of the substituents on the pyridine ring should transmit directly to the N-oxide oxygen atom which is an atom in the superexchange pathway, Cu–O–Cu.

3) Pyridine N-oxide is presently the only ligand which is monodentate and gives dimeric copper(II) complexes with a variety of substituents on the pyridine ring. As the experimental data for these pyridine N-oxide complexes have accumulated, it has become obvious that the relation between the magnetic properties of the complexes and the electronic nature of the substituents is much more complex than was anticipated earlier.

In order to clarify some of the causes which bring about a lack of correlation between the demagnetization or the d–d band positions and the electronic effects of the substituents, we have extended our previous studies.*[1,6] We have recently prepared a number of copper(II) halide complexes of pyridine N-oxides with a variety of electron-donating and electron-withdrawing substituents attached in 2-, 3- and 4-positions of pyridine ring. For purposes of comparison, some monomeric complexes of the type, $[Cu(X\text{-}PyO)_4](ClO_4)_2$, were also prepared and their spectral properties were characterized in connection with the Hammett's constants.

Experimental

Materials. Pyridine N-oxide, and 2-hydroxymethyl-, 3-hydroxymethyl-, 4-hydroxymethyl-, 4-methyl- and 4-nitro-pyridine N-oxides were obtained commercially. 3-Chloro-, 3-bromo-, 3-acetyl-, 4-acetyl-, 3-cyano-, 4-cyano-, 3-hydroxy-, 2-ethyl-, 3-ethyl- and 4-ethylpyridine N-oxides, and nicotinic acid-, ethylnicotinate-, ethylisonicotinate-, 2,4-lutidine-, quinoline-, 4-methylquinoline- and isoquinoline-N-oxides were prepared by oxidation of the corresponding pyridines by the method of Ochiai.[7] 4-Hydroxypyridine N-oxide was prepared by reaction of 4-nitropyridine N-oxide with dimethylaniline according to Ochiai's direction.[7] All these ligand materials were recrystallized from chloroform or benzene for use of the preparation of the copper(II) complexes.

The Preparation of the Copper(II) Complexes. *1 : 1 Complexes.* These complexes were prepared by heating the mixture of anhydrous copper(II) halide and the stoichiometric amount of ligand in ethanol on a hot plate for a short time. Purification was obtained by recrystallizing them from ethanol or N,N-dimethylformamide. Copper(II) chloride complexes with 2-hydroxymethylpyridine N-oxide, which crystallized as a yellowish green material from ethanol, exhibited a

normal magnetic moment, 1.88 B.M. at 11°C. The color of this compound gradually changed to yellow on standing in air for a week. The yellow compound was then transferred to a desiccator over silica gel for one month. After this period a very low magnetic moment, 0.37 B.M. at 19°C, was observed.*2

1 : 4 Complexes. These complexes were precipitated immediately from the ethanol solution of stoichiometric mixtures of copper(II) perchlorate hexahydrate and the ligands. They were purified by repeated washing with ethanol.

The preparation was repeated at least twice for each of the 1 : 1 and 1 : 4 complexes. The results of elementary analysis of the complexes are listed in Table 1.

Magnetic Susceptibility Determinations. These data were obtained by the Gouy method at room temperature. The effective magnetic moment, μ_{eff}, per copper atom was calculated from the expression $\mu_{eff} = 2.83\sqrt{\chi_M \cdot T}$ B.M. where χ_M is the molar susceptibility corrected using Pascal's constants[8] for the diamagnetism of the other atoms in the compounds. The magnetic moments observed at room temperature were corrected for minor room temperature variations to those at 25°C, $\mu_{eff}^{25°C}$, by using Bleaney and Bowers' equation[9] assuming $g=2.2$.[10] These results are presented in detail in Table 2.

Diffuse Reflectance Spectra. The diffuse reflectance spectra of some compounds were measured in 400—1200 mμ region on a Hitachi spectrophotometer of Model EPU-2A. Magnesium oxide was used as the standard of light reflectance and as the base material to dilute the compounds to obtain appropriate intensities in the reflected light. The spectra of other compounds were recorded in 340—1000 mμ region on a Hitachi spectrophotometer of Model EPS-3T without diluting the compounds with the base. The band maxima are recorded in Tables 3 and 4.

Results and Discussion

I. Nonapplicability of Hammett's Rule to Dimeric Complexes. The early studies of the effect of the ring substituent on the spin-spin coupling mechanism in the dimeric copper(II) halide complexes with pyridine *N*-oxides, the electronic natures of the substituents seemed to correlate well with the demagnetization.[6,11,12] However, the magnetic data of recently prepared complexes with a variety of substituents on the 3- and 4-positions in the pyridine ring revealed that no definite correlation exists between the electronic nature of the substituents in terms of Hammett's σ constants and the extent of the demagnetization or the d–d band positions.

Although some doubt had been thrown on the validity of the commonly used Hammett substituent constant,[13,14] Jaffé and coworkers[15] reported a linear relationship between the basicity

of a series of substituted pyridine *N*-oxides and the σ values.

Among the infrared active modes of substituted pyridine *N*-oxides,[16-18] Shindo[18] found that the N–O stretching frequencies of a variety of pyridine *N*-oxides derivatives correlate well with the Hammett's constant. Recently Kubota and Miyazaki[19] reported that a plot of the half-wave reduction potentials of substituted pyridine *N*-oxides against Hammett's σ constant gave a good linear relation.

II. Validity of Hammett's Rule in Monomeric Complexes. Recently, metal complexes with pyridine *N*-oxides were reported to confirm the correlation of physicochemical properties of the complexes with the electronic nature of the substituents.[6,11-12,20-27] The correlations were studied for complexes with substituents at the 4-position of the *N*-oxide molecules, where the electronic effect is transmitted to the *N*-oxide oxygen atom by a mesomeric mechanism. However, no test of correlations has been made for the copper(II) complexes with substituents attached in 3-position of the pyridine ring. In these studies furthermore the substituent constants used were σ in some cases and σ^+ or σ^- in others.[28] Hatfield and his coworkers[27] prepared the complexes of the type, $[Cu(X\text{-}PyO)_4](ClO_4)_2$, with X at 4-position in pyridine ring. They found that the d–d bands correlated with the σ^+ value of X.

We prepared the same type of complexes with X of electron-donating and electron-withdrawing nature at the 4- and 3-positions in pyridine ring. For these complexes, two linear relations between the d–d band positions, $\bar{\nu}_{max}$(kK), and Hammett's σ constant, were observed. One has a negative and the other a positive slope (*cf.* Fig. 1).[29] The line with the negative slope is for the compounds with substituents in the 3-position. This line further includes two more compounds, one with *p*-CH_3 and the other with H (standard). This linear relation in this case can be explained if it is assumed that the ligand field band positions are determined mainly by the electron density of the coordinating

oxygen atoms. Therefore as Hammett's σ constant decreases, these substituents produce larger electron densities on the oxygen atoms. This in turn leads to stronger ligand fields accompanied by higher wave numbers for the ligand field bands.

The line with the positive slope is for the compounds with 4-substituents of great electron-withdrawing power. This linear relation can be explained if it is assumed that back-bonding from the metal to the π-electron systems of ligand molecules[23,30-33] determines the band positions. The back-bonding is considered to take place through resonance structure B,[6] the weight of which should increase with the increase in the electron-withdrawing nature of the substituents.

The nonapplicability of Hammett's rule in the dimeric copper(II) halide complexes with pyridine *N*-oxides, could possibly indicate that no correlation between any physicochemical quantities exist. However, it was found that both for bromo and chloro complexes, a linear relation exists between the d–d band positions, $\tilde{\nu}_{max}$(kK), and the corrected magnetic moments, $\mu_{eff}^{25°C}$ (*cf.* Fig. 2). It would be more favorable to use J values, the separation energy between singlet and triplet state than $\mu_{eff}^{25°C}$. J values calculated from the observed magnetic moments assuming $g=2.2$, fitted a good linear relation with the d–d band positions ($\tilde{\nu}_{max}$ in kK). However, J values were not used in this paper because the J values calculated as above may be somewhat different from those determined from χ *versus* T curves. On the other hand, the values of $\mu_{eff}^{25°C}$ which were calculated from the χ values observed for the same compound at different temperatures, coincided well with each other within experimental errors.

This relation shows that greater demagnetization is accompanied with greater shift of d–d bands toward shorter wavelengths. This linear relationship between the ligand field bands and the magnetic moments can be cited as a magnetochemical support for the recent correlation of the spectrochemical series to the idea of symmetry-restricted covalency.[34-37] The spin-spin coupling mechanism should occur through the overlap of metal and ligand orbitals, giving a very symmetrically restricted covalency.

IV. Reasons for the Nonapplicability of Hammett's Rule in Dimeric Complexes. (*A*) *Steric Effects Previously Observed.* It was observed that, in many cases, irrespective of the polar effect of the substituents, the magnetic moments of complexes with 3-substituted ligands are smaller than those of the corresponding compounds with 4-substituted ligands. This observation seems to suggest a mechanism by which a greater magnetic interaction is produced between the copper(II) ions in a pair when a substituent is attached at a position closer to the central metal ion.

A similar trend was obtained in the study of the dimeric copper(II) complexes of the formula, $[Cu(\overset{2}{O}\cdot C_6H_4\cdot\overset{1}{C}H{=}N{-}R)Cl]_2$, where R is a mono- or di-substituted aryl group (*cf.* Fig. 3).[38,39]

Chatt and Shaw[40,41] described the metal complexes of the types, $[(PR'_3)_2NiRX]$ and $[(PR'_3)_2MR_2]$, where M=Ni, Co, Fe, and R=substituted aryl or

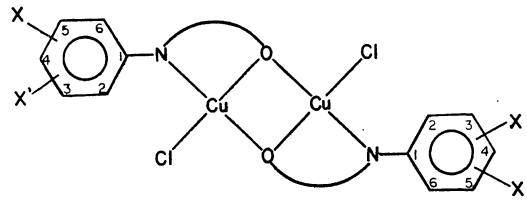

Fig. 3. X=H, Cl, CH_3 and NO_2

some other aromatic groups. They observed that the stability of these complexes has much increased when substituents were attached in the *ortho*-position of R. One of the causes for such additional stabilization of the *ortho*-substituted aryl complexes compared to the meta- or para-substituted aryl compounds, was attributed to the shielding effect of the metal atoms by the *ortho*-substituents.

Such shielding becomes most effective when the aryl group is rotated about the M–C bond such that its plane is perpendicular to that of the complex. Such perpendicular orientations of the aromatic ring with respect to the plane of the complex were observed in molecular models constructed for Chatt's complexes and those reported in this study. Such a stereochemical arrangement is postulated to play an important part in the stabilization of these complexes.

A stabilization of metal complexes by *ortho*-substituents was also observed by Yamada and Miki[42] in their mixed complexes of copper(II) with succinimide and picolines or lutidines.

(*B*) *Recent Results Indicative of Steric Effects.* In order to examine the contribution of the steric effect of substituents on the demagnetization or the d–d band shifts the effect of substituting methyl and ethyl groups in the 2-, 3- and 4-positions was first compared. The methyl group has a greater electron donating power than ethyl group at the 4-position. The Hammett's σ constants of these groups at this position are -0.170 and -0.151 respectively. In the 3-position, two σ values are proposed for ethyl group, -0.043 and -0.07.[43,44] The smaller value, -0.07, is nearly the same as that for the 3-methyl group, -0.069. The methyl group should therefore have almost the same or

a greater electron-donating power than ethyl group in the 3-position. Shindo and Kubota successfully correlated the Hammett's σ values with the N–O stretching frequencies[18] and the half-wave reduction potentials[19] of substituted pyridine *N*-oxides. They used the larger σ value, -0.043, for the 3-substituted ethyl group. The ethyl group which has less electron-donating power but a bulkier size produces a larger effect on the demagnetization or d–d band blue shift than the methyl group which has greater electron-donating power but smaller size. This indicates that the substituent effect in the dimeric copper(II) complexes is at least partly due to a steric factor. Furthermore, since the nature of the polar effect of alkyl groups is mainly inductive, the interpretation of the experimental results observed for the compounds with these substituents is less ambiguous than for those compounds where the substituents have both inductive and mesomeric properties.

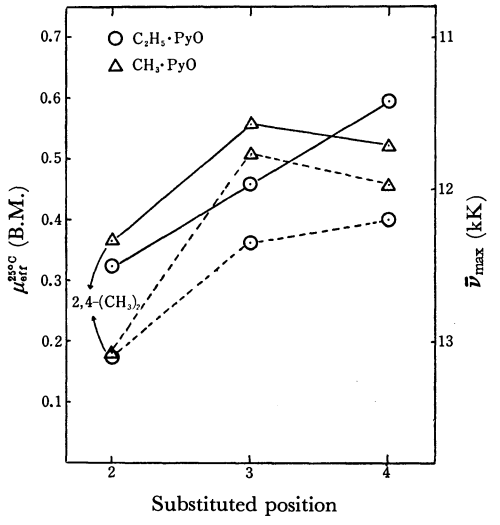

Fig. 4. Variations of magnetic moments ($\mu_{eff}^{25°C}$ in B.M.) and d–d band positions ($\bar{\nu}_{max}$ in kK) of copper(II) chloride complexes with methyl- and ethyl-pyridine *N*-oxides with substituted positions. Solid line is for magnetic moments and dashed line for d–d band positions. △ and ○ indicate complexes with methyl- and ethyl-pyridine *N*-oxides respectively.

The experimental results for chloro complexes are graphically given in Fig. 4. In the 4-position, the methyl group has a greater effect on the demagnetization and the d–d band blue shift than the ethyl group. This is as expected on the basis of the polar effect of substituents in terms of Hammett's constant. The steric effect of the ethyl group which should be larger because of its larger size still however seems not to be operative.

At the 3-position, the magnetic moment of the methyl compound increases to 0.55 B.M. from 0.52 B.M. of the 4-methyl compound as expected from the Hammett's σ values of this substituent. This indicates that, at this position, the steric effect of methyl group can not be observed.

However, at the same position, the magnetic moment value of the 3-ethyl compound decreases from that of the 4-ethyl compound, indicating a larger demagnetization in the 3-substituted compound. The demagnetization of 3-ethyl compound is larger compared to those of 4-methyl and 3-methyl compounds. These observations definitely indicate that the ethyl group in these complexes exerts a steric effect at 3-position. It is remarkable that of substituents with large size, they produce a larger demagnetization, even in the 4-position, than in the parent complex with pyridine *N*-oxide even when their electronic nature is electron-withdrawing in both inductive and mesomeric effects as is the case for $COOC_2H_5$, CH_3CO, *etc.* This seems to indicate stronger metal-ligand bonds in these complexes. Such strengthening of the metal-ligand bonds may occur through back-bonding, metal to ligand, which was observed in the monomeric compounds with pyridine *N*-oxides having the same electron-withdrawing substituents (*cf.* sect. II). However, the established structure of the parent complex is hardly suitable for such back-bonding mechanism (*cf.* sect. VII).

For substitution at 2-position, 2,4-dimethyl compounds were studied instead of the 2-methyl compounds because of the synthetic difficulty of preparing the pure 2-methyl compounds.[45-47]

The magnetic moment of this compound is much smaller than that of the 3-compound as well as that of the 4-compound. It is obvious that the methyl group in the 2-position has a large steric effect on the demagnetization phenomenon.

The magnetic moment of the 2-ethyl compound, 0.32 B.M., is even smaller than that of 2,4-dimethyl-compound, 0.37 B.M. The demagnetization effect of the 4-methyl group in the chloride complexes is estimated to be about 0.2 B.M. in a range from 0.5 to 0.7 B.M., the difference between the values of the 4-methyl and that of the parent complexes. These data indicate that in these dimeric complexes the 2-ethyl group because of its greater steric effect exerts a much greater demagnetization effect than the 2-methyl group.

Molecular framework models were built according to the established structures of the parent complex.[4,5] They indicate that when ethyl groups are attached in the 2-position of the pyridine rings which are almost perpendicular to the copper oxygen plane

they are located above or below the plane shielding the fifth and the sixth coordination site (*cf.* Fig. 9).

In accordance with the linear relation between the d–d bands and the magnetic moments, the d–d band positions of the methyl and ethyl compounds vary in the same way as the magnetic moments, as the substitution positions are changed. In contrast to the smooth variation in magnetic moments with substituted positions, the blue shift of d–d bands is much greater between 2- and 3-positions than between 3- and 4-positions, indicating that the ligand fields of 2-alkyl compounds are much greater than those of 3- and 4-alkyl compounds. This becomes apparent in the reflectance spectra of copper(II) chlorides with ethylpyridine *N*-oxides (*cf.* Fig. 5). Such discrepancy between the extents of the variations in magnetic moments and d–d band positions should be improved if the energy differences between singlet and triplet states were used instead of the magnetic moments.

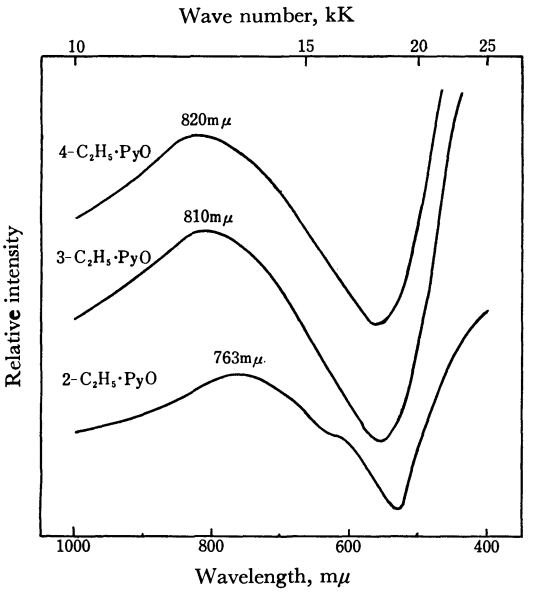

Fig. 5. Reflectance spectra of (ethylpyridine *N*-oxide)-copper(II) chloride.

The variations in spectral and magnetic properties of bromo complexes with changes in substitution positions are essentially the same as those observed for the chloro complexes. However, some interesting differences exist between bromo and chloro complexes in the relative magnitudes of the magnetic moments and the d–d band positions: 1. The magnetic moments of the 4-ethyl bromo complex is smaller than that of the 4-methyl bromo complex. 2. The slope of the line for the variations of magnetic moments with substitution positions is smaller for bromo complexes than for chloro complexes.

(*C*) *Interpretation of Steric Effect.* Yamada and Miki[48] reported that the d–d band of bis(*N*,*N*-diethylethylenediamine)copper(II) perchlorate appears at a much shorter wavelength than expected from its position in the spectrochemical series. They attributed this to the special steric condition of the ligand, which will make it more difficult for other ligands or molecules to approach the fifth and sixth coordination sites of copper(II) ion. It is well known that the quadri-coordinate, planar type of copper(II) complexes display the ligand field bands at much shorter wavelengths than those of sexa-coordinate or pseudo-sexa-coordinate copper(II) complexes. The very large value of the tetragonality ratio $R(\gamma_{Cu}/\gamma_{N_i})$ for this compound was pointed out by Jørgensen.[49,50] It is very probable that on the basis of Pauling's electroneutrality principle[51] the increase in the tetragonality of the complex with *N*-alkylethylenediamine compared to that of the parent ethylenediamine complex produces an increase in the strength of the coordinate bonds in the CuN_4 plane. If bonds to the fifth and sixth coordination position perpendicular to the CuN_4 plane which are present to some extent in the parent ethylenediamine complex, are broken or much weakened, extra electron migration from the ligands to the metal should occur through the bonds in the CuN_4 plane. According to the electroneutrality principle, any rearrangement of electron migration must keep the total electron flow-in as constant as possible.

This can also be described in terms of electron affinity. When the longer bonds perpendicular to the CuN_4 plane present in the parent compound are broken or weakened for some reason, the electron affinity of the metal should be increased. Such an increase in electron affinity of the metal, in turn, increases the strength of the four bonds in the plane.

In dimeric copper(II) halide complexes with pyridine *N*-oxides, the increased tetragonality of the complex due to the steric effect of the substituent, will produce stronger metal-ligand bonds, through which the super-exchange mechanism operates. This steric effect may provide a direct way for the determination of the variation of coordinate bond strength caused by changes in the stereochemistry of complexes. This steric factor which weakens the influence of other ions or mole-

cules on the fifth or sixth coordination position does not seem to be the only cause bringing about an increase in metal-ligand bond strength or the d–d band blue shift in copper(II) halide pyridine *N*-oxide complexes. The other factor seems to be due to the partial tetrahedral stereochemistry of these complexes which may call for less orbital overlap between metal and ligand. However, as the tetragonality increases with various substitutions on the pyridine ring, the tetrahedral nature decreases.

The combination of these two effects – the steric effect and the electronic effects of the substituents on the pyridine ring – are the prime factor which determines the nonapplicability of Hammett's rule to the magnetic and spectral properties of these dimeric copper(II) halide pyridine *N*-oxide complexes. The enhancement of stability of planar nickel(II) complexes by steric conditions compared to the octahedral ones have also been discussed recently.[52]

V. Further Experiments Indicative of the Steric Effect. (*A*) *Complexes with Quinoline N-Oxide.* In order to examine the steric effect in complexes with ligands other than pyridine *N*-oxides, copper(II) halide complexes with quinoline *N*-oxide, 4-methylquinoline *N*-oxide and isoquinoline *N*-oxide were prepared. The magnetic moments of the complexes with quinoline *N*-oxide, a ligand corresponding 2,3-disubstituted pyridine *N*-oxide, are smaller than those of the complexes with isoquinoline *N*-oxide, a ligand corresponding 3,4-disubstituted pyridine *N*-oxide. The behavior of the d–d band shift of these complexes followed the changes in the magnetic moments, as is demonstrated for bromo complexes in Fig. 6. On the other hand, however, the magnetic and spectral properties of 4-methylquinoline *N*-oxide complexes are not those expected from both steric and electronic considerations. Even though 4-methylquinoline *N*-oxide has a greater steric factor and greater electron-donating power than quinoline *N*-oxide, its complexes show smaller demagnetization and d–d band positions at larger wavelengths than those of quinoline *N*-oxide. Hatfield and coworkers[53,54] encountered the same situation in their study of methyl quinoline complexes.

One possible explanation for this may be that steric factors other than those mentioned above are encountered. A methyl group attached to a ligand of large size probably interferes with the smooth packing in the crystal compared to that of the complex of the parent ligand molecule. Such strains would also produce strains in the chemical bonding of the complex.

(*B*) *Complexes with Hydroxymethylpyridine N-Oxides.* If the group substituted on the pyridine ring also has some coordinating ability, the substituent effect might be opposed by the coordination effect. Under such conditions very little change in physical properties might be observed as the substitution positions on the ring are changed.

This was indeed observed for the complexes with hydroxymethylpyridine N-oxide. Figure 7 shows a plot of the data for the chloro complexes. The slopes of the two lines are not as steep as those for the corresponding methyl and ethyl compounds in Fig. 4 indicating that the two effects have at least partially cancelled each other. In Fig. 8 the spectral curves for these complexes are given.

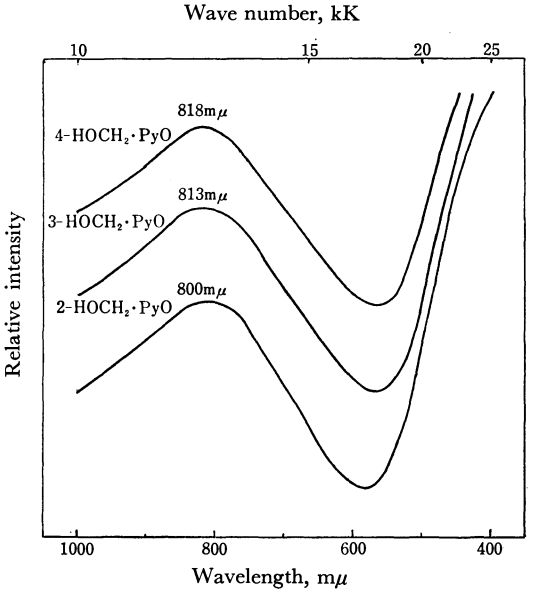

Fig. 8. Reflectance spectra of (hydroxymethylpyridine N-oxide)-copper(II) chlorides.

VI. Influence of Halogen Ions on d-d Band and Magnetic Moment. The influence of halide ions on the d–d band positions and the demagnetization in the chloro and bromo complexes is not what would be expected from the positions of these ions in spectrochemical series.

In almost all cases, the magnetic moments of bromo complexes are smaller than those of the corresponding chloro complexes.*[1f,12] Hatfield and coworkers[12] suggested that this phenomenon may be due to the difference in spin-orbit coupling and temperature independent paramagnetism between the chloro and bromo complexes. In a previous paper,*[1f] we suggested that the difference in nephelauxetic effects[34-37] of the chloride and bromide ions produces such differences in magnetic moments. The greater cloud expanding effect of the bromide ions will produce a greater overlapping of the relevant orbitals of the metal ions and the ligand molecules. This would give a greater covalency in their bonds and should give smaller magnetic moments for the bromo complexes.

Recently, Figgis and Nyholm summarized the contributions of the temperature independent paramagnetism and the spin-orbit coupling in metal complexes.[55,56] With a few exceptions, the d–d bands of bromo complexes with pyridine N-oxides appear at shorter wavelengths than those of the corresponding chloro complexes. The ligand fields of these bromo complexes are larger than those of the corresponding chloro complexes, suggesting smaller contribution, to spin-orbit coupling. The X-ray determinations of crystal structures of Cs_2CuCl_4 and Cs_2CuBr_4[57,58] revealed that these complexes contain flattened tetrahedral configurations with greater flattening for the bromocuprate ion in spite of its larger ionic size and its earlier position in the spectrochemical series.

Recent studies of copper(II) chloride and bromide complexes with aromatic amines revealed that, in some cases, their d–d bands appear where expected from the positions of these ions in the spectrochemical series whereas in others, the band positions appear in the reverse order.[59-63] Uhlig and Staiger[64] reported copper(II) chloride and bromide complexes of aminoalcohols with dimeric structures whose d–d band positions appear from compound to compound in the two different orders in the spectrochemical series as above. An explanation for such anomalous behavior of bromide and chloride ions in the order of spectrochemical series may be found in the recent concept of softness and hardness of metal ions and ligands.[65,66] However, at present, the physical basis of this concept is still somewhat ambiguous which makes a thorough discussion of this phenomenon difficult.[67,68]

Ito[69] investigated the anomalous phenomenon that ligands in copper(II) complexes are often out of order in the spectrochemical series. He[70] successfully classified, in conformity with the sense of the series, these ligands into three groups according to the stereochemistry of the complexes; planar-, octahedral- and the intermediate-type. Unfortunately, halide ions were not included in his classification. His classification also does not include the steric shielding effect discussed in this paper.

Since the copper(II) ion has one unpaired electron in any of these stereochemistries, a continuous variation from one stereochemistry to another seems to be possible.[71] Under such conditions, the large size of the bromide ion could display a steric shielding effect different from that of the smaller chloride ion. The cooperation of both factors, large size and cloud expanding, could produce the observed large effect of the bromide ion on the demagnetization and the d–d band blue shift.

It is interesting to note that a plot of the differences of the d–d band positions of the bromide and the chloride complexes with the same ligands, $\bar{\nu}_{max}$ (bromide) $-\bar{\nu}_{max}$ (chloride), against $\bar{\nu}_{max}$ (chloride) decreases from a large value for the 4-nitro compounds to a small value(approximately zero) for the complexes with the largest $\bar{\nu}_{max}$ values. The same type of convergency was observed for the differences in the magnetic moments of chloride and bromide complexes.

VII. Superexchange Pathways. The extent of the spin-spin coupling in dimeric copper(II) complexes varies significantly with the type of structure. Complexes of one structural type may reveal a considerable amount of demagnetization while others of a different structural type display little demagnetization. A part of this demagnetization is attributed to direct metal-metal exchange interaction. The magnetic moments of cupric acetate monohydrate, acetylacetone-mono-(*o*-hydroxyanil)copper(II), and (pyridine *N*-oxide)copper(II) chloride are 1.43 B.M., 1.37 B.M. and 0.77 B.M. at room temperature respectively[72] whereas the metal-metal distances in the established structures are 2.64 Å, 2.99 Å and 3.25 Å respectively. This fact seems to indicate that the observed demagnetization for copper(II) halide complexes with pyridine *N*-oxides is mainly produced by a superexchange mechanism involving bridging oxygen atoms. It is rather surprising that these pyridine *N*-oxide complexes reveal very low magnetic moments despite the fact that they contain rather weak metal-ligand bondings through which a superexchange mechansim must operate. One of the factors which enhances the electron exchange must be the magnitude of orbital-overlap between the related atoms or ions existing in the superexchange pathway.

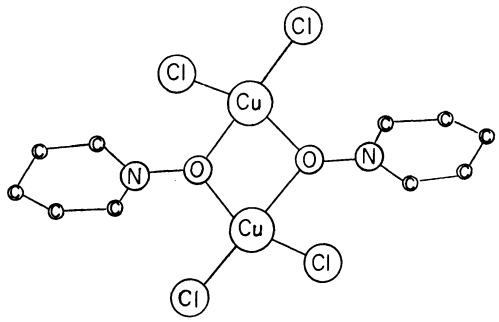

Fig. 9. Structure of (pyridine *N*-oxide)-copper(II) chloride.

On the basis of the known structure of the parent compound (*cf.* Fig. 9),[4,5] we suggest the following two pathways as the most likely ones in dimeric copper(II) halide complexes with pyridine *N*-oxides; one is a σ type- and the other a π type pathway (*cf.* Figs. 10a, 10b and 10c). Figure 10a

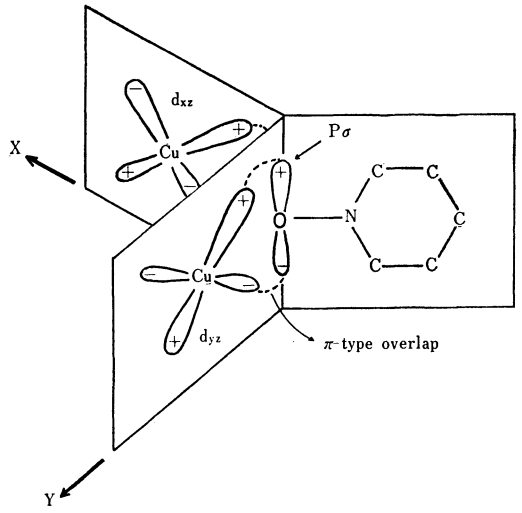

Fig. 10c. Electron exchange pathway of π-type.

provides a representation of the ligand orbitals necessary for describing electron exchange. Orbital-overlap schemes for electron exchange pathways of a σ-type and a π-type are given in Fig. 10b and 10c, respectively. For simplicity, the orbital-overlap schemes in these figures are drawn in idealized form. The actual mode of the orbital-overlapping may differ, in details, from this. The bond angles and other structural parameters should vary somewhat with the nature of the attached substituents or with the packing conditions of the individual molecules. In the structure of the parent complex,[4,5] determined by X-ray analysis, the plane of pyridine ring becomes nearly perpendicular to the Cu$\langle^{O}_{O}\rangle$Cu plane by rotation about the N–O bond, giving an angle of 70 degrees between these two planes. However, the figures were drawn for the two planes falling at essentially 90 degrees. This angle should vary somewhat from complex to complex.

Another orbital overlap of the σ type should also be examined for electron migration (second type). This is set up with the $3d_{x^2-y^2}$ or $3d_{z^2}$ orbitals of copper and an s orbital of oxygen. This orbital overlap has the characteristic of being rather insensitive to the bond angles.[73-75]

The sigma framework of complex molecules is often discussed in terms of localized bonds among hybrid atomic orbitals. This basis is intentionally avoided in Fig. 10 because it obscures the overlap patterns determining the geometric criteria for superexchange.

Of these two pathways the σ type is considered more effective for electron migration for the following reasons: 1. The orbital overlap in a σ type pathway is expected to be greater than those of a π type pathway. 2. Dubicki and Martin[76] suggested that, in copper(II) acetate or in the related compounds, the exchange between metal atoms in a molecule becomes operative *via* the bridging π system by mixing of metal d_{xy} and $d_{x^2-y^2}$ orbitals through spin-orbit coupling.[77] This can be applied to the electronic system of the complexes discussed here. Spin-orbit coupling may be decreased with an increase of the ligand field strength. However, the experimental evidence shows that greater ligand fields produce greater demagnetizations, suggesting that in these complexes the π pathway is less important. 3. The linear relation between the magnetic moments and d–d band positions is taken as evidence of greater importance of a σ pathway compared to a π pathway. Since in these complexes the strength of a σ type bond is believed to be the main factor determining the d–d band positions, it is very probable that the apparent parallelism between magnetic moments and d–d band positions, indicates that spin-spin coupling takes place primarily through the σ bonds. 4. The comparison of (pyridine *N*-oxide)-copper(II) chloride and acetylacetone-mono-(*o*-hydroxyanil)copper(II) whose structures have been determined by X-ray analysis is very useful in the examination of the relative importance of the factors controlling the exchange phenomenon for the following reasons: On the basis of its pK values, a phenolic oxygen produces a much stronger σ type bond than pyridine *N*-oxide's oxygen atom.[6,78] Nevertheless, the *N*-oxide complex and its related compounds display much larger demagnetization than the anil copper(II) complex and its related compounds.[72] This indicates that the most important factor in determining the electron exchange is the bond angles rather than the bond strengths in a pathway, though the latter should be the main factor when complexes with the same bond angles are compared. The importance of bond angles implies that the exchange mechanism operates *via* a σ type of orbital overlap rather than a π type. If electron migration takes place through a π type of orbital overlap, the demagnetization should not be sensitive to variations in bond angles. For a σ type of orbital overlap to be most effective, the bond angles, C–O–Cu_1 and C–O–Cu_2 in Fig. 11a or N–O–Cu_1 and N–O–Cu_2 in Fig. 11b, should be the same. The observed bond

angles of the *N*-oxide complex, 127° and 123°,[4,5] are nearly equal. On the other hand, the bond angles of the anil copper(II) differ quite a bit (130° and 111°).[79,80] However, the difference in bond angles in the latter is still not great enough to prevent completely the utilization of a σ type of orbital overlap for electron migration.

The effectiveness of a π pathway and the aforementioned second type of σ pathway for electron migration may be approximately equal in both complexes. It is of interest that among the anil copper(II) and its related complexes, salicylal-*o*-hydroxybenzylamine copper(II) has an extraordinary small magnetic moment, 0.87 B.M.[3,79,81-85] Nearly all tri-coordinated units of these complexes are composed of one *five* and one *six* membered rings. Only the hydroxybenzylamine copper(II) contains two six membered rings in the unit. Molecular framework models indicate that the condition of the equality of the C–O–Cu_1 and C–O–Cu_2 bond angles necessary for an effective σ pathway is best satisfied in this complex (*cf.* Fig. 12). Recent studies of *N*-*n*-propanolsalicylaldiminato-copper(II) and its related complexes[10,86,87] have shown that these complexes all have very low magnetic moments, *ca.* 0.5 B.M. They have tricoordinate units of six-membered rings. Molecular models again indicate only that the condition of similar size bond angle in these complexes is satisfied.

From this, it may be concluded that the large demagnetization observed in copper(II) halide complexes with pyridine *N*-oxides is caused by the availability of the σ type of pathway for electron migration, and the comparatively small amount of demagnetization in acetylacetone-mono-(*o*-hydroxyanil)copper(II) and its related compounds is attributable to the decreased efficiency for utilization of the σ pathway.

Two interesting features can be deduced from the orbital overlap schemes in Fig. 10: 1. The mesomeric effect of substituents attached to pyridine ring is transmitted to a p_π orbital through the π electron system of ligand molecule. In this way, the mesomeric effect of substituents becomes associated with the demagnetization mechanism. The inductive effect of substituents will be transmitted to s or p orbitals of oxygen atom by field effect, π inductive effect, or other effects.[88] 2. In this idealized picture, back-bonding through d_{xz} or d_{yz} orbitals of metal atom is not necessary since the p_σ orbital on the oxygen atom which overlaps these d orbitals is not in conjugation with the π electron system of the pyridine ring. This may be different from the situation to be found in the monomeric copper(II) perchlorate complexes with pyridine *N*-oxides in section II.

The relative effectiveness of direct metal-metal interaction and superexchange interaction in demagnetization should vary with the type of compounds.[2,5,6,12,54,72,79,80,85,89,90] For the latter interaction, the relative importance of the σ and π pathways is a problem for research and, it is expected to vary depending upon the structure of the compounds. It is a surprising fact that the magnetic moments of a great number of copper(II) alkanoates and benzoate fall at about 1.4 B.M.[72,76,91,92]

Molecular orbital calculations suggested by Cusachs, Kato and Jonassen[73] have been carried out for a model complex:[93] Copper(II) formate in the copper acetate cage structure. Although the direct Cu–Cu orbital overlap integrals are entirely insignificant, the two highest, singly occupied, molecular orbitals are of the sigma type with respect to the planes containing the copper and neighboring oxygen atoms, and dominate the computed orbital-orbital coupling terms. The orbital energies of these two molecular orbitals differ by only about 0.3 eV, so it is to be expected that there would be extensive configuration interaction, much as in the case of the ground state of H_2 at large internuclear distances. Coupling was calculated for the asymptotic limit of complete configuration interaction, or localization of a single electron in each half of the molecule, and found to vanish. It may be argued that these one-electron model calculations oversimplify the electron interaction terms quite severely, but no other method is currently available for such large molecules that does not do violence to some of the more important one- and two-electron contributions. These calculations do clearly support the present interpretation of the demagnetization mechanism as proceeding by coupling through the extended *sigma* framework of the molecule.

Progress in the study of spin-spin coupling mechanism in dimeric copper(II) complexes will require more examples of X-ray structural determination along with ESR and NMR experiments.[76]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 432—436 (1969)

Studies of Actinium(III) in Various Solutions. II. Distribution Behavior of Lanthanum(III) and Actinium(III) in Some Chelate Extraction Systems

Tatsuya SEKINE, Yasuaki KOIKE and Yuko HASEGAWA

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received June 20, 1968)

Distribution behavior of lanthanum(III) and actinium(III) at tracer concentrations was studied in metal chelate extraction systems where the organic phase was chloroform containing dibutylphosphate, thenoyltrifluoroacetone (TTA), β-isopropyltropolone or 5,7-dichloroxine. The separation factors for this pair of ions by extraction with these four chelating ligands were determined. The distribution behavior was also studied in the adduct chelate extraction systems where the organic phase was carbon tetrachloride containing mixed ligands, TTA-tributylphosphate (TBP) or TTA-methyl isobutyl ketone (MIBK). The adduct formation constants for actinium(III)-tris-TTA chelate with these neutral ligands were determined. Results were compared with previous results on the distribution behavior of other trivalent actinide and lanthanide ions in these systems. It was concluded that the separation of lanthanum-actinium was somewhat different from the separation of europium-americium in the same chelate extraction systems. The stabilities of the first adducts with TBP or MIBK of actinium TTA chelate were smaller than those of americium TTA chelate, but the stabilities of the second adducts showed just the reverse order. This tendency in adduct formation is the same as that observed among the lanthanum and europium adduct TTA chelates in previous work. Finally, the use of TTA-TBP mixture was recommended for the extraction of lanthanum(III) or actinium(III) at tracer concentrations based on the fact that the use of these mixed ligands resulted in much better recovery of material and better reproducibility of results than a single chelating ligand.

Little is known about the solvent extraction behavior of actinium except for the early studies of Hagemann,[1] who prepared actinium-227 using a TTA (thenoyltrifluoroacetone) extraction method, and of Peppard, Mason, Gray and Mech,[2] who studied the extraction of this element with TBP (tributylphosphate).

In the present paper, the authors measured the liquid-liquid distribution behavior of actinium(III) and lanthanum(III) in some metal chelate extraction systems in which Sekine and Dyrssen[3,4] previously studied the solvent extraction of europium(III) and americium(III). It was further intended to compare the liquid-liquid distribution behavior of the trivalent lanthanides and actinides.

Experimental

Tracer. Actinium-228 tracer was prepared by the method described in Part I of this series[5] just before use. Lanthanum-140 tracer was prepared from barium-140 by a method similar to actinium-228 as follows: A carrier-free barium-140 solution was stored a few days and adjusted to pH 5—6 using acetate buffer. The lanthanum-140 produced in the solution was extracted with 0.1 M TTA in chloroform. The organic layer was once washed with a fresh buffer solution at pH 5—6 and then the lanthanum-140 was back-extracted by shaking the organic layer with 0.1 M perchloric acid. The aqueous layer thus obtained was then washed with chloroform and used as a stock solution of this isotope.

Reagents. A mixture of DBP (dibutylphosphate) and monobutylphosphate was obtained from Tokyo Kasei Co. DBP was separated and purified by a solvent extraction method.[6] TTA was obtained from Dojindo & Co., IPT (β-isopropyltropolone) from Takasago Perfumery Co. and 5,7-dichloroxine from Tokyo Kasei Co. These chelating reagents were used without further purification. TBP and MIBK (methyl isobutyl ketone) were obtained from Tokyo Kasei Co. They were washed with 0.1 M perchloric acid, water and 0.1 M sodium hydroxide, in that order, and then

several times with water. Chloroform was washed three times with water. Other reagents were of an analytical grade.

Procedures. All procedures were carried out in a thermostatted room at 25±0.5°C. Lanthanum(III) carrier (initial concentration in the aqueous phase, 5×10^{-5} M) was added to the aqueous phase except for the TBP adduct experiments when the TBP concentration was low. A small amount of sulfanilate, acetate or carbonate (initial concentration in the aqueous phase, 0.01 M) was added to the aqueous phase when a buffer was necessary. It was confirmed that no change in extraction was caused by these buffers at this concentration. A 5 m*l* portion of the aqueous phase and a 5 m*l* portion of the organic phase were placed in tubes with glass stoppers (volume 20 m*l*) and agitated mechanically for 30 min and centrifuged. A 2 m*l* portion was pipetted from each phase and transferred to small glass test tubes and the γ-radioactivity measured with a well-type (NaI) scintillation counter. A small portion was also taken from the aqueous phase and the hydrogen ion concentration measured potentiometrically using a standard solution containing 0.0100 M perchloric acid and 0.09 M or 0.99 M sodium perchlorate as the standard of $-\log[H^+]$ 2.00 in 0.1 M or 1 M perchlorate media. When the hydrogen ion concentration exceeded 0.01 M, it was determined by a titration method.

The net distribution ratio of the trivalent metal ions M^{3+} was defined and determined as follows;

$$D = [M(III)]_{org,\ total}/[M(III)]_{total} = \frac{\gamma\text{-count-rate per ml org. phase}}{\gamma\text{-count-rate per ml aq. phase}}$$

Results

A) Extraction of Metal Chelates. In the extraction of metal chelates, the aqueous phase was kept at 0.1 M perchlorate. The organic phase was chloroform containing 0.1 M DBP, TTA or IPT, or chloroform containing 0.05 M 5,7-dichloroxine.

Assuming that extraction takes place by the following reaction (HA denotes the chelating acid),

$$M^{3+} + (3+n)HA(org) \rightleftarrows MA_3(HA)_n(org) + 3H^+ \quad (1)$$

$$D = \sum[MA_3(HA)_n]_{org}/[M^{3+}] \quad (2)$$

an equilibrium constant for the extraction may be defined if the chelate concentration is kept constant as

$$K = D[H^+]^3 \quad (3)$$

However, when the chelate concentration is not constant, a more involved equation[7] should be used.*1 In the present study, the chelate concentration was kept constant in each series of experiments, and thus Eq. (3) could be used.

Table 1 summarizes the separation of lanthanum(III) and actinium(III) by chelate extraction into chloroform. This table also summarizes previously reported data on the separation of europium(III) and americium(III).[3] The constants $D[H^+]^3$ were calculated from data obtained from the range of the distribution ratio $10>D>0.1$, because the values $D[H^+]^3$ for all the chelate extraction systems were approximately constant only in this range.

In the hydrogen ion concentration region where the distribution ratio is greater than 10, some decrease in the slope of the extraction curve from +3 was observed in the IPT system. This discrepancy was assumed due to aqueous chelate formation.[9] When the distribution ratio is less than 0.1, some decrease in the slope from +3 was also observed in actinium(III) chelate extraction systems, but no explanation can be given for this deviation.

The slope log$D$ *vs.* $-\log[H^+]$ plot for the 5,7-dichloroxine system was found to be +3 at least when $-\log[H^+]$ was below 7. This indicates that the hydrolysis of these ions is not very important

Table 1. Separation of La^{3+} and Ac^{3+} in 0.1M (Na, H)ClO_4 at 25°C by solvent extraction with some chelating acids in chloroform together with previous data on that of Eu^{3+} and Am^{3+} under the similar conditions[3]

Reagent (HA)	$[HA]_{org}$	log $SF_{La^{3+}-Ac^{3+}}$	log $SF_{Eu^{3+}-Am^{3+}}$	log $D_{La^{3+}}[H^+]^3$	log $D_{Ac^{3+}}[H^+]^3$	log $SF_{Eu^{3+}-La^{3+}}$	log $SF_{Am^{3+}-Ac^{3+}}$
Dibutylhydrogen-phosphate (DBP)	0.1M	+0.64	+1.36	−4.92	−5.56	+2.01	+1.29
2-Thenoyltrifluoro-acetone (TTA)	0.1M	+1.84	+0.48	−14.06	−15.90	+2.38	+3.70

if the hydrogen ion concentration is kept above 10^{-7} M.[10,11]

B) Extraction of Adduct Metal Chelates. The adduct formation of actinium(III)-tris-TTA chelate with TBP or MIBK was studied in carbon tetrachloride. In these experiments, the aqueous phase was adjusted to 1 M (H, Na)ClO_4 in order to compare results with the previous data.[4]

As a statistical treatment of adduct chelate formation in a solvent extraction system has been already given in a previous paper,[12] only a brief description will be given here. When metal tris-TTA chelate MA_3 forms adduct chelate complexes with an organophilic neutral ligand L, the reaction and formation constants may be described by

$$MA_3(org) + nL(org) \rightleftarrows MA_3L_n(org) \quad (4)$$

$$\beta_n = [MA_3L_n]_{org}/[MA_3]_{org}[L]^n_{org} \quad (5)$$

When these adduct chelates are formed in the organic phase and M^{3+} is the only metal species in the aqueous phase, the net distribution ratio may be generally written.

$$D = \frac{[MA_3]_{org} + [MA_3L]_{org} + [MA_3L_2]_{org} + \cdots}{[M^{3+}]} \quad (6)$$

When the net distribution ratio of the metal chelate extraction in the absence of the adduct forming ligand can be described as $D_0 = [MA_3]_{org}/[M^{3+}]$, the following equation is obtained from Eqs. (5) and (6) if the chelating ligand and hydrogen ion concentrations are kept constant;

$$D/D_0 = 1 + \beta_1[L]_{org} + \beta_2[L]^2_{org} + \cdots \quad (7)$$

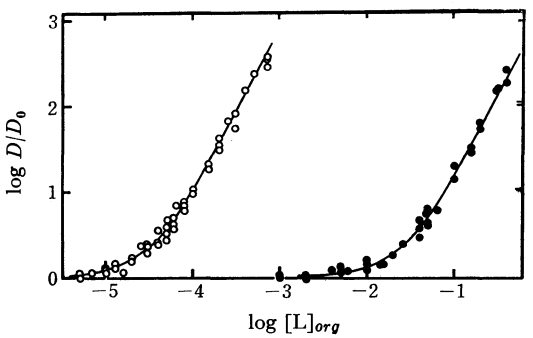

Fig. 1. The increase in the TTA extraction of actinium(III) by the adduct fromation shown as a function of the concentration of the adduct forming ligand.
Organic phase: Carbon tetrachloride containing 0.1 M TTA and TBP (open circles) or MIBK (closed circles).
Aqueous phase: 1M $NaClO_4$.
The solid curves were drawn as follows.
TBP: $Y = \log(1 + 10^{4.2}[L]_{org} + 10^{8.9}[L]^2_{org})$
MIBK: $Y = \log(1 + 10^{1.3}[L]_{org} + 10^{3.1}[L]^2_{org})$

Figure 1 shows the $\log D/D_0$ *vs.* $\log[L]_{org}$ plot of actinium(III)-tris-TTA chelate in carbon tetrachloride when the neutral ligand was TBP or MIBK.

The formation constants were determined in the same manner as described in Ref. 12 and are given in Table 2 together with the formation constants of lanthanum(III), europium(III), lutetium(III) and americium(III) tris-TTA chelates under the same experimental conditions as in Ref. 7. The solid curves in Fig. 1 are calculated from the formation constants given in Table 2.

It was found that the results on the extraction of carrier-free lanthanum(III) and actinium(III) were not very reproducible. The addition of non-radioactive lanthanum(III) (initial concentration in the aqueous phase, 5×10^{-5} M) improved the reproducibility very much, especially that of actinium extraction. The extraction of carrier-free actinium(III), however, was very reproducible when a mixture of TTA and TBP in carbon tetrachloride was employed as extractants instead of a single chelating agent.

12) T. Sekine and M. Ono, This Bulletin, **38**, 2087 (1965).

Discussion

The results are summarized as follows;

A) The extraction of actinium(III) with the four chelating reagents was always inferior to that of lanthanum(III). The separation of lanthanum(III) from actinium(III) using TTA, IPT or 5,7-dichloroxine was better than that of europium(III) from americium(III) with the same reagent, but the difference in extraction of lanthanum(III) and actinium(III) using DBP was inferior to that of europium(III) and americium(III). In a previous study,[3] americium(III) was extracted with 5,7-dichloroxine ten times better than europium(III), but the separation of actinium(III) from lanthanum(III) with this reagent, on the other hand, showed just the reverse tendency; lanthanum(III) extracted fifty times better than actinium(III).

B) In a previous work,[4] it was pointed out that the stability of the first adducts MA_3L was greater in the increasing order of extractability of the tris-TTA metal complexes $LaA_3L < EuA_3L < LuA_3L$, but the stability of the second complexes MA_3L_2 was greater in the reverse order $LaA_3L_2 > EuA_3L_2 > LuA_3L_2$. A similar tendency of stability was also observed in TBP adducts of actinide TTA chelates; the formation constants of the first adducts of actinium TTA chelate were smaller than those of americium TTA chelate. On the other hand, the stepwise formation constants K_2 of actinium adducts were larger than those of americium adducts.

The similarity in chemical properties of lanthanides and actinides has been explained in terms of their electronic configurations; the 4f orbitals (lanthanides) or 5f orbitals (actinides) are filled successively by electrons with increase in atomic number. In the case of lanthanum and actinium, however, a contribution from the 4f and 5f electrons to their chemical properties is not expected, and thus the chemical properties of these pairs of elements could be different to some extent.

Separation of two metal ions by a metal chelate extraction method is influenced by many factors. The separation factor (*SF* in Table 1) is defined,

$$SF = \frac{D_{La^{3+}}[H^+]^3}{D_{Ac^{3+}}[H^+]^3} \quad \text{(when } [HA]_{org} \text{ is the same)}$$

this equation can be altered as follows (*cf.* also Ref. 13).

The distribution ratio in a metal chelate extraction system can generally be written,

$$D = \frac{[MA_3]_{org} + [MA_3(HA)]_{org} + \cdots + [MA_3(HA)_n]_{org}}{[M^{3+}] + [MA^{2+}] + [MA_2^+] + [MA_3] + \cdots + [MA_n^{3-n}]} \quad (8)$$

13) T. Wakahayashi *et al.*, *J. Inorg. Nucl. Chem.*, **26**, 2255, 2265 (1964); **27**, 1141 (1965).

Let us discuss the case where only the MA_3 species is extracted into the organic phase for simplicity (a general discussion will also be possible). When we define the stability constants of metal chelates produced in the aqueous phase and the distribution constant of the non-charged metal chelate as follows,

$$\beta_n = \frac{[MA_n^{3-n}]}{[M^{3+}][A^-]^n} \quad (9)$$

$$K_{DM} = \frac{[MA_3]_{org}}{[MA_3]} \quad (10)$$

the distribution ratio can be described as

$$D = \frac{K_{DM}\beta_3[A^-]^3}{1 + \beta_1[A^-] + \beta_2[A^-]^2 + \beta_3[A^-]^3 + \cdots + \beta_n[A^-]^n} \quad (11)$$

The separation factor of two metal ions (denoted M_a and M_b) can be written from Eq. (11) as (the subscripts "*a*" and "*b*" denote the constants for M_a and M_b);

$$\frac{Da}{Db} = \frac{K_{DMa}\beta_{3a}}{K_{DMb}\beta_{3b}} \times \frac{1 + \beta_{1b}[A^-] + \beta_{2b}[A^-]^2 + \beta_{3b}[A^-]^3 + \cdots}{1 + \beta_{1a}[A^-] + \beta_{2a}[A^-]^2 + \beta_{3a}[A^-]^3 + \cdots} \quad (12)$$

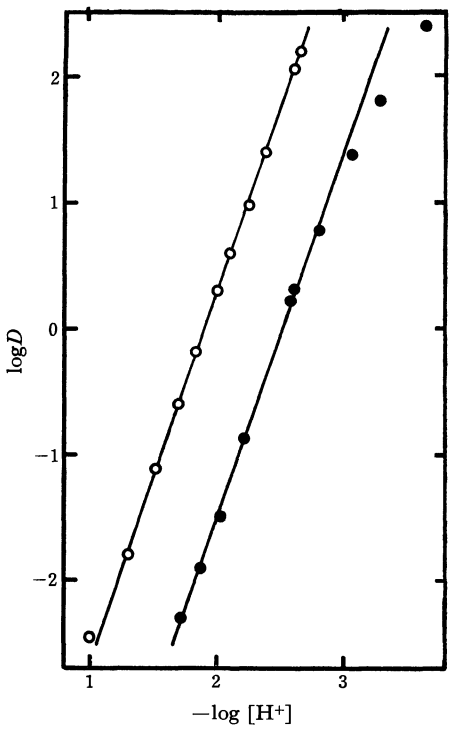

Fig. 2. Extraction of lanthanum(III) (open circles) and actinium(III) (closed circles) with mixed solvents as a function of the hydrogen ion concentration.
Organic phase: carbon tetrachloride containing 0.2 M TTA and 0.2 M TBP.
Aqueous phase: 1 M aqueous sodium perchlorate.

We see from Eq. (12) that the separation factor will not be constant over all hydrogen ion concentrations, but in the region where no aqueous chelate complexes are formed (where the slope of the plot log$D$ *vs.* $-\log[H^+]$ is $+3$), the separation factor can be written

$$SF = \frac{Da}{Db} = \frac{K_{DMa}\beta_{3a}}{K_{DMb}\beta_{3b}} \qquad (13)$$

Equation (13) shows that the separation of these two metal ions is concerned only with the stability and the extractability of the third chelate complexes.

No previous information on these factors for lanthanide and actinide chelate seems to have been reported. Further discussion on the separation of lanthanides and actinides by metal chelate extraction would be possible if we could obtain the K_{DM} and β_3 values of the chelates.

In Ref. 4, the general tendency of the stability of the adduct metal chelates was explained in terms of the residual coordination power of metal ions which is decreased if they form more stable complexes with the chelating ligands. This tendency is again found in the present results. The extractability of actinium(III) with TTA is smaller than that of lanthanum(III) or americium(III). This fact indicates a smaller β_3 value for actinium(III) than for the others.*2 Thus we may expect a larger residual coordination power in actinium tris-TTA chelate than in the other which causes the actinium tris-TTA chelates to form less stable first adducts and more stable second adducts.

As described, the extraction of carrier-free lanthanum or actinium in liquid-liquid systems containing only a chelating acid is not reproducible. When it is necessary to treat these ions at tracer concentrations, we recommend the use of mixed extractant systems. The extraction of carrie-free actinium was conveniently carried out with the use of TTA-TBP mixtures. Figure 2 shows the log$D$ *vs.* $-\log[H^+]$ plot of these ions when the organic phase was carbon tetrachloride containing 0.2 M TTA and 0.2 M TBP. In this system, the separation factor is 1.80 and the recovery of the materials almost quantitative. The reproducibility of the experimental results was excellent.

*2 As no information on the magnitude of K_{DM} values is available, we can not discuss the stabilities of these tris-TTA chelate, β_3, except from the extraction constants as seen from Eq. (13). However, it would not be unreasonable to assume that the separation factor is concerned more with β_3 than with K_{DM}, or the organophilic tendencies of the metal chelates would resemble each other because the metal ions in the chelate complex molecules are surrounded by three common organophilic molecules.

Chemical Effects Associated with β-Decay Process. III. The Chemical Behavior of ^{144}Pr Decayed from ^{144}Ce(III)-EDTA Complexes in the Solid Phase

Takanobu SHIOKAWA, Hiroshi KUDO*1 and Takashi OMORI

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received June 22, 1968)

The chemical behavior of ^{144}Pr formed by the β^--decay of ^{144}Ce in crystals of ^{144}Ce(III)-EDTA complexes has been investigated by means of ion-exchange techniques. The initial yield of $^{144}Pr^{3+}$ ion, which reflects the distribution of the ^{144}Pr atoms in the crystal, is independent of the dissolving condition, but is affected by the amount of hydration in the crystal. Abnormal behavior of ^{144}Pr atom has not been found in the ammonium salt. These results suggest that in the solid phase $^{144}Pr^{3+}$ or its precursor may be produced as a result of multiple charging of the daughter following electron shake-off and internal conversion of γ-rays.

A number of studies have been carried out on the chemical consequences of molecules resulting from the β^--decay of a constituent atom. The chemical behavior of the radioactive daughter atom depends on its recoil energy, charge and and electronic excitation resulting from the change in nuclear charge. Therefore, a change in oxidation

*1 Present address: Japan Atomic Energy Research Institute, Tokai, Ibaraki.

state of the radioactive daughter atom has become of interest. Cerium-praseodymium-144 possesses several advantages in its nuclear and chemical properties for a study of the chemical behavior of the radioactive daughter atoms formed by β^--decay. Several authors[1-4] reported the chemical behavior of ^{144}Pr in this system previously.

In an earlier paper,[2] the present authors investigated the chemical behavior of ^{144}Pr formed by β^--decay of the ^{144}Ce labeled cerium(III)-ethylenediaminetetraacetate (^{144}Ce(III)-EDTA) complex in the liquid phase. The results suggested that an increase in the nuclear charge of ^{144}Pr plays the most important role in the process of β^--decay of ^{144}Ce(III)-EDTA complex, and leads to the disruption of the complex molecule *via* intramolecular electron-transfer. The kinetic study[3] indicated the existence of an intermediate, produced as a result of β^--decay.

The present investigation was undertaken in the solid phase to obtain further information on the chemical behavior of ^{144}Pr formed by β^--decay of ^{144}Ce(III)-EDTA complex.

Experimental

Chemicals. Reagents used are as reported previously.[2]

The sodium salt of ^{144}Ce(III)-EDTA complex (Na-$^{144}CeY \cdot mH_2O$) was synthesized by the reaction of cerium(III) nitrate and the disodium salt of EDTA (Na_2H_2Y) in aqueous solution at pH 6.5. The solution was concentrated by evaporation and placed in an ice bath. The resulting crystalline product was recrystallized from a 90 per cent ethanol solution. In the process of recrystallization, the carrier-free ^{144}Ce was added. The ammonium salt of ^{144}Ce(III)-EDTA complex (NH_4-$^{144}CeY \cdot 5H_2O$) was prepared in a similar way, except that the ammonium salt of EDTA was used instead of the sodium salt.

The solid chelates were analyzed for Ce^{3+} and Y^{4-}, and then the hydration number of the crystal calculated by difference.[5]

Apparatus and Procedures. The solid complex, allowed to stand for more than three hours at 0°C, was dissolved in a 0.4 M sodium acetate buffer solution. The ionic strength was adjusted to 0.5 with sodium chloride. The final concentration of the complex ion was 1×10^{-3} M. The solution was placed in a bath at the desired temperature. To separate the free-ion, an aliquot of the solution was withdrawn through a Dowex 50W-X8 column (8 mm$\phi \times$10 mm, 50—100 mesh). The resin used had been treated with a proper buffer solution before use. All procedures were performed at 0 ± 0.5°C.

The yield of the free-ion fraction was obtained by counting the γ-activities of both the resin phase and the combined effluents, as described previously.[2] The pH of the solutioh was measured with a glass-electrode pH meter to an accuracy of ± 0.01.

Results

It was found that the yields of $^{144}Pr^{3+}$ ion, which represent the extent of molecular disruption due to β^--decay of ^{144}Ce(III)-EDTA complex increase or decrease with time after dissolution. As an example, Fig. 1 shows an increase in the apparent yield of $^{144}Pr^{3+}$ ion up to the plateau value in a neutral solution. It should be noticed that the cerium is also adsorbed to some extent on the resin under this condition. Since the adsorbability of the cerium(III) ion is independent of the lapse of time after dissolution, it is ascribed to the transfer of the EDTA complex to the cationic fraction on separation. Thus, the net yield of $^{144}Pr^{3+}$ ion formed by β^--decay of ^{144}Ce(III)-EDTA complex could be obtained by subtraction of the normal distribution from the apparent yield. Figure 2 shows the net yield curves for $^{144}Pr^{3+}$ ion at various pH values.

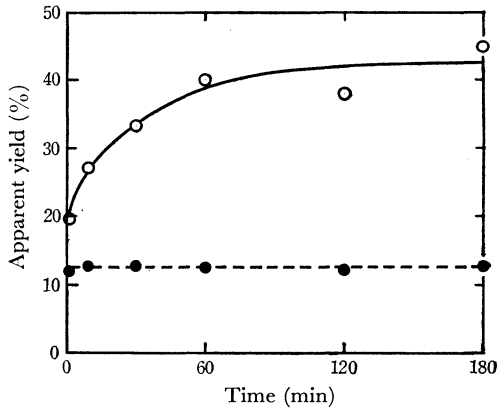

Fig. 1. Apparent yield of $^{144}Pr^{3+}$ and $^{144}Ce^{3+}$ in Na-$^{144}CeY \cdot 7H_2O$ dissolving at pH 7.08.
○: $^{144}Pr^{3+}$; ●: $^{144}Ce^{3+}$

The plateau yield of $^{144}Pr^{3+}$ ion increases in the neutral regions, pH 6.5, whereas it decreases in low pH regions. The distribution of the plateau yields of $^{144}Pr^{3+}$ ion as a function of pH is shown in Fig. 3.

The initial yield of $^{144}Pr^{3+}$ ion, which is defined as the yield just after dissolution of the crystal, could be obtained by extrapolation of the yield of $^{144}Pr^{3+}$ ion to zero time. The initial yield of $^{144}Pr^{3+}$ ion for a given crystal is quite independent

of the dissolving condition of the aqueous solution, while it is significantly affected by the hydration number of the crystal. The results are summarized in Table 1.

TABLE 1. INITIAL YIELD OF $^{144}Pr^{3+}$ ION RESULTING FROM β^--DECAY OF ^{144}Ce IN THE CRYSTAL OF EDTA COMPLEXES

Crystal	Initial yield (%)
$Na^{144}CeY \cdot 4H_2O$	3.9±0.4
$NH_4{}^{144}CeY \cdot 5H_2O$	4.7±0.4
$Na^{144}CeY \cdot 6H_2O$	5.4±0.4
$Na^{144}CeY \cdot 7H_2O$	6.0±0.4
$Na^{144}CeY \cdot 12H_2O$	9.1±0.3

Discussion

The general aspect of the distribution curve of the plateau yields of $^{144}Pr^{3+}$ ion as seen in Fig. 3 is similar to that observed in the liquid system.[3] Thus, the plateau yield of $^{144}Pr^{3+}$ ion could be explained by application of the mechanism proposed previously[2,3]; that is, tetrapositive ^{144}Pr produced as a result of simple β^--decay of ^{144}Ce(III)-EDTA complex would be reduced to a tripositive state by intramolecular electron-transfer. The tripositive praseodymium still forms an intermediate complex with an oxidation product of EDTA, but is liberated by proton attack as the free-ion form.

In a given crystal, however, the initial yields obtained under different dissolving conditions are essentially constant, as shown in Fig. 2. From Table 1, one can also see that the initial yield of $^{144}Pr^{3+}$ ion increases with hydration number of the crystal. These results strongly suggest the existence of a chemical species other than the intermediate in the solid state; *viz.*, $^{144}Pr^{3+}$ ion or a precursor, which transforms to $^{144}Pr^{3+}$ ion just after dissolution. In the solid phase, the intermediate is thought to be rather stable, and its contribution to the initial yield of $^{144}Pr^{3+}$ ion would be of minor importance. A possible alternative explanation could be that the initial molecular ion, ^{144}Pr(IV)-EDTA, can exist in the crystal, or that it can be stabilized to ^{144}Pr(III)-EDTA complex by intermolecular electron-transfer.

As pointed out above, the daughter atom formed by β^--decay will have a positive charge of one unit higher than the parent atom, and tetravalent ^{144}Pr may cause the disruption of EDTA complex *via* an intermediate. On the other hand, further ionization resulting from electron shake-off will take place, so that the daughter atom will have a positive charge greater than +5. In addition, multiple charging of ^{144}Pr will take place in consequence of the internal conversion of γ-rays. The yield is estimated to be 13% from the internal conversion coefficient.[6]

In comparison with theoretical estimates, relatively small values for the initial yields predict that all multiply charged species do not transform to the free praseodymium ion or its precursor. However, it should be noticed that in the solid phase the chemical effect associated with the β^--decay of ^{144}Ce is mainly attributed to the multiple

7) J. L. Hoard, E. Willstandter and J. V. Silverton, *J. Am. Chem. Soc.*, **87**, 1611 (1965).

8) For example, R. E. Cleary, W. H. Hamill and R. R. Williams, *J. Am. Chem. Soc.*, **74**, 4675 (1952); K. J. McCallum and A. G. Maddock, *Trans. Faraday Soc.*, **49**, 1150 (1953); G. Harbottle, *J. Chem. Phys.*, **22**, 1083 (1954).

charging of the daughter atoms following electron shake-off and Auger processes, so long as it is discussed in terms of the initial yield of $^{144}Pr^{3+}$ ion.

In order to understand the fate of the ^{144}Pr atom in the solid phase, it is very important to investigate the effect of the hydration number of the solid complex on initial yield. On the basis of a structural investigation of rare earth-EDTA complexes,[7] it seems reasonable to estimate that the structural formula of the sodium salt of ^{144}Ce-(III)-EDTA complex is $NaCeY(O_2H)_4 \cdot mH_2O$. Since the hydration numbers of the solid complexes used in this experiment varied from four to twelve, the complexes have fundamentally identical structures, being different in outer-sphere hydration. Accordingly, a linear increase in initial yields with hydration numbers of the EDTA complexes would suggest that water molecules in the outer-sphere affect either the decomposition of the EDTA complex resulting from the highly charged ^{144}Pr ion or the stabilization reaction of liberated ^{144}Pr ion in the solid phase.

It appeared of interest to study the initial yield of $^{144}Pr^{3+}$ ion in the ammonium salt of ^{144}Ce(III)-EDTA complex. In the (n,γ) reaction, retentions of the ammonium salts are always abnormally low.[8] No discrepancy, however, has been found in this system, as seen in Table 1. This fact suggests that because of the low recoil energy of the β^--decay of ^{144}Ce, ^{144}Pr could not interact with ammonium ion.

The chemical consequences of the β^--decay of the ^{144}Ce(III)-EDTA complex has been discussed hitherto mainly from the point of veiw of thermodynamical instability of the daughter molecular ion.[2,3] However, the present investigation in the solid phase reveals that the multiple charge of the daughter plays an important role in determining the chemical behavior of the ^{144}Pr atom.

Long-term Integration of Polarographic Currents and Its Analytical Application

Kiyoshi MATSUDA and Reita TAMAMUSHI

The Institute of Physical and Chemical Research, Yamato-machi, Saitama

(Received June 26, 1968)

The integral readout technique was applied to the accurate determination of average polarographic currents. The long-term integration of polarographic currents provides a useful method of compensating residual currents and thus of increasing the sensitivity and accuracy of the d. c. polarographic analysis. The analytical utility of the proposed method was tested with cadmium, lead, and zinc ions in chloride solutions; these ions were found to be determined with reasonable accuracy even at concentrations as low as 10^{-6} M. Depolarizers at concentrations of the order of 10^{-4} M can be determined accurately in air-saturated solutions. The present method has the considerable merit that its sensitivity is not affected by the degree of reversibility of the electrode reaction. The integral technique was also applied successfully to the compensation of residual currents by the twin-cell system, in which a pair of dropping mercury electrodes is not necessarily synchronized.

Increase in sensitivity and accuracy is an urgent requirement to the instrumental methods of analysis. The recent development in the modified alternating current (a.c.) polarography, the radio-frequency polarography, and the anodic stripping voltammetry has made it possible to determine the depolarizers at concentrations as low as 10^{-8} M. Their absolute accuracy, however, is not very high, and the sensitivity is low when the electrode reaction is slow.

The diffusion current in the direct current (d.c.) polarography has the advantage of good reproducibility and high accuracy, when applied to the determination of depolarizers. In the conventional d.c. polarographic method, however, the measurement of diffusion currents at lower concentrations becomes increasingly difficult because of the large contribution of residual currents. Many attempts have been made to eliminate the residual current and to increase the signal-to-noise

ratio; typical examples are the differential polarography, the derivative polarography,[1] and the tast polarography.[2] These methods generally require careful synchronization of a pair of dropping mercury electrodes (DME) or elaborate electronic instruments, and their practical usefulness is very much limited.

The application of integral readout methods is expected to be effective to overcome some of the above-mentioned difficulties and to increase the sensitivity and accuracy of the d.c. polarographic measurement. Booman *et al.* measured the charge transferred during a short period of electrolysis at solid electrodes by using a precision current integrator; they stated that a linear relation between the concentration and the charge transferred was obeyed to within 1%.[3] The integration of single sweep oscillopolarograms was proposed by Christie, Lauer, and Osteryoung.[4] Lauer and Osteryoung[5] reported that the integration of polargoraphic currents during a life of a single mercury drop is a suitable method for separation of capacitive and faradaic currents and for trace analysis.

The present paper deals with a new technique in which the polarographic current is integrated electronically over a long period of time (about 10 min) at a given electrode potential. The experimental results demonstrated the usefulness of the proposed technique for the elimination of residual currents and accurate measurement of average polarographic currents.

Experimental

Apparatus. The basic circuits of the apparatus used are shown in Fig. 1; both circuits (a) and (b) gave essentially the same results.

The principle of circuit (a) is similar to that of a linear bridge. The polarographic current, i_p, at a given electrode potential is integrated by the integrator, I_1, for a certain period of time (*e. g.*, about 10 min), while a constant current, i_c, is integrated by the other integrator, I_2; the sign and the magnitude of i_c are adjusted so that the output voltage of the inverter, INV, is opposite in its sign and exactly equal in its magnitude to the integrated value of the residual current at the given potential. The addition of both the signals from

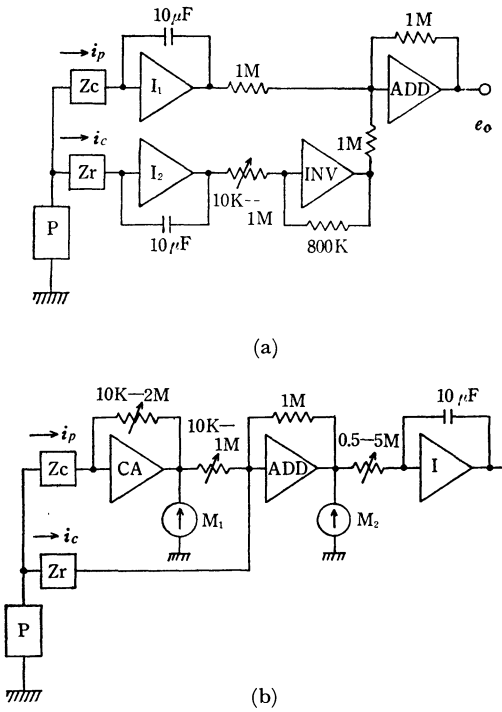

Fig. 1. Basic circuits of the plarographic current integrator with the residual current compensation: P, applying d. c. potentiometer; Z_c, polarographic cell; Z_r, variable resistance or a polarographic cell with supporting electrolyte solutions; I, integrator; ADD, adder; CA, current-to-voltage converter; INV, inverter; M, voltmeter. Chopper-stabilized operational amplifiers (Asia Seisakusho) were used in circuit (a), and solid-state differential operational amplifiers (Model 9814, Aiko Denki, Co., Ltd.) were used in circuit (b).

I_1 and INV by the adder, ADD, then eliminates the contribution of the residual current.

In circuit (b), the sign and the magnitude of the polarographic current, i_p, are changed by the current-to-voltage converter, CA; the residual current component is eliminated from the polarographic current by introducing a properly adjusted, constant current, i_c, to the summing point of the adder, ADD. The output signal of ADD is then integrated by the integrator, I, for a given period of time. In this circuit the adder, ADD, may be omitted by applying i_c directly to the summing point of the integrator, I.

The output voltage, e_o, of the apparatus was found to be strictly proportional to the input current over the wide range of current from a few nanoamperes to about 0.2 μA, the standard deviation of the slope being about 0.5%.

Cell and Reagents. The polarographic cell used was a glass beaker of a 100 cc capacity with a rubber stopper. The conventional DMEs of usual drop time and flow rate of mercury served as working electrodes. Either an internal mercury pool or an external saturated calomel electrode (SCE) was used as the counter electrode; the electric contact between the cell solution and the SCE was made by means of an agar bridge with a sintered glass tip.

5) G. Lauer and R. A. Osteryoung, *Anal. Chem.*, **39**, 1866 (1967).

The solutions were prepared from redistilled water and analytical reagent grade chemicals. When the measurement was carried out with a deaerated solution, purified nitrogen gas was passed over the solution.

All measurements were made in a water thermostat of 25.0 ±0.1°C.

Results and Discussion

Theory. At a given constant potential in the diffusion current plateau the instantaneous polarographic current, $i_p(t)$, at time t during the growth of a spherical mercury drop is given by

$$i_p(t) = k_1 nCD^{1/2}m^{2/3}t^{1/6} + k_2\sigma m^{2/3}t^{-1/3} \quad (1)$$

where k_1 and k_2 are constants, σ is the surface charge density at the given potential, and the other symbols have their usual meaning. Integration of Eq. (1) then gives the charge, $Q(t_d)$, transferred during the growth of a single mercury drop with a drop time of t_d,[5]

$$Q(t_d) = \frac{6}{7}k_1 nCD^{1/2}m^{2/3}t_d^{7/6} + \frac{3}{2}k_2\sigma m^{2/3}t_d^{2/3} \quad (2)$$

Multiplying Eq. (2) by θ/t_d we obtain the following equation representing the charge, $Q(\theta)$, transferred during the period of time of θ ($\theta \gg t_d$),

$$Q(\theta) = (\bar{i}_d + \bar{i}_r)\theta \quad (3)$$

$$\bar{i}_d = \frac{6}{7}k_1 nCD^{1/2}m^{2/3}t_d^{1/6}$$

$$\bar{i}_r = \frac{3}{2}k_2\sigma m^{2/3}t_d^{-1/3}$$

where $\bar{i}_d$ and $\bar{i}_r$ are the average diffusion current and the average charging current, respectively, over the drop life.

The output voltage, e_o, of the present apparatus, being proportional to $Q(\theta)$, is expected to give the average diffusion current when the contribution of the charging current is properly eliminated.

Compensation of Residual Currents. The long-term integration of polarographic currents almost completely eliminates the oscillation due to the periodical renewal of the mercury drop; this makes it possible to compensate the residual current by applying a constant current, i_c, in the way as described before.

The most important factor which determines the accuracy of the present method, when the method is applied to trace analysis, is the constancy of residual currents. Let us consider for example the determination of 1×10^{-6} M of cadmium in a 1 M potassium chloride solution. At the DME used, the residual current at −0.85 V *vs.* SCE in the deaerated supporting electrolyte solution was about 6×10^{-8} A when a SCE was used as an external counter electorde, and it was about ten times larger than the diffusion current of cadmium. Therefore, only 1% fluctuation in the residual current will result in an error of about 10% in the determination of cadmium.

The magnitude and constancy of residual currents in a deaerated potassium chloride solution were very much affected by the nature of the counter electrode and also by the purity of mercury of the DME. The residual current with an internal mercury pool was several times greater than that with the external SCE, and it increased gradually during the measurement, probably because of the dissolution of mercury. The increase in the residual current with an internal mercury pool was more remarkable in solutions saturated with air. When the external SCE was used, the residual current fluctuated slightly for a short period of time, but it reached a reasonably constant value after 1/2 to 1 hr. Therefore, the use of an external counter electrode such as a SCE is strongly recommended for trace analysis. The mercury of high purity should be used for the DME, because a slight contamination of mercury seems to increase the magnitude and instability of residual currents.

The complete compensation of residual currents, as shown in Fig. 2 (curve 1), was achieved by the careful adjustment of the magnitude of applying constant current, i_c. The differential polarography technique with a twin-cell system was also successful for compensating residual currents. The long-term integration method, when applied to the twin-cell system, has the advantage that it obviates the complication of synchronizing the two DME's. By using the twin-cell system, the residual current of an air-saturated potassium chloride solution with an external SCE was perfectly eliminated over the wide potential range from zero to −1.4 V, when the adjustment had been made at the potential of −0.85 V. The twin-cell technique seems to have another possibility of determining accurately the concentration of major component if a solution of a known concentration is used as the reference.

Relationship between the Output Voltage and the Concentration. The output voltage *vs.* concentration relationship was examined with cadmium, lead, and zinc ions in 1 M chloride solutions over the concentration range of 10^{-6}—10^{-3} M according to the following procedure. The constant current, i_c, necessary to compensate the residual current was determined first with the supporting electrolyte solution of a given volume. A known amount of the concentrated solution of the depolarizer was then added successively to the supporting electrolyte solution from a precision micro-syringe; the total volume of the added solution was always less than 1% of the initial volume of supporting electrolyte solution. When deaerated solutions were subjected to analysis, the purified nitrogen gas was bubbled through the solution for about 10 min after each addition of the depolarizer solution.

In each case, the output voltage of the apparatus increased linearly with the time of integration as

shown in Fig. 2, and the output voltage, $e_o(\theta)$, at a given time of integration (*e. g.* $\theta=640$ sec) was found to be perfectly proportional to the concentration of the depolarizer except for the deviation at the lowest concentrations. Figure 3 shows a typical example of the $e_o(\theta)$ *vs.* C (concentration) relationship. The significant deviation from the linearity at very low concentrations ($C<3\times10^{-6}$ M) is thought to be due to the adsorption of depolarizer on glass surfaces of the cell.

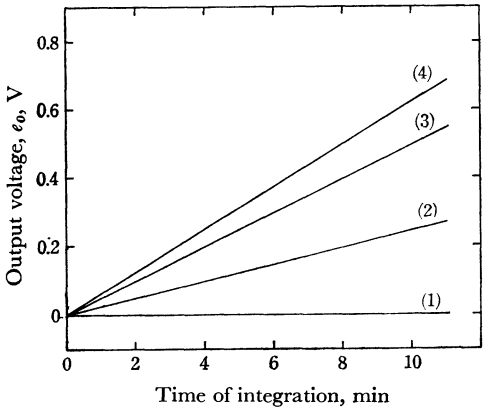

Fig. 2. Relation between the output voltage, e_o, and the time of intergration in deaerated 1 M KCl solutions with an external SCE: (1) 1 M KCl, (2) 4×10^{-5} M Cd(II) +1 M KCl, (3) 8×10^{-5} M Cd(II)+1 M KCl, (4) 1×10^{-4} M Cd(II)+1 M KCl. The residual current was compensated by applying constant current, i_c.

The accuracy of the present method, when the method was applied to the determination of cadmium, lead, and zinc ions in chloride solutions, is demonstrated in Table 1 in terms of the quantity, $(s_b/b)\times100$, where b is the slope of the $e_o(\theta)$ *vs.* C relationship and s_b the standard deviation of the slope.

Conclusion. The present study shows that the long-term integration of polarographic currents provides a very useful method of determining depolarizers in solutions with a relatively large but constant background. With this technique the diffusion current as small as one tenth of the residual current can be measured with reasonably high accuracy. The application of the twin-cell system to the present method seems to be very promising for compensating the residual current and for determining the major component. The present method, when compared with the conventional a.c. polarography, has similar sensitivity but higher accuracy; the method also has the advantage

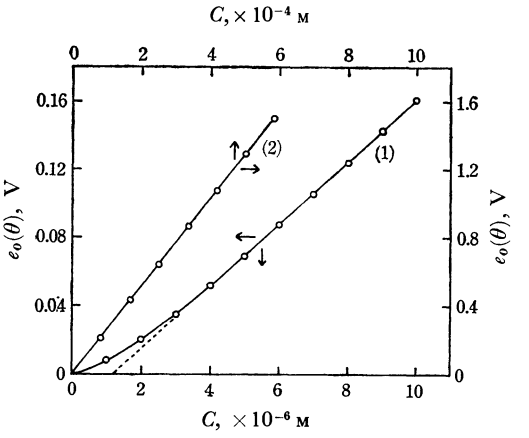

Fig. 3. Relationship between the output voltage, $e_o(\theta)$, at $\theta=640$ sec and the concentration, C, of cadmium ions in deaerated 1 M KCl solutions with an external SCE: (1) concentration range of 1×10^{-6} —1×10^{-5} M, (2) concentration range of 1×10^{-4}—6×10^{-4} M. The residual current was compensated by applying constant current, i_c. The $e_o(\theta)$ values for (1) and (2) are not calibrated for the sensitivity of the apparatus.

TABLE 1. STANDARD DEVIATION, s_b, FOR THE SLOPE, b, OF THE $e_o(\theta)$ *vs.* C RELATIONSHIP

System	Concn. range	$(s_b/b)\times100$
Cd(II) in deaerated 1M KCl at −0.85 V *vs.* SCE	$(1-10)\times10^{-6}$M	1.83

LEO: polyoxyethylene lauryl ether.

that its sensitivity is not affected by the degree of reversibility of the electrode reaction. From the standpoint of theoretical application, the long-term integration technique will provide a useful method of measuring the true average current at the DME. The accuracy of measurements may be increased by the use of a digital readout equipment.

The authors wish to thank Dr. Gen P. Satô of Sophia University for the valuable discussions and suggestions.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 443—446 (1969)

π-Allylic Coordination of Ethyl Acetoacetate to Palladium(II)*1

Yoshisato TEZUKA,*2 Tetsuya OGURA and Shinichi KAWAGUCHI*3

Department of Chemistry, Faculty of Science, Osaka City University, Sumiyoshi-ku, Osaka

(Received June 28, 1968)

The ethanolysis of diketene is accelerated by the addition of sodium tetrachloropalladate(II). Yellow crystals separated in the end of this reaction were identified as di-μ-chlorobis(π-1-ethoxycarbonyl-2-hydroxyallyl)dipalladium(II) on the ground of analytical data, molecular weight and infrared spectrum. The same complex was also prepared directly by the reaction of palladium(II) chloride with ethyl acetoacetate in water.

A number of π-allylic complexes have been synthesized from palladium(II) chloride and various mono-olefins or conjugated diolefins,[1] but those of unsaturated ketones and esters have been rather few. Tsuji and Imamura[2] prepared π-allylic palladium(II) complexes from α,β- and β,γ-unsaturated esters, Parshall and Wilkinson[3] from α,β-unsaturated ketones such as mesityl oxide, and Kasahara *et al.*[4] from α,β-unsaturated cyclic ketones. This paper reports a novel type of π-allylpalladium(II) complex containing ethoxycarbonyl and hydroxy groups as substituents at 1 and 2 positions, respectively.

In a previous paper[5] we reported copper(I) chloride complex of acrolein, the structure of which has been studied by X-ray and found to contain each acrolein molecule serving as a bridging group between two copper atoms *via* the double bond and the carbonyl oxygen atom.[6] As an extention of this series an unsaturated lactone, diketene was employed as a ligand, and its reactions with several metal compounds have been studied. In the course of these studies sodium tetrachloropalladate(II) was found to catalyze the alcoholysis of diketene and deposit the plladium(II) complex of the reaction product, ethyl acetoacetate.

Experimental

Materials. Diketene supplied by Daicel, Ltd. was used immediately after distillation under reduced pressure. Commercial palladium(II) chloride was evacuated at 300°C. A mixture of palladium(II) chloride and sodium chloride in the mole ratio of 1 : 2 was dissolved in ethanol. The solvent was then evaporated up to dryness and sodium tetrachloropalladate(II) thus prepared was further dried at 100°C *in vacuo*. Dichlorobis(benzonitrile)palladium(II) was prepared by the direct reaction between palladium(II) chloride and benzonitrile according to the Kharasch's method.[7] Dichloromethane, benzene and alcohols were purified by standard methods.[8]

Measurements. Palladium was determined gravimetrically as the dimethylglyoximato complex and chlorine as the silver salt.[9] The molecular weight was determined by the method of boiling point elevation of benzene. The ultraviolet absorption spectra were measured with a Hitachi EPS-2 recording spectrophotometer, and the infrared absorption spectra by means of a Hitachi infrared spectrophotometer EPI-2 or a Shimadzu infrared spectrophotometer IR-27. The proton magnetic resonance spectra were measured with a 60 Mc spectrometer, model JNM 3H 60 of Japan Electron Optics Laboratory, Ltd.

Reaction of Sodium Tetrachloropalladate(II) with Diketene in Ethanol. To a solution of sodium tetrachloropalladate(II) (5.6×10^{-3} mol) in ethanol (70 ml) was added gradually an ethanol solution of diketene

(1.18×10^{-2} mol) under stirring at room temperature. Together with white sodium chloride yellow palladium complex precipitated, which was recrystallized from benzene. The yield of light yellow needles was about 20% on the base of palladium employed.

Found: C, 26.79; H, 3.29; Cl, 12.8; Pd, 39.33%. Calcd for $C_6H_9O_3ClPd$: C, 26.56; H, 3.32; Cl, 13.1; Pd, 39.27%.

If a more dilute solution of sodium tetrachloropalladate(II) is employed, the ethanolysis of diketene is catalyzed by palladium(II), resulting in ethyl acetoacetate, but the ester complex is not separated due to its solubility. In one experiment a solution of 2.5 mg (8.5×10^{-6} mol) of sodium tetrachloropalladate(II) and 0.25 m*l* (3×10^{-3} mol) of diketene in 2 m*l* (40×10^{-3} mol) of ethanol was kept for 5 hr at 15°C. The gas chromatogram of this solution showed three peaks ascribable to diketene, ethanol and ethyl acetoacetate, and the conversion of diketene was estimated to be 90%. When a diketene solution in ethanol without the palladium(II) catalyst was kept standing overnight at room temperature, no trace of ethyl acetoacetate was found in the solution. The ethanolysis of diketene can thus be concluded not to proceed without a catalyst under these conditions.

Reaction of Palladium(II) Chloride with Ethyl Acetoacetate in Water. Palladium chloride (5.6×10^{-3} mol) was dissolved in 100 m*l* of water, to which ethyl acetoacetate (4.6×10^{-2} mol) was added. The mixture was kept at 40—60°C under stirring for about 40 hr. Brown precipitate formed was filtered off and the filtrate was kept standing for about 70 hr at room temperature. Yellow precipitate appeared, which was recrystallized from benzene, and the yield was about 20% on the base of palladium. The analytical data agree with values calculated for $PdCl(C_6H_9O_3)$ just as did the complex obtained in the reaction between sodium tetrachloropalladate(II) and diketene in ethanol.

Found: C, 26.88; H, 3.56; Cl, 13.2; Pd, 38.60%.

In a similar way the palladium(II) complex of methyl acetoacetate was prepared in the yield of about 10%. The solubilities of this complex in various solvents are even poorer than those of the complex of ethyl acetoacetate.

Found: C, 23.51; H, 3.02; Cl, 13.9; Pd, 41.00%. Calcd for $(C_5H_7O_3)PdCl$: C, 23.26; H, 3.10; Cl, 13.76; Pd, 41.25%.

Reaction of Dichlorobis(benzonitrile)palladium(II) with Diketene in Benzene. In the nitrogen atmosphere a benzene solution (500 m*l*) of dichlorobis(benzonitrile)palladium(II) (2.6×10^{-3} mol) was kept at around 60°C under stirring, to which 3.6×10^{-2} mol of diketene in 50 m*l* of benzene was added gradually. The solution turned from brown to yellow and yellow precipitate resulted. Yield of the crude product was about 80% on the base of palladium. After reprecipitation from ethanol by addition of petroleum ether the palladium complex gave the following analytical results.

Found: C, 20.71; H, 2.37; Cl, 16.02; Pd, 46.08%. Calcd for $C_4H_5O_2ClPd$: C, 21.15; H, 2.20; Cl, 15.63; Pd, 46.89%.

Reaction of Dichlorodi-μ-chlorobis(ethylene)dipalladium(II) with Diketene in Benzene. The reactant complex was prepared by the reaction between dichlorobis(benzonitrile)palladium(II) and ethylene in benzene according to the Kharasch's method.[7] A suspension of $PdCl_2(C_2H_4)$ (2×10^{-3} mol) in 250 m*l* of benzene was kept in the nitrogen atmosphere at room temperature under stirring, to which 3×10^{-2} mol of diketene in benzene was added gradually. The reaction mixture which was orange yellow at first turned to blue yellow and separated some solid. The precipitate was washed with benzene and dried at 80°C *in vacuo*. Results of the elemental analysis agreed again with values calculated for $PdCl(C_4H_5O_2)$.

Found: C, 20.43; H, 2.47; Pd, 46.07%.

Syntheses of Reference Complexes. Bis(acetylacetonato)palladium(II) was prepared by the reaction between palladium(II) chloride and excess amount of acetylacetone in water at around 60°C. Yellow complex obtained was recrystallized from benzene and dried at 100°C *in vacuo*.

Found: C, 39.57; H, 4.87%. Calcd for $(C_5H_7O_2)_2Pd$: C, 39.42; H, 4.60%.

Nickel(II) complex of ethyl acetoacetate was synthesized by the reaction between the nickel ammine complex and the ester in water. The product was recrystallized from dichloromethane and dried at 100°C *in vacuo*.

Found: C, 40.82; H, 6.27%. Calcd for $Ni(C_6H_9O_3)_2\cdot 2H_2O$: C, 40.24; H, 6.43%.

Results and Discussion

Di-μ-chlorobis(π-1-ethoxycarbonyl-2-hydroxyallyl)dipalladium(II). Light yellow crystals which were produced in the reaction of sodium tetrachloropalladate(II) with diketene in ethanol have the empirical formula $PdCl(C_6H_9O_3)$. When this compound was heated at around 180°C *in vacuo*, partial carbonization occurred and volatile substance was evolved, which was identified as ethyl acetoacetate by means of the gas chromatography and infrared spectra. It was also decomposed by dilute hydrochloric acid to set free ethyl acetoacetate. These results indicate that this is a palladium(II) complex of ethyl acetoacetate.

This complex is slightly soluble in benzene, dichloromethane, methyl and ethyl alcohols (10^{-2}—10^{-3} mol/*l* at room temperature). It is more soluble in dimethyl sulfoxide, but reddish yellow precipitate is separated therefrom on standing, which shows an identical infrared spectrum with what is obtained in the reaction between palladium(II) chloride and dimethyl sulfoxide. Tetrahydrofuran and pyridine also show high solubilities, but decomposition of the complex resulted on standing in either case. The molecular weight of this palladium(II) complex was determined to be 502 by measuring the boiling point elevation of benzene. This value nearly coincides with 541 calculated for the dimer, certifying the molecular formula $[PdCl(C_6H_9O_3)]_2$ and satisfying the usual coordination number four of palladium(II).

The infrared spectra were measured in the region of 400 through 5000 cm^{-1} by the potassium bromide disk method. Characteristic absorption bands are listed in Table 1 together with those for the corresponding complex of methyl acetoacetate. Infrared

Table 1. Characteristic infrared absorption bands of di-μ-chlorobis(π-1-ethoxycarbonyl-2-hydroxyallyl)dipalladium(II) (A) and di-μ-chlorobis(π-1-methoxycarbonyl-2-hydroxyallyl)dipalladium (II) (B) determined in the potassium bromide disk

Compex A, cm^{-1}	Complex B, cm^{-1}	Assignment

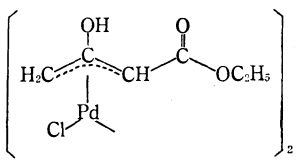
spectra of ethyl acetoacetate[10] and di-μ-chlorobis-(π-allyl)dipalladium(II)[11] were referred to in assigning absorption bands of the present complex. Although bis(acetylacetonato)palladium(II) is well known to be a usual enolate chelate,[12] corresponding palladium(II) complex of ethyl acetoacetate has not yet been reported. As shown in Table 1, the present complex does not show C=O and C=C stretching bands characteristic for the enolate chelate,[13] but has very strong peaks at 1675 and 1205 cm^{-1} indicating the presence of uncoordinated ethoxycarbonyl group. The peak at 3200 cm^{-1} must be attributed to an OH group. It is a quite novel and rather curious feature that the OH group of an enol form is preserved intact in this β-dicarbonyl complex. On the other hand peaks at 3080 and 1445 cm^{-1} may be ascribed to the stretching vibrations of end methylene and π-allylic C–C bonds, respectively.[11] Furthermore the absorption band at 546 cm^{-1} might be attributable to the skeletal deformation which was assigned by Fritz[11] as characteristic for the π-allyl group. These infrared informations strongly suggest the formula I for the palladium(II) complex of ethyl acetoacetate.



I

The stretching band of OH usually appears[14] at around 3600 cm^{-1}, and that of C=O at 1740 and 1715 cm^{-1} in the case of free ethyl acetoacetate. These bands are observed at 3200 and 1675 cm^{-1}, respectively in case of the present complex. These shifts to the lower frequency side suggest the presence of inter- or intramolecular hydrogen bonding between the two functional groups.

Proton magnetic resonance spectra are frequently utilized as one of the most powerful tools in the structural study of π-allylic metal complexes.[15] Unfortunately, however, suitable inert solvents are not available for the present complex. It is not enough soluble in alcohols or haloalkanes, and reacts with dimethyl sulfoxide and other better solvents. Thus useful informations can not be obtained from these studies. The X-ray analysis of this complex is now in progress and preliminary results[16] clearly support the structure I, and certify the presence of intermolecular hydrogen linkage which constitutes a one-dimensional polymeric structure. The palladium(II) complex of ethyl acetoacetate can now be named as di-μ-chloro-bis-(π-1-ethoxycarbonyl-2-hydroxyallyl)dipalladium(II).

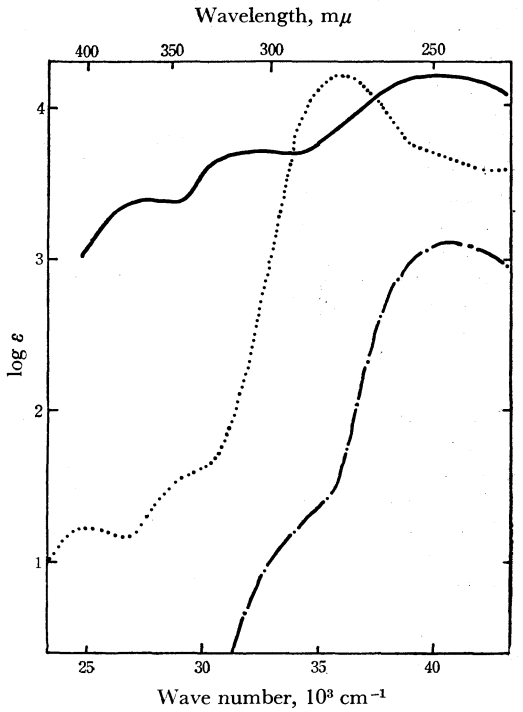


Fig. 1. Ultraviolet absorption spectra of ethyl acetoacetate ($C_6H_{10}O_3$) (-•-•-), $Ni(C_6H_9O_3)_2$ (·····) and $[PdCl(C_6H_9O_3)]_2$ (———).

The ultraviolet spectrum of this complex in ethanol is shown in Fig. 1 together with those of ethyl acetoacetate and its nickel(II) complex. A very broad band at around 250 mμ seems to be characteristic of the ligand. The nickel(II) complex of ethyl acetoacetate shows absorption maxima at 690 and 403 mμ, of which the extinction coefficients are both small and attributable to the d–d transition. The present π-allylic complex has very strong bands at 358 (log ε=3.38) and around 310 mμ (log ε=3.69). These absorptions may be related to the π-allylic structure of the complex. The absorption data of a related compound di-μ-chlorobis(π-1-methoxymethylallyl)dipalladium(II) in methanol were reported by Robinson and Shaw,[17] which show maxima at 330 (log ε=2.98), 229 sh (log ε=3.86) and 208 mμ (log ε=4.19). Some correspondence seems to exist between absorption data of these π-allylic palladium complexes, but their exact assignments are not possible.

Uncharacterized Complex $PdCl(C_4H_5O_2)$. The analytical data of the complex obtained in the reaction between dichlorobis(benzonitrile)palladium(II) and diketene nearly coincide with those calculated for $PdCl(C_4H_5O_2)$. It is hardly soluble in benzene or haloalkanes,but dissolves pretty well in methyl and ethyl alcohols. The same compound was also obtained in the reaction between di-chloro-di-μ-chlorobis(ethylene)dipalladium(II) with diketene in benzene. The analytical and infrared data suggest that this is not a complex of diketene itself. The nature of this complex is now under investigation.

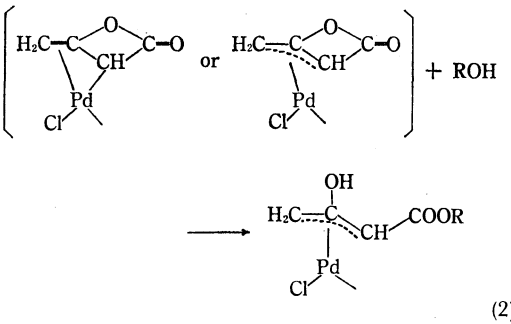
The Mechanism of Alcoholysis of Diketene in the Presence of Pd(II). When excess amount of diketene is added to an ethanol solution of sodium tetrachloropalladate(II), color of the solution turns from red to yellow in a few minutes and sodium chloride precipitates at the same time. Then irritative ordor of diketene changes gradually to agreeable one of the ester. Ethyl acetoacetate produced was identified by means of the gas chromatography.

The palladium(II) complex of the ester was deposited in the end of reaction when the tetrachloropalladate(II) was used in a higher concentration. This is a complex of the reaction product, and during the steady course of the catalytic alcoholysis of diketene, the ligand ester must be easily displaced by the substrate, diketene.

Diketene is known to be an acid of medium strength (pK_a=7.1),[18] and will liberate a proton to coordinate to palladium.

$$Na_2PdCl_4 + C_4H_4O_2 \rightleftarrows \underset{\text{II}}{PdCl(C_4H_3O_2)} + HCl + 2NaCl \qquad (1)$$

The intermediate II has not yet been identified but is just presumed here. The strong acidity of the reaction mixture and precipitation of sodium chloride support Eq. (1). The nucleophilic attack of an alcohol molecule on the carbonyl carbon may result in the rupture of the lactone ring.



(2)

The relative rate of the Pd(II) catalyzed alcoholysis in various aliphatic alcohols are in the decreasing order of MeOH>EtOH> *n*-PrOH~*i*-PrOH. This is the same tendency as that observed for the acid catalyzed esterification. Detailed informations concerning the mechanism of Pd(II) catalyzed alcoholysis of diketene must await further investigations.

The authors are grateful to Daicel, Ltd. for the generous gift of diketene. Thanks are also due to Mr. Kenichiro Noda for his help in the NMR measurements.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 447—452 (1969)

Association Involving Optically Active Ions. II. Association Constants of Tris(ethylenediamine)cobalt(III) and Tris(propylenediamine)-cobalt(III) Ions with Some Anions

Kazuko OGINO

Department of Chemistry, Faculty of Science, Tohoku University, Katahira-cho, Sendai

(Received June 30, 1968)

Association constants of [Co en$_3$]$^{3+}$ (en=ethylenediamine) and *d*- and *l*-[Co *d*-pn$_3$]$^{3+}$ (pn=propylenediamine; *d*- and *l*- refer to the sign of optical rotation at sodium D-line) with some anions have been determined spectrophotometrically. Values are as follows: [Co en$_3$]$^{3+}$·SO$_4^{2-}$ 49, [Co-en$_3$]$^{3+}$·glycollate$^-$ ~5, *d*-[Co *d*-pn$_3$]$^{3+}$·SO$_4^{2-}$ 70, *d*-[Co *d*-pn$_3$]$^{3+}$·*d*-tart^{2-} (tart^{2-}=bivalent tartrate anion) 30, *d*-[Co *d*-pn$_3$]$^{3+}$·*l*-tart^{2-} 28, *l*-[Co *d*-pn$_3$]$^{3+}$·SO$_4^{2-}$ 43, *l*-[Co *d*-pn$_3$]$^{3+}$·*d*-tart^{2-} ~7, *l*-[Co-*d*-pn$_3$]$^{3+}$·*l*-tart^{2-} ~16. These association constants are discussed in terms of the microscopic interaction between the ions. The effect of outer-sphere association on the circular dichroism and optical rotatory dispersion is also discussed.

In the outer-sphere association, ionic charges and radii are considered to be of primary importance. It is also known that other effects such as dipole moment and polarizability exert influence. However, few investigations have been made on the effect of microscopic construction of individual ions on the outer-sphere association. In a previous paper,[1] it was shown that stereospecificity exists in the association between tris(ethylenediamine)-cobalt(III), [Co en$_3$]$^{3+}$, and tartrate ions. It can be interpreted only on the basis of microscopic interaction between ions. In order to obtain more distinct information on such an interaction, association involving diastereoisomers of tris(propylenediamine)cobalt(III) ions, *d*- and *l*-[Co *d*-pn$_3$]$^{3+}$ (*d*- and *l*- refer to the sign of the optical rotation at sodium D-line), is investigated in this paper. These systems are considered to be appropriate for the present purpose because the two isomers are different from each other only in the mutual orientation of bonds. Association constants of these complex ions with tartrate and with sulfate are determined spectrophotometrically and effects of association on the circular dichroism (CD) and optical rotatory dispersion (ORD) are investigated.

Experimental

The complexes *d*-[Co *d*-pn$_3$]I$_3$·H$_2$O and *l*-[Co *d*-pn$_3$]Cl·*d*-tart·3H$_2$O (tart^{2-} denotes bivalent tartrate anion) were prepared according to the method reported in the literature.[2] The complex *d*-[Co *d*-pn$_3$]I$_3$·H$_2$O was treated with Na$_3$[Co(CN)$_6$]. The precipitate was washed to be free from iodide and then converted into perchlorate by passing through a column of Dowex 1, X-8 in the perchlorate form. Found: C, 18.10; H, 5.29; N, 14.16%. Calcd for [CoC$_9$H$_{30}$N$_6$](ClO$_4$)$_3$·H$_2$O: C, 18.12; H, 5.40; N, 14.09%. Molecular rotations at sodium D-line, and at peaks of ORD are as follows: $[M]_D$=150°, $[M]_{525}$=2250° and $[M]_{468}$=8000°. The complex *l*-[Co *d*-pn$_3$](ClO$_4$)$_3$ was obtained by the addition of perchloric acid into the solution of *l*-[Co *d*-pn$_3$]Cl·*d*-tart·3H$_3$O. Found: C, 18.92; H, 5.08; N, 14.45%. Calcd for [CoC$_9$H$_{30}$N$_6$](ClO$_4$)$_3$: C, 18.67; H, 5.22; N, 14.50%. $[M]_D$=1500°, $[M]_{515}$=4500° and $[M]_{431}$=5100°. The preparation of *d*-[Co en$_3$]-(ClO$_4$)$_3$ was described in the previous paper.[1]

The electronic absorption spectra were measured with a Shimadzu QV-50 Spectrophotometer, and the ORD and CD spectra were obtained with a JASCO ORD/UV-5 Optical Rotatory Dispersion Recorder. All measurements were carried out at 25°C and μ=0.1 (NaClO$_4$). The pH of the solution was adjusted so that tartrate ions are present as a bivalent anion in the solution. The concentration of the complexes was varied from 0.03 to 1.25 mM.

Results and Discussion

The absorbancy, CD and ORD of many complex ions are affected by the outer-sphere association, which is expressed by

$$M^{m+} + jX^{x-} \rightleftarrows MX_j^{(m-jx)+} \quad (j=1, 2, \cdots, n) \quad (1)$$

where M^{m+} and X^{x-} correspond to the complex ion and the counter ion, respectively. Association constants are defined by

$$K = [MX^{(m-x)+}]/([M^{m+}][X^{x-}]) \quad (2)$$

$$\beta_j = [MX_j^{(m-jx)+}]/([M^{m+}][X^{x-}]^j) \quad (3)$$

1) K. Ogino and U. Saito, This Bulletin, **40**, 826 (1967).

2) F. P. Dwyer, F. L. Garvan and A. Shulman, *J. Am. Chem. Soc.*, **81**, 290 (1959).

In the previous paper,[1] the relation between the association constants and the change of a partial molar quantity on association, Δ, was given in a generalized form (Eq. (12) in Ref. 1):

$$\Delta = \sum_{j=1}^{n} \Delta_{MX_j}\beta_j[X^{x-}]^j/(1 + \sum_{j=1}^{n} \beta_j[X^{x-}]^j) \quad (4)$$

which is valid for any property that is additive for $MX_j^{(m-jx)+}$, *e. g.*, absorbancy, electrical conductivity, *etc.* In the case of absorbancy, Δ and Δ_{MX_j} are defined by

$$\Delta = \varepsilon_{app} - \varepsilon_0 \quad (5)$$

and

$$\Delta_{MX_j} = \varepsilon_{MX_j} - \varepsilon_0 \quad (6)$$

respectively, where ε_0 and ε_{MX_j} are molar extinction coefficients of M^{m+} and $MX^{(m-jx)+}$, and ε_{app} is the apparent extinction coefficient of the solution:

$$\varepsilon_{app} = (\text{absorbancy})/([M^{m+}] + \sum_{j=1}^{n}[MX_j^{(m-jx)+}]) \quad (7)$$

In the case of CD and ORD, Δ and Δ_{MX_j} are defined similarly as in Eqs. (5) and (6):

$$\Delta = (\varepsilon_l - \varepsilon_r)_{app} - (\varepsilon_l - \varepsilon_0)_0 \quad (8)$$

$$\Delta_{MX_j} = (\varepsilon_l - \varepsilon_r)_{MX_j} - (\varepsilon_l - \varepsilon_r)_0 \quad (9)$$

for CD and

$$\Delta = [M]_{app} - [M]_0 \quad (10)$$

$$\Delta_{MX_j} = [M]_{MX_j} - [M]_0 \quad (11)$$

for ORD, where the subscripts *app*, 0 and MX_j have the same meanings as in Eqs. (5) and (6).

Assuming that only the species $MX^{(m-x)+}$ is formed and higher association is absent, Eq. (12) is obtained instead of Eq. (4).

$$\Delta = \Delta_{MX}K[X^{x-}]/(1 + K[X^{x-}]) \quad (12)$$

$$\Delta_{MX} = \varepsilon_{MX} - \varepsilon_0 \quad (13)$$

As has been explained in the previous paper,[1] the association constant K can be determined by use of Eq. (14).

$$[X^{x-}]/\Delta = [X^{x-}]/\Delta_{MX} + 1/(K\Delta_{MX}) \quad (14)$$

By plotting $[X^{x-}]/\Delta$ against $[X^{x-}]$, K is obtained as the ratio of slope to intercept of the resulting straight line. If other species, $MX_2^{(m-2x)+}, \cdots, MX_n^{(m-nx)+}$ were also formed, the plot of $[X^{x-}]/\Delta$ *vs.* $[X^{x-}]$ would not give a straight line, but give a curve dependent on the relative magnitude of Δ_{MX_j} and β_j. Whenever the curvature of the plot is small and can be approximated to be a straight line, an apparent 1 : 1 association constant can be obtained by use of Eq. (14). However, such an apparent constant should be a function of the ratio $\Delta_{MX_j}/\Delta_{MX}$, and since the ratio is expected to depend on the wavelength at which the absorbancy is measured, the apparent constant obtained at different wavelengths will not give a constant value.

Equation (14) was applied to the change of absorbancy of $[Co\,en_3]^{3+}$ on addition of sulfate, and the association constants were obtained to be 49, 47 and 50 from absorbancies at 260, 262 and 265 mμ, respectively. The small deviation of these values suggests that 1 : 1 association occurs predominantly.

The absence of higher association was also examined by the following procedure. When the change of absorbancy, CD or ODR at two concentrations $[X^{x-}]_1$ and $[X^{x-}]_2$ are measured to be Δ_1 and Δ_2 respectively, the ratio Δ_1/Δ_2 is given by

$$\frac{\Delta_1}{\Delta_2} = \frac{(\sum_{j=1}^{n} \Delta_{MX_j}[X^{x-}]_1^j)(1 + \sum_{j=1}^{n} \beta_j[X^{x-}]_2^j)}{(\sum_{j=1}^{n} \Delta_{MX_j}[X^{x-}]_2^j)(1 + \sum_{j=1}^{n} \beta_j[X^{x-}]_1^j)} \quad (15)$$

It is a function of the ratio $\Delta_{MX_j}/\Delta_{MX}$. When only 1 : 1 association takes place, Eq. (15) is simplified as

$$\frac{\Delta_1}{\Delta_2} = \frac{[X^{x-}]_1(1 + K[X^{x-}]_2)}{[X^{x-}]_2(1 + K[X^{x-}]_1)} \quad (16)$$

which does not contain Δ_{MX}, hence Δ_1/Δ_2 should be constant for any properties that are affected by association. This equation was applied to the changes of the absorbancy, ORD and CD of the system *d*-$[Co\,en_3]^{3+}$ and sulfate in the wavelengths where the changes caused by the addition of sulfate could be measured most accurately (*cf.* Figs. 4 and 5). The result for the absorbancy is shown in Table 1. At $[X^{x-}]_1 = 0.025$ M and $[X^{x-}]_2 = 0.01$ M, the value of Δ_1/Δ_2 is calculated to be 1.68 by use of Eq. (16) and $K = 49$. The values in Table 1 agree with it. The ratio for the change

Table 1. The ratio Δ_1/Δ_2 at $[X^{x-}]_1 = 0.025$ M and $[X^{x-}]_2 = 0.010$ M for absorbancy of the system, $[Co\,en_3]^{3+}$ and sulfate

mμ	Δ_1/Δ_2	mμ	Δ_1/Δ_2	mμ	Δ_1/Δ_2
267.5	1.7_0	257.5	1.6_4	216	1.7
265	1.6_4	255	1.6_8	210	1.7
262.5	1.6_7	225	1.6	206	1.6
260	1.6_8	220	1.7		

of ORD at 360—410 mμ and that for CD at 435—470 mμ were also found to agree with the calculated value within the experimental error.

From above observations it may be concluded that only the species $[Co\,en_3]^{3+}\cdot SO_4^{2-}$ are formed predominantly by the association under the experimental condition. Larsson[3] reported the evidence of higher association between $[Co\,en_3]^{3+}$ and sulfate ions. This difference may be due to the differences in sulfate concentrations and ionic strength: In the study by Larsson, sulfate concentration was varied from 0.015 to 1 M and other electrolytes were not added in solution, while in this study the

3) R. Larsson, *Acta Chem. Scand.*, **16**, 2267 (1962).

maximum sulfate concentration was 0.025 M and ionic strength was kept to be 0.1 with sodium perchlorate.

The absorbancy, CD and ORD of [Co *d*-pn_3]$^{3+}$ also changed on the addition of sulfate and tartrate. In Figs. 1 and 2 are shown the changes in the

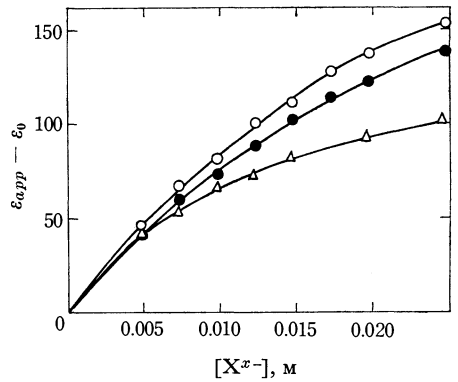

Fig. 1. Variation of the apparent extinction coefficient of *d*-[Co *d*-pn_3]$^{3+}$ at 265 mμ as a function of anion concentration, [X^{x-}], μ=0.1, 25°C.

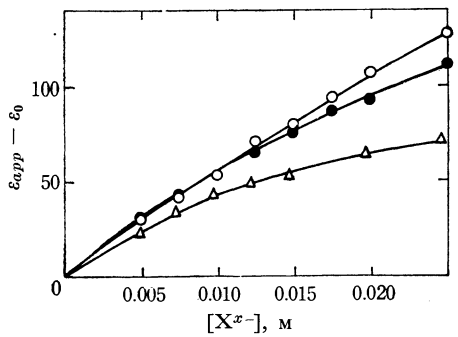

Fig. 2. Variation of the apparent extinction coefficient of *l*-[Co *d*-pn_3]$^{3+}$ at 265 mμ as a function of anion concentration, [X^{x-}], μ=0.1, 25°C.
—○—: X^{x-}=*d*-tart^{2-}, —●—: X^{x-}=*l*-tart^{2-}, —△—: X^{x-}=SO_4^{2-}

apparent extinction coefficient (*cf.* Eq. (5)) at 265 mμ. The changes are neither the same for *d*- and *l*-tartrate, nor for *d*- and *l*-[Co *d*-pn_3]$^{3+}$. From these plots association constants were determined by use of Eq. (14). In Table 2 the constants obtained are given. Using these association constants, the changes of CD and ORD spectra of *d*- and *l*-[Co *d*-pn_3]$^{3+}$ on the addition of sulfate could be explained by Eq. (16). This equation was also applied to the system *d*-[Co *d*-pn_3]$^{3+}$ and tartrate, but was not applied to the system *l*-[Co *d*-pn_3]$^{3+}$ and tartrate because of the limited accuracy of association constants and the small change of CD caused by the addition of tartrate (*cf.* Fig. 9).

It was shown by the X-ray analyses that the absolute configurations of *d*- and *l*-[Co *d*-pn_3]$^{3+}$

Table 2. Association constants at μ=0.1 and 25°C

	Absolute configuration	*d*-tart^{2-}	*l*-tart^{2-}	SO_4^{2-}	glycolate$^-$
d-[Co en_3]$^{3+}$	$\Delta(C_2)$[4]	26±2[1]		49±2	5±2
l-[Co en_3]$^{3+}$	$\Lambda(C_2)$	21±2[1]			
d-[Co *d*-pn_3]$^{3+}$	$\Delta(C_2)$[5]	30±2	28±2	70±2	
l-[Co *d*-pn_3]$^{3+}$	$\Lambda(C_2)$[6]	7±2	16±2	43±3	

are $\Delta(C_2)$[5] and $\Delta(C_2)$[6],*1 respectively, and *d*- and *l*-[Co *d*-pn_3]$^{3+}$ correspond to the "*lel*" type and the "*ob*" type according to Corey and Bailar's notation.[7] In the *lel* conformation, two sets of three N–H bonds are nearly parallel to the C_3 axis of the complex ion,[8] and the anion in the ion pair can be located along the direction of the C_3 axis so as to form hydrogen bonding with N–H hydrogen. On the other hand, in the *ob* conformation orientations of the N–H bonds are not the same to one another. As is seen in Table 2, the association constants for *lel*-$\Delta(C_2)$-[Co *d*-pn_3]$^{3+}$ are substantially larger than those for the *ob*-$\Lambda(C_2)$-isomer. Such a difference will be attributable to the difference in the orientation of N–H bonds in *lel* and *ob* isomer.

The conformations of [Co en_3]$^{3+}$ in the solution are predominantly *lel*. Association constants in Table 2 show that those for [Co en_3]$^{3+}$ are a little smaller than those for *lel*-Δ-[Co *d*-pn_3]$^{3+}$,*2 contrary

8) S. F. Mason and B. J. Norman, *J. Chem. Soc., A*, **1966**, 307.

*2 According to the potential energy difference calculated by Corey and Bailar,[7] *ca.* 64% of the total complex in the solution of tris(diamine)cobalt(III), is in the *lel* conformation, *ca.* 3% in the *ob* conformation, and the rest of the complex is in the intermediate conformations between *lel* and *ob*. The result of the calculation was supported by the experiments by Dwyer *et al.*[9] When it is assumed that the association constant between sulfate and [Co en_3]$^{3+}$ in conformations other than *lel* is about 43/70 (ratio of association constants of *ob*-Λ-[Co *d*-pn_3]$^{3+}$·SO_4^{2-} and *lel*-Δ-[Co *d*-pn_3]$^{3+}$·SO_4^{2-}) of that of [Co en_3]$^{3+}$ in the *lel* conformation, the hypothetical association constant of *lel*-[Co en_3]$^{3+}$·SO_4^{2-} is calculated to be 58, which is still smaller than the association constant of *lel*-Δ-[Co *d*-pn_3]$^{3+}$·SO_4^{2-}.

9) F. P. Dwyer, T. E. MacDermott and A. M. Sargeson, *J. Am. Chem. Soc.*, **85**, 2913 (1963); F. P. Dwyer, A. M. Sargeson and L. B. James, *ibid.*, **86**, 590 (1964).

to the expectation from the electrostatic theory that the larger ions should have smaller association constants. This indicates that the steric hindrance of the methyl group of propylenediamine is not significant in the association with sulfate and with tartrate. It may be because the methyl groups have trigonal orientation nearly perpendicular to the C_3 axis and do not interfere with the approach of anions along the direction of the C_3 axis.

Association constants of $[Co\ en_3]^{3+}$ with tartrate ions were discussed briefly in the previous paper.[1] They are about one half of that with sulfate but much larger than that with univalent glycollate. It suggests that the two carboxylate groups in a tartrate ion take part simultaneously in association. Therefore the two carboxylates in a tartrate ion should not be oriented trans to each other. Between the two gauche conformations of a *d*-tartrate ion in Fig. 3, I is considered to be more stable because

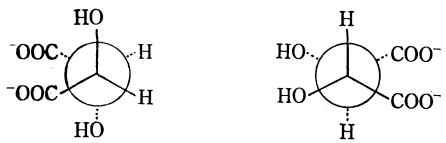

Fig. 3. Conformations of a *d*-tartrate ion viewed along the direction of the bond between two asymmetric carbon atoms.

two hydroxyl groups are trans to each other and hydrogen bonding is possible between $-COO^-$ and $-OH$. Thus, the bond $^-OOC-C-C-COO^-$ in a *d*-tartrate ion is arranged as a right handed screw in an ion-pair, while in an *l*-tartrate ion it is arranged as a left handed screw. The difference in the association constants of *lel*-Δ- and *ob*-Λ-$[Co\ d\text{-}pn_3]^{3+}$ with *d*- and *l*-tartrate ions is supposed to be related to the relative configuration of the

complex ion and the ^-OOC–C–C–COO^- screw in the tartrate ion. A consideration with the aid of molecular models reveals that association of *d*-tartrate ion with complex ions of $\Delta(C_2)$ configuration is more preferable to that with complex ions of $\Lambda(C_2)$ configuration. This assumption is in accord with the results in Table 2. The difference in the association constants of tartrate ions with *lel*-Δ- and *ob*-Λ-$[Co\ d\text{-}pn_3]^{3+}$, which have the same charge and nearly the same size, shows the importance of the microscopic construction of ions in the outer-sphere association.

Using the association constant in Table 2, absorption and CD spectra of $[Co\ en_3]^{3+}$ and $[Co\ d\text{-}pn_3]^{3+}$ were analyzed in terms of 1 : 1 association by use of Eq. (12). In Figs. 4 and 5 are shown the absorption spectrum and the ORD curve of the ion-pair $[Co\ en_3]^{3+}\cdot SO_4^{2-}$. The absorbancy increases by association at wavelengths 270—230 mμ, but it decreases at shorter wavelengths. The absorbancy of *lel*-Δ- and *ob*-Λ-$[Co\ d\text{-}pn_3]^{3+}$ change similarly by the association with sulfate as that of $[Co\ en_3]^{3+}$.

Figures 6 and 7 show CD spectra of *lel*-Δ- and *ob*-Λ-$[Co\ d\text{-}pn_3]^{3+}$ in the absence and in the presence of 0.025 M sodium sulfate. The CD bands of these complexes in the absence of sulfate were discussed in a seperate paper.[10] As can be seen in

10) K. Ogino, K. Murano and J. Fujita, *Inorg. Nucl. Chem. Letters*, **4**, 351 (1968).

Figs. 6 and 7 the sign of the change on addition of sulfate (*cf.* Eq. (8)) is negative in the *d–d* abosprtion region and positive in the charge transfer region for *lel*-Δ-[Co *d*-pn_3]$^{3+}$, while the sign of the change is reversed for *ob*-Λ-[Co *d*-pn_3]$^{3+}$. Figures 8 and 9 are CD spectra of *lel*-Δ- and *ob*-Λ-[Co *d*-pn_3]$^{3+}$ in 0.025 M *d*- and *l*-tartrate solutions. The changes in CD produced by the addition of sulfate and tartrate are larger for *lel*-Δ-[Co *d*-pn_3]$^{3+}$ than for *ob*-Λ-[Co *d*-pn_3]$^{3+}$. As can be seen from Eq. (12) such a difference is attributable to differences of both K and Δ_{MX} which is defined by

$$\Delta_{MX} = (\varepsilon_l - \varepsilon_r)_{MX} - (\varepsilon_l - \varepsilon_r)_0 \qquad (17)$$

$(\varepsilon_l - \varepsilon_r)_{MX}$ being the circular dichroism of the ion-pair. Vales of Δ_{MX} were obtained at each wavelength and are also given in Figs. 6 and 7. It is seen that the larger change of CD of *lel*-Δ-[Co *d*-pn_3]$^{3+}$ than that of *ob*-Λ-[Co *d*-pn_3]$^{3+}$ caused by the addition of the same amount of sulfate is due to larger values of both K and Δ_{MX} of the *lel*-$\Delta(C_2)$-isomer. Values of Δ_{MX} were obtained also for the association of *lel*-Δ-[Co *d*-pn_3]$^{3+}$ with tartrate (Fig. 8). The difference of Δ_{MX} values for *lel*-$\Delta(C_2)$- and *ob*-$\Lambda(C_2)$-isomer and for *d*- and *l*-tartrate may be related to the different structure in the outer-sphere association due to different conformations.

The author wishes to thank Professor Kazuo Saito and Dr. Junnosuke Fujita for their helpful advice and encouragement, and Mr. Hide Saito from whom the complex *l*-[Co *d*-pn_3]Cl·*d*-tart·$3H_2O$ was obtained.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 452—456 (1969)

The Stability of Fused Rings in Metal Chelates. IV. Preparation and Relative Stability of Copper(II) Complexes with Tetradentate Schiff Base Ligands

Yasuo NAKAO, Naoki NONAGASE and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka

(Received July 1, 1968)

Relative stability of sixteen aldehyde- and the corresponding ketone-Schiff base chelates has been investigated in terms of their decomposing temperature and half-wave potential against the reduction of copper(II) at the dropping mercury electrode. The previous conclusion, established for copper(II) tridentate Schiff base complexes, that Schiff base chelates of aldehydes are generally less stable than those of corresponding ketones has been proved to be valid also for copper(II) tetradentate Schiff base complexes if there is no serious steric hindrance in the Schiff base ligand. As a result of this investigation, six new copper(II) chelates were synthesized and characterized.

In a previous paper[1] we have pointed out that copper(II) chelates of aldehyde-Schiff bases are generally less stable than those of the corresponding ketone-Schiff bases. This conclusion was, however, drawn only from the comparison of relative stability of some copper(II) chelates with tridentate Schiff bases derived from glyoxylate or pyruvate and various amino acid residues. The investigation has recently been extended to copper(II) chelates with tetradentate Schiff bases derived from some other aldehydes or ketones and various diamines or glycylglycine. Thus the validity of the former conclusion has been reinvestigated on the basis of experimental data on the relative stability of sixteen copper(II) tetradentate chelates.

The carbonyl compounds employed in this work were not only glyoxylate and pyruvate but also salicylaldehyde, benzoylacetone, benzoylacetaldehyde and 2-hydroxyacetophenone. On the other hand, ethylene-, trimethylene- and tetramethylenediamine, and glycylglycine were employed as amino compounds to form Schiff bases with the above described carbonyl compounds. Structural formulae of the sixteen copper(II) - Schiff base chelates derived from those carbonyl and amino compounds are illustrated in Fig. 1, I—XVI. Among those complexes, I, III, IV, V, VII and XVI are new compounds; the complexes shown by the odd numbers are chelates of aldehyde-Schiff bases,

1) Y. Nakao, K. Sakurai and A. Nakahara, This Bulletin, **39**, 1471 (1966).

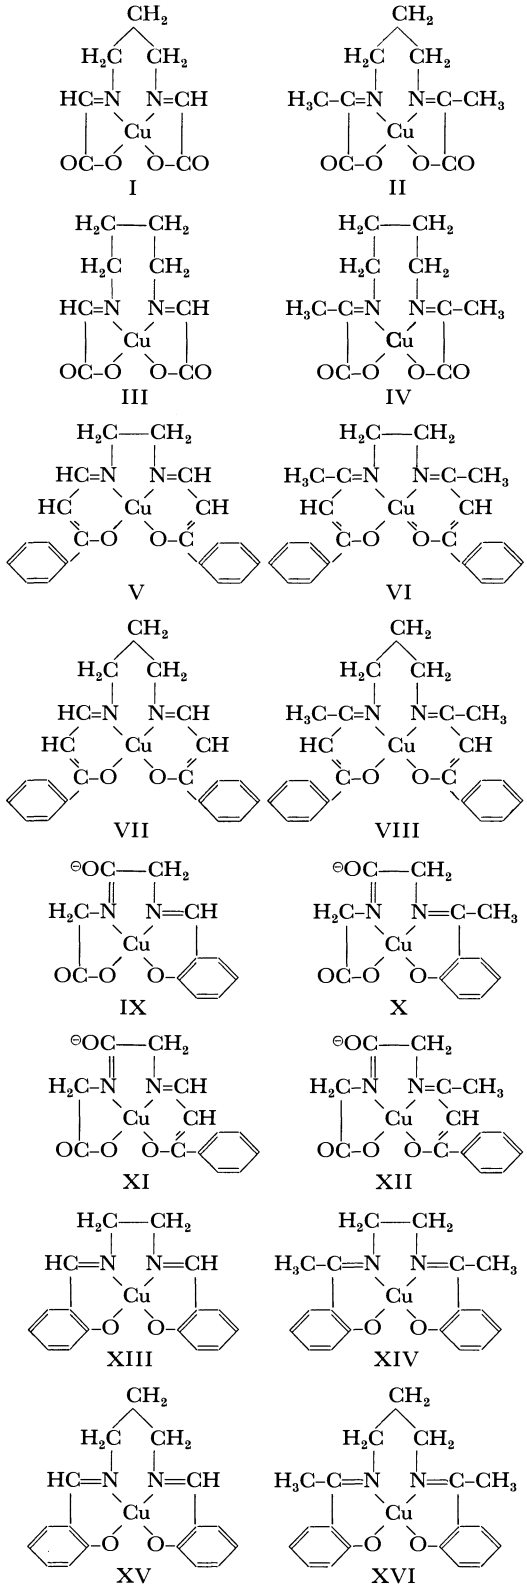

Fig. 1. Structural formulae of copper (II) chelates of aldehyde- and ketone-Schiff bases.

while those shown by the even numbers are of ketone-Schiff bases.

The relative stability of copper(II)-aldehyde- and -ketone-Schiff base complexes has been determined in terms of their decomposing temperature and half-wave potential of the reduction of copper(II) at the dropping mercury electrode.[2] The numerical data are tabulated in Table 1.

Copper(II) Complexes of Schiff Bases derived from Glyoxylate or Pyruvate and Various Diamines (I—IV). The copper(II) complex of Schiff base derived from pyruvate and trimethylenediamine, II, has been reported in a former paper.[2] The corresponding complex of aldehyde-Schiff base derived from glyoxylate and trimethylenediamine, I, has newly been prepared and compared with II. Both of them consist of the same skeletal structure (5-6-5 fused-chelate-ring*[1]) and are blue crystals, but they distinctly differ from each other in decomposing temperature and half-wave potential of the reduction of copper(II). The numerical data tabulated in Table 1 apparently support the previous conclusion that aldehyde-Schiff base complex is less stable than the corresponding ketone-Schiff base complex. The same trend is also observed in the comparison of bis-(glyoxylate)- and bis(pyruvate)-tetramethylenediamine complex, III and IV, in which the fused-chelate-ring is 5-7-5.

Further it may be concluded from the comparison of I and III, or II and IV, that if the carbonyl moiety in Schiff base ligand is same, 5-6-5 fused ring system is more stable than 5-7-5 system. (I<II; III<IV; I>III*[2]; II>IV).

Copper(II) Complexes of Schiff Bases derived from Benzoylacetaldehyde or -acetone and Ethylene- or Trimethylene-diamine (V—VIII). The copper(II) chelates of Schiff base derived from benzoylacetone and ethylenediamine, VI, and that from benzoylacetone and trimethylenediamine, VIII, were reported by Martell *et al.*[3] In the present investigation we have newly prepared the corresponding chelates of aldehyde-Schiff bases, V and VII. As is clear from Table 1, the Schiff base complexes of ethylenediamine, V and VI, are reddish brown, whereas those of trimethylenediamine, VII and VIII, are greenish brown. The

*[1] The abbreviation 5-6-5 indicates the fused-chelate-ring structure containing five-, six- and five-membered ring in clockwise direction.

2) A. Nakahara, H. Yamamoto and H. Matsumoto, This Bulletin, **37**, 1137 (1964).

*[2] Though this particular relation, I>III, does not seem to be decisive because of the fact that the decomposing temperature of the complex I is rather lower than that of the complex III, the conclusion might be supported from the comparison of strain in the fused ring system of the respective chelates.

XV	2 : 1 salicylaldehyde : trimethylenediamine	green-brown	276—280 (decomp.)	−0.53 V (irrev.) (50% H_2O-pyridine)
XVI	2 : 1 2-hydroxyacetophenone : trimethylenediamine	green	242—247 (decomp.)	−0.49 V (irrev.) (50% H_2O-pyridine)

extraordinary difference is also found in their decomposing temperature and half-wave potential. It is noteworthy that even this kind of distinct difference is accompanied by the slight change of fused ring from the 6-5-6 to 6-6-6 system.

The aldehyde-Schiff base complexes are proved, also here, to be less stable than the corresponding ketone-Schiff base complexes; in the comparison of the same two aldehyde-Schiff base chelates, or ketone-Schiff base chelates, the stability of the 6-5-6 fused ring structure is higher than that of the 6-6-6 structure. (V<VI; VII<VIII; V>VII; VI>VIII).

Copper(II) Complexes of Schiff Bases with Glycylglycine (IX—XII). As already reported,[4] copper(II) chelates of Schiff bases derived from salicylaldehyde, 2-hydroxyacetophenone, benzoylacetaldehyde or benzoylacetone and glycylglycine have the structure of 5-5-6 fused ring and appear reddish purple. Thier decomposing temperature and half-wave potential in polarographic measurement are indicated in Table 1, from which the following relation in their relative stability is easily concluded: IX<X; XI<XII. The validity of the previous conclusion that Schiff base chelates of aldehydes are less stable than those of ketones is thus well supported.

Copper(II) Complexes of Schiff Bases derived from Salicylaldehyde or 2-Hydroxyacetophenone and Ethylene- or Trimethylenediamine (XIII—XVI). Bis(salicylaldehyde)-ethylenediimine chelate, XIII, -trimethylenediimine chelate, XV, and bis(2-hydroxyacetophenone)ethylenediimine chelate, XIV, have long been known since the work of Tsumaki *et al.*[5] In addition to those, we have newly prepared bis(2-hydroxyacetophenone)trimethylenediimine chelate, XVI.

Inspection of the numerical data for these chelates in Table 1 reveals that the situation on relative stability of aldehyde- and ketone-Schiff base chelates is the reverse of the cases described above. In other words, the Schiff base complexes of aldehydes are more stable than those of ketone, so far as these particular chelates are concerned. However, the reversal of this kind may be attributed to a steric hindrance resulting from the bulky methyl group of the 2-hydroxyacetophenone moiety. The steric effect of the methyl group can easily be duplicated by using a Stuart Model. Although this effect of methyl group does not seem to be so serious, but still it may be great enough to weaken the coordination of the tetradentate ligand to some extent. For this reason, it may be understood that the ketone Schiff base chelates, XIV and XVI,

4) A. Nakahara, K. Hamada, I. Miyachi and K. Sakurai, This Bulletin, **40**, 2826 (1967).

5) P. Pfeiffer, E. Breith, E. Lübbe and T. Tsumaki, *Ann.*, **503**, 84 (1933).

become less stable than the aldehyde-Schiff base chelates, XIII and XV. In the case of complex X, in which the Schiff base ligand consists of glycylglycine and 2-hydroxyacetophenone, the steric hindrance of the same methyl group has not been necessary to be taken into account. This is because of the reason that the complex X contains only one 2-hydroxyacetophenone moiety in the molecule, and hence the steric effect of methyl group is considered to be not so serious as that in complexes, XIV or XVI.

Thus the previous conclusion that Schiff base chelates of aldehydes are generally less stable than those of corresponding ketones is proved to be valid also for tetradentate chelates, whenever there is no serious steric hindrance in the ligand.

Experimental

Syntheses of Ligands. *Sodium Glyoxylate* was prepared from tartaric acid according to the direction of Metzler *et al.*[6]

Benzoylacetaldehyde was prepared from acetophenone according to the direction in the literature.[7]

Bis(benzoylacetaldehyde)ethylendiimine. To a mixture of 5.2 g of benzoylacetaldehyde and 0.8 g of sodium hydroxide in 80 m*l* of ethanol was added 2.4 g of ethylenediamine dihydrochloride. The mixture was stirred and heated at about 55°C for several hours, and was then filtered. The filtrate was concentrated to some extent and allowed to stand for a few hours in a refrigerator; thereupon yellow crystals were deposited. The product was filtered and recrystallized from ethanol. Mp 143—144°C. Found: C, 74.99; H, 6.17; N, 8.64%. Calcd for $C_{20}H_{20}O_2N_2$: C, 75.00; H, 6.26; N, 8.75%.

Bis(2-hydroxyacetophenone)trimethylenediimine. A mixture of 5.9 g of 2-hydroxyacetophenone and 1.6 g of trimethylenediamine was dissolved in 10 m*l* of ethanol. The mixture was stirred and heated at about 70°C for half an hour. Upon cooling the solution yellow crystals were deposited. This was filtered and recrystallized from ethanol. Mp 127°C. Found: C, 73.17; H, 7.01; N, 8.81%. Calcd for $C_{19}H_{22}O_2N_2$: C, 73.55; H, 7.10; N, 9.03%.

Preparation of Metal Chelates. *Copper(II) Complex of Bis(glyoxylate)trimethylenediimine(I).* To a mixture of 1.8 g of trimethylenediamine and 5.7 g of sodium glyoxylate in 10 m*l* of water was added a freshly precipitated cupric oxide (*ca.* 2 g). The mixture was vigorously stirred at 10°C for about four hours; hereupon a bluish crystalline powder was gradually deposited. This was recrystallized from water. Found: C, 30.25; H, 4.19; N, 10.32%. Calcd for $Cu(C_7H_8O_4N_2)\cdot 1.5H_2O$: C, 30.60; H, 4.01; N, 10.20%.

Copper(II) Complex of Bis(pyruvate)trimethylenediimine(II). Although the method of preparation of this compound had already been reported in the previous paper,[2] the procedure was a little simplified by the use of copper(II) acetate in place of freshly precipitated copper(II) oxide.

Copper(II) Complex of Bis(glyoxylate)tetramethylenediimine (III). To a mixture of 2.2 g of tetramethylenediamine and 5.7 g of sodium glyoxylate monohydrate in 50 m*l* of water was added 5.0 g of copper(II) acetate monohydrate. The mixture was stirred at 20°C for one hour to give a pale blue crystalline powder. This was filtered and washed several times by water. Found: C, 29.79; H, 5.12; N, 8.30%. Calcd for $Cu(C_8H_{10}O_4N_2)\cdot 3.5H_2O$: C, 29.58; H, 5.24; N, 8.62 %.

Copper(II) Complex of Bis(pyruvate)tetramethylenediimine (IV). To a freshly precipitated cupric oxide, obtained from 10 g of copper(II) sulfate pentahydrate in 50 m*l* of water was added 4.4 g of pyruvic acid and 2.2 g of tetramethylenediamine. The mixture was stirred and heated at 40°C for about two hours. After it had been filtered, the solution was, to some extent, evaporated *in vacuo*, and then allowed to stand for a few hours in a refrigerator; hereupon a blue powder was deposited. This was filtered and recrystallized from water. Found: C, 34.93; H, 6.07; N, 8.05%. Calcd for $Cu(C_{10}H_{14}O_4N_2)\cdot 3H_2O$: C, 34.93; H, 5.82; N, 8.17%.

Bisbenzoylacetaldehyde-ethylenediiminocopper(II) (V). To a mixture of 2.2 g of bis(benzoylacetaldehyde)ethylenediimine and 35 m*l* of acetone was added a freshly precipitated copper(II) oxide obtained from 4.0 g of copper(II) sulfate pentahydrate. The mixture was stirred and heated at 60°C for about three hours. After it had been filtered, the solution was cooled to give reddish brown crystals. This was recrystallized from acetone. Found: C, 62.76; H, 4.58; N, 7.31%. Calcd for $Cu(C_{20}H_{18}O_2N_2)$: C, 62.91; H, 4.72; N, 7.34%.

Bisbenzoylacetone-ethylenediiminocopper(II) (VI) and Bisbenzoylacetone-trimethylenediiminocopper(II) (VIII), were prepared according to the method of Martell *et al.*[3]

Bisbenzoylacetaldehyde-trimethylenediiminocopper(II) (VII). Seven grams of benzoylacetaldehyde, 1 g of sodium hydroxide and 3.4 g of trimethylenediamine dihydrochloride were mixed together in 80 m*l* of ethanol. The mixture was stirred and heated at 60°C for three hours. After it had been filtered, the solution was concentrated under vacuum until the volume became to about 20 m*l*. To this solution of bisbenzoylacetaldehyde-trimethylenediimine was added copper(II) oxide, which had been obtained from 10 g of copper(II) sulfate pentahydrate, and 50 m*l* of acetone. The copper(II) chelate, VII, was thus obtained and purified according to the same procedure as described for the preparation of the chelate V. Found: C, 64.19; H, 5.06; N, 6.95%. Calcd for $Cu(C_{21}H_{20}O_2N_2)$: C, 63.72; H, 5.06; N, 7.08%.

Copper(II) Chelates of Glycylglycine-Schiff Bases (IX–XII). The preparation of these chelates were already reported.[4]

Bissalicylaldehyde-ethylenediiminocopper(II) (XIII), Bis-2-hydroxyacetophenone-ethylenediiminocopper(II) (XIV), and Bissalicylaldehyde-trimethylenediiminocopper(II) (XV), were prepared according to the method of Tsumaki *et al.*[5]

Bis-2-hydroxyacetophenone-trimethylenediiminocopper (II) (XVI). Two grams of bis-2-hydroxyacetophenone-trimethylenediimine was dissolved in 40 m*l* of acetone, and was mixed together with freshly precipitated copper(II) oxide, which had been obtained from 4.0 g of copper(II) sulfate pentahydrate. The mixture was stirred and heated at 60°C for four hours. After it had been filtered, the solution was cooled to give green crystals. This was recrystallized from acetone. Found: C, 61.61; H, 5.48; N, 7.56%. Calcd for $Cu(C_{19}H_{20}O_2N_2)$: C, 61.37; H, 5.38; N, 7.54%.

The Spectrophotometric Determination of Thorium(IV) with Bromopyrogallol Red*1,*2

Kôichi Tonosaki* and Takayoshi Sakai**,*3

*Chemical Department, Faculty of Science, Hirosaki University, Bunkyō-chō, Hirosaki

**Hirosaki High School, Shintera-machi, Hirosaki

(Received July 3, 1968)

Bromopyrogallol red reacts with thorium(IV) to form a stable complex with an absorption maximum at 645 mμ against a reagent blank. The maximum absorbance is obtained in the pH range of 5.6 to 5.9 when the solution is heated in a boiling water bath for 20 min. The color system obeys Beer's law in the range 6 to 106 μg of thorium in 25 ml. The molar absorptivity of the complex is calculated to be 5.0×10^4 at 645 mμ. The sensitivity of the reaction is 0.004 μg thorium per cm^2. The complex has the composition 1 to 2 in metal to ligand. The effect of diverse ions on the determination is also examined.

Bromopyrogallol red (5,5′-dibromopyrogallol sulfophthalein), which was first prepared by Vodak *et al.*[1] as a chromogenic dye-stuff, reacts with many metal cations to form colored complexes and has widely been used as a metallochromic indicator in complexometric titrations. The present paper describes a new spectrophotometric method for the determination of thorium(IV), using bromopyrogallol red as a color reagent.

Various dye-stuffs, including thorin,[2] neo-thorin,[2] quinalizarin,[3] naphthazarin,[4] quercetin,[5] eriochrome black T,[6] solochromate fast red,[7] arsenazo III,[8] xylenol orange[9] and methylthymol blue,[9] have been used as color reagents in the spectrophotometric determination of thorium. No work has been reported, however, on the reaction between thorium(IV) and bromopyrogallol red.

It was found that in the presence of excess reagent, thorium(IV) reacts sensitively with bromopyrogallol red under heating to form a stable complex with a metal to ligand ratio of 1 to 2. This work was done to determine optimum conditions for the spectrophotometric determination of thorium(IV).

Experimental

Reagents. *Standard Thorium(IV) Solution.* About 1×10^{-2} M thorium(IV) solution was prepared by dissolving guaranteed reagent thorium(IV) nitrate tetrahydrate in about 0.1 N nitric acid. The solution was

*1 This work was presented at the Tohoku Branch Meeting of the Chemical Society of Japan, Hirosaki, October, 1967.

*2 After this manuscript had been completed, the authors received a report by Vasilenko *et al.*[12] The report was on the spectrophotometric study of the interaction of thorium(IV) with BPR. They applied a sodium acetate-hydrochloric acid medium as the buffer solution. The range of mesurement for thorium was 2 to 60 μg per 25 ml with a 1 to 2 complex at pH 5.0 and 630 mμ. The sensitivity of the reaction and the effect of diverse ions was not given.

standardized by EDTA titration using xylenol orange[10] as an indicator. It was diluted with water to desired concentrations.

Bromopyrogallol Red (abbreviated BPR; MW, 558.16 as free acid) *Solution.* A 1×10^{-3} M BPR solution was prepared by dissolving the right amount of Dotite BPR reagent, which has been preserved in a desiccator overnight, in 50%v/v ethanol.

Stock solutions of diverse ions were prepared from their reagent grade chemicals in appropriate concentrations. A 0.25 M acetate buffer solution was also used for pH adjustment.

Apparatus. A Hitachi-Perkin Elmer spectrophotometer, model 139, was used with 1 cm glass cells. A Hitachi-Horiba glass-electrode pH meter, Model M-4, was used for pH measurement.

All measurements were carried out at 25±0.5°C.

Standard Procedure. To a sample solution containing up to 100 μg of thorium in a 50 m*l* Erlemeyer flask, 1.0 m*l* of a 1×10^{-3}M BPR solution and 10 m*l* of 0.25 M acetate buffer solution with a pH of 5.7 were added, and the solution diluted with water to about 20 m*l*. It was heated in a boiling water bath for 20 min. The solution was cooled with running water to room temperature, transferred to a 25 m*l* volumetric flask, and diluted to the mark with water. After the solution had been kept for 20 min at 25°C, the absorbance of the solution was measured at 645 mμ using the reagent blank as a reference.

Results and Discussion

Absorption Curves. The absorption curves of the solutions containing thorium(IV) and BPR at various pH values are shown in Fig. 1. These curves were obtained by measuring the absorbance of the colored solutions against the reagent blank which contained the same amount of BPR.

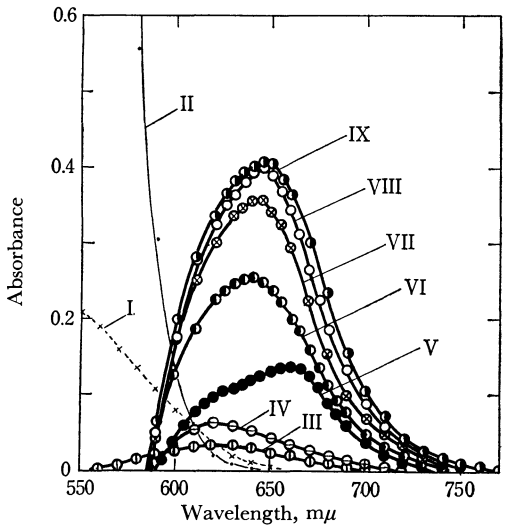

Fig. 1. Absorption cruves of BPR and its thorium complex in the presence of excessive reagent
BPR: 4.01×10^{-5} M, Th(IV): 47.1 μg in 25 m*l* (8.11×10^{-6} M), μ: 0.1. BPR *vs.* water — pH: I, 14.0; II, 6.22. Thorium-BPR complex *vs.* BPR — pH: III, 2.30, 4.10, IV, 4.60; V, 4.78; VI, 5.05; VII, 5.53; VIII, 5.60—5.95; IX, 6.05—6.30.

Below pH 4.6, the solution had an absorption maximum at about 620 mμ. The curves obtained at pH 4.8 (Curve V) had shoulders at about 630 mμ. Between pH 5.5 and 6.3, however, the solutions gave absorption curves with an absorption maximum at about 645 mμ. Therefore, it may be said that in the presence of excess BPR, two complexes are formed between thorium(IV) and the reagent; the complex with an absorption maximum at about 645 mμ was used for the determination of thorium.

The Effect of pH. The absorbance of the solution as a function of pH was measured at 645 mμ. From the curve shown in Fig. 2 (Curve I), it is found that the maximum absorbance is obtained in the pH range 5.6 to 6.2. Between pH 5.6 and 5.9, the absorbance of the solution remained almost unchanged for several hours, while above pH 6.0, the complex showed a tendency to precipitate when the solution was allowed to stand for more than about 2 hr. The color development was, therefore, made at pH 5.7.

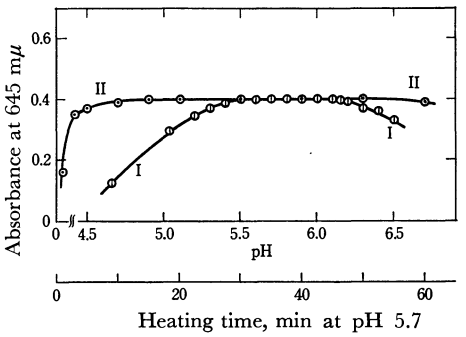

Fig. 2. Effects of pH and heating time.
I: pH, II: Heating time, Th(IV): 47.1 μg. BPR: 4.01×10^{-5} M, μ: 0.1, Reference: Reagent blank

The Effect of Heating Time. The color reaction of BPR with thorium(IV) is very slow at room temperature; several hours were required for complete color development. The effect of heating time on color formation was examined in a boiling water bath at a constant pH of 5.7. As shown in Fig. 2 (Curve II), maximum color development was obtained when the solution was heated for 15 to 40 min.

The Effect of the Amount of Reagent. The effect of the reagent concentration on color development was examined. It is seen in Fig. 3 that constant absorbance is obtained with 0.6 to 1.6 m*l* of a 1×10^{-3} M BPR solution. Therefore, 1.0 m*l* was chosen as the working volume of the reagent.

Color Stability. The absorbance of the solution prepared at pH 5.7 was measured as a function of time following the preparation of the solution.

Table 1. Comparison with other reagents

Reagent	Molar absorptivity $\times10^4$	Sensitivity μg/cm²
Bromopyrogallol Red	5.08(645 mμ)	0.004
Thorin[2]		0.03(545 mμ)
Neo-thorin[2]		0.02(600 mμ)
Quinalizarin[3]		0.02(590 mμ)
Naphthazarin[4]	2.24(620 mμ)	0.01
Quercetin[5]	3.30(422 mμ)	0.007
Eriochrome Black T[6]	3.50(700 mμ)	0.004
Solochromate Fast Red[7]	1.39(490 mμ)	0.017
Arsenazo III[8]	13.00(665 mμ)	
Xylenol Orange[9]	7.70(568 mμ)	0.003
Methylthymol Blue[9]	3.94(568 mμ)	0.006

There was no change in absorbance over a period of 24 hr.

Calibration Curve. From the foregoing results, a calibration curve for the determination of thorium was prepared in the manner described above. Figure 4 shows that Beer's law is obeyed over the range 6 to 106 μg (0.2 to 4.2 ppm) of thorium at 645 mμ and pH 5.7. According to Sandell's notation,[11] the sensitivity of the reaction is 0.004μg of thorium per cm². The molar absorptivity is calculated to be 5.08×10^4. The latter two values were compared with those of other methods as listed in Table 1. This indicates that the proposed method is less sensitive than the arsenazo III method.[8] However, it compares with the xylenol orange method[9] in sensitivity. The reproducibility of the method was examined using a solution containing 47.6 μg of thorium. From data obtained from twelve determinations, the standard deviation was calculated to be 0.0036 (0.88%) in absorbance.

The Effect of Diverse Ions. The effect of diverse ions on the determination of thorium was examined. The results are summarized in Tables 2 and 3, from which it is seen that cobalt(II), nickel(II), zinc(II), strontium(II), sulfate and chloride ions do not interfere, but many other ions, especially aluminum(III), lanthanum(III), zirconium(IV), yttrium(III), cadmium(II), fluoride,

Composition of the Complex. Attempts were made to characterize the thorium(IV)-BPR complex by two usual methods, the continuous variation method and the mole ratio method. These experiments were performed at a constant pH value of 5.7. Absorbance measurements were made at four wavelengths between 620 and 680 mμ. As shown in Fig. 5, the results obtained with the method of continuous variations indicate that thorium(IV) forms chiefly a 1 to 2 complex with BPR at pH 5.7. The results obtained with the mole ratio method (Fig. 6) show that a 1 to 1 complex is also formed under the same conditions. It may be concluded, therefore, that depending on the amount of reagent, two complexes of different compositions, 1 to 1 and 1 to 2, are formed between thorium(IV) and BPR. It was found, moreover, that another 1 to 1 complex with an absorption maximum at 550 mμ was formed in the pH range 1.3 to 4.2.

The authors wish to thank Dr. Makoto Otomo for his discussion and Mr. Kôichi Tanaka and Takaaki Ôsaga for their assistance. This investigation was partly supported by a grant from the Ministry of Education.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 460—464 (1969)

Two-dimensional Dual-band Thin-layer Chromatographic Separation of Polynuclear Hydrocarbons

Hidetsuru MATSUSHITA and Yasutomo SUZUKI

National Institute of Industrial Health, Kizuki-Sumiyoshi, Kawasaki

(Received July 13, 1968)

A two-dimensional dual-band thin-layer chromatographic procedure for the separation of a mixture containing many polynuclear hydrocarbons is described. A chromatoplate composed of two adsorbent layers, aluminum oxide G and acetylated cellulose, is used in this chromatography. A sample containing various polynuclear hydrocarbons is first developed on an aluminum oxide G layer with *n*-hexane - ether (19 : 1, v/v) and then on an acetylated cellulose layer with methanol-ether-water (4 : 4 : 1, v/v). A mixture of 15 polynuclear hydrocarbons was completely separated into its components by this treatment. This method was then applied to the separation of a vacuum-sublimation extract of particulates obtained from Tokyo air. The extract was separated into 69 spots, and it was proved that several hydrocarbons, including benzo(*a*)pyrene, has been isolated in a pure state.

The separation and determination of polynuclear hydrocarbons including benzo(*a*)pyrene, a potent carcinogen, in urban air pollutants is of importance in relation to the rapid increase in lung-cancer mortality in many countries in the world within the last 30 years. Thin-layer chromatography has recently attracted much attention in connection with the separation of the hydrocarbons, and several methods have been reported.[1-12] However, these methods do not seem to give a satisfactory separation for a sample containing many polynuclear hydrocarbons, such as an extract from air pollutants. For example, thin-layer chromatography using aluminum oxide G as the adsorbent and *n*-hexane-ether (19 : 1,v/v) as the developing solvent gives a good separation of a mixture of phenanthrene, pyrene, perylene, and dibenzo(*a*,*h*)anthracene, but it gives only a poor separation for a mixture of benzo(*a*)pyrene, benzo(*b*)fluoranthene, perylene, and benzo(*e*)pyrene. On the other hand, chromatography using a partially-acetylated cellulose as the adsorbent and methanol-ether-water (4 : 4 : 1,v/v) as the developing solvent gives a good separation for the latter mixture, but a poor separation for the former.

This paper is concerned with a new method for the two-dimensional thin-layer chromatographic separation of a complex mixture of polynuclear hydrocarbons. The thin-layer chromatoplate in the present method is composed of two adsorbent layers, aluminum oxide G and acetylated cellulose. The former layer is used in the first development, and the latter, in the second development.

Experimental

Hydrocarbons. The polynuclear hydrocarbons tested were anthracene, phenanthrene, pyrene, benzo(*a*)anthracene, chrysene, benzo(*e*)pyrene, benzo(*b*)fluoranthene, benzo(*a*)pyrene, perylene, anthanthrene, benzo(*ghi*)perylene, dibenzo(*a*,*h*)anthracene, coronene, dibenzo(*a*,*i*)pyrene, and benzo(*k*)fluoranthene. The benzo(*b*)fluoranthene was a kind gift to us from Dr. B. T. Commins (MRC Air Pollution Research Unit, St. Bartholomew's Hospital Medical College, London). The benzo(*e*)pyrene and benzo(*k*)fluoranthene were kindly presented by Professor M. Kuratsune(Kyushu University, Japan). The other hydrocarbons were obtained from the Koch-Light Co., Ltd., London.

Adsorbents. Aluminium oxide G acc. to Stahl (E. Merck) and 26% acetylated cellulose were used

as the adsorbents. The latter adsorbent was prepared by the acetylation of cellulose powder by the method of Wieland, Lüben, and Determann.[3] Camag's cellulose powder D for thin-layer chromatography was dried at 110°C for 30 min and then cooled in a desiccator containing concentrated sulfuric acid. The dried cellulose powder (30 g) was then acetylated in a mixed solution of benzene (675 m*l*), acetic anhydride (225 m*l*), and concentrated sulfuric acid (0.9 m*l*). Twenty-six percent acetylated cellulose was obtained by the reaction at 70°C for 9 hr. The cellulose was washed by methanol and ether and dried completely in an electric furnace at about 80°C.

Applicator and Coating. A chromatoplate with two adsorbent layers of aluminium oxide G and acetylated cellulose was prepared by the use of the applicator shown in Fig. 1. This is analogous to the applicator devised by Gilmore and Cortes.[13] The trough of the applicator (20 cm × 3.6 cm) was divided into two parts by a strip of stainless steel inserted into the grooves of the front and rear gates of the applicator. One part of the divided trough had the dimensions of 16 cm × 3.6 cm, and the other part, 4 cm × 3.6 cm. The strip-end in contact with the glass plate was shaped like a knife edge.

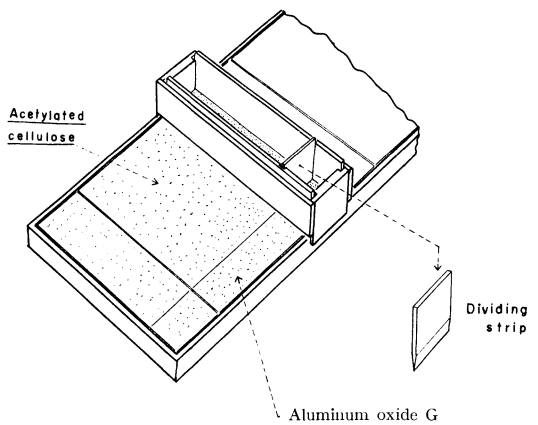

Fig. 1. Applicator for preparing dual band thin layer chromatoplate.

Slurries of the adsorbents were prepared by mixing them with a 10% methanol aqueous solution. The mixing ratio of the adsorbent to the methanol solution was 7 : 11 (g/m*l*) for aluminum oxide G and 10 : 45 (g/m*l*) for acetylated cellulose.

A slurry of aluminum oxide G was poured into the smaller part of the trough, and a slurry of acetylated cellulose, into the larger part of the trough. Then, they were immediately spread over glass plates (20 cm × 20 cm) in a thickness of 300μ. This gave a chromatoplate consisting of an aluminum oxide G layer (4 cm × 20 cm) and an acetylated cellulose layer (16 cm × 20 cm). The boundary line between the two adsorbent layers was very sharp. After having been left for about 3 hr for superficial drying at room temperature, the chromatoplate was activated by heating it at 110°C for 1 hr. The activated plate was then stored in a chamber kept at a relative humidity of about 20%. The humidity was easily controlled by putting a petri-dish containing a saturated potassium acetate aqueous solution on the bottom of the chamber.

Sample Application. A mixture of polynuclear hydrocarbons was applied to the lower left corner of the aluminium oxide G layer at a point 15 mm from the bottom of the layer and 10 mm from the layer boundary. The relative humidity of the atmosphere in the spotting box was kept at about 20% by putting a petri-dish containing a saturated potassium acetate aqueous solution into the box. The amounts applied to the layer were in the range of 0.03—0.4μg for each polynuclear hydrocarbon.

Development and Detection. The first development was carried out on the aluminum oxide G layer in a paper-lined chamber equilibrated with freshly-prepared *n*-hexane - ether (19 : 1, v/v) and also with a saturated potassium acetate aqueous solution. The development was continued until the front of *n*-hexane - ether (19 : 1, v/v) reached 150 mm. The developing time was about 35 min. The plate was then removed from the chamber, air-dried for about 5 min, rotated 90°, and inserted into the second chamber which had been equilibrated with freshly-prepared methanol-ether-water (4 : 4 : 1,v/v). The second development was continued until the solvent front reached 100 mm from the layer boundary. The developing time here was about 55 min.

The spots separated on the chromatoplate were detected by means of their fluorescence under ultraviolet light. All the polynuclear hydrocarbons except chrysene and phenanthrene were detected under long-wave ultraviolet light (365 mμ). Chrysene and phenanthrene were detected under short-wave ultraviolet light (253 mμ). The irradiation time of the short-wave ultraviolet light should be made as short as possible in order to prevent the photochemical decomposition of polynuclear hydrocarbons.

Results

Separation of Polynuclear Hydrocarbons. The R_f values of the 15 hydrocarbons are listed in Table 1. The hydrocarbons which had overlapped each other on the aluminum oxide G layer upon the first development were adequately separated by the second development on the acetylated cellulose layer. This is clearly demonstrated in Fig. 2.

It must be noted that the first development on the aluminium oxide layer should be carried out in a chamber kept at a constant relative humidity of about 20%, because the R_f values of the hydrocarbons are highly affected by the humidity of the atmosphere in a developing chamber.[14,15] Development at a higher or at a lower humidity gave an unsatisfactory separation of the polynuclear hydrocarbons, as is shown in Table 1.

* R_f values were mean of 3 determinations. Deviation of each R_f value from the mean value was within 0.03. Developing temperature was 18 ± 2°C.

** Repeated development was carried out on acetylated cellulose layer with intermittent drying of 10 min in a room.

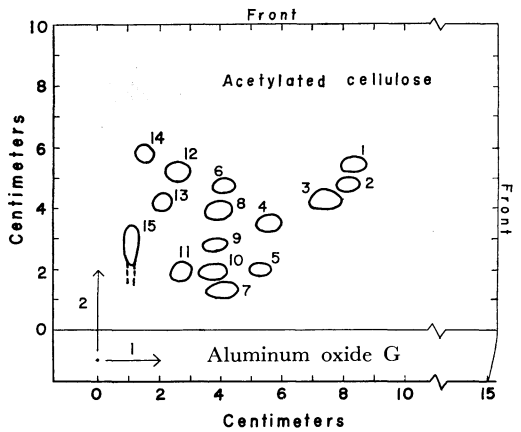

Fig. 2. Two-dimensional dual band thin layer chromatogram of polynuclear hydrocarbons.
The number of each spot corresponds to that of polynuclear hydrocarbon cited in Table 1.

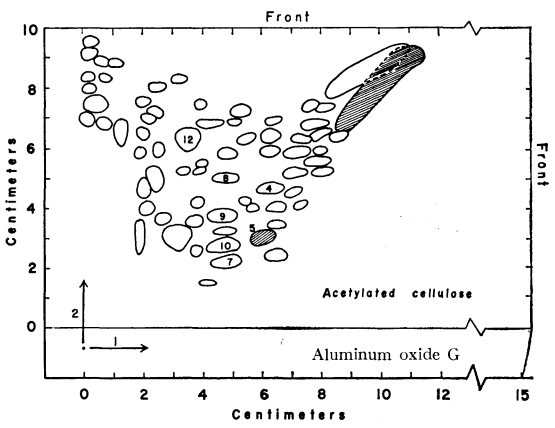

Fig. 3. Two-dimensional dual band thin layer chromatogram of vacuum sublimation extract from suspended particulates in Tokyo air.
Separation on acetylated cellulose layer was carried out by developing the plate three times to the 10 cm mark in methanol-ether-water with intermittent drying of 10 min in a room. The number indicated for several sports corresponds to that of polynuclear hydrocarbons cited in Table 1. The spot with oblique lines is that detected by short-wave ultraviolet light irradiation.

In the second development, spots of polynuclear hydrocarbons on the aluminum oxide G layer migrated rapidly with a rise in the solvent front, were deformed to a very small shape like a hairline on the layer boundary, and then were further separated into several spots on the acetylated cellulose layer. Since the spots separated on the acetylated cellulose layer took small, oval shapes, a high separability and detectability were obtained.

Separation of an Extract from Air Pollutants. The present method was used in the separation of an extract from air pollutants in Tokyo. Suspended particulates in Tokyo air were collected on a glass fibre filter (Gelman A, Gelman Instrument Co.) using a high-volume air sampler (Staplex Co.). The polynuclear hydrocarbons in

the particulates were extracted by vacuum sublimation, which had been proved to be more advantageous than solvent extraction for the extraction of polynuclear hydrocarbons.[16-18] The vacuum sublimation was carried out for about 30 min under conditions of 300°C and 0.007 mmHg for the particulates (185.5 mg) collected on a glass fibre filter. The sublimate which deposited on the narrow range of the inner surface of the sublimation tube (2 mm in inner diameter)was easily dissolved by 180 μl of benzene inserted into the tube by a microsyringe. Two microliters of the solution were used for the separation by the present thin-layer chromatography. Figure 3 shows the chromatogram for the sublimation extract of particulates in Tokyo air. Sixty-nine spots were detected on the chromatogram by means of their fluorescence under long- or short-wave ultraviolet light. A spot containing benzo(*a*)pyrene which had been obtained by the first development was further separated into 9 spots by the second development. The fluorescence and excitation spectra of the benzene extract of the spot corresponding to benzo(*a*)pyrene were entirely coincident with the spectra of the pure benzo(*a*)pyrene solution, as is shown in Fig. 4. Other polynuclear hydrocarbons, such as benzo(*b*)-fluoranthene, benzo(*k*)fluoranthene, perylene, benzo(*ghi*)perylene, chrysene, and benzo(*a*)anthracene, were also proved to be isolated in a pure state from the sublimation extract by spectrofluorometry.

Discussion

The present chromatography has some advantages for the separation of polynuclear hydrocarbons over the hitherto-reported thin-layer chromatographies which use a single adsorbent layer.[1-12] The separation efficiency is high, since spots of the hydrocarbons are scattered all over the acetylated cellulose layer in the present method. The high separation efficiency comes from the combined use of the two adsorbent layers which are different in separation characteristics. Another advantage of the present method is the high sensitivity. For example, the minimum detectable value of benzo-(*a*)pyrene is 0.001 μg or less in the present method, while the value is 0.007 μg in the one-dimensional chromatography using silica gel as the adsorbent layer and *n*-hexane - *o*-dichlorobenzene - pyridine (10 : 1 : 0.5,v/v) as the developing solvent.[6] This high sensitivity comes from the combined use of two different chromatographies; adsorption chromatography in the first and partition chromatography in the second development. The adsorption force of aluminium oxide G for the hydrocarbons is very much weakened by the second developing solvent, which contains water as one component, as may easily be understood from the facts that the R_f values of the hydrocarbons on the aluminum oxide layer are highly affected even by the moisture content in a developing chamber and increase remarkably with an increase in the moisture content.[14,15] For these reasons, the spots on the aluminum oxide G layer are rapidly transferred to the boundary between the two adsorbent layers as very small, hairline-like spots and then separated into components on the acetylated cellulose layer with the rise of the second developing solvent. The hairline-like spots cause very small oval spots on acetylated cellulose after the second development, resulting in the enhancement of the sensitivity in the detection of polynuclear hydrocarbons.

Furthermore, the fluorescence intensities of the hydrocarbons on the acetylated cellulose layer are not much reduced even after having been left for a prolonged period in a dark room, although the fluorescences on the aluminum oxide layer change in color and are reduced remarkably in intensity by the same treatment.

In the present method, the two adsorbents should be so selected as to equalize approximately the moving speeds of the first developing solvent on the two layers. If the moving speeds differ markedly, the spots of hydrocarbons on the aluminum oxide layer will be found on a heavily-curved line after the first development, as is illustrated schematically in Fig. 5. This often has an adverse effect on the separation. For this reason, we selected acetylated cellulose prepared from cellulose D (Camag) as the adsorbent in the second development. Acetylated cellulose prepared from cellulose D-O (Camag) and MN 300 acetylated cellulose (M. Nagel) were not suitable for the adsorbent in this method, because the moving speeds of the first developing solvent on these cellulose layers

were considerably higher than that on the aluminum oxide G layer.

In an accurate determination of the benzo(*a*)pyrene in air pollutants, it should first be isolated completely from the other hydrocarbons. However, the benzo(*a*)pyrene fraction obtained by the column, paper or thin-layer chromatography, which is ordinarily used, is frequently contaminated by other hydrocarbons, some of which interfere with an accurate determination of the benzo(*a*)pyrene. The benzo(*a*)pyrene fraction obtained by the present chromatography was completely isolated from such hydrocarbons as benzo(*k*)fluoranthene, benzo(*e*)pyrene, benzo(*b*)fluoranthene, and perylene, and proved to be spectrofluorometrically pure. Thus, the present method may also make possible an accurate determination of the benzo(*a*)pyrene in air pollutants.

Effects of the Addition of Chlorohydrocarbons on the Oxidation of Propylene*1; A Consideration of the Negative Temperature Coefficient

Mitsuo MASAI, Etsuro ECHIGOYA*2 and Kiyoshi MORIKAWA*3

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo

(Received June 15, 1967)

A small amount of allyl chloride, 1,1-dichloroethane, or chloroform was added to the reactant in the oxidation of propylene in an inert fluidized-bed reactor. A negative temperature coefficient is observed in the conversion of propylene and in the formation of various products, but not propylene oxide, in the experiments with allyl chloride or 1,1-dichloroethane added. The results of the chloroform-adding experiments show a positive temperature coefficient in the conversion of propylene and in the formation of gaseous products. The results of the work described here are discussed on the basis of the probable reaction scheme. The results of the chloroform-adding experiments support the proposed catalytic effect of the chlorocarbene on the decomposition of acetaldehyde. It is concluded that the negative temperature coefficient is attributable to the apparent inactivity of acetaldehyde (the branching agent) in the high-temperature region in this reaction atmosphere.

Previous works[1,2] using an inert fluidized-bed reactor have shown that a very pronounced negative temperature coefficient is observed in the conversion of propylene and in the formation of acetaldehyde, propylene oxide, acrolein, propionaldehyde, carbon monoxide, methane, and ethylene in an excess-propylene atmosphere. The purpose of the present paper is to describe the results of oxidation experi-

ments featuring the addition of allyl chloride, 1,1-dichloroethane, or chloroform to the reactant (propylene and oxygen) using an inert fluidized-bed reactor, and also to discuss the cause of the negative temperature coefficient on the basis of the reaction scheme reported previously.[2,3]

In the same reaction system, Kamiya studied the effects of the addition of chloroform or other halogenated hydrocarbons to the reactant;[4] his results showed the acceleration of the reaction by the addition of these substances. Hurst, Skirrow, and Tipper accounted for the low overall activation energy in terms of the enhanced decomposition of hydroperoxide by the hydrogen bromide added in the oxidation of butene.[5] Seakins demonstrated the strong accelerating effect of chloroform on the chain propagation in the oxidation of propane.[6]

There have been many discussions of the negative temperature coefficient.[7] Among these, Yenikolopyan discussed it in terms of the decrease in branching resulting from the decomposition of the hydroperoxy, the acetyl, and the acetyl peroxy radicals in the oxidation of propylene.[7] Shtern demonstrated that, in the oxidation of propane, the induction period was shortened by the addition of acetaldehyde to the reaction system in the low-temperature region, but no effect was observed in the high-temperature region.[8] McMillane and Calvert showed that the estimated rate constants of the oxidation of the acetyl radical were 0.7×10^{8} $l\cdot mol^{-1}\cdot sec^{-1}$ at 290°C and 3.8×10^{8} at 36°C;[9] these values were obtained on the postulation that the rate constant of the decomposition reaction of the acetyl radical increases normally with an increase in the temperature. Seakins and Hinshelwood discussed the observed maximum of the rate against the temperature on the basis of a kinetic study.[10]

In the present work, experiments featuring the addition of allyl chloride or 1,1-dichloroethane showed a temperature dependence of the reaction results, except in the formation of propylene oxide, similar to that observed in the previous works.[1,2] A different temperature dependence was, however, observed in the chloroform adding experiments. The results obtained will be discussed on the basis of a reaction scheme reported before.[2,3] It will be concluded that the negative temperature coefficient is attributable to the apparent inactivity of acetaldehyde (the branching agent) at a high temperature in this reaction atmosphere.

Experimental

Materials. The allyl chloride and the 1,1-dichloroethane, both of G. R. quality, were obtained from the Tokyo Kasei Kogyo Co., Ltd. (Tokyo). The chloroform, containing 1% of ethanol as a stabilizer, was obtained from the Wako Junyaku Kogyo Co., Ltd. (Osaka). The propylene gas, the oxygen, and the silicon carbide have been described before.[1]

Apparatus. This was as has been described for Exp. A in a previous paper.[2]

Procedures. These were as have been described for Exp. A in a previous paper.[2] The concentrations of the additives were 0.50—0.58 vol% for the allyl chloride, 0.48—0.55 vol% for the 1,1-dichloroethane, and 0.50—0.55 vol% for the chloroform, according to the reaction temperature.

Analysis. This was done as has been described for Exp. A in a previous paper.[2]

Results

The results of the oxidation experiments are shown in Figs. 1—9. In these figures, the full lines with black points are for the oxidation experiments with the additives, while the dotted lines with open points are for the oxidation experiments without the additives (standard experiment).

The additions of allyl chloride and 1,1-dichloroethane gave similar results, as is shown in Figs. 1 and 4, 2 and 5, and 3 and 6. The remarkable difference due to the additives is the increase in the yield of propylene oxide with the rise in the temperature (Figs. 1 and 4). Methane and ethylene are increased by these additives (Figs. 2 and 5). The amount of carbon monoxide and the conversion of propylene are increased by these additives (Figs. 3 and 6). Negative temperature coefficients are observed in these experiments except in the case of propylene oxide (Figs. 1—6).

Considerable differences are observed between the chloroform-adding experiments and the standard experiment as is shown in Figs. 7—9. Acetaldehyde (AA) and propylene oxide (PO) are considerably decreased at a high temperature. While acrolein (Acr) and propionaldehyde (PA) are increased slightly at a higher temperature (Fig. 7), the results for Acr and PA are nearly the same as the results shown in Figs. 1 and 4. The temperature co-

efficients for the formations of methane, ethylene (Fig. 8), carbon monoxide, and carbon dioxide, and for the conversion of propylene (Fig. 9) are reversed by the addition of chloroform. Ethylene is increased in all the experiments with additives (Figs. 2, 5, and 8).

Discussion

As has been described above, the lowest temperature at which the reaction occurs is not affected by the addition of allyl chloride, 1,1-dichloroethane, or chloroform. These facts indicate that these additives do not affect the initiation step. The considerable differences observed between the results of the adding experiments and the standard experiment show that these additives remarkably affect the reaction in the early steps of the chain.

The results described above will be discussed

below on the basis of a reaction scheme reported before.[2,3] The main part of the scheme is shown in Table 1. In this scheme, PO is mainly formed *via* AA in an excess-propylene atmosphere as has been discussed before.[2],*4

Effects of the Addition of Allyl Chloride and 1,1-Dichloroethane. While nearly the same results are obtained by the addition of these two additives, the forms of their decompositions are different; *i. e.*, one is radical, and the other is monomolecular:[11]

$$CH_2{=}CHCH_2Cl \rightarrow CH_2{=}C\dot{H}CH_2 + \dot{C}l$$
$$CH_3CHCl_2 \rightarrow CH_2{=}CHCl + HCl$$

The chlorine atom most likely reacts with propylene to form hydrogen chloride and the allyl radical, and also probably recombines into chlorine. Hydrogen chloride is produced by both these additives.

*4 There may be some objection to this previously obtained conclusion.[2] The objection will be that, under the conditions of Exp. B_1 of the previous paper,[2] bromine or bromine compounds may interfere with the formation of PO. This objection cannot be sustained, however, because the interaction between bromine or bromine compounds and PO can be neglected, as has been discussed in "*4" in a previous paper,[2] and also because the addition reaction of the bromine atom to the double bond of propylene does not interfere with the same addition reaction of the allyl peroxy radical, for an excess of propylene is present in the reaction atmosphere.[2]

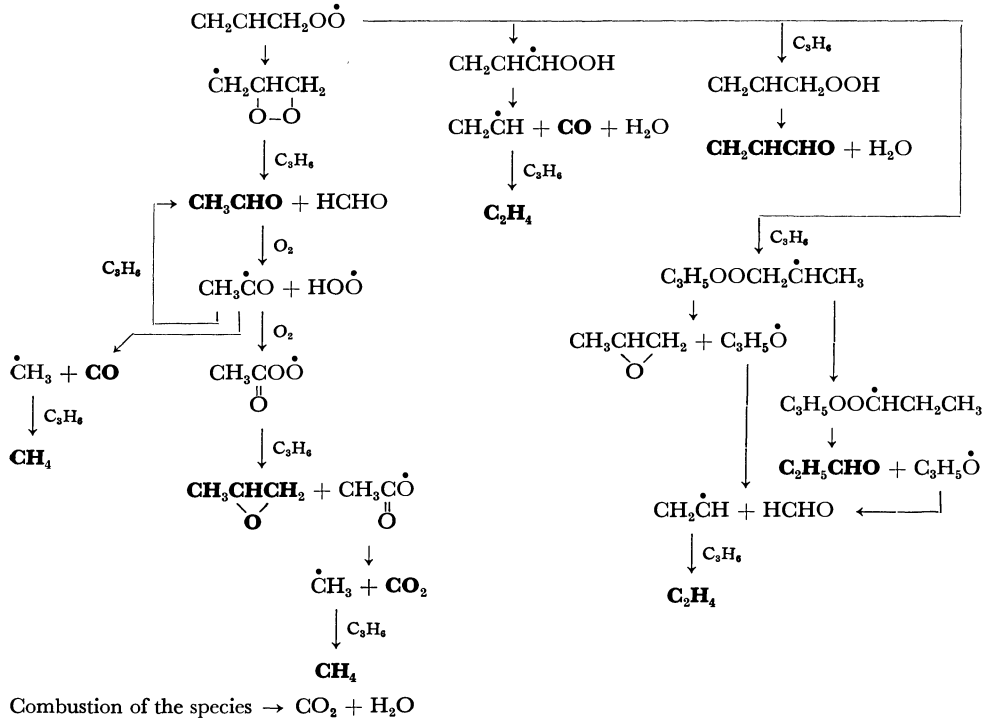
Table 1. The main part of the scheme[2)]



Quite similar results are obtained in these two adding experiments; this suggests that the hydrogen chloride is a predominantly effective species in both these experiments.*5 The increase in the formation of methane and carbon monoxide may be attributed to the enhanced decomposition of AA, as hydrogen chloride is known to accelerate the decomposition of AA slightly.[13)] The yield of AA is little affected by the presence of these two additives or, therefore, by the presence of hydrogen chloride (Figs. 1 and 4). This suggests that the true amount of AA formed should be increased, if we consider the increased consumption of AA resulting from the enhanced decomposition. The amount of ethylene, which is mainly formed from the allyl peroxy radical (Table 1), is also increased (Figs. 2 and 5). These increase in the formation of AA and ethylene may indicate an increased formation of the allyl peroxy radical. If so, the increased conversion of propylene can be explained in terms of the increased formation of the allyl peroxy radical. The degree of the increase in the formation of ethylene is less than those of methane and carbon monoxide at 460°C in the two adding experiments. This indicates that the reaction of the allyl peroxy radical to AA becomes predominant in comparison with the reaction to ethylene at 460°C.

The most notable feature in these two adding experiments is the positive temperature coefficient observed in the formation of PO (Figs. 1 and 4). The positive temperature coefficient observed in the PO formation is mainly due to the increased formation of PO at 460°C in the two adding experiments. This increase can be ascribed to the increased formation of AA, as has been discussed above, because it has been suggested that PO is formed mainly through the addition of the acetyl peroxy radical to the double bond of propylene.[2)] The low yield of PO in the 360—420°C region in the two adding experiments (Figs. 1 and 4) indicates that the increase in the formation of the allyl peroxy radical, discussed above, contributes only a little to the formation of PO. The route to PO *via* the addition of the allyl peroxy radical to the double bond of propylene has already been established to be minor.[2)] The true amount of AA formed is certainly smaller at 360—420°C, as has been discussed above; This is the reason for the low yield of PO in this temperature region.

The Effects of Chloroform. Contrary to the case with the standard experiment, and also to the former two adding experiments, the positive temperature coefficients of the conversion of propyl-

*5 In the case of 1,1-dichloroethane, the presence of vinyl chloride should be considered. The accelerating effect of vinyl chloride on propane oxidation has been reported.[12)] The resemblance of the results of the two adding experiments are so remarkable that it may be reasonable to consider the hydrogen chloride formed as the predominantly effective species.

12) M. Seakins, *Proc. Roy. Soc.*, **A277**, 279 (1964).
13) H. Fromherz, *Z. physik. Chem.*, **B25**, 301 (1934).

ene and of the formation of methane, ethylene, and carbon monoxide are observed in the chloroform-adding experiments. Decrease in the formation of AA and PO are noticed in the higher-temperature region.

For the decomposition of chloroform, two kinds of reactions have been reported.*6 Reaction (1) has been proposed in the presence of peroxide:[14a]

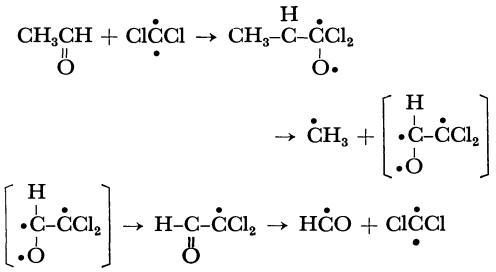
$$CHCl_3 \rightarrow \dot{C}Cl_3 + \dot{H} \qquad (1)$$

Reaction (2) has been reported to have an activation energy of 47 kcal/mol:[12]

$$CHCl_3 \rightarrow :CCl_2 + HCl \qquad (2)$$

The bond-dissociation energy of CCl_3–H is 95.7 kcal/mol.[15] Therefore, reaction (2) is more probably predominant.*7 The chlorocarbene $:CCl_2$ is an electrophilic and relatively stable radical.[14b] The chlorocarbene has been shown to add to double bonds such as C=C and C=N.[14b]

Therefore, it is reasonable to suggest the addition of the chlorocarbene to the carbonyl group of AA. The scheme of this suggested reaction is as follows;



Thus, the chlorocarbene is regenerated. This hypothetical catalytic action of the chlorocarbene on the decomposition of AA is supported by the results of the chloroform-adding experiments and also by a reaction scheme reported earlier[2] (Table 1). Here, the effect of hydrogen chloride is considered to be small in view of the results of the allyl chloride and 1,1-dichloroethane-adding experiments.

Table 2 shows that the addition of chloroform increased the formation of methane considerably in comparison with ethylene and carbon monoxide. In the case of the addition of allyl chloride or 1,1-dichloroethane, the increase in methane is not very obvious in comparison with ethylene and carbon monoxide. As a result of the reaction of the chlorocarbene and AA, only the formation of methane is increased. The decreases in AA and PO also support the catalytic effect of the chlorocarbene.

Table 2. Comparison of the effects of the additives on the formation of methane, ethylene and carbon monoxide at 420°C (the values for the standard experiments are taken as unity)

Product	Additive		
	$CHCl_3$	C_3H_5Cl	CH_3CHCl_2
CH_4	5.8	1.7	2.0
C_2H_4	3.3	1.6	1.7
CO	2.5	1.3	1.5

As has been discussed in the case of the former two additives, hydrogen chloride accelerates the oxidation reaction considerably at 360°C. In the chloroform-adding experiments at 360°C, only the value of ethylene varies from those of the standard experiment. Therefore, the decomposition of chloroform into the chlorocarbene and hydrogen chloride is not as sufficient at 360°C as at 420°C.

As has been shown in the discussions of the former two additives, the negative temperature coefficient of the oxidation reaction is observed in spite of the acceleration by hydrogen chloride. Because of the catalytic effect of the chlorocarbene on AA, which is the degenerate branching agent,[2,3] the main path of the oxidation reaction changed from I to II as below:

$$\text{I} \quad C_3H_5O\dot{O} \rightarrow AA \rightarrow PO$$

$$\text{II} \quad C_3H_5O\dot{O} \rightarrow AA \xrightarrow{:CCl_2} CH_4$$

Therefore, the change in the temperature coefficient from negative to positive is quite reasonable because of the increase in the concentration of the chlorocarbene with the rise in the reaction temperature.

Thus, the catalytic action of the chlorocarbene—though hypothetical—on the decomposition of AA changes these temperature correlations. The hypothetical reaction is the branching reaction, for number of radicals increases in the course of the reaction of AA with the chlorocarbene. This probably shows that the negative temperature coefficient is caused by the retarded reactivity of AA in the high-temperature region in this reaction atmosphere. This accords with Shtern's conclusion[8] described above, that AA does not behave as a branching agent in the temperature region where the negative temperature coefficient is observed. The cause of this inactivity of AA has not yet been elucidated.[8]

The authors wish to thank the Nippon Petrochemicals Co., Ltd., for supplying the propylene gas and also the Mitsui Mining and Smelting Co., Ltd., for supplying the silicon carbide.

*6 The route to $\dot{C}HCl_2$ is not considered here, because $\dot{C}HCl_2$ is not as stable as $\dot{C}HBr_2$[14a] and also because no precise and accurate value of D($CHCl_2$–Cl) can be found.

14) J. I. G. Cadogon and M. J. Perkins "The Chemistry of Alkene," ed. by S. Patai, Interscience Pub., London (1964), a) p. 589; b) pp. 640—642.

15) J. A. Kerr, *Chem. Rev.*, **66**, 465 (1966).

*7 The reverse reaction of reaction (1) is a radical recombination reaction: The activation energy for this reverse reaction is negligible. Therefore, the activation energy of reaction (1) is 95.7 kcal/mol.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 470—474 (1969)

The Reaction of Alcohols and Hydrocarbons in a Silent Electric Discharge. I. The Decomposition of 2-Propanol by the Discharge*1

Teruo HIRAKI

Institute of Commodities, Faculty of Economics, Kagawa University, Takamatsu

(Received April 2, 1968)

The reaction of 2-propanol under a silent electric discharge was studied using two kinds of discharge tubes. One was Siemen's tube, which was used for investigating a silent discharge decomposition of 2-propanol. The other was a special tube that had one side of the walls made of copper or its salts; it was used for studying the effects of the wall on the decomposition. The main liquid products were acetaldehyde, acetone, *dl*-2-butanol, 2-methyl-2-propanol, 2-methyl-2-butanol, and hydrocarbons. The gaseous products were methane, C_2—C_4-hydrocarbons, carbon monoxide, carbon dioxide, and hydrogen. These components were obtained in every run, regardless of the type of tube used. However, the distribution of the products varied with the sort of tube. The formation of 2-methyl-2-butanol can be explained by the addition of a 1-hydroxyisopropyl radical with the ethylene produced; the only product formed by adding this radical to ethylene was the one-to-one adduct. By replacing one side of the glassy walls with a wall of a glass-filter-packed copper or its salts, the yield of 2-methyl-2-propanol was increased relatively, and those of 2-methyl-2-butanol and *dl*-2-pentanol were decreased.

Kawamoto *et al.*[1] found that acrylonitrile and higher cyanides were produced by the reaction of prussic acid with ethylene in a silent electric discharge. The higher cyanides seem to be formed by a chain telomerization.

A similar telomerization may also occur in the discharge reaction of 2-propanol and ethylene, considering Urry's[2] research on the peroxide- and light-induced additions of several alcohols to olefins, and the fact[3,4] that the *α*-C-alkylations of primary and secondary alcohols result not only from peroxide- or light-induced reaction, but also from gamma-ray irradiation.

It would be interesting to ascertain if a silent electric discharge initiates the telomerization. In the present paper, preliminarily, the author wishes to report some observations on the chemical behavior of 2-propanol submitted to silent discharge, including a study of the effects on the reaction of a wall made of copper or its salts.

Experimental

Material. 2-Propanol was purified by column distillation after it had been refluxed over potassium carbonate. No impurity was found by gas chromatographical analysis using a 3-m column of PEG-6000.

Packing. The packing material shown in Table 1 was prepared by the method described in Kawamoto's[5] paper.

Discharge Tubes. The discharge tubes used are shown in Fig. 1-a. Two kinds of tubes, here simply noted as tube 1 and tube 2, were used.

Tube 1 was a Pyrex tube of the Siemen type[6] with a gap length of 2.5 mm and an effective length of 45 cm. The outside (B) of the discharge tube was filled with water, while the inner tube (A) was filled with a 3% $CuSO_4$ solution. Electrodes (C) were inserted into both (A) and (B).

Tube 2 was a Pyrex tube with a glass filter which had an effective length of 30 cm, an outside diameter of 2 cm, and a space gap 2.5 mm long. The outside (B) of the discharge tube and a glass filter (D) were filled with water and 5 g of the packing material respectively. Electrodes (C) were inserted into both (B) and (D).

Apparatus and Procedure. The experiment was performed by using the flow system and the reflux system. The apparatus for the flow system and the reflux system are shown in Figs. 2 and 3. The reduced copper for packing was prepared by passing purified

Fig. 3. The apparatus for a reflux system.

hydrogen on copper salt for 3—5 hr and at a velocity of 1.0—1.4 *l*/hr through the filter heated to 180°C. The apparatus for purifying hydrogen is illustrated in Fig. 1-b. Hydrogen coming from the reservoir (E) was passed through a tube (G) containing heated copper gauze in order to remove the oxygen in the hydrogen, and then through a bottle (H) containing a 30% sodium hydroxide solution and a solid sodium hydroxide tube (I). The hydrogen flow rate was measured by passing it through a calibrated flowmeter (F).

In the case of the flow system, as soon as the 2-propanol had fallen at a regular velocity from a dropping funnel (J) into a pot, a heater (K) turned it into vapor, which was then introduced into a discharge tube (M). The reaction products that passed through the tube were separated into a condensable part and non-condensable gases by three traps (N) cooled to 0°C.

In the case of the reflux system, 2-propanol in a still pot (P) was vaporized by heating it to 110°C; the vapor was then passed through the discharge tube (M). The reaction products passed through the discharge field were preliminarily separated into a condensable part and non-condensable gases by a condenser (O) kept at 55°C. The condensable products came back to the still pot again. The non-condensable part was further separated from the condensable products by two traps (N) cooled at 0°C. The volume of non-condensable gas was measured by a calibrated gas holder (Q).

The high tension was applied to the discharge tube from a transformer (L; capacity, 15 kV) which used a 60-cycle alternating current.

Analyses. The reaction products were identified by comparing their retention times on gas chromatography with those of authentic samples. The non-condensable products were analyzed by gas chromatography (column, 3 m activated charcoal at 100°C; carrier gas, hydrogen). For the analyses of C_3 and C_4-hydrocarbons and of hydrogen, a 3-m column of HMPA (Hexamethylphosphoric triamide) and a 3-m column of molecular sieve-13X were used at 35°C (carrier gas, helium).

The condensable products were identified not only by gas chromatography (column, tricresyl phosphate, PEG-6000 and silicon DC-550 at 100°C; carrier gas, helium), but also by derivatization. Thus, 2-methyl-2-propanol, obtained as a fraction boiling at 81—82°C, and *dl*-2-butanol (bp 99—100°C) were converted into their 3,5-dinitrobenzoates,*2 the melting points of the derivatives being 140—141°C and 75—76°C respectively. They showed no depression of the melting points when mixed with authentic specimens. The quantitative analysis of the liquid products was performed by gas chromatography (column, 3 m, PEG-6000 at 100°C; carrier gas, He).

Results and Discussion

The decomposition of 2-propanol was performed under the experimental conditions shown in Table 1; the reaction products which have been identified are listed in Table 2. The subscripts A and B in these tables indicate a flow system and a reflux

*2 The 3,5-dinitrobenzoates of 2-methyl-2-propanol and *dl*-2-butanol were prepared according to the procedure of Shriner *et al.*: R. L. Shriner, R. C. Fuson and D. Y. Curtin, "The Systematic Identification of Organic Compounds," 4th ed., John Wiley & Sons, New York (1956), p. 212.

** The yields of each compound produced were given by (grams of each compound per grams of total reaction product) × 100.

*** Hydrocarbons contain 2-methylbutane, 2,3-dimethylbutane, *n*-hexane, 1-hexene, *etc.*

system respectively.

In general, the reaction rate was too low under a reflux system to discuss chemismus.

When Siemen's Tube Was Used (Exp. Nos. 6_B and 7_A). The main liquid products formed in the decomposition of 2-propanol at 85°C were acetone, acetaldehyde, *dl*-2-butanol, 2-methyl-2-propanol, and 2,3-dimethylbutane. A small amount of 2-methyl-2-butanol was also formed.

The percentage compositions of compounds shown in Table 2 are the average of three experiments; the fluctuations in the yields of these compounds were less than 1%.

The main gaseous products which were formed in this reaction were methane, ethane, ethylene, acetylene, C_3 and C_4-hydrocarbons, carbon monoxide, carbon dioxide, and hydrogen.

The characteristic of the action of silent discharge on a compound seems to be the electronic excitation of the molecule. Some of the molecules may be transformed by inelastic collisions into vibrationally-excited molecules. The activated molecules thus formed are considered to change into radicals or atoms, and into a very small amount of ionized

TABLE 3. THE ASSUMED RADICALS AND REACTION SCHEME

$CH_3\dot{C}HCH_3 \xrightarrow{C_2H_4} CH_3CH(\dot{C}_2H_4)CH_3 \xrightarrow{i\text{-PrOH}} CH_3CH(C_2H_5)CH_3$ (6)

$CH_3\dot{C}HCH_3 \xrightarrow{\text{coupling}} (CH_3)_2CHCH(CH_3)_2$ (7)

molecules,*3 as has been reported by many workers.[7] The radicals assumed to be formed from 2-propanol under the silent discharge, and a part of the postulated reaction scheme, are shown in Table 3. The methyl radical can be thought to be formed not only in the formation process of the Radical III in Table 3, but also in the secondary reaction, since more methane*4 than acetaldehyde was produced in every run.

It can be thought that *dl*-2-butanol is formed by two processes: the combination of a methyl radical with a 2-hydroxypropyl radical (Reaction 3), and the addition of a 1-hydroxyethyl radical to the ethylene formed during the reaction (Reaction 5). Although the process of reaction (5) has been proposed in radiolysis,[3] reaction (3) is thought to be the main process for formation of *dl*-2-butanol in the present study, since the yields of C_2-hydrocarbons, including ethylene, are very low.

It has been reported by Bach[8] that the processes induced by the discharge reaction are similar to those induced by radiolysis. However, when present study (Exp. No. 6_B; at 15—32°C) is compared with the study of the radiolysis of liquid 2-propanol,*5 it is found that the glycols which were produced in the radiolysis were not formed by the discharge.

Much acetone and acetaldehyde were obtained in this reaction. This is similar to the case in the radiolysis of 2-propanol.[3] The dehydrogenation of 2-propanol to give acetone in radiolysis or photolysis has been postulated to occur through the 1-hydroxyisopropyl radical by Atkinson and Di,[9] or through the transfer of a pair of hydrogen atoms from 2-propanol by Raphael *et al.*[10] or McDonell.*5 In our reaction, the latter seems to be the main process (but not necessarily the only one) for forming acetone, because, were acetone formed by a process such as has been proposed by Atkinson and Di, some pinacols would be produced at the same time by the great quantity of the 1-hydroxyisopropyl radical formed.

Finally, the liquid hydrocarbons seem to be formed

*3 Devins and Burton found, in the decomposition of ammonia under a silent discharge, that the contribution of ionized molecules was very low; J. C. Devins and M. Burton, *J. Am. Chem. Soc.*, **76**, 2618 (1954).

*5 McDonell and Newton have been reported that the *G*-values of the products formed in the radiolysis of liquid 2-propanol were as follows: H_2 (2.71), C_1—C_4-hydrocarbons (1.76), total carbonyl (2.96), *vic*-glycols (0.39); W. R. McDonell and A. S. Newton, *J. Am. Chem. Soc.*, **76**, 4651 (1954). Spinks and Woods have discussed how the products of the radiolysis of liquid methanol are very similar to those of the radiolysis of methanol vapor, and so are those of the radiolysis of ethanol. Therefore, the products of the radiolysis of 2-propanol vapor are thought to be similar to those of the radiolysis of the liquid 2-propanol; J. W. T. Spinks and R. J. Woods, "An Introduction to Radiation Chemistry," John Wiley & Sons, New York (1964).

through the isopropyl radical, which may be derived from the excited 2-propanol.

Whan a Special Tube Filled with Copper or Its Salts Was Used. It has been discussed in detail by Semenov[11] how, in photolysis, the reaction products are greatly affected by the nature of the substances forming the wall, as well as by the size of the vessel. However, Inoue[12] found, in a discharge reaction, that the size of the vessel had no influence on the reaction rate. In order to check the wall effects on the decomposition of 2-propanol, the reaction was carried out in a tube packed with copper or its salts (all runs except Nos. 6_B and 7_A in Tables 1 and 2).

Comparing the Glassy Wall with a Wall of Copper or Its Salts. The product pattern was somewhat simplified by changing the glassy wall to a copper(II) hydroxide wall. For example, the gas chromatogram showed seventeen peaks for the products from the 7_A run, but only ten peaks for the 1_A run (PEG-6000, 100°C, He). Thus, the former contains more kinds of hydrocarbons and unidentified, high-boiling products than 1_A.

A similar product pattern was obtained in the presence of the other packing materials, too, except in the case of metallic copper. When the reaction was carried out in a tube with a metallic copper wall (Exp. No. 5_A), the percentages of all the liquid products except hydrocarbons and acetaldehyde were almost the same as with 7_A (using glass walls).

The reaction rate and the amounts of 2-methyl-2-butanol, *dl*-2-pentanol, and all the carbonyl compounds except methyl vinyl ketone were greatest when the glassy-wall tube was used.

Effects of Packing Substances. When the two reduced coppers, 1 and 2 (Exp. Nos. 2_A and 4_A respectively), were used as packing, as compared with the original copper salts (Exp. Nos. 1_A and 3_A), the following differences were noticed in the liquid products: (1) the acetone yield increased remarkably; (2) the yields of 2-methyl-2-propanol and methyl vinyl ketone decreased; and (3) the relative yields of *dl*-2-butanol, 2-methyl-2-butanol, and *dl*-2-pentanol were almost the same, regardless of the reduction treatment.

The reason why the 2-propanol excited by the discharge changes almost entirely into acetone in the presence of the reduced coppers is considered to be as follows: Metallic copper and reduced copper are effective catalysts for the dehydrogenation of alcohols.[13] Although these coppers behave excellently as catalysts, usually at a high temperature, Taylor[14] showed that the irradiation of radioactive rays makes a solid catalyst active, even at a low temperature, by destroying the catalyst poison, forming a positive hole on the surface, trapping electrons, *etc.* Similar effects might be brought about by the silent discharge.

2-Methyl-2-propanol, hydrocarbons, and methyl vinyl ketone were obtained in the highest yields when copper(II) hydroxide was used as packing (Exp. No. 1_A). This packing material aids in forming hydrocarbons especially. This fact implies that the C–O-bond breaking in 2-propanol occurs rather preferably in the presence of this material.

On the other hand, relatively much methyl vinyl ketone was produced in the presence of copper salts. This product may be formed by the combination of a vinyl radical with an acetyl radical. The acetyl radical can be thought to be formed by a secondary reaction of the acetone or acetaldehyde produced, since the photolysis[15] and the radiolysis[16] of acetone and acetaldehyde have been known to produce the acetyl radicals. The vinyl radical can be formed by the elimination of a hydrogen atom from the ethylene produced under a silent discharge, as has been suggested by Tsutsumi[17] and by Thomas *et al.*[18] The yields of ethylene, acetylene, 1-butene, and 1,3-butadiene in gaseous products were highest in the presence of copper salts. Therefore, the vinyl radical seems to be increased in those cases. For this reason, the methyl vinyl ketone may be obtained in the highest yield in the presence of copper salts.

The main conclusions to be drawn from these results are as follows: (1) Despite the different kinds of discharge tubes, the liquid products consisted of similar components, but the compositions of the products depend on the kind of tube. (2) The 2-hydroxypropyl radical was regarded as an important intermediate in the reaction. (3) The only radical addition product was the one-to-one adduct. (4) On the wall of copper(II) hydroxide, C–O-bond breaking in the 2-propanol occurred rather preferably upon the discharge. (5) Copper(II) hydroxide and hydroxide carbonate might give more of the vinyl radical than other materials. (6) Generally speaking, the selectivity was a little higher in the presence of packing than in its absence.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 475—478 (1969)

The Configuration of 6,8(9)-*p*-Menthadien-2,4-diols and *p*-Menthane-2,4-diols

Yoshitsugu SAKUDA

Chemistry Laboratory, Kochi Women's University, Kochi

(Received May 6, 1968)

The 6,8(9)-*p*-menthadien-*trans*-2,4-diol (I) and 6,8(9)-*p*-menthadien-*cis*-2,4-diol (II) were obtained by the oxidation of *l-cis*-carvyl acetate with selenium dioxide. The hydrogenation of each 6,8(9)-*p*-menthadien-2,4-diol gave a different pair of *p*-menthane-2,4-diols, one pair being *p*-menthane-2,4-diols (III and IV) from *trans*-2,4-diol (I) and the other pair being *p*-menthane-2,4-diols (V and VI) from *cis*-2,4-diol (II). The absolute configurations of the *p*-menthane-2,4-diols (III, IV, V and VI) were assigned as follows on the basis of the chemical evidence, the IR and NMR data, and the Cotton-effect sign of the oxidation products of these isomers: III, (1S : 2R : 4S); IV, (1R : 2R : 4S); V, (1R : 2R : 4R) and VI, (1S : 2R : 4R)-*p*-menthane-2,4-diol. The identification of these diastereoisomeric diols III–VI made possible the assignment of a configuration to diols I and II.

In previous papers[1,2] some 8(9)-*p*-menthendiols and 8(9)-*p*-menthen-aldols were prepared by the oxidation of 8(9)-*p*-menthen-ols and those acetates with selenium dioxide. The configuration of the reaction product was assigned on the basis of the chemical evidence and the IR spectra. Now new diols, 6,8(9)-*p*-menthadien-*trans*-2,4-diol (I) and 6,8(9)-*p*-menthadien-*cis*-2,4-diol (II), have been obtained from *l-cis*-carvyl acetate by selenium dioxide oxidation, followed by the saponification of the reaction product.

In a study of the mechanism by which olefins are oxidized with selenium dioxide, Schaefer and Horvath[3] and Olson[4] have shown that selenium dioxide or its conjugate acid acts as an electrophile and attacks a double bond, thus forming a carbonium ion. When Schaefer's mechanism is applied in the case of carvyl acetate the reaction process is as is shown in Fig. 1. This view of the mechanism of the oxidation appears to accord well with that by which the two diols, I and II, are produced.

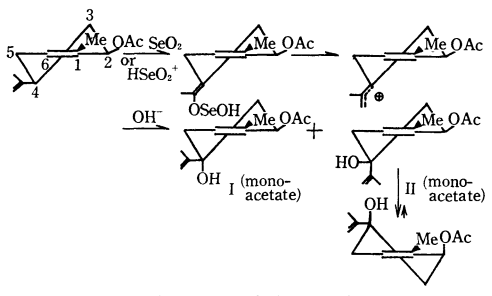

Fig. 1. Oxidation of *l-cis*-carvyl acetate.

The hydrogenation of the unsaturated diols, I and II, yielded four diastereoisomeric *p*-menthane-2,4-diols, III, IV, V, and VI. *p*-Menthane-2,4-diol, mp 93—94°C, was prepared by Wallach[5] by the catalytic hydrogenation of the 6-*p*-menthen-2,4-diol obtained by the hydration of sabinol. However, there has been no experimental evidence with respect to a spatial arrangement of the hydroxyl and methyl groups. This paper will report on the preparation and the configuration of these diols, I—VI.

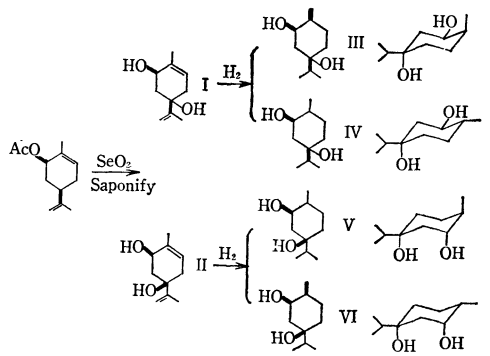

Fig. 2. The configurational assignment of 6,8(9)-*p*-menthadien-2,4-diols (I, II) and *p*-menthane-2,4-diols (III—VI).

6,8(9)-*p*-Menthadien-*trans*-2,4-diol (I) and -*cis*-2,4-diol (II). *l-cis*-Carvyl acetate was oxidized with a solution of selenium dioxide dissolved in *t*-butyl alcohol at room temperature. The diols, I and II, were separated by column chromatography from the saponified product of the less volatile part of the reaction mixture.

6,8(9)-p-Menthadien-trans-3,4-diol (I). The IR spectrum of I showed the bands at 898, 1650, and 3100 cm^{-1} due to the isopropenyl group and that at 3400 cm^{-1} due to the hydroxyl group. The NMR spectrum of I in chloroform-*d*, shown in Fig. 3a, exhibited well-separated signals; this is consistent with that spectrum expected for 6,8(9)-*p*-menthadien-ol.

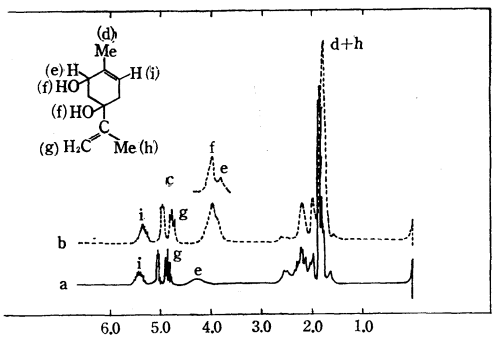

Fig. 3. NMR spectra of (a) I in $CDCl_3$ (——), (b) II in CCl_4 (-----) and (c) fragment of II in CCl_4 + C_6H_6 (-----).

6,8(9)-p-Menthadien-cis-2,4-diol (II). The IR spectrum of II showed the bands at 900, 1647, and 3100 cm^{-1} due to the isopropenyl group and that at 3360 cm^{-1} due to the hydroxyl group. The NMR spectrum of II in carbon tetrachloride shown in Fig. 3b was analogous with that of I except for the signal at δ 3.7—4.1 ppm. The NMR spectrum of II, measured in a mixed solvent of carbon tetrachloride and benzene, showed that the absorption at δ 3.7—4.1 ppm appears as two clear splitting signals, at δ 3.60 ppm due to the carbinol proton at the C-2 position and at δ 3.86 ppm due to two hydroxyl protons (Fig. 3c). It was assumed that a strong intramolecular hydrogen bond exists in II from the fact that the OH proton signal of II appeared at a lower field than that of I. The presence of the intramolecular hydrogen bond in II was further evidenced by the measurement of the IR spectra of I and II.[6] The IR spectrum of I in a dilute solution of carbon tetrachloride showed two bands, at 3635 (ε 49) and 3606 (ε 88) cm^{-1}; the lower-frequency band has a weak shoulder at 3590 cm^{-1}. The band at 3635 cm^{-1} is attributed to the free secondary hydroxyl group, and the band at 3606 cm^{-1}, to the hydroxyl group which interacts with the π-electron of the isopropenyl group.[7,8] The IR spectrum of II showed two bands, at 3612(ε 66) and 3550(ε 69) cm^{-1}; the higher-frequency band has a shoulder at 3595 cm^{-1}. The band at 3612 cm^{-1} is attributed to the free tertiary hydroxyl group, and the band at 3550 cm^{-1}, to the OH–O intramolecularly-hydrogen-bonded hydroxyl group. Considering the value of the difference between free and bonded OH bands, it was assumed that II is a *cis*-cyclohexene-1,3(2,4)-diol.[7a] Thus the NMR and IR data provided adequate evidence for determining the configuration of II to be 6,8(9)-*p*-menthadien-*cis*-2,4-diol. Furthermore, the fact that the configuration of each of the diols, I and II, is 6,8(9)-*p*-menthadien-2,4-diol was confirmed by the hydrogenation of I and II.

***p*-Menthane-2,4-diols III, IV, V and VI.** Upon the hydrogenation of the double bond, each of

the diols, I and II, would be expected to give two *p*-menthane-2,4-diols, a pair of diastereoisomers epimeric at the C-1 position. Indeed, the I diol gave two products, III and IV, and the II diol gave V and VI. The IR and NMR data for these four diastereoisomeric *p*-menthane-2,4-diols are shown in Table 1. The IR spectra of V and VI in a dilute solution of carbon tetrachloride showed the band at 3535 cm^{-1} due to the intramolecularly-hydrogen-bonded hydroxyl group. Considering the value of the difference between free and bonded OH bands, it was assumed that V and VI are *cis*-cyclohexane-1,3(2,4)-idol.[7a] The NMR spectra of V and VI, measured after adding one drop of concentrated hydrochloric acid to a chloroform-d solution, showed no broad absorption at δ 3.0 or 3.3 ppm. From this fact, the absorption at δ 3.0 or 3.3 ppm was assigned to the OH proton signal. The fact that the OH proton signals of both the V and VI diols appear at a lower field than those of III and IV can account for the presence of strong intramolecular hydrogen bonds in V and VI.

Then it was confirmed that each of four diols, III, IV, V, and VI was diastereoisomeric *p*-menthane-2,4-diol. The IR spectrum of each of the four compounds obtained by the oxidation of III, IV, V, and VI with Jones' reagent[9] showed the band at 1700 cm^{-1} due to the carbonyl group and that at *ca.* 3400 cm^{-1} due to the hydroxyl group. The IR spectrum of the oxidation product of III coincided with that of the oxidation product of V. Each of the four oxidation products of III, IV, V, and VI gave the same 2,4-dinitrophenylhydrazone (2,4-DNP), which was identified as carvenone 2,4-DNP by a direct comparison with an authentic sample. When a mixture of the oxidation product of IV, ethyl alcohol, and sulfuric acid was left to stand overnight under the same conditions as those under which 2,4-DNP was prepared, dehydration occurred and carvenone produced. This fact confirmed that when a 2,4-DNP was derived from each oxidation product of III, IV, V, and VI, dehydration occurred and that, consequently, only carvenone 2,4-DNP was produced from the four oxidation products. From these facts it was concluded that each original diol, III, IV, V, and VI, is diastereoisomeric *p*-menthane-2,4-diol.

Absolute Configuration of *p*-Menthane-2,4-diols III, IV, V and VI. The optical rotatory dispersion spectra of the three oxidation products of III, V, and VI with Jones' reagent are shown in Fig. 4.

The oxidation product of III exhibits a strong positive Cotton effect, the oxidation product of V exhibits a strong negative Cotton effect, and the oxidation product of VI exhibits a weak negative Cotton effect. Considering the Cotton-effect signs of these oxidation products, it was concluded that the oxidation products of III and V are enantiomer, and that the oxidation product of V possesses an axial methyl group at the C-1 position and that the oxidation product of VI possesses an equatorial methyl group at the C-1 position. Assuming that the conformations of these original diols are maintained throughout the oxidation procedure with Jones' reagent, the absolute configuration of each diol, III, IV, V, and VI, was assigned as is shown in Fig. 1; that is to say, III, IV, V and VI are (1S : 2R : 4S), (1R : 2R : 4S), (1R : 2R : 4R), and (1S : 2R : 4R)-*p*-menthane-2,4-diol respectively.

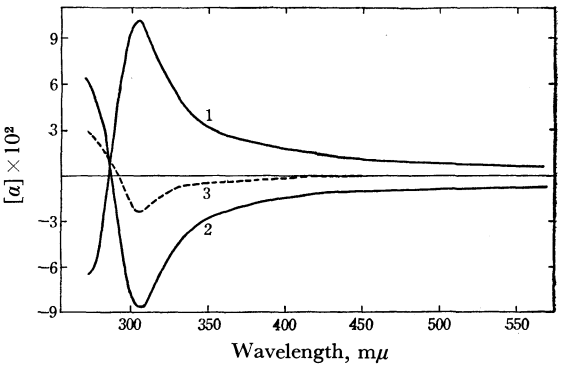

Fig. 4. Cotton effect of the oxidation products of III (curve 1), V (curve 2) and VI (curve 3).

Experimental

The NMR spectra were recorded with a Varian A-60 NMR spectrometer using TMS as the internal standard. The IR spectra in the 2500—4000 cm^{-1} region were determined with a Perkin-Elmer Model 621 grating spectrophotometer using a stoppered sodium chloride cell with a path length of 2.00 cm. The ORD spectra were determined in methanol with a Nippon Bunko ORD/UV-5 spectropolarimeter. The reaction products were analyzed by gas chromatography using a diethylene glycol succinate column at 150 and 190°C.

Samples. *l-cis-Carvyl Acetate.* *l-cis*-Carveol was prepared from *l*-carvone by reduction with lithium aluminium hydride[10] and was purified *via* its 3,5-dinitrobenzoate. Physical constants:[11] mp 23—24°C, bp 81—82°C/2 mmHg, n_D^{25} 1.4955, d_4^{25} 0.9524, $[\alpha]_D$ −24.4. *l-cis*-Carvyl acetate was prepared by refluxing the pure *l-cis*-carveol thus obtained with acetic anhydride and with anhydrous sodium acetate. Bp 90—92°C/2 mmHg, n_D^{25} 1.4731, d_4^{25} 0.9689, $[\alpha]_D$ −42.9.

6,8(9)-*p*-Menthadien-*trans*-2,4-diol(I) and -*cis*-2,4-diol (II). These two diols were prepared from *l-cis*-carvyl acetate by selenium dioxide oxidation as follows.

9) K. Bowden, I. M. Hellbron, E. H. H. Jones and B. C. L. Weedon, *J. Chem. Soc.*, **1946**, 39.

10) R. H. Reitsema, *J. Am. Chem. Soc.*, **75**, 1996 (1953).

11) R. G. Johnston and J. Read, *J. Chem. Soc.*, **1934**, 233.

A solution of *l-cis*-carvyl acetate (97 g, 1/2 mol) in benzene (97 g) was stirred, drop by drop, into a solution of selenium dioxide (28 g, 1/4 mol) dissolved in *t*-butyl alcohol (225 g, 3 mol). The temperature of the reaction mixture rose to 45°C. The mixture was then left to stand at room temperature overnight. After the solvent had been removed, the remaining product was distilled under reduced pressure, giving two fractions: 1 (bp 65—90°C/2 mmHg (28 g)) and 2 (bp 91—110°C/2 mmHg (19.2 g)). Fraction 1 consisted mainly of unchanged carvyl acetate. Fraction 2 was saponified and was then chromatographed on a silica-gel column, giving I and II. The yield of I plus II was 10% based on the sample used. I, mp 107—108°C, $[\alpha]_D$ +20.0 (*c* 3.7, ethanol). Found: C, 71.62; H, 9.87%. Calcd for $C_{10}H_{16}O_2$: C, 71.39; H, 9.58%. II, bp 110—111°C/2 mmHg, n_D^{25} 1.5045, d_4^{25} 1.0508, $[\alpha]_D$ +14.0 (*c* 11.8, ethanol).

(1R : 2R : 4R)-*p*-Menthane-2,4-diol (V) and (1S : 2R : 4R)-*p*-Menthane-2,4-diol (VI). A solution of II (1.6 g) in ethanol (50 cc) containing Raney Ni (*ca.* 2 g) was shaken for 8 hr at 40—60°C under a 100—110 atm. H_2 pressure. The total semisolid hydrogenation product (1.6 g) gave two peaks corresponding in those retention times to V and VI on the gas chromatogram. The area ratio of the peaks of V and VI was 7 : 2. After the filtration of the liquid compound, the remaining crystals were recrystallized from hexane. Three recrystallizations gave needles of V, mp 76.5°C. Found: C, 69.22; H, 11.48%. Calcd for $C_{10}H_{20}O_2$: C, 69.76; H, 11.62%. The liquid filtrate was chromatographed on an alumina column. Elution with a methanol-ether mixture (1 : 30) gave 35 fractions, which were then analyzed by gas chromatography. Fractions 1—16 consisted of the solvent alone. Fractions 17—20 gave the liquid diol, VI. Found: C, 70.30; H, 11.62%. Calcd for $C_{10}H_{20}O_2$: C, 69.76; H, 11.62%. Fractions 21—35 gave mixtures of V and VI.

(1S : 2R : 4S)-*p*-Menthane-2,4-diol (III) and (1R : 2R : 4S)-*p*-Menthane-2,4-diol (IV). *trans*-Diol (I) was hydrogenated in the same way as was *cis*-diol (II) described above. The total crystalline hydrogenation product gave two peaks, corresponding in retention time to the two *p*-menthane-2,4-diols, III and IV, on the gas chromatogram. The area ratio of the peaks of III and IV was 1 : 4. The product was recrystallized from hexane, hexane - ethyl acetate (4 : 1), ether, benzene, and hexane - ethyl acetate (9 : 1) successively. Twenty-three recrystallizations gave white flakes of III, mp 153°C. Found: C, 70.00; H, 11.72%. Calcd for $C_{10}H_{20}O_2$: C, 69.76; H, 11.62%. After the solvent had been removed from the combined mother liquors, the remaining product was chromatographed on an alumina column. Elution with a methanol-ether mixture (1 : 30) gave 55 fractions, which then were analysed by gas chromatography. Fractions 1—16 consisted of the solvent alone. Fractions 17—26 gave white needles of IV, mp 115—116°C. Found: C, 69.84; H, 11.72%. Calcd for $C_{10}H_{20}O_2$: C, 69.76; H, 11.62%. Fractions 27—55 gave mixtures of III and IV.

Oxidation of Four *p*-Menthane-2,4-diols, III, IV, V, and VI, with Chromic Acid. A solution of chromic trioxide (46 mg, 0.46 mmol), concentrated sulfuric acid (0.1 cc), and water (0.5 cc) was added, over a ten minutes period, to a solution of V (38 mg, 0.22 mmol) dissolved in acetone (1 cc), and then cooled to 0°C, while the mixture, cooled in an ice-water bath, was being stirred vigorously. The mixture was then poured into ice water and extracted with ether. The evaporation of the ether gave a viscous oil (35 mg) which showed characteristic absorptions at 1700 cm^{-1} due to the carbonyl group and at 3400 cm^{-1} due to the hydroxyl group. The 2,4-DNP of this carbonyl compound was prepared in the usual way; mp 165—166°C, UV λ_{max}^{alc} 387 mμ. Found: N, 16.69%. Calcd for $C_{16}H_{23}O_5N_4$: N, 16.80%. This 2,4-DNP was identified as carvenone 2,4-DNP by a mixed-melting-point determination and by a direct comparison of the IR spectra. The III, IV, and VI diols were oxidized in the same way as in the case of V. The 2,4-DNP of each of these three oxidation products was prepared and melted at the same mp, 165—166°C; all were identified as carvenone 2,4-DNP.

Dehydration of Oxidation Product of the IV Diol. From the fact that each of the four oxidation products of III, IV, V, and VI gave the same 2,4-DNP, it was assumed that dehydration occurred when the 2,4-DNP was derived. To confirm this, the following experiment was carried out. A solution of the oxidation product (50 mg) of IV with chromic trioxide, ethanol (3 cc), concentrated sulfuric acid (0.2 cc), and water (0.3 cc) was left to stand at room temperature overnight. This conditions were the same as in the case of the derived 2,4-DNP. After water had been added, the reaction mixture was extracted with ether. The extract was chromatographed on a silica-gel column. Elution with petroleum ether - ethyl acetate (9 : 1) gave carvenone as an initial elute; it was identified by its UV spectrum, λ_{max}^{alc} 234 mμ, and 2,4-DNP; mp 165—166°C.

The author wishes to express his deep thanks to Professor Robert D. Stolow of Tufts University for his kind advice and to Professor Shô Ito of Tohoku University and Mr. Tsuyoshi Shishibori of Hiroshima University for their measurement of the NMR, IR, and ORD spectra.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 479—482 (1969)

The Synthesis of Poly-L-arginine Hydrobromide and Copolymers of L-Arginine and Other Amino Acids*1

Tadao HAYAKAWA, Yoshiyuki KONDO, Hiroyuki YAMAMOTO and Yukiko MURAKAMI

Institute of High Polymer Research, Faculty of Textile Science and Technology, Shinshu University, Ueda

(Received May 13, 1968)

Pure crystalline $N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine N-carboxyanhydride hydrochloride was obtained from $N^{\alpha,\omega,\omega'}$-tricarbobenzyloxy-L-arginine and thionyl chloride. It was polymerized to poly-$N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine. This polymer was converted to poly-N^{ω}-carbobenzyloxy-L-arginine by treating it with alcoholic potassium hydroxide; also, both carbobenzyloxy groups of the protected polymer were completely removed into poly-L-arginine by treating them with hydrogen bromide in glacial acetic acid. Several copolymers containing L-arginine residue were also prepared by the copolymerization of the above NCA and the NCAs of other amino acids, such as γ-benzyl-L-glutamate, L-alanine, and N^{ε}-carbobenzyloxy-L-lysine.

The natural α-amino acids found in protein give polyamino acids upon the polymerization of all the corresponding α-amino acid N-carboxyanhydride (α-amino acid.NCA) except arginine. Because of the high basicity of the guanido group, the preparation of the pure NCA of L-arginine derivative is difficult and has not been reported in detail.[1,2]

These synthetic methods of producing poly-L-arginine have been reported: (a) poly-L-ornithine prepared by the NCA method was guanidized into poly-L-arginine with 1-guanyl-3,5-dimethylpyrazole or isomethylthiourea,[3,4] and (b) poly-L-nitroarginine prepared by the N-carbothiophenyl method was reduced to poly-L-arginine hydrochloride with stannous chloride in formic acid.[5] In the former case, however, it is very difficult to guanidize quantitatively the ornithyl residues of poly-L-ornithine into poly-L-arginine, and in the latter case, no polymer with a high molecular weight has been prepared. In addition, it is difficult to synthesize copolymers with other amino acids by the use of the above methods.

In this report, the synthesis of poly-L-arginine hydrobromide and copolymers of L-arginine and other amino acids, such as L-glutamic acid, L-alanine, and L-lysine, will be described. The synthetic route of poly-L-arginine (V) is summarized in Eq. (1).

Dicarbobenzyloxy-L-arginine NCA hydrochloride (II) was obtained from tricarbobenzyloxy-L-arginine (I)[6] by the use of thionyl chloride in dioxane. The infrared absorption spectrum of Compound II showed absorptions at 1850 cm^{-1} and 1785 cm^{-1}. These might correspond to the C=O groups in the five-membered ring of NCA. Poly-$N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine was prepared as follows: NCA hydrochloride (II) was treated with silver oxide in dry acetone to remove any hydrogen chloride and was then polymerized in dioxane by adding triethylamine as an initiator. Polymerization was allowed to proceed at room temperature, the solution became a clear gel after several days. The molecular weight was found to be about 30000 by titration with N/50 CH_3ONa in methanol. Poly-$N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine (III) was treated with alcoholic potassium hydroxide to convert it into poly-N^{ω}-carbobenzyloxy-L-arginine (IV) by the elimination of one carbobenzyloxy group of the protected guanido group of III. Poly-L-arginine hydrobromide was obtained by treating III or IV with HBr in glacial acetic acid at 50°C. The acid hydrolyzate of poly-L-arginine hydrobromide gave only one spot of arginine upon paper chromatography and showed no racemization of arginine. The copolymerization of $N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine NCA and other amino acid NCAs (γ-benzyl-L-glutamate, L-alanine and N^{ε}-carbobenzyloxy-L-lysine) was performed. The yield, molecular weight, and amino acid composition of each copolymer were determined. The molar ratio was determined quantitatively by paper chromatography

after acid hydrolysis. The results of the elemental analyses of these copolymers are shown in Table 1. In a way similar to that of poly-L-arginine synthesis, one carbobenzyloxy group of the arginine residue and the benzyl group of glutamate in these copolymers were removed (see Table 2) by treating them with alcoholic potassium hydroxide. Also, all the protecting groups of the copolymers were removed by treating them with hydrogen bromide in glacial acetic acid. The liberated homopolymer and copolymers were soluble in water and showed positive Biuret and Sakaguchi reactions.

Poly-L-arginine and the copolymers containing a L-arginyl residue provide a valuable model of natural basic proteins, such as salmine and clupeine, which have a high arginine content. The physicochemical properties of these polymers, such as the infrared spectra, X-ray analyses, and optical rotatory dispersion, will be reported in the near future.

Experimental

$N^{\alpha,\omega,\omega'}$-Tricarbobenzyloxy-L-arginine(I). $N^{\alpha,\omega,\omega'}$-Tricarbobenzyloxy-L-arginine (I) was prepared from L-arginine hydrochloride and carbobenzyloxy chloride as has been described by Zervas *et al.*[6]

$N^{\omega,\omega'}$-Dicarbobenzyloxy-L-arginine NCA Hydrochloride (II). To a solution of tricarbobenzyloxy-L-arginine (I) (2.0 g) in 5 m*l* of dioxane, thionyl chloride (1.0 m*l*) was added; the mixture was then allowed to stand for 5 hr at room temperature. When to this mixture dry ether was added, a white precipitate was obtained. This precipitate was filtered, washed with dry ether, and recrystallized from dry acetone and ether. Yield, 1.45 g (83.1%); mp 62°C (decomp.).

Found: C, 54.71; H, 5.37; N, 11.04; Cl, 6.94%. Calcd for $C_{23}H_{25}O_7N_4Cl$: C, 54.71; H, 4.99; N, 11.10; Cl, 7.02%.

$N^{\omega,\omega'}$-Dicarbobenzyloxy-L-arginine NCA. To a solution of $N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine NCA hydrochloride (II) (1.45 g) in 20 m*l* of dry acetone, dry silver oxide (1.5 g) was added. The mixture was stirred until it showed negative in a chloride test and was then passed through a dry charcoal column to purify it.[7] The acetone in the clear filtrate was removed to dryness *in vacuo*; an oily residue was thus obtained. Yield 1.0 g (83.3 %). The residue was used for immediate polymerization.

Poly-$N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine (III). To a solution of $N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine NCA (1.0 g) in 5 m*l* of dioxane, 0.0028 m*l* of triethylamine was added as an initiator; the mixture was polymerized in a sealed tube at room temperature. The polymerization proceeded until a clear gel was obtained. After one week, the reaction mixture was heated in a boiling water bath for 5 hr. After it had been cooled, the mixture was stirred into 100 m*l* of water. The polymer was collected by centrifugation, washed with water, and dried. Yield, 0.8 g (88.0%); $[\alpha]_D^{20}$ +13.1° (*c* 0.6, dioxane) and $[\alpha]_D^{20}$ −20.3° (*c* 0.5, trifluoroacetic acid). Equiv. mol wt≒30000 (by titration of the carboxyl end group with N/50 CH_3ONa in methanol).

Found: C, 62.25; H, 5.79; N, 13.11%. Calcd for $(C_{22}H_{24}O_5N_4)_n$: C, 62.25; H, 5.70; N, 13.20%.

Poly-$N^{\omega,\omega'}$-carbobenzyloxy-L-arginine (IV). To a solution of poly-$N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine (III) (200 mg) in 1.2 m*l* of dioxane, 1.2 m*l* of 0.6 N potassium hydroxide in 95% ethanol was added and shaken for 2 hr at room temperature. The solution was acidified with acetic acid. After the removal of the organic solvent, the polymer was precipitated by the addition of water. The polymer was collected by centrifugation

7) J. Noguchi, N. Nishi, M. Itaya and S. Tokura, *Kogyo Kagaku Zasshi* (*J. Chem. Soc. Japan, Ind. Chem. Sect.*), **69**, 745 (1966).

and dried. Yield, 102 mg (74.4%); $[\alpha]_D^{20}$ +20.4° (*c* 0.2, 2-chloroethanol) and $[\alpha]_D^{20}$ −28.6° (*c* 0.3. trifluoroacetic acid).

Found: C, 57.89; H, 6.16; N, 19.02%. Calcd for $(C_{14}H_{18}O_3N_4)_n$: C, 57.92; H, 6.25; N, 19.30%.

Poly-L-arginine Hydrobromide (V). (a) Poly-$N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine (100 mg) was dissolved in 10 m*l* of 6 N hydrogen bromide in glacial acetic acid and stirred for 90 min at 50°C. The reaction mixture was then evaporated to dryness *in vacuo*, and the residue was treated with dry ether. The polymer was collected by centrifugation and washed with ether. This polymer was dissolved in a minimum amount of water and reprecipitated with ethanol. It was then collected by centrifugation, washed with ether, and dried. Yield, 32 mg (57.1%) (b) Poly-N^{ω}-carbobenzyloxy-L-arginine (115 mg) was treated in the way described above. Yield, 57.5 mg (61.2%); $[\alpha]_D^{20}$ −49.2° (*c* 1.0, water).

Found: C, 28.64; H, 5.60; N, 21.56%. Calcd for $(C_6H_{13}ON_4Br\cdot H_2O)_n$: C, 28.25; H, 5.93; N, 21.96%.

Hydrolysis of Poly-L-arginine Hydrobromide. A solution of poly-L-arginine hydrobromide (62.5 mg) in 10 m*l* of 6 N hydrochloric acid was hydrolyzed at 105°C for 24 hr. The hydrolyzate gave only arginine upon paper chromatography. The hydrolyzate was $[\alpha]_D^{20}$ +26.3°, which agrees with the value of authentic L-arginine.

Copoly(γ-benzyl-L-glutamate, $N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine)(2 : 1). To a solution of γ-benzyl-L-glutamate NCA (0.7 g) and $N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine NCA (0.62 g) in 13 m*l* of dioxane, 0.0055 m*l* of triethylamine was added as an initiator, and the mixture was polymerized in a sealed tube at room temperature for 5 days. The reaction mixture was heated for 2 hr in a boiling water bath, and then poured into water. The polymer precipitated was collected by centrifugation and dried. Yield, 1.0 g (87.2%). The analytical data and the molecular weight are shown in Table 1.

Other Copolymers. Copoly(γ-methyl-L-glutamate, $N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine) (2 : 1); copoly(L-alanine, $N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine) (1 : 1) and (2 : 1); copoly(N^{ε}-carbobenzyloxy-L-lysine, $N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine) (3 : 2) and (2 : 1) were prepared by the copolymerization of $N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine NCA and the corresponding amino acid NCAs in the molar ratios presented above. The yields, the molecular weights, and the analytical data are shown in Table 1.

Hydrolysis of Copolymers. A portion of these polymers were hydrolyzed with 6 N hydrochloric acid

at 105°C for 24 hr. The amino acid compositions were determined quantitatively by paper chromatography. The data are shown in Table 1.

Copoly(L-alanine, N^{ω}-carbobenzyloxy-L-arginine) (1 : 1). To a solution of copoly(L-alanine, $N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine) (1 : 1) (200 mg) in 0.9 m*l* of dioxane, 0.9 m*l* of 0.6 N potassium hydroxide in 95% ethanol was added. The mixture was shaken at room temperature for 2 hr. The mixture was then acidified with acetic acid, and the polymer precipitated by the addition of water. The polymer was collected by centrifugation, washed with water, ethanol, and ether, and dried. The yield and the analytical data are shown in Table 2. Copoly(L-glutamic acid, N^{ω}-carbobenzyloxy-L-arginine) (2 : 1) and copoly(N^{ε}-carbobenzyloxy-L-lysine N^{ω}-carbobenzyloxy-L-arginine) (3 : 2) were prepared in a similar way by treatment with alcoholic potassium hydroxide. The yield and the analytical data are shown in Table 2.

Copoly(L-lysine hydrobromide, L-arginine hydrobromide) (3 : 2). Copoly(N^{ε}-carbobenzyloxy-L-lysine, $N^{\omega,\omega'}$-dicarbobenzyloxy-L-arginine) (3 : 2) (200 mg) was dissolved in 10 m*l* of 6 N hydrogen bromide in glacial acetic acid, stirred for 90 min at 50°C, and evaporated to dryness *in vacuo*. The residue was treated with dry ether. The polymer was collected by centrifugation, washed with ether, and dried. This polymer was redissolved in a minimum amount of water and reprecipitated with ethanol and ether. The yield and the analytical data are shown in Table 3. From the corresponding protected copolymers, copoly(L-glutamic acid, L-arginine hydrobromide) (2 : 1) and copoly(L-alanine, L-arginine hydrobromide) (1 : 1) were prepared in the same way. The yield and the analytical data are shown in Table 3.

The authors wish to express their thanks to Professor Junzo Noguchi of Hokkaido University for his encouragement and valuable disccusions, and are also indebted to the Kaishin Kisei Domei of this Faculty for its financial support.

Intramolecular Hydrogen Bonds. XIII.[1] The Preferable Conformation of α-Hydroxy-carboxylic and *o*-Hydroxybenzoic Acids

Nobuo Mori, Yuzuru Asano, Toshiko Irie and Yojiro Tsuzuki

Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received May 21, 1968)

The infrared hydroxyl and carbonyl stretching absorption spectra of salicylic, mandelic, and α-hydroxyisobutyric acids have been measured in dilute carbon tetrachloride solutions. The spectral data indicate that the first two acids exist exclusively in an internally-bonded conformation, one where the phenolic and the alcoholic hydroxyl groups form a hydrogen bond with the carbonyl oxygen atom of the *cis*-carboxyl structure, while the last acid takes, apart from such a conformation, another internally-bonded conformation, one where the hydroxyl group of the *trans*-carboxyl structure interacts with the alcoholic oxygen atom.

It is well known that the carboxyl group in a carboxylic acid takes the *cis*-structure exclusively, a structure in which the carbonyl and the hydroxyl group are *cis* in respect of the C–O bond, but not the *trans*-structure where both groups are *trans*.

1) Part XII: N. Mori, Y. Asano and Y. Tsuzuki, This Bulletin, **41**, 1871 (1968).

An indirect estimation of the stabilization energy indicates the former to be more stable by *ca.* 3 kcal/mol than the latter.[2] When a strong proton-acceptor atom, such as an oxygen or a nitrogen atom, is present close to the carboxyl group, the *trans*-structure can exist to a considerable extent as a result of the hydrogen bond formation between that atom and the carboxyl-OH group; the enthalpy of this hydrogen bond formation is, in general, at most 1.5 kcal/mol with *α*-alkoxyalkanoic acids[3] and at most 3.3 kcal/mol with *o*-alkoxybenzoic acids.[4] These values are comparable to those of ordinary intramolecular OH-to-O hydrogen bonds forming similar 5- or 6-membered rings (*e. g.*, 2.2 and 2.1 kcal/mol with *β*-methoxyethanol and *γ*-methoxypropanol respectively[5]). A simple comparison of these energies seems to suggest that, in *α*-hydroxy-carboxylic and *o*-hydroxybenzoic acids, the carboxyl group may take the *trans*-structure to a significant extent, working through hydrogen bonding with the *α*- or *o*-hydroxyl-oxygen atom. In order to verify this suggestion,we have attempted the infrared investigation of the intramolecular hydrogen bonding in salicylic, mandelic, and *α*-hydroxyisobutyric acids in dilute carbon tetrachloride solutions. The last two acids examined as *α*-hydroxy acids are not indispensable, but they are accessible in the pure, crystalline form.

Experimental

Samples. All the acids were known crystalline compounds; they were prepared and purified by the methods described in the literature, and some known derivatives of them were prepared. Their melting and boiling points were equal to, or very close to, the reported values. The carbon tetrachloride was fractionated over phosphorus pentoxide.

Infrared Measurements. The hydroxyl- and the carbonyl-stretching region were measured at 25°C using a grating, double-beam spectrophotometer, Model DS-403G, of the Japan Spectroscopic Co., Ltd. Since the solubility of each acid in the solvent is very low, in most cases saturated solutions were employed. The concentrations of the derivatived used were 0.002 and 0.001 mol/*l* for the OH and the CO measurements respectively. The cells used were 5.0 and 1.0 cm in optical path length for the OH and the CO measurements respectively. The observed frequencies were calibrated against those of a standard polystyrene film.

Results and Discussion

The OH and the CO spectra of representative acids are shown in Figs. 1—3, while the spectral data of all the compounds are summarized in Tables 1 and 2.

Salicylic Acids (1—6).*1 In the monomeric OH region, each of the acids shows only two bonded OH bands, with maxima around 3530 and 3200 cm^{-1}; the higher frequency band is sharp and almost symmetric, while the lower frequency band is broad and is obscured by the C–H and the dimeric carboxyl-OH bands.

These acids can take the three internally-bonded forms, I, II, and III, shown in Fig. 4. In this figure, the numerical values added to Form I are the observed frequencies of the respective groups, while those in parentheses added to the other

*1 The relative intensity to the OH band is about 0.015.
*2 The approximate frequency of the center of the broadened part on the higher frequency side of the monomeric *cis*-COOH band.
*3 These two bands are associated with two rotational isomers (*cis* and gauche form) around the C_1–O bond of the COOMe group.[1]
*4 Very slightly soluble.
*5 This band probably contains the C=O overtone band.

forms are the frequencies which would be expected on the basis of the reported spectral data of the reference compounds, including *o*-methoxybenzoic acid (8), methyl salicylates (9—11), and methyl *o,o'*-dihydroxybenzoate (12).

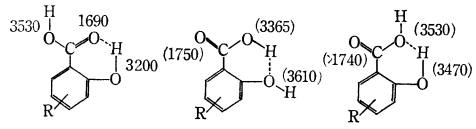

Fig. 4. Internally-bonded forms of salicylic acids.

The appearance of the two OH bands gives evidence of the preferential existence of Form I, since there are no other detectable absorptions corresponding to any of the interacted phenolic and carboxyl OH groups in the other forms. These findings agree completely with those based on the carbonyl data; in the monomeric C=O region these acids show a single absorption due to the internally bonded, *cis*-carboxyl C=O group, but there are no absorptions which correspond to the free carbonyl groups in Forms II and III. The very weak shoulder appearing at 1702 cm^{-1}, which is observed in all the salicylic acids, can not definitely be assigned at the present time.

Mandelic Acids (13—19). In the monomeric OH region, these acids show an intense band at 3535 cm^{-1} and a broadened part centered at *ca.* 3565 cm^{-1}. Apart from these, a very weak absorption band appears near 3445 cm^{-1} with a relative intensity of *ca.* 0.015.

These acids can take the three internally-bonded forms, IV, V, and VI, shown in Fig. 5, where the values in parentheses are the frequencies of the

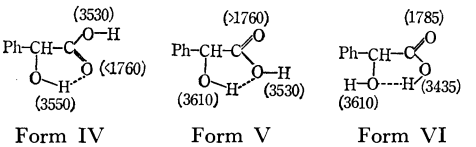

Fig. 5. Internally-bonded forms of mandelic acids.

corresponding groups which would be expected on the basis of the spectral data of the reference compounds, including *α*-methoxyphenylacetic acid (20), methyl mandelate (21), and methyl *α*-methoxyphenylacetate (22). According to these comparisons, only Form IV can reasonably explain the appearance of the two overlapped, strong bands. The very weak band of the lowest frequency can be due either to the carbonyl overtone or to a minor amount of the *trans*-carboxyl group, judging from both the relative intensity and the position at which it appears. However, the carbonyl overtone seems responsible for it, since the observation of carbonyl spectra shows the presence of no *trans*-carboxyl group. The carbonyl spectra each contain only two bands, which correspond to the *cis*-carboxyl and the dimeric carboxyl group; there is no absorption of the *trans*-carboxyl group, which could be expected to appear near 1790 cm^{-1}.

α-Hydroxyisobutyric Acid (23). In the monomeric OH region, this acid shows four bands, at 3623 (weak), 3575 (strong), 3534 (strong), and 3436 cm^{-1} (weak). On the basis of a comparison of these data with those of *α*-methoxyisobutyric acid (24) and ethyl *α*-hydroxyisobutyrate (25), the two strong bands can be assigned to the bonded alcoholic and the *cis*-carboxyl OH group in Form VII (see Fig. 6, in which the frequencies in parentheses are those expected).

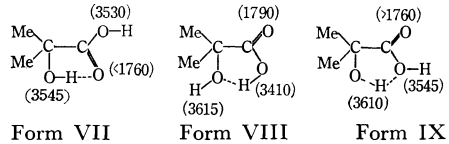

Fig. 6. Internally-bonded form of *α*-hydroxyisobutyric acid.

As for the last band, its intensity is too high for it to be that of a carbonyl overtone; therefore, it may be predominantly due to a *trans*-carboxyl absorption overlapped with the carbonyl overtone. The first weak band may be assigned to either or to both of the two, free and bonded, alcoholic OH species in Forms VIII and IX. In view of the appearance of the weak, *trans*-carboxyl OH and CO band, however, the assignment to the free OH species in Form VIII is rather more reasonable.

In the monomeric C=O region, the acid shows a weak and a strong band at 1788 and 1755 cm^{-1}; these bands can be assigned to the *trans*-carboxyl group in Form VIII and to the *cis*-carboxyl group in Form VII respectively. The precise proportion of the *trans*-carboxyl group to the whole can not be calculated because the respective molecular absorption coefficients are unknown. From the intensity ratio of the apparent bonded OH bands, however, it can be calculated to be approximately 0.16.

It is interesting that the acid takes the *trans*-

carboxyl structure VIII to a significant extent, while mandelic and salicylic acids take no such structures. The difference can not decisively be explained at the present time, but it seems attributable to some unknown factors other than steric effects, because the latter two acids, rather than the former, would be expected to meet the steric requirements for taking the *trans*-structures for the following reasons: (1) *α*-hydroxyisobutyric acid may involve the steric repulsion between the two *α*-methyl groups and the free alcoholic OH group in the *trans*-structure (such a repulsion has already been proposed in the cases of *α,α*-dialkylethyleneglycols[11]) and, therefore, it may prefer the *cis*-Structure VII, which involves no such repulsion, while (2) mandelic and salicylic acids may not involve steric effects strong enough to make the presence of *trans*-structures II and VI completely impossible, since even *α*-methoxyphenylacetic and *o*-methoxybenzoic acids prefer the *trans*-structures to an appreciable extent.

Substituent Effects on the OH Frequencies. The alcoholic and carboxyl OH frequencies of mandelic acids are almost constant irrespective of the substituent, while those of salicylic acids change depending on the substituent. The correlation with the ordinary Hammett *σ*-constant[12] is shown in Fig. 7, where the ordinate is the difference in frequency between unsubstituted (γ^{H}_{OH}) and substituted acid (γ^{R}_{OH}), and the abscissa, the Hammett *σ*-constant. In the case of salicylic acids, the relatively large deviation of some phenolic OH plots from the straight line would not be due to the inexactness

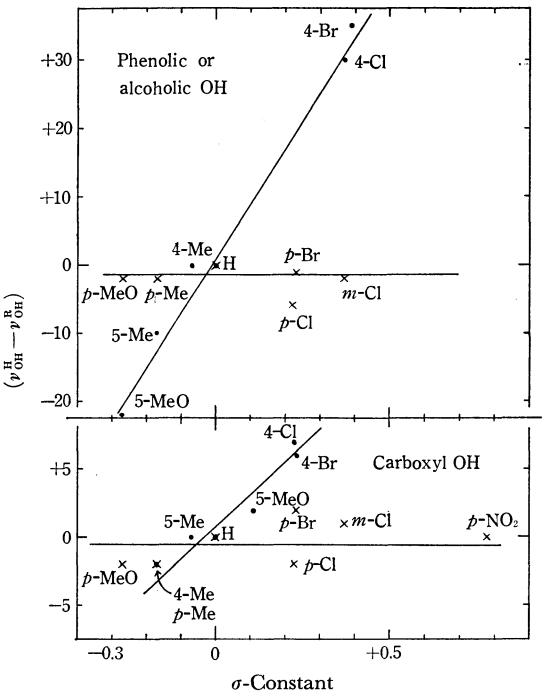

Fig. 7. Correlation of ν_{OH} with Hammett *σ*-constant in salicylic (—•—) and mandelic acids (—×—).

of the frequencies, but, rather, due mainly to the electronic effects of the substituent, influencing the hydrogen bonding through the carbonyl-oxygen atom. A detailed study of this problem is in progress and will be reported in the next part of this series of studies.

Intramolecular Hydrogen Bonds. XIV.[1] Correlation of the Hydroxyl and the Carbonyl Frequencies of Methyl Salicylates with Hammett's Substituent Constants

Nobuo Mori, Yuzuru Asano and Yojiro Tsuzuki

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo

(Received June 5, 1968)

The infrared OH and C=O stretching spectra of methyl 4- or 5-substituted salicylates have been measured in dilute carbon tetrachloride solutions, and the respective peak-frequencies have been correlated with ordinary Hammett's σ-constants. The best linear relationship has been established between the γ_{OH} and the $(\sigma_{OH}-0.38\sigma_{COOMe})$ values and between the $\gamma_{C=O}$ and the $(\sigma_{COOMe}-0.49\sigma_{OH})$ values, where σ_{OH} and σ_{COOMe} are the σ-constants of a substituent with respect to the OH and the COOMe group respectively. Besides, in other internally-bonded phenol systems, including *o*-bromophenols, *o*,*o*'-dihalophenols, and salicylic acids, the plotting of the OH frequencies against the $(\sigma_{OH}-A\sigma_X)$ values gave the best linear relationship, where A is a constant depending on the kind of proton acceptor, X. The value of A can be a measure of the electronic effects of the substituent, influencing the bonded OH frequency through X.

In general, the spectroscopic properties of ring-substituted aromatic compounds can be correlated with the electronic nature of the substituents. In unassociated phenols,[2] benzoates,[3] and benzoic acids,[4] for example, the respective infrared OH and C=O stretching frequencies have been correlated with Hammett's σ-constants.

In internally-associated phenol systems, such as *o*-hydroxybenzaldehyde-anils (mono-substituted in the anil moiety)[5] and *p*-substituted phenylglyoxylic acids,[6] the hydrogen-bonded OH and C=O frequencies change linearly with the σ-constants.

On the other hand, the additivity of electronic effects of substituents has been pointed out,[7] and these effects have been reported with the carbonyl stretching modes of substituted benzoic acids.[8] Accordingly, very interesting is a system of benzene compounds, each of which contains a substituent with electronic effects which contribute to the interaction between two other substituents, both attached to the same benzene ring. An infrared investigation has previously been reported on the substituent effect on the interaction between the OH and the C=O group in 2-hydroxy-5-substituted-acetophenones;[9] in this case, the observed spectral shift, $\Delta\gamma_{OH}$, was correlated with the term of $(\sigma_p+\sigma_m)/2$, suggesting that equal proportions of the two tautomeric structures contribute to the interaction. However, their bonded OH bands appeared in the complex C–H stretching absorption region, thus reducing the accuracy of the reported band frequencies.

The present investigation has been performed on the electronic effects of a substituent exerted on the hydrogen bonding in methyl 4- and 5-monosubstituted salicylates, the bonded OH bands of which can easily and reliably be assigned.[10]

A major work on the chelation in substituted salicylates has been performed by Brooks and his co-workers,[10] but their interest was primarily in the problem of the so-called *o*-effects of adjacent substituents on the chelation.

Another subject of this investigation is the correlation of the OH frequencies with Hammett's σ-constants in the systems of internally-bonded phenolic compounds, such as substituted *o*-halophenols and salicylic acids, which may be expected to have essentially the same mechanism of hydrogen-bond formation.

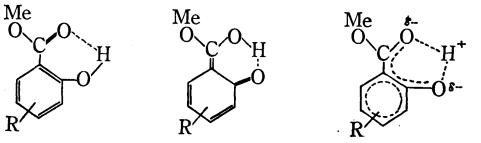
Experimental

Samples. All the esters, except for the 4-bromo-homologue, were known substances and were prepared by the methods described in the literature. The purified esters had almost, or completely, the same melting or boiling points as the reported values. The methyl 4-bromosalicylate was prepared by essentially the same method as the known 4-chloro-compound.

Infrared Measurement. This was carried out in almost the same manner as has been described in the preceding paper,[1] at an operating temperature of *ca.* 25°C, using a grating, double-beam spectrophotometer, Model DS-403G, of the Japan Spectroscopic Co., Ltd. The OH-stretching region was measured in a concentration of 0.002 mol/*l* or less in carbon tetrachloride, while the C=O stretching region was measured in a concentration of 0.001 mol/*l* or less. The cells used were 5.0 and 1.0 cm in optical path-length for the OH and the C=O measurements respectively. At those concentrations, no intermolecular hydrogen bonding was present, as has been described in the literature.[10]

Results and Discussion

The infrared OH and C=O spectra of three representative esters are shown in Fig. 1, while the spectral data of all the esters are summarized in Table 1. In the OH region, each of the esters shows only a very broad, intense, bonded OH band, with a distinct maximum in a frequency range from 3140 to 3222 cm^{-1}; the OH absorption begins near 3500 cm^{-1}, and the lower frequency side merges into the C–H absorption region. The carbonyl bands, which are sharp and, in most cases, almost symmetrical, appear near 1700 cm^{-1}; this frequency is lower than the 1730 cm^{-1} of methyl benzoate but much higher than the 1650 cm^{-1} of tautomeric *o*-hydroxyacetophenones.[9] The relatively small lowering of the carbonyl frequency from 1730 cm^{-1} suggests that the intramolecular hydrogen bonding in these esters can be explained by structure I, but not by a mixture of the two tautomeric structures I and II or by the meso-ionic structure III. In fact, the observation of the infrared spectra has shown none of the absorption bands to be expected for the quinoid-carbonyl (near 1650 cm^{-1}) and the C⋯O half double bond (near 1400 cm^{-1}).



I II III

In these esters, therefore, the conformation of the carbonyl group*1 can be fixed by chelation with the phenolic OH group.[10] In this case, however, the coplanarity of the two substituents and

*1 In general, a carboxylate ester function itself, while strongly preferring a roughly planar conformation resulting from the resonance interaction between the alkoxy-oxygen and the carbonyl group,[11] may be exclusively in a *cis*-arrangement,[12] where both groups are *cis* in respect of the C–O bond, but not trans, because of the electrostatic repulsion of filled orbitals.[13] Accordingly, the *cis*-arrangement is the normally preferred one.[14]

the benzene ring is not implied.

In substituted phenols[2] and benzoates,[3] the respective OH and C=O stretching frequencies become lower and higher respectively as the electron-withdrawing by the substituents increases. The substituent effects on both frequencies are interpreted in terms of the changes in the electronegativities of, respectively, the hydroxyl-oxygen and the carbonyl-carbon atom corresponding to the changes in the substituents. That is, as the electron-withdrawal by the substituents increases, the O–H bond of substituted phenols is weakened, resulting in a decreased OH stretching frequency, while the carbonyl double-bond character of substituted benzoates is increased (the contribution of the polar structure, $\overset{+}{C}-\overset{-}{O}$, to the resonance is decreased), resulting in an increased C=O stretching frequency.

In the case of the present salicylates, a substituent is expected to have electronic effects on the characteristics of the O–H and the C=O bond, both being involved in the hydrogen-bonding interaction, and thus to have an effect on the interaction itself. For example, the interaction will be strengthened by the increase in the polarity of the O–H bond and will simultaneously be weakened by the decrease in the polarity of the C=O bond, as the electron-withdrawal by the substituent increases. The sum of the two effects, reversely influencing the interaction in this way, is reflected by the observed bonded OH and C=O frequencies. In the above case, for example, the frequency of the OH group involved in the interaction will be decreased with an increase in the O–H polarity and will be simultaneously increased as a result of the interaction being weakened by the decrease in the C=O polarity.

On the basis of the above considerations, the observed OH and C=O frequencies were plotted against the respective ordinary Hammett's σ-

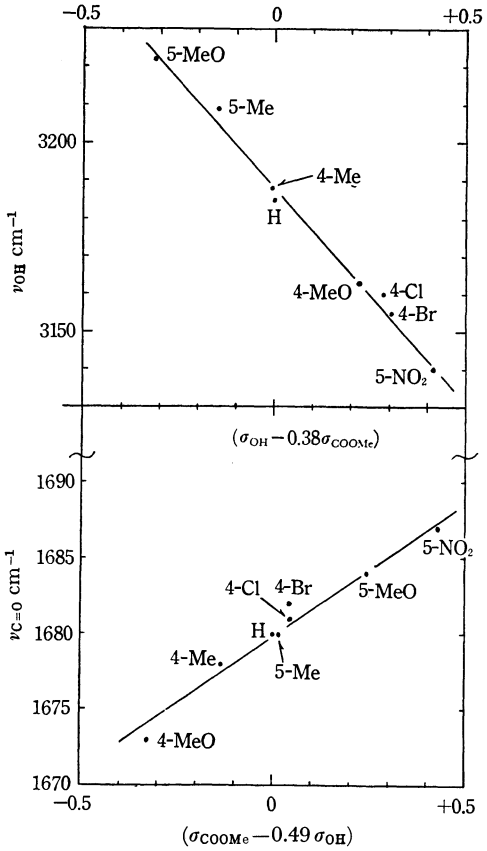

Fig. 2. Correlation of ν_{OH} and $\sigma_{C=O}$ with σ-constant in methyl salicylates.

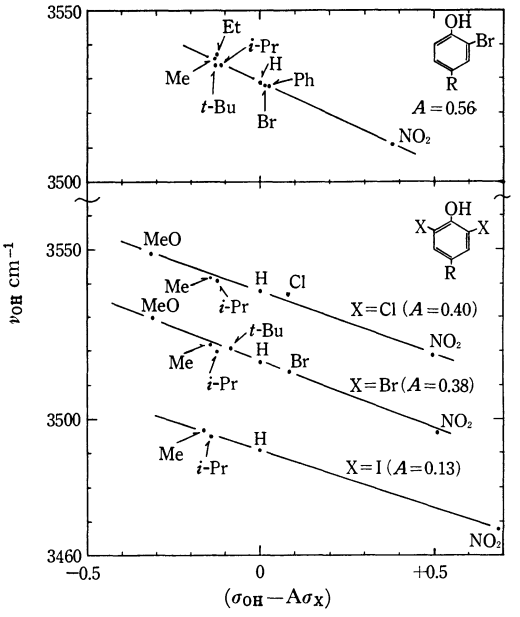

Fig. 3. Correlation of ν_{OH} with σ-constant in o-bromophenols and in o,o'-dihalophenols.

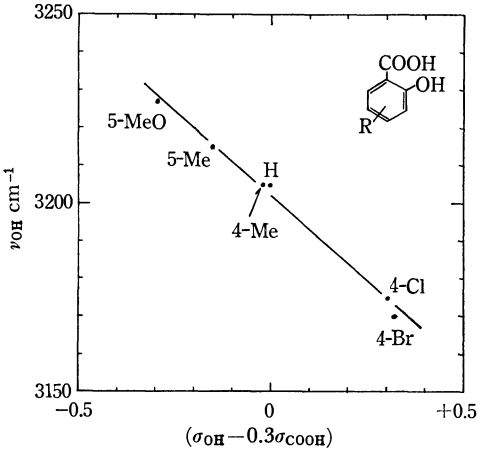

Fig. 4. Correlation of ν_{OH} (phenolic) with σ-constant in salicylic acids.

constants.[15] The best linear relationship has been established between the values of γ_{OH} and $(\sigma_{OH}-0.38\sigma_{COOMe})$ and between those of $\gamma_{C=O}$ and $(\sigma_{COOMe}-0.49\sigma_{OH})$, as is shown in Fig. 2, where σ_{OH} and σ_{COOMe} are the Hammett σ-constants of a substituent with respect to the OH and COOMe groups respectively. In the former relationship, the factor of 0.38 seems to be a measure of the electronic effect of the substituent on the bonded OH frequency, operating through the proton-accepting carbonyl group, while the factor of 0.49 in the latter is a similar measure of the substituent effect influencing the bonded C=O frequency through the proton-donating hydroxyl group.

In some systems of phenolic compounds, including substituted o-bromophenols,[16] o,o'-dihalophenols,[17] and salicylic acids,[1] a linear relationship has been further obtained between the values of γ_{OH} and $(\sigma_{OH}-A\sigma_X)$,*2 as is shown in Figs. 3 and 4, where the OH frequencies used in the plotting are those reported in the literature. However, the reported OH frequencies of o-hydroxyacetophenones[9] have not provided a linear relationship. Accordingly, the intramolecular hydrogen bonding in the former three systems of compounds can probably be explained in terms of essentially the same structure as that of the methyl salicylates.

In the cases of the p-substituted o,o'-dihalophenols, each forming a similar 5-membered ring through the hydrogen bonding, the OH frequency can be determined by the constant of A, which increases with the halogens in the order: I (0.13)<Br(0.38)<Cl(0.40), which is equivalent to the order of their electronegativities. It is well known[18] that, in o-halophenols, the spectral shifts, $\Delta\gamma_{OH}$, increase with the halogens in the order: F<Cl<Br<I, which is the reverse of the order of the electronegativities and is different from that of the hydrogen bond enthalpies. However, the disagreement in the orders has not yet been elucidated. Though the present investigation does not deal with this problem, the value of A seems to imply the operation of another significant factor in the hydrogen-bond formation.

15) H. H. Jaffé, *Chem. Revs.*, **53**, 191 (1953).

*2 The value of A is a constant depending on the kind of proton-acceptor, X, and the terms of σ_{OH} and σ_X are ordinary Hammett σ-constants of a substituent with respect to the OH and X group respectively.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 492—498 (1969)

Ethylidenation of L-Sorbose[1-3]

Takashi MAEDA, Masumi KIYOKAWA and Kanji TOKUYAMA

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received June 8, 1968)

The ethylidenation of L-sorbose (I) with acetaldehyde dimethylacetal in the presence of an acid was studied. When the reaction was interrupted at the initial stage, an equilibrium mixture of the two possible cyclic acetals, 1,2-*O*-(III) and 1,3-*O*-ethylidene-*α*-L-sorbopyranose (V), was obtained. When the reaction was allowed to proceed for longer periods of time, 1,3:4,6-di-*O*-ethylidene-*β*-L-sorbofuranose (IX) was mainly isolated; the transformation of this to two diastereoisomeric 2,3:4,6-di-*O*-ethylidene-*α*-L-sorbofuranoses (XV and XVIII) required the use of highly acidic conditions. A pathway of I→(III⇄V)→IX→(XV+XVIII) was tentatively proposed for the ethylidenation of I.

The acetonation of L-sorbose (I) yields 1,2-*O*-isopropylidene-*α*-L-sorbopyranose (II) as the initial product;[4,5] this is then converted into 2,3:4,6-di-*O*-isopropylidene-*α*-L-sorbofuranose (VII) exclusively.[6] Although the presence of an equilibrium between II and 1,3-*O*-isopropylidene-*α*-L-sorbopyranose (IV) at the initial stage of the reaction has reasonably been anticipated from the acetalation of glycerol,[7] IV could not be isolated. This discrepancy must be considered on stereochemical grounds. As has been pointed out by Brown, Brewster, and Schechter,[8] the formation of a six-membered *O*-isopropylidene ketal is inhibited because one of the two methyl groups is necessarily axial in the chair conformation for the six-membered ring. On the other hand, there is no axial methyl group in a six-membered ethylidene acetal, so that 1,3-*O*-ethylidene-*α*-L-sorbopyranose (V) can be expected to be isolated from the ethylidenation of I. The isolation of V may give important information regarding the complicated reaction mechanisms of the acetalation of I.[4,9,10] This paper will report on the ethylidenation of I with acetaldehyde dimethylacetal[11] in the presence of an acid. The products from this reaction were isolated by preparative thin-layer chromatography and were identified on the basis of chemical and proton magnetic resonance (PMR) spectroscopic evidence. The assignment of the PMR spectra shown in Tables 1 and 2 is based on the chemical shifts with reference to the corresponding acetonated compounds.[2,10,12]

The treatment of I with acetaldehyde dimethylacetal in the presence of *p*-toluenesulfonic acid at 40°C for 2.7 hr or under weaker conditions afforded one diethylidene compound (IX) and four monoethylidene compounds, the latter of which were purified as the acetates, IIIa, Va, VIa, and XIIIa. The Va acetate showed bands due to a hydroxyl group in its infrared spectrum. This hydroxyl group was considered to be a tertiary one, because no acetylation occurred with acetic anhydride in pyridine at ordinary temperatures, whereas reduction was observed with a Fehling solution. The methylation of Va with methyl iodide in the presence of silver oxide yielded VIa. This product, VIa, was also obtained by the ethylidenation of methyl *α*-L-sorbopyranoside (XXI),[13] followed by acetylation. Thus, the structures of Va and VIa were determined to be the 4,5-di-*O*-acetates of V and methyl 1,3-*O*-ethylidene-*α*-L-sorbopyranoside (VI). The PMR spectra of Va and VIa in chloroform-d

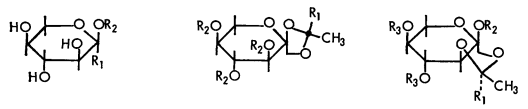
a) not determinable. b) $J_{1,4}=0.8$

show a doublet due to H_3 at a higher filed (τ 6.52), a doublet-doublet due to H_4 (τ 4.47—4.58) and a multiplet due to H_4 (τ 5.02—5.03) at a lower field; the large coupling constants of $J_{3,4}$, $J_{4,5}$, and $J_{5,6}$, (9.3—10.2 Hz) are consistent with the proposed pyranose structures.[12,14,15]



I $R_1 = CH_2OH$, $R_2 = H$
XXI $R_1 = CH_2OH$, $R_2 = CH_3$
XXII $R_1 = CH_2OTs$, $R_2 = H$
XXIII $R_1 = COOCH_3$, $R_2 = H$

II $R_1 = CH_3$, $R_2 = H$
III $R_1 = R_2 = H$
IIIa $R_1 = H$, $R_2 = Ac$

IV $R_1 = CH_3$, $R_2 = R_3 = H$
V $R_1 = R_2 = R_3 = H$
Va $R_1 = R_2 = H$, $R_3 = Ac$
VI $R_1 = R_3 = H$, $R_2 = CH_3$
VIa $R_1 = H$, $R_2 = CH_3$, $R_3 = Ac$

Chart 1

The combined data of elemental analysis, optical rotation, and the infrared spectrum established that IIIa was the tri-*O*-acetate of monoethylidene-*α*-L-sorbose. The PMR spectrum in chloroform-d showed three three-proton singlets due to acetoxyls and signals due to H_3 (doublet), H_4 (doublet-doublet), and H_5 (multiplet) in the H–C–OAc region (τ 4.5—5.0). The large coupling constants of $J_{3,4}$ and $J_{4,5}$ (9—9.7 Hz) indicated its pyranose structure in the 1C conformation. Therefore, the structure of IIIa was determined to be the 3,4,5-tri-*O*-acetate of 1,2-*O*-ethylidene-*α*-L-sorbopyranose (III).

When the ethylidenation was allowed to continue for longer periods of time, the amount of diethylidene derivative (IX) increased at the expense of the monoethylidene compounds. The compound IX was considered to have a tertiary hydroxyl group for the same reasons as was Va. The methylation of IX with methyl iodide in the presence of silver oxide gave a glycoside (X), which was also isolated from the reaction mixture to a limited extent. The PMR spectrum of X in chloroform-d shows two one-proton quartets due to the methine protons of ethylidene groups at τ 5.27 and 5.28. Since the signal due to the methine proton of an ethylylidene ring in chloroform-d appeared at τ 4.70 for five-membered ring of IIIa and at τ 5.25—5.27 for the six-membered rings of Va and VIa, the ethylidene groups of X were assigned to those of six-membered rings. These data and their positive optical rotations apparently established that the structures of IX and X were 1,3:4,6-di-*O*-ethylidene-*β*-L-sorbofuranose, the ethylidene analog of 1,3:4,6-di-*O*-isopropylidene-*β*-L-sorbofuranose (VIII),[10] and methyl 1,3:4,6-di-*O*-ethylidene-*β*-L-sorbo-furanoside, respectively. The partial deacetalation of X with 60% acetic acid gave a monoethylidene sorboside (XI), which was then purified as a diacetate (XIa). The PMR spectrum of XIa in chloroform-d (see Fig. 1) shows singlets at τ 7.93 due to two acetyl methyls and at τ 6.73 due to one methoxy methyl, a doublet at τ 8.67 ($J=5.0$ Hz) due to one ethylidene methyl, and a quartet at τ 5.37 due to one methine proton of a six-membered ethylidene group. The patterns of the remaining protons are quite similar to those of methyl 1,3-

15) The evidence of PMR indicates that the favored conformations of Va and VIa are the 1C chair from.

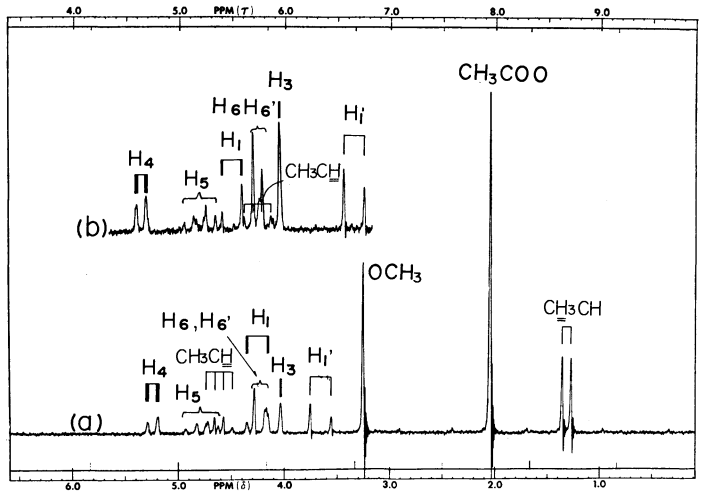

Fig. 1. PMR spectra of XIa in chloroform-d (a) and benzene-d_6 (b) at 60 MHz.

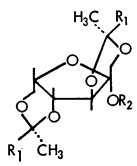
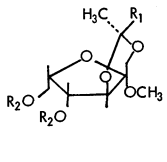
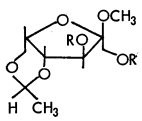
O-isopropylidene-4,6-di-*O*-acetyl-*β*-L-sorbofuranoside (XII), showing a remarkable low-field shift of H_4.[2] Therefore, XI was identified as methyl 1,3-*O*-ethylidene-*β*-L-sorbofuranoside; the formation of XI supports the structure of IX.







VIII $R_1 = CH_3$, $R_2 = H$

IX $R_1 = R_2 = H$

X $R_1 = H$, $R_2 = CH_3$

XI $R_1 = R_2 = H$

XIa $R_1 = H$, $R_2 = Ac$

XII $R_1 = CH_3$, $R_2 = Ac$

XIII R = H

XIIIa R = Ac

Chart 2

The exclusive formation of IX as compared to the predominant formation of VII from the acetonation of I under similar conditions is noteworthy. This fact suggests that IX is more stable than VIII in an acidic medium. This stability of IX can be attributed to the absence of an axial methyl group in the chair conformations of the *O*-ethylidene group.[8]

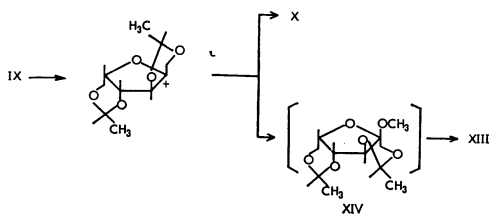


Chart 3

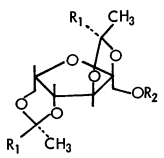
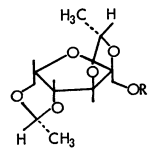
The negative value of optical rotation shows the anomeric configuration of XIIIa to be an *α*-anomer. The PMR spectrum of XIIIa in chloroform-d shows the presence of a six-membered ethylidene ring $\left(CH_3C\underline{H}<^{O}_{O}\ \tau\ 5.37\right)$; the signal due to H_3 is shifted downfield remarkably, while the signal due to H_4 is shifted upfield, in comparison with those observed in the spectrum of XIa. Therefore, the structure of XIII was determined to be methyl 4,6-*O*-ethylidene-*α*-L-sorbofuranoside.[2] The small coupling of $J_{3,4}$ (=0.6 Hz) also supports this furanose structure. The formation of X and XIII was proposed to be as follows: no isolation of 1,3:4,6-di-*O*-ethylidene-*α*-L-sorbofuranose results from its stereochemical instability.





VII $R_1 = CH_3$, $R_2 = H$

XV $R_1 = R_2 = H$

XVa $R_1 = H$, $R_2 = Ac$

XVI $R_1 = H$, $R_2 = Ts$

XVII $R_1 = H$, $R_2 = trityl$

XVIII R = H

XVIIIa R = Ac

XIX R = Ts

XX R = trityl

Chart 4

Drastic conditions were required for the formation of 2,3:4,6-di-*O*-ethylidene-*α*-L-sorbofuranose. When

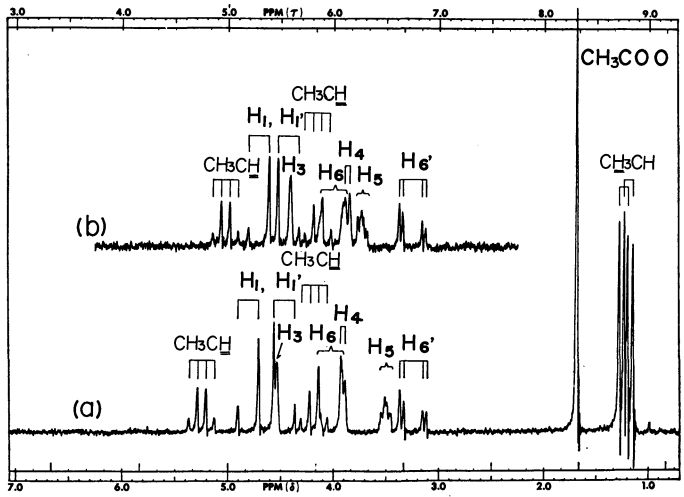


Fig. 2. PMR spectra of XV (a) and XVIII (b) in chloroform-d at 60 MHz.

I was treated with acetaldehyde dimethylacetal using a high concentration of sulfuric acid, a syrup was obtained which contained two isomers (XV and XVIII) with two ethylidene groups and negative optical rotations. Both derivatives, XV and XVIII, easily afforded acetates (XVa and XVIIIa), tosylates (XVI and XIX), and tritylates (XVII and XX respectively), and were both converted into methyl 2-keto-L-gulonate (XXIII) by Reichstein's procedure.[6] Further, XVI (or XIX) was identical with one of the two tosylates derived from the ethylidenation of 1-*O*-tosyl-L-sorbose (XXII).[16] These facts suggested the presence of a C_1-hydroxyl group in both isomers. The PMR spectra of the XVa and XVIIIa acetates (see Fig. 2) included the characteristic signals for a furanose structure, a somewhat broad singlet due to H_3 ($J_{3,4}$=0.5 Hz) and a doublet due to H_4 ($J_{4,5}$=5.8 Hz). Therefore, the structures of XV and XVIII were determined to be the diastereoisomers of 2,3:4,6-di-*O*-ethylidene-*α*-L-sorbofuranose, which differ only at the acetal center of the 2,3-*O*-ring since those methyl groups on the 1,3-dioxanes fused at the 4,6-position of furanose rings have been found to be equatorial in both isomers on the basis of non-bonded interactions[7a] and also on the basis of extensive studies of acetals.[17]

Ethylidene methine protons in chloroform-d appeared as quartets at τ 4.58 and 5.37 for XVa and at τ 4.83 and 5.37 for XVIIIa. Signals at a lower field were assignable to the protons on the dioxolane rings, as has been described above. Since the ethylidene methine proton on the dioxolane ring fused directly to the five-membered cyclic system is deshielded when *endo*,[17-19] XV (τ 4.58) and XVIII (τ 4.83) are assigned the H-*endo* and H-*exo* configurations[20,21] respectively.

As has been mentioned above, the expected 1,3-*O*-ethylidene pyranose V was successfully isolated; this suggested the presence of an equilibrium between 1,2-*O*-acetal (III) and 1,3-*O*-acetal (V) in the initial stage of the acetalation, much as in the acetalation of glycerol.[7] Further, the pathway of IX→(XV+XVIII) was also confirmed. Thus, the reaction pathway of I→(III⇄V)→IX→(XV+XVIII) for the ethylidenation of L-sorbose (I) was established; a detailed discussion of this will be presented elsewhere.

Experimental

Thin-layer chromatography was performed on silica gel using ether - *n*-hexane (2 : 1 v/v) as a solvent. The separated materials were developed with iodine. In the cases of preparative thin-layer chromatography (PTC), the developed zones were extracted with acetone. The evaporation of the acetone under reduced pressure gave the materials.

The PMR spectra were measured on a Varian A-60 spectrometer at 60 MHz in chloroform-d and/or benzene-d_6, using tetramethylsilane as the internal reference at

the ordinary probe temperature. All the melting points were measured on a Kofler block and were corrected. The optical rotations were determined in a 10 cm microtube in chloroform containing 1% ethanol, and the concentrations were recorded in percentages.

The solvents used were removed under reduced pressure below 40°C.

Ethylidenation of L-Sorbose (I). a) To a mixture of dry, finely-powdered L-sorbose (I) (15 g) and acetaldehyde dimethylacetal (50 ml), dioxane (50 ml) containing *p*-toluenesulfonic acid (TsOH) (1 g) was added. The suspended solution was vigorously stirred for 2.7 hr at 40°C, and then neutralized with potassium carbonate. After the removal of the unreacted L-sorbose (I) (7 g) and the excess potassium carbonate by filtration, the filtrate was concentrated to a yellow syrup (10.5 g). The chloroform solution (100 ml) of the syrup was washed with water (3×15 ml). From the chloroform layer, a di-*O*-ethylidene compound (IX) was isolated by a procedure (c) described below. The combined water was evaporated to a thick syrup (4.14 g). Without purification, the syrup was treated with acetic anhydride (20 ml) in pyridine (25 ml) at 0—5°C. After 3 hr, the solution was evaporated to give a syrup (4.7 g), from which IIIa (R_f 0.5—0.6, 0.27 g), VIa (R_f 0.44—0.51, 0.42 g), and XIIIa (R_f 0.39—0.49, 0.38 g) were then isolated by PTC. IIIa: syrup, $[\alpha]_D^{22}$ −45.7 (*c* 0.341). Found: C, 50.95; H, 6.02%. Calcd for $C_{14}H_{20}O_9$: C, 50.60; H, 6.07%. VIa: needles (recryst. from *n*-hexane), mp 93—94°C, $[\alpha]_D^{24}$ −58.4 (*c* 0.527). Found: C, 51.23; H, 6.59%. Calcd for $C_{13}H_{20}O_8$: C, 51.31; H, 6.63%. XIIIa: syrup, $[\alpha]_D^{23}$ −31.2 (*c* 1.020). Found: C, 51.30; H, 6.60%. Calcd for $C_{13}H_{20}O_8$: C, 51.31; H, 6.63%.

b) A solution of I (3.0 g) and acetaldehyde dimethylacetal (15 ml) in dimethylsulfoxide (15 ml) containing TsOH (0.3 g) was stirred at room temperature. After 3.3 hr, the solution was neutralized with ammonia water and then concentrated to a syrup (4.9 g). Without purification, the syrup was treated with acetic anhydride (20 ml) in pyridine (25 ml) at 0—5°C. After 3 hr, the solution was evaporated to give a syrup (3.9 g), from which IIIa (0.18 g), and Va (R_f 0.16—0.28, 0.16 g) were then isolated by PTC. Va: needles (recryst. from *n*-hexane, mp 140—142°C, $[\alpha]_D^{24}$ −24.7 (*c* 0.458). Found: C, 49.66; H, 6.19%. Calcd for $C_{12}H_{18}O_8$: C, 49.65; H, 6.25%.

c) A suspended solution of I (15 g) and acetaldehyde dimethylacetal (35 ml) in dioxane (50 ml) containing TsOH (1.0 g) was vigorously stirred at 40°C for 4.5 hr. The solution was made alkaline with potassium carbonate and then concentrated to a syrup (16.2 g), whose thin-layer chromatogram showed the presence of IX as the major product and X as the minor one. Several purifications of the syrup by PTC afforded IX (R_f 0.39—0.49, 2.5 g) and X (R_f 0.52—0.61, 0.52 g). IX: syrup, $[\alpha]_D^{24}$ +66.0 (*c* 1.006). Found: C, 51.48; H, 7.02%. Calcd for $C_{10}H_{16}O_6$: C, 51.72; H, 6.94%. X: syrup, $[\alpha]_D^{28}$ +68.1 (*c* 1.036). Found: C, 53.77; H, 7.35%. Calcd for $C_{11}H_{18}O_6$: C, 53.65; H, 7.37%.

d) A mixture of I (4.2 g), acetaldehyde dimethylacetal (30 ml), and sulfuric acid (6 g) was stirred at 30°C for 3 hr. The solution was neutralized with a a sodium carbonate solution and then concentrated to a syrup. The syrup was extracted with acetone, and the acetone removed. The chloroform solution of the residue was washed with water and dried, and the solvent removed. The purification of the residue (6.3 g) by PTC (R_f 0.14—0.27) gave crude crystals (3.9 g). The crystals were then treated with acetic anhydride (25 ml) in pyridine (25 ml) at 5°C. After standing overnight, the reaction mixture was poured over ice water and extracted with chloroform. The chloroform was washed with a sodium carbonate solution and then with water, and dried, after which the solvent was removed. From the residue, XVa (R_f 0.46—0.60, 1.28 g) and XVIIIa (R_f 0.38—0.49, 2.0 g) were isolated by PTC. XVa: plates (recryst. from *n*-hexane), mp 71—72°C, $[\alpha]_D^{20}$ −21.5 (*c* 0.783). Found: C, 52.33; H, 6.54%. Calcd for $C_{12}H_{18}O_7$: C, 52.55; H, 6.62%. XVIIIa; columns (recryst. from *n*-hexane), mp 53—54°C, $[\alpha]_D^{20}$ −24.0 (*c* 0.504). Found: C, 52.59; H, 6.46%. Calcd for $C_{12}H_{18}O_7$: C, 52.55; H, 6.62%.

Methyl 1,3-*O*-Ethylidene-4,6-di-*O*-acetyl-β-L-sorbofuranoside (XIa). A solution of X (1.19 g) in 60% acetic acid (50 ml) was heated at 95°C for 45 min. The solvent was removed twice by the addition of an excess of ethanol and by subsequent concentration. Without further purification, the residual syrup (1.04 g) was acetylated with acetic anhydride (20 ml) and pyridine (30 ml) in a refrigerator for 4 hr. The evaporation of the solvent gave a syrup (1.3 g), which was purified by PTC and then by recrystallization from *n*-hexane. XIa (197 mg) was obtained, mp 61—62°C, $[\alpha]_D^{24}$ +53.7 (*c* 0.536). Found: C, 51.50; H, 6.62%. Calcd for $C_{13}H_{20}O_8$: C, 51.31; H, 6.63%.

(R)-2,3:(R)-4,6-Di-*O*-ethylidene-α-L-sorbofuranose (XV). To a solution of XVa (0.7 g) in methanol (5 ml), 0.1 N methanolic sodium methoxide (150 ml) was added. After the mixture had stood at room temperature for 10 min, the solvent was removed, and then the mixture was extracted with chloroform. The chloroform was washed with water and dried, and the solvent was removed. The recrystallization of the residue from *n*-hexane gave needles (0.43 g), mp 58—59°C, $[\alpha]_D^{20}$ −8.5 (*c* 0.562). Found: C, 51.86; H, 6.96%. Calcd for $C_{10}H_{16}O_6$: C, 51.72; H, 6.94%.

(S)-2,3: (R)-4,6-Di-*O*-ethylidene-α-L-sorbofuranose (XVIII). A mixture of XVIIIa (1.55 g) in methanol (100 ml) and 0.1 N methanolic sodium methoxide (100 ml) was stirred at room temperature for 10 min. XVIII was then obtained in the above-described manner. XVIII: needles (recryst. from ethyl acetate and *n*-hexane), mp 82—83°C, $[\alpha]_D^{20}$ −9.5 (*c* 0.927). Found: C, 51.80; H, 6.85%. Calcd for $C_{10}H_{16}O_6$: C, 51.72; H, 6.94%.

Methyl 1,3-*O*-Ethylidene-4,5-di-*O*-acetyl-α-L-sorbopyranoside (VIa). a) A mixture of Va (0.15 g), methyl iodide (10.5 g), and silver oxide (1 g) was refluxed for 9 hr. The precipitates were removed by filtration, and the filtrate was concentrated to give a syrup. The syrup was purified by PTC (R_f 0.44—0.51), followed by recrystallization from *n*-hexane. VIa (0.1 g) was obtained.

b) A solution of methyl α-L-sorbopyranoside (XXI) (1.4 g), acetaldehyde dimethylacetal (28 ml), and TsOH (0.14 g) was stirred at room temperature. After 2 hr, the solution was neutralized with methanolic sodium methoxide. After the removal of the solvent, the residue was extracted with chloroform and the solvent removed. The residue was treated with acetic anhydride (20 ml) in pyridine (20 ml) at 5°C for 4 hr and then worked up by a procedure similar to that used in the ethylidena-

tion of I (a). VIa (0.1 g) was thus obtained.

Methyl 1,3:4,6-Di-*O*-ethylidene-β-L-sorbofuranoside (X). A mixture of IX (0.14 g), methyl iodide (14 g), and silver oxide (0.5 g) was refluxed for 4.7 hr. The precipitates were removed by filtration, and the filtrate was concentrated to give a syrup. The purification of the syrup by PTC (R_f 0.52—0.61) gave X (0.1 g).

1-*O*-Tosyl-(R)-2,3:(R)-4,6-di-*O*-ethylidene-α-L-sorbofuranose (XVI). A solution of XV (0.2 g) and tosyl chloride (0.5 g) in pyridine (3 ml) was kept overnight at room temperature. The solution was then poured over ice, extracted with chloroform which had been washed with a sodium bicarbonate solution and then with water, dried, and evaporated to dryness. The recrystallization of the residual syrup from methanol and water gave needles (0.26 g), mp 70—72°C (dec.), $[\alpha]_D^{24}$ −8.2 (*c* 0.970). Found: C, 52.84; H, 5.76; S, 8.26%. Calcd for $C_{17}H_{22}O_8S$: C, 52.85; H, 5.70; S, 8.29%.

1-*O*-Tosyl-(S)-2,3:(R)-4,6-di-*O*-ethylidene-α-L-sorbofuranose (XIX). A solution of XVIII (0.3 g) and tosyl chloride (0.5 g) in pyridine (3 ml) was worked up in a procedure similar to the above. XIX (0.35 g) was thus obtained as needles (recryst. from methanol and and water), mp 72.5—73°C, $[\alpha]_D^{24}$ −7.0 (*c* 0.814). Found: C, 53.15; H, 5.61; S, 8.49%. Calcd for $C_{17}H_{22}O_8S$: C, 52.85; H, 5.70; S, 8.29%.

Ethylidenation of 1-*O*-Tosyl-L-sorbose (XXII). A mixture of XXII (1.5 g) and acetaldehyde dimethylacetal (30 ml) was stirred at room temperature in the presence of sulfuric acid (2.2 g) for 3.7 hr and then neutralized with a sodium bicarbonate solution. The solvent was removed to give a syrup, which was then dissolved in chloroform, washed with water, and dried. The evaporation of the chloroform gave a syrup, from which XV (R_f 0.26—0.32, 0.56 g) and XVIII (R_f 0.39—0.45, 0.65 g) were isolated by PTC.

1-*O*-Trityl-(R)-2,3:(R)-4,6-di-*O*-ethylidene-α-L-sorbofuranose (XVII). To a solution of XV (0.3 g) in pyridine (6 ml), trityl chloride (1 g) was added. After standing at room temperature for 8 days, the solution was poured over ice and then extracted with chloroform. The chloroform was washed with a sodium carbonate solution, with hydrochloric acid, and then with water, and the solvent was removed. Crude crystals (1.25 g) were purified by PTC (R_f 0.41—0.49), followed by recrystallization from *n*-hexane. XVII was thus obtained as plates (0.09 g), mp 130—133°C, $[\alpha]_D^{24}$ −32.8 (*c* 2.903). Found: C, 73.69; H, 6.47%. Calcd for $C_{29}H_{30}O_6$: C, 73.40; H, 6.37%.

1-*O*-Trityl-(S)-2,3:(R)-4,6-di-*O*-ethylidene-α-L-sorbofuranose (XX) was obtained from XVIII (0.5 g), by a procedure similar to the above (PTC: R_f 0.54—0.59, 0.42 g). XX: columns (recryst. from *n*-hexane), mp 162—163°C, $[\alpha]_D^{23}$ −35.5 (*c* 0.738). Found: C, 73.43; H, 6.32%. Calcd for $C_{29}H_{30}O_6$: C, 73.40; H, 6.37%.

Oxidation of 2,3:4,6-di-*O*-ethylidene-α-L-sorbofuranoses (XV and XVIII). To a solution of a crude mixture of XV and XVIII (1.95 g) in water (24 ml) containing potassium hydroxide (1.11 g), a potassium permanganate (2.8 g) solution (31 ml) was added, batch by batch, over a 2.5-hr period. After the mixture had then been stirred at 25—26°C for 1.2 hr, the precipitates were removed by filtration, the filtrate was saturated with carbon dioxide, and then the water was removed. The residue was extracted with hot ethanol and the ethanol was concentrated to a powder, which was then dissolved in water (2 ml). The pH of the water was adjusted to 1.0 with hydrochloric acid under cooling. The acidic solution was extracted with ethyl acetate. The removal of the ethyl acetate gave a syrup; this solution in methanol (6 ml) containing one drop of hydrochloric acid was refluxed for 6 hr, and then the solvent was removed without heating to give methyl L-gulonate (XXIII) (0.04 g), mp 151—153°C. This was identical with an authentic sample.[6]

The authors wish to express their gratitude to Professor Toshihiko Okamoto, University of Tokyo, and Dr. Ken'ichi Takeda, Director of this Laboratory, for their encouragement.

Hydrogenation and Hydrogenolysis. XI.[1] The Hydrogenation of Methoxy- and Ethoxyanilines with a Ruthenium Catalyst*1

Shigeo NISHIMURA and Hisashi YOSHINO

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo

(Received June 10, 1968)

Hydrogenation of methoxy- and ethoxyanilines with a ruthenium catalyst was investigated at 80°C under the hydrogen pressure of 80—100 kg/cm^2. The amount of hydrogenolysis which occurred during hydrogenation varied with solvent from 35.1% in methanol to 8.5% in *t*-butyl alcohol in the hydrogenation of *p*-methoxyaniline. With use of *t*-butyl alcohol as solvent, good yields of methoxy- and ethoxycyclohexylamines were obtained from corresponding alkoxyanilines. It was shown that the rate of formation of cyclohexylamine increases with increasing polarity of solvent. *m*-Alkoxyanilines were found to hydrogenolyze more readily than the corresponding ortho or para isomers. For the greater tendency of meta isomers toward hydrogenolysis, an explanation based on the ionic cleavage of the carbon-oxygen bond was suggested.

In the preceding paper,[1] we have reported an effective method of the hydrogenation of methoxy- and ethoxyanilines, the alkoxyl group of which is rather labile to hydrogenolysis, with the rhodium oxide catalyst prepared by the lithium nitrate fusion of rhodium chloride. Over this catalyst, hydrogenolysis occurred only to slight extent and methoxy- and ethoxycyclohexylamines were obtained in excellent yields.

The hydrogenation of alkoxyanilines with ruthenium catalysts is usually accompanied by more extensive hydrogenolysis than with rhodium, although ruthenium has proved to be a useful metal in the catalytic hydrogenation of aromatic amines.[2] Freifelder and Stone[3] hydrogenated various alkoxyanilines with a ruthenium dioxide as catalyst in methyl or ethyl alcohol at elevated temperature and pressure. However, hydrogenation of methoxy- and ethoxyanilines gave only rather low yields of the corresponding alkoxycyclohexylamines under these conditions, except in the case of *o*-ethoxyaniline where 2-ethoxycyclohexylamine was obtained in 78.7% yield.

In this paper, we have investigated the ruthenium-catalyzed hydrogenation of methoxy- and ethoxyanilines, especially with reference to the effect of solvents on accompanying hydrogenolysis. It has been shown that the nature of the solvent used has a profound effect on the extent of hydrogenolysis and that the rate of formation of cyclohexylamine increases with increasing polarity of the solvent.

Experimental

Catalyst. The ruthenium hydroxide, prepared from aqueous solutions of ruthenium chloride and lithium hydroxide according to the procedure described previously,[4] was used as the catalyst throughout the experiments.

Hydrogenation and Analysis of Products. These were carried out in the same way as described in the preceding paper.[1] On direct gas chromatography of the reaction mixture, *n*-butyl alcohol could not be separated from cyclohexylamine and the analysis in this case was done after separation of produced amines from the solvent through their hydrochlorides. Alkoxycyclohexylamines gave two peaks on gas chromatogram, except in the case of 2-methoxy isomer where only one peak was obtained probably because of insufficient separation. The areas of the larger peaks, which probably corresponded to the cis isomers, were 84.3, 67.6, 93.1, 82.3 and 66.7% for 3-methoxy-, 4-methoxy-, 2-ethoxy-, 3-ethoxy- and 4-ethoxycyclohexylamines, respectively.

Solvents. All solvents used in hydrogenations were carefully dehydrated according to the methods recommended in the literature,[5] otherwise small amounts of hydrolysis products, alkoxycyclohexanols, were often formed during hydrogenation.

d) Methylcyclohexane.

Results and Discussion

The effect of various solvents was investigated in the hydrogenation of *p*-methoxyaniline at 80°C under the hydrogen pressure of 80—100 kg/cm² in the presence of ruthenium hydroxide and a small amount of lithium hydroxide, which has been shown to be an effective catalyst system for hydrogenation of aniline.[6] The results are summarized in Table 1. It is seen that hydrogenolysis occurred most extensively in methanol and ethanol, and varied considerably with the kind of solvent from 35.1% in methanol to 8.5% in *t*-butyl alcohol. It is noteworthy that hydrogenolysis took place to greater extent in less polar non-alcoholic solvents (isopropyl ether and methylcyclohexane) than in *t*-butyl alcohol. The amount of hydrogenolysis was thus found to be the smallest in *t*-butyl alcohol of the solvents investigated.[7] In Fig. 1 the rate of formation of cyclohexylamine, obtained on the basis of the amount of cyclohexylamine formed during half-hydrogenation time, is plotted *versus* the reciprocal of the dielectric constant of the solvent in which hydrogenation was carried out. It will be seen that the rate of formation of cyclohexylamine is a function of polarity of solvent: the greater the dielectric constant of a solvent is, the larger is the rate of formation of cyclohexylamine in the solvent. As noted above, the extent of hydrogenolysis is not always in the order of polarity of solvent. Generally, hydrogenation proceeded more slowly in non-alcoholic solvents than in alcoholic solvents (see Table 1) and probably this is the reason of rather large amounts of hydrogenolysis obtained in the former solvents notwithstanding their small dielectric constants. If we assume that the effect of solvent on the rate of hydrogenation is similar for alkoxyaniline and for the intermediate allyl-type ethers which probably undergo hydrogenolysis when further hydrogenated,[8] it may be considered that the change in the rate of formation of cyclohexylamine in various solvents represents the effect of solvents on the rate of hydrogenolysis of the alkoxyl group. Thus, the effect of solvents indicated in Fig. 1 can be interpreted as showing the effect of polarity of solvent on the rate of hydrogenolysis of the carbon-oxygen linkage. The observed effect thus suggests that more polarized transition states are involved in hydrogenolysis of the intermediates leading to the formation of cyclohexylamine. This is also in line with the currently accepted mechanism of catalytic hydrogenolysis in which an ionic cleavage of the carbon-oxygen bond is involved.[9]

Since it has been found that hydrogenolysis occurs only to a small extent in *t*-butyl alcohol, isomeric methoxy- and ethoxyanilines have been hydrogenated in this solvent, the results being summarized in Table 2. It is seen that hydrogenolysis is generally at low level and methoxy- and

7) A similar effect of solvents was reported in hydrogenation of some benzyl alcohols with platinum oxide catalyst, where the amount of hydrogenolysis decreased with solvent in the order : primary>secondary>tertiary alcohol [Y. Ichinohe and H. Ito, This Bulletin, **37**, 887 (1964)].

8) This may be presumed by considering that the hydrogenolysis probably occurs by the S_N type mechanism (see Ref. 9) and such reaction will occur more easily in the allyl-type ether than in the corresponding aryl ether, because the formation of the transition state of carbonium ion character will be much favored in the allyl-type ether.

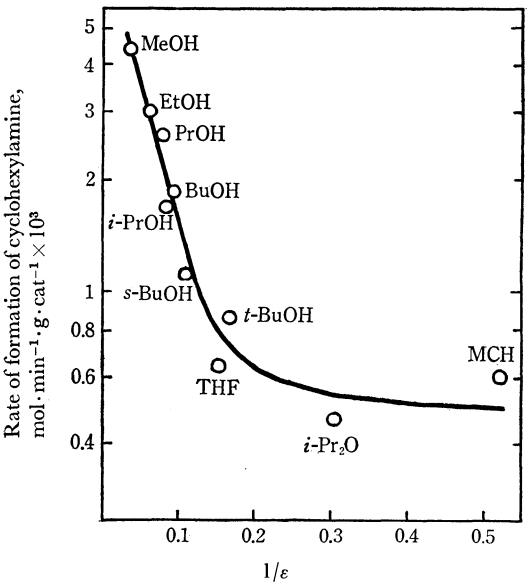

Fig. 1. Effect of solvents on the rate of formation of cyclohexylamine as a function of the reciprocal of dielectric constant in hydrogenation of *p*-methoxyaniline with Ru catalyst.

ethoxycyclohexylamines were obtained in more than 80% yields by distillation of products. Thus, the hydrogenation of alkoxyanilines with ruthenium hydroxide catalyst in *t*-butyl alcohol affords an excellent alternative method for the synthesis of alkoxycyclohexylamines.[10] The relative rates of formation of cyclohexylamine are also listed in the last column of Table 2, taking the rate for *o*-ethoxyaniline as unity. A noteworthy feature of the results is the fact that the meta isomers hydrogenolyze more easily than the corresponding ortho and para isomers. These results are in contrast with those obtained previously with rhodium catalyst in which the rate of formation of cyclohexylamine increased in the order: ortho<meta<para isomer, although differences between meta and para isomers were rather small.[1] The greater tendency of the meta isomer toward hydrogenolysis has been observed also in other hydrogenations.[11] It appears difficult to explain this phenomenon only either by the steric factor or by the probability of the formation of allyl-type ethers.[12] On the basis of an ionic cleavage of the carbon-oxygen bond, it may be suggested that the electron-releasing ability of the amino group at the meta position will stabilize the transition states of carbonium ion character when the allyl-type ethers undergo hydrogenolysis, as shown below in one example of dihydro intermediates. Such an effect will not be expected in the allyl-type intermediates resulting from the hydrogenation of *o*- or *p*-alkoxyaniline.[13]

a) Methoxy- or ethoxyaniline (0.1 mol) was hydrogenated in 30 ml of anhydrous *t*-butyl alcohol under 80—100 kg/cm² in the presence of 0.2 g of ruthenium hydroxide and 0.02 g of $LiOH \cdot H_2O$.

b) I: Alkoxycyclohexylamine. II: Cyclohexylamine. III: Secondary products. IV: Alkoxyaniline

10) Although hydrogenolysis occurred more extensively with the ruthenium catalyst than with rhodium oxide catalyst (see Ref. 1), use of the ruthenium catalyst will be advantageous in hydrogenations at a larger ratio of substrate to catalyst because of lesser decrease in the rate during hydrogenation.

11) More extensive hydrogenolysis in meta isomer than in ortho or para isomer has been observed, *e. g.*, in hydrogenation of isomeric dimethoxybenzenes with platinum metal catalysts (Y. Takagi and S. Nishimura, unpublished results). *Cf.* also H. A. Smith and R. G. Thompson, "Advances in Catalysis," Vol. 9, p. 727 (1957).

12) M. Freifelder, Y. H. Ng and P. F. Helgren, *J. Org. Chem.*, **30**, 2485 (1965).

13) *p*-Methoxyaniline was reported to hydrogenolyze to a much greater extent than the meta isomer in hydrogenation with rhodium-on-alumina in the presence of one equivalent of acetic acid.[12] This fact may support the explanation suggested above, but similar results were also obtained in ethanol with ethoxy- and propoxyanilines. For further discussion, a detailed study will be necessary.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN VOL. 42 502—505 (1969)

Synthesis of 1- and 2-Piperidinophenazine Derivatives

Hideo ENDO and Masao TADA

The Research Institute for Tuberculosis, Leprosy and Cancer, Tohoku University, Kitayoban-cho, Sendai

and Ken KATAGIRI

Shionogi Research Laboratory, Shionogi & Co., Ltd., Fukushima-ku, Osaka

(Received June 19, 1968)

A number of new piperidinophenazines have been prepared by the reactions of various halogenophenazines and their oxides, including several new compounds, with piperidine. The halogen-activating effect of the oxide groups in 1- or 2-halogenophenazine oxides, which had previously been known, was also observed in the present piperidination. It has been found that 1-chlorophenazine was considerably less reactive than 2-chlorophenazine in the piperidination, that but the 5-oxide group in 1-chlorophenazine-5-oxide enhanced the reactivity of chlorine.

As a part of our general scheme for the synthetic study of phenazine derivatives and the investigation of their biological activities,[1,2] we have carried out the synthesis of 1- and 2-piperidinophenazine derivatives from halogenophenazines. In the present paper, we shall describe our results in full detail.

Landquist reported that the reaction of 2-chlorophenazine-5,10-dioxide (I) with boiling piperidine gave 2-piperidinophenazine-5,10-dioxide (II) and 2-piperidinophenazine-mono-*N*-oxide as dark red crystals (mp 159°C).[3] Investigating this reaction further, we found that the reaction of I with piperidine under the same conditions yielded II and two piperidinophenazine-mono-*N*-oxides: reddish violet crystals (III) (mp 128°C) and reddish orange crystals (IV) (mp 167°C). In an attempt to decide the position of the *N*-oxide group in III and IV, 2-chlorophenazine-5-oxide (V)[4] and 3-chlorophenazine-5-oxide (VI)[4] were treated with boiling piperidine for 8 hr to give III in a 31% yield and IV in a 43% yield respectively. IV was also obtained in a 41% yield from 3-bromophenazine-5-oxide (VII)[5] under the same conditions. II, III, and IV were heated with zinc powder in acetic acid to yield piperidinophenazine (VIII), which was also derived in a 29% yield from 2-chlorophenazine (IX)[4] by treatment with boiling piperidine for 50 hr. VIII was also obtained in a 31% yield from 2-bromophenazine (X).[5] VIII was heated with diluted sulfuric acid at 200°C for 8 hr in a sealed tube to form 2-hydroxyphenazine (XI), which has already been described by Vivian.[6] From these experiments, it is clear that the structures of III and IV are 2-piperidinophenazine-5-oxide and 3-piperidinophenazine-5-oxide respectively.

The treatment of 2-chloro-9-methylphenazine (XII)[7] with piperidine in the presence of cuprous chloride for 50 hr gave 9-methyl-2-piperidinophenazine (XIII). 2-Chloro-9-methylphenazine-5-oxide (XIV) was prepared by the Wohl-Aue reaction of *p*-chloronitrobenzene with *o*-toluidine or by the oxidation of XII with hydrogen peroxide in acetic acid, and was then submitted to piperidination, thus forming 9-methyl-2-piperidinophenazine-5-oxide (XV). XV was reduced with zinc powder in acetic acid to afford XIII. The same treatment of 2-chloro-7-methoxyphenazine (XVI)[8] and 2-chloro-9-methoxyphenazine (XVII)[9] with piperidine for 50 hr in the presence of cuprous chloride afforded 7-methoxy-2-piperidinophenazine (XVIII) and 9-methoxy-2-piperidinophenazine (XIX) respectively. 2-Chloro-7-methoxyphenazine-5-oxide (XX)[4] was treated with piperidine for 25 hr to give a mixture of XVIII and 7-methoxy-

2-piperidinophenazine-5-oxide (XXI). By reduction, XXI was converted into XVIII. The piperidination of 2-chloro-9-methoxyphenazine-5-oxide (XXII), which had been derived from XVII by the oxidation, afforded a mixture of XIX and its *N*-oxide derivative (XXIII). XIX was also obtained from XXIII by reduction.

XXVII: R_1=R_2=H; R_3=N⟨⟩

The treatment of 1-chlorophenazine (XXIV)[4] with piperidine in the presence of cuprous chloride or cupric chloride for 70 hr gave 1-piperidinophenazine (XXV) in an 8% yield. Thus, although the 1-chloro compound (XXIV) is considerably less reactive to nucleophilic attack than the 2-chloro isomer (IX), it has been found that, in the corresponding 5-oxide (XXVI),[4] the reaction proceeded much more easily. Namely, XXVI was treated with piperidine for 25 hr to give both a 3% yield of XXV and a 28% yield of 1-piperidinophenazine-5-oxide (XXVII), which was then reduced with zinc powder in acetic acid to form XXV.

The halogen-activating effect of the oxide groups in halogenophenazine oxides has already been reported by Pachter and Kloetzel[4] and by Vivian[6] in the case of alcoholysis and hydrolysis. The present experiments reveal that halogens in halogenophenazine oxides, I, V, VI, VII, XIV, XX, XXII, and XXVI, are replaced with piperidine more readily than those of the corresponding phenazines.

We shall report elsewhere on the growth-inhibitory activity of the compounds described above against Crocker Sarcoma 180.[10]

Experimental[11]

The Reaction of 2-Chlorophenazine-5,10-dioxide (I) and Piperidine. A mixture of I (3.0 g) and piperidine (30 m*l*) was submitted to the reaction conditions employed by Landquist[3]: when the mixture was refluxed for 1.5 hr, 2-piperidinophenazine-5,10-dioxide (II) (mp 173—174°C; 1.25 g) was obtained as violet-black needles (from a mixture of benzene and petroleum ether). From the benzene-petroleum ether mother liquor, red crystals (1.0 g) were obtained after the evaporation of the solvent. The crystals were dissolved in benzene, and the solution was then passed through a column of alumina and eluted with benzene. From the first effluent, a mixture of 2- (V) and 3-chlorophenazine-5-oxide (VI) (0.2 g) was obtained. The column was then further eluted with chloroform, yielding crude crystals. Recrystallization from a mixture of benzene and ligroin gave 3-piperidinophenazine-5-oxide (IV) (mp 166—167°C; 210 mg) as reddish-orange needles.

10) H. Endo, M. Tada and K. Katagiri, *Sci. Rep. Res. Inst. Tohoku Univ. Ser. C*, to be published.

11) All melting points are uncorrected.

$C_{17}H_{17}N_3O$: C, 73.09; H, 6.13; N, 15.04%.

The mother liquor was evaporated to dryness, and the residue was recrystallized from diluted methanol to yield 2-piperidinophenazine-5-oxide (III) (mp 127—128°C; 200 mg) as reddish-violet needles.

Found: C, 73.29; H, 6.05; N, 14.90%. Calcd for $C_{17}H_{17}N_3O$: C, 73.09; H, 6.13; N, 15.04%.

2-Piperidinophenazine-5-oxide (III). A mixture of V (1.5 g) and piperidine (15 ml) was refluxed for 8 hr. After the addition of water (0.5 l) and acetic acid (8 ml), the resulting precipitate was filtered, washed with water, dried, and dissolved in chloroform. The chloroform solution was then passed through a column of alumina and eluted with chloroform. From the first effluent, V (0.4 g) was recovered, while from the second effluent III (560 mg) was obtained.

3-Piperidinophenazine-5-oxide (IV). *a) From VI.* A mixture of VI (1.5 g) and piperidine (15 ml) was refluxed for 8 hr; the reaction mixture was then treated as in the case of III to give IV (780 mg).

b) From VII. A mixture of VII (500 mg) and piperidine (5 ml) was refluxed for 8 hr; then the reaction mixture was treated as in the case of III to yield IV (210 mg).

2-Piperidinophenazine (VIII). *a) From IX.* A solution of IX (1.5 g) in piperidine (15 ml) was refluxed for 50 hr and then poured into water (0.5 l). The crystals thereby separated were dissolved in chloroform. The solution was passed through a column of alumina and eluted with chloroform. From the effluent, orange crystals were obtained; they were recrystallized from methanol to yield VIII (mp 129—130°C; 540 mg) as orange needles.

Found: C, 77.38; H, 6.59; N, 15.98%. Calcd for $C_{17}H_{17}N_3$: C, 77.53; H, 6.51; N, 15.96%.

b) From X. A solution of X (0.5 g) in piperidine (5 ml) was treated as in the case of a) above to afford VIII (160 mg).
